World Journal of Gastroenterology  
Volume 15 Number 25 July 7, 2009

### INTRODUCTION

*World Journal of Gastroenterology* is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

A systematic review of the efficacy and safety of herbal medicines used in the treatment of obesity. *World J Gastroenterol* 2009; 15(25): 3073-3085 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3073.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3073>

## Abstract

This review focuses on the efficacy and safety of effective herbal medicines in the management of obesity in humans and animals. PubMed, Scopus, Google Scholar, Web of Science, and IranMedex databases were searched up to December 30, 2008. The search terms were "obesity" and ("herbal medicine" or "plant", "plant medicinal" or "medicine traditional") without narrowing or limiting search elements. All of the human and animal studies on the effects of herbs with the key outcome of change in anthropometric measures such as body weight and waist-hip circumference, body fat, amount of food intake, and appetite were included. *In vitro* studies, reviews, and letters to editors were excluded. Of the publications identified in the initial database, 915 results were identified and reviewed, and a total of 77 studies were included (19 human and 58 animal studies). Studies with *Cissus quadrangularis* (CQ), *Sambucus nigra*, *Asparagus officinalis*, *Garcinia atroviridis*, ephedra and caffeine, Slimax (extract of several plants including *Zingiber officinale* and Bofutsushosan) showed a significant decrease in body weight. In 41 animal studies, significant weight loss or inhibition of weight gain was found. No significant adverse effects or mortality were observed except in studies with supplements containing ephedra,

## INTRODUCTION

The prevalence of obesity is increasing worldwide<sup>[1]</sup> resulting in an association with major health problems such as type 2 diabetes, ischemic heart disease, stroke, and cancer. It is necessary to treat obese individuals by both lifestyle interventions and/or pharmacological therapy. Pharmacologic treatment and surgical interventions used in some circumstances are not always appropriate<sup>[2]</sup>. Unfortunately, drug treatment of obesity despite short-term benefits, is often associated with rebound weight gain after the cessation of drug use, side effects from the medication, and the potential for drug abuse<sup>[3]</sup>. Pharmacologic options include sibutramine, orlistat, phentermine, diethylpropion, and fluoxetine or bupropion. Phentermine and diethylpropion have potential for abuse and are only approved for short-term use. Approved medications for long term use in the treatment of obesity are sibutramine and orlistat, however, these agents should be used with caution in patients with a history of cardiovascular disorders<sup>[4]</sup>. The general public uses many other methods for weight

loss including herbs, vitamins, nutritional supplements, and meal replacement preparations. Rigorous scientific studies have not been carried out on these products, and in many cases safety and efficacy take a back seat to marketing.

Complementary and alternative therapies have long been used in the Eastern world but recently these therapies are being used increasingly worldwide<sup>[5]</sup>. When conventional medicine fails to treat chronic diseases and conditions such as obesity efficaciously and without adverse events, many people seek unconventional therapies including herbal medicine<sup>[6]</sup>. Although the number of randomized trials on complementary therapies has doubled every 5 years and the Cochrane library included 100 systematic reviews of unconventional interventions<sup>[7]</sup>, none of these studies specifically mentioned herbal therapy in obesity.

This review aimed to evaluate the current science on the efficacy and safety of herbal medicines in the management of obesity.

## DATA SOURCES AND STUDY SELECTIONS

PubMed, Scopus, Google Scholar, Web of Science, and IranMedex databases were searched up to December 30, 2008 for all human and animal studies investigating the effects (both harmful and beneficial) of treating obesity with herbal medicines. The search terms were "obesity" and ("herbal medicine" or "plant", "plant medicinal" or "medicine traditional") without narrowing or limiting search elements. Only publications with available abstracts were reviewed. The main outcome measures sought at the end of treatments as anti-obesity effects, were body weight, body fat including fat mass/fat weight or fat percentage/visceral adipose tissue weight, triceps skin fold thickness, waist or hip circumference, and appetite or amount of food intake.

Herbal medicines are defined in this review as raw or refined products derived from plants or parts of plants (e.g. leaves, stems, buds, flowers, roots, or tubers) used for the treatment of diseases. The synonyms of herbal medicines are herbal remedies, herbal medications, herbal products, herbal preparations, medicinal herbs, and phytopharmaceuticals, etc.

All of the abstracts from human and animal studies with the main outcome of change in anthropometric measures such as body weight and waist-hip circumference, body fat (weight or mass of visceral adipose tissue, fat mass or percent), amount of food intake, and appetite in participants were included. Even studies on other relevant diseases such as diabetes were also reviewed and included if the appropriate outcomes were shown. *In vitro* studies, review articles, and letters to the editor were excluded. Unpublished data such as theses were also excluded. Two reviewers independently examined the title, abstract and references of each article meeting the inclusion criteria and eliminated duplications and those showing exclusion criteria.

## FINDINGS

Of the publications identified from the initial database search, 915 results were identified and reviewed for inclusion or exclusion. A total of 77 studies were included (19 human and 58 animal studies). Human studies included 17 randomized clinical trials (RCTs) and two before-after clinical trials<sup>[8-26]</sup>. RCTs reported random allocation of humans to herbal medicines *vs* (placebo/another plant/combination of plants) with or without specific dietary and exercise programs outlined in Tables 1 and 2 as weight loss programs. Human subjects were healthy overweight, obese or with impaired glucose tolerance test volunteers. Animal studies included healthy, genetically or experimentally obese or diabetic mice, rats and other rodents. The route of administration of herbs in almost all studies was oral intake with the exception of some animal studies as indicated in Table 2.

## HUMAN STUDIES

### **Change in human body weight**

All studies showed loss of body weight except one<sup>[21]</sup> which seemed to have problems with the study design, and one other study<sup>[10]</sup> which showed a significant decrease only in body fat. Studies with *Cissus quadrangularis* (CQ)<sup>[26]</sup> or combined with *Irrwingia gabonensis* (IG)<sup>[15]</sup>, a combination of *Sambucus nigra* and *Asparagus officinalis*<sup>[16]</sup>, calcium hydroxycitrate in *Garcinia atroviridis*<sup>[18]</sup>, supplements containing ephedra and caffeine<sup>[9,13,20]</sup>, and Slimax as an extract of several plants including *Zingiber officinale*<sup>[8]</sup> and Bofutsushosan<sup>[14]</sup> showed significant decreases in body weight.

### **Body fat**

A significant decrease in body fat was shown with CQ<sup>[26]</sup>, supplements containing ephedra and caffeine<sup>[9,13]</sup>, a natural compound containing capsicum and some lipotropic nutrients<sup>[10]</sup>, Bofutsushosan<sup>[14]</sup>, and calcium hydroxycitrate in *Garcinia atroviridis*<sup>[18]</sup>. These phytopharmaceuticals showed a significant decrease in triceps skin fold thickness indicating significant loss of fat.

### **Waist and hip circumference**

Efficient decreases in both waist and hip circumferences in trials with a supplement containing ephedra and caffeine<sup>[9]</sup> and Slimax (extract of several plants including *Zingiber officinale*<sup>[8]</sup>) were shown whereas *Caralluma fimbriata*<sup>[19]</sup> and CQ with or without IG<sup>[15]</sup> significantly decreased waist size.

### **Food intake**

Decreases in appetite or amount of food or energy intake with a supplement containing ephedra and caffeine<sup>[20]</sup> and *Caralluma fimbriata*<sup>[19]</sup> were shown (not significant) but hydroxycitric acid (HCA-SX) with or without *Gymnema sylvestre*<sup>[23]</sup> decreased the amount of food intake efficiently. A natural compound containing capsicum and other lipotropic nutrients<sup>[10]</sup> did not significantly change energy intake.

**Table 1** Human studies considering the anti-obesity effects of herbal medicines

Authors	Target	Herbs (scientific name)	Study	Dose/duration	Groups	Main outcome	Other relevant effects & complications
Ignjatovic et al <sup>[8]</sup> 2000	Healthy volunteers	Slimax: extract of several plants: <i>Hordeum vulgare</i> , <i>Polygonatum multiflorum</i> , <i>Dimocarpus longan</i> , <i>Ligusticum sinense</i> , <i>Lilium brownie</i> , and <i>Zingiber officinale</i>	RCT	6 wk	C: Placebo I: Compound	Sig. decrease in body wt. & waist & hip Cir. & BMI	Modification of lipid metabolism with sig. effect on the accumulation & the release of lipid from adipose tissue
Boozer et al <sup>[9]</sup> 2001	Over wt. (n = 35)	An herbal supplement: ( <i>Ma Huang</i> & <i>Guarana</i> )	RCT (double-blind)	72 mg (ephedra) 240 mg (caffeine)/8 wk	C: Placebo (n = 24) I: Compound (n = 24)	Sig. decrease in body wt. & total body fat & sig. greater reduction in hip & waist Cir.	Greater reduction in serum TG, potentially treatment-related dropouts (23%) in the active group and none in the placebo group. Dry mouth, insomnia & headache were reported
Hoeger et al <sup>[10]</sup> 1998	Healthy	A natural dietary compound of chromium picolinate, inulin, capsicum, L-phenylalanine, and other lipotropic nutrients	RCT (double-blind)	4 wk	C: wt. loss program (n = 67) I: wt. loss program + compound (n = 56)	Sig. decrease in body fat percent, fat mass & FFM, but no sig. difference in body wt. BMI and energy intake	
Ziauddin et al <sup>[11]</sup> 2004	Hyperlipidemic (n = 30)	<i>Terminalia arjuna Roxb</i>	Before-after CT			Sig. improvement in obesity. Reduction in body wt. in some cases	Sig. decrease in serum total lipid levels. Sig. relief of palpitation, dyspnea, chest & joint pain. Reduction in BP in some cases
Abidov et al <sup>[12]</sup> 2006	Obese non-diabetic women (n = 32)	A compound of <i>Aralia mandshurica</i> (A) and <i>Engelhardtia chrysolepis</i> (E) extracts named ARALOX	RCT	450 mg (A) & 450 mg (E)/d	C: Diet + placebo I: Diet + compound	Decrease in total body wt. & fat wt.	Reduction in perilipin content in adipocytes and plasma TG. Stimulate activity of hormone sensitive lipase
Greenway et al <sup>[13]</sup> 2004	Human (obese & over wt.) healthy	Herbal supplement containing caffeine and ephedra	RCT (double-blind)	210 mg (e) & 72 mg (c)/12 wk	C: Placebo I: Compound	Sig. decrease in body wt. & the percentage of fat	No differences in lipid levels, or BP were shown. No serious adverse effect
Hioki et al <sup>[14]</sup> 2004	Obese women with IGT (n = 80)	Bofu-tsusho-san containing ( <i>Ephedrae Herba</i> , <i>Glycyrrhizae Radix</i> , <i>Forsythiae Fructus</i> , <i>Schizonepetae Spica</i> &...)	RCT (double-blind)	Equivalent of (24 mg/ephedrine & 280 mg caffeine/24 wk)	C: wt. loss program I: wt. loss program + compound	Compared to baseline the I group lost significantly more body wt. & abdominal visceral fat & the placebo group lost sig. body wt. & had no sig. change in abdominal visceral fat	No decrease in RMR. Sig. improvement in insulin resistance compared to week 0. Loose bowel movements resulted in three withdrawals
Oben et al <sup>[15]</sup> 2008	Human (obese & over wt.)	A combination of <i>Cissus quadrangularis</i> (CQ) & <i>Irvingia gabonensis</i> (IG)	RCT (double-blind)	300 mg (CQ) & 500 mg (IG) per day/10 wk	C: Placebo I: CQ CQ + IG	Sig. decrease in body wt. & body fat percent & waist size in both I groups but the combination group (CQ + IG) resulted in larger reductions	Sig. decrease in Chol & LDL of plasma and fasting blood glucose levels
Chrubasik et al <sup>[16]</sup> 2008	Healthy (n = 80)	A combination of <i>Sambucus nigra</i> (S) and <i>Asparagus officinalis</i> (A)	Before-after CT	(S): 1 mg anthocyanin, 370 mg flavonol, 150 mg hydroxycinnamate (A): 19 mg saponin per day	-	Sig. decrease in mean of the wt.	Sig. improvement of BP, physical and emotional well-being and quality of life

Udani <i>et al</i> <sup>[17]</sup> 2007	Healthy ( <i>n</i> = 25)	Proprietary fractionated white bean extract	RCT (double-blind)	2000 mg/14 wk	C: Placebo + wt. loss program I: Extract + wt. loss program	In both groups, decrease in body wt. & waist size from baseline was sig. but no sig value between groups	There were no adverse effect
Roongpisuthipong <i>et al</i> <sup>[18]</sup> 2007	Obese women	Calcium hydroxycitrate in <i>Garcinia atroviridis</i>	RCT	2 mo	C: Diet I: Diet + extract	Sig. decrease in body wt. & greater reduction in BMI. Sig. decrease in the triceps skin fold thickness	
Kuriyan <i>et al</i> <sup>[19]</sup> 2007	Over wt. ( <i>n</i> = 50)	Caralluma fimbriata	RCT	1 g/60 d	C: wt. loss program I: wt. loss program + extract	Sig. decrease in waist Cir. & hunger levels. Greater decrease in body wt., BMI, hip Cir., body fat & energy intake but not sig.	
Hackman <i>et al</i> <sup>[20]</sup> 2007	Obese & over wt. women ( <i>n</i> = 41)	Multinutrient supplement containing ephedra (e) and caffeine (c)	RCT (double-blind)	40 mg (e) and 100 mg (c)/9 mo	C: Control supplement I: Multinutrient supplement	Sig. decrease in body wt. decrease in appetite	Sig. decline in serum chol, TG, glucose, fasting insulin & leptin levels & minor adverse effects like dry mouth, insomnia, nervousness and palpitation were reported
Garrison <i>et al</i> <sup>[21]</sup> 2006	Over wt. women	Proprietary extracts of Magnolia officinalis and phellodendron amurense	RCT	750 mg/6 wk	C: Placebo I: Extract	No sig. wt. gain for the I group but sig. wt. gain in C. groups	The I groups tended to have lower levels of cortisol in the evening
Coffey <i>et al</i> <sup>[22]</sup> 2004	Human (over wt. & obese) ( <i>n</i> = 102)	Product containing ephedrine, caffeine & other ingredients.	RCT (double-blind)	12 wk	C: Placebo I: Compound	Additional wt. loss (1/5 kg) & greater reduction in BMI & waist Cir. No difference in body fat & fat mass percent was shown	No difference in pulse, diastolic & systolic BP & adverse events
Preuss <i>et al</i> <sup>[23]</sup> 2004	Obese ( <i>n</i> = 60)	Hydroxycitric acid (HCA-SX) and a combination of HCA-SX and niacin-bound chromium (NBC) and Gymnema sylvestre extract (GSE)	RCT (double-blind)	HCA-SX: 4667 mg GSE: 400 mg NBC: 4 mg/8 wk	C: Placebo I1 = HCA-SX I2 = GSE + NBC + HCA-SX All groups had wt. loss program	5%-6% decrease in body wt. & BMI & sig. decrease in food intake in both I groups	Sig. decrease in serum lipids & leptin & increase in HDL & excretion of urinary fat metabolites in both I groups. There were mild adverse effects but not significant between groups
Udani <i>et al</i> <sup>[24]</sup> 2004	Obese ( <i>n</i> = 24)	A proprietary fractionated white bean ( <i>Phaseolus vulgaris</i> )	RCT (double-blind)	3000 mg/8 wk	C: Placebo I: Extract	Decrease of body wt. with 129% difference	Reduction of TG three times greater than C. group. No adverse effect was shown
Bhatt <i>et al</i> <sup>[25]</sup> 1995	Healthy ( <i>n</i> = 58)	Guggulu (Medohar)	RCT	1/5, 3 g/30 d	C: wt. loss program I: wt. loss program + extract	Higher mean wt. reduction in I group. In I group, all patients > 90 kg lost wt. but 3 in C group did not lose wt.	
Oben <i>et al</i> <sup>[26]</sup> 2007	Over wt. & obese	<i>Cissus quadrangularis</i>	RCT (double-blind)	300, 1028 mg	C: Placebo I: Two extract formulation: CQR-300, CORE	Sig. decrease in body wt & body fat	Sig. decrease in serum lipids and glucose. Sig. increase in HDL-C plasma 5-HT and creatinine levels

Cir: Circumference; BP: Blood pressure; BMI: Body mass index; sig.: Significant; C: Control; I: Intervention; RCT: Randomized control trial; CT: Clinical trial; TG: Triglyceride; HDL: High density lipoprotein; LDL: Low density lipoprotein; Chol: Cholesterol; IGT: Impaired glucose tolerance.

### Other effects

Anti-hyperlipidemic, antihyperglycemic, and other relevant anti-obesity effects of medicinal plants in human studies are summarized in Table 1.

### Adverse effects

No significant adverse effects compared to controls were mentioned and no mortality was reported, except in studies with supplements containing ephedra and

**Table 2 Animal studies on the anti-obesity effects of herbal medicines**

<b>Authors</b>	<b>Target</b>	<b>Herbs (scientific name)</b>	<b>Dose/duration</b>	<b>Groups</b>	<b>Main outcome</b>	<b>Other relevant effects &amp; complications</b>
Wang et al <sup>[27]</sup> 2000	Rat (obese)	Haidonghua powder: Laminaria japonica Aresch & Benincasa hispida (Thunb.) Cogn. <i>etc</i>	(2.5 g/kg)	-	Sig. decrease in Lee's index & size of fat cells	Did not influence the function of thyroid gland & metabolism of water & salt
Jeon et al <sup>[28]</sup> 2003	Mouse	Rhus vemiciflua Stokes	8 wk	C: HFD I: HFD + extract	Sig. suppression of body wt. gain and lower wt. of subcutaneous adipose tissue	Lowered plasma TG
Alarcon-Aguilar et al <sup>[29]</sup> 2007	Mouse	Hibiscus sabdariffa	120 mg/kg 60 d	C: Healthy & obese (by MSG) + placebo I: Same groups + extract	Sig. decrease in body wt. gain in obese mice & increased liquid intake in both groups	No sig. change in TG & Chol levels. Increase in ALT levels was shown but was not sig.
Urías-Silvas et al <sup>[30]</sup> 2008	Mouse	Fructans extracted from Agave tequilana (TEQ) and Dasylirion spp (DAS)	10% supplement	C: STD I: STD + Raftilose/DAS/TEQ	Sig. decrease in body wt. gain & food intake. The (TEQ) group had the lowest value	Lower serum glucose & Chol level but Sig. decrease in TG levels was shown in Raftilose group. Higher concentration of GLP-1 & its precursor & proglucagon mRNA in I groups
Park et al <sup>[31]</sup> 2007	Rat	Platycodon grandiflorum	150 mg/kg 7 wk	C: NLD/HFD I: Same groups + extract	Sig. decrease in body wt & subcutaneous adipose tissue wt. & adipocytes size in I group	Sig. decrease in plasma TG & Chol concentrations, up-regulation of FABP mRNA expression induced by HFD
Jongwon et al <sup>[32]</sup> 2005	Rat (obese by HFD)	Allium victorialis var. platyphyllum leaves	100 mg/kg 2 wk	-	Considerable reduction of retroperitoneal, epididymal and total abdominal fat pad wt.	Sig. decrease in hyperlipidemia and increased lipid content in feces
Kobayashi et al <sup>[33]</sup> 2001	Rat	Evodiamine an alkaloid of a fruit: Evodia rutaecarpa	0/02%, 0/03% of the diet 12 wk	C: Control I: Extract	Sig. decrease in perirenal fat wt. & decrease of epididymal fat mass	Sig. decrease of lipid in liver & serum FFAs. Sig. increase of lipolytic activity in perirenal fat tissue & specific GDP binding in brown adipose tissue mitochondria as the biological index of heat production
Jin et al <sup>[34]</sup> 1994	Rat	Jiang-zhi jian-fei yao: the refined Rhubarb	Injected intragastrically		No sig. increase in body wt. but reduction of food intake. Decreased size of abdominal adipose cells	Prolongation of stomach evacuation time and acceleration of intestinal movements
Kim et al <sup>[35]</sup> 2008	Rat	Juniperus chinensis	1% supplement /79 d	C: NLD/HFD I: HFD + extract	Sig. decrease in body wt gain & visceral fat pad wt.	Sig. decrease in blood lipid, leptin & insulin levels. Sig. reversal of the down-regulation of genes implicated in adipogenesis & increased gene expressions & phosphorylations related to FABO
Shih et al <sup>[36]</sup> 2008	Mouse (obese by HFD)	Momordica charantia (bitter melon)	4 wk	C: Control I: Rosiglitazone/extract	Sig. decrease in epididymal white adipose tissue wt. & visceral fat wt.	Sig. improvement in blood glucose, leptin, and FFA. Influenced PPAR $\alpha$ /PPAR $\gamma$ expression
Pang et al <sup>[37]</sup> 2008	Rat (obese by HFD)	Ilex paraguariensis			Sig. decrease in body wt. of visceral fat-pad wt.	Sig. decrease in blood and hepatic lipid, glucose, insulin and leptin levels. Reversed the down-regulation of genes implicated adipogenesis, thermogenesis & enhanced expression of uncoupling proteins in adipose tissue
Bruno et al <sup>[38]</sup> 2008	Mouse	Green tea	0%, 1%, 2% (wt:wt.)/6 wk	C: Obese/lean I: Same groups + extract	Sig. decrease in body wt. of both I groups	In obese I group, sig. decrease in hepatic steatosis was observed dose dependently. Liver enzymes decreased. 30%-41% and 22%-33% lower serum ALT and AST activities were shown, respectively

Lee <i>et al</i> <sup>[39]</sup> 2008	Mouse	A combination of <i>Morus alba</i> , <i>Melissa officinalis</i> and <i>Artemisia capillaries</i>	12 wk	-	Sig. decrease in body wt. gain & adipose mass	Decreased serum levels of TG, Chol & inhibited hepatic lipid accumulation, and increased hepatic mRNA levels of enzymes responsible for FABO
Choi <i>et al</i> <sup>[40]</sup> 2008	Mouse (obese by HFD)	Cucurbita moschata	500 mg/kg 8 wk	-	Sig. suppression of body wt. & fat storage increase but amount of food intake was not affected	
Huang <i>et al</i> 2008 <sup>[41]</sup>	Rat	<i>Momordira charantia</i> L. (Bitter melon)	5%	C: HFD I1: HFD + plant I2: HFD + thiazolidinedione	Sig. decrease in the number of large adipocytes in both I groups. Sig. decrease in adipose tissue mass in I group compared to L group	Sig. decrease in enzymes of adipose tissue implicating reduction of insulin resistance in I group as compared to C group
Lemaire <i>et al</i> <sup>[42]</sup> 2007	Rat (obese)	<i>Cyperus rotundus</i> <td>45, 220 mg/kg 60 d</td> <td>-</td> <td>Sig. decrease in wt. gain without affecting food consumption</td> <td></td>	45, 220 mg/kg 60 d	-	Sig. decrease in wt. gain without affecting food consumption	
Lei <i>et al</i> <sup>[43]</sup> 2007	Mouse	Pomegranate leaf	400/800 mg per kilogram 5 wk	C: HFD/NLD I: Same groups + extract	Sig. decrease in body wt. & energy intake and adipose pad wt. percents in I. group. Sig. decrease in appetite of obese mice on NLD was shown	Sig. decrease in serum TG, Chol, glucose levels & Chol/HDL ratio, inhibition of intestinal fat absorption
Aoki <i>et al</i> <sup>[44]</sup> 2007	Mouse (obese by HFD)	Licorice flavonoids oil (LFO)	0/5%, 1%, 2% 8 wk	C: Placebo I: Extract	Sig. decrease of abdominal white adipose tissue & body wt. gain with 1% & 2% LFO groups, decrease of adipocyte size	Improvement of fatty degeneration of hepatocytes and changes in genes implicating regulation of lipid metabolism with 2% concentration
Oluyemi <i>et al</i> <sup>[45]</sup> 2007	Rat	<i>Garcinia cambogia</i> seed (bitter cola)	200, 400 mg/kg 5 wk	C: Placebo I: Extract	Sig. decrease in body wt.	Sig. decrease in TG pool of adipose tissue & liver but sig. increase of HDL & decreased LDL
Han <i>et al</i> <sup>[46]</sup> 2006	Mouse (obese by HFD)	<i>Kochia scoparia</i>	1%, 3%/3 d	-	Prevented the increases in body & parametrial adipose tissue wt.	Sig. increase the fecal content & fecal TG levels in day 3
Goyal <i>et al</i> <sup>[47]</sup> 2006	Mouse (obese gold thioglucose)	<i>Zingiber officinale</i>	250 mg/kg 8 wk	C: Placebo I: Extract	Sig. decrease in body wt.	Sig. decrease in serum Chol, TG, glucose, and insulin
Kishino <i>et al</i> <sup>[48]</sup> 2006	Rat and mouse	<i>Salacia reticulata</i>	0/5% 8 wk in mice 0/2% 35 d in rats	C: HFD I: HFD + plant	Sig. decrease in the body wt. and visceral fat mass increase	Sig. decrease in plasma TG, 4 h after ingestion; Sig. decrease in energy efficiency, plasma leptin and adiponectine levels
Jayaprakasam <i>et al</i> <sup>[49]</sup> 2006	Mouse	Cornelian cherry (cornus mas) (Purified anthocyanins (A) & ursolic acid (u))	1 g/kg (A), 500 mg/kg (u) 8 wk	C: HFD I: HFD + A/A + u	24% decrease in wt. gain in (A) group	Elevated insulin levels; Sig. decrease of liver TG in A + u group
Moreno <i>et al</i> <sup>[50]</sup> 2006	Rat	<i>Arachis hypogaea</i> nutshell	1% (wt:wt) /12 wk	C: HFD I: HFD + extract	Sig. decrease in body wt. gain and liver size	Increased fecal lipid excretion. Reduced TG content of liver and serum glucose and insulin
Galisteo <i>et al</i> <sup>[51]</sup> 2005	Rat (obese)	<i>Plantago Ovata</i>	3/5% 25 wk	C: STD I: STD + extract	Sig. decrease in body wt. gain	Sig. improvement of lipid profile, FFA & insulin & TNF- $\alpha$ & hypoaldinectinemia
Zhao <i>et al</i> <sup>[52]</sup> 2005	Mouse (obese by hyperalimentation)	Phillyrin (Fructose forsythia)			Sig. decrease in wet wt. of fat & fat index & diameter of fat cells & lee index	Decrease in jejunum microvillus area, and serum levels of TG & Chol
Chen <i>et al</i> <sup>[53]</sup> 2005	Rat	Bitter melon ( <i>Momordica charantia</i> )	0/75% or 7/5 g per kilogram 7 wk	C: LFD/HFD I: LFD/HFD + extract	Lower energy efficiency and visceral fat mass after 4 wk in I group	Reduced plasma glucose and hepatic TG but higher serum FFA after 4 wk; Higher plasma catecholamine after 7 wk in I group; Sig. decrease in hepatic TG & steatosis and sig. increase of serum epinephrine & FFA in HFD group of I

Han et al <sup>[54]</sup> 2005	Rat	Coleus forskohlii	50 g/kg	C: Sham operated/ ovariectomized + control diet I: Same groups + extract	Reduced body wt.& food intake & fat accumulation
Han et al <sup>[55]</sup> 2005	Mouse	Chikusetsu saponins isolated from Panax japonicus rhizomes	1%, 3%/9 wk	C: HFD I: HFD + extract	Prevented body wt. gain & increase of parametrial adipose tissue wt.
Han et al <sup>[56]</sup> 2005	Mouse	Zingiber officinale Roscoe	1%, 3%/8 wk	C: HFD I: HFD + plant	Sig. decrease in body wt. gain at 2-8 wk with 3% & in final parametrial adipose tissue wt. with 1% concentration
Cha et al <sup>[57]</sup> 2004	Mouse	Acanthopanax senticosus	0/5 g per kilogram 12 wk	C: NLD/HFD I: NLD/HFD + extract	HFD group of I had lower wt. gain but no difference in food consumption was shown
Kim et al <sup>[58]</sup> 2005	Rat	Crude saponin of Korean red ginseng	200 mg/kg 3 wk, ip	C: NLD/HFD I: NLD/HFD + extract	Reduced body wt., food intake & fat content in HFD group of I similar to those fed with NLD
Yun et al <sup>[59]</sup> 2004	Mouse	Wild Ginseng	250, 500 mg/kg	C: HFD I: HFD + extract	Sig. inhibition of body wt. gain dose dependently. Decrease of white & brown adipocytes diameters
Junbao et al <sup>[60]</sup> 2004	Rat (obese)	Semen cassiae	6%	-	Sig. decrease in body wt. & lee index
Kim et al <sup>[61]</sup> 2004	Rat	Adlay seed (CoixLachrymajobi var. mayuen)	50 mg/100 g of body wt.	C1: NLD C2: HFD + saline (sham group) I: HFD + plant	Sig. decrease in body wt. & food intake & epididymal and peritoneal fat & white adipose tissue size as compared to sham group
Kwon et al <sup>[62]</sup> 2003	Rodent	Dioscorea nipponica Makino	5%/8 wk	C: HFD I: HFD + plant	Sig. decrease in body wt. & adipose gain
Lu et al <sup>[63]</sup> 1999	Rat (obese by hyperalimentation)	Inspissation tea (Guangdong kudingcha)		C: Control II: Extract I2: Fenfluramine	Stronger modulation on lymphocytes hypertrophy and quantity was shown in II group
Yoshikawa et al <sup>[64]</sup> 2002	Rat (obese)	Salacia reticulata	125 mg/kg 27 d		Suppression of body wt. and periuterine fat storage increase in female rats but no effect on male rats
Xie et al <sup>[65]</sup> 2002	Mouse	Ginseng berry	150 mg/kg 12 d, ip	C: Diabetic/lean diabetic + placebo I: Same groups + extract	Sig. decrease in body wt. as compared to day 0 in diabetic group of I. wt. loss in lean mice was shown
Yamamoto et al <sup>[66]</sup> 2000	Rat	CT-II, an extract from Nomame Herba	8 wk, 12 wk, 6 mo	C: Lean/obese + HFD I: Same groups + HFD + plant	Sig. inhibition of body wt. gain dose dependently without affecting food intake in lean rats after 12 wk. Sig. decrease in body wt. gain in obese mice after 24 wk
Han et al <sup>[67]</sup> 1999	Mouse	Oolong tea	10 wk	C: HFD I: HFD + extract	No sig. difference in food intake but prevented obesity & liver induced by a HFD
					Enhancement of noradrenalin induced lipolysis & inhibition of pancreatic lipase activity

Pusztai <i>et al</i> <sup>[68]</sup> 1998	Rat	Kidney bean (Phaseolus vulgaris)	130, 150, 280 g/kg 10-70 d	C: Lean/obese + LFD/HFD I: Same groups + extract	The growth was retarded dose- dependently lower body fat	Sig. decrease of body protein in lean I group. Sig. decrease in plasma insulin levels in obese I group. Sig. pancreatic growth after long term feeding in all I groups
Nagasawa <i>et al</i> <sup>[69]</sup> 1991	Mouse (obese)	Tree peony root (Paenia suffruticosa)	0/5% 30 wk	C: Control I: Extract	Sig. decrease in food intake and Lee index	Improvement in glucose tolerance. No sig. difference in serum FFA levels
Wang <i>et al</i> <sup>[70]</sup> 2008	Mouse	Parasitic loranthus from Loranthaceae or Viscaceae	20 d	-	Sig. decrease in body wt. & food intake	High inhibitory ability on FAS- Loran thaea was nearly 400 fold stronger than that from the viscaceae
Hu <i>et al</i> <sup>[71]</sup> 2008	Mouse (female)	Escins extracted from Aesculus turbinata Blume (Hippocastanaceae)	2%/11 wk	I: HFD C: HFD + extract	Suppressed the increase in body & parametrial adipose tissue wt.	Suppressed the increase of liver TG content; increased TG in feces after fat ingestion
Ohkoshi <i>et al</i> <sup>[72]</sup> 2007	Mouse	Nelumbo nucifera Gaertn leaves (Nymphaeaceae)	50%	C: STD/HFD I: Same groups + extract	Sig. suppression of body wt. gain	Exhibition of lipolytic activity especially in visceral adipose tissue; $\beta$ adrenergic receptor pathway was partly involved
Kang <i>et al</i> <sup>[73]</sup> 2004	Rat	PM-F2-OB composed of <i>Lycii Fructus</i> , <i>Rehmanniae Radix</i> , <i>Coicis Semen</i> , <i>Carthami Flos</i> , <i>Hoelen</i> , <i>Angelicae Radix</i> , <i>Nelumbinis Semen</i> , <i>Radix Dioscorea</i> and <i>Aurantii Fructus</i>	6 wk	C: STD/HFD I: Same groups + plant	No sig. difference in wt. change if STD was used but in HFD group of I resulted in sig. decrease in body wt. gain but showed no sig. difference in amount of food intake	Sig. decrease in serum Chol/ LDL and total lipids; reduction of kidney fat wt./FFA/PL & TG to levels equal or below the normal diet
Mary <i>et al</i> <sup>[74]</sup> 2003	Rabbit	Caps HT2 A herbal formulation	5 mg/kg (iv) 30 d 100/200/300/ 400/mg per kilogram orally	-	Sig. decrease in body wt.	Sig. increase in HDL after oral administration and decrease in atherogenic index in oral administration; Sig. increase of the release of LPL enzyme and sig. hypolipidemic effect in IV groups
Wu <i>et al</i> <sup>[75]</sup> 2005	Rat (diabetic by STZ )	Astragalus polysaccharide (APS) a component of Astragalus membranaceus roots	400 mg/kg (APS) 5 wk	-	Sig. decrease in body wt.	Sig. decrease in plasma glucose; improved insulin sensitivity
Xie <i>et al</i> <sup>[76]</sup> 2005	Mouse (Genetically obese)	Total, Ginsenosides in Chinese ginseng (TG CG), from leaves and the stem of Panax ginseng	100, 200 mg/kg (ip) 12 wk & 150, 300 mg/kg (oral)/12 wk	C: Placebo I: Extract	Sig. decrease in body wt.	Sig. decrease in FBG in 200 mg/kg dose after injection Sig. decrease in FBG in 300 mg/kg dose
Palit <i>et al</i> <sup>[77]</sup> 1999	Mouse	Galega officinalis	10% (w/w) of the diet 28 d	C: Diabetic/NL I: Same groups + plant	Sig. decrease in body wt. in both I groups, sig. wt. loss in normal mice independent of a reduction in food intake but in diabetic mice wt. loss was with reduced food intake	Striking loss of body fat in both groups; Sig. decrease in serum glucose in both groups but Sig. decrease in serum insulin in diabetic mice
Oi <i>et al</i> <sup>[78]</sup> 1999	Rat	Garlic	8 g/kg of diet 28 d	C: HFD I: HFD + extract	Sig. decrease in body wt. & perirenal adipose tissue wt. & epididymal fat pad	Sig. decrease in plasma TG levels; sig. decrease in mitochondrial protein and (UCP) in brown adipose tissue, and in urinary noradrenaline and adrenaline excretion
Yoshida <i>et al</i> <sup>[79]</sup> 1995	Mouse (obese and lean)	Bofu-tsusho-san	1/4%, 4/7% of wt. of food 8 wk	-	Sig. decrease in body wt. & retroperitoneal white adipose tissue wt. and no change in food intake	Sig. increase in GDP binding dose dependently
He <i>et al</i> <sup>[80]</sup> 2008	Rat (obese by STZ & HFD)	Yi-Qi-Yang-Yin-Ye	2, 4, 8 g/kg 4 wk	-	Body wt. decreased	Decrease in TG/Chol/ LDL/FFA/FBG/insulin; improvement of glucose tolerance

Jeong et al <sup>[81]</sup> 2008	Rat (fatty)	Gyeongshang angjeehwan: Liriope platyphylla F.T./Wang & T. Tang (Liliaceae), Platycodongrandiflorum A. DC. (Campanulaceae). Schisandrachinensis K. Koch (Magnoliaceae). Ephedra sinica Stapf (Ephedraceae)	8 wk	C: Placebo I: Compound	Sig. decrease in food intake & body wt. gain & abdominal fat	Sig. decrease in plasma leptin levels; decrease in circulating TG and inhibition of lipid accumulation in liver; increase of mRNA of genes responsible for FABO
Park et al <sup>[82]</sup> 2005	Rat (obese by diet)	Platycodon grandiflorum	150 mg/kg 7 wk	C: Convert to NLD/HFD I: Same groups + extract	Sig. decrease in wt. of body & adipose tissues in rats converted to NLD as compared to those remained on HFD	Sig. decrease in fat cell number & size in both I groups as compared to their state before intervention; decrease of FABP expression in HFD group of I
Akagiri et al <sup>[83]</sup> 2008	Mouse (obese by HFD)	Bofutsushosan (BOF)	1%/4 wk	C: Placebo I: Compound	The wt. of WAT and increase in size of adipocytes inhibited	Expression of UCP1 mRNA in WAT was found but not sig.
Kim et al <sup>[84]</sup> 2005	Mouse (diabetic)	Pine extract (bark and needle)	21 d	C: Control I: Extract	Sig. decrease in body wt.	Effectively suppressed the increase of postprandial blood glucose level by delaying absorption of diet
Attele et al <sup>[85]</sup> 2002	Mouse (obese diabetic)	Panax ginseng berry	150 mg/kg (ip) 12 d	C: Control I: Extract	Sig. loss of wt. with a sig. reduction in food intake & a very sig. increase in energy expenditure & body temperature	Sig. improvement in glucose tolerance & sig. reduction in serum insulin levels & plasma chol levels

MSG: Monosodium glutamate; FABO: Fatty acid  $\beta$  oxidation; STD: Standard diet; LFD: Low fat diet; NLD: Normal diet; HFD: High fat diet; FABP: Fatty acid binding protein; FFM: Fat free mass; sig.: Significant; AST: Aspartate transaminase; ALT: Alanine transaminase; C: Control; I: Intervention; FAS: Fatty acid synthetase; UCP: Uncoupling protein; GDP: Guanosine 5' diphosphate; FAS: Fatty acid synthetase; TG: Triglyceride; HDL: High density lipoprotein; LDL: Low density lipoprotein; FBC: Fasting blood glucose; ip: Intraperitoneal; iv: Intravenous. Caps HT2 is a herbal formulation containing methanolic extract of selected parts of plants: commiphora mukul; Allium Sativum; Plumbago indica/some carpus anacardium/Hemidesmus indicus/Terminalia arjuna/Tinospora cordifolia/Withania somnifera ocimum sanctum.

caffeine<sup>[9,20]</sup> which caused minor adverse effects such as dry mouth, insomnia, nervousness, palpitation and headache. Bofutsushosan<sup>[14]</sup> caused loose bowel movements.

## ANIMAL STUDIES

### Change in body weight and body fat

The majority of animal studies (41 out of 58) showed significant weight loss or inhibition of weight gain when supplemented with high fat diets containing extracts of plants, with or without an efficient decrease in fat mass<sup>[27-85]</sup> (Table 2).

### Food intake

Clinical trials with *Agave tequilana* (TEQ) and *Dasylirion* spp (DAS)<sup>[50]</sup>, Pomegranate leaf<sup>[43]</sup>, Korean red ginseng<sup>[58]</sup>, Tree peony<sup>[69]</sup>, Gyeongshang angjeehwan containing a variety of plants including platycodon grandiflorum, Magnoliaceae and Ephedra<sup>[81]</sup>, Parasitic loranthus<sup>[70]</sup>, and Panax ginseng berry<sup>[85]</sup> showed significant reductions in food intake or appetite. In studies with *Cucurbita moschata*<sup>[40]</sup>, *Cyperus rotundus*<sup>[42]</sup>, Nomame Herba<sup>[66]</sup>, *Acanthopanax senticosus*<sup>[57]</sup> PM-F2-OB (a traditional herbal medicine used for the treatment of obesity in Korea composed of *Lycii Fructus*), and several other plants<sup>[73]</sup>, bofu-tsusho-san<sup>[75]</sup>, *Galega officinalis*<sup>[77]</sup>, and Oolong tea<sup>[67]</sup>, no change in the amount of food intake or appetite was observed.

## DISCUSSION

In many studies<sup>[8-10,12-16,20-23,27,39,73,74,79-81,83]</sup>, a combination of plants or compounds containing minerals and/or chemical extracts of plants were investigated and the scientific names are summarized in Tables 1 and 2. Most of these studies showed anti-obesity effects such as decreasing body weight in humans or body weight gain in animals with or without changes in body fat.

Currently available anti-obesity medications attack the body fat dilemma in three different ways. They can stimulate metabolism, suppress appetite, affect serotonin, or they can impede digestion of fat. In this review, we can categorize the target effects of herbal medicines in the same way.

*Arachis hypogaea*<sup>[50]</sup> decreased body weight gain, liver triglyceride content and liver size in association with increased fecal lipid excretion, suggesting an inhibitory mechanism on lipid absorption. *Phillyrin*<sup>[52]</sup>, *Allium victorialis*<sup>[32]</sup>, Pomegranate leaf<sup>[43]</sup>, *Kochia scoparia*<sup>[46]</sup>, *Panax japonicus*<sup>[55]</sup>, Oolong tea<sup>[67]</sup>, and *Aesculus turbinata* Blume<sup>[71]</sup> also had the same effect.

A decrease in food intake as a result of a decrease in appetite and an influence on hormonal status was observed with TEQ and DAS<sup>[50]</sup>, Pomegranate leaf<sup>[43]</sup>, Korean red ginseng<sup>[58]</sup>, Tree peony<sup>[69]</sup>, Gyeongshang angjeehwan containing a variety of plants including platycodon grandiflorum and Magnoliaceae and

ephedra<sup>[81]</sup>, and Parasitic loranthus<sup>[70]</sup>, refined Rhubarb<sup>[34]</sup>, *Caralluma fimbriata*<sup>[19]</sup> and Panax ginseng berry<sup>[85]</sup>. Possible stimulation of metabolism has been reported as a mechanism of action for compounds such as Slimax<sup>[8]</sup>, supplements containing ephedra<sup>[9,13,14,20]</sup> and *Terminalia arjuna Roxb*<sup>[11]</sup> which showed modification of lipid metabolism and a reduction in serum lipid levels.

Ephedra known as *Ma Huang* is a well known natural product with amphetamine-like stimulation effects. Although its efficacy in weight loss need more investigations, its adverse effects are well established in the literature. In this review, nine studies investigated the effects of ephedra as one of the major components in the combinations with caffeine<sup>[9,13,22]</sup> or with several other plants<sup>[14,20,79,81,83]</sup> 5 of which were human studies<sup>[9,13,14,20,22]</sup>.

In one study<sup>[13]</sup>, efficient decreases in body weight and fat were observed with the administration of 210 mg caffeine and 72 mg ephedra per day for 12 wk with an improvement in lipid metabolism and blood pressure without serious adverse effects. In this study, the weight loss at 12-wk was  $-3.5 \pm 0.6$  kg with the test compound which was significantly ( $P < 0.02$ ) higher than that of the placebo. The percentage fat loss shown by DXA was  $-7.9\% \pm 2.9\%$  and  $-1.9\% \pm 1.1\%$ , respectively ( $P < 0.05$ ). In another study<sup>[20]</sup>, ephedra at a dose of 40 mg/d and caffeine at a dose of 100 mg/d for a longer time (9 mo) was found to be more efficient than the previous study in lowering body fat and weight, improving lipid metabolism and blood pressure and had no serious adverse effects. The treatment group lost significantly more body weight (-7.18 kg) and body fat (-5.33 kg) than the control group (-2.25 and -0.99 kg, respectively). The difference in data from these two studies possibly resulted from the different dosages and duration of interventions.

In a human study<sup>[9]</sup>, a significantly greater weight loss was observed ( $-4.0 \pm 3.4$  kg or 3.5% of baseline) in the test group vs ( $-0.8 \pm 2.4$  kg or 0.09% of baseline) in the placebo group. Changes were significantly greater for body fat and percentage of body fat in the active group ( $-3.5 \pm 3.3$  kg and  $-2.1\% \pm 3.0\%$ ) in comparison to the placebo group ( $-0.7 \pm 2.9$  kg and  $-0.2\% \pm 2.3\%$ ). The tested product also produced several untoward side effects, leading to some actively treated subjects withdrawing from the study. Additional long-term studies are needed to elucidate the effects of chronic treatment. Thus further examinations in healthy individuals using scientific combinations and dose/duration adjustments are required.

Four studies<sup>[58,59,65,70]</sup> investigated different doses and types of ginseng which is a very popular Chinese herbal medicine. Ginseng significantly decreased weight gain and efficiently improved glucose tolerance<sup>[59,76]</sup>.

It has been reported<sup>[58]</sup> that hormonal influences can reduce food intake and decrease serum leptin and neuropeptide Y in the brain hypothalamus although not significantly. Thus the anti-obesity effect of this plant requires further investigation.

CQ, a succulent vine native to West Africa and Southeast Asia, has been used in traditional African and Ayurvedic medicine for more than a century. Although some studies have examined other uses for CQ, its role in fighting against obesity and for symptoms of

metabolic syndrome has recently attracted interest in other parts of the world, because of its milder adverse effects comparing to ephedra. In this review, two studies focused on this herb<sup>[15,26]</sup>. CQ in combination with IG<sup>[15]</sup> induced marked reductions in body weight and fat. In addition, a reduction in waist size of 1.0 cm in the placebo group vs 21.9 cm in the CQ-IG group was observed.

As we focused on herbal medicines, all dietary interventions such as the consumption of fruits and vegetables, whole grains, different types of fibers, functional food components including omega three fatty acids or phytochemicals such as flavonoids were omitted. Lifestyle modification is still the safest and efficacious method of inducing a persistent weight loss. In this review, some of the studies were carried out on subjects who simultaneously received diet and exercise programs (mentioned as weight loss programs in Tables). These results demonstrated that specific phytochemical supplements increase the effectiveness of weight loss programs and additional significant anti-obesity effects are observed.

Although few studies mentioned adverse effects, it should be noted that many serious adverse events which would have stopped a trial of a pharmaceutical agent would likely not have been identified by the authors' search methods. Moreover, important safety issues including significant adverse events or supplement-drug interactions relevant to many clinical populations may not be fully addressed by the trials available for review.

## CONCLUSION

Compliance with conventional weight-management programs, which often include increasing energy expenditure via physical activity, is low. It is not surprising to see the marketing of many new dietary slimming aids aimed at satisfying the need for palatable (as well as safe, effective, and therapeutic) options. In accord with this approach there are numerous investigations on the effectiveness of medicinal plants as natural supplements to reduce body weight. In this paper a variety of herbal supplements had beneficial effects on obesity especially compounds containing ephedra, CQ, ginseng, bitter melon (*Momordica charantia*), and zingiber. Most of the introduced herbals (Tables 1 and 2) have also been shown to have antioxidant effects, and with regard to the role of oxidative stress in the pathophysiology of some diseases and conditions, their further positive effects may be very promising<sup>[86-95]</sup>. Attention to these natural compounds and further work on the isolation and characterization of their constituents is highly recommended.

of the inoculation of rabbits with the virus of rabbit hemorrhagic disease. This model displays biochemical and histological characteristics, and clinical features that resemble those in human AHF. In the present article an overview is given of the most widely used animal models of AHF, and their main advantages and disadvantages are reviewed.

Tuñón MJ, Alvarez M, Culebras JM, González-Gallego J. An overview of animal models for investigating the pathogenesis and therapeutic strategies in acute hepatic failure. *World J Gastroenterol* 2009; 15(25): 3086-3098 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3086.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3086>

## Abstract

Acute hepatic failure (AHF) is a severe liver injury accompanied by hepatic encephalopathy which causes multiorgan failure with an extremely high mortality rate, even if intensive care is provided. Management of severe AHF continues to be one of the most challenging problems in clinical medicine. Liver transplantation has been shown to be the most effective therapy, but the procedure is limited by shortage of donor organs. Although a number of clinical trials testing different liver assist devices are under way, these systems alone have no significant effect on patient survival and are only regarded as a useful approach to bridge patients with AHF to liver transplantation. As a result, reproducible experimental animal models resembling the clinical conditions are still needed. The three main approaches used to create an animal model for AHF are: surgical procedures, toxic liver injury and infective procedures. Most common models are based on surgical techniques (total/partial hepatectomy, complete/transient devascularization) or the use of hepatotoxic drugs (acetaminophen, galactosamine, thioacetamide, and others), and very few satisfactory viral models are available. We have recently developed a viral model of AHF by means

## INTRODUCTION

Acute or fulminant hepatic failure (AHF) is a severe liver injury accompanied by hepatic encephalopathy which causes multiorgan failure with an extremely high mortality rate, even if intensive care is provided. Management of severe AHF continues to be one of the most challenging problems in clinical medicine<sup>[1]</sup>. Liver transplantation has been shown to be the most effective therapy, but the procedure is limited by shortage of donor organs combined with the disadvantage of needing immunosuppressant treatment<sup>[2,3]</sup>. Survival rates are substantially improved today compared with the mortality rate that approximated 100% when the

syndrome was first described nearly five decades ago. Nonetheless, survival has plateaued in recent years, prompting us to consider whether major new advances in disease understanding are needed to further improve the overall outcome<sup>[4]</sup>.

Since 1970, when Trey and Davidson<sup>[5]</sup> introduced the term fulminant hepatic failure, various authors have suggested different classifications aimed to establish prognosis and adequate therapeutic strategies. These classifications are fundamentally based on time elapsed from onset of clinical symptoms or jaundice to the development of encephalopathy<sup>[6-9]</sup>. The causes of AHF are varied and in many patients remain unknown. A 6-year study (1992-1998) carried out in Spain into the causes of AHF indicated that the basic etiopathogenic agents of AHF were viral hepatitis (39%), unknown cause (30%), toxins or drugs (21%) and others (10%)<sup>[10]</sup>. Acute viral hepatitis constitutes a frequent cause of AHF<sup>[7,11,12]</sup>. The viruses causing hepatitis A, B and E are capable of producing AHF, which is rarely seen with hepatitis C virus. The hepatitis B virus is the main causal agent worldwide, responsible for 70% of all cases of viral origin<sup>[13]</sup>. The hepatitis E virus causes AHF principally in women in their third term of pregnancy. Other viruses involved comprise the herpes virus, varicela-zoster, cytomegalovirus, Epstein-Barr virus, human herpes type 6, adenovirus and paramyxovirus, mainly in the setting of immunosuppression<sup>[14]</sup>. Non-steroidal anti-inflammatory analgesic and anti-bacterial drugs are among the pharmaceuticals which most frequently trigger AHF<sup>[7,15-17]</sup>. Other less common causes of AHF include pregnancy, veno-occlusive disease, Budd-Chiari syndrome, Wilson's disease, hemochromatosis, tumoral metastases, sepsis, ischemia and hepatic transplant failure<sup>[18,19]</sup>.

Etiologies also vary worldwide with considerable differences apparent between Western countries and the developing world. In Europe and North America a large proportion of cases are due to acetaminophen and to idiosyncratic drug reactions<sup>[20]</sup>, whereas reports from emerging countries in Asia and Africa feature viral illnesses, particularly hepatitis B and E<sup>[17]</sup>. The resulting clinical picture is remarkably similar across the different etiologies, reflecting common patterns of response of the innate immune system and the resulting inflammatory response<sup>[21]</sup>. Determining etiology is important for two reasons: specific antidotes or therapies may be indicated once the diagnosis is known, and knowing the cause provides a reasonably valid guide to predicting outcome.

The AHF syndrome occurs as a result of the functional failure of a large part of the hepatic parenchyma, and severity is proportional to the level of hepatic damage. AHF provokes profound physiological alterations characterized by encephalopathy, hemodynamic changes and coagulopathy, with frequent development of cerebral edema and renal failure<sup>[14,22,23]</sup>. Diagnosis is based on biochemical and hematological data indicating hepatic cell hypofunction. Although prolonged prothrombin time not corrected by vitamin K and impairment of factor V are

widely used, research into prognostic indexes remains an open field of investigation<sup>[24]</sup>.

The pathophysiology of AHF is an area of great interest. It is evident that a relationship must exist between different pathogenic factors, such as bacteria toxins, cytokines, free radicals and other components of the inflammatory system which cause local lesions<sup>[25]</sup>. It seems that the endothelium is the first to release vasoactive agents which affect local and distal blood flow in the critical phase of the disease, with nitric oxide, prostacyclins and endothelins being essential components of the response<sup>[26]</sup>. Hyperbilirubinemia is generally conjugated and jaundice is an early indicator which progresses rapidly. Severe coagulation problems arise as a result of a variety of mechanisms. Consumption of factor V indicates hepatic damage regardless of vitamin K levels. Renal failure occurs in 30%-75% of cases, and is associated with a poor prognosis. Thrombocytopenia is also common<sup>[27]</sup>. An increase in the plasma concentration of aromatic amino acids (AAA) and normal or slightly elevated values for branched amino acids (ACR) are typical findings in patients with AHF. In fact, a fundamental clinical parameter for AHF is the Fischer index, that is, the ACR/AAA molar ratio, which decreases as the severity of hepatic symptoms develops<sup>[28]</sup>. An increase in the amino acids phenylalanine and tyrosine, and a decrease in the Fischer index have been reported in both surgical models<sup>[29]</sup> and models using galactosamine<sup>[30]</sup>.

Intracranial hypertension is a major cause of morbidity and mortality of patients suffering from fulminant hepatic failure. The etiology of this intracranial hypertension is not fully determined, and is probably multifactorial, combining a cytotoxic brain edema due to the astrocytic accumulation of glutamine, and an increase in cerebral blood volume and cerebral blood flow; in part due to inflammation, to glutamine and to toxic products of the diseased liver<sup>[31]</sup>. Cerebral edema is a potential life-threatening complication in patients with AHF who progress to grade III/IV encephalopathy<sup>[26]</sup>. The current view on the pathogenesis of cerebral edema is that hyperammonemia plays a main role. High arterial ammonia concentrations have been proposed as a predictor of brain herniation and mortality in patients with AFL<sup>[32-34]</sup>. Moreover, arterial ammonia concentration, ammonia delivery to the brain, and its metabolic rate are higher in patients with high intracranial pressure, and increased arterial ammonia correlates with increased cerebral flow<sup>[35]</sup>. Recent work has also suggested free radical formation occurring at a mitochondrial level as being the potential mediator of cellular dysfunction as opposed to ammonia *per se*<sup>[36]</sup>.

Research into the molecular mechanisms of hepatic regeneration has aroused wide-spread interest<sup>[37,38]</sup>. Although little is still known about the hepatic regenerative process, it is clear that cellular loss and damage in the liver are accompanied by a lack of regenerative activity<sup>[39]</sup>. Plasma levels of hepatocyte growth factor (HGF) and transforming growth factor (TGF)- $\beta$  rise<sup>[40]</sup>. An increase in the activity of the

fibrinolytic system, responsible for the activation of both HGF and TGF- $\beta$ , is also observed<sup>[41]</sup>. It has been reported that the serum of people affected by AHF has a negative effect upon culture cell growth when compared with a control serum, due to cell proliferation inhibition rather than to an increase of apoptosis<sup>[42]</sup>. Recent studies using various animal models have shown that the over-expression of calpastatin, an endogenous inhibitor of calpain, helps prevent further liver damage when hepatic regeneration is compromised<sup>[43]</sup>.

Knowledge concerning the pathophysiological basis of the AHF hemodynamic alterations, immunological dysfunction, and multiorgan failure is still very rudimentary. It is therefore crucial to investigate the molecular basis of AHF in more depth<sup>[44]</sup>. Furthermore, although many AHF treatment options have been proposed and applied in recent years, only hepatic transplantation is widely accepted among clinical specialists. However, the lack of donors combined with the high costs, technical difficulties, viability issues and the disadvantage of needing life-long pharmacological immunosuppressant treatment following surgical intervention (with the added complication that the immunosuppressant agents used themselves produce side effects in the kidneys, liver and other organs), mean that liver transplantation is not always an option. For these reasons, other therapeutic options to bridge patients to recovery or stabilization have to be considered. Artificial liver support, intended to remove protein-bound toxins and water-soluble toxins without providing synthetic function, and bioartificial liver support systems, using hepatocytes in an extracorporeal device connected to the patient's circulation, are being tested, and molecular adsorbent recirculating systems (MARS)<sup>[45]</sup> or cell-based therapies are increasingly the focus of attention<sup>[46,47]</sup>. These systems improve clinical and biochemical parameters and can be applied safely to patients<sup>[48]</sup>, but their effectiveness and viability have not yet been conclusively demonstrated<sup>[38]</sup>. In terms of clinical applications, functional studies using animal models are absolutely crucial.

## ANIMAL MODELS OF AHF

Knowledge of the pathophysiology and treatment of AHF are limited by the lack of satisfactory animal models. Many attempts have been made to develop a suitable model which can be replicated, using a wide variety of species and approaches, from surgical models to the use of hepatotoxic drugs (Table 1). However, to date a simple model which accurately reproduces the pattern of human AHF has not been reported, and the models currently in use present significant limitations<sup>[49,50]</sup>.

An ideal model would present well-defined clinical and biochemical criteria, and, as in the case of the King's College AHF prognostic criteria<sup>[11]</sup>, be capable of providing an accurate prognosis. However, none of the models which have been developed until now meet these requirements. Furthermore, the clinical and biochemical criteria used to indicate the existence of AHF in animal models often have very little in common with those used in clinical practice. However, given the current state of

knowledge concerning AHF and the difficulties involved in carrying out research on patients, animal models have a fundamental role to play in future studies despite their limitations. Therefore, although progress is being made, research in this field must continue, with the aim of developing a reliable and suitable animal model, capable of accurately reflecting the human clinical syndrome and presenting a minimum of disadvantages<sup>[51]</sup>.

Ideal AHF models, according to criteria widely accepted (Table 2)<sup>[49-54]</sup>, would benefit from complying with a series of requirements including that the model should be reversible, ie that some animals would survive the process if a suitable treatment were administered, and that the results obtained can be replicated, i.e. that death occurs at recognised intervals and that the extent of hepatic damage can be measured and standardised. Furthermore, death would need to be a result of hepatic damage, i.e. the complications produced following damage would need to accurately reflect the typical human clinical picture and death should be the direct result of the liver damage produced. Therefore, the untreated animals should die with signs of progressive hepatic failure within a recognised period of time. In addition, the animal used would need to be of a size permitting sufficient samples of blood and tissue to be taken during treatment. Finally, all the methods used should represent the lowest possible health risk for personnel participating in the research. An additional criterion could be the use of a conscious animal model to evaluate the development of hepatic encephalopathy, since this is an essential part of the pathology of AHF<sup>[55]</sup>.

Numerous studies have been carried out in an attempt to develop a suitable AHF model. The majority of animal models are based on surgical techniques or hepatotoxic drugs. Surgical models include the use of hepatic ischemia and partial/total hepatectomy, whilst chemical models are based on the use of drugs and toxins such as acetaminophen, azoxymethane, concanavalin A, galactosamine, halothane, thioacetamide, amatoxin-endotoxin, etc. Nevertheless, to date, no model accurately reflects human AHF, and most demonstrate significant limitations.

### Surgical models

Surgical models of AHF can be divided into three categories: hepatectomy (total or partial), devascularization (total or partial) and models which are a combination of the previous two.

**Total and partial hepatectomy:** Surgical models employing total or partial hepatectomy have been successfully developed in various animal species following the first attempt carried out by Mann on dogs in 1921<sup>[56]</sup>. It has been demonstrated that 95% liver resection in rats provides a good AHF model<sup>[57]</sup>, whilst a less than 90% hepatectomy is the upper limit for a liver regeneration research model in mice, as higher values produce mortal hepatic failure<sup>[58]</sup>. A potentially reversible model using pigs has been described which combines partial hepatectomy (70%) with porta-caval derivation and produces death from AHF after an interval which is sufficiently prolonged

**Table 1 Main AHF animal models in different species**

<b>Animal model</b>	<b>Species</b>	<b>Advantages/disadvantages</b>
Surgical		
Total/partial hepatectomy	Pig, dog, rabbit, rat, mouse	Hepatic encephalopathy; reproducible/no reversibility; no long-term survival
Total/partial devascularization	Pig, dog, rabbit, rat	Hepatic encephalopathy; reproducible/no reversibility; no long-term survival
Chemical		
Acetaminophen	Pig, dog, rabbit, rat, mouse	Hepatic encephalopathy; no hazard/non-reproducible; variable interval between damage and death; species and age variability
Amanitin	Pig	Hepatic encephalopathy; specific toxic effects; large animal
Azoxymethane	Mouse	Hepatic encephalopathy; reproducible/small size; hazard
Carbon tetrachloride	Pig, rabbit, rat, mouse	Hepatic encephalopathy/non reproducible; extrahepatic toxicity; small time window before death
Concanavalin A	Rat, mouse	Hepatic encephalopathy/small size
Galactosamine	Pig, dog, rabbit, rat, mouse	Hepatic encephalopathy; biochemical markers/non-reproducible; hazard; variable interval between damage and death; species differences
Lipopolysaccharide	Rat, mouse	Hepatic encephalopathy/non-reproducible; small size; hazard; small time window before death
Thioacetamide	Rabbit, rat, mouse	Hepatic encephalopathy; reproducible; large time window before death/hazard
Viral		
Rabbit hemorrhagic disease	Rabbit	Hepatic encephalopathy; reproducible; no hazard

**Table 2 Main criteria for an AHF animal model (according to Terblanche and Hickman (1991))**

Reversibility	Suitable treatment may reverse and improve survival
Reproducibility	Reproducible end-points are required to standardize the model
Death from liver failure	Should reflect biochemical, histological and clinical changes including death from AHF
Therapeutic window	Time for treatment should be available between insult and death
Adequate animal size	Size large enough to allow blood and tissue analysis to take place serially
Minimal hazard to personnel	Minimum risk for operators and associated staff

to enable studies of hepatic support measures to be carried out. In addition, the animal is of an appropriate size, and the technique does not represent a health hazard<sup>[59]</sup>.

The partial hepatectomy models are equivalent to patients who have undergone large liver resections for liver tumors. It has been demonstrated by DNA analyses of rats subjected to various levels of partial hepatectomy that induced AHF is a consequence of both an increased rate of apoptosis and a reduction in liver regeneration<sup>[60]</sup>. Moreover, models of partial hepatectomy have been used to test the usefulness of different support systems. Thus, intraperitoneal transplant of syngeneic-bioencapsulated bone marrow cells, which can transdifferentiate into hepatocyte-like cells in the peritoneal cavity of 90% hepatectomized rats, increases the survival rate of these animals<sup>[61]</sup>. Examination of the effects of a series of allogenic hepatocyte transplantations in rats with subtotal hepatectomy indicates that intrasplenic hepatocyte transplantation 1 d before liver surgery shows the best results in terms of survival<sup>[62]</sup>. The usefulness of an artificial liver module having a liver lobule-like structure has been recently tested in rats with combined partial hepatectomy and hepatic ischemia, demonstrating that in treated

rats the increase in blood ammonia was completely suppressed and all animals recovered<sup>[63]</sup>.

The clinical equivalent of liver total hepatectomy is the massive liver damage due to liver trauma or a primary graft failure<sup>[51]</sup>. Main disadvantages are the absence in circulation of the toxic substances and inflammatory factors which play a role in the pathogenic mechanisms of AHF. Advantages are related to replicability and its usefulness in the *in vivo* study of artificial support devices in the absence of toxic products eliminated or produced by the damaged liver. Despite the disadvantages indicated, total hepatectomy has been used on rats to study hepatic regeneration<sup>[64]</sup>, and with pigs as a replicable model for testing the effectiveness and function of various temporary support device systems<sup>[65,66]</sup>. A new surgical model for hepatectomy in pigs, requiring prior to *en bloc* hepatectomy a Y-shaped bypass starting with end-to-side anastomosis between the vena cava and the portal vein, followed by anastomosis to the intrathoracic vena cava has been recently described. This model permits total hepatectomy with minimal blood loss under stable circulation without requiring an extracorporeal bypass<sup>[67]</sup>.

**Devascularization:** Complete devascularization of the liver may be achieved by portacaval shunt followed by occlusion of the hepatic artery, and in most cases also occlusion of the common bile duct and accessory hepatic vessels<sup>[68,69]</sup>. Depending on the time of temporary occlusion of the hepatic artery the model is more or less reversible. These techniques have been successfully used to induce a reproducible hepatic failure in pigs, which could be useful in the study of different artificial and/or bioartificial hepatic support devices<sup>[70,71]</sup> or to test the effects of antioxidant molecules such as N-acetylcysteine<sup>[72]</sup>. For example, a reproducible model has been developed using dwarf pigs for the study of reversible devascularization through hepatic artery ligation and porto-caval anastomosis, where intracranial pressure was monitored in addition to other classic parameters

indicative of AHF. This model provides an 8-h therapeutic window, enabling tests on different bioartificial support systems to be carried out<sup>[73]</sup>. In fact, with the use of a similar model in pigs, albumin dialysis using the molecular adsorbents recirculating system (MARS) has been reported to attenuate extracellular brain ammonia and lactate levels<sup>[74]</sup>. Hepatic devascularization in pigs has also allowed the demonstration that endothelium-dependent hyperpolarization of vascular smooth muscle contributes to the development of hyperdynamic circulation in AHF<sup>[75]</sup>.

A model using total clamping of the portal triad in dogs demonstrated that the damage caused by ischemia-reperfusion as a consequence of the surgical procedure was reduced following administration of a bradykinin  $\beta 2$  receptor antagonist<sup>[76]</sup>. Dogs were also used in another AHF model employing porto-caval derivation combined with bile duct ligation, in order to test a new system of bioartificial liver by inoculation of hepatocytes. This model was configured by inoculating porcine hepatocyte spheroids into the cell circuit of a hollow fiber bioreactor<sup>[77]</sup>. Recently a new pig model has been developed in which a 75%-80% liver resection is combined with an ischemia period<sup>[78]</sup>.

Studies carried out on survival time, technical ease, safety and reproducibility of AHF surgical models have reported that devascularization was more useful for studying the development and treatment of AHF caused by ischemia and related side effects, whilst partial hepatectomy was the most suitable technique for studying liver deficiency status and AHF treatment via bioartificial support devices<sup>[79]</sup>.

### **Chemical models**

The use of chemical agents such as acetaminophen, thioacetamide or galactosamine may reproduce a number of important AHF clinical characteristics, such as hypoglycemia, encephalopathy, and increased blood levels of hepatic enzymes, and hepatotoxic chemical agents are still frequently used as a model for AHF. However, repeated administration or a support therapy may be required in some models. In addition, intracranial hypertension, one of the main characteristics of human AHF, is absent in some chemical models whilst in other cases, an increase in toxins involved in hepatic encephalopathy and cerebral edema in human AHF cannot always be demonstrated<sup>[49]</sup>.

**Acetaminophen:** Acetaminophen (paracetamol) is a commonly used drug which can produce hepatic damage. In fact, it is the drug most frequently used to commit suicide in the United Kingdom despite the existence of the antidote acetylcysteine. Acetaminophen overdoses are the number one causes of AHF in USA, United Kingdom, and most of Europe, accounting for nearly 50% of USA cases<sup>[13]</sup>. Acetaminophen toxicity is dose-dependent, but its effects can be exacerbated by fasting, cytochrome P-450 inducer drugs and especially by alcohol. Studies on both hepatocyte cultures and mice have shown that c-jun kinases (JNK) play a major role in

the toxic effect of the drug<sup>[80]</sup>. More recently, it has been shown that apoptosis signal-regulating kinase 1 (ASK1), a member of the mitogen-activated protein kinase kinase family, is activated by acetaminophen overdose in mice, most likely *via* a mechanism involving thioredoxin-ASK1 dissociation, and that it plays a role in acetaminophen-induced liver injury through JNK activation<sup>[81]</sup>. The fact that JNK inhibition is not protective in acute carbon tetrachloride-mediated or anti-Fas antibody-mediated hepatic injury, suggests specificity for the role of JNK in the pathogenesis of acetaminophen-induced liver failure, thereby identifying JNK as an important therapeutic target in the treatment of acetaminophen hepatotoxicity<sup>[82]</sup>.

The results of numerous studies with animal models using acetaminophen to induce AHF have produced heterogeneous results due to the existence of significant variations in the hepatic detoxifying metabolism of the drug related to species and age<sup>[83,84]</sup>. Under normal conditions, acetaminophen hepatic metabolism is produced by glucuronidation and sulfation reactions, with formation of metabolites which are later excreted through the kidney. When an excess of the drug is present, normal detoxifying pathways are saturated and the drug is metabolized through cytochrome P-450 to N-acetyl-p-benzoquinoneimine which, unless conjugated with glutathione, is thought to interrupt mitochondrial calcium flux and to induce cell damage by the formation of hydroxyl radicals, nitrites, and nitrates, leading to apoptosis and cell necrosis<sup>[85]</sup>. Therefore, in order to potentiate acetaminophen toxicity, inducers of the cytochrome P-450 systems such as phenobarbitone and 3-methylcholanthrene, glutathione depletion induced by the glutathione synthetase inhibitor buthionine sulfoximine or a combination of both systems are used<sup>[84,86]</sup>.

Other important aspects which have not been standardized in acetaminophen models, and which produce variable results, include the optimal drug dose, the most suitable method of administration and the necessity or not of induction of the cytochrome P-450 system<sup>[86,87]</sup>. Lack of standardization is the origin of some of the major disadvantages of these models, specifically, their lack of reproducibility and the variable interval between inducing damage and the death of the research animals<sup>[49,52]</sup>. Furthermore, in some rodents significant differences have been found in concentrations of the main coagulation factors compared to those found in human AHF<sup>[88]</sup>.

Acetaminophen-induced animal models of AHF are widely used to improve our insight into the metabolic and physiological derangements of AHF and to facilitate the development of new therapeutic modalities. Thus, implantation of encapsulated lentivirally immortalized human hepatocytes rescue mice from lethal doses of acetaminophen, confirming that lentiviral vectors represent tools of choice for immortalization of non-dividing primary cells and that immortalized human hepatocytes are promising reagents for cell-based therapy of acute liver failure<sup>[89]</sup>. More recently, it has

been found that adult-derived mononuclear bone marrow fraction is capable of significantly increasing the survival rate of rats with acetaminophen-induced AHF<sup>[90]</sup>. Research has also shown that acetaminophen-induced hepatocellular damage is associated with increased circulating catecholamines, which may contribute to the pathophysiology of acetaminophen-induced hepatotoxicity by compromising hepatic perfusion, and that toxicity may be abolished by the use of  $\alpha$ (1) antagonists<sup>[91]</sup>.

**Galactosamine:** D-galactosamine is a molecule which, when metabolized *via* the galactose pathway in the liver, causes serious metabolic alterations and hepatic necrosis through depletion of different uridine intracellular mediators<sup>[49]</sup>, and has therefore been used to develop AHF models. In one of the first models using rabbits<sup>[92]</sup>, death occurred between 21 and 44 h, following a coma lasting on average 2.6 h, with histologic and biochemical findings compatible with AHF. Furthermore, it was possible to show that in this same species, hepatotoxin did not cross the hematoencephalic barrier<sup>[93]</sup>. More recently, galactosamine has been used on anesthetized dogs. This model also displays the characteristic effects of human AHF, such as an increase in blood levels of liver enzymes, bilirubin, ammonium or lactate and the associated coagulopathy, hypoglycemia, coma and increase in intracranial pressure<sup>[94]</sup>. However, the effects were not the same in dogs without anesthesia, probably due to the added effect of the anesthetic. A reproducible model has been developed with pigs which, because of their size, are suitable for the assessment of different support systems designed for treating AHF in humans<sup>[95]</sup>. Significant differences in galactosamine sensitivity across different species exist. Furthermore, the interval between damage caused and death is not uniform, the agent is expensive to use in large-scale models, and lastly, it carries health risks<sup>[50]</sup>.

Galactosamine models have been used to investigate the renal damage which accompanies AHF<sup>[96]</sup> and the liver metabolic pathways involved<sup>[97]</sup>. In addition, the potential protective effects of substances such as the chimeric protein hyper-IL-6<sup>[98]</sup> or 1,6 diphosphate fructose have been investigated in rats<sup>[99]</sup>. Cardiotrophin 1 may improve the outcome of D-galactosamine-induced AHF through its effects on anti-apoptosis and cell repair<sup>[100]</sup>. Blocking of N-methyl-D-aspartate receptors prevents ammonia-induced death<sup>[101]</sup> and also prevents or delays death of rats by galactosamine-induced AHF<sup>[102]</sup>. Moreover, this model has been used to identify the contribution of cytosolic polypyrimidine tract-binding protein to the mechanisms of hyperinsulinemia by stabilization of mRNA encoding insulin and its secretory granule proteins<sup>[103]</sup>. D-galactosamine models have also allowed testing of different extracorporeal hepatic support devices<sup>[104]</sup> and bioartificial systems, including hepatocytes transfected with the human gene interleukin-1 receptor antagonist in rats<sup>[105]</sup>, the use of a nonwoven fabric bioreactor containing porcine hepatocytes<sup>[47]</sup>, or the study of the

potential effects of cerebrospinal fluid drainage and cranial decompression in rats<sup>[106]</sup>.

A combination of D-galactosamine and lipopolysaccharide has also been widely used to induce AHF in rats. This model has allowed the demonstration of the potential therapeutic role of vascular endothelial growth factor<sup>[107]</sup>. Using this approach, evidence for a direct link between tumour necrosis factor (TNF)- $\alpha$  and Fas/FasL in mediating hepatocyte apoptosis has been provided<sup>[108]</sup>, it has been reported that type I inositol 1, 4, 5-triphosphate receptors increase in the kidney<sup>[109]</sup>, and it has been demonstrated that transcription factor early growth response (Egr)-1 plays an important role in acceleration of hepatic inflammation, apoptosis, and subsequent mortality in acute liver injury<sup>[110]</sup>. Research with this model has also found that the expression and activity of both leukotriene C4 synthase and microsomal glutathione-S-transferase are up-regulated, being partly responsible for cysteinyl leukotriene hepatic accumulation<sup>[111]</sup>, and that a combination of 5-hydroxyindole acetic acid, glucose,  $\beta$ -hydroxybutyrate, and phosphate concentrations in the plasma is a potential marker for AHF, as well as for the early prognosis of AHF<sup>[112]</sup>. Studies using SP600125, a small molecule JNK-specific inhibitor have confirmed the role of JNK as a critical apoptotic mediator in galactosamine/lipopolysaccharide-induced AHF<sup>[113]</sup>. Very recently it has been demonstrated that in mice challenged with D-galactosamine and lipopolysaccharide, deficiency of uncoupling protein-2, which plays a role in liver cell death through its involvement in the production of reactive oxygen species and adenosine, provides protection under endotoxic stress conditions, underlining the significant role of the bioenergetic status in critical illness<sup>[114]</sup>.

**Carbon tetrachloride:** Carbon tetrachloride has been widely used to induce chronic liver damage, especially as a model of primary hepatic cirrhosis. Nevertheless, its use to induce AHF has been very limited due to low reproducibility and wide variation between species<sup>[50,115]</sup>. The mechanism of action is produced in the endoplasmic reticulum by formation of reactive intermediates through isoenzymes of cytochrome P-450<sup>[116]</sup>. This mechanism also involves significant alterations to mitochondrial calcium homeostasis and is dose-dependent<sup>[117]</sup>.

A relatively uniform model was developed using pigs which induced coma and death between 12 and 52 h through a combination of pretreatment with phenobarbital and a 2-h interruption of arterial blood flow followed by intragastric administration of the toxin<sup>[118]</sup>. The administration of carbon tetrachloride in rats has been shown to simultaneously induce both severe damage processes and hepatic regeneration<sup>[119]</sup>. Depending on the dose administered, exposure time, the presence of exacerbating agents, or the age of the organism affected, regeneration can occur and lead to the total recovery of the damaged liver<sup>[120,121]</sup>.

Rats have been used for the study of intrasplenic transplant of hepatocytes<sup>[122]</sup>, and to investigate the mechanisms involved in compensatory liver regeneration which avoids progressive toxic damage<sup>[43]</sup>. Carbon

tetrachloride-induced AHF has also allowed the demonstration in rats of the therapeutical efficacy of Gabexate mesilate, a synthetic protease inhibitor<sup>[123]</sup>, the sulfated polysaccharide extracted from brown algae fucoidan<sup>[124]</sup>, or naringenin-loaded nanoparticles<sup>[125]</sup>, but not of granulocyte colony stimulating-factor<sup>[126]</sup>.

Criticisms of these models include the fact that carbon tetrachloride mainly affects the central zone of the hepatic acinus, and the characteristic massive necrosis of human AHF is not present. Furthermore, carbon tetrachloride is not completely metabolized in the liver and some of the non-metabolized toxin affects and damages other organs, especially the lungs and kidneys<sup>[52]</sup>. Finally, there is a wide variation in species and age sensitivity, basically due to different levels of development and effectiveness of the cytochrome P-450 detoxifying system<sup>[49]</sup>.

**Thioacetamide:** Thioacetamide causes hepatocellular necrosis following biotransformation by monooxygenases<sup>[127]</sup>, and has been used to explore the role of reactive oxygen species<sup>[128]</sup>, and the protective effect of antioxidants such as curcumin<sup>[129]</sup>, pro-regenerative substances<sup>[130]</sup>, or the worsening of encephalopathy following long-term treatment with substances such as indometazine<sup>[131]</sup>. Using the thioacetamide model of AHF, it has been recently shown that cannabinoids and capsaicin improve liver function<sup>[132]</sup> and that *Ginkgo biloba* ameliorates hepatic damage most probably due to its free radical-scavenging effects<sup>[133]</sup>. Simvastatin improves encephalopathy and survival in thioacetamide-treated rats, an effect that is offset by N(G)-nitro-L-arginine methyl ester (L-NAME), a non-selective inhibitor of nitric oxide synthase (NOS), which supports the role of nitric oxide in liver damage and encephalopathy<sup>[134]</sup>. Moreover, the fact that L-NAME administration, but not L-canavanine (specific inhibitor of inducible NOS), had detrimental effects on the severity of hepatic damage and motor activities in thioacetamide-treated rats, suggests that constitutive NOS activities play a major protective role<sup>[135]</sup>.

**Azoxymethane:** Azoxymethane administration induces in mice alterations similar to those encountered in human AHF<sup>[136]</sup>. In fact, it has been shown that mice present decreased locomotor activity followed by loss of righting and corneal reflexes, are hyperammonemic, and develop spontaneous hypothermia and brain amino acid profiles typical of AHF in other species including humans. These findings demonstrate that azoxymethane treatment affords a reproducible model which may be suitable for the study of the cerebral complications of AHF<sup>[137]</sup>. Induction of AHF in C57BL/6J mice by using azoxymethane has recently allowed the observation that altered expression of zonula occludens-2 precedes increased blood-brain barrier permeability, suggesting that zonula occludens-2 may play an important role in the pathogenesis of brain edema in AHF<sup>[138]</sup>.

**Concanavalin A:** A single injection of concanavalin A has also been proposed as a model of AHF as it induces

hepatocellular destruction<sup>[139]</sup> through mechanisms which appear to involve participation of immune cells, including macrophages and activated CD4+ T cells<sup>[140]</sup>. The use of this animal model has demonstrated that suppressor of cytokine signaling-1 (SOCS1) plays an important negative role in fulminant hepatitis and that forced expression of SOCS1 is therapeutic in preventing the disease<sup>[141]</sup>. In concanavalin A-treated mice it has been reported that TNF- $\alpha$  levels are not affected by adiponectin, whereas IL-10 production is increased. Therefore, adiponectin might play a role in the control and limitation of inflammation in the liver, and a contribution has been suggested for IL-10 in adiponectin-mediated hepatoprotection<sup>[142]</sup>. siRNA delivery for osteopontin, which has been implicated in various helper T cell type 1 immunity-mediated diseases, has therapeutic potential in concanavalin A-mediated AHF<sup>[143]</sup>.

**Other models:** AHF has also been induced through the use of poisons such as the derivative of *Amanita phalloides* which, although not a frequent cause of poisoning, has well-known effects on humans. In fact, the effect of amatoxins is due to ARN polymerase induction, producing cell toxicity in hepatocytes, intestinal mucosal cells and kidney tubular cells and they have been used in combination with lipopolysaccharide to develop an animal model of AHF using pigs<sup>[144]</sup>. Models with pigs have also been reported which combine amanitine with lipopolysaccharide, with the aim of studying survival following orthotopic liver transplant and tacrolimus administration<sup>[145]</sup>.

Other models employ parenteral administration of *Propionebacterium acnes* and lipopolysaccharide in mice to study the inhibition of the acquired immune response<sup>[146]</sup>, and intraportal administration of  $\alpha$ -amanitine and lipopolysaccharide in pigs to study bioartificial liver support devices<sup>[147]</sup>.

Intrahepatic upregulation of the immunoactivating molecules CD40 and CD40 ligand (CD40L) are early mechanisms for liver cell damage in human and murine AHF. The use of a model based on intrahepatic overexpression of CD40L by adenoviral-mediated gene transfer (AdCD40L) in mice, has led to the demonstration that CD40-CD40L interaction can induce liver damage, and that CD40L-induced AHF depends on competent lymphocytes<sup>[148]</sup>.

Although their use has been limited, various models combining drug administration and surgical procedures have been described, such as a combination of 70% liver resection and endotoxin administration in rats<sup>[149]</sup>, or resection of all of three hepatic arteries combined with intraportal injection of carbon tetrachloride<sup>[150]</sup>.

### Viral models

Despite the fact that viral hepatitis is a main cause of AHF in many countries, the use of infective agents to develop animal models of AHF has in general been unsuccessful and only the use of transgenic mice overexpressing virus B hepatitis proteins (HBV) or BALB/cj mice infected with MHV-3<sup>[151,152]</sup> has shed some light

on virus-induced AHF mechanisms. However, these murine models display significant limitations as regards the absence of intracranial pressure measurements, or the lack of data concerning toxins involved in hepatic encephalopathy and cerebral edema, as well as the small size of the models used which renders testing of new liver support systems impossible<sup>[49,50]</sup>.

More recently, our research group has described a new animal model of AHF using experimental infection of rabbits with 104 hemagglutination units of an isolate of the rabbit hemorrhagic disease virus (RHDV)<sup>[153]</sup>. First reported two decades ago, RHDV is a member of the *Caliciviridae* family which causes an acute and highly fatal disease in wild and domestic rabbits<sup>[154]</sup>. Rabbit hemorrhagic disease (RHD) is a viral hepatitis which displays surprising clinical, anatomopathological and transmission mode similarities to fulminant human viral hepatitis B, C, and E<sup>[155]</sup>. The virus does not replicate in any other vertebrate<sup>[156]</sup> and to date there is no indication that it can be transmitted to humans, even among those populations most exposed to the virus.

It has been shown that the viral antigen can already be found in hepatocytes at 12 h postinfection (p.i.) and that at 36 h and 48 h p.i., it is localised in 60%-80% of hepatocytes<sup>[157]</sup>. RHD is characterized by a high morbidity and a mortality rate that approaches 90%<sup>[153,158]</sup>. Rabbits die within 36 to 54 h p.i. with clinical signs characteristic of progressive AHF and coma. In addition, the interval between infection and death, in the majority of animals, provides a wide therapeutic window which indicates that our model complies with another of the essential prerequisites of a good AHF animal model, that is, the existence of a sufficiently prolonged interval between intervention and death to enable research into various treatment methods or liver support technologies. In addition, the use of a medium-sized animal facilitates serial collection of blood samples, and makes easier monitoring of intracranial pressure and biochemical alterations produced during the course of the infection<sup>[153]</sup>.

This model reproduces representative biochemical and histological parameters and clinical signs of human AHF. Thus, significant increases in blood transaminase and lactate dehydrogenase activities, and in blood bilirubin concentrations, are detected. Moreover, blood concentration of aromatic amino acids increases significantly, with a decrease in the Fischer index and hypoglycemia. Prolonged prothrombin time, a prognostic element in AHF, and exhaustion of factor V and VII are systematic findings. These effects could occur as a consequence of diminished synthesis of clotting factors and the development of disseminated intravascular coagulation<sup>[153]</sup>. In addition to biochemical and histological abnormalities, infected rabbits demonstrate a clinical picture consistent with AHF. Prostration and side recumbency are present at later stages and neurologic symptoms (convulsions, ataxia, and posterior paralysis) rapidly progress to coma and brain death in the terminal phases. In our model, intracranial pressure rises progressively

in the terminal phases, suggesting a loss of intracranial compliance, and short episodic spikes are also observed. The rise in intracranial pressure in RHDV-infected animals is accompanied by an increase in plasma ammonia levels<sup>[153]</sup>.

Histological and immunohistochemical examination reveals necrotic areas associated with hemorrhages and neutrophil infiltration, and large apoptotic areas with a high caspase 3 expression, mainly in the periportal areas of hepatic acini<sup>[159]</sup>. A significant increase in inducible nitric oxide synthase expression and TNF- $\alpha$  activity, similar to those reported in AHF<sup>[160]</sup>, are also observed in infected rabbits<sup>[161]</sup>. TNF- $\alpha$  may lead to cell proliferation or to apoptosis, and its over-expression correlates with both apoptosis and hepatic regeneration in AHF<sup>[162]</sup>. Balance between proliferation and apoptosis may be influenced by an excess of reactive oxygen species that, if not neutralized by glutathione and antioxidant enzymes, may cause mitochondrial damage and cytosol release of cytochrome c, causing caspase activation and cell death<sup>[163]</sup>. This also happens in RHDV-infected rabbits, which show impaired glutathione levels and antioxidant enzyme activities<sup>[161]</sup>, with a marked activation of the apoptotic intrinsic pathway<sup>[159]</sup>.

Therefore, RHDV experimental infection induces an AHF in rabbits which has a number of physiological and biochemical features seen clinically in humans, is highly reproducible, has a long therapeutic window and generates intracranial hypertension and an associated-encephalopathy. Thus, it is the first successful model using infective agents and satisfies the criteria applicable to an animal model of AHF. This model could provide a useful tool for the study of AHF and the evaluation of new liver support technologies in humans.

## CONCLUSION

AHF is a potentially devastating syndrome whose treatment has been limited by the lack of satisfactory animal models. The potential disadvantages of surgical models are that they do not offer reversibility or recovery, they are difficult to replicate, they depend on surgical skill, many of the clinical and biochemical parameters typical of human AHF are not present, and that they do not reproduce an environment complicated by the release of inflammatory mediators and products of cell necrosis. Thus, their usefulness is limited to the evaluation of various liver support systems. Models using hepatotoxins do not suffer from the above limitations, but nevertheless they may present disadvantages, such as the necessity for adjusting dosage and the potential health hazard which in most cases such chemical agents represent. As for the only viral model developed to date which has proved to be viable, induced RHDV infection in rabbits, it is reproducible and presents characteristics similar to human AHF. The only limitation is that the only susceptible species is the rabbit, although this could also be considered an advantage as it does not represent a health hazard to researchers.

## Abstract

Hepatitis B virus (HBV) is a common viral pathogen that causes a substantial health burden worldwide. Remarkable progress has been made in our understanding of the natural stages of chronic HBV infection. A dynamic balance between viral replication and host immune response is pivotal to the pathogenesis of liver disease. Knowledge of the HBV genome organization and replication cycle can unravel HBV genotypes and molecular variants, which contribute to the heterogeneity in outcome of chronic HBV infection. Most HBV infections are spontaneously resolved in immunocompetent adults, whereas they become chronic in most neonates and infants at a great risk of developing complications such as cirrhosis and hepatocellular carcinoma (HCC). Those with chronic HBV infection may present in one of the four phases of infection: immune tolerance, immune clearance [hepatitis B e antigen (HBeAg)-positive chronic hepatitis B (CHB)], inactive carrier state, and reactivation (HBeAg-negative CHB). Understanding the dynamic nature of chronic HBV infection is crucial in the management of HBV carriers. Long-term monitoring and optimal timing of antiviral therapy for chronic HBV infection help to prevent progression of HBV-related liver disease to its later stage, particularly in patients with higher risk markers of HCC, such as serum DNA concentration, HBeAg status, serum aminotransferase, HBV genotypes, and pre-core or core mutants.

## INTRODUCTION

Hepatitis B virus (HBV) infection is a major health problem worldwide. Some individuals can develop acute HBV infection and achieve complete immune clearance of virus, yielding a life-long immunity, while others can develop chronic HBV infection depending on the host immune response. Chronic HBV infection is associated with a wide range of clinical manifestations, from an asymptomatic carrier state with a normal liver histology to severe and chronic liver diseases, including cirrhosis and hepatocellular carcinoma (HCC)<sup>[1,2]</sup>.

There is a particular concern in the Asia-Pacific region, where chronic HBV infection is prevalent, with a carrier rate of approximately 10% of chronic HBV carriers. About 25%-40% of them will eventually die of liver disease (cirrhosis with and without HCC) with a death rate of 50% for male carriers and 15% for female carriers, respectively. Chronic HBV infection is a dynamic process with a replicative or a non-replicative (or low replicative) phase based on virus-host interaction which is pivotal to the pathogenesis of liver disease. Understanding the dynamic nature of chronic HBV infection is crucial in the management of HBV carriers. Long-term monitoring and optimal timing of antiviral therapy for chronic HBV infection patients can help to prevent progression of HBV-related liver disease to its later stage<sup>[3,4]</sup>.

## PATHOLOGY OF HBV INFLAMMATORY REACTION

Viral hepatitis, characterized by diffused inflammatory

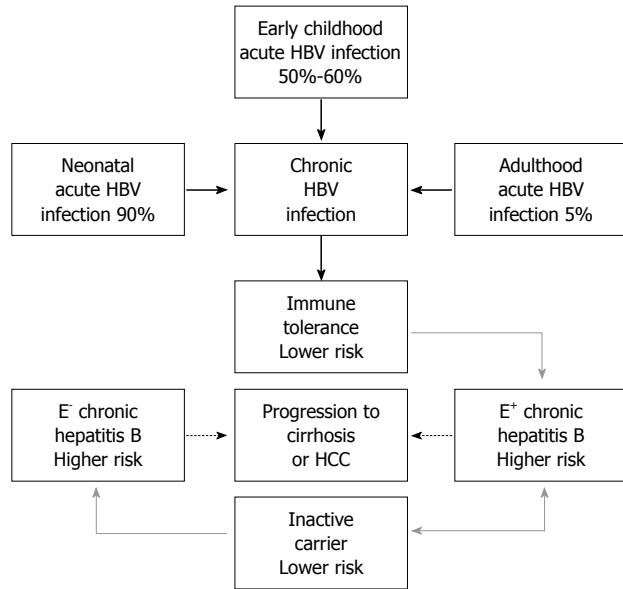

reaction, is associated with cell damage and death. It has been recently reported that HBV replication is associated with cell death, which is different from the widely accepted non-cytopathic characteristics of HBV<sup>[5]</sup>. The mechanism of cell damage is generally defined as the result of cytotoxic T-lymphocyte (CTL)-mediated immune responses to viral infection<sup>[6]</sup>. Another typical process causing cell death is apoptosis. It has been shown that HBV proteins, such as HBx and HBsP, can induce apoptosis<sup>[7]</sup>. A careful light microscopic examination of HBV genotypes A-C transfected cells can reveal rounded up and death cells which are apoptotic signs. To identify the observed cell death, FAC is used because apoptotic cells can show phosphatidylserine on cell membrane. HepG2 cells can be transfected with HBV genotypes A-C. Cells observed under a phase contrast microscope, can be stained with apoptosis markers and analyzed by flow cytometry. HBsP expression can be detected by Western blotting assay. BH3 sequences can be aligned and analyzed with the vector NT1. HBV genotypes A-C transfected cells display cell death which has been further proved as apoptosis. HBsP, a pro-apoptotic protein, is detectable during transfection of virus genomes. Different apoptotic effects are correlated with the expression of different genomes. Alignment and analysis of the HB3 domains of three virus genomes can reveal a slight variance. It has been reported that variant HBsP expression and BH3 sequence of HBV genotype may be involved in differential apoptotic effects on transfected cells<sup>[8]</sup>. However, HBV can also directly cause death of hepatocytes<sup>[6]</sup>.

## HBV TRANSMISSION AND INFECTION

In high endemic regions, such as Asia, Africa, Pacific Islands and the Arctic, early perinatal and horizontal infection in childhood is the main route of HBV transmission with a hepatitis B surface antigen (HBsAg) positive rate of 8%-15%, while in low endemic areas, such as Western countries, HBV is a predominant disease in adolescents and adults due to high risk sexual behaviors or drug injections, with a HBsAg positive rate of less than 2%<sup>[9]</sup>.

The vast majority of early perinatal or horizontal infections in childhood are the main route of HBV transmission in untreated infants whose mothers are hepatitis B e antigen (HBeAg) positive, and over 90% of them will become chronic HBV carriers. In contrast, about 90% of HBV infections may occur as acute infection and only 5%-10% may occur as chronic infection in adults. This dramatic difference in chronic rates is believed to reflect the host immunologic status and the time of infection.

Although infants whose mothers are HBeAg-positive HBV carriers are at a high risk of developing infection and subsequently become viral persistence, the age of infants at the time of HBV infection is inversely correlated with the chronic rate<sup>[10,11]</sup>. A HBc/HBe-specific Th-cell tolerance model can show the reversibility of T-cell tolerance. It has been shown that a single prenatal dose of HBeAg can result in apparent T-cell tolerance

**Figure 1 Phases of chronic hepatitis B virus (HBV) infection.** Thick arrows indicate HBV infection rates in different age groups, dotted arrows indicate changes in histology, grey arrows indicate changes at risk of progressing to cirrhosis or HCC (E+: HBeAg positive; E-: HBeAg negative).

in mice at the age of 8-12 wk, but the tolerance may disappear at the age of 16 wk<sup>[12]</sup>, suggesting that T-cell tolerance can be maintained and HBcAg/HBeAg will continuously present. HBc/HBe-specific thymocytes are absent in thymus and this “repertoire renewal process” requires about 16 wk. Similarly, human fetus may be exposed to tolerogenic HBeAg in uterus not infected at birth. The longer the elapsed time before HBV infection is, the greater the probability of renewing HBc/HBe-specific T-cell repertoire is, because the neonate would no longer be exposed to HBeAg<sup>[13]</sup>.

There is an obvious difference between patients infected with HBV in adolescence or adulthood immediately entering immune clearance phase, and short duration and tendency quiescent after seroconversion from HBeAg to antibody against HBeAg (anti-HBe). Such patients are termed “healthy” carriers. In contrast, patients with early HBV infection have a prolonged immune tolerance phase and a prolonged immune clearance phase, indicating that their diseases tend to progress after HBeAg seroconversion.

## STAGES OF HBV INFECTION

Remarkable progress has been made in our understanding of the four natural stages of chronic hepatitis B (CHB): immune tolerance stage, immune clearance stage, inactive HBsAg carrier stage, and reactivation stage. However, not all CHB infection patients go through all the four stages (Figure 1).

### Immune tolerance stage

Patients with perinatal or early childhood-acquired HBV infection have an initial tolerance stage characterized by the presence of HBeAg, high serum DNA level, normal serum aminotransferase level, and minimal or

no inflammation on liver biopsy<sup>[14]</sup>. Such manifestations can rarely be seen in those who are infected with HBV in later childhood or adulthood and whose infection subsequently develop into chronic HBV infection<sup>[14]</sup>.

Although a high serum DNA level in liver disease patients with minimal or no inflammation is considered as a sequela of immune tolerance to HBeAg, it has been shown that HBeAg may promote HBV chronicity by functioning as an immunoregulatory protein<sup>[15]</sup>. For example, in transgenic mice, transplacental transfer of maternal HBeAg may preferentially behave as a tolerogen and inactive HBe/HBc-specific Th cells through at least central deletion of high-affinity HBe/HBcAg-specific CD4 T cells or clonal ignorance and anergy in periphery blood, resulting in ineffective cytotoxic T cell lysis of infected hepatocytes. Such a mechanism may be responsible for the high chronic HBV infection rate (-90%) observed in babies infected by their HBeAg positive mothers accounting for the inability of infants to clear perinatal HBV infection. After neonatal or prenatal HBV infection (absent in uterus tolerance), secretion of monomeric HBeAg in the relatively Th2-biased neonatal immune system may also have an anti-inflammatory influence on nucleoprotein-specific immune response by eliciting Th2-like cytokines. Secreted HBeAg can also enter thymus. It has been subsequently reported that HBeAg specific Th2-like cells can preferentially survive tolerance production to a greater extent than HBeAg-specific Th1-like cells<sup>[16]</sup>. Therefore, chronicity resulting from vertical transmission of HBV characterized by the predominance of HBeAg-specific Th2-like cells and secretion of anti-inflammatory cytokines, such as IL-4, IL-5, and IL-10, can enhance antibody production, and viral persistence would characterize the HBeAg-specific T-cell response. If the *status quo* of various clonal tolerance phenotypes could be maintained as long as the HBeAg concentration and/or the non-inflammatory hepatic environment remain unchanged, the immune tolerance would last 1-4 decades. During this phase, the rate of spontaneous or treatment-induced HBeAg seroconversion is less than 5%<sup>[17,18]</sup>. Patients in the immune tolerance phase are considered at a low risk of progressing to cirrhosis or HCC based on serial monitoring of virological, clinical and ultrasonographic assessments.

Although antiviral therapy is not recommended for immune tolerance patients, they should be closely monitored for progression to the immune clearance phase. Once this occurs, antiviral therapy should be considered more diligently after 6-12 mo if HBeAg seroconversion does not occur because disease progression can occur in the immune clearance phase.

### **Immune clearance stage**

As the host immune system matures, a nonspecific increase in hepatic inflammation or decrease in HBeAg serum concentration, perhaps due to the emergence of core promoter region or pre-core region mutants, may allow activation of intermediate-or low-avidity HBeAg-specific T cell clones that are not physically deleted and/or reverse the anergic state of others<sup>[17]</sup>. Therefore,

treatment modalities for chronic HBV infection should be directed at activating the relatively low-avidity HBeAg-specific T cells. Such a shift from HBeAg-specific Th2 cell tolerance to Th1 cell activation may recognize HBV-related epitopes on hepatocytes, and immune-mediated hepatocellular injury ensues, the so called clearance phase of CHB infection. Then, IL-2, INF and tumor necrosis factor are secreted following inflammation. The HBcAg-specific T-cell response is characterized by CTL induction, liver injury and inhibition of viral replication<sup>[6]</sup>. In patients with prenatally acquired HBV infection, transition from immune tolerance phase to immune clearance phase occurs during the second or third decade of life. Although HBV replication and viremia continue in the liver, the serum virus level becomes lower in immune clearance phase than in immune tolerance phase when viral replication is completely unopposed. The active phase of CHB is often marked by increased levels of alanine aminotransferase (ALT), necrotic inflammatory activity, and cycling HBV-DNA and HBeAg due to liver injury. Pre-core minus mutants and mutations within the core gene begin to accumulate at the time of ALT flare up because they have a better ability to evade immune clearance<sup>[19]</sup>, suggesting that nucleoprotein antigens are the major immune attacking foci during chronic HBV infection, perhaps because the nucleoprotein-specific T-cell repertoire has been eroded to a lesser extent than the envelope-specific repertoire simply due to the lower concentration of HBe/HBcAgs. CD4<sup>+</sup> HBeAg-specific T cells, identified in HBeAg-single-Tg and TCR-HBeAg-Tg mice, are not deleted or anergized and remain quiescent in the presence of serum HBeAg, but can mediate seroconversion and liver injury once they are activated. These HBeAg-specific T cells escape tolerance induction due to their low avidity and/or low TCR density<sup>[18]</sup>.

This active phase is characterized by the presence of HBeAg, high serum HBV DNA and aminotransferase levels, as well as active inflammations and fibrosis in the liver. A key event in the natural history of HBeAg positive CHB patients is HBeAg seroconversion<sup>[20]</sup>. Several studies have shown that seroconversion with a marked reduction in HBV replication is associated with biochemical and histological remission of inflammatory activity in the majority of patients<sup>[2,10,20]</sup>. Most studies showed that the mean annual rate of spontaneous HBeAg seroconversion ranges 8%-15% in children or adults with an elevated ALT level<sup>[20]</sup>. Although the ALT level is normal in most Asian children, their spontaneous HBeAg seroconversion rate is less than 2% during the first 3 years of age and then increases to 4%-5%. In some cases, spontaneous flare up of hepatitis is not frequently recognized because it is usually asymptomatic. Since subsequent HBeAg seroconversion would not occur in such flare up of hepatitis, it can thus be viewed as an abortive attempt at seroconversion. However, some patients present with a symptomatic flare up of hepatitis that mimics acute hepatitis and even present with fulminant hepatic failure. Regression of fibrosis occurs several months or years after HBeAg seroconversion. These flare ups of hepatitis may precede the disappearance

of HBeAg and development of HBeAg antibody, culminating in the remission of hepatitis activity. It has been recognized that the duration of immune clearance phase and the frequency and severity of flare ups are correlated with the risk of progressing to cirrhosis and HCC<sup>[21-23]</sup>.

### **Inactive HBsAg carrier stage**

This inflammatory phase of HBV infection also leads to HBeAg seroconversion and enters into inactive HBsAg carrier status. Inactive carriers form the largest group of chronic HBV infection patients. After seroconversion, most patients remain negative for HBeAg and positive for anti-HBe antibody with an undetectable or a low HBV DNA level, while the minority have undetectable viral loads. Biopsy findings can range from mild inflammation and minimal fibrosis to inactive cirrhosis if the disease is severe during immune clearance<sup>[20]</sup>.

The progress of inactive HBsAg carrier state is usually benign. A long-term follow-up (up to 18 years) of these carriers can indicate a sustained biochemical remission and a very low risk of developing cirrhosis or HCC in them<sup>[19]</sup>. Patients even with no cirrhosis may develop liver cancer in their inactive HBsAg carrier state. In addition, approximately 20%-30% of inactive HBsAg carriers may undergo spontaneous reactivation of hepatitis B during the follow-up. Multiple episodes of reactivation or sustained reactivation can cause progressive liver damage and even decompensation. HBV reactivation is usually asymptomatic but can occasionally mimic acute viral hepatitis. Some carriers eventually become HBsAg negative and develop anti-HBs. The estimated incidence of delayed HBsAg clearance is 1%-2% per year in Western countries where HBV infection is acquired in adulthood, and 0.05%-0.8% per year in endemic areas where HBV infection is mostly acquired perinatally or in early childhood. Prognosis can be improved by loss of HBsAg as liver disease is inactive or non-progressive, but HBsAg clearance does not completely prevent occurrence of liver decompensation or HCC in patients with cirrhosis<sup>[23-25]</sup>.

### **Reactivation stage**

Chronic HBeAg-negative patients can be divided into chronic inactive HBsAg carriers and CHB patients with biochemical and intermittent virological activity<sup>[5]</sup>. HBeAg-negative chronic hepatitis may recur in one third of inactive HBV carriers without serum reversion of HBeAg<sup>[22,23]</sup>.

It is believed that seroconversion of HBeAg to HBeAb is accompanied with cessation of HBV replication and remission of liver disease. However, HBsAg-negative CHB has been recognized as an important form of chronic hepatitis, and e-antigen negativity is due to mutations in pre-core and core promoter regions. The most frequent pre-core mutation is a G-A change in nucleotide 1896 (G1896A) which creates a stop codon<sup>[23]</sup> and the most common core promoter mutation involves a substitution of nucleotides 1762 and 1764, which can result in loss of HBeAg synthesis. Loss of circulating HBeAg can decrease the induction of HBeAg-specific Th2 cell activity and result in a predominance of inflammatory

Th1-like cells<sup>[16]</sup>. HBeAg-negative CHB (pre-core mutant) occurs as the predominant species during typical HBV infection with wild-type virus which is selected during the immune clearance phase (HBeAg seroconversion). Several studies have shown that HBeAg may be a target antigen on HBV-infected hepatocytes<sup>[5,15,18]</sup>. Failure to produce a target antigen may be a means of evading immune clearance. The clonal heterogeneity of HBeAg-specific T-cell tolerance may explain how a primarily tolerogenic protein can exert its pressure on the immune response to the selection of HBeAg negative mutant. For example, high-avidity HBeAg-specific T-cell clones may be tolerized and low-activity T-cell clones may be activated and involved in selecting HBeAg-negative mutant in the same patient<sup>[18,24-26]</sup>. The occurrence of HBeAg-negative mutants during chronic active HBV infection, especially in the presence of a high viral load, is correlated with an exacerbation of liver injury and a worse prognosis. Serum HBeAg can act as an efficient T-cell tolerogen which reduces the frequency of liver injury and down-regulates anti-HBc production. Anergy of HBc/HBeAg and HBeAg specific T-cells depends on HBeAg concentration and is reversible in the absence of HBeAg, which may explain the correlation between pre-core and core promoter mutations and severe liver injury<sup>[19,22,27,28]</sup>.

Progress to this phase occurs spontaneously or to inactive carriers during immune suppression. Some patients can progress directly from HBeAg positive to HBeAg negative CHB. Identification of pre-core/core promoter mutations and recognition of HBeAg negative CHB indicate that the disease occurs after HBeAg seroconversion<sup>[19]</sup>. Age is significantly higher in HBeAg-negative patients than in HBeAg-positive patients. ALT and HBV DNA levels are significantly lower in e-antigen negative patients than in e-antigen positive patients. However, spontaneous recovery is rarer, long-term prognosis is poorer, and histological lesions are more severe in HBeAg-negative patients than in HBeAg-positive patients. Necrotic inflammatory activity is almost identical in both HBeAg-negative and positive patients. However, fibrotic activity is higher in e-antigen negative patients than in e-antigen positive patients. The estimated annual incidence of cirrhosis is 2%-6% in HBeAg positive CHB patients and 8%-10% in HBeAg negative CHB patients. The higher incidence of cirrhosis in HBeAg-negative patients is related to age and fibrosis stage, suggesting that HBeAg-negative chronic hepatitis can progress to cirrhosis and HCC in the natural history of HBV infection rather than *de novo* infection with HBV variants that do not produce HBeAg<sup>[29-31]</sup>. HBeAg-specific T cell tolerance is reversible in the absence of tolerogen. Since antiviral treatment can reduce HBeAg and viral load possibly in combination with HBc/HBeAg-specific immunization, it can alleviate chronic HBV infection by shifting the cytokine profile from Th2 to Th0/1<sup>[26,32]</sup>.

### **Occult HBV infection**

Occult HBV infection is defined as the existence of HBV DNA in serum, although it is not considered as a phase of CHB<sup>[33,34]</sup>.

In addition to a symptomatic and serologically

**Table 1 Characteristics of chronic hepatitis B at different stages**

Phase	ALT	HBsAg	HBeAg	HBeAb	HBV DNA (IU/mL)	Th cell biased	Liver histology
Immune tolerance	Usually normal	Present	Present	Absent	≥ 20000	Th <sub>2</sub> cell	Normal or mild inflammation
Immune clearance	Elevated	Present	Present	Absent	≥ 20000	Th <sub>2</sub> /Th <sub>1</sub> cell	Active inflammation
Inactive HBsAg carrier	Usually normal; can have flares	Present	Absent	Present	> 20000	Th <sub>1</sub> cell	Mild inflammation or inactive cirrhosis
HBeAg <sup>-</sup> CHB	Period flares	Present	Absent	Present	> 20000 < 20000	Th <sub>1</sub> cell	Active inflammation
Occult hepatitis B	Rarely elevated	Absent	Absent	Present when HBV recovered	< 20000	Th <sub>1</sub> cell	From normal to cirrhosis HCC

evident infection, occult persistent HBV carriage has been identified since nucleic acid amplification assay enhances its sensitivity to hepadnaviral genomes and their replicative intermediates. There is evidence that occult HBV infection is a common and long-term consequence of acute hepatitis B resolution. This form of residual infection is termed as secondary occult infection (SOI). The data from the woodchuck model of HBV infection indicate that exposure to a small amount of hepadnavirus can also cause primary occult infection where virus genome but not serological makers of virus exposure are detectable without liver involvement. However, both forms of virus replicate at a low level in the lymphatic system. Serological testing for SOI can reveal the presence of antibodies to HBV core antigen (anti-HBc), which has been recognized not only as a valuable marker of prior HBV exposure but also as an indicator of progressing occult HBV infection<sup>[35]</sup>. It has been recently reported that up to 20% of individuals with occult HBV carriage are not reactive to anti-HB<sub>x</sub> or any other serological indicators of HBV exposure, and detection of naturally acquired antibodies to HBsAg (anti-HBc) does not exclude the existence of occult HBV infection<sup>[33,36]</sup>.

The severe consequences of occult HBV infection have not been fully recognized. There is evidence that occult HBV can be a source of virus contamination in blood and organ donations, as well as a reservoir from which full blown hepatitis can arise<sup>[37]</sup>. Case reports also indicate that immunosuppression caused by chemotherapy or immunomodulatory agents or immunodeficiency due to HIV infection or hematological malignancies can induce reactive occult infection<sup>[38,39]</sup>. Mild necrotic inflammation has been documented in liver samples obtained from acute hepatitis B patients many years after recovery<sup>[40]</sup>. Liver fibrosis and cirrhosis of unknown origin have been explained by occult HBV infection in many retrospective studies<sup>[35,41,42]</sup>. The oncogenic potency of occult HBV persistence becomes progressively evident and is further elevated in alcoholics and patients with other liver ailments like hepatitis C<sup>[41,42]</sup>. No reports are available on the treatment of occult HBV infection (Table 1).

## CONSEQUENCES OF CHRONIC HBV INFECTION

Individuals with chronic HBV infection are at an increased risk of developing end-stage liver diseases

including cirrhosis, hepatic failure, and HCC. It has recently been estimated that about 53% of HCC cases in the world are related to HBV infection. The lifetime risk of developing HCC is increased even in patients with cleared HBsAg or occult HBV infection. Further risk factors include chronic HCV infection, exposure to aflatoxin B<sub>1</sub>, alcohol abuse, obesity and diabetes<sup>[4,43]</sup>. Thus, it is important to identify HBV-infected patients at a higher risk of progressing to HCC.

The reason why some CHB patients progress to HCC remains unknown. Host factors, such as immune response to HBV, genetic predisposition to HCC, high HBV replication rate, mutations within the HBV genome, are related with HCC. Many observations revealed that the major factor for the development of HBV-associated HCC is the immune system<sup>[41,43,45]</sup>. Development of hepatitis, chronic hepatitis, and HCC could be exclusively observed in mice reconstituted with bone marrow and in non-transgenic animals, but not in controls, suggesting that ineffective immune response is the principle oncogenic factor during chronic HBV infection of human beings. In other words, the same T-cell response has different effects. If T cell response is strong enough, HBV can be eliminated from the liver. If not, a pro-carcinogenic effect can be induced by triggering necrotic inflammatory disease without final eradication of HBV from the liver. It can, thus, be concluded that the immune system-mediated chronic inflammation of the liver, continuous cell death and subsequent cell proliferation may increase the frequency of genetic alteration and the risk of developing cancer. However, the molecular basis of inflammatory liver carcinogenesis caused by HBV remains largely unsolved. Cytokines modulate inflammation and the presence of inflammatory cells with the production of inflammatory cytokines activates cellular oxidant-generating pathways. Reactive oxygen species that are generated in inflammatory conditions induce oxidative DNA damage and increased oxidative stress caused by chronic inflammation can produce genetic mutations and gross chromosomal alterations<sup>[4,44,45]</sup>. Extensively oxidative DNA damage has been detected in hepatocytes of HBV-transgenic mice and humans with chronic hepatitis<sup>[46]</sup>.

HBV genotype C infection is associated with a higher risk of developing HCC than HBV genotype B infection<sup>[29]</sup>. The BCP A1762T/G1764A mutant is associated with an increased risk of developing HCC

compared with the double wild type variant, whereas the pre-core G1896A mutation is associated with a decreased risk of developing HCC compared with the wild-type variant. Several mechanisms of liver carcinogen are related to the BCP A1762T/G1764A mutation which may enhance HBV virulence by increasing host immune response and viral replication, or by altering the coding region of the X antigen. Mutant BCP may augment the host immune response to HBV-infected hepatocytes by diminishing circulating HBeAg and increasing hepatocyte apoptosis and regeneration, thus leading to liver injury<sup>[47,48]</sup>. The BCP mutation appears to enhance the efficacy of viral replication either by modulating the relative levels of pre-core and core RNAs or by creating a transcription factor binding site for hepatocyte nuclear factor 1. Mutations in the BCP region over lapping the coding sequence of the X antigen of HBV may result in changes of amino acids, K130M and V131I, in the X gene. These amino acid changes may interfere with cell growth control and DNA repair, thus leading to HCC<sup>[49,50]</sup>. There is experimental evidence that HBx, a multifunctional protein with oncogenic potentials, can interact with a large number of cellular factors and modulate their normal function, thus leading to deregulation of normal cell activities and HCC<sup>[46,51]</sup>. Despite its importance in HCC development, the clinical significance of genetic variability in the X genetic region still remains poorly understood<sup>[52]</sup>.

Several factors, including age, male gender, repeated episodes of severe acute exacerbation, and HBV reactivation after HBeAg seroconversion, are related with the risk of developing advanced liver disease in patients with CHB. Previous studies showed that HBV genotype C infection is associated with later HBeAg seroconversion and multiple episodes of acute exacerbation without HBeAg seroconversion than genotype B HBV infection<sup>[9,21,25,30,49]</sup>. The delayed HBeAg seroconversion may prolong the inflammation process and subsequently result in more severe liver damage<sup>[50]</sup>. Several nucleotide mutations in the pre-core and core promoter regions may reduce HBeAg production and are associated with advanced liver disease<sup>[47]</sup>. In Asia, genotype C and T1762 and A1764 mutants may play a role in HBV-related liver cirrhosis, and can be used in predicting the clinical outcome of patients with chronic HBV infection.

### Abstract

**AIM:** To evaluate rational and experiential intelligence in irritable bowel syndrome (IBS) sufferers.

**METHODS:** We recruited 100 subjects with IBS as per Rome II criteria (50 consulters and 50 non-consulters) and 100 healthy controls, matched by age, sex and educational level. Cases and controls completed a clinical questionnaire (including symptom characteristics and medical consultation) and the following tests: rational-intelligence (Wechsler Adult Intelligence Scale, 3rd edition); experiential-intelligence (Constructive Thinking Inventory); personality (NEO personality inventory); psychopathology (MMPI-2), anxiety (state-trait anxiety inventory) and life events (social readjustment rating scale). Analysis of variance was used to compare the test results of IBS-sufferers and controls, and a logistic regression model was then constructed and adjusted for age, sex and educational level to evaluate any possible association with IBS.

**RESULTS:** No differences were found between IBS cases and controls in terms of IQ ( $102.0 \pm 10.8$  vs  $102.8 \pm 12.6$ ), but IBS sufferers scored significantly lower in global constructive thinking ( $43.7 \pm 9.4$  vs  $49.6 \pm 9.7$ ). In the logistic regression model, global constructive thinking score was independently linked

to suffering from IBS [OR 0.92 (0.87-0.97)], without significant OR for total IQ.

**CONCLUSION:** IBS subjects do not show lower rational intelligence than controls, but lower experiential intelligence is nevertheless associated with IBS.

### INTRODUCTION

Irritable bowel syndrome (IBS) is a common disease worldwide, with a prevalence in the general population ranging from 2% to 15%, depending on the definition criteria used<sup>[1,2]</sup>. Its pathophysiology is unknown, yet several biological factors have been implicated<sup>[3]</sup>; and aside from these biological factors, psychosocial factors have long been known to be involved in IBS. While anxiety has consistently been associated with IBS<sup>[4]</sup>, to what precise degree it is a cause or consequence remains unresolved<sup>[5]</sup>. Personality traits, and neuroticism in particular, have been linked to IBS, although it is a matter of debate whether they are associated with consultation behavior<sup>[6]</sup> or with the disease itself<sup>[7]</sup>.

Cognition (beliefs, interpretation and expectations) plays a pivotal role in the interaction of subjects with

the environment, and cognitive abilities should drive this interaction on a daily basis and for long-term success. Several items of information suggest that cognitive processes may be important in IBS. Abnormal illness behavior which has been associated with many chronic diseases, including non-consulters' IBS<sup>[8]</sup>, is to a great extent the result of a cognitive process<sup>[9]</sup>, involving appraisal and interpretation, and is likely associated with worry<sup>[10]</sup>. Hypervigilance as to abdominal perceptions may be viewed as a cognitive process<sup>[11,12]</sup>. IBS patients use less effective coping styles<sup>[6,13]</sup>, which are indeed modulated (appraisal of threat, adapting the response to the situation) by the use of cognitive abilities.

Although intelligence is not easy to define<sup>[14]</sup>, it may be construed as the ability to solve problems<sup>[15]</sup>. Problems arising from life may be categorized as abstract problems, which call for an analytical approach and a slow response, and daily life problems, which call for automatic analysis and a quick response. Solving abstract problems is a task performed by rational intelligence and can be measured by IQ<sup>[14]</sup>. IQ has been found to be associated with health<sup>[16]</sup> and longevity<sup>[17]</sup>, likely through an influence on health knowledge and health behavior<sup>[18]</sup>. Attree *et al*<sup>[19]</sup> recently found a lower IQ in IBS subjects *vs* controls. Rational intelligence might enhance one's ability to identify environmental factors precipitating bowel symptoms and change one's lifestyle accordingly.

Solving daily problems is not a rational task but rather relies on cognitive abilities to interpret events efficiently. Epstein proposed the concept of constructive thinking (experiential intelligence), defined as automatic thoughts in daily life to survive at a minimum cost of stress<sup>[20]</sup>. According to his cognitive-experiential theory, constructive thinking operates passively and automatically at a preconscious level, thinking in terms of associations and broad categories, is closely connected with emotions, interpreting experience, and guiding conscious thoughts and behaviour. It can be measured by the Constructive Thinking Inventory (CTI), which is independent of IQ and moderately related to success in life and physical well-being<sup>[21]</sup>. Under the hypothesis of stress-driven changes in brain-gut interaction (IBS as emotional motor system output)<sup>[22]</sup>, it might be hypothesized that the lower a person's constructive thinking, the higher the stress generated by daily life and, by extension, the higher the possibility of suffering from IBS symptoms.

Accordingly, this study sought primarily to assess whether IBS sufferers might be different to healthy non-IBS sufferers in terms of intelligence (rational and experiential), and, secondarily, whether there might be a link between intelligence and IBS-related medical consultation.

## MATERIALS AND METHODS

### Study design

Case-control study including IBS sufferers and matched healthy subjects.

### Study population

Cases were defined as subjects, both consulters and non-consulters, who met the Rome II IBS criteria. An IBS consulter was defined as any currently symptomatic subject who had consulted a physician due to bowel symptoms and had been diagnosed with IBS after an appropriate work-up. An IBS non-consulter was defined as any subject from the general population with symptoms of IBS who had not consulted a physician in this connection.

Controls were defined as subjects from the general population without recurrent abdominal pain or bowel symptoms, who suffered no relevant chronic diseases and had undergone no relevant abdominal surgery.

### Recruitment, selection and inclusion

IBS consulters were recruited from primary care and secondary-level gastroenterologist offices at the 7th Health Area of Madrid (Spain), which provides medical attention to approximately 515 000 inhabitants. Patients diagnosed with IBS in accordance with the above definition, were invited to participate. Patients were not enrolled at a tertiary-care facility so as to better represent the population of patients with IBS.

IBS non-consulters and healthy controls were recruited from the general population residing in the same geographical area as patients. Members of the public were directly approached at corporate offices, leisure centers or department stores and invited to participate in the study. Relatives of recruited IBS patients and patients or patients' relatives attending medical facilities were excluded. After initial agreement, all subjects were briefly interviewed about any medical conditions (to exclude relevant chronic diseases), recurrent abdominal pain, bowel-related symptoms (to classify them as potential IBS subjects as per Rome II criteria or as subjects free of bowel-related symptoms), and prior medical consultation on account of such symptoms (to classify them as non-consulters): subjects with bowel-related symptoms who failed to meet the Rome II criteria as well as subjects who met the Rome II criteria but reported consulting a physician in this regard were not selected.

All subjects selected-IBS consulters, non-consulters, and controls-completed a clinical questionnaire, which included questions on sociodemographic data, symptoms and medical resource utilization, including number of physician visits due to bowel symptoms in the prior year. This questionnaire was successfully used in a population-based IBS study<sup>[2]</sup>, and enables Rome II criteria as well as consultation behavior in the preceding year to be verified. Inclusion criteria for IBS subjects (patients and non-patients) were age 18-65 years and Rome II criteria checked by the clinical questionnaire. Healthy controls were matched to IBS patients by age ( $\pm$  5 years), sex, and educational level (junior school, high school, and university). Exclusion criteria were history of psychiatric disease requiring treatment; significant visual or hearing deficit; and inability to complete the set of instruments used in the study.

## Instruments

In addition to the clinical questionnaire, the study design included instruments that measured IBS severity, rational intelligence, non-intellectual intelligence, personality traits, psychopathology, and life events. These instruments were respectively.

### **Functional bowel disease severity index (FBDSI)**

The FBDSI was developed by Drossman *et al*<sup>[23]</sup> and has been shown to correlate with symptoms interference with daily functioning and health related quality of life<sup>[24,25]</sup>. It comprises three variables, namely: current pain [evaluated by a visual analog scale (VAS)]; diagnosis of functional chronic abdominal pain (chronic pain without bowel dysfunction); and the number of medical visits in the preceding 6 mo. Severity was classified as mild (< 37), moderate (37-110) or severe (> 110). Since severity in IBS subjects as rated by the complete index included medical consultation, both the complete FBDSI and current pain assessed by VAS were analyzed.

### **Wechsler Adult Intelligence Scale, 3rd edition (WAIS-III)**

The WAIS-III was designed as a comprehensive test of cognitive ability for adults. It contains 11 subtests and three additional subtests. Variables obtained are three IQ scores (total IQ, verbal IQ, and performance IQ). It has been adapted and validated for use in the Spanish population, and results were scored using normative values<sup>[26]</sup>. The test was taken in quiet surroundings and all subjects underwent a brief psychological interview beforehand; special care was taken to minimize potential anxiety regarding test performance. Moreover, it was clearly stated at the time of inclusion that test results would in no case be linked to any care change in IBS subjects or to any specific psychological intervention. Subjective scoring of the WAIS-III was done blinded to subjects' study group.

## CTI

The CTI is a self-administered test developed by Epstein under the conceptual framework of Cognitive-Experiential Theory<sup>[20]</sup>. Constructive thinking is a set of automatic habitual thoughts used in daily life, and is regarded as a measure of experiential intelligence<sup>[21]</sup>. CTI provides a global measure of constructive thinking, six subscales (Emotional coping, Behavioral coping, Personal superstitious thinking, Categorical thinking, Esoteric thinking, and Naïve optimism), and two validity subscales (Defensiveness scale and Validity scale). This test has been adapted and validated for use in the Spanish population, normative values for which are available<sup>[27]</sup>. T-scores were obtained using a computerized scoring software program. Under the rules of the Spanish Manual, tests were deemed invalid when the T-score was above 70 on the defensiveness scale or below 30 on the validity scale.

### **NEO personality inventory (NEO-PI)**

The NEO-PI is a widely used personality inventory designed to measure personality based on the "big five"

theory. The Spanish version is a validated instrument and normative data are available. T-scores for the five traits (neuroticism, extroversion, openness, agreeableness, and conscientiousness) were obtained using a computerized scoring software program.

### **State-trait anxiety inventory (STAI)**

A widely used questionnaire with a validated Spanish version, the STAI is a 40-item self-report measure designed to assess anxiety. Subjects indicate how they generally or right now feel, by rating the frequency of their feelings of anxiety on a 4-point scale ranging from 1 (almost never) to 4 (almost always).

### **Minnesota multiphasic personality inventory 2 (MMPI-2)**

The MMPI-2 is a widely used inventory for the assessment of psychopathological personality. Normative values for the Spanish population are available. Clinical scales were included (hypochondriasis, depression, hysteria, psychopathic deviate, paranoia, psychasthenia, schizophrenia, hypomania, and social introversion).

### **Social readjustment rating scale (SRRS)**

The SRRS is a measure of stressful life events developed by Holmes and Rahe in 1967<sup>[28]</sup>, consisting of a 61-item list of significant life events. A validated Spanish version exists, which includes a scale of each item's emotional impact scored from 0 to 100<sup>[29]</sup>. On the 61-item checklist, the participants marked events that they had experienced in the previous year. The number of stressful life events and their total emotional impact in the preceding year were obtained for each subject.

## Statistical analysis

Primary analysis was intended to disclose differences in intelligence (rational and non-intellectual) between IBS subjects (both patients and non-patients) and healthy controls. For this purpose, analysis of variance was used to perform univariate comparisons of WAIS-III and CTI measures, and sociodemographic data, personality traits and life events were also compared between the respective groups. To evaluate to what extent global constructive thinking and IQ variables might be associated with suffering from IBS, a logistic regression model was constructed (model 1), adjusting for age, sex and educational level; a full model was constructed to adjust for variables showing significant differences between IBS and control subjects, excluding those with correlation coefficients of 0.7 or higher with Global CTI score or IQ.

A secondary analysis was performed to evaluate the possible implication of measured factors in medical consultation sought because of IBS symptoms. To this end, IBS consulters and non-consulters were compared, using the same statistical model. To evaluate illness behavior, a multiple regression model was constructed (stepwise forward method), with the number of physician visits in the last year as a dependent variable and global constructive thinking, total IQ, neuroticism, number of life stressful events, clinical scales of MMPI-2

and state and trait anxiety as independent variables. Data are expressed as mean  $\pm$  SD, unless otherwise stated. Statistical analysis was performed using the SPSS version 13 computer software package.

### **Composition of case group and calculation of sample size**

We chose a ratio of 1:1 for IBS consulters and non-consulters in the case group, which may well represent the entire IBS population in this country (49% of IBS subjects as defined by the Rome II criteria had visited a physician in the previous year)<sup>[30]</sup>.

As there were no experimental data at the time of protocol design (January 2003) for making assumptions in similar settings, a five-point difference in the overall CTI scale was taken as relevant. This five-point estimate was based on the Spanish correction manual, which suggests that T-scores of 45 to 55 be regarded as normal, and 35 to 44 as moderately low. Since the mean T score for the general population could be expected to be 50, the minimum value for inferring a relevant lower score would be 44 (a five-point margin being sufficient to detect relevant differences). Hence, assuming a standard deviation of 10 (since this is a T-score), and with  $\alpha$  and  $\beta$  risks set at 0.05 and 0.1 respectively, 85 subjects would be needed in each group.

In so far as IQ was concerned, a difference of 10 points was estimated as relevant. Assuming a standard deviation of 15, then, with the same  $\alpha$  and  $\beta$  risk, the sample size would be 56 subjects in each group. Accordingly, a sample of 85 subjects in each group would be enough to enable a mean difference of eight points or higher to be detected. Allowing for the possibility of a 15% data loss, the final sample size was set at 100 subjects per group.

For the secondary analysis, assuming the same relevant differences in mean scores and the same standard deviations, a sample size of 50 per group (consulters and non-consulters) would provide a power of 80% with an  $\alpha$  risk of 0.1.

### **Ethics**

The study was formally approved by the Institutional Ethics Committee, and prior informed consent was obtained in writing from all participants.

## **RESULTS**

A total of 73 IBS consulters and 81 IBS non-consulters were recruited. Twenty-three IBS consulters were not included because of psychiatric diagnosis requiring treatment (four patients), not accomplishing Rome II criteria (two patients), incomplete information (one patient) or lack of adequate matching control (16 patients). Thirty-one IBS non-consulters were not included due to not accomplishing Rome II criteria (10 subjects), incomplete information (one subject) or lack of adequate matching control (20 subjects).

The study covered 100 subjects with IBS (50 consulters and 50 non-consulters) and 100 matching healthy controls. Of these, 70 were female in each case. The mean age of

IBS: Irritable bowel syndrome. <sup>a</sup>P < 0.05 (ANOVA), <sup>b</sup>P < 0.001 (ANOVA) vs controls.

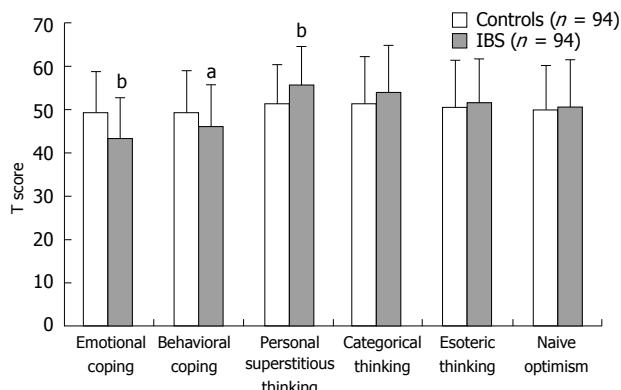

IBS subjects was 37.2  $\pm$  12.6 years, and there were no differences vis-à-vis healthy controls (37.2  $\pm$  13.1). Both groups reported 18 subjects with junior school, 23 with high school, and 59 with university education. Controls and IBS subjects were similar in terms of: marital status (single 50 and 53, and married 43 and 40, respectively); work status (student 10 and 9, gainfully employed 85 and 84, retired or unemployed 7 and 7, respectively); and family monthly income (€ 2684  $\pm$  1469 and € 2354  $\pm$  2272, respectively).

### **IBS features**

Among IBS sufferers, 31 were classified as per the Rome II criteria as diarrhea-predominant, 26 as constipation-predominant, and 43 as alternating. With respect to severity of IBS, 55 subjects were classified as mild, 37 as moderate, and eight as severe, with a mean FDSI score of 47.0  $\pm$  49.4, and a mean current VAS pain of 29.2  $\pm$  24.7. Seventy-seven subjects reported IBS symptoms of more than 2 years duration.

### **Intelligence, personality, psychopathology, anxiety and life events in IBS subjects**

Comparison of intelligence, personality, and life events between controls and IBS subjects were shown in Table 1. Six subjects (four controls, one IBS consulter, and one IBS non-consultor) produced invalid CTI scores, so that they and their matched counterparts were excluded from the analysis. IBS subjects registered similar IQ test results

**Figure 1** Subscales of constructive thinking in IBS and controls. <sup>a</sup>P < 0.05, <sup>b</sup>P < 0.01 vs controls.

**Table 2** Regression models to evaluate the association of Global CTI and IQ with suffering IBS

	Model 1	Full model
Global CTI score	0.93 (0.90-0.97) <sup>d</sup>	0.92 (0.87-0.97) <sup>b</sup>
Total IQ	0.99 (0.96-1.03)	0.99 (0.97-1.04)
Stressful life events (SRRS)		1.05 (0.97-1.15)
State anxiety		1.05 (0.99-1.10)
1-Hypochondriasis		1.19 (1.11-1.27) <sup>d</sup>
2-Depression		0.95 (0.90-1.00)
3-Hysteria		0.96 (0.90-1.02)
4-Psychopathic deviate		1.02 (0.96-1.08)
6-Paranoia		1.04 (0.99-1.10)
7-Psychasthenia		1.01 (0.93-1.09)
8-Schizophrenia		0.93 (0.85-1.01)
9-Hypomania		1.02 (0.97-1.07)

Adjusted by age, sex and educational level. <sup>b</sup>P < 0.01 (ANOVA); <sup>d</sup>P < 0.001 (ANOVA). Hosmer and Lemeshow goodness-of-fit test for the full model: P = 0.16. CTI: Constructive Thinking Inventory.

to the controls, without differences in total, verbal and performance IQ. However, IBS subjects scored lower in global constructive thinking and higher in neuroticism, and reported more stressful life events in the prior year than did controls. The detailed CTI subscale scores obtained by healthy controls and IBS subjects are shown in Figure 1.

Global CTI score was correlated to neuroticism ( $r = 0.71$ ) and trait anxiety ( $r = 0.71$ ), so these last variables were not included in the model. Table 2 shows the results of the logistic regression model. When neuroticism and trait anxiety were included, scale 1 of MMPI-2 (hypochondriasis) [OR 1.19 (1.11-1.27)] and global CTI score [OR 0.93 (0.87-0.99)] remained independently related, at the same magnitude, to suffering from IBS, without significant OR for any other variable.

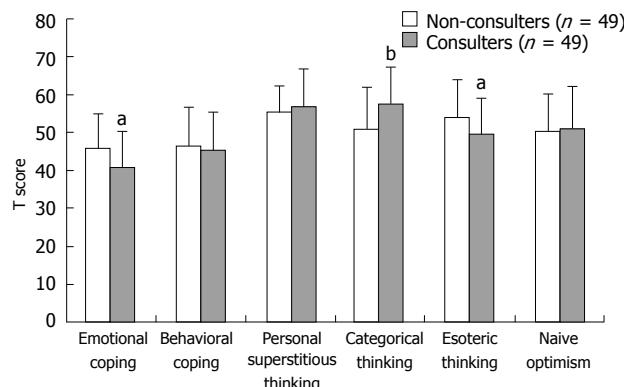

### IBS consulters vs non-consulters

Two subjects (one IBS consultor and one IBS non-consultor) produced invalid CTI scores and were thus excluded from the analysis. There were no significant differences between IBS consultors and non-consultors in terms of age, sex, educational level, marital status, work status and family monthly income. Furthermore, IBS features (distribution of subtypes, evolution of

**Table 3** Comparison of intelligence, personality, and life events between IBS consultors and non-consultors

	IBS non-consultors (n = 49)	IBS consultors (n = 49)

bowel symptoms) were similar in both groups, except for severity, with differences between consultors and non-consultors in FDSI scores ( $70.8 \pm 57.8$  vs  $23.5 \pm 21.7$ ;  $P < 0.001$ ) and current pain on VAS ( $34.4 \pm 25.5$  vs  $23.5 \pm 21.7$ ;  $P < 0.05$ ). IBS consultors displayed lower total and verbal IQ and lower global constructive thinking than did IBS non-consultors, without differences in personality traits and stressful life events in the preceding year (Table 3). CTI subscale scores obtained by IBS consultors and non-consultors are shown in detail in Figure 2.

In the logistic regression model, adjusted for age, sex and educational level, no variable was independently

**Table 4** Results of stepwise multiple linear regressions to predict number of physician visits among IBS consulters

Dimension	Variables entered in the model	Standardized coefficient ( $\beta$ )	Model
Step 1	1-Current pain (VAS)	-0.38 <sup>b</sup>	$r^2 = 0.13^d$
Step 2	1-Current pain (VAS) 2-Age	-0.39 <sup>b</sup> -0.33 <sup>a</sup>	$r^2 = 0.22^d$

<sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ ; <sup>d</sup> $P < 0.001$ .

associated with IBS-related health care seeking. Among those who had sought health care, the number of physician visits correlated with age ( $r = 0.31$ ;  $P < 0.05$ ), current pain ( $r = 0.38$ ;  $P < 0.01$ ) and hypochondriasis ( $r = 0.29$ ;  $P < 0.05$ ). The number of physician visits among IBS consulters was predicted by current pain, evaluated by VAS, and age in the stepwise multiple linear regression model (Table 4).

## DISCUSSION

The main finding of our study is that experiential rather than rational intelligence is associated with IBS *per se*, supporting the role of cognitive factors, specifically through generation of stress from daily life events.

Our results reject the hypothesis of IBS subjects having a lower rational intelligence. Attree *et al*<sup>[19]</sup> recently reported that IBS subjects had a full and verbal IQ slightly lower than controls and a deficit in verbal vs performance IQ. Differences in our results may be due to differences in the study sample. We studied a convenience sample of subjects with IBS covering the whole spectrum of the disease, without interest in psychological management or prior psychiatric diagnosis, while Attree *et al*<sup>[19]</sup> included a group of IBS subjects who had previously expressed an interest in participating in research at a school of psychology. Indeed, our finding that consulters displayed a slightly lower full and verbal IQ than non-consulters points to this explanation. Although a subtle cognitive impairment in some IBS patients cannot be ruled out, this would not seem to be true of the majority of IBS subjects.

Our results support the hypothesis of a lower level of constructive thinking among IBS subjects. The main CTI measure is defined as the ability to adapt the way of thinking to different situations (flexibility in thinking), while one of the main scales (emotional coping) is primarily described as the ability to appraise situations as a challenge rather than a threat. The relationship between physical symptoms and constructive thinking seems to be mediated by stress, mostly self-produced, through the generation of negative emotions<sup>[31]</sup>. Moreover, in a common stressful situation such as pregnancy, constructive thinking was shown to impact both on cognitive appraisal of stress (reducing the need for coping and adjustment) and on active coping responses, once the situation has been perceived as stressful<sup>[32]</sup>. Low constructive thinking suggests that subjects with IBS have a higher probability of experiencing daily life events

that are not intrinsically stressful, as being stressful, due to cognitive appraisal.

Stress is thought to play a pre-eminent role in generating and sustaining IBS symptoms. Over 50% of IBS subjects-consulters<sup>[33]</sup> and non-consulters alike<sup>[34]</sup> report that stressful events precipitate or worsen their symptoms. While some previous studies have observed that IBS subjects experience a slightly greater number of stressful life events than do controls or patients with other digestive disease<sup>[35,36]</sup>, other studies have observed no differences in this regard<sup>[6,37]</sup>. In a prospective study, Levy *et al*<sup>[38]</sup> failed to find differences between IBS subjects and controls in the number of positive or negative daily events, but self-reported daily stress was higher among IBS subjects. Hence, daily events are perceived as being more stressful by IBS subjects, and indeed, a recent Japanese study showed that IBS subjects scored higher on a perceived stress scale<sup>[39]</sup>.

Emotional distress plays a role in IBS and may also impact on daily stress. The association between low constructive thinking and IBS does not seem to be explained by emotional distress, as an association in multivariate analysis persisted even when adjusting for emotional distress measures, like MMPI clinical scales. Although we excluded subjects with a psychiatric diagnosis requiring treatment, our sample of IBS subjects still suffer higher emotional distress than control subjects, to a level similar to that reported by Drossman *et al*<sup>[6]</sup>.

Constructive thinking correlated to neuroticism; a correlation has been previously reported with the CTI emotional coping subscale, which has been deemed to represent the cognitive component of neuroticism<sup>[21]</sup>. Neuroticism is a broad concept that includes cognitive, affective, and behavioral traits<sup>[40]</sup>. Most<sup>[5,41-44]</sup>, although not all<sup>[36]</sup> studies have reported an association between neuroticism and IBS. However, constructive thinking seems to account for the relationship between neuroticism and IBS, suggesting the relevance of cognitive factors in IBS.

Several studies have shown that IBS is associated with less effective strategies to cope with stress<sup>[45,46]</sup>, specifically with symptoms. Thus, the difference between constructive thinking and coping response merits some comment. Constructive thinking would be mostly implicated in the automatic and holistic cognitive appraisal of any event, prior to the occurrence of emotion, and operates at a preconscious level in a way in which a person is unaware<sup>[47]</sup>. Coping is usually defined as cognitive and behavioural efforts to manage a troubled person-environment relationship; it is the reaction to a conscious appraisal of the situation<sup>[48]</sup>. Thus, interpretational activity may occur outside awareness and may be the non-conscious trigger of an emotional response<sup>[49]</sup>. Such a process is likely involved in the activation of the anterior cingulate cortex during subliminal and supraliminal stimulation<sup>[50]</sup>. Moreover, hypnotherapy is effective in IBS and, although the underlying mechanism is unknown<sup>[51]</sup>, it might be hypothesized that it operates partly through a change in preconscious appraisal of internal events<sup>[52,53]</sup>.

Another interesting finding is the association between constructive thinking and IBS-related medical consultation. In the 1980s and 1990s, psychological factors were regarded as predictors of health care sought by IBS subjects<sup>[6,54]</sup>, but recent population-based studies suggest that such factors are not quite so important<sup>[7,39,55]</sup>. Our results are closer to these latter studies, inasmuch as severity of symptoms is seen as the leading factor accounting for medical consultation, without any role for psychological factors. Nevertheless, univariate analysis showed a lower level of constructive thinking in those who had sought health care compared to those who did not; consulters displayed lower emotional coping and higher categorical thinking scores than non-consulters, a finding that points to appraisal of events (i.e. symptoms) as a threat and a more rigid mindset inclined to simplistic solutions as the main differences in thinking between those seeking care and non-consulters. However, constructive thinking does not seem to have a significant role in illness behavior, in view of the lack of correlation with the number of physician visits.

The main limitation of our study lies in the fact that subjects were not extracted from the general population strictly at random. We opted for a semi-random approach owing to the difficulties posed by recruiting our target population in a purely random fashion. There were four requirements for inclusion, namely: presence of bowel symptoms as per Rome II or, alternatively, absence of such symptoms; absence of any psychiatric diagnosis requiring treatment; consent to undergo in-depth evaluation, including a 2-h WAIS-III interview and a number of self-administered questionnaires; and, the need to be matched by age, sex and educational level. The direct-invitation approach allowed for a brief 5-min conversation to assess these criteria, and subjects were recruited in different environments (work and leisure centers) unrelated to medical facilities. Indeed, results from control subjects support this approach, since test profiles proved quite similar to data expected from the general population (mean T-scores of around  $50 \pm 10$ ; IQ around  $100 \pm 15$ ). In the case of IBS non-consulters, the data were comparable to the results of Mearin *et al*<sup>[2]</sup> based on a random Spanish-population sample. Thus, the results in no way suggest that there was any selection bias.

## COMMENTS

### Background

Irritable bowel syndrome (IBS) has been related to psychological distress and consequences of the stress driven emotional outputs. Cognitive abilities drive the interaction of the subject with the environment, which is the basis for stress, and may participate in abnormal illness behaviour, hypervigilance, and less effective coping abilities. One study suggested a lower intelligence in IBS patients.

### Research frontiers

This study is the first to comprehensively evaluate intelligence (rational and experiential intelligence) in an adequate sample of cases and controls.

### Innovations and breakthroughs

The potential role of intelligence in the pathophysiology of IBS is tested. This arm (cognition ability) of the subject-environment interaction has not been formally tested.

### Applications

This study provides support for the role of experiential intelligence in IBS.

Moreover, experiential intelligence may be improved with psychological therapies.

### Peer review

The authors exposed patients and controls to eight different psychological tests in an effort to identify correlations/associations for IBS and psychological phenotypes. The article is well written and the contents are credible.

**RESULTS:** The absolute enhanced value in the arterial phase correlated with the level of VEGF and MVD ( $P = 0.047$ ,  $P = 0.001$ ). The relative enhanced value in arterial phase and tumor-aorta enhancement ratio (arterial) correlated with MVD ( $P = 0.003$ ,  $P = 0.022$ ). Tumor-aorta enhancement ratio (arterial) correlated negatively with the extent of fibrosis ( $P = 0.004$ ). The tumors with greater MVD and higher expression of VEGF tended to show high enhancement in the arterial dominant phase. On the other hand, the tumors with a larger amount of fibrosis showed a negative correlation with the grade of enhancement during the arterial phase.

**CONCLUSION:** Enhancement patterns on dynamic CT correlated with angiogenesis and may be modified by the extent of fibrosis.

## Abstract

**AIM:** To evaluate retrospectively the correlation between enhancement patterns on dynamic computed tomography (CT) and angiogenesis and fibrosis in pancreatic adenocarcinoma.

**METHODS:** Twenty-three patients with pancreatic adenocarcinoma underwent dynamic CT and tumor resection. In addition to the absolute and relative enhanced value that was calculated by subtracting the attenuation value on pre-contrast from those on contrast-enhanced CT in each phase, we defined one parameter, "tumor-aorta enhancement ratio", which was calculated by dividing enhancement of pancreatic cancer by enhancement of abdominal aorta in each phase. These enhancement patterns were correlated with the level of vascular endothelial growth factor (VEGF), microvessel density (MVD), and extent of fibrosis.

## INTRODUCTION

Pancreatic cancer is one of the leading causes of cancer-related death, with an overall 5-year survival rate of < 5%<sup>[1]</sup>. Surgical resection is still the only potentially curative treatment for pancreatic cancer. However, the resection rate is < 40%<sup>[2,3]</sup> because of the difficulty in achieving early detection. In addition, the results of other treatment methods including radiation therapy and chemotherapy are also poor.

Angiogenesis is the development of new blood vessels and is required for tumor growth. In the 1970s, Folkman reported that the development of neoplasms is angiogenesis-dependent<sup>[4,5]</sup>, with this process induced by angiogenic factors such as vascular endothelial growth factor (VEGF). As a result, microvessel density (MVD) increases in neoplasms. Recently, it has been clarified that the grade of tumor angiogenesis is a useful prognostic marker in human cancers<sup>[6-9]</sup>, including pancreatic cancer<sup>[10-14]</sup>. Generally, tumors with strong expression of angiogenesis show a poor prognosis. Therefore, anti-angiogenic treatment may be effective in improving the prognosis of patients with neoplasms including pancreatic cancer.

Evaluation of the grade of angiogenesis is important as a prognostic marker and is necessary for deciding the indications and evaluating the effect of anti-angiogenic treatment. For this, biopsy is necessary. However, because repeated biopsy is often difficult and invasive, and the specimen obtained does not always reflect the entire tumor, to establish the grade of tumor angiogenesis by non-invasive imaging may be important clinically. There have been several reports evaluating the correlation between angiogenesis and imaging findings in several types of cancers<sup>[15-18]</sup>, but only a few such reports on pancreatic adenocarcinoma<sup>[19,20]</sup>. Recently, perfusion computed tomography (CT) has been used to measure the hemodynamic characteristics of various tumors, and many authors have reported the results of perfusion CT in this context<sup>[21-23]</sup>. The correlation of perfusion CT findings and MVD in lung cancer<sup>[24,25]</sup> and the evaluation of the effect of anti-angiogenic therapy by perfusion CT<sup>[26,27]</sup> have been described. However, this method requires an additional procedure for conventional CT examination and a special CT machine or software. In addition, its usefulness for pancreatic cancer is now under investigation. For the present, anti-angiogenesis agents are still not approved for the treatment of pancreatic cancer. However, as a preliminary investigation for future clinical application, to predict the grade of angiogenesis by conventional dynamic multidetector CT (MDCT), most commonly performed for the diagnosis of pancreatic cancer, would be useful clinically.

The purpose of the present study was to evaluate the validity of conventional dynamic MDCT findings to predict angiogenesis in pancreatic cancer. We analyzed retrospectively the correlation between the enhancement on CT and the histopathological findings, including the grade of tumor angiogenesis, with special reference to MVD and expression of VEGF, and the extent of fibrosis in surgically resected pancreatic adenocarcinoma.

## MATERIALS AND METHODS

### Patients

Thirty-six patients with pancreatic cancer underwent surgical resection between January 2003 and October 2004. Among them, 10 patients did not receive dynamic CT examination and were excluded from the study.

Additionally, two with adenosquamous carcinoma and one with mucinous carcinoma were excluded. Finally, 23 patients (15 men and eight women; age range, 34-79 years; mean age, 62.6 years) with tubular adenocarcinoma of the pancreas were evaluated. All patients underwent dynamic CT, surgical resection, and histopathological examination. The range of tumor sizes was 20-48 mm and the mean was 40.5 mm.

Our institutional review board approved this retrospective study and informed consent for the use of medical records was obtained from the patients.

### CT imaging

CT images were obtained using a multi-detector row CT scanner (LightSpeed Ultra 16; GE Medical Systems, Milwaukee, WI, USA). The scanning parameters were 2.5 mm section thickness, pitch of 1.5, 120 kV, and auto mA. After pre-contrast CT scans, arterial dominant phase images of dynamic CT were obtained starting 30 s after the beginning of the intravenous bolus injection (3 mL/s) of 100 mL of iodized contrast medium at 300 mg/mL. The pancreatic phase and the late phase (near equilibrium phase) were also obtained, starting at 50 and 90 s after injection, respectively.

### Imaging analysis

Two radiologists (Y.H., T.G., one with > 7 years and the other with > 23 years of experience in pancreatic imaging) evaluated retrospectively all images and determined a decision with consensus circular regions of interest (ROI) were decided in the most enhanced area of the tumor in the pancreatic phase, excluding cystic or necrotic areas and adjacent pancreatic parenchyma, and in the abdominal aorta of the same slice, and ROIs in the other phases were drawn on the same site. Attenuation values were measured in Hounsfield units (HU) (absolute enhanced value). The relative enhanced value was calculated by subtracting the attenuation value on pre-contrast CT from those on contrast-enhanced CT in each phase. Furthermore, we defined one parameter as follows. The “tumor-aorta enhancement ratio” was calculated by dividing the attenuation value (HU) of pancreatic cancer by that of the abdominal aorta in each phase of contrast-enhanced CT, as a parameter of the grade of tumor enhancement. The ratio in arterial dominant phase was defined as the “tumor-aorta enhancement ratio (arterial)”, and in the pancreatic phase “tumor-aorta enhancement ratio (pancreatic)” and in late phase “tumor-aorta enhancement ratio (late)”, respectively.

### Immunohistochemical staining

Surgical specimens of 5 mm thickness were cut in the axial plane for pancreatic head cancer and the sagittal plane for pancreatic body and tail cancer. Formalin-fixed, paraffin-embedded tissues were sectioned at 4 µm thickness. The sections were stained with hematoxylin and eosin. Immunohistochemical and elastica van Gieson (EVG) staining was performed in the section that corresponded to the particular CT slices employed for the evaluation of enhancement pattern of the tumor. Immunohistochemical

staining was performed using the dextran polymer system (EnVision+ System; DAKO, Glostrup, Denmark). Color development was performed using 3,3'-diaminobenzidine tetrahydrochloride (DAKO), followed by hematoxylin counterstaining. For the detection of VEGF, which is an angiogenic factor, we used rabbit polyclonal anti-VEGF antibodies (A-20; Santa Cruz Biotechnology, Santa Cruz, CA, USA) at a dilution of 1:100. The sections were heated in citrate buffer (pH 6.0; 10 mmol/L) using microwaves at 95°C for 20 min, and incubated at 4°C overnight in humid chambers with primary antibodies. For the detection of CD34 expressed on small-vessel endothelial cells, we used mouse monoclonal anti-CD34 antibodies (clone GBEnd/10; IMMUNOTECH, Marseilles, France) at a dilution of 1:200. The sections were incubated at room temperature for 1 h with primary antibodies. Islets of Langerhans and endothelium of arterial branches were used as internal positive controls for VEGF and CD34, respectively.

### Histopathological analysis

One author (Y.H.) evaluated the anonymous histological specimens without any information about the radiological images under assistance of one pathologist (Y.N., with > 30 years of experience). The level of VEGF staining was scored in comparison with that in the islets of Langerhans as a positive control: score 1, extremely weak; score 2, weak; score 3, mildly weak; score 4, almost equal. Each CD34-stained slide was scanned at a low magnification ( $\times 40$ ) to determine five "hot spot" areas of the largest number of microvessels. MVD was determined according to the mean number of microvessels counted in the five hot spots at high magnification ( $\times 200$ ). The extent of fibrosis was scored according to the ratio of fibrosis in the tumor with EVG staining in which elastic fibers were stained dark brown and collagen fibers were stained pink, with a score of 1, 0%-25%; 2, 25%-50%; and 3, 50%-100%.

### Statistical analysis

Statistical software (Dr. SPSS II for windows; SPSS, Chicago, IL, USA) was used for statistical analysis. The extent and dynamics of enhancement on dynamic CT were correlated with the level of VEGF, MVD and extent of fibrosis, to analyze whether the dynamic CT parameters defined above reflect the histopathological findings, including tumor angiogenesis. In addition, we also analyzed the correlation among the expression of VEGF, MVD and fibrosis. For these analyses, Spearman's rank correlation test was used.  $P < 0.05$  was considered to indicate a significant difference.

## RESULTS

### Correlation between absolute and relative enhanced values and histopathological findings

Table 1 shows the averages of the absolute attenuation value (HU) of the tumor and abdominal aorta in each phase of dynamic CT, and Table 2 shows the averages of the relative enhanced value (HU).

**Table 1 Absolute attenuation value (HU)**

	Pre-contrast	Arterial phase	Pancreatic phase	Late phase
Pancreatic cancer				
mean $\pm$ SD	41 $\pm$ 4	61 $\pm$ 13	80 $\pm$ 13	86 $\pm$ 11
Median	41	56	81	85
Range	32-48	41-93	60-104	64-106
Abdominal aorta				
mean $\pm$ SD	45 $\pm$ 4	284 $\pm$ 50	185 $\pm$ 40	139 $\pm$ 21
Median	45	295	171	136
Range	38-51	205-409	127-307	107-208

**Table 2 Relatively enhanced value (HU)**

	Arterial phase	Pancreatic phase	Late phase
Pancreatic cancer			
mean $\pm$ SD	20 $\pm$ 14	39 $\pm$ 15	45 $\pm$ 13
Median	19	38	43
Range	6-54	15-70	23-74
Abdominal aorta			
mean $\pm$ SD	239 $\pm$ 51	140 $\pm$ 40	94 $\pm$ 22
Median	248	125	91
Range	157-365	86-269	69-171

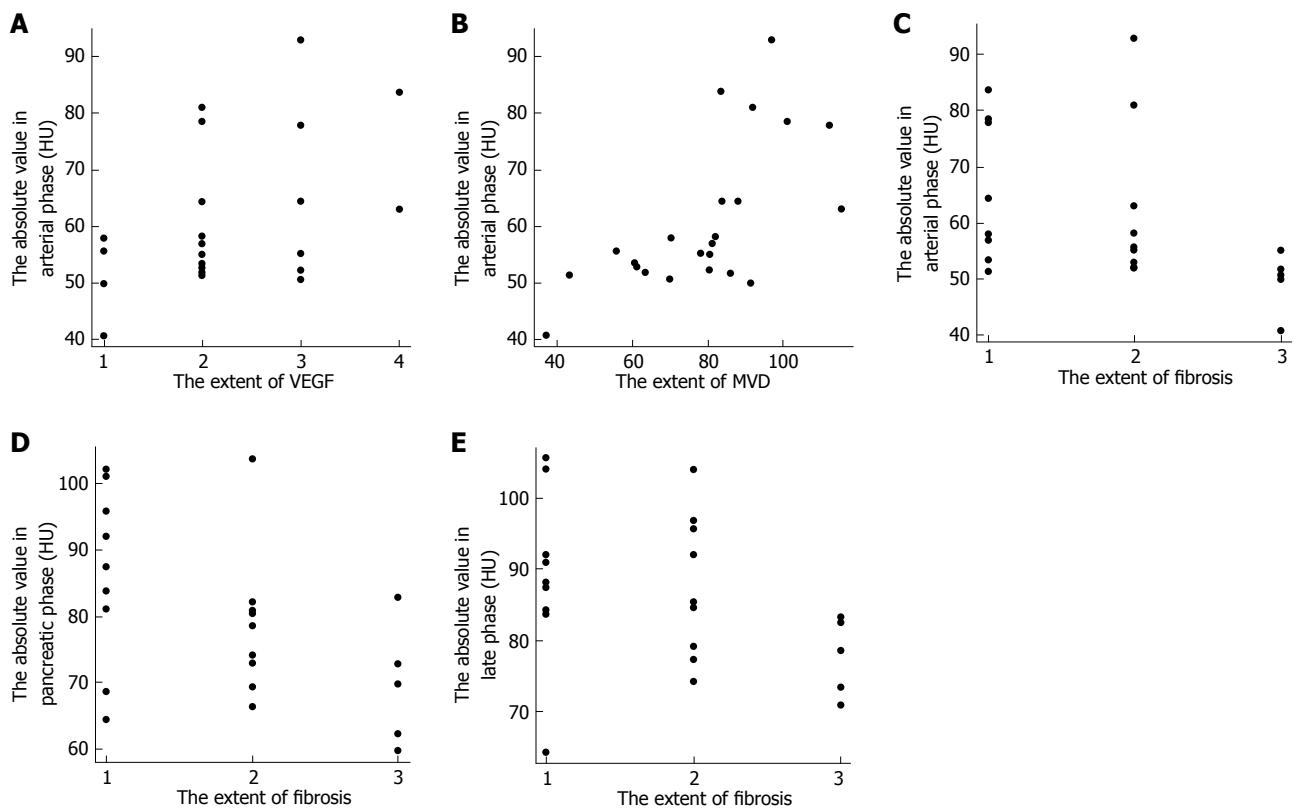

**Table 3 Tumor-aorta enhancement ratio**

	mean $\pm$ SD	Median	Range
Tumor-aorta enhancement ratio (arterial)	0.835 $\pm$ 0.053	0.066	0.029-0.216
Tumor-aorta enhancement ratio (pancreatic)	0.291 $\pm$ 0.12	0.244	0.139-0.569
Tumor-aorta enhancement ratio (late)	0.487 $\pm$ 0.129	0.483	0.295-0.816

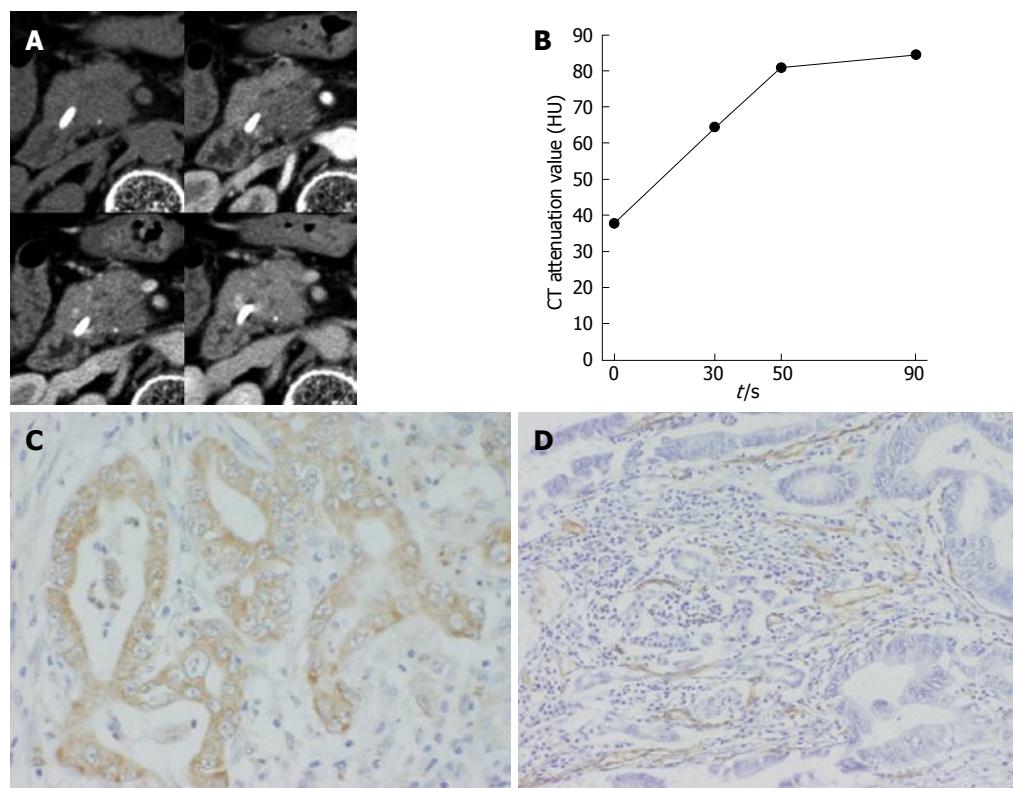

The absolute value of pre-contrast CT correlated significantly with none of the histopathological findings, or the level of VEGF, MVD or fibrosis. The absolute value in the arterial phase correlated significantly with the level of VEGF and MVD ( $P = 0.047$ ,  $P = 0.001$ ) (Figure 1A and B, Figures 2 and 3). The absolute value in the arterial, pancreatic and late phases correlated significantly and negatively with the extent of fibrosis ( $P = 0.006$ ,  $P = 0.018$ ,  $P = 0.035$ ) (Figure 1C-E and Figure 4). None of the relatively enhanced values in any phase correlated significantly with the level of VEGF. The relatively enhanced value in the arterial phase correlated significantly with MVD ( $P = 0.003$ ) (Figure 5A). All of the relatively enhanced values in the arterial, pancreatic and late phase correlated significantly and negatively with the extent of fibrosis ( $P = 0.003$ ,  $P = 0.020$ ,  $P = 0.039$ ) (Figure 5B-D).

### Correlation between tumor-aorta enhancement ratio and histopathological findings

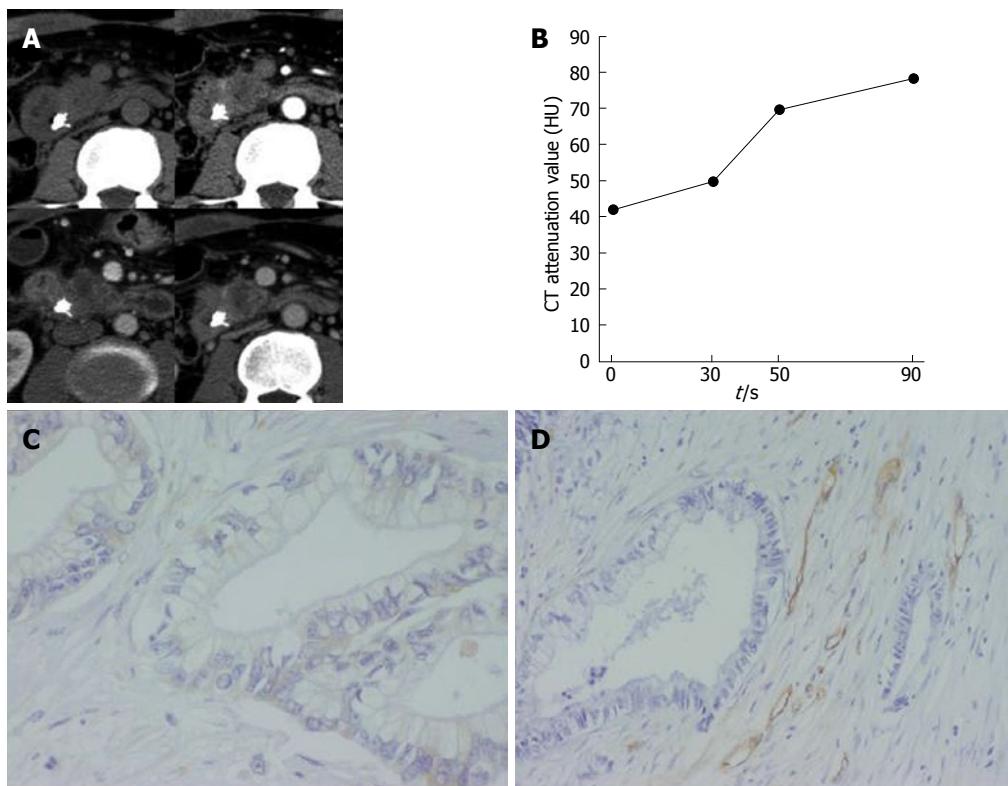

The averages of the tumor-aorta ratio are shown in Table 3. None of tumor-aorta enhancement ratios in any phase correlated significantly with the level of VEGF. Tumor-aorta enhancement ratio (arterial) was correlated significantly with MVD ( $P = 0.022$ ) (Figure 6A), and significantly and negatively with the extent of fibrosis ( $P = 0.004$ ) (Figure 6B).

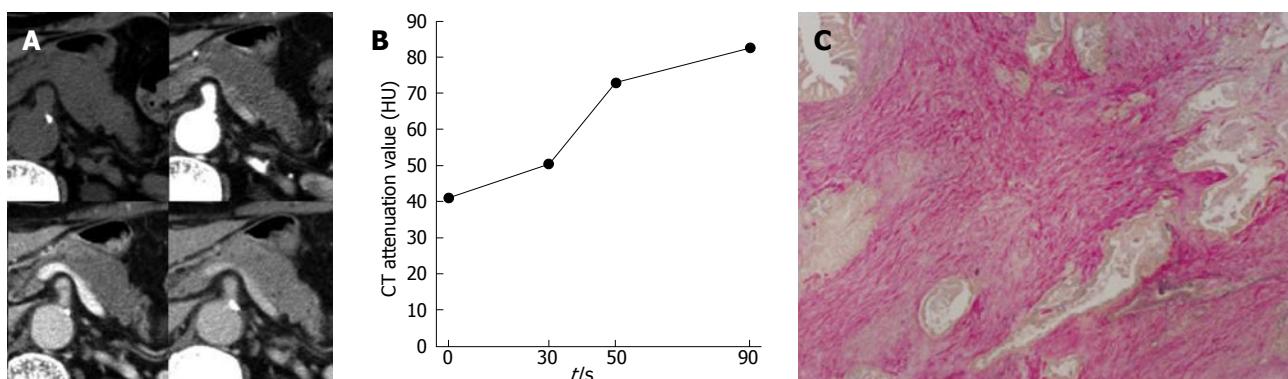

**Figure 1** Scatter plots showing correlation between absolute values and histopathological findings. A: The absolute value in the arterial phase correlated significantly with the level of VEGF ( $r = 0.418, P = 0.047$ ); B: The absolute value in the arterial phase correlated significantly with MVD ( $r = 0.649, P = 0.001$ ); C: The absolute value in the arterial phase correlated significantly and negatively with the extent of fibrosis ( $r = -0.556, P = 0.006$ ); D: The absolute value in the pancreatic phase correlated significantly and negatively with the extent of fibrosis ( $r = -0.488, P = 0.018$ ); E: The absolute value in the late phase correlated significantly and negatively with the extent of fibrosis ( $r = -0.442, P = 0.035$ ).

**Figure 2** Moderately differentiated tubular adenocarcinoma in a 73-year-old woman. A: Transverse dynamic CT images; B: Time-attenuation curve. Dynamic CT scans showing marked enhancement in the arterial phase; C: Photomicrograph showing immunoreactivity to VEGF, which is depicted as brown cytoplasm. The score was 4 (high expression) (Anti-VEGF stain; original magnification,  $\times 400$ ); D: Photomicrograph showing abundant microvessels and depicting vessel walls that appeared brown (Anti-CD34 stain; original magnification,  $\times 200$ ).

**Figure 3 Well-differentiated tubular adenocarcinoma in a 44-year-old man.** A: Transverse dynamic CT images; B: Time-attenuation curve. Dynamic CT scans showing low enhancement in the arterial phase; C: Photomicrograph showing immunoreactivity to VEGF, which is depicted as brown cytoplasm. The score was 1 (extremely weak) (Anti-VEGF stain; original magnification,  $\times 400$ ); D: Photomicrograph showing few microvessels and depicting vessel walls, which appear brown (Anti-CD34 stain; original magnification,  $\times 200$ ).

**Figure 4 Moderately differentiated tubular adenocarcinoma in a 79-year-old man.** A: Transverse dynamic CT images; B: Time-attenuation curve. Dynamic CT scans showing gradual enhancement; C: Photomicrograph showing abundant fibrosis and collagen fibers, which appear pink. The score was 3 (EVG stain; original magnification,  $\times 40$ ).

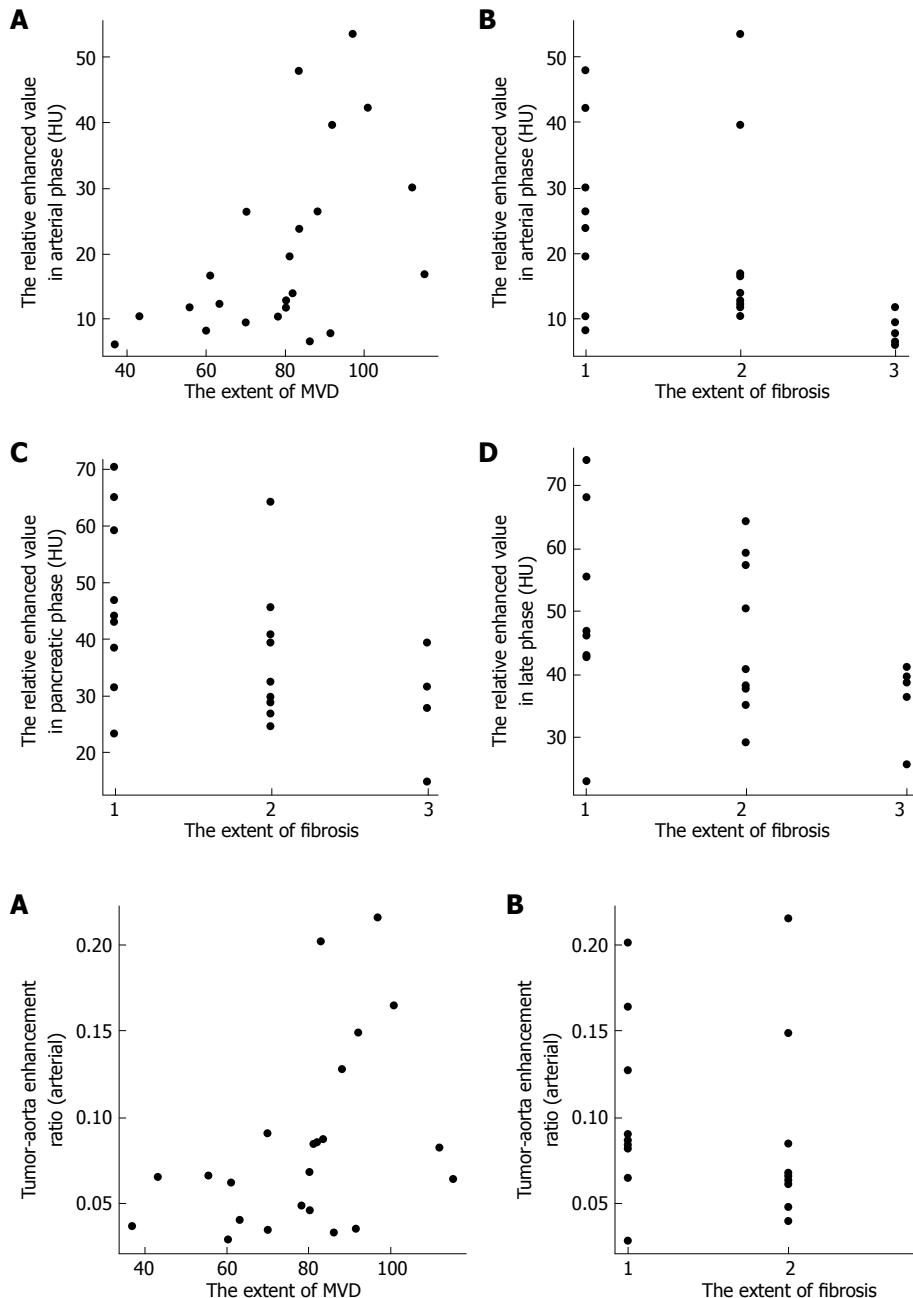

### Correlation among histopathological findings

The level of VEGF was correlated significantly with MVD ( $P = 0.037$ ). The extent of fibrosis was not correlated significantly with the level of VEGF and MVD.

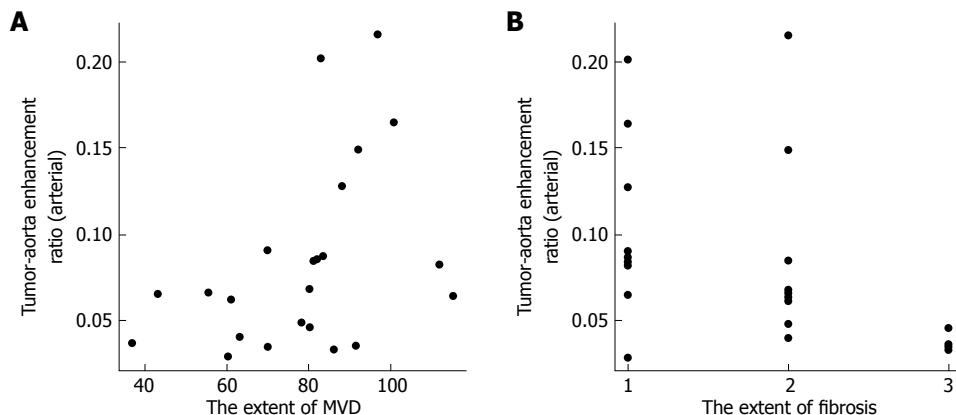

### DISCUSSION

The correlation between conventional dynamic MDCT findings and angiogenesis in lung<sup>[15]</sup> and renal cell cancer has been reported previously. These studies have revealed that the attenuation value of the peak enhancement of the tumor and the enhancement ratio (peak enhancement value divided by time) are correlated

positively with the extent of angiogenesis. However, it is not realistic to apply these results to pancreatic cancer, which usually has abundant fibrosis and tends to show gradual enhancement with the peak enhancement in the equilibrium phase<sup>[28,29]</sup>. To overcome this important problem in the common type of pancreatic cancer, we analyzed the correlation with enhancement of each phase and angiogenesis and fibrosis. In general, contrast agents have two-compartment pharmacokinetics with intravascular and extravascular-extracellular (interstitium) components. The enhancement of the tumor depends on the concentration of the injected agent, blood flow, blood volume, permeability, and extravascular-

**Figure 5** Scatter plots showing correlation between the relative enhanced values and histopathological findings. A: The relatively enhanced value in the arterial phase correlated significantly with the extent of MVD ( $r = 0.593, P = 0.003$ ); B: The relatively enhanced values in the arterial phase correlated significantly and negatively with the extent of fibrosis ( $r = -0.590, P = 0.003$ ); C: The relatively enhanced values in the pancreatic phase correlated significantly and negatively with the extent of fibrosis ( $r = -0.483, P = 0.020$ ); D: The relatively enhanced values in the late phase correlated significantly and negatively with the extent of fibrosis ( $r = -0.433, P = 0.039$ ).

**Figure 6** Scatter plots showing correlation between tumor-aorta enhancement ratio and histopathological findings. A: Tumor-aorta enhancement ratio (arterial) was correlated positively with MVD ( $r = 0.477, P = 0.022$ ); B: Tumor-aorta enhancement ratio (arterial) was correlated negatively with the extent of fibrosis ( $r = -0.575, P = 0.004$ ).

extracellular components. The contrast agents in the arterial dominant phase are predominantly the intravascular component. In the pancreatic phase (near portal dominant phase), they pass into the extravascular-extracellular components. The enhancement in this phase is considered to be a mixture of intravascular and extravascular-extracellular components. Tissues with adequate blood supply generally show the highest enhancement in this phase. The contrast agents in late phase (equilibrium phase) are both intravascular and extravascular-extracellular components, and the enhancement depends mainly on the extravascular-extracellular components. In addition to absolute and relative enhanced values, we employed the tumor-aorta enhancement ratio, which was calculated by dividing

the attenuation value (HU) of pancreatic cancer by that of the abdominal aorta in each phase of contrast-enhanced CT, as a parameter of the grade of tumor enhancement. This parameter was decided in order to exclude the influence of the intravascular concentration of an injected contrast agent that is dependent on cardiac output and circular blood volume. We think that this parameter reflects tumor enhancement more exactly than the absolute and relative attenuation values. Tumor-aorta enhancement ratio (arterial) is considered to reflect mainly the amount of arterial blood flow and volume of intratumoral blood spaces. Tumor-aorta enhancement ratio (pancreatic) may depend on vascular permeability in addition to intratumoral blood flow and/or blood volume. Tumor-aorta enhancement ratio (late) may

reflect mostly the extravascular-extracellular component.

In the present study, several findings of dynamic CT showed significant correlations with the histopathological findings. MVD in the tumor correlated significantly with the absolute value in the arterial and pancreatic phases, relative enhanced value in the arterial phase and the tumor-aorta enhancement ratio (arterial). This may have resulted from the increased vascular space and/or increased blood flow in tumors with increased MVD. The absolute value in the arterial phase also correlated significantly with the level of VEGF, probably for the same reason as in the case of MVD. On the other hand, the absolute value and relatively enhanced value in the arterial and pancreatic phases and tumor-aorta enhancement ratio (arterial) correlated significantly and negatively with the extent of fibrosis. This may have resulted from the smaller intratumoral blood spaces and blood flow in the tumors, with abundant fibrosis resulting in an absolutely lower volume of contrast inflow into this kind of tumor. Both the absolute value and relatively enhanced value in the late phases correlated significantly and negatively with the extent of fibrosis. It is known that the tumors with abundant internal fibrosis show prominent delayed enhancement in the late-phase of dynamic CT because of an increased extravascular-extracellular component. Therefore, the results obtained in our tumor were not consistent with previous speculations. This may also have been caused by the smaller amount of blood inflow into the tumors with more abundant fibrosis. We need to study this issue further with a more delayed phase on dynamic CT.

Histologically, the extent of VEGF expression was correlated significantly with MVD. However, the extent of fibrosis was not correlated significantly with the level of VEGF or MVD. These results support the similarity of the findings of dynamic CT between tumors with increased MVD and expression of VEGF. However, these findings may be modified by the extent of intratumoral fibrosis, which has no direct correlation with VEGF expression and MVD.

There are several limitations in the present study. First, the protocol of dynamic CT was not entirely appropriate. The late phase was earlier than the widely accepted equilibrium phase of dynamic CT of the pancreas. We used a fixed amount of contrast material. The grade of enhancement might be influenced by several factors such as patient weight, cardiac output, and CT tube wear<sup>[30,31]</sup>. Since we analyzed the validity of conventional dynamic CT retrospectively and preliminarily, we did not adopt these factors in the present study. Second, the attenuation value (HU) reflects not only the vascular characteristics of immature vessels formed by tumor angiogenesis, but also those of pre-existing mature vessels. Third, there are several other factors that affect the enhancement pattern of pancreatic cancers, such as the shape of intratumoral blood spaces and vasoactive elements. Fourth, the attenuation value (HU) in each phase on conventional dynamic MDCT may reflect various levels of blood flow, blood volume, vascular permeability and extravascular-

extracellular components. In particular, new capillaries formed by tumor angiogenesis are immature and have greater permeability than normal capillaries<sup>[32]</sup>. Further investigation, including by perfusion CT, is needed in this regard. In spite of these limitations, we think that our results provide some useful indication for the estimation of angiogenesis and intratumoral fibrosis in pancreatic cancer. After clinical application of anti-angiogenesis agents for pancreatic cancer, evaluation of the results obtained this study should be performed.

In conclusion, there was a significant correlation between the enhancement in conventional dynamic CT and angiogenesis and fibrosis in pancreatic adenocarcinoma. The tumors with greater MVD and expression of VEGF tended to show high enhancement in the arterial dominant phase. On the other hand, the tumors with a larger amount of fibrosis showed a negative correlation with the grade of enhancement during the arterial phase. Dynamic CT features that are caused by angiogenesis may be modified by the extent of intratumoral fibrosis.

## COMMENTS

### Background

Prognosis of pancreatic cancer is poor. Recently, it has been clarified that the grade of tumor angiogenesis is a useful prognostic marker in human cancer, including pancreatic cancer. Therefore, evaluation of the grade of angiogenesis by imaging may be important as a prognostic marker and is necessary for deciding the indications and evaluating the effect of anti-angiogenic treatment.

### Research frontiers

To establish the grade of tumor angiogenesis by non-invasive imaging may be important clinically. However, there are only a few such reports on pancreatic adenocarcinoma. In the present study, the authors analyzed the correlation between enhancement on dynamic multidetector computed tomography (MDCT) and histopathological findings, including the grade of tumor angiogenesis, and the extent of fibrosis in surgically resected pancreatic adenocarcinoma.

### Innovations and breakthroughs

This study predicted the grade of angiogenesis by conventional dynamic MDCT that is performed most often for the diagnosis of pancreatic cancer. The tumors with strong angiogenesis tended to show high enhancement in the arterial dominant phase. On the other hand, tumors with a larger amount of fibrosis showed a negative correlation with the grade of enhancement during the arterial phase.

### Applications

Anti-angiogenesis agents are still not approved for the treatment of pancreatic cancer at present. However, as a preliminary investigation for future application, prediction of the grade of angiogenesis by conventional dynamic MDCT would be useful clinically.

### Terminology

Angiogenesis is the process of new blood vessel formation. This consists of endothelial sprouts of preexisting vessels and is stimulated by angiogenic factors such as vascular endothelial growth factors. Recently, angiogenesis has been recognized as an important factor of tumor growth and metastasis.

### Peer review

The author retrospectively evaluated the correlation between enhancement patterns on dynamic computed tomography and angiogenesis and fibrosis in pancreatic adenocarcinoma.

376 patients with LC and 171 patients with CC. The female/male ratio was 3:1 in CC and 2.7:1 in LC patients. Celiac disease ( $P < 0.001$ ), irritable bowel syndrome (IBS) ( $P < 0.001$ ), and thyroid diseases ( $P < 0.001$ ) were found to have a higher occurrence in MC compared to the control group. No statistical differences in the occurrence of colorectal cancer, diabetes and IBD were found between the MC group and the control group.

**CONCLUSION:** This is the largest group of patients with MC known to the authors that has been studied to date. Conditions such as celiac disease, IBS, and thyroid diseases were found to be related to MC. Furthermore, neither an increased risk of colorectal cancer nor IBD was associated with MC in this study.

### Abstract

**AIM:** To examine the demographic data on a large multi-ethnic population of patients with microscopic colitis (MC) in Southern California and to determine the association of MC with inflammatory bowel disease (IBD) and colorectal cancer.

**METHODS:** All patients diagnosed with MC by colonic biopsy from 1996-2005 were identified utilizing a pathology database. All biopsies were reviewed by experienced pathologists utilizing standard histologic criteria. Patients' medical records were reviewed and data regarding patient age, co-morbidities, sex, ethnicity, and medications were analyzed. An age- and sex-matched standard control group was also generated. Chi-square test was used to evaluate the associations of co-morbidities between lymphocytic colitis (LC), collagenous colitis (CC) and the control group.

**RESULTS:** A total of 547 cases of MC were identified,

### INTRODUCTION

Microscopic colitis (MC) is a condition characterized by chronic, watery diarrhea with normal endoscopic appearance of colonic mucosa, yet abnormal histology. Further classification of this condition based on histology reveals two distinct entities: collagenous colitis (CC) and lymphocytic colitis (LC). Although both entities demonstrate colonic intraepithelial lymphocytosis, increased inflammatory cells within the lamina propria and preserved crypt architecture, the presence of a

thickened sub-epithelial collagen band is characteristic of CC.

The incidence of CC is approximately 0.6–2.3/100 000 per year with a prevalence of 10–15.7/100 000, while LC has an incidence of 3.1/100 000 per year and a prevalence of 14.4/100 000<sup>[1,2]</sup>. However, more recently published data from Olesen *et al*<sup>[3]</sup> suggests that the incidence of microscopic colitides are on the rise. Observational studies have also suggested associations between MC and various autoimmune diseases including thyroid, rheumatoid, celiac, and inflammatory bowel disease (IBD)<sup>[4–7]</sup>. Various medications have also been linked with MC in published case reports. Currently, little is known regarding cancer risk associated with MC.

With the number of reported cases clearly increasing, surprisingly, its etiology is still mostly unknown. Furthermore, the relationship between collagenous and LC and their association with other diseases has yet to be clearly defined. Should a connection between MC and colorectal cancer or IBD exist, this would have huge ramifications on the management of MC. Most of the currently available data on MC are from European studies with relatively small and homogeneous populations. There are even fewer comparative studies on the subtypes of MC.

The purpose of this study was to observe and report the demographic data on a large multi-ethnic population in Southern California, USA, with MC. We also report on the pattern of concurrent diseases and cancers in this group of patients.

## MATERIALS AND METHODS

All patients diagnosed with MC (both collagenous and LC) from 1996 to 2005 by colonic biopsy were identified using the pathology database at Kaiser Permanente (a large health maintenance organization) in Southern California and the search words “MC, LC and CC”. This region includes eight major Kaiser Permanente medical centers that serve over three million members throughout Southern California.

The histological criteria for inclusion in this study were defined as follows: (1) An increase in intraepithelial lymphocytes (more than 10 lymphocytes/100 epithelial cells); (2) Surface epithelial damage; (3) Absent or minimal crypt architectural damage; (4) An increase in sub-epithelial collagen band > 10 micrometers was required for the diagnosis of CC (Figure 1).

Experienced gastrointestinal pathologists (JM, SW, NK, RZ, MK, JP, KG) at Kaiser Permanente reviewed all biopsies.

Patients with ulcerations, erythema or any other visible abnormalities seen on the colonic mucosa during the endoscopic exam were excluded from the study. We included patients with a history of colorectal cancer.

We reviewed medical records using the Kaiser Permanente Database System and recorded data regarding patient age at diagnosis, sex, ethnicity, and concurrent medical conditions. All medications taken by patients, within 1 year prior to the diagnosis of collagenous or LC,

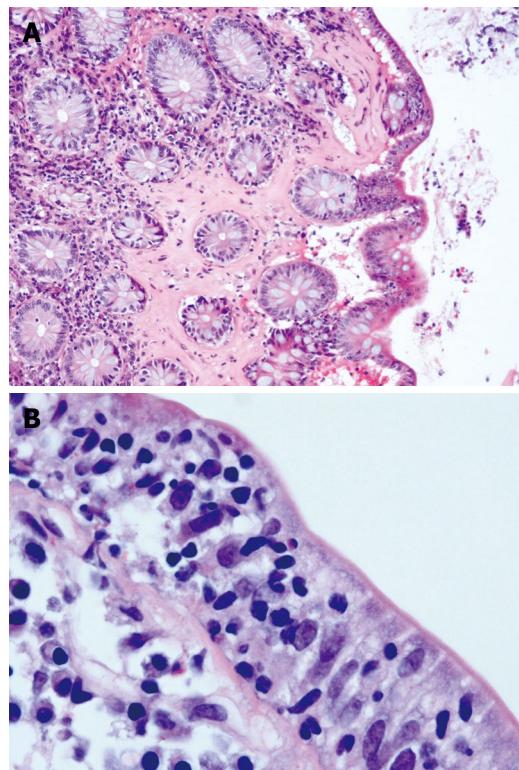

Figure 1 Collagenous colitis (A) and lymphocytic colitis (B).

were also recorded for analysis.

Demographic data such as age at diagnosis, sex and ethnicity is presented as means and standard deviation. An age- and sex-matched standard control group was also randomly generated from the same Kaiser Permanente database. We used a chi-square test to evaluate the associations of co-morbidities between LC, CC and the control group.

Differences in the clinical characteristics between LC and CC were also evaluated using the chi-square test. Differences were assumed as significant at a *P* value of less than 0.05.

The study protocol was approved by the Internal Review Board of Kaiser Permanente in Southern California.

## RESULTS

From January 1996 to July 2005 a total of 547 patients were identified with MC from our database. There were 27.1% male subjects, while 72.9% were female. The average age at diagnosis was 61.7 years for both men and women. We were able to identify the ethnicity in 465 cases. The percentage of each ethnic group was as follows: 72.4% Caucasian, 6.9% Hispanic, 2.6% Asian, 2.9% African American, and 0.2% Middle Easterners.

## CC

**Demographics:** A total of 171 patients were identified as having CC. The average age at diagnosis in these patients was 63.8 years with a standard deviation of 13.5 years. The range for age at diagnosis was between

**Table 1 Comparison of our demographic data against published demographic data in collagenous colitis (mean  $\pm$  SD)**

	Total number	Age at diagnosis (yr)	Gender ratio M/F
Goff <i>et al</i> <sup>[8]</sup> 1997	31	66	5/26
Fernandez-Banares <i>et al</i> <sup>[1]</sup> 1999	23	57.8 $\pm$ 2.9	4/19
Agnarsdottir <i>et al</i> <sup>[9]</sup> 2002	71	66.1 $\pm$ 14.3	8/63
Olesen <i>et al</i> <sup>[3]</sup> 2004	51	Not reported	6/45
Koskela <i>et al</i> <sup>[18]</sup> 2004	30	56.5 $\pm$ 12.7	10/20
Kao <i>et al</i> 2006	171	63.8 $\pm$ 13.5	42/129

29 to 93 years. The sex distribution was 24.6% male and 75.4% female. The ratio between male and female ratio was about 1:3. Of the 171 patients identified, we were able to identify the ethnicity of 152 patients. The percentage of each ethnic group was as follows: 80.7% Caucasian, 5.3% Hispanic, 2.3% African American and 0.6% Asian. No patients identified as Middle Easterners were observed<sup>[8,9]</sup> (Table 1).

**Associated diseases:** Of the CC population identified, the most common endocrinopathies were as follows: hyperlipidemia (42.7%), diabetes (14%) and thyroid disease, including hyperthyroidism, hypothyroidism and Grave's disease (21%). The three most common rheumatologic and other inflammatory disorders were rheumatoid arthritis (7%), fibromyalgia (3.5%) and Raynaud/CREST syndrome (2.9%). Other diseases diagnosed in these patients included giant cell/temporal arteritis ( $n = 3$ , 1.75%), polymyalgia rheumatica ( $n = 2$ , 1.16%), systemic lupus erythematosus ( $n = 1$ , 0.58%) and scleroderma ( $n = 1$ , 0.58%). Only five patients in the CC group were diagnosed with celiac disease (2.92%). One of these patients had the diagnosis of celiac disease prior to the diagnosis of CC. Thirty patients were diagnosed with irritable bowel syndrome (IBS) prior to the diagnosis of CC, while only one patient was diagnosed with irritable bowel after the diagnosis of CC was made. We observed one patient with an established diagnosis of IBD prior to the diagnosis of CC. During a median follow up of 3 years, none of our CC patients have subsequently been diagnosed with IBD.

Compared with the control group, patients with CC had higher rates of thyroid disease ( $P < 0.001$ ). We also observed a higher rate of celiac disease ( $P < 0.01$ ), IBS, ( $P < 0.001$ ) rheumatoid arthritis ( $P < 0.001$ ) and Raynaud/CREST syndrome ( $P < 0.01$ ) in our patients with CC (Table 2).

**Cancer:** The three most common cancers found in CC patients were breast ( $n = 4$ , 2.34%), lung ( $n = 3$ , 1.75%) and colorectal cancer ( $n = 5$ , 2.82%). Four patients were diagnosed with cancer prior to the diagnosis of CC. Only one patient was diagnosed with colorectal cancer following the diagnosis of CC. This patient was a 79-year-old female diagnosed with colorectal cancer by screening colonoscopy 5 years after the diagnosis of CC was made.

Kao <i>et al</i> 2006	376	60.7 $\pm$ 16.1	106/270

No cancer demonstrated a statistical difference compared with the control group, including colorectal cancer.

## LC

**Demographics:** A total of 376 patients were identified as having LC. The average age at diagnosis in this group was 60.7 years, with a standard deviation of 16.1 years. The age range at diagnosis was between 19 to 98 years. Sex distribution was 28.1% male and 71.8% female. The ratio between men and women was about 1:2.5. Of the 376 patients identified, ethnicity was determined in 313 cases. The percentage of each ethnic group was as follows: 68.8% Caucasian, 7.71% Hispanic, 3.45% Asian, 3.19% African American and 0.26% Middle Eastern (Table 3).

**Associated diseases:** Of the total LC population, the most common endocrinopathies were as follows: hyperlipidemia = 44.1%, diabetes = 14.6% and thyroid disease (including hyperthyroidism, hypothyroidism and Grave's disease) = 18.8%. Rheumatoid arthritis was seen in 3.99% of the LC patients. Fibromyalgia was observed in 4.52%, while Raynaud/CREST syndrome was observed in 1.33% of the LC population. Others diseases such as giant cell/temporal arteritis ( $n = 2$ , 0.53%), polymyalgia rheumatica ( $n = 6$ , 1.6%), systemic lupus erythematosus ( $n = 3$ , 0.8%) and scleroderma ( $n = 1$ , 0.27%) were also

**Table 4 Comparison of concurrent diseases between lymphocytic colitis and the control group**

Disease	Number of patients affected	Percentage (%)	Compared to control group
Hyperlipidemia	166	44.10	NS
Diabetes type I and II	55	14.60	NS
Thyroid diseases <sup>1</sup>	71	18.80	P < 0.01
Rheumatoid arthritis	15	3.99	P < 0.01
Fibromyalgia	17	4.52	P < 0.01
Raynaud/CREST syndrome	5	1.33	P < 0.01
Giant cell/temporal arteritis	2	0.53	P < 0.025
Polymyalgia rheumatica	6	1.60	NS
SLE	3	0.80	P < 0.025
Scleroderma	1	0.27	NS
Celiac disease	13	3.46	P < 0.001
IBS	43	11.40	P < 0.001
IBD	1	0.27	NS

<sup>1</sup>Thyroid diseases including hypothyroidism, hyperthyroidism and Grave's disease.

observed. Thirteen patients were diagnosed with celiac disease (3.46%) and six of these patients had a diagnosis of celiac disease prior to the diagnosis of LC. Forty three patients were thought to have IBS prior to the diagnosis of LC, while seven were diagnosed with IBS after the diagnosis of LC was made. Overall, 11.4% of patients with LC were diagnosed with IBS. We observed one patient with an established diagnosis of IBD prior to the diagnosis of LC. During a median follow up of 3 years, none of our LC patients have subsequently been diagnosed with IBD.

Patients with LC had a higher rate of thyroid diseases ( $P < 0.01$ ) compared with the control group. Diseases thought to be autoimmune-related, such as rheumatoid arthritis ( $P < 0.01$ ), Raynaud/CREST syndrome ( $P < 0.01$ ), SLE ( $P < 0.025$ ), fibromyalgia ( $P < 0.01$ ), and temporal arteritis ( $P < 0.025$ ) also had statistically higher rates of occurrence in patients with LC. IBS ( $P < 0.001$ ) and celiac disease ( $P < 0.001$ ) also occurred more often in patients with LC (Table 4).

**Cancer:** The three most common cancers found in our LC patients were breast ( $n = 20$ , 5.31%), prostate ( $n = 7$ , 1.86%) and lung ( $n = 4$ , 1.06%). Five patients were diagnosed with colorectal cancer prior to the diagnosis of LC. None were diagnosed with colorectal cancer after the diagnosis of LC had been made.

No cancer was noted to have a statistical difference compared with the control group, including colorectal cancer.

### CC vs LC

Despite a significant population size difference, we found little statistical difference between collagenous and LC, in terms of their associated diseases. Interestingly, we found a higher rate of irritable bowel disease diagnosed concurrently with CC than with LC ( $P < 0.05$ ).

## DISCUSSION

Increasingly, MC has become more and more recognized worldwide, yet little is known about its pathophysiology and the long term outcome of the disease. Currently, multiple hypotheses exist for the pathophysiology of MC and include immune dysregulation/autoimmunity. This hypothesis is further supported by findings that human leukocyte antigen haplotype is increased in A1 and DRW53 in LC<sup>[10]</sup>. While others have found increases in DQ2 and DQ1, three in LC and CC<sup>[11]</sup>. Autoantibodies such as ANA have also been found to be higher in patients with MC<sup>[12]</sup>. Indeed, multiple retrospective clinical studies have noted a higher incidence of autoimmune diseases in patients diagnosed with MC. This suspected relationship between immune dysregulation/autoimmunity and MC has led to the question of whether MC is a pre-IBD entity? If so, does the patient with MC require a higher level of surveillance and more aggressive treatment to prevent IBD from developing? These concerns were further illustrated by multiple case reports that seemed to convincingly suggest that MC may be the initial phase of a full blown IBD. However, the above theory has never been formally addressed in a large population study. In our investigation we were able to validate the previously known association between LC, CC and various autoimmune diseases, celiac disease and thyroid disorders in a large population study. Yet, interestingly, we found no significant correlation between IBD and CC/LC. Therefore, LC and CC may not be an indicator for intense surveillance to detect progression to IBD. To date, none of our LC or CC patients have been diagnosed with IBD.

Another theoretic risk for patients with MC is colorectal cancer. This concern is based on the IBD model where chronic inflammation can lead to increased dysplasia and malignancy. Thus far, to the authors' knowledge, only one study has evaluated the risk of colorectal cancer in MC. Chan *et al*<sup>[13]</sup> studied 117 patients diagnosed with CC during a mean follow-up period of 7 years to examine the risk of colorectal cancer. A similar risk of colorectal cancer was found in MC patients and the general population in that study. Only one patient was diagnosed with colorectal cancer after being diagnosed with MC. This was confirmed in our study as no increase in colorectal cancer occurrence was found between our patients with MC and the control group.

Interestingly, we found that IBS was associated with MC in approximately 13% of our MC patients. Other studies have also shown a correlation between IBS and MC, with IBS diagnosed in up to 23% of patients with LC<sup>[14,15]</sup>. The relationship is unclear, however it could be due to a similar clinical presentation between MC and IBS, as suggested by Barta *et al*<sup>[16]</sup>. There is also increasing evidence to support an inflammatory process in the pathogenesis of IBS. Furthermore, studies have shown that increasing amounts of intraepithelial lymphocytes can be seen in patients diagnosed with post infectious

IBS<sup>[17]</sup>. Usually, the number of lymphocytes does not reach that needed for the diagnosis of MC in most post infectious IBS patients, however, there have been cases where patients with a clinical history of post infectious IBS have been diagnosed with MC. To accurately distinguish these entities is important, as their management and treatment may be very different. For example, currently, colonoscopy is rarely performed for the diagnosis of IBS. However, as a result of our findings, colonoscopy with random biopsy may be warranted as a part of the workup for suspected diarrhea predominant IBS in the future.

Endocrinopathies such as thyroid dysfunction and diabetes have been known to have correlations with MC as noted in previously published studies. Several studies showed that diabetes was found in up to 8.3% of CC patients and in up to 13.5% of LC patients<sup>[18,19]</sup>. Despite reports of these associations, our study did not show a statistical significance when compared with our control group. One possible explanation for this is that LC, CC and diabetes tend to occur more frequently in elderly populations and thus could easily be thought of as related diseases. In a recent published study by Williams *et al*<sup>[20]</sup> after risk stratification of their data by age, the risk association between MC and the general population was no longer significant. Another possible explanation is that most of the previous studies were smaller in size which may have led to sampling error. However, the same argument can not be used to explain the high occurrence of thyroid dysfunction previously reported<sup>[21]</sup>. Indeed, we found a statistically higher occurrence of thyroid dysfunction in LC and CC patients when compared to the control group. The association between thyroid dysfunction, LC and CC is still unknown, although some suggest autoimmunity as a possible cause.

There are several limitations to our study. For example, because routine screening for other disorders that may be related to MC (such as celiac disease) were not performed in a prospective format, the prevalence of these associated disorders may be underestimated. Another limitation is the lack of long term follow up. Because of this lack of long term follow up, it is possible that colorectal cancers and IBD may not have had sufficient time to manifest. Due to this, we continue to actively follow these patients and long term data should be forthcoming in the future. Another limitation involves the retrospective nature of this study for which selection bias is commonly seen. However, we hope that the large patient population would minimize such bias.

Our analysis produced many interesting observations and provoked thoughtful questions regarding the etiology, disease mechanism, and associations with other diseases and medications in the largest study to date on MC. Several of these findings have been previously noted, however, some other relationships have yet to be reported. We believe that the large number of patients in our study makes this study less vulnerable to sampling error and provides a good representation of MC.

## COMMENTS

### Background

The prevalence of microscopic colitis (MC) is on the rise worldwide, yet little is known about the natural history and etiology of this disease. Currently, it is believed that the disease follows a benign course; however, cases have been reported in association with inflammatory bowel disease (IBD). Its association with colorectal cancer is also poorly understood.

### Research frontiers

Case reports have suggested that MC can evolve into IBD, but no studies have been carried out to thoroughly evaluate this relationship.

### Innovations and breakthroughs

This is the largest study published to-date that addresses the important question of whether patients with MC have a higher prevalence of IBD compared to the general population. It also provided additional clinical information regarding this rarely-studied disease.

### Applications

This study, which evaluated the largest population to-date, demonstrated that there is no increase in the incidence of IBD or colorectal cancer in patients with MC. It also showed that MC can mimic symptoms of irritable bowel syndrome which should be considered during evaluation.

### Terminology

MC is a condition characterized by chronic, watery diarrhea with normal endoscopic appearance of the colonic mucosa. It is further divided into lymphocytic colitis and collagenous colitis based on its histologic appearance.

### Peer review

This is an interesting paper addressing a topic which often remains scarcely investigated. The article is well balanced and the discussion is clear and exhaustive.

### Abstract

**AIM:** To describe the clinical presentation and complications of portal hypertension (PH) secondary to myelofibrosis with myeloid metaplasia (MMM).

**METHODS:** Medical records for 123 patients with MMM were reviewed.

**RESULTS:** Thirteen patients with PH secondary to MMM were identified. Median ages at time of MMM and PH diagnosis were 61 and 66 years, respectively. The interval from MMM diagnosis to presentation with one of the PH features ranged from 1 to 11 years. Variceal bleeding and ascites were the most common presentations. Of the eight patients who presented with variceal bleeding, six patients underwent endoscopic variceal ligation (EVL) with no variceal recurrence or hematological worsening during a 12-mo follow up period.

**CONCLUSION:** Patients with MMM might develop PH. Exact mechanisms leading to PH in MMM are still controversial. As in other etiologies, variceal bleeding and ascites are the most common presentations. Anemia may correlate with, and/or predict, the severity of the PH presentation in these patients. EVL can successfully control variceal bleeding in MMM. Further clinical studies are required.

### INTRODUCTION

The term “myelofibrosis with myeloid metaplasia (MMM)” is usually referred to for patients with chronic idiopathic myelofibrosis (CIM), also known as angiogenic myeloid metaplasia (AMM), and for those with advanced phases of polycythemia vera [post polycythemic myeloid metaplasia (PPMM)] and essential thrombocythemia [post thrombocythemic myeloid metaplasia (PTMM)]. All three represent chronic stem cell-derived clonal myeloproliferative diseases that, in the case of myeloid metaplasia, are accompanied by an intense reactive bone marrow fibrosis that leads to ineffective erythropoiesis and extramedullary hematopoiesis in multiple organs, predominantly the spleen. However, extramedullary hematopoiesis may also occur at sites other than the spleen, including lymph nodes causing lymphadenopathy and also in the liver resulting in hepatomegaly and possibly, with other contributing factors, portal hypertension (PH)<sup>[1,2]</sup>.

Patients with MMM present with variable clinical and histomorphologic features. The typical clinical features include hypermetabolic symptoms (fever, fatigue and weight loss), marked splenomegaly and anemia<sup>[3]</sup>. PH with subsequent ascites and gastrointestinal hemorrhage from ruptured varices has been described in patients with MMM<sup>[4-8]</sup>. Only a few published studies have discussed this issue extensively. Furthermore, these reports described and focused on PH in CIM which represents a subgroup of MMM. In this retrospective study, we describe 13 patients with PH secondary to MMM.

## MATERIALS AND METHODS

After obtaining approval from the Institutional Review Board of our institution, the study patients were identified through the use of a comprehensive institutional database of medical diagnoses and procedures. Between January 1, 1995 and December 31, 2007, an estimated number of 123 patients with MMM were evaluated at the Mayo Clinic, Rochester, MN. The diagnosis of MMM was confirmed on the basis of traditional criteria that included bone marrow fibrosis associated with splenomegaly and leukoerythroblastosis (immature granulocytes and nucleated red cells). Patients with bone marrow fibrosis resulting from other disorders were excluded. This included patients with myelodysplastic syndrome, acute myelofibrosis, or chronic myelogenous leukemia.

From this sample, a subgroup of 13 patients with clinical evidence of PH was identified. Although the gradient between wedged and free hepatic venous pressure was not assessed in many patients, the diagnosis of PH was based on clinical criteria [e.g. esophageal varices by endoscopy, ascites with Serum-Ascites Albumin Gradient (SAAG) > 1.1] in conjunction with imaging studies. Patients with liver disease and patients having risk factors for liver disease such as chronic alcohol consumption were excluded. Patients with PH due to other diseases were also excluded. The medical records for these 13 patients with PH secondary to MMM were comprehensively reviewed. Pertinent clinical and laboratory variables were recorded for all patients.

## RESULTS

Thirteen patients with PH secondary to MMM were identified. Table 1 shows their pertinent clinical characteristics, presentation and laboratory values within 1 wk of PH diagnosis. Nine male (69%) and four female patients (31%) were identified: six patients (46%) had AMM, six patients (46%) had PPMM, and one patient (8%) had PTMM. The age of the patients ranged from 49 to 88 years (median, 67 years). Median ages and range at time of MMM and PH diagnoses were 61 (45-79) years and 66 (47-84) years respectively. The interval from MMM diagnosis to presentation with one of the PH features ranged from 1 to 11 years (median, 5 years).

Variceal bleeding and ascites were the most common presentations. Six patients (46%) initially presented with GI bleeding (five patients presented with acute upper GI bleeding and one presented with melena). Among those six patients; three presented with GI bleeding only, two presented with both GI bleeding and ascites, and one presented with GI bleeding and jaundice. All the six patients were diagnosed as having mild to moderate esophageal varices (Grade 1 to 2). Five patients (38%) presented initially with ascites. Among these five patients; three had only ascites at presentation, two presented with GI bleeding with the ascites, and one patient presented with abdominal

pain in addition to ascites. SAAG was calculated in patients with ascites; all had SAAG above 1.1 which was considered as indicative of PH. Amongst all 13 patients, 12 of them (92%) eventually developed at least one episode of ascites within 6 mo from initial presentation. Jaundice was never the sole presenting feature. One patient presented with jaundice in addition to GI bleeding. Another patient developed jaundice afterwards, during the course of the disease. None presented with encephalopathy.

All patients (100%) had splenomegaly; nine patients (69%) had hepatomegaly and consequently nine patients (69%) had both. Eleven patients (84%) had elevated alkaline phosphatase levels at time of PH diagnosis, nine patients (69%) had elevated aspartate aminotransferase levels, and eight patients (62%) had both enzyme levels elevated. Median and range values for all liver tests are displayed in Table 1. Hyperbilirubinemia was present in four patients (31%) at time of PH diagnosis but jaundice was uncommon. Four patients (31%) had low albumin, with a median albumin level of 4 g/dL (2.8-4.4 g/dL). Ten patients (77%) were anemic at the time of PH diagnosis. Median hemoglobin level was 10 mg/dL (6.6-13.9 mg/dL). Three patients (23%) were diagnosed with portal vein thrombosis at time of

PH diagnosis, indicated by either abdominal doppler ultrasound (US) or CT or MRI. Among these three patients with portal vein thrombosis, one patient had high white blood cell count and low hemoglobin, while the other two patients had white blood counts and hemoglobin levels within normal limits but had decreased portal blood flow velocity indicated by abdominal doppler US. Among the 10 patients who did not have thrombosis, eight patients have undergone liver biopsy: all eight showed non cirrhotic liver parenchyma with varying degrees of extramedullary hematopoiesis, and infiltration of liver sinusoids with hematopoietic cells (myeloid metaplasia). Two of these eight patients also had mild fibrotic changes but none of them had truly cirrhotic features. All patients, including those without thrombotic etiology, had splenomegaly. Of the eight patients presenting with variceal bleeding, six patients underwent endoscopic variceal ligation (EVL) requiring 1-4 sessions. These six patients were followed up by endoscopies at 1, 3 and 12 mo to inspect for the re-appearance of varices. Varices were completely obliterated with no recurrence at the 12 mo time point. No hematologic worsening was recorded during the 12 mo follow-up period. The other two patients underwent endoscopic variceal sclerotherapy (EVS) but were not followed up. Interestingly, three patients (23%) had pulmonary hypertension concurrent with PH, with no cardiopulmonary causes.

## DISCUSSION

PH has been reported in 7%-18% of AMM, which represents a subgroup of MMM<sup>[8,9]</sup>. In this study, simple mathematical calculation revealed an 11% prevalence of symptomatic PH in MMM. However, as in other most etiologies, PH secondary to MMM is usually asymptomatic and diagnosis of PH in these patients is often not made until they become symptomatic, which sometimes does not become apparent for up to 11 years. In the present study we found that the median interval for our patients to present with one of the PH features is 5 years, ranging from 1-11 years. Taking into consideration that the median survival for patients with MMM is 4 years<sup>[10-15]</sup>, this suggests that many MMM patients die due to the underlying disease before they become symptomatic from PH. Therefore, we believe that a prevalence of 11% represents the prevalence of symptomatic PH and that the true prevalence of PH in MMM, including the asymptomatic PH, is higher.

When patients become symptomatic, they usually present either with acute upper GI bleeding from ruptured varices or in the form of melena, or they present with ascites. Other presentations such as jaundice and encephalopathy are unlikely.

Exact mechanisms leading to PH in MMM are still controversial. In the absence of portal and/or hepatic vein thromboses two theories have been proposed. The first theory states that PH develops in MMM patients due to sinusoidal narrowing and intrahepatic obstruction

caused by extramedullary hematopoiesis and infiltration of the liver by myeloid cells leading to increased intrahepatic resistance<sup>[6,16,17]</sup>, while the other theory states that PH develops in such patients due to increased portal blood flow through the enlarged spleen<sup>[8,18,19]</sup>.

Portal vein thrombosis is a major cause of PH in hematological disorders<sup>[6,16,18]</sup>. It is still unclear whether portal vein thrombosis in MMM is caused by a hypercoagulable state and hyperviscosity related to underlying disease or as a consequence of stasis due to elevated sinusoidal pressure. In our study, PH in three of our patients (23%) was due to thrombosis of the portal and/or hepatic veins as indicated by imaging studies. The three patients had prothrombin time within normal limits. However, one of these patients had a very high white blood cell count (49 000 cells/mL), possibly contributing to thrombosis by increasing the blood viscosity. When thrombosis is absent, PH has been related to an increased intrahepatic resistance and sinusoidal narrowing due to the myeloid metaplasia<sup>[6,16,17]</sup> and/or due to a marked increase in portal flow as a consequence of marked splenomegaly<sup>[8,18,19]</sup>. In our report, the 10 patients who did not have portal vein thrombosis had splenomegaly; six of them had dilated splenic veins with increased portal blood flow indicated by abdominal doppler ultrasound. The increase in portal flow itself may explain PH. In fact, few cases of PH in myelofibrosis patients secondary to increased splenic and/or portal flow with minimal hematopoiesis have been reported<sup>[20,21]</sup>. On the other hand, Sikuler *et al*<sup>[22]</sup> experimentally demonstrated that in the absence of structural alteration of the liver, PH does not develop as a consequence of an increased portal flow. They proposed that the main contributory factor is the increased intrahepatic resistance caused by obstruction due to extramedullary hematopoiesis of the liver. In our group of patients, liver biopsy in those six patients with increased portal flow and another two patients without increased portal flow showed infiltration of liver sinusoids with hematopoietic cells and myeloid metaplasia. Therefore six of our patients, without thrombotic etiology, have both enhanced portal flow and increased intrahepatic resistance as contributing factors. Hence, it seems that in absence of thrombosis, both enhanced portal flow from the enlarged spleen and intra-hepatic sinusoidal obstruction have synergistic effects, so that even a slight increase in resistance in the face of enhanced portal flow might produce clinically significant PH.

Patients with PH characteristically exhibit a hyperdynamic circulation with increased cardiac output and decreased peripheral resistance<sup>[23]</sup>. Overactivity of some vasodilator factors has been proposed and there is a growing body of evidence suggesting that endogenous NO accounts for much of this activity<sup>[24-26]</sup>. Anemia, which is a very common feature in patients with MMM, has been shown to further worsen the hyperdynamic circulation associated with PH<sup>[27-29]</sup>. In this group of patients, 10 patients (77%) were anemic at the time of PH

diagnosis. At presentation, a total of four patients had a picture of severe PH. Three of these four patients had profound anemia (hemoglobin 6.6, 6.9 and 7.1 mg/dL) suggesting that anemia, possibly by worsening the hyperdynamic circulation, might have a role in exacerbating PH and that anemia may correlate with and/or predict the severity of the PH presentation in these patients. Experimental studies have demonstrated that increasing blood hemoglobin levels partially correct PH hyperdynamic circulation in rats<sup>[30]</sup>. However, clinical data focusing on the role of anemia on the hyperdynamic state are scant and more studies are needed.

The optimal management of PH secondary to MMM and management of subsequent variceal hemorrhage and ascites have not been well established. Based on the theory of increased portal flow due to splenomegaly as a mechanism for the PH in MMM patients, splenectomy would be a reasonable choice. In fact, splenectomy, which is commonly performed for patients to relieve abdominal discomfort and early satiety caused by the mass effect of the enlarged spleen, has effectively reversed PH in selected patients<sup>[4,31]</sup>. However, increased blood flow from an enlarged spleen is not the sole mechanism for development of PH in MMM patients. Also, the enlarged spleen may possibly be the main or even the only site for red cell production in patients with advanced MMM. Moreover, there are some unique post-operative complications such as massive hepatomegaly due to extramedullary hematopoiesis in 16%-24% of splenectomized MMM patients leading to liver failure in some cases, post-splenectomy extreme thrombocytosis in up to 50% of splenectomized MMM patients, and the major concern of leukemic transformation. All these factors, together with the knowledge that splenectomy has not been shown to improve overall survival in MMM patients, must be strongly considered before proceeding for splenectomy to manage PH<sup>[3,32-34]</sup>.

PH caused by intra-hepatic or portal obstruction requires interventional or surgical portosystemic shunting. Relief of intra-hepatic PH in patients with MMM can be accomplished by implantation of a transjugular intrahepatic portosystemic shunt (TIPS)<sup>[35-37]</sup>. TIPS is an effective and well established procedure that involves creation of a side-to-side portacaval shunt in the liver and it has very good efficacy for intractable ascites. However, such a procedure needs ideal candidates who display normal liver synthetic function with little interventional risk. Only a few reports have been published regarding the use of TIPS for PH secondary to MMM, but these have proved to be effective<sup>[3,35-39]</sup>. Few data exist regarding the outcomes of this procedure in MMM patients and more studies are needed to examine whether it prolongs survival or just alleviates variceal hemorrhage and recurrent ascites.

Managing the acute bleeding episodes consists of general resuscitative measures such as volume and blood replacement, and specific measures to stop bleeding. EVL<sup>[40-42]</sup> as well as EVS<sup>[7]</sup> have been utilized successfully

for the management of GI bleeding in MMM patients. EVL has been reported to have very good efficacy, with fewer therapeutic sessions and complications when compared to EVS in variceal bleeding due to other etiologies<sup>[43]</sup>. In our report, six out of eight patients who had variceal bleeding underwent EVL with no variceal recurrence or hematological worsening during a brief 12 mo follow up period. Nevertheless, there is a paucity of data regarding the use of EVL in patients with MMM-associated PH and further studies are required. We report our successful experience with EVL in this small group of patients.

In conclusion, patients with MMM might develop PH. Exact mechanisms leading to PH in MMM are still controversial. In the absence of portal vein thrombosis, both increased intrahepatic resistance due to sinusoidal narrowing caused by extramedullary hematopoiesis and a rise in portal pressure, via an increase in portal blood flow secondary to increased splenic blood flow from an enlarged spleen, might play a role in the pathogenesis of PH. Clinical presentation is similar to PH due to other etiologies with variceal bleeding and ascites being the most common presentations. Anemia may correlate with, and/or predict the severity of, the PH presentation in these patients. EVL can successfully control variceal bleeding in MMM. Further clinical studies are required.

## COMMENTS

### Background

Patients with myelofibrosis with myeloid metaplasia (MMM) present with variable clinical features. The typical clinical features include constitutional symptoms, splenomegaly and progressive anemia. Portal hypertension (PH) with subsequent variceal bleeding and ascites has been described.

### Research frontiers

Few published studies have discussed PH in patients with MMM. However, these small reports described and focused on PH in chronic idiopathic myelofibrosis (CIM) which represents a subgroup of MMM.

### Innovations and breakthroughs

In this retrospective study, the authors describe clinical presentation and complications of 13 patients with PH secondary to MMM. The article also discusses the possible mechanisms leading to PH in these patients and the possible treatment options.

### Applications

Patients with MMM might develop PH. As in other etiologies, variceal bleeding and ascites are the most common presentations. Exact mechanisms leading to PH in MMM are still controversial. Interestingly, anemia may correlate with and/or predict the severity of the PH presentation in those patients. Endoscopic variceal ligation can successfully control variceal bleeding in these patients. However, further clinical studies and trials are required.

### Terminology

PH is an increase in the pressure within the portal vein and its tributaries. It is defined as a portal pressure of 12 mmHg or more compared with a normal figure of 5-8 mmHg. Myelofibrosis with myeloid metaplasia is a term referred to for patients with CIM, also known as angiogenic myeloid metaplasia, and advanced phases of polycythemia vera and essential thrombocythemia.

### Peer review

This is a retrospective study of patients with myelofibrosis and PH. The authors describe the clinical presentation and complications of this unusual condition. The paper is well written and includes a discussion of the pathogenesis of PH in myelofibrosis.

acid (BA) levels in inflammatory bowel disease (IBD) subgroups with defined clinical manifestations.

**METHODS:** Comprehensive serum BA profiling was performed in 358 IBD patients and 310 healthy controls by liquid chromatography coupled to electrospray ionization tandem mass spectrometry.

**RESULTS:** Serum levels of hyodeoxycholic acid, the CYP3A4-mediated detoxification product of the secondary BA lithocholic acid (LCA), was increased significantly in Crohn's disease (CD) and ulcerative colitis (UC), while most other serum BA species were decreased significantly. Total BA, total BA conjugate, and total BA glycoconjugate levels were decreased only in CD, whereas total unconjugated BA levels were decreased only in UC. In UC patients with hepatobiliary manifestations, the conjugated primary BAs glycocholic acid, taurocholic acid, and glycochenodeoxycholic acid were as significantly increased as the secondary BAs LCA, ursodeoxycholic acid, and taurooursodeoxycholic acid compared to UC patients without hepatobiliary manifestations. Finally, we found that in ileocecal resected CD patients, the unconjugated primary BAs, cholic acid and chenodeoxycholic acid, were increased significantly compared to controls and patients without surgical interventions.

**CONCLUSION:** Serum BA profiling in IBD patients that indicates impaired intestinal barrier function and increased detoxification is suitable for advanced diagnostic characterization and differentiation of IBD subgroups with defined clinical manifestations.

### Abstract

**AIM:** To determine free and conjugated serum bile

detoxification state and intestinal barrier function in inflammatory bowel disease. *World J Gastroenterol* 2009; 15(25): 3134-3141 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3134.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3134>

## INTRODUCTION

The pathophysiology of inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC) is not yet completely understood. In recent years, it has become obvious that genetic, immunological, environmental and microbial factors contribute to the etiology of IBD<sup>[1-5]</sup>. The concept of multilevel dysfunction of the intestinal detoxification system is accepted as an important aspect of the pathophysiology of IBD<sup>[6]</sup>. Intestinal epithelial cells are of major importance as a physiological barrier against components of the intestinal lumen such as bacteria, nutrients and toxins. Protective mechanisms that maintain intestinal barrier function include detoxification and biotransformation of luminal substances, as well as the control of junctional proteins in cell-cell contacts. These processes are influenced by lipids and the availability of adequate cellular lipid processing<sup>[7]</sup>.

Bile acids (BAs) are involved in these processes. First of all, intestinal reabsorption is a critical step in enterohepatic circulation (EHC) of BAs<sup>[8]</sup>. Once synthesized in the liver and secreted via the bile duct into the duodenum, BAs are effectively absorbed in the distal ileum and transported back to the liver via the portal vein, which contributes to the pool of BAs in the blood<sup>[9,10]</sup>. Absorption in the distal ileum may be hampered in CD by terminal ileitis or by ileocecal resection, which tends towards decreased fasting and slightly increased postprandial blood BA levels<sup>[11-15]</sup>. There have also been indications of abnormal blood BA levels in UC<sup>[16,17]</sup>. Furthermore, EHC and enterohepatic detoxification of BAs depend on a carefully adjusted regulatory network of BA-binding transcription factors, including farnesoid X receptor (FXR) and pregnane X receptor (PXR)<sup>[9,18]</sup>. For instance, like ursodeoxycholic acid (UDCA), the endogenous toxic lithocholic acid (LCA) belongs to a group of potent PXR agonists<sup>[19-21]</sup> that comprises steroid hormones, vitamins and β-carotene<sup>[22]</sup>. Several detoxification genes and ATP-binding cassette transporters are down-regulated in intestinal cells of IBD patients<sup>[23]</sup>, and PXR as a major transcriptional regulator of these detoxification genes is decreased in UC patients<sup>[23]</sup>. Finally, despite their potential toxic activities, BAs can also confer gut mucosal protection against bacteria and other cell damaging constituents of the gut lumen by two mechanisms<sup>[10]</sup>. In the proximal small intestine, BAs inhibit bacterial growth directly via their pharmacological properties, whereas in the distal small intestine, BAs mediate their antimicrobial effect indirectly via activation of FXR<sup>[24,25]</sup>. For instance, binding of chenodeoxycholic acid (CDCA) to FXR and

subsequent activation of the receptor is followed by up-regulation of genes that are involved in the prevention of bacterial overgrowth and promotion of epithelial integrity<sup>[26]</sup>.

In the present multicenter study, serum BA profiling was performed retrospectively in 358 IBD patients and in 310 age-matched healthy controls to assess the influence of different IBD phenotypes with various clinical manifestations on BA composition. The results further elucidate the intestinal contribution to BA homeostasis and detoxification, which is much less understood compared to corresponding processes in the liver<sup>[24,27]</sup>.

## MATERIALS AND METHODS

### **Patients and specimens**

Blood samples of IBD patients and healthy volunteers were from the University Hospitals of Regensburg and Heidelberg (Germany), the Konventhospital Barmherzige Brüder Linz (Austria), and the Innsbruck Medical University (Austria). Informed consent was obtained from all patients, and the study was approved by the respective ethics committees. Samples of the Regensburg patients were from the serum bank of the German IBD network of excellence ("Kompetenznetz CED"). Blood samples were collected irrespective of the individual diet. For BA analysis, sera and clinical data were obtained from 197 CD patients (62% females; aged 16-84 years, mean age, 40 years; 46 with active disease, 43 with chronic active disease, 108 in remission) and 161 UC patients (63% females; aged 17-90 years, mean age, 40 years; 42 with active disease, 40 with chronic active disease, 79 in remission). The diagnosis was based on clinical, radiological and pathological criteria according to the guidelines of the German Gastroenterological Association (DGVS). CD patients were subgrouped according to the Vienna Classification with respect to disease behavior and localization. A CD activity index (CDAI) > 150 was regarded as "active CD", duration of CDAI > 150 for > 3 mo as "chronic active CD", and CDAI < 150 as "CD in remission". UC patients were classified according to the Truelove-Witts index: A Truelove-Witts index > 6 was regarded as "active UC", a Truelove-Witts index > 6 for > 3 mo as "chronic active UC", and a Truelove-Witts index < 6 as "UC in remission". Sera from 310 healthy blood donors (60% females; aged 19-66 years, mean age, 40 years) served as controls. All samples were stored frozen at -20°C until analysis.

### **Materials for BA analysis**

Cholic acid (CA), CDCA, deoxycholic acid (DCA), LCA, UDCA, hyodeoxycholic acid (HDCA), glycocholic acid (GCA), glycochenodeoxycholic acid (GCDCA), glycdeoxycholic acid (GDCA), glycolithocholic acid (GLCA), glycoursoxycholic acid (GUDCA), glycohydeoxycholic acid (GHDCA), taurocholic acid (TCA), taurochenodeoxycholic acid (TCDC), taurodeoxycholic acid (TDCA), tarolithocholic acid (TLCA), tauro-

sodeoxycholic acid (TUDCA), taurohyodeoxycholic acid (THDCA) standard substances, as well as deuterated BA internal standard (IS) substances ( $D_4$ -CA, -CDCA, -DCA, -LCA, -UDCA, -GCA, -GCDCA) were purchased from Sigma-Aldrich Chemie GmbH (Taufkirchen, Germany), Steraloids Inc. (Newport, RI, USA), Campro Scientific GmbH (Berlin, Germany), Larodan Fine Chemicals AB (Malmö, Sweden), and were at least of 95% purity. Ammonium acetate (98%), hydrochloric acid (p.a.), as well as HPLC grade methanol and acetonitrile were purchased from VWR Int. GmbH (Darmstadt, Germany). Ultra pure water (18.2 MΩcm) was obtained from a Milli-Q Plus system (Millipore GmbH, Schwalbach, Germany).

### **BA extraction**

For serum BA extraction, the method of Tagliacozzi *et al*<sup>[28]</sup> was applied with some modifications. Twenty-five microliters of a mixed IS BA solution (6-140 μmol/L in methanol) was pipetted into a 1.5-mL reaction tube and vacuum-evaporated. Two hundred and fifty microliters serum and 30 μL 1 mol/L hydrochloric acid were added (pH < 1), and the mixture was shaken for 1 min. After addition of 1 mL acetonitrile, the mixture was shaken for 2 min and centrifuged at 14000 g for 15 min. The acetonitrile supernatant was transferred to a new reaction tube and vacuum-evaporated. The residue was dissolved in 250 μL methanol/water 1:1 (v/v) that contained 10 mmol/L ammonium acetate by shaking and sonication, and centrifuged at 14000 g for 5 min. Ten microliters of the clear methanolic supernatant was used for analysis. Calibration samples were prepared by spiking pooled control serum with 0, 25, 50, 75 and 100 μL of a combined BA standard solution that contained appropriate amounts of each BA (0.5-70.5 μmol/L).

### **Liquid chromatography coupled to electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS) determination of BAs**

BAs were analyzed by LC-ESI-MS/MS using the following instrumentation. An HTS PAL autosampler (CTC Analytics AG, Zwingen, Switzerland), an Agilent 1100 series binary HPLC pump (Agilent Technologies Sales & Services GmbH & Co KG, Waldbronn, Germany) combined with a Micromass Quattro Ultima tandem MS (Waters GmbH, Eschborn, Germany) operated in negative-ion mode. BA separation was performed on a Symmetry C18 reversed-phase HPLC column (50 mm × 2.1 mm, 3.5 μm particle size; Waters GmbH) by gradient elution at a flow rate of 0.3 mL/min. The 25-min elution cycle consisted of a stepwise linear change from 90% solvent A (methanol/water 1:1, v/v, 10 mmol/L ammonium acetate) + 10% solvent B (methanol, 10 mmol/L ammonium acetate) to 100% B; in detail: 0-6 min A/B = 90/10; 6-12 min A/B = 72/28; 12-16 min A/B = 60/40; 16-22 min A/B = 0/100; 22-25 min A/B = 90/10. The mass spectrometer was operated in multiple-reaction monitoring (MRM) with a cone voltage of 80 V and a collision gas pressure

of 250 kPa argon. Unconjugated BAs were detected unfragmented using a collision energy of 10 eV. Glycine- and taurine-conjugated BAs were analyzed by their specific product ions at m/z 74 and 80 using collision energies of 35 and 85 eV, respectively. In detail, the retention times and MRM transitions were as follows: TCA (6.0 min, 514→80), TUDCA (4.0 min, 498→80), THDCA (4.8 min, 498→80), TCDCA (9.3 min, 498→80), TDCA (10.2 min, 498→80), TLCA (13.7 min, 482→80), GCA (6.2 min, 464→74), GUDCA (4.1 min, 448→74), GHDCA (4.9 min, 448→74), GCDCA (9.5 min, 448→74), GDCA (10.4 min, 448→74), GLCA (13.9 min, 432→74), CA (7.1 min, 407→407), UDCA (5.1 min, 391→391), HDCA (6.0 min, 391→391), CDCA (11.0 min, 391→391), DCA (11.8 min, 391→391), LCA (14.8 min, 375→375). Quantification was performed by peak ratios of BA peak areas and corresponding IS peak areas. BAs without identical deuterated ISs were related to the IS with the nearest retention time, as well as the similar MRM transition.

### **Statistical analysis**

The significance of differences in BA concentrations was determined between cohorts with  $n \geq 10$  by Mann-Whitney U test for non-normally distributed data using SPSS for Windows version 14.0 (SPSS Inc., Chicago, IL, USA). A two-sided P value < 0.05 was considered statistically significant.

## **RESULTS**

### **Differentiation of CD, UC and controls by characteristic BA profiles**

Based on previous findings on BA metabolism in IBD and our earlier results on dysregulation of xenobiotic nuclear receptors including PXR in IBD<sup>[23]</sup>, serum BA levels and composition were determined in the two major IBD phenotypes, CD and UC, and in healthy controls. The most significant differences in serum BA concentrations were found in comparison to controls. BA concentrations were decreased predominantly in both IBD subgroups, CD and UC (Tables 1-3). Considering individual BA species, as in CD, most BAs were decreased significantly in UC patients compared with controls, but several BA conjugates, for instance TCDCA, GCDCA and GDCA, were decreased more significantly in CD than in UC patients (Table 1).

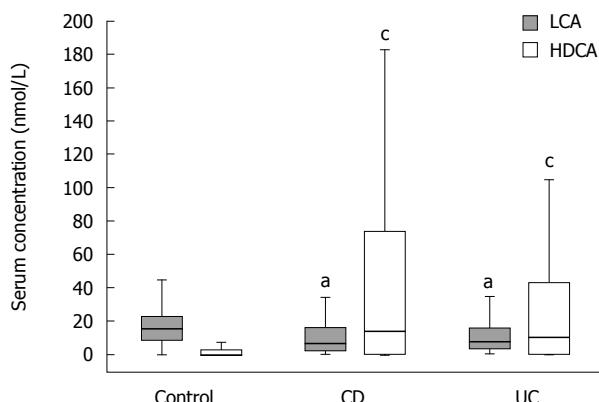

While serum levels of LCA, known to be the strongest PXR agonist, were significantly lower, serum levels of HDCA, the CYP3A4-mediated detoxification product of LCA, were always significantly higher in CD and UC patients compared to controls (Figure 1).

If total serum BA levels were considered (Table 4), we found that total unconjugated and total BA tauroconjugate levels, respectively, were decreased significantly in UC patients, but other than in CD patients, there was no decrease in total BA, total BA conjugate, and total BA glycoconjugate levels compared to controls. Moreover, total BA conjugate levels, as well as total BA glycoconjugate and

tauroconjugate levels alone, were increased significantly in UC vs CD patients. However, if levels relative to total BA conjugate levels were considered, total BA tauroconjugate levels were increased significantly but total BA glycoconjugate levels were decreased significantly in UC vs CD patients. In addition, UC patients were characterized by a significantly decreased ratio of total deoxy-BA, LCA, and LCA conjugate levels to total BA levels compared to CD patients and controls (Table 4).

#### Hepatobiliary manifestations influence BA composition in UC

IBD is often accompanied by extraintestinal manifestations (EMs), such as hepatobiliary diseases, and eye, joint and skin affections<sup>[29,30]</sup>. We therefore investigated whether IBD patients with EMs showed different serum

BA profiles. While we found no influence of EMs on serum BA levels in CD patients (data not shown), UC patients with hepatobiliary diseases, e.g. primary sclerosing cholangitis (PSC), hepatitis, or cholelithiasis, had significantly increased BA concentrations compared to UC patients without EMs, especially levels of the primary BAs TCA, GCA and GCDCA, as well as the secondary BAs LCA, UDCA and TUDCA (Table 2).

#### Previous bowel resection influences BA composition in CD

Intestinal reabsorption of BAs is a physiological function of the terminal ileum, therefore, surgical interventions in this region may influence serum BA levels caused by impaired EHC. While there were no UC patients with surgical interventions included in the present study, CD patients showed significant variations in serum BA concentrations correlated to previous bowel resection (Table 3). Overall, compared to controls and CD patients without surgical interventions, ileocecal resection alone was associated with the most intensive decrease of primary and secondary BA conjugates, such as TCDCA, TDCA, GCA and GDCA, as well as a marked increase in the unconjugated primary BAs, CA and CDCA. In addition, CD patients with ileocecal resection and other surgical interventions, e.g. ileostomy, sigmoidostomy, transversostomy, fistula excision, and hemicolectomy, had significantly decreased TCDCA compared to controls and CD patients without surgical interventions. Furthermore, in CD patients with colectomy, TCDCA, as well as the secondary BAs GDCA and DCA, were decreased significantly compared to those in controls and patients without surgical interventions.

**Table 3** Effect of surgical interventions on serum bile acids and conjugates in CD cohorts (nmol/L)

#### No effects of disease activity and medical treatment on BA composition in CD and UC

We also investigated whether serum BA composition was influenced by disease activity and different therapeutic medications in IBD patients, since mucosal inflammation, as well as pharmacologically induced changes in the inflammatory process in IBD may influence BA reabsorption, which results in changed serum BA profiles. Overall, serum BA composition in CD and UC were independent of disease activity and medical treatment (data not shown).

#### DISCUSSION

During the past three decades, BA analysis in IBD has been achieved in serum, bile or feces from small patient cohorts by radioimmunoassay or gas-liquid chromatography detecting total BAs and selected

individual BAs, respectively<sup>[17,31-34]</sup>. In the present study, we applied a sensitive high-throughput LC-ESI-MS/MS method with minimal sample preparation steps for simultaneous determination of 18 different BA species as serum BA profiles in a large cohort of IBD patients and controls. We analyzed the main unconjugated human primary, secondary and tertiary BAs, i.e. CA, CDCA, DCA, LCA, UDCA, HDCA, and their respective glycine and taurine conjugates. Comparing a whole profile of BA subspecies in various IBD phenotypes may reflect intestinal malfunction and disease states more sensitively than just considering total or selected individual BA levels.

Thus, we showed that decreased serum BA levels were not restricted to CD alone, as previously reported<sup>[13-15,35]</sup>, but were also found in UC if a defined set of specific BAs were considered. This is contradictory to the few reports on abnormal blood BA levels in UC patients. Ejderhamm and Strandvik<sup>[17]</sup> have reported increased primary serum BAs, CA and CDCA, in juvenile active UC patients compared to healthy controls, while there were no significant differences for CA, but decreased CDCA levels in our UC cohort compared to controls. Kostic *et al*<sup>[16]</sup> have reported decreased total plasma BA levels in CD and UC patients compared to controls, but we did not find significant differences in total BA, total BA conjugate, and total BA glycoconjugate levels between UC patients and the control group. Only total BA taurourconjugate and unconjugated BA levels were reduced significantly in UC patients *vs* controls. However, because of their relatively low contribution to total BA and BA conjugate levels compared to the most abundant BA glycoconjugates, this effect was not dominant and may explain the missing reports on decreased total BA levels in UC patients. In summary, our data confirm studies that have shown a decrease in serum

BA levels in CD patients, which reflects the strongest impact on intestinal BA reabsorption during EHC. This can be explained by the fact that BA reabsorption takes place predominantly in the distal small intestine<sup>[10]</sup>, which is usually more affected in CD in contrast to colon-restricted UC. Therefore, most serum BA levels in UC patients are not decreased as much as in CD patients.

Furthermore, it is noteworthy that the levels of the unconjugated primary BAs, CA and CDCA, in CD and UC patients were not significantly different from the controls, except for decreased CDCA in UC patients. The explanation that there is an increased compensatory synthesis of primary BAs in IBD, as suggested by Rutgeerts *et al*<sup>[13]</sup> in Crohn's ileitis, assumes an accelerated bacterial deconjugation of the respective glyco- and tauroconjugates in the intestine. Indeed, the reduced serum levels of TCA, TCDCA, GCA, and GCDCA shown in Table 1 support this assumption, which is in agreement with previous findings of unusually high intestinal BA deconjugation in CD and UC<sup>[36,37]</sup>. Apart from deconjugation, the quantitatively most important bacterial biotransformation of BAs is 7α-deoxidation of CA and CDCA by *Eubacteria* in the colon, which yields DCA and LCA, respectively<sup>[38,39]</sup>. In UC patients, we found significantly reduced ratios of total deoxy-BA (including DCA, LCA, and its conjugates) to total BA levels compared to those in CD patients and controls, which may reflect an abnormal colonic bacterial flora with reduced deoxidation capacity. In addition, bacterial overgrowth in the small intestine and colon of IBD patients may enhance the described BA biotransformation processes and contribute to the imbalance of BA species distribution in the EHC. Decreased intestinal BA levels, especially of conjugated BAs, may promote bacterial overgrowth because of a loss of their antimicrobial properties<sup>[10,26]</sup>. Since IBD patients included in this study were not stratified according to the use of antibiotics, this effect has not been evaluated and needs further systematic investigation in well-defined patient cohorts.

The invariably increased HDCA and decreased LCA in IBD compared to control sera, irrespective of the clinical findings (EMs, surgical interventions, disease activity or medication), indicates accelerated enterohepatic LCA detoxification *via* CYP3A4<sup>[18]</sup>. Whether serum HDCA elevation is additionally caused by increased intestinal reabsorption or impaired hepatic excretion cannot be resolved by the present data and has to be further investigated.

Moreover, the influence of hepatobiliary EMs on serum BA levels in IBD is demonstrated clearly in UC patients, who showed a significant increase in primary and secondary BAs compared to EM-free patients. This confirms previous observations when elevated serum levels of total primary BA conjugates have been seen in IBD patients with liver diseases<sup>[31,40]</sup>. Although serum LCA levels in UC patients with hepatobiliary EMs were found to be normal compared to controls, in accordance with

the findings of Dew *et al*<sup>[40]</sup>, they were significantly higher compared to those in UC patients without EMs and with arthralgia/arthritis. Elevated BA levels are particularly found in patients with PSC, which is often associated with IBD<sup>[29,41]</sup>. However, it cannot be ruled out that the significantly increased serum levels of TUDCA, UDCA and LCA found in our UC cohort with hepatobiliary EMs were caused by therapeutic administration of UDCA, which is being used increasingly for the treatment of cholestatic liver diseases<sup>[42-44]</sup> and PSC-associated UC<sup>[45,46]</sup>. UDCA medication not only causes increased primary BA biosynthesis, but UDCA is also metabolized to additional TUDCA and LCA<sup>[47]</sup>, which yields increased serum levels in these patients. Nonetheless, we assume that disturbed EHC of BAs in IBD is highly susceptible to additional hepatobiliary EMs.

With surgical interventions predominantly appearing in CD patients, we found that ileocecal resection exerts the strongest impact on serum BA levels in CD patients, since BA reabsorption is located predominantly in the terminal ileum<sup>[10]</sup>. Compared to patients without surgical interventions, the finding that patients with ileocecal resection showed significantly decreased conjugated BAs but increased unconjugated primary BAs, i.e. CA and CDCA, may be explained by an increased compensatory synthesis of primary BAs in IBD, as previously suggested<sup>[13]</sup>, associated with an enhanced bacterial deconjugation of the respective glyco- and tauroconjugates in the remaining intestinal sections<sup>[36,37]</sup>. In addition, concerning the elevated CA levels in patients with ileocecal resection, we confirm the previous findings of Tougaard *et al*<sup>[48]</sup>. As expected, unlike ileocecal resection, the influence of colectomy on serum BA levels in CD was less significant, since only small amounts of BAs are reabsorbed in this intestinal region.

To summarize, using mass spectrometric BA species profiling instead of total BA determination, we showed the characteristic impact of different IBD phenotypes with intestinal and hepatobiliary manifestations on BA homeostasis and detoxification. Further prospective studies on prominent BAs in well-defined IBD cohorts are necessary to confirm their diagnostic and prognostic value.

## COMMENTS

### Background

Inflammatory bowel disease (IBD) is a multifactorial disorder with as yet incompletely elucidated causes. Since bile acids (BAs) derived from the liver are directly involved in intestinal processes primarily by facilitating lipid digestion, IBD has an impact on BA metabolism. This correlation may be reflected in unusual BA blood levels that differentiate between the two clinical IBD phenotypes, Crohn's disease (CD) and ulcerative colitis (UC), as well as between CD and UC subgroups with diverse clinical manifestations.

## Research frontiers

Besides their digestive functions, BAs have recently been found to play an important regulatory role in numerous metabolic processes, e.g. energy and lipid balance and elimination of harmful substances. They are mediated by binding appropriate nuclear receptors in the cell that depend on the molecular type of BA, which can be differentiated by means of high performance mass spectrometry. Thus, quantifying diverse BAs simultaneously, a characteristic profile of main and rare BAs is available that reflects medical conditions far better than measuring total BA levels or individual abundant BAs.

## Innovations and breakthroughs

Applying BA profiling in IBD patients, the authors showed that most but not all BA species are decreased in CD and UC patient sera, but with different intensity. BA decrease is highly pronounced in CD patients with surgical interventions in the gut except for unconjugated primary BAs. On the other hand, UC patients with additional liver and gallbladder diseases show clearly increased levels of primary and secondary BAs. Finally, the authors found a marked decrease in the toxic BA lithocholic acid, together with a marked increase in its physiological detoxification product, hyodeoxycholic acid, irrespective of the IBD phenotype or clinical manifestation, which shows accelerated detoxification activity in IBD patients.

## Applications

Serum BA profiling may serve as an additional diagnostic tool for IBD characterization and differentiation. In combination with expression profiles of pregnane X receptor (PXR)-regulated genes, it may allow us to estimate the BA detoxification potential of IBD patients.

## Terminology

Primary BAs are directly synthesized in the liver and secondary BAs are derived from primary BAs by biochemical modification by intestinal bacteria. BAs can be conjugated, mainly with the amino acids glycine and taurine, or unconjugated. The enterohepatic circulation leads to a maximum physiological recycling of BAs and comprises liver synthesis, intestinal excretion via the bile duct, intestinal reabsorption, and return transport to the liver via the portal vein. Liquid chromatography tandem mass spectrometry is a sensitive analytical method for simultaneous determination of structural related biomolecules like BAs. The nuclear BA receptors farnesoid X receptor and PXR mediate most of the physiological effects of BAs, e.g. expression of detoxification genes by PXR.

## Peer review

This work expand the knowledge about the role of BA metabolism in IBD. It is a well-conducted study.

### Abstract

**AIM:** To investigate the presence of high-risk human papilloma virus (HPV) in esophageal squamous cell carcinomas (ESCCs) in a non-selected Mexican population.

**METHODS:** Cases with a pathological diagnosis of squamous cell carcinoma of the esophagus were obtained from Department of Pathology files, at the National Cancer Institute in Mexico City during the period between 2000 and 2008. Slides from each case were reviewed and cases with sufficient neoplastic tissue were selected for molecular analysis. DNA was extracted from paraffin-embedded tissue samples for polymerase chain reaction analysis to detect HPV DNA sequences. Demographic and clinical data of each patient were retrieved from corresponding clinical records.

**RESULTS:** HPV was detected in 15 (25%) of ESCCs. HPV-16 was the most frequently observed genotype, followed by HPV-18; HPV-59 was also detected in

one case. Unfortunately, HPV genotype could not be established in three cases due to lack of material for direct sequencing, although universal primers detected the presence of HPV generic sequences. No low-risk HPV genotypes were found nor was HPV-16/18 co-infection. HPV presence in ESCC was not significantly associated with gender, age, alcohol consumption, smoking, anatomic location, or histologic grade. All patients belonged to low and very low socioeconomic strata, and were diagnosed at advanced disease stage. Male patients were most commonly affected and the male:female ratio in HPV-positive ESCC increased two-fold in comparison with HPV-negative cases (6.5:1 vs 3.1:1).

**CONCLUSION:** High prevalence of high-risk HPV in ESCC in Mexico does not support the hypothesis that HPV-associated ESCC is more common in areas with higher ESCC incidence rates.

Human papilloma virus and esophageal carcinoma in a Latin-American region. *World J Gastroenterol* 2009; 15(25): 3142-3147 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3142.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3142>

### INTRODUCTION

With regard to incidence and prevalence, esophageal cancer exhibits striking geographical variations due to unknown factors between countries, as well as between different regions of the same country. According to the World Health Organization, incidence-rate spectra are located between Western Africa -at the low-risk end, and China at the high-risk end, including the so-called "Asian esophageal cancer belt"<sup>[1]</sup>.

Among Latin American countries, Mexico and Peru have the lowest mortality rates for esophageal carcinoma, in both males and females, whereas Brazil, Argentina and Chile, have the highest mortality rates<sup>[2]</sup>. Mexico has a low esophageal cancer risk, with mortality rates in male and female inhabitants *ca* 2 and *ca* 1 per 100 000, respectively<sup>[3]</sup>.

Esophageal carcinoma has been related to tobacco, alcohol, fungal toxins, nutritional deficiencies, and hot food and beverages<sup>[4]</sup>. In addition, human papilloma virus (HPV), a major cause of carcinoma of the cervix uteri throughout the world, is suspected of being related to the development of this carcinoma. Meta-analyses by Syrjänen<sup>[5]</sup> (2002) showed that HPV DNA was detected in 15.2% of esophageal squamous cell carcinomas (ESCCs). To date, total or partial sequencing identified > 200 genotypes of HPV, which are categorized into the following four cervical oncogenicity-based risk groups: high, probably high, low and undetermined risks<sup>[6]</sup>. High-risk HPV is considered to cause neoplastic transformation of normal epithelial cells, through expression of early transforming viral proteins E6 and 7, resulting in cell cycle-machinery deregulation and expression of several transforming oncogenes<sup>[7]</sup>.

High-risk HPV-associated ESCC is hypothesized to be consistently more common in countries with higher ESCC risk<sup>[8]</sup>. In a recent study by Castillo *et al*<sup>[9]</sup>, HPV DNA was detected in 34% and 19% of esophageal carcinomas in Colombia and Chile, respectively; HPV-16 was the most frequent genotype in both countries. It is noteworthy that the HPV detection rate in ESCCs was found to be two-fold higher in Colombia than in Chile, whereas the esophageal cancer mortality rate showed an inverse relationship.

The aim of the present study was to investigate the presence of high-risk HPV DNA in ESCCs, among a non-selected Mexican population.

## MATERIALS AND METHODS

### Subjects

Cases with a pathological diagnosis of squamous cell carcinoma of the esophagus were obtained from Department of Pathology files, at the National Cancer Institute in Mexico City during the period between 2000 and 2008. Slides from each case were reviewed and cases with sufficient neoplastic tissue were selected for molecular analysis. Because the majority of the cases of esophageal cancer seen at our Institution correspond to advanced clinical stages, elective surgery is not performed. Subsequently, DNA was extracted from paraffin-embedded tumor samples, obtained during a panendoscopic procedure; adjacent normal esophageal mucosa was not sampled. Demographic and clinical data of each patient were retrieved from corresponding clinical records.

### DNA extraction and HPV detection

Twenty micrometer sections of formalin-fixed and paraffin-embedded tumors were de-waxed by incubation

with N-octane and washings with 100% ethanol. This process was repeated twice, and the pellet was dried. Deparaffinized samples were digested with 1 mL of lysis buffer (Tris-HCl 10 mmol/L pH 8.0, EDTA 0.1 mol/L pH 8.0, SDS 0.5%, Proteinase K 200 µg/mL, RNase A 20 µg/mL) at 55°C for 3 h. DNA was extracted with phenol/chloroform precipitations as described by Sambrook *et al*<sup>[10]</sup>. To test DNA suitability for polymerase chain reaction (PCR) amplification the DNA obtained was amplified for: β-globin gene (PCO4/GH2O) under conditions described by Resnick *et al*<sup>[11]</sup>. Samples were later submitted to HPV amplification with three sets of the following universal primers recognizing distinct size fragments of L1 gene: L1C1/L1C2, MY09/MY11, and GP5/GP6<sup>[12-14]</sup>. HPV type-specific amplification was also performed with primers designed to amplify the E6 gene of HPV type 16 and 18 as described by Lizano *et al*<sup>[15]</sup>.

HPV PCR products were electrophoresed in a 1.2% agarose gel and visualized by ethidium bromide staining. HPV typing was carried out by direct sequencing of PCR products by means of the BigDye™ Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems). The resulting sequences were analyzed in BLAST data bank for comparison with known HPV sequences. HPV 16 and 18 specific amplification was conducted for every DNA sample. DNA extracted from CaSki and Hela HPV containing cell lines were used as positive controls.

### Statistical analysis

Fisher's exact test was applied for categorical variables. A probability value  $P < 0.05$  was considered statistically significant.

## RESULTS

In 60 cases of ESCC, DNA quality was adequate for PCR analysis to detect HPV DNA sequences, as demonstrated by β-globin gene amplification. There were 47 male and 13 female patients, with a mean age of 62.7 years (range, 27-85 years) and 61.2 years (range, 47-80 years), respectively. Thirty-six subjects consumed alcohol (ranging from occasional to 60 years drinkers) but frequency and alcoholic-beverage type could not be precisely assessed. In 14 subjects, previous history of alcohol consumption was unknown and ten patients denied alcohol consumption. Smoking habit was recorded in 28 patients (from occasional to up to 60 years of smoking; frequency was not known), whereas in 16 subjects smoking habit was unknown; 16 patients did not smoke. Clinical history of esophageal achalasia was not recorded in any case, and there were previous symptoms of gastro-esophageal reflux disease (GERD) in two patients. Finally, oesophageal surgery was performed in one patient 26 years previously due to direct trauma. All patients belonged to low and very-low socioeconomic strata, the majority of these were agricultural workers.

All patients were diagnosed at advanced disease stage. Among these, 42 patients (70%) were treated with chemo- and/or radiotherapy and three subjects underwent esophagectomy immediately after neoadjuvant

ESCCs: Esophageal squamous cell carcinomas.

therapy. Finally, 18 patients (30%) refused any treatment. During follow-up, seven patients (11.7%) died of oesophageal carcinoma, whereas one of these died of causes not related to the neoplastic disease. The majority of patients were alive but with disease at 1 year or less of follow-up, but did not return for subsequent medical care. Regardless of the presence of HPV, all patients with ESCCs belonged to low and very-low socioeconomic strata, the majority of these were agricultural workers (data not shown). HPV presence in ESCCs was also unrelated to anatomic location, histologic grade or patient condition (alive or dead) at hospital discharge.

HPV universal primers and HPV-16 and -18 specific primers detected the presence of HPV DNA in 15 (25%) of 60 ESCCs. Cases of HPV DNA consisted of 13 males and two females with a mean age of 63.4 years (range, 37-76 years) and 62.5 years (range, 47-78 years), respectively. There were no statistical differences or associations ( $P > 0.05$ ) between HPV status and gender, age, previous history of alcohol consumption and smoking, anatomic location, histologic grade or patient

**Figure 1** Identification of HPV with general primers L1C1/C2. PCR products were run in 2% agarose gel. Lanes 1-16 correspond to representative positive and negative cases. DNA extracted from Caski cell lines were used as a positive control. Neg: PCR mixture without DNA; L: 100 bp ladder.

**Figure 2** Representative electropherograms showing fragments of HPV-16, -18 and -59 genomic sequences, obtained from the analysis of PCR products L1C1/C2 from HPV-positive samples.

condition (alive or dead) at hospital discharge (Table 1).

Direct PCR-product sequencing detected 12 cases of high-risk HPV. As summarized in Table 2, HPV-16 was the most frequently detected genotype, followed by HPV-18; interestingly HPV-59 was also detected in one case (Figures 1 and 2). In three of 15 HPV-positive cases (20%), HPV genotype could not be specified although universal primers detected the presence of HPV generic sequences. Low-risk HPV DNA sequences were not detected and we found no HPV-16/18 co-infections among the cases under study.

## DISCUSSION

PCR analysis in this study demonstrated the presence of high-risk HPV in 25% of ESCCs from a small set of Mexican patients; HPV-16 was the most frequent viral genotype followed by HPV-18. Interestingly, HPV-59 was also detected in one case; to our knowledge, this HPV genotype has not been previously reported in other ESCC studies. No low-risk HPV genotype was detected. In addition, HPV-16/18 co-infection was not found.

High-risk HPV-genotypes distribution in Mexican ESCCs observed in the present study is in agreement with that reported in the studies of cervical carcinomas in Mexico, in which HPV-16 is the most frequent genotype, followed by HPV-18, then by other high-risk HPV genotypes<sup>[16]</sup>. A similar high-risk HPV distribution was observed in a South American study of ESCC in Colombia and Chile<sup>[9]</sup>, as well as a small Mexican series of lung carcinoma<sup>[17]</sup>. HPV-16 is not only the most prevalent high-risk genotype in cervical carcinomas<sup>[18]</sup> and in young females with normal Papanicolaou smears<sup>[19]</sup>, but also in HPV-associated ESCC, worldwide<sup>[5]</sup>.

HPV prevalence in Mexican women, as analyzed in cervical smears, has been reported to range 16.7%-23%, depending on the age group<sup>[20]</sup>, and detected in 92% of cervical cancers<sup>[21]</sup>. A study of HPV prevalence in men showed a 62% HPV global positivity in samples from external genitalia of Mexican men, with 13% oncogenic types<sup>[22]</sup>.

Since the Syrjänen<sup>[5]</sup> studies in the early 1980s, several studies have been conducted in different countries and in different geographical regions of the same country, to identify HPV DNA in ESCC. Utilizing molecular methods, the majority of these studies have shown the presence of high-risk HPV in a variable proportion of cases<sup>[23-27]</sup>; others, however, have failed to demonstrate HPV traces in EC, even from highly prevalent regions<sup>[28,29]</sup>. Differences in such figures could be attributed, first, to the sensitivity and specificity of molecular methods employed to detect HPV DNA<sup>[5]</sup>; it is widely accepted that PCR is the most sensitive method for detecting HPV DNA, and can detect as few as 20 copies or less<sup>[30]</sup>.

According to the concept of “Condemned Mucosa Syndrome” proposed by Pillai and Nair<sup>[31]</sup>, HPV promotes neoplastic transformation in a previously damaged mucosa with the aid of other carcinogenic agents. With regard to alcohol consumption and/or smoking, there were no substantial differences between HPV-positive and HPV-negative ESCCs, in this study. The present study also examined the possible association between the presence of HPV DNA and esophageal disorders involving membrane damage, such as achalasia and GERD. However, patients in the present study had no clinical history of esophageal achalasia. In two cases of ESCC in which there were previous symptoms of GERD and in another case with direct trauma-related esophageal surgery 26 years previously, HPV DNA was not detected.

The majority of our Mexican patients suffering

from ESCC, were native to rural and semi-urban areas of Mexico, thus indicating low yearly income and a low level of education. Indeed, low socioeconomic status is characterized by, among others, nutritional deficiencies, poor hygiene habits and lack of health and public services, including drinking water supply, conditions that taken together could also predispose to esophageal carcinogenesis. Low socioeconomic status has also been associated with an increased risk of cervical intraepithelial neoplasia and cervical invasive carcinoma, among HPV-positive Mexican women<sup>[32]</sup>.

Interestingly, the male:female ratio in HPV-positive ESCC increased two-fold in comparison with HPV-negative cases (6.5:1 vs 3.1:1). This ratio is higher than that reported from Colombia and Chile (0.75:1 vs 1.1:1)<sup>[9]</sup>. However, the gender-ratio between HPV-positive and -negative cases was not statistically significant. This finding does not allow us to draw any conclusion, due in part, to the small number of cases under study. No such comparison has been explored in other ESCC series, but its meaning warrants further research.

The etiological role of HPV in mucosal malignancy development has been supported on the basis of high-risk HPV localization and expression of viral oncoproteins in neoplastic cell nuclei, the characteristic squamous and basaloid morphology of malignant tumors, the occurrence of HPV-associated malignant neoplasms in anatomic sites where HPV is known to cause benign papillomas and where HPV direct exposure is suspected, and the elevation of serum antibodies against E6/E7 in patients harboring HPV-associated invasive cancers, among others<sup>[33]</sup>. The etiological significance of HPV detected in ESCCs is yet to be established. It is noteworthy that the present study was unable to find the association of basaloid morphology with HPV presence in ESCC. Although HPV-positive ESCC frequency was high, the mere presence of viral DNA does not necessarily imply its etiological involvement. It is necessary to conduct further studies to examine viral DNA integration into host carcinoma cells, localization in malignant cells, and monoclonality of HPV-positive cells.

The HPV transmission route detected in ESCCs is also of interest. HPV infection of the esophageal mucosa is highly suspected to occur in a direct fashion. In a recent case-control study<sup>[34]</sup>, HPV oral infection was strongly associated with a sub-group of oropharyngeal squamous cell carcinomas, in which high-risk sexual behaviors (i.e. oral, vaginal) were recorded, regardless of alcohol and tobacco use. Notwithstanding the association between oral HPV infection and sexual behavior, a Finnish HPV Family Study<sup>[35]</sup> has shown that persistent high-risk HPV infection in a mother is a major risk factor for oral and genital infections by this virus in her offspring; this susceptibility appears to be modulated by the immune system. Thus, it could be argued that previous high-risk HPV oral infection, may predispose asymptomatic carriers for further ESCC development.

In conclusion, one fourth of ESCCs diagnosed in a Mexican population were found to harbor high-risk

HPV DNA. Elevated high-risk HPV prevalence of ESCC in Mexico, where ESCC incidence is relatively low, does not support the hypothesis that HPV-associated ESCC is more common in areas with higher ESCC incidence rates. Further studies are warranted to evaluate the etiological significance of HPV detected in Mexican ESCCs.

## COMMENTS

### Background

Esophageal carcinoma is a dismal disease which exhibits striking geographical variations in incidence and prevalence between countries and between different regions of the same country, due to unknown factors. Western Africa has the lowest incidence rates and China the highest. Among Latin America countries, Mexico and Peru have low mortality rates for esophageal carcinoma, whereas Brazil, Argentina and Chile have the highest. In Mexico, mortality rates in male and female inhabitants are ca 2 and ca 1 per 100 000, respectively.

### Research frontiers

Esophageal carcinoma is multifactorial in origin; tobacco, alcohol, fungal toxins, nutritional deficiencies, hot food and beverages, as well as infectious agents, are related to esophageal carcinogenesis. Among infectious agents, high risk human papilloma virus (HPV), a major cause of carcinoma of the cervix uteri throughout the world, is strongly implicated in the etiology of esophageal carcinoma. High-risk HPV DNA sequences have been detected in approximately 15.2% of esophageal squamous cell carcinomas (ESCCs) worldwide, HPV-16 and -18 being the most frequent genotypes.

### Innovations and breakthroughs

In this study, the authors found the presence of high-risk HPV DNA in 25% of ESCCs. HPV-16 and -18 were the most frequent genotypes, but they also demonstrated the presence of HPV-59 in one of the cases, a genotype not previously reported in ESCCs anywhere. On the other hand, the results do not support the hypothesis that HPV-associated ESCC is more frequent in areas with higher ESCC incidence rates, because ESCC is not a common cancer in Mexico. Interestingly, the male:female ratio in HPV-positive ESCC increased two-fold in comparison with HPV-negative cases (6.5:1 vs 3.1:1).

### Applications

By knowing the prevalence of high-risk HPV-associated ESCC, this study among others, may contribute to the design of future strategies for the prevention of HPV-related malignancies, through the development of effective vaccines.

### Terminology

HPVs are DNA viruses that infect basal skin and mucosal cells. HPVs are categorized according to their cervical oncogenicity-based risk, with high, probably high, low and undetermined risks.

### Peer review

This study examined HPV infection in ESCCs in Mexican patients. This is an interesting study and the manuscript is written well.

Is percutaneous endoscopic gastrostomy tube placement safe in patients with ventriculoperitoneal shunts? *World J Gastroenterol* 2009; 15(25): 3148-3152 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3148.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3148>

### Abstract

**AIM:** To investigate whether percutaneous endoscopic gastrostomy (PEG) tube placement is safe in patients with ventriculoperitoneal (VP) shunts.

**METHODS:** This was a retrospective study of all patients undergoing PEG insertion at our institution between June 1999 and June 2006. Post-PEG complications were compared between two groups according to the presence or absence of VP shunts. VP shunt infection rates, the interval between PEG placement and VP shunt catheter insertion, and long-term follow-up were also investigated.

**RESULTS:** Fifty-five patients qualified for the study. Seven patients (12.7%) had pre-existing VP shunts. All patients received prophylactic antibiotics. The complication rate did not differ between VP shunt patients undergoing PEG (PEG/VP group) and non-VP shunt patients undergoing PEG (control group) [1 (14.3%) vs 6 (12.5%),  $P = 1.000$ ]. All patients in the PEG/VP group had undergone VP shunt insertion prior to PEG placement. The mean interval between VP shunt insertion and PEG placement was 308.7 d (range, 65-831 d). The mean follow-up duration in the PEG/VP group was 6.4 mo (range, 1-15 mo). There were no VP shunt infections, although one patient in the PEG/VP group developed a minor peristomal infection during follow-up.

### INTRODUCTION

Percutaneous endoscopic gastrostomy (PEG) tube placement has been widely used for long-term nutritional support in patients with severe neurological impairment ever since it was first described by Gauderer *et al*<sup>[1]</sup> in 1980. However, patients requiring PEG tube placement may have concomitant hydrocephalus requiring insertion of a ventriculoperitoneal (VP) shunt, and VP shunts themselves are frequently associated with complications, such as shunt infection, obstruction, and migration with or without erosion into nearby structures. Shunt infection is a relatively common complication, occurring in 3% to 29% of patients<sup>[2-6]</sup>; its mortality rate is 30% to 40%<sup>[6]</sup>. There are a number of factors that can expose intraperitoneally placed catheters to bacterial pathogens in PEG patients with pre-existing VP shunts. Therefore, the presence of a VP shunt in a patient requiring PEG placement raises concerns about potential life-threatening complications such as VP shunt infection and VP shunt malfunction. A few studies have evaluated the safety of PEG placement in patients with VP shunts, but the results have been inconclusive. Furthermore, the study design, methods of PEG placement, control groups, and the use of antibiotics in these studies have been highly diverse.

Thus, to date, controversy still exists as to whether PEG

placement is safe in patients with VP shunts. This study was therefore designed to report our single center experience with PEG placement in patients with VP shunts, looking specifically at PEG-related complications and VP shunt infections. Relevant publications were also reviewed.

## MATERIALS AND METHODS

### Study design and patients

We performed a retrospective study on all patients who underwent PEG tube placement for enteral feeding at Uijeongbu St. Mary's Hospital between June 1999 and June 2006. A preliminary chart review identified the subset of patients with endoscopic records indicating PEG tube placement. A total of 55 patients were identified. Those patients with VP shunts were identified and assigned to the combined PEG and VP shunt (PEG/VP) group. The patients undergoing PEG tube placement (but without VP shunts) were assigned to the control group. A more detailed chart review was performed, evaluating patient ages at the time of the procedure, underlying disorders, comorbid diseases, number of PEG placements, and PEG-related complications. Adjustment for comorbidity was carried out for patients in this study using Charlson's comorbidity index<sup>[7]</sup>. Post-PEG placement complications were compared between the two groups. Furthermore, the incidence of VP shunt infections, interval between PEG placement and VP shunt catheter insertion, position of the abdominal shunt catheter, follow-up duration, and outcome of long-term follow-up were investigated in the PEG/VP group.

The requirement for informed consent was waived, because the study design was retrospective.

### PEG tube placement

All PEGs were placed by gastroenterologists. A commercially available gastrostomy tube (US Endoscopy, Mentor, Ohio, USA) was introduced by standard pull-through technique. Enteral feeding was discontinued 12 h before PEG tube placement. All patients received prophylactic or perioperative antibiotics and received intravenous sedation and topical pharyngeal anesthesia. In each patient, the stomach was endoscopically inflated with air, and following satisfactory transillumination of the stomach in the left hypochondrium or epigastrium, the needle was passed through this site directly into the stomach. A guide wire was advanced through the needle, and the commercially available gastrostomy tube was placed over the wire from the aerodigestive tract, through the stomach, to the abdominal wall. In each patient with a pre-existing VP shunt, the shunt tract was carefully demarcated so it could be avoided during PEG tube placement.

### Statistical analysis

With respect to demographic data and complications in the two groups, continuous variables were compared using Student's *t*-test, and discrete variables were compared using the Chi-square test or Fisher's exact probability test.

**Table 1** Baseline patient characteristics *n* (%)

	PEG/VP ( <i>n</i> = 7)	Control ( <i>n</i> = 48)	<i>P</i> value
Age (yr)	55.3 ± 12.3	61.0 ± 16.6	0.387
Sex (M/F)	5/2	31/17	1.000
Primary diagnosis			0.897
Cerebrovascular disease	7 (100)	36 (75)	
Amyotrophic lateral sclerosis		4 (8.3)	
Hypoxic brain damage		2 (4.2)	
Parkinson's disease		2 (4.2)	
Malignancy		2 (4.2)	
Aspiration pneumonia		1 (2.1)	
Pharyngeal paralysis		1 (2.1)	
Diabetes mellitus	2 (28.6)	10 (20.8)	0.639
Tracheostomy	6 (85.7)	25 (52.1)	0.122
Mean number of PEG placements	1.3 ± 0.5	1.6 ± 1.1	0.459
Charlson's index score	3.0 ± 1.6	3.5 ± 1.9	0.504

PEG: Percutaneous endoscopic gastrostomy; VP: Ventriculoperitoneal; PEG/VP: Patients with PEG tubes and VP shunts; Control: Patients with PEG tubes alone.

A probability value of  $< 0.05$  was considered statistically significant. All data were analyzed using SPSS 11.0 (SPSS Inc, Chicago, Illinois, USA).

## RESULTS

Over a 7-year period, 55 patients underwent PEG tube placement at our hospital. Selected clinical characteristics of the patients are provided in Table 1. Seven patients (12.7%) had pre-existing VP shunts at the time of PEG placement (PEG/VP group), and 48 patients had no VP shunts (control group). There was no difference in the mean age between the PEG/VP and control groups ( $55.3 \pm 12.3$  vs  $61.0 \pm 16.6$  years,  $P = 0.387$ ) and no difference in the sex ratio between the two groups (male/female: 5/2 vs 31/17,  $P = 1.000$ ). The primary diagnosis in all patients in the PEG/VP group was cerebrovascular disease, and all patients underwent VP shunt placement for hydrocephalus secondary to cerebral hemorrhage. In the control group, reasons for PEG tube placement included cerebrovascular disease in 36 patients (75%), amyotrophic lateral sclerosis in 4 (8.3%), hypoxic brain damage in 2 (4.2%), Parkinson's disease in 2 (4.2%), malignancy in 2 (4.2%), aspiration pneumonia in 1 (2.1%), and pharyngeal paralysis in 1 (2.1%). There were two patients (28.6%) with diabetes mellitus in the PEG/VP group and 10 (20.8%) in the control group ( $P = 0.639$ ). Six patients (85.7%) in the PEG/VP group had tracheostomies at the time of PEG tube placement, as did 25 patients (52.1%) in the control group ( $P = 0.122$ ). A total of 88 PEG tube placements were performed in 55 patients. The mean number of PEG placements per patient was  $1.3 \pm 0.5$  in the PEG/VP group and  $1.6 \pm 1.1$  in the control group ( $P = 0.459$ ). There was no difference in Charlson's comorbidity index score between the two groups ( $3.0 \pm 1.6$  vs  $3.5 \pm 1.9$ ,  $P = 0.504$ ). All patients received prophylactic or periprocedural antibiotics.

There was one complication (14.3%) after PEG tube placement in the PEG/VP group, and there were six complications (12.5%) in the control group ( $P = 1.000$ ).

**Table 2 Diagnosis of complications n (%)**

	<b>PEG/VP (n = 7)</b>	<b>Control (n = 48)</b>	<b>P value</b>
Complications	1 (14.3)	6 (12.5)	1.000
Wound infection	1	3	
Stomal leakage		1	
Bleeding		1	
Gastroesophageal reflux disease		1	
VP shunt infection	No	-	

Complications in the control group included three peristomal infections, one stomal leak, one case of bleeding, and one case of gastroesophageal reflux. There was no post-PEG VP shunt infection, malfunction, neurologic deterioration, or meningitis in patients with pre-existing VP shunts (Table 2). Because no VP shunt infections were identified based on clinical features (signs and symptoms), a detailed definition of shunt infection (CSF culture or leukocyte count) was not needed.

Long-term outcomes in patients with pre-existing VP shunts are shown in Table 3. In the PEG/VP group, the interval between VP shunt insertion and PEG tube placement ranged from 65 to 831 d (mean,  $308.7 \pm 260.5$  d). The abdominal end of the VP shunt catheter was positioned in the right abdomen in five patients and in the left abdomen in two patients. Of the seven patients with pre-existing VP shunts, two had diabetes mellitus and six had tracheostomies. The mean follow-up duration was  $6.4 \pm 4.5$  mo (range, 1-15 mo). One patient in the PEG/VP group had only a minor peristomal infection during follow-up. Four patients did well, and two required PEG tube replacement due to self-removal. One patient resumed eating and was able to have the PEG tube removed 96 d after placement. No patient died during follow-up.

## DISCUSSION

In this study, patients with pre-existing VP shunts accounted for 7 (12.7%) of the 55 patients having PEG tubes inserted over a 7-year period. The incidence of PEG-related complications was 14.3% (1/7) among patients with VP shunts. The incidence of PEG-related complications was 12.5% (6/48) among patients without VP shunts. There was no difference between the groups with regard to complication rate and when disregarding the primary underlying disorder, presence of diabetes mellitus, and tracheostomy state. No VP shunt infections were identified in the patients with both PEG tubes and VP shunts during the mean follow-up duration of 6.4 mo. The mean interval between VP shunt insertion and PEG tube placement was  $308.7 \pm 260.5$  d.

Ever since Gauderer *et al*<sup>[1]</sup> introduced the endoscopic placement of feeding gastrostomy tubes in 1980, clinicians have been able to perform the PEG procedure with a shorter operative time and without the need for laparotomy. This procedure has been shown to have fewer complications and lower cost compared to the traditional open gastrostomy originally described by Stamm

in 1894<sup>[8-10]</sup>. However, PEG-related complications, including wound infection, bleeding, gastric leakage, tube dysfunction, and aspiration pneumonia, occur in approximately 10% of all cases<sup>[10]</sup>. Stomal site infections occur in 2.9% to 8.8% of patients<sup>[11-13]</sup>, and peritonitis occurs in 0.5% to 6.6% of patients<sup>[12,14-16]</sup>. Major complications requiring surgical intervention, including intraperitoneal abscess and fistula formation, occur in 2% to 3% of all patients<sup>[10]</sup>. In this study, the incidence of PEG-related complications was 14.3% in the PEG/VP group and 12.5% in the PEG alone group. All complications were manageable with conservative therapy. Despite the small numbers of patients, especially in the PEG/VP group, these incidences were similar to those seen in previous reports, and no other major complications occurred.

VP shunt placement is the major neurological procedure required in the treatment of hydrocephalus. However, VP shunts are frequently associated with serious complications, including shunt obstruction, meningitis, and intraperitoneal infection. According to the available literature, the rate of shunt infection ranges from 3% to 29% after VP shunting procedures<sup>[2-6]</sup>. Many of these complications occur at the abdominal sites of VP shunts. Patients with indwelling peritoneal shunts could be at risk for infection, even without PEG tubes.

Therefore, we hypothesized that the incidence of VP shunt infection would be higher in those patients with VP shunt catheters and PEG tubes. However, the question is, do PEG tubes increase VP shunt complication rates? To date, there have been seven reports addressing the safety of PEG tubes in patients with VP shunts (Table 4)<sup>[17-23]</sup>. There is only one prospective study in the literature<sup>[17]</sup>. The number of patients in these studies with both PEG tubes and VP shunts ranged from 6 to 55, and the VP shunt infection rate ranged from 0% to 50%. Most patients have had their VP shunts placed first, followed by PEG insertion. Two separate studies looked at VP shunt infection rates in patients undergoing VP shunt placement before PEG tube placement and in patients undergoing PEG tube placement before VP shunt placement. Infection rates were higher in patients undergoing PEG tube placement first, although not to a statistically significant degree<sup>[22,23]</sup>. In the study of Taylor *et al*<sup>[19]</sup>, PEG tubes and VP shunts were simultaneously placed in 16 patients; VP shunt infections occurred in eight patients (50%). Therefore, the investigators recommended that simultaneous PEG tube/VP shunt insertion be avoided. The VP shunt infection rate was higher in tracheostomy patients in the study of Taylor *et al*<sup>[19]</sup>, but it was not higher in our study. With regard to the time interval between PEG tube and VP shunt insertion, Graham *et al*<sup>[17]</sup> insisted that a 1-wk interval is safe. However, this interval has been more than 1 mo in most previous reports, and Nabika *et al*<sup>[22]</sup> recommended a 1-mo interval because three of four patients developing VP shunt infections in their study had PEG tubes and VP shunts placed within 1 mo of each other. In our study, the mean interval between the two was very long (308.7 d). We think this may have contributed to the absence of

**Table 3** Long-term outcomes in patients with PEG tubes and VP shunts

No. of case	Sex/age (yr)	PEG-VP shunt interval (d)	Position of abdominal shunt catheter	DM	Complication	Follow-up (mo)	Outcome

VP shunt infections in our study. Concerning the control group, there have been two studies with VP shunt patients serving as the control group<sup>[19,22]</sup>. The VP shunt infection rates were 50% (8/16) in the PEG/VP group and 0% (0/21) in the control group in one study due to simultaneous insertion<sup>[19]</sup>, but the VP shunt infection rates were 17.4% (4/23) in the PEG/VP group and 4.9% (6/123) in the control group ( $P = 0.0519$ ) in the other study<sup>[22]</sup>. Therefore, except for simultaneous insertion, the VP shunt infection rates of patients with PEG and VP shunts are not significantly different from those seen in control patients with VP shunts. Only one report has addressed the question of mortality<sup>[23]</sup>. In this report, the all-cause mortality at 1 year after PEG tube placement in patients with VP shunts was 21%, and PEG tube placement in patients with VP shunts was not associated with excessive mortality compared to PEG tube placement alone. Prophylactic antibiotics were given in all studies, except for one. That study used percutaneous fluoroscopic antegrade technique in 23 children, 2 (9%) of whom developed VP shunt infections<sup>[18]</sup>.

The limitations of our study are similar to those of previously published studies. Firstly, our study was retrospective. Secondly, the number of study patients was small; specifically, there were only seven patients with PEG tubes and VP shunts. Thirdly, the control group in our study was composed of patients with PEG

tubes alone, not patients with VP shunts. However, despite these limitations, our study and literature review suggest that PEG tube placement is safe in patients with VP shunts, especially those in whom the VP shunt is inserted first, those in whom the interval between PEG tube and VP shunt insertion is greater than 1 mo, and those in whom prophylactic antibiotics are used.

## COMMENTS

### Background

Percutaneous endoscopic gastrostomy (PEG) tube placement has been widely used for long-term nutritional support in patients with severe neurological impairment. These patients requiring PEG tube placement may have concomitant hydrocephalus requiring insertion of a ventriculoperitoneal (VP) shunt. However, the presence of a VP shunt in a patient requiring PEG placement raises concerns about potential life-threatening complications such as VP shunt infection and VP shunt malfunction. Therefore, we aimed to investigate if PEG tube placement is safe in patients with VP shunts.

### Research frontiers

To date, controversy still exists as to whether PEG placement is safe in patients with VP shunts. There have been seven reports addressing the safety of PEG tubes in patients with VP shunts. There is only one prospective study in the literature.

### Innovations and breakthroughs

This study suggests that PEG tube placement is safe in patients with VP shunts, especially those in whom the VP shunt is inserted first, those in whom the interval between PEG tube and VP shunt insertion is greater than 1 mo, and those in whom prophylactic antibiotics are used.

## Applications

To confirm whether PEG placement is safe in patients with VP shunts, a large scale prospective study including a control group which has patients with VP shunts is needed.

## Peer review

This paper presents a series of patients with preexisting ventriculoperitoneal shunt, who needed a percutaneous endoscopic gastrostomy. The authors conclude that percutaneous endoscopic gastrostomy after previous ventriculoperitoneal shunt is safe. The paper may help to support the indication even in this group, if a gastrostomy is needed.

lifetime costs, life expectancy, and incremental cost-effectiveness ratio (ICER).

**RESULTS:** In the base-case analysis, the non-dominated strategies in cancer survivors were COL5, and COL3. The ICER for COL3 in cancer survivors was \$5593/life-year saved (LYS), and did not exceed \$10000/LYS in one-way sensitivity analyses. If the risk of CRC in cancer survivors is at least two times higher than that in the general population, COL5 had an ICER of less than \$10500/LYS among both good and poor prognosis of index cancer. If the age of cancer survivors starting CRC screening was decreased to 40 years, the ICER of COL5 was less than \$7400/LYS regardless of screening compliance.

**CONCLUSION:** Our study suggests that more strict and frequent recommendations for colonoscopy such as COL5 and COL3 could be considered as economically reasonable second primary CRC screening strategies for Korean male cancer survivors.

What is the most cost-effective strategy to screen for second primary colorectal cancers in male cancer survivors in Korea? *World J Gastroenterol* 2009; 15(25): 3153-3160 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3153.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3153>

## INTRODUCTION

A recent improvement in cancer survival owing to early diagnosis and advances in treatment has raised the issue of second primary cancers (SPCs) in cancer survivors after their primary treatment<sup>[1,2]</sup>. Due to carcinogenic effects of cancer-related treatment, genetic susceptibility

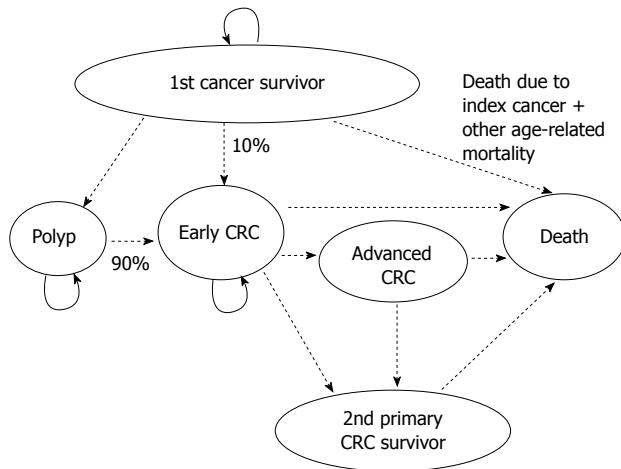

ity or unhealthy behavior such as smoking, alcohol and obesity, cancer survivors are at increased risk for SPCs, not only at the original site but at other sites as well<sup>[3,4]</sup>. Recent studies have shown that the age-standardized incidence rate was 2.3 times higher for an SPC than for a first cancer in the Korean general male population<sup>[5]</sup>. Specifically, the age-standardized incidence rate was about four times higher for second than for first primary colorectal cancers (CRCs)<sup>[5]</sup>. It is well-known that screening for CRC reduces mortality through detection of malignancy at an earlier, more treatable stage as well as by identification and removal of the precursor lesion, the adenomatous polyp<sup>[6]</sup>. These findings suggest that more thorough surveillance and screening for second primary CRC is needed for the cancer survivors.

Many previous studies have focused on the cost-effectiveness (CE) of CRC screening in the general population<sup>[6-9]</sup>, and several panels have recommended CRC screening for the general population<sup>[10-12]</sup>. As the risk of CRC and life expectancy are quite different between cancer survivors and the general population, screening guidelines for the general population could not be applied to the cancer survivors. However, until now, there have been few recommendations for CRC screening for cancer survivors. To suggest a feasible economic strategy of second primary CRC screening for cancer survivors in Korea, we constructed a decision-analytic model, and compared the CE results of cancer screening in cancer survivors and in the average-risk general population.

## MATERIALS AND METHODS

The natural history of a simulated male cancer survivors' cohort was modeled with and without second primary CRC screening until age of 75 years (Figure 1). For simplicity and comparison with results from the general population, we assumed that all male cancer survivors enter at age 50 years, which most guidelines for the general population recommended for starting CRC screening<sup>[10-12]</sup>. We developed a Markov model using TreeAge-Pro 2007 software (TreeAge Software Inc., Williamstown, Massachusetts). The Markov model estimated the clinical and economic consequences of eight different screening strategies as follows: (1) no screening, (2) fecal occult blood test (FOBT) annually (FOBT1), (3) FOBT every 2 years (FOBT2), (4) sigmoidoscopy every 5 years (SIG5), (5) double contrast barium enema every 5 years (DCBE5), (6) colonoscopy every 10 years (COL10), (7) colonoscopy every 5 years (COL5), and (8) colonoscopy every 3 years (COL3).

Individuals were placed into health states defined by the presence or absence of a colorectal polyp or second primary CRC (early or advanced) 1 year after the index cancer diagnosis. Cases of positive screening test results were worked up with a colonoscopy, and individuals diagnosed with polyps underwent polypectomy. The probability of perforation was assigned to colonoscopy, sigmoidoscopy, DCBE and polypectomy<sup>[8,13,14]</sup>. Mortality caused by the risk of perforation was assumed to be

**Figure 1** Markov model of second colorectal cancer (CRC) screening in Korean male cancer survivors.

0.02%<sup>[9,14]</sup>. Colonoscopy was repeated every 3 years for surveillance after polypectomy<sup>[15]</sup>. We assumed that 80% of male cancer survivors underwent the initial screening test, independent of whether they were compliant with past tests. The compliance of follow-up or surveillance colonoscopy was assumed to be 100%. We also assumed that 90% of CRCs develop from polyps<sup>[15,16]</sup>, and the latent period between early stage and advanced stage was assumed to be 2 years<sup>[9]</sup>. The relative risk of CRC in Korean male cancer survivors was assumed to be four times higher than that in the general population<sup>[5]</sup>. Age-specific transition probabilities and prevalence were calculated between normal, polyp, and CRC to yield an incidence rate of polyp and CRC derived from previous literature and the Korea Central Cancer Registry<sup>[7,17-19]</sup>. The stage-specific CRC mortality were applied uniformly to all malignancies regardless of the means of detection (by symptoms or screening) or the state of detection (diagnosed *vs* undiagnosed cancer). Age-specific mortality from index cancer and other causes was estimated based on the above sources combined with statistics published by the National Center for Health Statistics<sup>[20]</sup> and Korea Central Cancer Registry<sup>[21]</sup>. As there have been few studies on mortality from second primary CRC, we calculated the additional yearly probability of dying from a second primary CRC based on cancer stage from previous studies of CRC as the first index cancer<sup>[22-23]</sup>.

We obtained the data on the costs of CRC treatment by stage and time period from the National Health Insurance Corporation (social insurer of the national health insurance (NHI) with a universal coverage of population)<sup>[24]</sup>. Costs of screening tests were obtained from the fee schedule of the National Health Insurance Corporation (the NHI of Korea has a fee schedule applied to all insured services)<sup>[25]</sup>. Costs were expressed in US dollars and the exchange rate was 955 Korean Won for one US dollar in 2006<sup>[26]</sup>. As the indirect costs of cancer screening are not established in Korea, we included only direct medical costs.

Our main outcome measures were discounted lifetime costs, life expectancy, incremental cost-effectiveness

**Table 1** Summary of assumptions

Parameter	Base case value (range)	Ref.
Sensitivity & specificity of colorectal screening tests	Sensitivity of FOBT for colorectal polyps/cancer	0.1/0.5
	Sensitivity of colonoscopy for colorectal polyps/cancer	0.9/0.95
	Sensitivity of double contrast barium enema for colorectal polyps/cancer	0.5/0.8
	Sensitivity of sigmoidoscopy for colorectal polyps/cancer	0.46/0.52
	Specificity of FOBT	0.9
	Specificity of colonoscopy	1
	Specificity of double contrast barium enema	0.9
	Specificity of sigmoidoscopy	0.95
Natural history of colorectal polyp/cancer sequence	Prevalence of polyps at age 50 yr	0.20 (0.1-0.4)
	Annual polyp incidence rate in cancer survivors	Age specific
	Percent of cancers originating as polyps	90%
	Relative risk of colorectal cancer in cancer survivor compared with the general population	4 (1-5)
	Age specific incidence rate of colorectal cancer without polypoid precursors in cancer survivors	Age specific
	Age specific incidence rate of colorectal cancer with polypoid precursors in cancer survivors	Age specific
	Dwelling time of colorectal cancer in early stages	2 yr
	Percent of colorectal cancers detected in early stages with no screening	5% (2%-10%)
	Five-year all cause survival for early 2nd primary colorectal cancer	90% (80%-95%)
	Five-year all cause survival for advanced 2nd primary colorectal cancer	60% (40%-70%)
Natural history of cancer survivors	Five-year survival for index cancer	40% (20%-80%)
	Age specific mortality except the index cancer	Age specific
	Age of cancer survivors for starting colorectal cancer screening, year	50 (40-60)
	Compliance of 2nd colorectal cancer screening	80% (60%-100%)
Complications and unintended consequences	Rate of perforation of colon in colonoscopy	0.20% (0.1%-0.3%)
	Rate of perforation of colon in polypectomy	0.40% (0.2%-0.5%)
	Rate of perforation from sigmoidoscopy	0.01% (0.005%-0.05%)
	Rate of perforation from double contrast barium enema	0.005% (0.001%-0.01%)
	Death rate due to perforated colon	0.2% (0.1%-5%)
Cost (dollar <sup>1</sup> ) & discount rate	Sigmoidoscopy	31.3
	Colonoscopy	61.7
	Double contrast barium enema	68.5
	FOBT	2.7
	Polypectomy, biopsy and pathologic exam	189
	Treatment of early cancer for first year	7330 (5860-8800)
	Treatment of advanced cancer for first year	14660 (10050-15080)
	Treatment of cancer after first year	2094 (1670-2510)
Discount rate	Cost to repair the endoscopic perforation	3141 (2510-3770)
	Discount rate	0.03 (0-0.05)

<sup>1</sup>Exchange rate: 955 Korean Won for one US dollar in 2006; <sup>2</sup>Estimated by calibration to national data on colorectal polyp and cancer incidence.

ratio (ICER), which were compared for different CRC screening strategies. Because there are uncertainties with respect to quality of life associated with CRC screening, colorectal polyp, and second CRC, we conducted the base case analysis using increase in life expectancy as the primary outcome. Incremental CE analysis was performed by ranking the 16 strategies in order of increasing effectiveness. After eliminating strategies that were more or equally costly and less effective than a competing strategy [i.e. ruled out by simple dominance], we calculated the ICER for each strategy (additional cost divided by life-year saved (LYS)] compared with the next least expensive strategy. Strategies exhibiting extended dominance were eliminated from the rank-ordered list, and ICERs of the remaining strategies were recalculated<sup>[27]</sup>. Future costs and life-years were discounted at an annual rate of 3%. We compared the results from male cancer survivors with that from general male population.

Sensitivity analyses were performed to assess the

stability of the results of a plausible range of several parameters, such as prevalence of colorectal polyps at age 50 years, 5-year survival rates of second primary CRC, complications of screening test or polypectomy etc (Table 1). We performed detailed analyses by changing key variables of the index cancer such as 5-year survival rate of first cancer, relative risk of CRC in cancer survivors compared with that in general population. In addition, we evaluated the effects of changing age of subjects for starting second primary CRC screening and compliance rate on the CE of our results.

## RESULTS

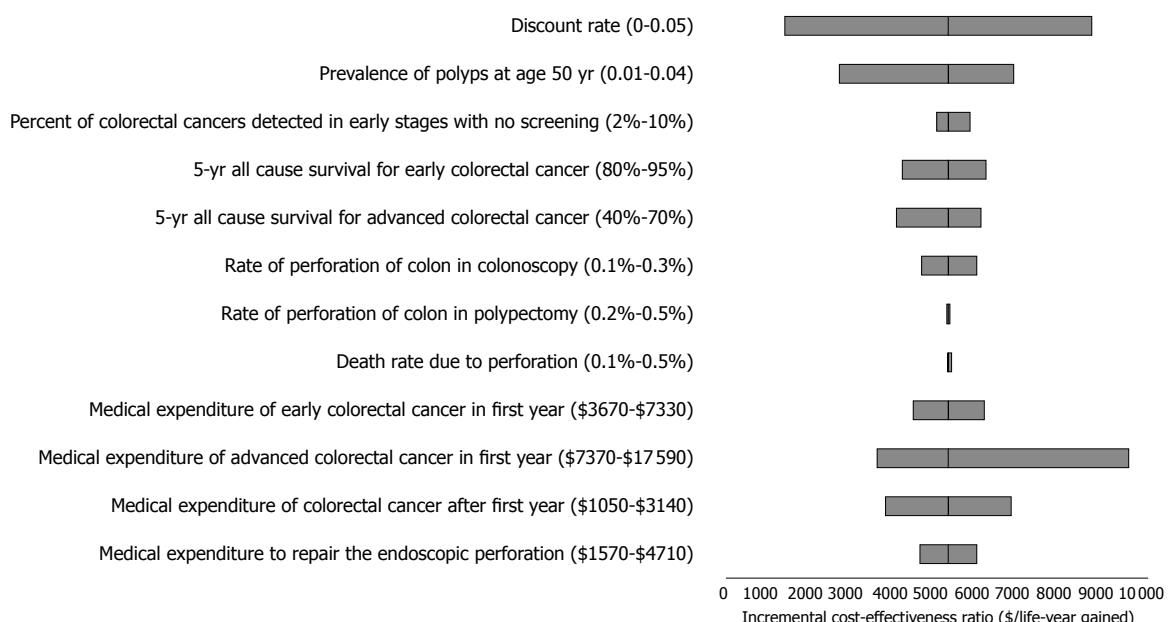

### Base case

In the base-case analysis at 80% screening compliance, all screening strategies extended life expectancy both in male cancer survivors and the general population (Table 2). The strategies which were not ruled out by simple

COL: Colonoscopy; SIG: Sigmoidoscopy; DCBE: Double contrast barium enema; FOBT: Fecal occult blood test. Ellipse indicates no data (incremental CR ratios not calculated for these strategies because they were dominated). <sup>1</sup>Exchange rate, 955 Korean Won for one US dollar in 2006; <sup>2</sup>Incremental CE ratio (dollar/year) = Incremental cost per person/incremental years of life gained.

**Figure 2 Sensitivity analyses on cost-effectiveness from the perspective of colonoscopy every 3 years vs colonoscopy every 5 years in male cancer survivors.**

dominance nor extended dominance (non-dominated strategies) in the general population were COL10, COL5, and COL3, while those in cancer survivors were COL5 and COL3. The ICER for COL3 in cancer survivors was \$5593 per LYS. In cancer survivors, the lifetime total cost per person associated with "FOBT annually" was larger than that associated with no screening, while COL5 and COL3 were less costly than no screening.

### Sensitivity analyses

Figure 2 shows the results of one-way sensitivity analyses on CE from the perspective of COL3 vs COL5 in male cancer survivors. In most cases, COL5 and COL3 were non-dominated strategies, and the ICER of COL3 ranged between \$1480 and \$9192.

Table 3 shows the results of two-way sensitivity analyses by changing risk of second CRC and 5-year survival rate of index cancer in Korean male cancer

survivors. If the risk of CRC in cancer survivors was at least three times higher than that in the general population, screening with COL5 in cancer survivors had an ICER of less than \$4000 per LYS in the entire range of 5-year survival of index cancer between 20% and 80%. If the risk of CRC in cancer survivors was two times higher than that in the general population, COL5 in cancer survivors had an ICER of less than \$10 500 per LYS in both types of index cancer with poor and good prognosis. If the risk of CRC in cancer survivors was the same as that in the general population, non-dominated strategies were no screening, COL10, COL5, and COL3, and the ICER of COL5 was more than \$25 000 per LYS, while the ICER of COL10 ranged between \$2315 in index cancer with good prognosis and \$19 650 in index cancer with poor prognosis.

Table 4 shows the results of sensitivity analysis by changing compliance of CRC screening and age of cancer

**Table 3** Two-way sensitivity analysis by changing variables of index cancer such as 5-yr survival rate of first cancer and relative risk of colorectal cancer in Korean male cancer survivors

survivors for starting CRC screening. If the age of cancer survivors for starting CRC screening was 50 years or older, COL3 had an ICER of less than \$14 600 per LYS, regardless of the screening compliance. If age for starting CRC screening in cancer survivors was 40 years, the ICER of COL5 was less than \$7400 per LYS saved in all cases of CRC screening compliance.

## DISCUSSION

We constructed a computer simulation to suggest economic strategies of second primary CRC screening

for cancer survivors in Korea, and compared the CE results of CRC cancer screening in cancer survivors and in the average-risk general population. As all non-dominated strategy were those using colonoscopy in both cancer survivors and the general population, more strict and frequent recommendation of colonoscopy such as COL5 and COL3 could be considered economic strategies for male cancer survivors.

Until now, there has been no explicit threshold of CE below which policy makers will consider accepting the strategy. In the US, a figure of \$50 000 per Quality Adjusted Life-Year (QALY) has frequently been quoted

for many years as being cost-effective<sup>[43]</sup>. The World Health Report 2002 suggested that interventions costing less than three times Gross Domestic Product (GDP) per capita for each Disability Adjusted Life-Year (DALY) averted represented good value for money<sup>[44]</sup>, which is usually well in excess of \$50 000 per QALY in many high-income countries<sup>[43]</sup>. In our study, the ICER for COL3 was less than \$6000 per LYS in a base line analysis, and did not exceed \$10 000 per LYS in one-way sensitivity analyses. Our findings also suggest that if the risk of CRC in cancer survivors is at least two times higher than that in the general population, COL5 could be a cost-effective strategy for second primary CRC screening for cancer survivors of both good and poor prognosis of index cancer, with an ICER of less than \$10 500 per LYS. As our primary outcomes are not QALY or DALY, direct comparisons might be difficult. The GDP per capita of Korea was more than \$20 000 in 2006. When we approximately applied these CE thresholds, in most cases, COL5 and COL3 could be considered a cost-effective method for second primary CRC screening for Korean male cancer survivors, regardless of the index cancer. Even if the index cancer were CRC, our finding could be applied and be consistent with the CRC surveillance guidelines of the American Society of Clinical Oncology (ASCO)<sup>[45]</sup>. In ASCO guidelines, routine annual colonoscopies are not recommended for all CRC patients, and colonoscopy every 3–5 years could be sufficient to detect new CRCs and polyps<sup>[45]</sup>.

It is also important to consider the changes in CE of these strategies according to age of starting second primary CRC screening in cancer survivors. Little is known about the CE if cancer survivors start second primary CRC screening above or below age 50, at which most guidelines recommend starting CRC screening in the general population. Our findings suggest that for male cancer survivors in older age, COL3 had more favorable CE results, regardless of screening compliance. For younger cancer survivors aged 40 years old, COL5 could be considered a CE strategy with ICER of less than \$7600 per LYS.

Interestingly, in our study of Korea, COL10, COL5 and COL3 had lower total medical costs than no screening of male cancer survivors. In other countries, screening for CRC usually leads to more costs than no screening. Cost estimates for the medical care of CRC treatment in the US range from \$25 000 to \$70 000 and the cost of COL is about \$1000<sup>[9,16]</sup>. However, in Korea, the cost estimate of CRC treatment in the first year ranges from \$7000 to \$14 000 while the cost of COL was about \$60<sup>[24,25]</sup>. The ratio of treatment cost to COL cost ranges from 25:1 to 70:1 in the US and 120:1 to 230:1 in Korea. Due to the difference in cost structures, screening with colonoscopy might be more cost-effective in Korea than in other countries. However, CRC screenings are not covered by the Korean NHI scheme in either the general population or cancer survivors. Instead, the Korean government started the national cancer screening program (NCSP) in 1999, which was

extended to include CRC screening in 2004<sup>[11]</sup>. The government covers 50% of the screening cost for the insured and 100% for low-income people. However, the primary method for CRC screening in the Korean NCSP is FOBT annually. Our study shows that the strategy of "FOBT annually" is always the dominant strategy in male cancer survivors, and costs more than the strategy of no screening.

The major barrier to promotion of colonoscopy as a primary CRC screening tool is the lack of manpower to deliver colonoscopy to the public in Korea. In these human-resource limited setting, it is important to identify the more vulnerable population who has a greater potential to receive benefits. Our study suggests that cancer survivors who are at increased risk of second primary CRC have a favorable result of CE of CRC screening compared with the general population. Even in younger cancer survivors aged 40 years old, COL5 might be economically feasible, while COL10 is usually recommended for the Korean general population aged 50 years old. Therefore, at least for cancer survivors, CRC screening should be covered by the Korean NHI scheme and screening methods using colonoscopy are needed to be recommended as a primary screening strategy for CRC in this population.

### **Limitations**

Our analysis has several limitations. In the design of the model, we tried to reduce the complex natural history of CRC to a few essential states and to avoid assumptions on treatments for which little or no published data existed. For instance, we assumed that 90% of second primary CRC arose from polyps. We used several sets of data from the general population, such as prevalence of colorectal polyp by age, polyp recurrence rate, and treatment costs of second primary CRC, if there were no published data available in cancer survivors. There were possible differences between these two populations. However, when we performed sensitivity analyses, the CE results were usually insensitive to the plausible range of these uncertain parameters. Second, we calculated only the direct costs and did not take into account the impact of CRC and screening on indirect costs. Third, in our study, recently developed CRC screening strategies such as CT colonoscopy were not included. However, the cost of CT colonoscopy is about four times higher than that of colonoscopy in Korea, while the sensitivity and specificity of CT colonoscopy is not superior to that of colonoscopy<sup>[46]</sup>, and this new method does not seem to be an economically-efficient strategy.

In conclusion, with an increased population of long-term cancer survivors, effective systems for their health promotion are needed. Implementation of the economic SPC screening program might be one of the important interventions to improve their health. Our study showed that COL3 or COL5 might be suggested as a primary strategy for second primary CRC screening in cancer survivors who have a higher risk of CRC than the general population. This study supports the evidence

and rationale for second primary CRC screening in male cancer survivors.

## COMMENTS

### Background

Recent improvement in cancer survival due to early diagnosis and advances in treatment has raised the issue of second primary cancers (SPCs) in cancer survivors after their primary treatment. The age-standardized incidence rate is about four times higher for second primary colorectal cancer (CRC) than for first primary CRC in Korea. However, until now, there have been few recommendations and economic evaluations of CRC screening for cancer survivors.

### Research frontiers

To suggest a feasible economic strategy of second CRC screening for cancer survivors in Korea, the authors constructed a decision-analytic model, and compared the cost-effectiveness results of cancer screening between in male cancer survivors.

### Innovations and breakthroughs

Non-dominated strategies were those using colonoscopy in both cancer survivors and the general population, and more strict and frequent recommendations for colonoscopy (COL) such as COL5 (screening every 5 years) and COL3 (screening every 3 years) could be considered as economic strategies for male cancer survivors.

### Applications

The major barrier to promoting colonoscopy as a primary CRC screening tool is the lack of manpower to deliver colonoscopy to the public in Korea. In these human-resource limited settings, it is important to identify the most vulnerable population who has more potential to receive the benefits. In younger cancer survivors aged 40 years old, COL5 might be economically feasible, while COL10 is usually recommended for the Korean general population aged 50 years old. Therefore, at least for cancer survivors, CRC screening should be covered by the Korean national health insurance scheme and screening methods using colonoscopy should be recommended as a primary screening strategy for CRC in this population.

### Terminology

SPC: A SPC is a new primary cancer developing in a person with a history of cancer.

### Peer review

The authors investigated the cost-effective strategy of CRC screening for cancer survivors in Korea. The article is well written and the contents are reliable.

## Abstract

**AIM:** To characterize the types of mutations present in the 23S rRNA genes of Malaysian isolates of clarithromycin-resistant *Helicobacter pylori* (*H pylori*).

**METHODS:** Clarithromycin susceptibility of *H pylori* isolates was determined by E test. Analyses for point mutations in the domain V of 23S rRNA genes in clarithromycin-resistant and -sensitive strains were performed by sequence analysis of amplified polymerase chain reaction products. Restriction fragment length polymorphism was performed using *Bsa* I and *Mbo* II enzymes to detect restriction sites that correspond to the mutations in the clarithromycin-resistant strains.

**RESULTS:** Of 187 isolates from 120 patients, four were resistant to clarithromycin, while 183 were sensitive. The MIC of the resistant strains ranged from 1.5 to 24 µg/mL. Two isolates had an A2142G mutation and another two had A2143G mutations. A T2182C mutation was detected in two out of four clarithromycin-resistant isolates and in 13 of 14 clarithromycin-sensitive isolates. Restriction enzyme analyses with *Bsa* I and *Mbo* II were able to detect the mutations.

**CONCLUSION:** Clarithromycin resistance is an un-

## INTRODUCTION

*Helicobacter pylori* (*H pylori*) is a microaerophilic, Gram-negative bacterium, and is implicated often as the causative agent of chronic gastritis, duodenal and gastric ulcers, and gastric carcinoma<sup>[1,2]</sup>. *H pylori*-associated disorders usually regress or heal completely after treatment with antibiotics<sup>[3]</sup>. Clarithromycin is a macrolide that has been used frequently in combination with other antimicrobial agents for the treatment of *H pylori* infection<sup>[4-6]</sup>. However, resistance to clarithromycin has become one of the major reasons for treatment failure<sup>[7]</sup>. The prevalence of *H pylori* resistance to clarithromycin varies among different countries, such as 12% in Japan, 1.7%-23.4% in Europe and 10.6%-25% in North America<sup>[8,9]</sup>.

Clarithromycin acts by binding to the peptidyl transferase region of 23S rRNA and inhibits bacterial

protein synthesis. Resistance to clarithromycin results from structural changes in the 23S rRNA molecule caused by mutation of the 23S rRNA gene<sup>[10,11]</sup>. Adenine to guanine transitions at positions 2142 and 2143 are the main 23S rRNA mutations in clarithromycin-resistant isolates<sup>[12-14]</sup>. All these mutations have been shown to confer resistance to this macrolide by mutagenesis study<sup>[15]</sup>. Other mutations that have been observed in clarithromycin-resistant *H pylori* isolates are A2515G and T2717C, A2116G, G2141A, A2144T, T2182C, G2224A, C2245T, and T2289C<sup>[16]</sup>. The A2142C/G and A2143G mutation also generate specific restriction sites, namely *Mbo* II and *Bsa* I, and these may be used for the rapid screening of clarithromycin resistance.

In the present study, we determined the prevalence of clarithromycin resistance in our local *H pylori* strains and characterized the types of mutations that occurred in the resistant strains. In addition, we determined whether the Restriction fragment length polymorphism (RFLP) technique was suitable for rapid detection of the mutations among our local isolates.

## MATERIALS AND METHODS

### **Patients**

The patients enrolled in this study were the patients who underwent endoscopy for gastrointestinal symptoms at the Gastroenterology Unit, National University of Malaysia Hospital between 2005 and 2007. Written informed consent was obtained from all patients before biopsies were taken from the antrum and corpus of each patient.

### ***H pylori* culture and antimicrobial susceptibility determination**

Biopsy samples were cultured on Columbia agar supplemented with 10% ox blood. Plates were incubated at 37°C under microaerophilic condition for 5-7 d. Bacterial isolates were identified according to colony morphology, Gram-staining, urease, catalase and oxidase. The cultures were stored at -80°C in Brucella broth supplemented with 15% glycerol and fetal calf serum (Invitrogen, USA).

The MIC of clarithromycin was determined by the E-test method. E tests (AB Biodisk, Sweden) were performed on Columbia agar supplemented with 10% ox blood. The plates were incubated under microaerophilic condition for 3-5 d. Isolates were classified as clarithromycin-resistant if MIC was > 1 µg/mL. *H pylori* strain ATCC43504 was included as a control clarithromycin-sensitive strain.

### **DNA extraction and polymerase chain reaction (PCR) amplification of 23S rRNA gene**

DNA extraction was carried out using the Nucleospin® Tissue Kit (Macherey-Nagel, BD Biosciences, USA) and stored at -20°C until use. The primers used for PCR amplification were Hp5 forward, 5'-GTCGTGCCAA GAAAAGCGTCT-3' (positions 1672-1693; GenBank

accession number U27270), and Hp2 reverse, 5'-TGTG TGCTACCCAGCGATGCTC-3' (positions 2811-2790; GenBank accession number U27270). PCR was carried out on 10 mmol/L dNTP (Promega, USA), 10 pmol of each primer, 1.25 U *Taq* DNA polymerase (Promega), and genomic DNA of *H pylori*. The PCR was performed in a GeneAmp PCR System 2400 thermal cycler (Perkin Elmer, USA) for 30 cycles with the following cycling conditions: 94°C for 1 min, 58°C for 30 s and 72°C for 30 s. The PCR products were then analyzed by electrophoresis using 1% agarose and stained with ethidium bromide.

### **DNA sequencing and sequence analysis**

PCR products were purified using a QIAquick PCR purification kit (Qiagen). Sequencing was performed using BigDye® Terminator v3.1 sequencing kit and analyzed on ABI PRISM® 377 Genetic Analyzer. The sequences were analyzed using free ClustalW software (<http://www.ebi.ac.uk/clustalw>).

### **RFLP analysis**

To detect the A-G point mutations at positions 2142 and 2143, the amplified PCR products were digested with the *Mbo* II and *Bsa* I (MBI Fermentas, Lithuania) restriction enzymes, respectively, and analyzed on 1.6% agarose gels. *Mbo* II-digested PCR products that contained the A2142G mutation were expected to yield two fragments (476 and 662 bp) when digested with *Mbo* II, whereas the PCR products that contained the mutation A2143G were expected to yield three fragments (60, 418 and 666 bp) when digested with *Bsa* I.

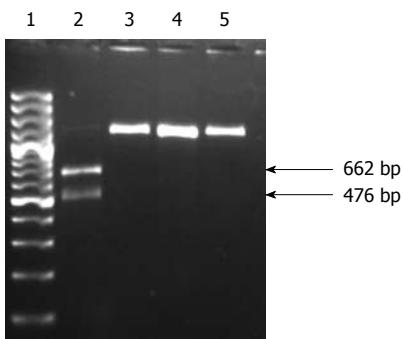

## RESULTS

### **Antimicrobial susceptibility**

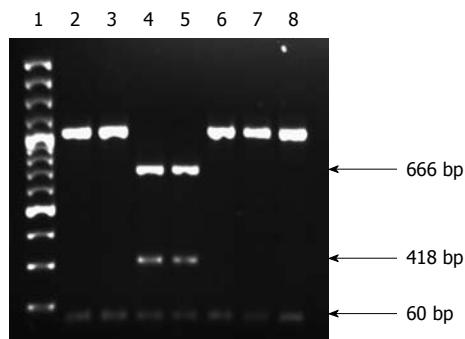

A total of 187 *H pylori* were isolated from gastric biopsies of 120 patients. Four of these isolates (2.1%) from four patients were resistant to clarithromycin, while 183 isolates from 116 patients were sensitive to clarithromycin. The MIC values of all the clarithromycin-resistant isolates ranged from 1.5 to 24 µg/mL (Table 1). The patients with clarithromycin-resistant isolates had never been treated for *H pylori* infection.

### **PCR amplification of 23S rRNA and sequence analysis**

All the clarithromycin-resistant strains and 14 randomly selected clarithromycin-sensitive strains from 14 different patients were subjected to DNA extraction and PCR amplification of domain V of the 23S rRNA gene. The mutations in domain V of 23S rRNA were determined by comparing the sequences of clarithromycin-resistant and -sensitive isolates with the sequences of the reference strain ATCC43504. All of the clarithromycin-resistant isolates were shown to have point mutations of either A2142G or A2143G, while none of the 14 clarithromycin-sensitive isolates had these types of mutations. T2182C mutation was detected in both clarithromycin-resistant and -sensitive isolates.

**Figure 1** RFLP analysis of 23S rRNA to detect the A2142G mutation using *Mbo* II restriction enzyme. Lane 1: 100 bp DNA ladder; Lane 2: Digestion product of resistant isolate with A2142G mutation, showing two fragments of 662 and 476 bp; Lanes 3 and 4: Digestion products of two clarithromycin-resistant isolates with A2143G mutation; Lane 5: Digestion product of a clarithromycin-sensitive isolate with T2182C mutation.

**Figure 2** RFLP analysis of 23S rRNA to detect the A2143G using *Bsa* I restriction enzyme. Lane 1: 100 bp DNA ladder; Lanes 2 and 3: Digestion products of two clarithromycin-resistant isolates with A2142G mutation; Lanes 4 and 5: Restriction analysis of resistant isolates with A2143G mutation, showing three fragments of sizes 666, 418 and 60 bp; Lanes 6-8: Digestion products of clarithromycin-sensitive isolates.

**Table 1** MIC value of clarithromycin and mutations in the domain V 23S rRNA of *H pylori* isolates

Clarithromycin MIC ( $\mu\text{g/mL}$ ) and phenotype	Mutation site	Number of isolate(s)
24 (R)	A2142G	1
24 (R)	A2143G, T2182C	1
3 (R)	A2143G	1
1.5 (R)	A2142G, T2182C	1
< 0.016 (S)	T2182C	13
< 0.016 (S)	No mutation	1

R: Resistant; S: Sensitive.

#### RFLP analysis of clarithromycin-resistant and -sensitive isolates

Sequence analysis of restriction sites of the amplified V domain of the 23S rRNA gene of the resistant strains showed restriction sites that could be digested with *Bsa* I and *Mbo* II. Digestion of the amplified PCR product with *Mbo* II produced two fragments of 662 and 476 bp sizes in strains with the A2142G mutation. No fragment was produced with the A2143G or T2182C mutation (Figure 1). Resistant isolates with the A2143G mutation produced three fragments of 662, 476 and 60 bp when digested with *Bsa* I. No restriction fragment was produced in strains with A2142G and T2182C mutations (Figure 2). None of the clarithromycin-sensitive isolates and the negative control (ATCC43504) produced restriction fragments when digested with *Mbo* II and *Bsa* I, which indicated the absence of A2142G and A2143G mutations.

#### DISCUSSION

The prevalence of clarithromycin resistance was found to be low among the isolates in the present study. To the best of our knowledge, this was the first study that reported and characterized clarithromycin-resistant strains in Malaysia.

Clarithromycin is used worldwide for *H pylori* eradication therapy. *H pylori* strains that are resistant to clarithromycin have been reported increasingly

in several studies<sup>[9,17]</sup>. As resistance will often lead to failure of eradication therapy, knowledge of the current susceptibility patterns of local *H pylori* isolates could help in determining the choice of appropriate treatment for the patient. In the present study, the prevalence of clarithromycin resistance was still low; however, physicians should bear in mind the possibility of clarithromycin resistance if their patient does not respond to this antibiotic.

Versalovic *et al*<sup>[18]</sup> have shown that A2142G and 2143G mutations of 23S rRNA genes in *H pylori* are associated with resistance to clarithromycin. A mutagenesis study performed by Taylor *et al*<sup>[15]</sup> has confirmed that the A2142G and A2143G mutations are associated with clarithromycin resistance of *H pylori*. A review by Mégraud<sup>[8]</sup> of several studies worldwide has shown that 81.5% of the mutations in clarithromycin-resistant isolates were the A2142G or A2143C mutations. In our study, either A2142G or A2143G mutations were found in the clarithromycin-resistant isolates, or they were absent in the clarithromycin-sensitive isolates. The mutations found in our local strains were in accordance with the findings in other countries. The mutations were also associated with low-level resistance.

Another type of mutation detected in our isolates was T2182C. This mutation was detected in most of the strains studied, which suggests a common occurrence among our local strains. This mutation is not new and has been described in previous reports<sup>[19,20]</sup>. This mutation is not associated with clarithromycin resistance<sup>[21]</sup>. However, it has not been discussed whether this type of mutation occurs commonly in *H pylori*. Mutations other than A2142G and A2143G have been reported in other studies<sup>[16,22]</sup>, but among our strains, sequence analysis showed that the mutations were limited to these types only. Although the low number of resistant isolates in our study limit the scope of detection, the results suggest that clarithromycin resistance of *H pylori* in Malaysia can be predicted by detection of mutations at positions 2142 and 2143 of the 23S rRNA gene. The resistance to clarithromycin among the four patients is considered primary resistance

because they were never treated previously for *H pylori* eradication.

Knowledge about the molecular mechanism of resistance is important as it can be used to facilitate the development of other molecular methods to detect resistance. It has been shown that PCR-RFLP can be used to detect mutations in clarithromycin-resistant isolates<sup>[23,24]</sup>. Using this technique in our study, it was demonstrated that only strains with the A2142G and A2143G mutations produced restriction fragments when digested with *Mbo* II or *Bsa* I. This alleviated the need to use the more expensive and time-consuming processes of sequencing and analysis to look for mutation sites.

In conclusion, we showed that there was a low prevalence of clarithromycin resistance in our local strains of *H pylori*. The A2142G or A2143G mutations detected were in accordance with the findings in other countries. These mutations were not found among the analyzed clarithromycin-sensitive strains. T2182C mutation was a common occurrence in our local isolates. Other types of mutations associated with clarithromycin resistance were not observed in our resistant strains. The A2142G or A2143G mutations were detected also by RFLP, thus making it a rapid method for the detection of clarithromycin-resistant strains in our local isolates.

## COMMENTS

### Background

The incidence of clarithromycin-resistant *Helicobacter* is increasing worldwide. This limits the therapeutic options available for eradicating the bacterium. Clarithromycin resistance has been attributed to mutations in the 23S rRNA gene.

### Research frontiers

Clarithromycin acts by binding to the peptidyl transferase region of 23S rRNA and inhibits bacterial protein synthesis. There are many types of mutations observed in the 23S rRNA genes of clarithromycin-resistant *Helicobacter pylori* (*H pylori*). There is little information on the prevalence and characteristics of clarithromycin resistance in *H pylori* strains isolated from Malaysian patients. In the present study, the authors determined the prevalence of resistance and characterized the types of mutations present in their resistant strains.

### Innovations and breakthroughs

The study gave an insight into the low prevalence of clarithromycin resistance among the *H pylori* strains studied. The A2142G and A2143G mutation detected were in accordance with the findings in our other countries. However, other types of mutations associated with clarithromycin resistance were not observed among our resistant strains.

### Applications

The A2142G and 2143G mutations in the 23S rRNA genes in *H pylori* can be detected easily by restriction fragment length polymorphism (RFLP) analysis of the polymerase chain reaction (PCR) product of the genes, using *Mbo* II or *Bsa* I. This eliminates the need to detect these mutations by sequencing.

### Peer review

This is a straightforward study that determined the prevalence of clarithromycin resistance in *H pylori* strains isolated from the authors' institute in Malaysia. The types of mutations that occurred in the resistant strains were further characterized by PCR and sequencing. Finally, the authors evaluated whether the RFLP technique was suitable for rapid detection of the mutations among these isolates. Although the sample size of clarithromycin-resistant isolates was relatively small, the techniques and methodology used were appropriate and standard. The information is potentially useful for the clinical management of *H pylori* infection in Malaysia, and also for our overall appreciation of the global distribution and prevalence of antibiotic resistance of this important pathogen.

### Abstract

**AIM:** To investigate microvascular injury quantitatively in the small bowel with respect to cardiopulmonary bypass (CPB) and related mechanisms.

**METHODS:** In 10 male SD rats, normothermic CPB was established and continued with a flow rate of 100-150 mL/kg per minute for 60 min, while another 10 sham-operated animals served as controls. An approximate 10-cm loop of the terminal ileum was exteriorized for observation by means of intravital fluorescence microscopy. The small bowel microcirculatory network including arterioles, capillaries, and collecting venules was observed prior to CPB, CPB 30 min, CPB 60 min, post-CPB 60 min and post-CPB 120 min. The intestinal capillary perfusion, microvascular permeability and leukocyte adherence were also measured.

**RESULTS:** The systemic hemodynamics remained stable throughout the experiment in both groups. In CPB animals, significant arteriolar vasoconstriction, blood velocity reduction and functional capillary density diminution were found. As concomitances, exaggerated albumin extravasation and increased leukocyte accumulation were also noted. These changes were more pronounced and there were no signs of restitution at the end of the observation period.

**CONCLUSION:** CPB induces significant microcirculatory

injury of the small bowel in rats. The major underlying mechanisms are blood flow redistribution and generalized inflammatory response associated with CPB.

### INTRODUCTION

Despite excellent improvements, there is increasing evidence to show that cardiopulmonary bypass (CPB) is related to a generalized inflammatory response and splanchnic edema formation in both clinical and experimental investigations<sup>[1-5]</sup>. Impairment of gastrointestinal perfusion during CPB may lead to loss of mucosal vascular integrity and increased permeability. The translocation of microorganisms and endotoxin into the systemic circulation can result in a continuing toxic insult and systemic tissue injury. This is thought to be one of the essential mechanisms in the development of sepsis, shock, post-perfusion complications, and multiple organ failure after CPB<sup>[5-7]</sup>. Identification of rational clinical therapeutic approaches requires a precise elucidation of the underlying pathophysiological processes of the intestinal microvasculature induced by CPB.

However, the exact regional hemodynamic and functional changes of the small intestine in terms of the response to CPB remain unclear. Indirect methods may not be sufficient to delineate the pathomechanisms of intestinal microcirculatory conditions within the

different tissue compartments such as muscle, submucosa, and mucosa<sup>[8-10]</sup>. An appropriate experimental model is needed to investigate the variety of microvascular alterations including capillary perfusion injury, microvascular endothelial integrity loss, and leukocyte activation under both physiological and pathological conditions. In this study, using a rat model of CPB, we directly observed and quantitatively analyzed the microvascular alterations in small bowel by means of fluorescent intravital microscopy, aiming to demonstrate the influence of CPB in the different functional units of the microcirculatory network.

## MATERIALS AND METHODS

### Animal preparation

Adult male Sprague-Dawley rats (450-550 g) served as experimental animals. All animals received humane care in compliance with the principles of laboratory animal care formulated by the National Society of Medical Research and the Guide for the Care and Use of Laboratory Animals published by the US National Institutes of Health (Publication No. 85-23, revised 1996). Rats were anaesthetized with intraperitoneal administration of ketamine (50 mg/kg) and chlorpromazine (2 mg/kg). After tracheostomy and intubation, the animals were mechanically ventilated with about 10 mL/kg tidal volume, 60 breaths/min respiratory rate, and 100% inspiratory concentration of O<sub>2</sub>. Anesthesia was maintained throughout the experiment with additional doses of intravenous ketamine.

### CPB techniques

A rat CPB model previously developed by our group, with consistent excellent survival, was used in the current study<sup>[11]</sup>. Briefly, the right femoral artery was cannulated with a 24-gauge heparinized catheter for arterial pressure monitoring and blood gas analysis. The homolateral femoral vein was cannulated with a 20-gauge catheter for blood and fluid infusion. Following heparinization (500 U/kg), a 16-gauge catheter, modified to a multi-side-orifices cannula in the forepart, was inserted into the right jugular vein and advanced to the right atrium for blood drainage by gravity and siphon. A 22-gauge catheter was cannulated to the right carotid artery as the arterial infusion line for the CPB circuit. The membrane oxygenator was specially designed with a surface area for gas exchange of 0.05 m<sup>2</sup> and the total assembly dynamic priming volume of 4 mL. A rolling pump was used to drive the blood through silicone arterial inflow tubing and then returned to the right carotid artery. Priming was composed of 8 mL heparinized fresh homologous blood obtained from a donor and 8 mL synthetic colloid (HAES-steril®). The CPB flow-rate was gradually adjusted, stabilized and performed at 100-150 mL/kg per minute throughout the experiment. To ensure the mean arterial pressure (MAP) above 60 mmHg and the hematocrit about 30%-40%, additional whole blood and Ringer's solution was given during the

experiment to supply the blood and fluid loss caused by surgery, sampling, leakage and evaporation. Body central temperature was monitored with a rectal probe and maintained at 36.5-38.0°C by a heating lamp placed above.

### Intravital microscopy

A modified intravital microscope (Shanghai 2XC4TV, China) with a 100 W mercury arc lamp was used to observe the intestinal microcirculation. With I<sub>2/3</sub> and N<sub>2</sub> filter blocks interposed into the light path, the green (530-560 nm) and the blue (450-490 nm) light was selected, respectively for epi-illumination. For *in vivo* microscopy, fluorescein isothiocyanate conjugated to bovine serum albumin (FITC-BSA), which fluoresces under blue light, allowed visualization of the intestinal microvessels. Acridine orange, which fluoresces under green light, stains leukocytes and allows their adhesion in the microvasculature to be monitored. The microscopic images were acquired by a charge-coupled device digital camera (Olympus C-5050, Japan), recorded by a digital video system (Cannon MVX-150i, Japan), and displayed on a high-resolution monitor (Patriot 798HD, China) for off-line analysis. The final magnification of the images can be approximately achieved by 250 × and 650 × with 10 × and 25 × long-distance objectives.

### Experimental protocol

The animals were randomly divided into two groups. In the CPB group, 10 rats were subjected to the CPB circuit and received extracorporeal perfusion for 60 min. After the bypass was terminated, the remaining priming solution was infused gradually to maintain the main arterial pressure around 60 mmHg. Ten sham operated animals which were cannulated, heparinized and subjected to the CPB circuit but without CPB served as controls, and the CPB circuit was weaned 1 h later. The dosage of heparin for anticoagulation was the same in both groups.

In all animals, *via* a small transverse abdominal incision, an approximate 10 cm loop of ileum was exteriorized and placed on a movable stage attached to the microscope. A 10 mm incision along the antimesenteric border was made with an electric microcautery device for visualization of the mucosal surface. The exposed segment was gently extended, held in place by stay sutures, and covered with a glass microscopical cover slide. The tissues were constantly superfused with warm Ringer's lactate at 37°C to avoid drying and local hypothermia.

The intestinal microcirculation was visualized after intravenous administration of FITC-BSA (0.2 mL/100 g body weight, 5%) and acridine orange (0.1 mL/100 g body weight, 0.2%). To avoid damage to the microcirculation due to long periods of light exposure, the recording time varied 30-60 s. The microvasculature of smooth muscle and the submucosa was assessed from the serosal side in the oral closed part of the segment by adjusting the focus level of the microscope. The villous microcirculation was visualized from the mucosal surface

**Table 1** Macrohemodynamic parameters in CPB and sham animals (mean  $\pm$  SD)

Variables	Groups	Prior to CPB	CPB 30 min	CPB 60 min	Post CPB 60 min	Post CPB 120 min
MAP (mmHg)	CPB	74 $\pm$ 8	77 $\pm$ 7	75 $\pm$ 6	75 $\pm$ 5	72 $\pm$ 5
	Sham	73 $\pm$ 5	75 $\pm$ 6	77 $\pm$ 6	75 $\pm$ 7	77 $\pm$ 5

<sup>a</sup>P < 0.05, <sup>b</sup>P < 0.001 vs sham group; <sup>c</sup>P < 0.001 vs baseline.

through the longitudinal incision in the aboral part of the segment.

After stabilization for about 15 min, four non-overlapping regions of interest were defined and measured to obtain representative values for every parameter. The quantitative analysis of intestinal microcirculation was performed by means of the standard technique usually used in intravital microscopic studies in small animals<sup>[12,13]</sup>. A computer-controlled image analysis system (ImageJ 1.30V, National Institutes of Health, USA) was applied in those processes. Microcirculatory parameters were recorded prior to CPB, CPB 30 min, CPB 60 min, post-CPB 60 min, and post-CPB 120 min. In addition, the systemic arterial pressure was monitored continually and the arterial blood gas analyses were performed repeatedly throughout the experiments.

### Statistical analysis

SPSS for Windows 11.0.1 (SPSS Inc. 2001, USA) was used for statistics. All data were expressed as means  $\pm$  SD. Following analysis of variance, the Student's *t* test was used as a test for statistical significance of normal distributed values between the groups. To analyze differences within each group for time effects, paired Student's *t* tests including a correction of the error according to Bonferroni probabilities for repeated measurements were used. *P* < 0.05 was considered statistically significant.

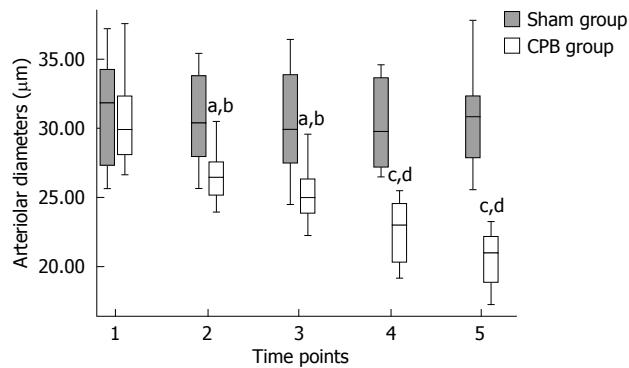

## RESULTS

### Macrohemodynamic parameters

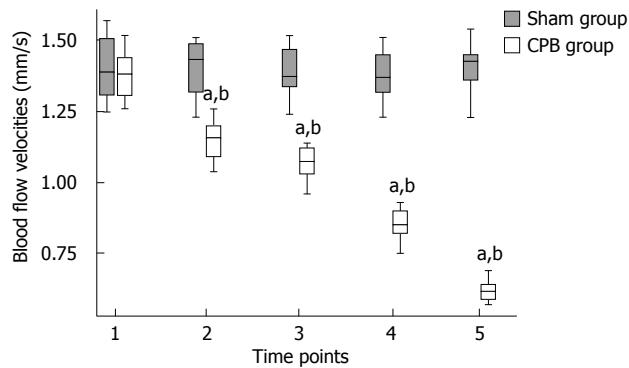

The MAP remained constant and the results of blood gas analysis were within the acceptable range in both groups using this experimental design and CPB technique (Table 1). However, during the entire bypass period, the heart kept beating and lung perfusion persisted. Due to the existence of the shunt, this could result in lower blood oxygenation in the CPB group vs the sham. As is the nature of CPB, hemodilution and a significant decrease in pH were observed in our model similar to that seen in clinical practice.

### Capillary perfusion

In the CPB group, a significant pathological segmental

vasoconstriction not ascribed to undulating vasomotion was detected in small vessel segments. Mean arteriolar diameters of single arterioles in the mucosal layer were found to be diminished from 30.82  $\pm$  3.57 prior to CPB to 20.59  $\pm$  1.97  $\mu$ m (*P* < 0.001) at the end of the experiment (Figure 1). Blood flow was apparently reduced in the collecting venules in the submucosa, with the red blood cell flow velocities reduced from 1.38  $\pm$  0.08 mm/s prior to initiation of CPB to 0.62  $\pm$  0.04 mm/s (*P* < 0.001) at 2 h after bypass (Figure 2). As a consequence, a concomitant hemoconcentration, typical sludge phenomena and cell aggregates within

<sup>a</sup> $P < 0.001$  vs sham group; <sup>b</sup> $P < 0.001$  vs baseline.

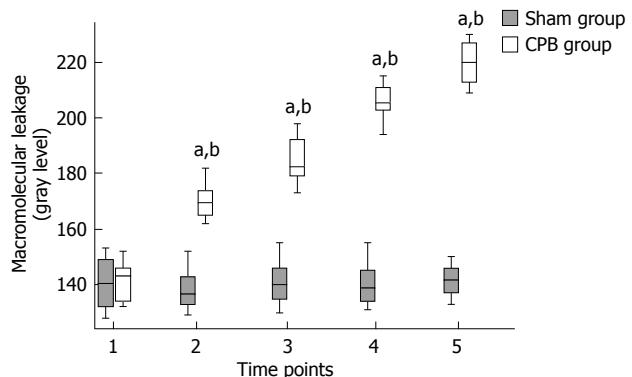

**Figure 3** Interstitial fluorescence after administration of FITC-BSA in muscular layer. A: Control animals. FITC-BSA was contained within the vessels and the capillaries are easily identified; B: CPB animals. FITC-BSA extravasated from the capillaries into the interstitium, and a brighter flare surrounded the microvasculature (Magnification,  $\times 650$ ).

these vessels could be observed. In the control animals, the arterioles showed no changes in diameter and the blood cell velocities remained constant throughout the observation period. Functional capillary density (FCD) was expressed as the length of FITC-BAS perfused capillaries per observational area. Both the intestinal mucosa and the smooth muscle layer were analyzed. In the sham group, the perfusion was homogeneous in both compartment capillary networks (Table 2). However, in the CPB group, the FCD values decreased significantly during and after bypass and reached only 30% of initial values at the end of the observation period.

#### Microvascular permeability

A significant increase in macromolecular leakage induced by CPB was observed in this study. Under circumstances resulting in increased microvascular permeability to macromolecules, FITC-BSA was seen to leak from the vasculature, appearing as a flare in the perivascular interstitium. The interstitial fluorescent intensity was proportional to the degree of FITC-BSA leakage from the vessels. In control animals, the vascular

**Figure 4** Macromolecular leakage of intestinal microcirculation in muscular layer. FITC-BSA leakage was represented as the gray level of Intestinal fluorescent intensity. Values are expressed as means  $\pm$  SD, <sup>a</sup> $P < 0.001$  vs baseline; <sup>b</sup> $P < 0.001$  vs sham group (Time points: see Figure 1).

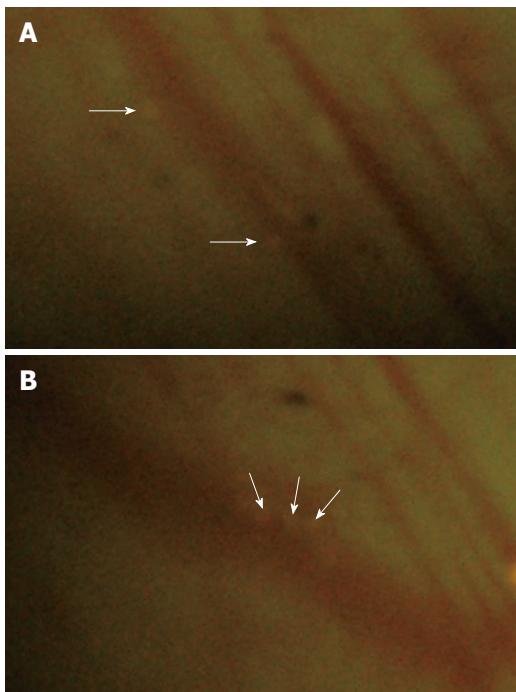

integrity was maintained with no observed increases in interstitial fluorescence during the experimental period (Figures 3 and 4). In the CPB group, the interstitial fluorescence increased at all time points from a gray level of  $141.8 \pm 7.3$  at the beginning of CPB to  $219.9 \pm 7.1$  at 2 h after weaning off bypass ( $P < 0.001$ ).

#### Leukocyte adhesion

Leukocyte adhesion was analyzed within postcapillary venules of the intestinal submucosa. A leukocyte was considered to be adherent in each vessel segment if it did not move or detach from the endothelial lining for at least 30 s. Stationary leukocytes that had migrated to the interstitium but remained in close proximity to the capillaries were also regarded as adherent. Data was expressed as the number of adherent leukocytes per  $100 \mu\text{m}$  length of venular endothelial surface. In the sham group, only occasional adherent leukocytes ( $2.7 \pm 0.9$  cells/ $100 \mu\text{m}$ ) were found firmly adhered to the microvascular endothelium throughout the experimental period (Figures 5 and 6). In the CPB group, a rapid, sustained, and significant increase in leukocyte adherence (about 10-fold at the end of experiments) was induced within the submucosal capillaries ( $P < 0.001$ ) during and after CPB.

## DISCUSSION

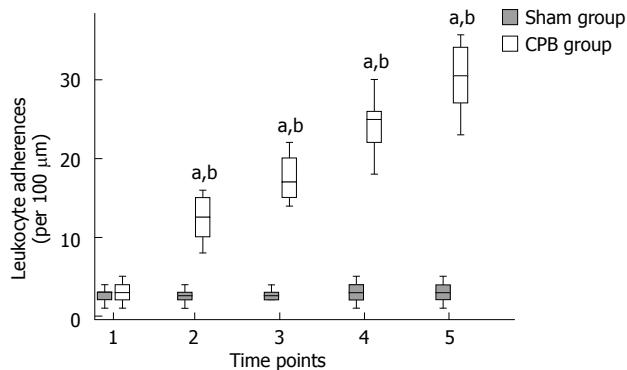

Nowadays, due to various improvements, CPB has made cardiovascular surgery more and more practical and safe even in high-risk patients. However, there are still many complications which are thought to result from

**Figure 5 Leukocyte adhesion in intestinal submucosa.** A: Control animals. Few adherent leukocytes (arrows) were observed within the microcirculation; B: CPB animals. Numerous adherent leukocytes (arrows) were observed within the capillaries.

a systemic inflammatory response and non-occlusive visceral ischemia<sup>[5,7,14,15]</sup>. Recent research has suggested that the intestinal mucosa is extremely sensitive to ischemia-reperfusion (I/R) injury and the gut is both the source and the target of inflammatory mediators<sup>[16,17]</sup>. These changes might contribute to a severe loss of intestinal function with significant complications or even multiorgan failure and systemic shock as a pathological consequence. In clinical practice, the incidence of gastrointestinal complications is low (0.58%-2.0%), however, they are associated with an unacceptable high mortality (15%-63%), especially in patients with pre-existing impairment of bowel perfusion<sup>[15,18,19]</sup>. With the aim of identifying effective preventive and therapeutic approaches, studies on the underlying pathomechanisms of CPB in small bowel capillary perfusion seem to be imperative.

Methods such as laser Doppler flow measurements and tonometry have been described in this area, but they are both indirect measures which do not allow quantitative analysis in different segments of the microvascular bed<sup>[9,20,21]</sup>. In contrast, intravital microscopy allows direct observation and quantitative analysis of the tissues and organs at the level of microcirculation and acquires more information on the pathologic role of CPB. The mesentery has been used frequently in studies of the intestinal microvasculature, but it has very little in common with intestinal microvascular networks<sup>[22,23]</sup>. In our experiments, the use of intravital microscopy employing different fluorescent dyes, allowed the simultaneous quantitative investigation of the microcirculation within all layers of the small intestine, i.e. subserosa, smooth muscle, submucosa and

**Figure 6 Quantitative analysis of leukocyte adhesion in intestinal submucosa.** Adherent leukocytes per 100  $\mu\text{m}$  length of venule. Values are expressed as means  $\pm$  SD. <sup>a</sup>P < 0.001 vs baseline; <sup>b</sup>P < 0.001 vs sham group (Time points: see Figure 1).

mucosa. For the first time, we directly investigated the intestinal microcirculatory changes within different layers relating to CPB by intravital microscopy.

The majority of studies on CPB relating to pathophysiological processes have been performed in large animal models<sup>[24]</sup>. These models have substantial limitations, mainly in that their costs are extremely high, instruments are very complex and they are too labor intensive. Rats are one of the most standard models for intravital microscopy and have been extensively used for the experimental investigation of multiple organ injury in various areas<sup>[12,13,22]</sup>. In our experiments, a rat CPB model with full flow perfusion was established. This model also reduced the cost of animals and equipment.

In the CPB group, the blood pressures were kept constant at a physiological level throughout the experiments without vasoactive drugs and the systemic temperatures were stable at around 37°C. Despite the consistent condition of systemic hemodynamics, microvascular perfusion impairments of the small bowel were clearly demonstrated. Arteriolar vasoconstriction, the reduction in blood cell velocities, together with the consequence of intravascular hemoconcentration and sludge formation, reflected hypoperfusion at the microvascular level. The reduction in the FCD values at the end of the observation period to approximately 30% of the pre-bypass values revealed that the capillary bed had been severely injured. The extravasation of FITC-BSA showed a distinct increase in the permeability of the vascular wall which might result in a loss of the natural barrier function against toxins and microorganisms. This might aggravate the injury to capillary perfusion further. Enhanced leukocyte adherence to the venular wall within submucosal vessels was also demonstrated in this study, which indicated that activated leukocytes may be the primary mediators and may have a causative role in the following pathophysiological sequelae.

The potential underlying pathogenesis of the intestinal injury induced by CPB includes several pathophysiological mechanisms<sup>[1,14,15,25]</sup>, such as a transient reduction in systemic blood pressure and low cardiac outflow (LCO), hypotemperature in the bypass process,

redistribution of local organ blood flow, reactions of inflammatory mediators or vasoconstrictive agents, and obstruction of arterioles with fragments of cells or tissues. With our model, due to the fact that the flow rate of the bypass circuit was kept constant and the arterial blood pressure remained unchanged, the influences of macrohemodynamics could be avoided. This allowed the conclusion that the observed changes in microvascular perfusion in the small bowel were not only a result of systemic hypoperfusion or LCO syndrome. By keeping the systemic and tissue temperatures in the normal range, we could exclude the effects of temperature on the microvascular perfusion in our study. Redistribution of blood flow and induction of inflammatory response seemed to be the major mechanisms responsible for the observed results<sup>[2,26]</sup>. Non-physiological patterns of perfusion originating from the rolling pump results in maldistribution of blood flow away from visceral organs as a reaction to CPB which serves as the primary contributor to microvascular impairments. It is important to note that the degree of damage to the microcirculation reached a maximum even after CPB removal for 2 h, suggesting that the ensuing inflammatory process as a consequence of CPB could be the dominant mechanism. The contact of blood and blood cells with the bypass circuit surfaces, the trauma induced by mechanical stress from the pump, together with the I/R injury of the gastrointestinal tract resulting from the transient decrease in local blood flow can induce the release of inflammatory mediators (e.g. cytokines, thromboxane, and histamine, etc), secretion of proteases (e.g. collagenase and elastase), activation of complements, extravasation of leukocytes, and the generation of oxygen free radicals<sup>[6,12,23]</sup>. These substances may lead to vasoconstriction, hemoconcentration and sludge formation, endothelial cell swelling and the consequent occlusion of vessels, and an increase in vascular permeability.

In conclusion, using intravital microscopy, progressive microvascular injury in the small bowel was demonstrated in a rat CPB model. The ensuing injury response was associated with microvascular perfusion failure, vascular permeability increase, and promotion of circulating leukocyte adherence. These changes in microvessels were even more prominent after the bypass period and no signs of restitution could be observed. The observed phenomena may have resulted from the redistribution of blood flow in different organs and the generation of inflammatory metabolites with potential negative effects on microvascular perfusion during and after CPB. The information obtained from our experiments will facilitate further investigations of different therapeutic regimens aimed at ameliorating microvascular damage due to CPB.

## COMMENTS

### Background

Impairment of intestinal microvascular perfusion induced by cardiopulmonary bypass (CPB) is thought to be related to mucosal edema formation and

microvascular barrier injury, which may result in postoperative gastrointestinal complications and multiple organ failure. A better understanding of the microvascular alterations during and after CPB will facilitate the identification of therapeutic strategies.

### Research frontiers

In general, experimental investigations on the intestinal injury induced by CPB are scarce. The identification of rational clinical therapeutic approaches requires a precise elucidation of the underlying pathophysiological processes of intestinal microvasculature induced by CPB.

### Innovations and breakthroughs

With a novel rat model of CPB, the authors quantitatively investigated the microvascular alterations post CPB in small bowel by means of fluorescent intravital microscopy, which allows the simultaneous quantitative investigation of the microcirculation of the small intestine.

### Applications

By understanding pathomechanisms of CPB in small bowel capillary perfusion, this study may help to identify effective preventive and therapeutic approaches.

### Terminology

Functional capillary density (FCD) is one of the parameters obtained by intravital microscopy using epi-illumination of the tissue surface or transillumination of thin tissue layers. FCD, defined as the length of red cell-perfused capillaries per observation area ( $\text{cm}^{-1}$ ), has been used as an indicator of the quality of tissue perfusion in various animal models. Quantitative analysis of FCD in randomly selected regions of the tissue is performed by means of a computer-assisted video analysis system which allows calculation of the length of RBC-perfused capillaries.

### Peer review

In this paper, the authors used intravital microscopy for assessment of intestinal microcirculation in rats during and after CPB. The authors confirmed arteriolar vasoconstriction, blood velocity reduction and FCD diminution, exaggerated albumin extravasation and increased leukocyte accumulation in intestine in rats during and after CPB.

## Abstract

**AIM:** To assess the reliability and validity of the translated version of Nepean Dyspepsia Index (NDI) in Chinese patients with documented functional dyspepsia (FD).

**METHODS:** The translation process included forward translation, back translation, pretest and cross-cultural adaptation. Reliability and validity of the translated version were examined by asking 300 subjects to complete the Chinese version of the NDI. The mean age of subjects was 39.24 years and 68.7% of the subjects were women. Internal consistency analysis with Cronbach's  $\alpha$  was performed to test the reliability. Correlation analysis was used to assess the content validity. Factor analysis and structural equation models were used to assess the construct validity.

**RESULTS:** The Cronbach's  $\alpha$  coefficients ranged 0.833-0.960, well above the acceptable level of 0.70. Correlation analysis showed that each item had a strong correlation with the corresponding domain, but a weak correlation with other domains. Confirmatory factor analysis indicated that the comparative fit index was 0.94, higher than the acceptable level of 0.90.

## INTRODUCTION

Functional dyspepsia (FD) is a common clinical condition characterized by chronic or recurrent upper abdominal pain associated with a variety of gastrointestinal symptoms in the absence of organic disease<sup>[1]</sup>. An epidemiological survey in Western countries showed that 19%-41% of the population have symptoms of FD<sup>[2]</sup>. The report on the incidence of FD in citizens of Tianjin, China, revealed that the number of patients with FD accounts for 23.29% of the total population<sup>[3]</sup>. Since FD greatly affects the quality of life (QOL) of patients<sup>[4-6]</sup>, and contributes to a higher medical cost<sup>[7,8]</sup>, it represents an important healthcare problem in modern society. However, treatment of FD is still controversial and no single therapy is uniformly effective, partially due to lack of a reliable evaluation instrument<sup>[9]</sup>. Many difficulties exist in the single treatment approach to FD<sup>[10]</sup>. A combined approach, which includes herbal medicine, acupuncture and massage therapy, may be more effective than any single treatment<sup>[11]</sup>.

In addition to symptom evaluation, assessment of QOL has been recognized as a major factor for overall

health outcome assessment in FD clinical studies. Nepean Dyspepsia Index (NDI) was designed to measure both symptom scores and impairment of the dyspepsia-specific health-related QOL (H-QOL). Since the development of NDI in 1998<sup>[12]</sup>, it has been used as an outcome assessment in many FD clinical researches<sup>[13,14]</sup> and translated into several languages including French, Dutch, Italian, German, Spanish, and American English<sup>[15,16]</sup>. NDI has proven vital in the diagnosis of FD<sup>[12]</sup>, and its utility has been validated<sup>[4,17]</sup>. A number of studies about the effect of FD on QOL in Western patients are available<sup>[7,18,19]</sup>. However, the effect of FD on the QOL in Asian patients has not received great attention.

Since no validated disease-specific questionnaire is currently available for assessing the impact of FD on the QOL, we translated the original version of NDI (25 items) into Chinese. We also assessed the reliability and validity of this translated version in Chinese patients with documented FD in order to provide researchers, clinicians, and patients with a suitable questionnaire to assess FD.

## MATERIALS AND METHODS

### Ethics

This study was approved by the Ethics Committee of Chengdu University of Traditional Chinese Medicine. All subjects provided their written consent before participation in this study.

### Demographics

Four hundred and six Chinese outpatients with a suspected diagnosis of FD were screened between March 20, 2007 and June 1, 2007. One hundred and six patients were excluded and the symptom scores for the remaining 300 patients enrolled in our study were  $2.970 \pm 3.515$  for burping/belching,  $4.690 \pm 3.770$  for fullness after eating or slow digestion,  $1.800 \pm 2.886$  for nausea,  $2.367 \pm 3.421$  for inability to finish a regular meal,  $1.540 \pm 3.038$  for bad breath,  $3.050 \pm 3.575$  for bitter/sour tasting fluid coming up into mouth or throat,  $0.670 \pm 1.855$  for vomiting,  $5.790 \pm 2.939$  for discomfort in upper abdomen,  $0.786 \pm 2.185$  for cramps in upper abdomen,  $1.306 \pm 2.803$  for burning sensation in upper abdomen,  $5.130 \pm 3.567$  for pain or ache in upper abdomen,  $1.206 \pm 2.601$  for pressure in upper abdomen,  $5.300 \pm 3.516$  for bloating in upper abdomen,  $0.903 \pm 2.380$  for burning sensation in chest (heartburn), and  $0.640 \pm 2.045$  for pain or ache in chest. The mean age of subjects was 39.24 years and 68.7% of the subjects were women.

The study was performed at Chengdu, Wuhan and Changsha medical centers, which comprise five hospitals in total. Before inclusion in the trial, all patients underwent physical examination, abdominal ultrasonography and upper gastrointestinal endoscopy to exclude organic gastrointestinal cause for their symptoms. Patients at the age of 18 years and older were considered eligible in the study. If their endoscopy was either normal or showed only chronic superficial gastritis, they were diagnosed with FD according to

Rome-III criteria<sup>[20]</sup> with no cholecystitis or cholelithiasis on their sonogram. Patients with a history of upper gastrointestinal surgery, or who were pregnant or lactating, were excluded. Mental deficiency, psychiatric, cardiovascular, hepatic, and renal diseases were the additional exclusion criteria. The investigation was carried out in a quiet environment. Specialists explained each item to the patients so that the patients could understand and complete the questionnaire correctly.

### Chinese version of NDI

The original 25-item NDI<sup>[17]</sup> consists of three parts: a symptom checklist that measures the frequency, intensity and level of discomfort of 15 upper gastrointestinal symptoms over the prior 14 d, 25 items designed to assess QOL, and an 11-item questionnaire designed to measure the relevance or importance of the above items.

The QOL includes four domains, namely interference (13 items), know/control (seven items), eat/drink (three items), and sleep/disturb (two items). The scores were determined with a five-point Likert scale which ranges "not at all"-“extremely”. The NDI for QOL score ranges 0-99, higher scores indicate poorer QOL. Symptoms were scored separately from questions representing the QOL. The higher the score of each individual symptom is, the severer the symptom is.

After permission, the original version of NDI was translated into Chinese according to the WHO-QOL methodology of cross-culture adaptation for QOL<sup>[21]</sup>. Forward translation from the original English version was performed independently by two gastroenterologists with good English. Both forward versions were then reconciled and incorporated into the Chinese version. Back translation was carried out by an English teacher understanding the Chinese language with no knowledge of NDI. The semifinal version was derived from reconciliation of the original, back and forward translations. A pretest, NDI for five patients with FD was performed. The final version was obtained after cross-cultural adaptation.

### Statistical analysis

The reliability of NDI was evaluated for internal consistency using Cronbach's  $\alpha$ . Correlation analyses were used to assess the content validity. Factor analysis and structural equation models were used to assess the construct validity.

All data were analyzed with SPSS 13.0 version. Data derived from descriptive statistical analysis were presented in the form of percentages including categorical variables and calculation of the mean.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Checklist of symptoms

The total score for each symptom on the checklist was calculated by adding its corresponding frequency, severity and level of discomfort. As stated above, higher scores were elicited for symptoms of discomfort, bloating, and

**Table 1 Internal consistency of items in each domain**

Factor	Domain	Cronbach's $\alpha$
1	Interference	0.944
2	Know/control	0.906

24	0.709	0.814	0.527	0.487
25	0.631	0.577	0.327	0.294

pain or ache in upper abdomen, and fullness after eating or slow digestion.

### Reliability

The scores were evaluated using Cronbach's  $\alpha$  coefficient. An  $\alpha$  score  $> 0.7$  was considered internally consistent as previously described<sup>[22]</sup>. The Cronbach's  $\alpha$  coefficient ranged 0.833-0.960 (Table 1).

### Validity

The content validity of 25 items and four-field scores were regarded as 29 independent variables. Pearson item-dimension correlation coefficient was employed to evaluate the content validity. Most of the coefficients were higher than 0.6 ( $P < 0.01$ , Table 2).

### Construct validity

The values of the four preceding factors were above 1.0, and their cumulative factor loading rate was 69.287%. The rotated component matrix showed that component 1 had more loadings on items 1, 9-16, 20, 21 and 25; component 2 had more loadings on items 2, 3, 17-20, 22-24; component 3 had more loadings on items 4-6; component 4 had more loadings on items 7 and 8 (Table 3). The confirmatory factor analysis indicated that

degrees of freedom = 269, minimum fit function chi-square = 1703.32 ( $P < 0.0001$ ), normal theory weighted least chi-square = 1809.13 ( $P < 0.0001$ ), comparative fit index (CFI) = 0.94, non-normal fit index = 0.94. A structural equation model of construct validity is illustrated in Figure 1.

## DISCUSSION

QOL has received increasing attention as more foci are placed on individual satisfaction as an important health outcome in clinical studies. In addition, QOL is particularly significant in diseases lacking of obvious biological or clinical markers, such as FD<sup>[23,24]</sup>. FD greatly affects the QOL of patients. However, treatment of FD is still controversial and no single therapy is uniformly effective, in part, due to the absence of a reliable evaluation instrument.

From our symptom checklist scores, symptoms with the highest scores were discomfort, bloating, and pain or ache in upper abdomen and fullness after eating or slow digestion, all of which are congruent with the main symptoms of FD according to Rome-III criteria<sup>[25]</sup>. However, heartburn, a major symptom in the Rome-III criteria, had a lower score in our study, possibly due to lack of patient comprehension or lack of adequate explanation by the investigator.

In clinical trials, Leeds dyspepsia questionnaire (LDQ) and MOS 36-item short-form health survey (SF-36) have been applied as an evaluation instrument for FD<sup>[26-28]</sup>. LDQ is a valid, reliable and responsive instrument for measuring the presence and severity of dyspepsia, but it lacks of QOL assessment<sup>[29]</sup>. As it is

**Figure 1** Structural equation model of construct validity.

known that, in addition to symptoms, QOL assessment represents a major part of health outcome assessment in clinical studies of FD. However, as different diseases cause different symptoms which necessitate disease-specific H-QOL instruments. SF-36, a generic QOL measurement, contains a large number of questions, the majority of which are often irrelevant to a particular disease. As a result, it may be insensitive to changes in the relevant items due to interference from the irrelevant items. Thus, the evaluation of FD should contain two aspects, namely symptom measure and disease-specific H-QOL assessment. The NDI addresses both aspects.

The original NDI consists of 42 questions, and is shortened to 25 items, excluding those items with a negative response rate of over 60%. The remaining 25 items represent the clinically relevant QOL concepts in subjects with FD<sup>[17]</sup>. Our study was based on the revised version of 25 items.

In order to maintain the sensitivity of the original version, our questionnaire considered differences in language, cultural diversities, and life style. After our version of the NDI was established, its reliability and validity were evaluated using Cronbach's  $\alpha$ . We found that all domains were above 0.80, demonstrating that our scale has an excellent reliability. Correlation analysis demonstrated that each item had a strong correlation with the corresponding domain, but a weak correlation with other domains, supporting that our questionnaire is valid. In addition, our results are in accordance with the original NDI design, representing superior construct

validity. Confirmatory factor analysis also indicated that the CFI was higher than the acceptable level of 0.90<sup>[25,30]</sup>, demonstrating that our scale has a good construct validity.

In the past, FD research in China was limited by the absence of a valid assessment instrument for the disease. Our results suggest that the Chinese version of NDI with excellent psychometrics would promote the clinical study of FD and align its medical course in China with international practice in future.

Our study has some limitations, including lack of extensive demographic characteristics, analysis of multi-dimensional factors (such as education, career, financial and social status), "test-retest" in reliability assessment, and discriminating validity in validity assessment, all of which need to be further studied.

## ACKNOWLEDGMENTS

The authors thank Associate Professor Yuan-Tao Hao and postgraduate student Qi Tian (Institute of Medical Statistics and Epidemiology, Sun Yat-Sen University) for their cooperation and technological support regarding both the study design and statistical analysis. The authors also thank Dr. Hong Wei (Teaching Hospital of Chengdu University of TCM), Dr. Xiao-Ying Wu (No. 2 People's Hospital of Chengdu City), Associate Professor Hong-Xing Zhang (No.1 People's Hospital of Wuhan City), and Dr. Jin-Xiang Hu (Teaching Hospital of Hunan University of TCM), for their medical advice regarding FD diagnosis and efforts in recruiting subjects.

## COMMENTS

### Background

Functional dyspepsia (FD) is a common non-organic disease in the world. However, treatment of FD is still controversial, partially due to lack of a reliable evaluation instrument. Since 1998, the Nepean Dyspepsia Index (NDI) has been designed to diagnose FD and proven to be valid in measuring both symptom scores and impairment of dyspepsia-specific health-related quality of life (H-QOL) in FD patients.

### Research frontiers

In addition to symptom evaluation, assessment of QOL has been recognized to be more and more important in overall health outcome assessment in FD clinical studies. In this study, the reliability and validity of the Chinese NDI translated from its English version which reflects the dyspepsia-specific H-QOL in Chinese FD patients, were assessed.

### Innovations and breakthroughs

Studies on validation of NDI for FD in Western countries are widely available. However, NDI has not been translated and validated in China, since much attention is not paid to the effect of FD on the QOL of patients. This is the first study to translate the original version of NDI (25 items) into Chinese and to assess its reliability and validity in Chinese FD patients.

### Applications

By validating the translated version of NDI, this study may provide researchers, clinicians, and patients with a suitable questionnaire for the assessment of FD.

### Terminology

Reliability is the extent to which the measurements of a test remain consistent over repeated tests of the same subject under identical conditions. Validity, containing construct, content and convergent validity, refers to the degree to which evidence and theory support the interpretations of test scores entailed by proposed tests. Assessment of the validity of a scale involves evaluation of the scale in relation to the desired conclusion on the basis of prevailing standards.

**Peer review**

The authors have made a detail description of how to use the Chinese version of NDI to diagnose FD patients in China. The study is clinically important, because a Chinese version of NDI is needed to diagnose and compare FD patients in China and other countries.

## INTRODUCTION

Hepatitis C virus (HCV) infection is a major cause of chronic hepatitis, liver cirrhosis and hepatocellular carcinoma worldwide<sup>[1]</sup>. Currently, there is no vaccine to prevent the infection and no specific antiviral drug directed against the disease. Gene therapy has emerged as a novel approach to combat HCV infection in the last few years<sup>[2,3]</sup>. However, one of the most important obstacles to overcome is “targeting”: the appropriate genes must be delivered to and expressed in HCV infected hepatocytes without harming normal tissues. This problem could be addressed by using a promoter that has a higher level of activity in HCV infected liver cells *vs* normal cells.

HCV is a member of the Flaviviridae family, containing approximately 9.5 kb of positive strand RNA. The viral genome encodes a large precursor polyprotein which is cleaved into functional proteins such as core, envelope (E1, E2) and non-structural proteins (NS2-NS5)<sup>[4,5]</sup>. The viral core protein consists of 191 amino acids and has an apparent molecular mass of 21 kDa. In addition to being the viral capsid protein, it also functions as a transcriptional regulator of various viral and cellular promoters. Some groups have reported that HCV-core protein activates the human

## Abstract

**AIM:** To examine whether 2'-5'oligoadenylate synthetase (*OAS*) gene promoter can be specifically activated by hepatitis C virus (HCV)-core protein.

**METHODS:** Human embryo hepatic cell line L02 was transfected with pcDNA3.1-core plasmid and selected by G418. Expression of HCV-core was detected by reverse transcription polymerase chain reaction and Western blotting. The *OAS* promoter sequence was amplified from the genomic DNA and inserted into pGL3-basic vector. The resultant pGL3-OAS-Luci plasmid was transiently transfected into L02/core cells and luciferase activity was assayed.

**RESULTS:** L02/core cell line stably expressing HCV-core protein was established. The pGL3-OAS-Luci construct exhibited significant transcriptional activity in the L02/core cells but not in the L02 cells.

**CONCLUSION:** HCV-core protein activates the *OAS* gene promoter specifically and effectively. Utilization of *OAS* gene promoter would be an ideal strategy for developing HCV-specific gene therapy.

c-myc, Erk, IL-2, and SV40 early promoters, and trans-suppresses some cellular promoters such as p53 and p21<sup>[6-12]</sup>. Though the mechanisms of these regulations are still unclear, it is possible that these properties of HCV-core protein influence host cell growth, survival, and carcinogenesis. Therefore, utilization of a promoter that is predominantly active in HCV-core positive hepatocytes would be an ideal strategy for developing HCV-specific gene therapy.

During the investigation of interferon (IFN)-inducible JAK-STAT signaling affected by HCV, Naganuma *et al*<sup>[13]</sup> found that HCV-core protein specifically activated the 2'-5'oligoadenylate synthetase (*OAS*) gene promoter in human hepatocyte cells, while the E1, E2, and NS5A proteins did not activate the *OAS* gene promoter. These data indicate that *OAS* promoter might be used to restrict gene expression in HCV-core positive liver cells. However, the role of HCV-core protein in modulating *OAS* gene expression is much controversial, some other groups have reported that HCV-core protein does not affect the activation of IFN-responsive genes (including *OAS* gene), although it modulates the JAK/STAT signaling pathway<sup>[14-16]</sup>. So whether this viral core protein interferes with the *OAS* promoter and whether the promoter could be used to target gene therapy remain to be demonstrated. For these reasons, in the present study, we cloned the *OAS* promoter and examined its activity in the HCV-core expressing liver cells *in vitro*.

## MATERIALS AND METHODS

### Cell culture

Human embryo hepatocyte derived L02 cell line was obtained from Institute of Biochemistry and Cell Biology, Shanghai Institute for Biological Sciences (Shanghai, China). The cells were routinely grown in DMEM medium supplemented with 10% fetal bovine serum, 100 U/mL penicillin and 100 µg /mL streptomycin.

### Stable transfection and establishment of stable cell line

The pcDNA3.1-core, which contains the complete coding region of HCV-core protein (1b genotype) under the control of cytomegalovirus (CMV) immediate early promoter, was kindly provided by Professor Jun Cheng (Institute for Epidemic Disease Research, Beijing Ditan Hospital, China). The L02 cells were seeded in 6-well culture plates at 70% confluence 24 h before transfection. Cells were transfected with 2 µg of pcDNA3.1-core plasmid using Lipofectamine 2000 (Invitrogen) according to the manufacturer's instructions. For establishment of stable cell line, the transfected cells were subjected to selection medium containing 400 mg/L G418 until several G418-resistant clones (L02/core) were obtained, and then the cells were maintained in G418 at a concentration of 200 mg/L. Non-transfected L02 cells were used as parallel control.

### Reverse transcription polymerase chain reaction (RT-PCR) analysis for core-specific gene expression

Total RNA was isolated from L02/core cells with TRIzol reagent (Invitrogen) and reversely transcribed using RevertAid™ First Strand cDNA Synthesis Kit (MBI Fermentas). PCR was subsequently performed with HCV core-specific primers: 5'-ATGAGCACCAATCCTAAA C-3' (forward), and 5'-GGCTGAAGCGGGCAC-3' (reverse). The cycle parameters were as follows: 95°C for 1 min, 52°C for 50 s, and 72°C for 1 min; 30 cycles. The PCR products were electrophoresed in a 1.5% agarose gel containing ethidium bromide and visualized by UV illumination. The expected size of the PCR product for HCV-core mRNA was 572 base-pairs.

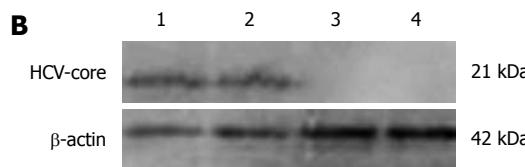

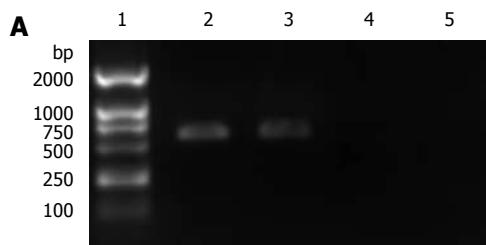

### Western blotting analysis for core protein

The L02/core cells were collected, washed with PBS and lysed in ice-cold lysis buffer (20 mmol/L Tris HCl, pH 7.5, 150 mmol/L NaCl, 5 mmol/L EDTA, 1% Nonidet P-40, 1 mg/L Aprotinin, 100 mg/L PMSF). The protein concentration of the whole cell extract was measured using Bio-Rad DC protein assay kit. Equal amounts of cell lysates (60 µg protein) were separated by 12% SDS-PAGE and transferred to PVDF membranes. The membranes were blocked for more than 1 h in PBS containing 2% nonfat milk and 0.25% Tween-20 and then immunoblotted using anti-HCV core monoclonal antibody (1:500, Santa Cruz). Immunoreactive bands were detected using horseradish-peroxidase-conjugated secondary antibodies (1:1000) in conjunction with an enhanced chemiluminescent system.

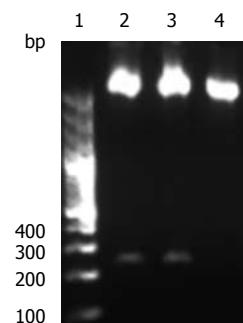

### Promoter cloning and luciferase assay

Template genomic DNA was extracted from human whole blood using DNAzol BD reagent (Invitrogen). The *OAS1* promoter sequence (-157 to +82) was amplified by PCR from the genomic DNA. The primers incorporating *Sac*I and *Hind*III restriction sites were: 5'-CCGAGCTCGGGATCAGGGAGTGT-3' (forward) and 5'-CCCAAGCTTGATCGGGAACACG-3' (reverse). The PCR fragment was digested and cloned into the *Sac*I / *Hind*III sites of pGL3-basic vector (Promega) to generate pGL3-OAS-Luci. Negative and positive control constructs were pGL3-basic lacking any promoter sequence, and pGL3-promoter containing the SV40 promoter sequence.

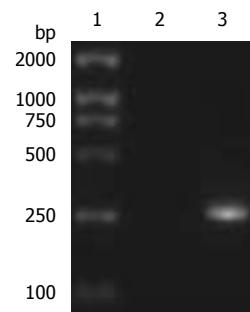

These luciferase reporter plasmids were transiently transfected into L02/core and L02 cells using Lipofectamine 2000 (Invitrogen). The cells were harvested 48 h after the transfection. Luciferase assays were performed according to the manufacturer's protocols (Promega). Briefly, cells were lysed with reporter lysis buffer, and the luciferase activity was determined using a luminometer. A β-galactosidase expression plasmid (pSV-β-galactosidase; Promega) was co-transfected to allow normalization for transfection efficiency. All experiments were performed at least three times in each plasmid and represent the relative luciferase activity as average.

**Figure 2 PCR product of OAS promoter.** A 240 bp visible fragment consistent with the predicted size was observed by electrophoresis. 1: DL2000 marker; 2: Negative control; 3: PCR product.

**Figure 4 Transcriptional activity of the OAS promoter in L02 and L02/core cells.** The OAS promoter showed significant transcriptional activity in the presence of HCV-core protein (L02/core), but not in the normal liver cells (L02). The data shown are the mean ± SD from three independent experiments.

#### Transcriptional activity of OAS promoter in HCV-core positive or negative cells

The *OAS* promoter sequence was amplified by PCR from human genomic DNA. As shown in Figure 2, a 240 bp visible fragment consistent with the predicted size was obtained by electrophoresis. Sequencing analysis confirmed that the cloned gene was identical with the original sequence in GenBank (accession number NW\_925395). The *OAS* promoter was put upstream of the firefly luciferase gene in the pGL3-basic vector which lacks eukaryotic promoter and enhancer sequences. The resultant pGL3-OAS-Luci plasmid was confirmed by double enzyme digestion with *Sac* I and *Hind* III (Figure 3).

To examine the transcriptional activity of the *OAS* gene promoter, the pGL3-OAS-Luci was transiently transfected into L02/core and L02 cells, and the firefly luciferase activity obtained was compared with those from the pGL3-basic and pGL3-promoter plasmid. As shown in Figure 4, the pGL3-OAS-Luci construct exhibited significantly higher transcriptional activity in the presence of HCV-core protein (L02/core). The relative luciferase activity was almost 1.2 fold of pGL3-Promoter, and 10-15 fold of the baseline activity of the pGL3-basic vector. In contrast, this *OAS* promoter construct resulted in no or little luciferase activity in the normal liver cell line L02. These findings suggest that HCV-core protein strongly activates the *OAS* gene promoter.

## Statistical analysis

All data are shown as the mean ± SD. Statistical analysis was performed using the *t* test. *P* < 0.05 was considered statistically significant.

## RESULTS

### HCV-core expression in stably transfected L02 cells

In order to investigate the effect of HCV-core on the *OAS* promoter, L02 cells were transfected with pcDNA3.1-core plasmid and were selected on the basis of their resistance to G418 for 2 wk. Expression of HCV-core was detected by RT-PCR and Western blotting. As shown in Figure 1A, 572 bp visible fragments, consistent with the predicted size of HCV-core mRNA, were detected in L02/core cell clones. No PCR-amplification product was found in the pcDNA3.1 transfected L02 cells, neither in the nontransfected L02 cells. The expression of HCV-core protein was confirmed by immunoblotting using anti-HCV core monoclonal antibody. As shown in Figure 1B, HCV-core protein of the expected molecular mass of 21 kDa was observed in L02/core cells, whereas no expression was detected in pcDNA3.1 transfected or nontransfected L02 cells. These data demonstrate that hepatocyte line stably expressing HCV-core protein has been established.

## DISCUSSION

To increase the specificity and safety of gene therapy, the expression of the therapeutic gene need to be tightly controlled within the target tissue. This is particularly important for toxic gene strategies because inappropriate transgene expression may lead to severe toxicity. Targeted expression of therapeutic genes can be accomplished at several levels. The first approach for targeting specificity is at the level of vector delivery<sup>[17]</sup>. The strategies include exploiting natural viral tropisms, and incorporating tissue-specific ligands or monoclonal antibodies onto the surface of viral vectors or liposomes. However, there will undoubtedly be some genes delivered to local and distant normal tissues. Therefore, further safeguards must be put in place to ensure that gene delivery to these tissues does not result in significant expression and toxicity. One attractive approach to this problem is to use promoter elements to control gene expression tightly at the transcriptional level.

Many tissue and tumor specific promoters have been developed in target gene therapy. For example, the  $\alpha$ -fetoprotein promoter has been used to drive gene expression in hepatic carcinoma cells, the tyrosinase promoter in melanoma cells, the prostate specific antigen promoter in prostate cancer cells, and the carcinoembryonic antigen promoter in adenocarcinomas<sup>[18]</sup>. The results of these studies have demonstrated the feasibility of using specific promoters for targeting gene therapy in various cancer cell types.

Although several promoters have been identified more active in HCV-core positive hepatocytes, most of these promoters are much weaker than commonly used viral promoters such as the CMV early promoter, the Rous sarcoma virus long terminal repeat, and the SV40 early promoter. Consequently, their applications in gene therapy are hampered by the low expression. In the present study, we cloned the human *OAS* promoter and examined its transcriptional ability in the HCV-core positive hepatocytes and normal liver cells. We found that the luciferase expression driven by *OAS* promoter was markedly increased in the presence of core protein, but not in the normal liver cells. These data strongly suggest that HCV-core protein can activate *OAS* promoter. Since HCV-core protein plays an important role in persistent infection and hepatocellular carcinogenesis, and amino acid sequence of core protein is relatively conserved, utilization of the *OAS* promoter to drive therapeutic gene expression would be an ideal strategy for developing HCV-specific gene therapy.

## COMMENTS

### Background

The current standard therapy for chronic hepatitis C is inadequate for the majority of patients. Gene therapy has emerged as a novel approach to combat hepatitis C virus (HCV) infection in the last few years. However, a specific promoter is required to restrict transgene expression only in HCV infected cells. Since HCV-core protein plays an important role in persistent infection

and hepatocellular carcinogenesis, and amino acid sequence of core protein is relatively conserved, utilization of a promoter that is predominantly active in HCV-core positive hepatocytes would be an ideal strategy for HCV targeting gene therapy.

### Research frontiers

To increase the specificity and safety of gene therapy, the expression of the therapeutic gene need to be tightly controlled within the target tissue. This is particularly important for toxic gene strategies because inappropriate transgene expression may lead to severe toxicity. Targeted expression of therapeutic genes can be accomplished at several levels, including vector targeting and tissue-specific gene expression. However, no HCV-specific gene delivery system has yet been developed. One attractive approach to this problem is to use promoter elements to control gene expression tightly at the transcriptional level.

### Innovations and breakthroughs

In the present study, the authors cloned the 2'-5'oligoadenylate synthetase (*OAS*) promoter and examined its activity in the human embryo hepatocytes expressing HCV-core *in vitro*. They demonstrated that HCV-core protein can activate *OAS* gene promoter specifically and effectively.

### Applications

Utilization of *OAS* gene promoter to drive therapeutic gene expression would be an ideal strategy for developing HCV-specific gene therapy.

### Terminology

L02/core is the human embryo hepatocyte that stably expresses HCV-core protein. *OAS* is a metabolic enzyme originally identified as a regulator of the ribonuclease L (RNase L) pathway during viral infection.

### Peer review

This is a well written and interesting paper.

## Abstract

**AIM:** To compare postoperative quality of life (QOL) in patients with gastric cancer treated by esophagogastrectomy reconstruction after proximal gastrectomy.

**METHODS:** QOL assessments that included functional outcomes (a 24-item survey about treatment-specific symptoms) and health perception (Spitzer QOL Index) were performed in 149 patients with gastric cancer in the upper third of the stomach, who had received proximal gastrectomy with additional esophagogastrectomy.

**RESULTS:** Fifty-four patients underwent reconstruction by esophagogastric anterior wall end-to-side anastomosis combined with pyloroplasty (EA group); 45 patients had reconstruction by esophagogastric posterior wall end-to-side anastomosis (EP group); and 50 patients had reconstruction by esophagogastric end-to-end anastomosis (EE group). The EA group showed the best postoperative QOL, such as recovery of body weight, less discomfort after meals, and less heart burn or belching at 6 and 24 mo postoperatively. However, the survival rates, surgical results and Spitzer QOL index were similar among the three groups.

**CONCLUSION:** Postoperative QOL was better in the EA than EP or EE group. To improve QOL after

proximal gastrectomy for upper third gastric cancer, the EA procedure using a stapler is safe and feasible for esophagogastrectomy.

Zhang H, Sun Z, Xu HM, Shan JX, Wang SB, Chen JQ. Improved quality of life in patients with gastric cancer after esophagogastrectomy reconstruction. *World J Gastroenterol* 2009; 15(25): 3183-3190 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3183.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3183>

## INTRODUCTION

Although the incidence of gastric carcinoma has been decreasing continuously during the past decade, gastric cancer remains the second most common cause of cancer-related deaths worldwide. Given equivalent results with regards to survival, the impact of anastomotic methods on quality of life (QOL) becomes even more important. It has been reported that QOL is the main outcome for judging the efficacy of treatment modalities when no overall survival differences are demonstrated<sup>[1]</sup>. There is still no consensus on how to choose a reconstruction method for proximal gastrectomy in patients with upper third gastric cancer<sup>[2]</sup>. This study was designed to compare in detail different types of esophagogastrectomy.

Proximal gastrectomy impacts severely on physical and mental health, and has highly negative consequences for QOL at 6 and 24 mo. Although postoperative QOL has been shown to be important in the surgical literature<sup>[3]</sup>, there have only been a few studies on QOL in patients after proximal gastrectomy. For patients undergoing oncological surgery, QOL is generally accepted as an important outcome parameter, in addition to long-term survival, mortality, and complication rates. In order to provide patients with improved postoperative

QOL, many surgeons seek the optimal surgical methods. Compared with total gastrectomy, the advantages of proximal gastrectomy were shorter operation times, less blood loss and convenience of procedure<sup>[4]</sup>. No previous studies have assessed different types of esophagogastrectomy in terms of QOL.

The aim of this study was to assess outcome in terms of QOL in patients after proximal gastrectomy, by comparing three types of esophagogastrectomy, in order to find the optimal reconstruction method that offers the optimal postoperative QOL at 6 and 24 mo.

## MATERIALS AND METHODS

### **Patients**

Between January 2002 and December 2005, 195 patients with proximal gastric cancer were treated at the Department of Surgical Oncology, First Affiliated Hospital of China Medical University, Shenyang, China. Only 149 patients who were in the present prospective randomized study met the following study criteria: (1) underwent curative resection with lymph node dissection; (2) had no history of other organ malignancies; and (3) had more than 15 lymph nodes retrieved and confirmed by a specialist pathologist. The exclusion criteria included: (1) age > 80 years; (2) renal, pulmonary, or heart failure; (3) undergoing palliative surgery; (4) tumor recurrence during the survey; (5) preoperative or postoperative adjuvant chemotherapy or radiotherapy; and (6) albumin level < 3.5 g/dL and a lymphocyte count lower than 1000 lymphocytes/mm<sup>3</sup> in peripheral blood.

### **Surgical procedure**

The standard surgical procedure and extent of lymph node dissection were defined according to the recommendations of the Japanese Research Society for the Study of Gastric Cancer<sup>[5]</sup>. All patients were treated with stapler suture for digestive tract reconstruction after malignancy removal during the primary surgical procedure. Esophagogastrectomy was performed by using a mechanical stapler (Ethicon Endo-Surgery, USA). In addition, a row of external seromuscular sutures with interrupted absorbable stitches was also performed.

### **Esophagogastrectomy procedure and randomization**

All patients underwent esophagogastrectomy with curative intent and were randomized using a table of random numbers into three groups. To perform esophagogastric anterior wall end-to-side anastomosis combined with pyloroplasty (EA procedure), the anastomosis should be 2-3 cm under the gastric incision line, to guarantee the blood supply of the anastomosis. The stapler inserted into the remnant stomach through the gastric antrum and the center rod of the circular stapler was pierced through the center of the anterior wall, and during this stapling, an ischemic area is not created at all. The esophagus was then anastomosed to the anterior wall in the center of the remnant stomach.

A 3-4 mm wide serosal surface of the anterior wall of the remnant stomach strapped the esophagus circularly. After completion of esophagogastrectomy, the left end of the gastric stump was fixed to the diaphragm. Furthermore, the pyloroplasty was done in the standard manner with interrupted sutures<sup>[6-8]</sup>. To perform esophagogastric posterior wall end-to-side anastomosis (EP procedure), the stapler that was inserted into the remnant stomach through the anterior wall, and the center rod of the circular stapler was pierced through the center of the posterior wall. To perform esophagogastric end-to-end anastomosis (EE procedure), the center rod of the circular stapler was pierced through the left end of the staple line of the stomach.

### **Evaluation of QOL and follow-up study**

Functional outcome was assessed using a 24-item survey designed to assess treatment-specific symptoms, largely gastrointestinal function<sup>[9]</sup>. The questions were scaled according to the Eastern Cooperative Oncology Group<sup>[10]</sup>. The Spitzer QOL index, which reflects the patient's postoperative health perception<sup>[11]</sup>, is a global health assessment with a valid questionnaire that includes five items rated on a three-point scale: activity, daily living, health, support of family and friends, and outlook. The answers were analyzed in a quantitative fashion using a scoring system: the scores ranged from 0 (unsatisfactory result with severe symptoms) to 2 (excellent result with no symptoms); low scores reflected more symptoms. Questionnaires were administered at 6 and 24 mo postoperatively and annually thereafter until tumor recurrence. Average scores were calculated for each question. The Ethics Committee approved the study protocol and informed consent was obtained from each patient. Patients were closely followed after surgery until December 2007. The median follow-up duration was 42.5 mo (range, 9-67 mo). At the time of the last follow-up, 115 patients (77.2%) were alive, no patient was lost to follow-up, and 34 (22.8%) had died from recurrence or other causes.

### **Statistical analysis**

All statistical analyses were performed using Statistical Package for Social Science software for Windows version 13.0 (SPSS, Chicago, IL, USA). Data were expressed as mean  $\pm$  SD. Categorical data were compared using the Kruskal-Wallis test, Mann-Whitney U test, analysis of variance and  $\chi^2$  test.  $P < 0.05$  was considered as statistically significant. For calculation of survival rate, the Kaplan-Meier method was used, and compared using the log-rank test.

## RESULTS

### **Patient characteristics**

Table 1 summarizes clinicopathological factors in relation to the three groups. There were 95 (65%) male and 54 (35%) female patients, with a mean age of 61.5  $\pm$  6.5 years. There were no significant differences in the

**Table 1** Clinicopathological factors of the three groups

Clinicopathological factors	EA group (54)	EP group (45)	EE group (50)	P
Age (yr)	62.5 ± 5.4	56.6 ± 7.6	65.1 ± 8.6	0.668
Gender				0.775
Male	36	29	30	
Female	18	16	20	
Tumor size (cm)	4.6 ± 1.6	5.0 ± 1.7	4.8 ± 1.3	0.963
Histological type				0.993
Well-differentiated	18	15	17	
Moderately differentiated	20	17	19	
Poorly differentiated	10	9	8

IIIb	5	5	3	

clinicopathological features such as sex, age, tumor size, histological type, Lauren's classification, lymph node status, or lymphovascular invasion among the three groups.

### Overall survival rate and surgical results

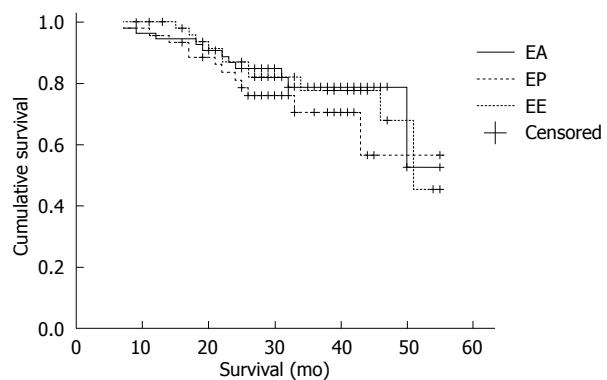

The survival time was defined as the time from diagnosis until last contact, date of death, or the date used as a cutoff for the follow-up database, in which case the survival information was censored. The 2-year survival rate was 79.6%, 73.3% and 78.0% for the EA, EP and the EE group, respectively. The survival rates were similar in all treatment groups ( $P = 0.713$ , Figure 1). The surgical results did not differ among the three groups (Table 2).

### Six months postoperative QOL evaluation

The evaluation scores for eating time were 1.83, 1.58 and 1.42 in EA, EP and the EE groups, respectively. The EA group had a significantly shorter eating time than the EP group (1.83 vs 1.58,  $P = 0.005$ ) and the EE group (1.83 vs 1.42,  $P = 0.000$ ).

The evaluation scores for dietary volume were 1.20, 0.60 and 0.58 in the EA, EP and the EE groups, respectively. The EA group had a significantly better dietary volume than the EP group (1.20 vs 0.60,  $P = 0.000$ ) and the EE group (1.20 vs 0.58,  $P = 0.000$ ).

The evaluation scores for heartburn or belching were 1.37, 0.73 and 0.80 in the EA, EP and the EE groups, respectively. The EA group had significantly less heartburn or belching than the EP group (1.37 vs 0.73,  $P = 0.000$ ) and the EE group (1.37 vs 0.80,  $P = 0.000$ ) (Table 3).

**Figure 1** Kaplan-Meier survival curves for EA, EP and EE patients ( $P = 0.713$ ) (Censored indicate patients who were still alive at follow up).

Most parameters tended to be normalized sooner after surgery in the EA group.

### Twenty-four months postoperative QOL evaluation

The evaluation scores for body weight were 1.48, 1.13 and 1.14 in the EA, EP and the EE groups, respectively. The EA group had significantly better body weight recovery than the EP group (1.48 vs 1.13,  $P = 0.005$ ) and the EE group (1.48 vs 1.14,  $P = 0.030$ ).

The evaluation scores for heartburn or belching were 1.78, 1.73 and 1.38 in the EA, EP and the EE groups, respectively. The EA group (1.78 vs 1.38,  $P = 0.005$ ) and the EP group (1.73 vs 1.38,  $P = 0.023$ ) had significantly less heartburn or belching than the EE group.

The evaluation scores for postprandial discomfort were 1.69, 1.07 and 1.22 in the EA, EP and the EE groups, respectively. The EA group showed less postprandial discomfort than the EP group (1.69 vs 1.07,  $P = 0.000$ ) and the EE group (1.69 vs 1.22,  $P = 0.001$ ) (Table 4).

### Comparison of evaluation scores of postoperative QOL between 6 and 24 mo in the same group

When the QOL scores between 6 and 24 mo were compared in the same group, the frequency of eating, food consistency, food volume, body weight, appetite, and heartburn or belching at 24 mo were all improved significantly in each group compared with at 6 mo. The eating time at 24 mo was significantly shorter than at 6 mo in the EP and EE group (EP,  $P = 0.031$  and EE,  $P = 0.000$ ). The postprandial discomfort at 6 mo was significantly less than at 24 mo in the EE group ( $P = 0.048$ ). Wound pain at 24 mo was significantly less than at 6 mo in the EA group ( $P = 0.031$ ).

It can be seen that, as postoperative time progresses, most symptoms improved, especially in terms eating frequency, food consistency, food volume, body weight, appetite, and heartburn or belching, and the total scores at 24 mo were all improved significantly compared with at 6 mo in the EA ( $P = 0.015$ ), EP ( $P = 0.007$ ) and EE ( $P = 0.011$ ) groups (Table 5).

### Spitzer index evaluation

The data from the Spitzer index (Tables 6 and 7) showed

<sup>a</sup>P < 0.05.

that after all the postoperative and oncological problems were solved, proximal gastrectomy was quite compatible with normal life. From the results of Spitzer index evaluation, we also concluded that patients after proximal gastrectomy may have a nearly normal life with activity and daily living at 6 and 24 mo.

## DISCUSSION

The choice of reconstruction method after proximal gastrectomy remains a controversial issue. Previously, several studies have found no difference in the 5-year

survival among patients with proximal gastrectomy and those with total gastrectomy<sup>[6,7]</sup>. Proximal gastrectomy for early gastric cancer in the upper third of the stomach is an appropriate operation in terms of radical treatment and safety. Proximal gastrectomy was introduced to improve performance status of patients and minimize late postoperative complications such as reflux esophagitis<sup>[8,12-15]</sup>.

It is well known that moderate malnutrition is often associated with gastric cancer surgery<sup>[16]</sup>, and that esophagogastrectomy reconstruction is more favorable to the natural food passage of the duodenum

than esophagojejunostomy. It has been shown that independent prognostic factors such as ensuring radical cure, maintaining food passage in the duodenum, and less excision of the stomach, are very important for postoperative QOL<sup>[17,18]</sup>. A high incidence of

reflux symptoms after simple esophagogastronomy has prompted the development of several novel reconstructions to prevent reflux<sup>[12,19-21]</sup>. Previous reports have shown that proximal gastrectomy is more likely to produce complications such as heartburn and poor

appetite, and worsen nutritional status compared to other types of gastrectomy<sup>[22]</sup>. To prevent or minimize postgastrectomy complications, proximal gastrectomy with an interposed jejunal pouch has been advocated as an organ-preserving strategy to improve QOL<sup>[13,23-25]</sup>. However, there some studies have shown that patients with an interposed jejunal pouch need a second operation because of food stasis or disordered gastric emptying, and the length of the jejunal pouch is still under discussion<sup>[26-28]</sup>.

To avoid postoperative symptoms, there is no consensus on the need for pyloroplasty after proximal gastrectomy. Our study suggested that pyloroplasty improved gastric emptying and decreased stomach stasis. Other studies have shown that pyloroplasty might significantly relieve gastric distention and speed up gastric emptying<sup>[29,30]</sup>. Our data showed that most patients suffered from heartburn and postprandial abdominal fullness after proximal gastrectomy. However, patients in the EA group showed significantly less heartburn and postprandial abdominal fullness compared to the other groups. Pyloroplasty as a draining procedure helps the patient have fewer complications such as gastric distention, nausea and vomiting, and promotes faster gastric emptying<sup>[31]</sup>. Patients with pyloroplasty may recover 80% of the dietary volume in the short term after surgery. In addition, our study found that pyloroplasty also helped to recover or improve body weight in the long term, postoperatively. Our study suggested that patients treated with an EA procedure had a better QOL than the other groups, however, this was correlated with pyloroplasty and promoted gastric emptying to some extent.

The EA procedure decreased the postoperative reflux symptoms in the long term. This simple and

safe technique does not result in postgastrectomy syndrome. The mortality rate was zero and the absence of early postoperative complications highlighted the safety of this procedure. Thus, proximal gastrectomy reconstruction by EA provided excellent clinical results in patients with proximal gastric cancer.

After proximal gastrectomy, body weight decreased (approximately 5-10 kg) below baseline after the first few postoperative months, and later, the weight stabilized if there were no tumor recurrence, and recovered slowly almost to baseline. Our study showed that even 2 years postoperatively, the EA group showed a significantly better recovered or improved body weight than the other groups. Seven patients in the EA group recovered 100%, and more than two-thirds of patients maintained at least 85% of baseline weight 2 years after surgery. In summary, the EA procedure benefited the patients with upper third gastric cancer in terms of body weight.

Some patients after proximal gastrectomy suffered from reduced meal size, due to microgastrria. To avoid microgastrria, the esophagogastrostomy performed by the EE procedure may help to maintain the longest distance from the pylorus to the anastomotic stoma. The center rod of the circular stapler is pierced through the left end of the staple line of the stomach. The longest distance from the pylorus to the esophagogastrostomy site can be found in this position. The longer distance will reduce microgastrria and also decrease the tension of the stoma.

There were some limitations in our study. Firstly, the patients were not at the same stage in terms of their gastric cancer; 32.2% were early stage patients. Although QOL in the EA group was better than in the other two groups, whether QOL in the EA group is better than that for other reconstruction methods, or if it reaches

the threshold of normal QOL requires further study. Whether QOL in the EA group will remain improved after long-term follow-up (5-year or longer) requires further research.

The clinical implications of this study showed that the EA procedure seems to confer clinical benefit in terms of postoperative QOL, especially in the form of improved meal intake, reduced gastroesophageal reflux, and improved body weight, however, overall survival rate and surgical results are the same using all three procedures. Our data suggest that, to avoid gastroesophageal reflux and improve QOL in patients with upper third gastric cancer after proximal gastrectomy, the EA procedure for reconstruction using a stapler is safe and feasible for esophagogastrectomy. However, better reconstruction methods are still required to decrease postoperative symptoms in the future.

## COMMENTS

### Background

Given equivalent results with regards to survival, the impact of anastomotic methods on quality of life (QOL) becomes even more important. QOL is the main outcome for judging the efficacy of treatment modalities when no overall survival differences are demonstrated.

### Research frontiers

There is still no consensus on how to choose a reconstruction method for proximal gastrectomy in patients with upper third gastric cancer. This study was designed to compare in detail different methods of esophagogastrectomy.

### Innovations and breakthroughs

No previous studies have assessed different methods of esophagogastrectomy in terms of QOL. The aim of this study was to assess outcome in terms of QOL in patients after proximal gastrectomy, by comparing three methods of esophagogastrectomy, in order to find the optimal reconstruction method that offers the optimal postoperative QOL.

### Applications

The clinical implications of this study showed that the anterior wall end-to-side anastomosis combined with pyloroplasty (EA) procedure seems to confer clinical benefit in terms of postoperative QOL, especially in the form of improved meal intake, reduced gastroesophageal reflux, and improved body weight.

### Terminology

The Spitzer QOL Index, which reflects the patient's postoperative status of health perception, is a global health assessment with a valid questionnaire, which includes five items: activity, daily living, health, support of family and friends, and outlook.

### Peer review

The authors evaluated postoperative QOL in patients with upper third gastric cancer, who received proximal gastrectomy with additional esophagogastrectomy. The results suggest that to avoid gastroesophageal reflux and improve QOL for patients with upper third gastric cancer after proximal gastrectomy, the EA procedure of reconstruction using a stapler is safe and feasible for esophagogastrectomy.

### INTRODUCTION

Primary aortoenteric fistula is an extremely rare but potentially fatal cause of gastrointestinal bleeding. We present the case of a 49-year-old man with no past history of abdominal aortic aneurysm, who presented with recurrent gastrointestinal bleeding.

### CASE REPORT

A 49-year-old man was admitted to the emergency room with clinical signs of gastrointestinal bleeding (massive hematemesis, tachycardia of 140 bpm, and blood pressure of 70/40 mmHg). His hemoglobin was 5.5 g/dL. The patient was resuscitated with intravenous fluids and transfusion of 4 U of packed red blood cells. His medical history included multiple sclerosis with minimal neurological deficit, which was treated with Copaxone and Novitropan. He had had no previous surgery or peptic ulcer disease.

An initial evaluation with upper endoscopy and colonoscopy presented as normal. Twenty-four hours later, the patient had recurrent bleeding and required a transfusion of an additional 2 U of packed red blood cells. Repeated upper endoscopy showed blood in the stomach and duodenum, but no source of bleeding could be found. The patient was taken to the angiography suite, where flash aortography and visceral angiography showed no active extravasation of contrast material.

The left gastric artery was embolized empirically with fibered platinum coils, which was tolerated well by the patient. Blood pressure began to normalize immediately after embolization, and the patient's condition stabilized. To evaluate the source of bleeding, he underwent CT examination and capsule endoscopy, which appeared to be normal.

Technetium-99m-red blood cell scintigraphy was used to identify the site of bleeding during the next short episode of hematochezia, but it was inconclusive for bleeding. On a subsequent occasion, the patient displayed an episode of fresh blood in a nasogastric tube. Upper endoscopy (session four) revealed multiple gastric erosions. The patient became unstable with clinical

### Abstract

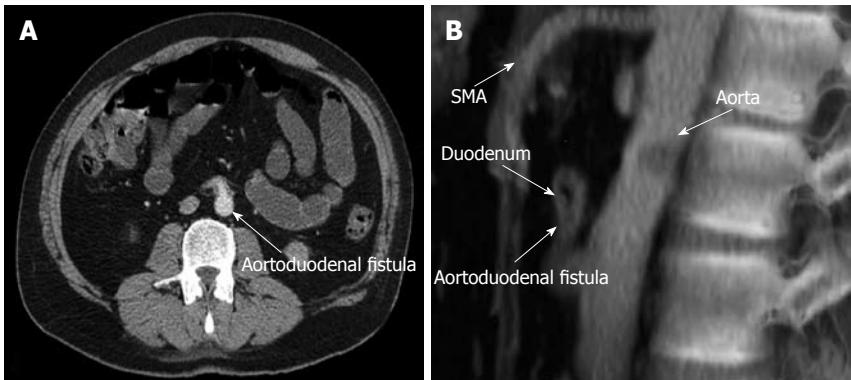

A diagnosis of primary aortoenteric fistula is difficult to make despite a high level of clinical suspicion. It should be considered in any elderly patient who presents with upper gastrointestinal bleeding in the context of a known abdominal aortic aneurysm. We present the case of young man with no history of abdominal aortic aneurysm who presented with massive upper gastrointestinal bleeding. Initial misdiagnosis led to a delay in treatment and the patient succumbing to the illness. This case is unique in that the fistula formed as a result of complex atherosclerotic disease of the abdominal aorta, and not from an aneurysm.

**Figure 1 CT and lateral aortography.** A: CT showing direct extravasation of contrast material from the aorta into the duodenal lumen (arrow); B: Lateral aortography showing aortoduodenal fistula. Note there is no evidence of abdominal aneurysm.

**Figure 2 Perioperative findings of primary fistula between the third part of the duodenum and aorta.** A Foley catheter was inserted to control the bleeding.

signs of ongoing bleeding. Exploratory laparotomy and gastrotomy were performed with undersuturing of acute gastric ulcers (most were located in the fundus). Intraoperative endoscopy showed no other site of bleeding throughout the stomach, duodenum and 1.5 m of proximal small intestine. Twenty-four hours perioperatively, the patient received 10 red packed cells and other blood supplements and high-dose omeprazole (Omeprazole infusion of 8 mg/h for 72 h, following 40 mg of omeprazole orally per day). The recovery was uneventful and 8 d after surgery, the patient was observed in the regular ward.

Ten days postoperatively, the patient had another episode of bleeding accompanied by syncope with hematochezia and hematemesis. Since he had been receiving fluid resuscitation, blood pressure was undetectable. The patient underwent full cardiopulmonary resuscitation (CPR) and was sent to the operating theater. Repeated angiography and CT revealed an aortoduodenal fistula that had not been detected 3 wk previously (Figure 1).

Exploratory laparotomy was performed and the aortoduodenal fistula was found between the anterior wall of the aorta and the third part of the duodenum. The bowel was full of fresh blood. The fistula was disconnected and a Foley catheter was inserted into the aorta to control the bleeding (Figure 2). This occurred whilst the patient was in prolonged CPR, with a clamp on the descending aorta through left thoracotomy. After 2 h resuscitation in the operating theater, the patient

developed disseminated intravascular coagulation and developed bradycardia and acidosis. His blood pressure and urine output dropped drastically and he died on the operating table from irreversible hemorrhagic shock.

Pathological examination of periaortic tissue revealed non-specific inflammation in the connective tissue, fibrin and blood cells. No postmortem examination was performed.

## DISCUSSION

The diagnosis and treatment of aortoenteric fistulas are difficult. Nevertheless, in a patient with hematemesis and melena who has undergone an aortobifemoral bypass or aortic interposition grafting without esophagogastro-duodenal pathology, a diagnosis of aortoenteric fistula should not be overlooked<sup>[1]</sup>. Primary aortoduodenal fistulas are nearly always associated with abdominal aortic aneurysm, mostly atherosclerotic. In the present clinical case, the available clinical, instrumental and radiological supports made such a diagnosis feasible.

The penetrating aortic ulcer has been recognized recently as an independent pathological entity. It may penetrate through the aortic wall, which leads to fistulas into adjacent organs. Certik *et al*<sup>[2]</sup> have reported the case of a 78-year-old woman who was admitted to hospital with massive gastrointestinal hemorrhage. Endoscopy did not reveal the cause of hemorrhage. The diagnosis was made by CT that showed a primary aortoduodenal fistula without aortic aneurysm, and the patient underwent a successful operation. During urgent surgery, the penetrating atherosclerotic ulcer was found to be the cause of the aortoduodenal communication.

The classic presentation of an aortoduodenal fistula is that of a "herald bleed" (brief, with spontaneous resolution), followed anywhere from hours to weeks later by a massive upper gastrointestinal bleed. A high index of suspicion and rapid diagnosis is imperative as exsanguinating hemorrhage may occur. An aortoduodenal fistula or erosion is rarely seen endoscopically<sup>[3]</sup>. Endoscopy may disclose another cause of bleeding, as was discovered in our patient. Therefore, normal findings, a positive finding of gastritis or ulcers without active bleeding do not rule out aortoduodenal fistula. Careful inspection of the distal duodenum should be performed in the setting of unexplained torrential bleeding. More commonly, fresh blood or clots may be found in the third portion of the duodenum.

CT with contrast is the most suitable diagnostic test and provides a reported detection rate of 30%-61%<sup>[4-6]</sup>. CT may show the abnormal communication between the aorta and the intestine. Angiography is seldom a helpful procedure, unless a pseudoaneurysm is seen<sup>[7]</sup>, and the diagnosis is usually made or confirmed by laparotomy. Surgical repair is the only therapeutic option.

In summary, a diagnosis of primary aortoenteric fistula should be considered in any patient known to have abdominal aortic aneurysm or lower abdominal pain associated with midline mass and upper gastrointestinal bleeding of unexplained etiology. A herald bleed is an indication for prompt intervention. Endoscopy is the first step in diagnosis, and CT may be used for confirmation. An emergency exploratory laparotomy should be performed as soon as the diagnosis is considered.

Pentoxifylline: A first line treatment option for severe alcoholic hepatitis and hepatorenal syndrome? *World J Gastroenterol* 2009; 15(25): 3194-3195 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3194.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3194>

### Abstract

Although favourable results of pentoxifylline (PTX) used in treatment of severe alcoholic hepatitis patients with a Maddrey discriminant function score  $\geq 32$  have been previously reported, it is not currently recommended as a first line treatment for alcoholic hepatitis owing to lack of evidence for its efficacy as compared to the standard treatment with corticosteroids. In a very recent issue of *World Journal of Gastroenterology*, Dr. De BK and colleagues compared for the first time the two treatment modalities head to head in a randomized controlled study, demonstrating the advantage of PTX over corticosteroids in terms of patients' survival and risk-benefit profile. The advantage of PTX over corticosteroids in survival of patients with severe alcoholic hepatitis was found to be related to the prevention of hepatorenal syndrome in their study. This study raises the question of the use of PTX as a standard treatment for severe alcoholic hepatitis. Considering the fact that PTX presented a spectacular efficiency in prevention of hepatorenal syndrome in their study as well as that previous studies have shown that this effect is possibly related to a primary renoprotective action because it is irrelevant of tumor necrosis factor- $\alpha$  synthesis inhibition or improved liver function, we tempted to speculate that PTX might be an effective option for prevention and/or treatment of hepatorenal syndrome complicating other forms of advanced liver disease. This attractive theory remains to be elucidated by pressing future studies in view of the lack of effective treatment modalities for hepatorenal syndrome.

### TO THE EDITOR

We read with great interest the article recently published by Dr. De and colleagues in *World Journal of Gastroenterology*<sup>[1]</sup>, who evaluated in a randomized double-blind controlled study the advantage of pentoxifylline (PTX) over prednisolone in treatment of severe alcoholic hepatitis [Maddrey discriminant function (DF) score  $\geq 32$ ]. The most important observation was the significantly reduced mortality of patients after treatment with PTX (14.71%) as compared to those after treatment with prednisolone (35.29%,  $P = 0.04$ ). Reduced mortality in patients after treatment with PTX was found to be related to a significant reduction in the development of hepatorenal syndrome. Among patients who died, hepatorenal syndrome developed in 50% of prednisolone-treated patients but in none of PTX-treated patients.

Current guidelines of the American College of Gastroenterology recommend the use of glucocorticosteroids in treatment of patients with severe alcoholic hepatitis as defined by the Maddrey score (DF  $\geq 32$ )<sup>[2,3]</sup>. Primary use of PTX in treatment of severe alcoholic hepatitis patients is not recommended due to the lack of evidence for improvement in patient-oriented outcomes<sup>[2]</sup>. Also, the early switch of corticosteroids to PTX, if no improvement in bilirubin is seen after 7 d of treatment, has been proved to be an inefficient treatment strategy<sup>[4]</sup>. However, a number of French experts in the field consider PTX a reasonable alternative to corticosteroids for severe acute alcoholic hepatitis based on the

favourable results of previous studies comparing PTX with placebo<sup>[5,6]</sup>.

Specifically, up to now, the use of PTX in treatment of severe alcoholic hepatitis has been supported by two clinical studies<sup>[5,6]</sup>. The first one was conducted in 1991 by McHutchison *et al*<sup>[5]</sup>, in patients with severe alcoholic hepatitis (defined as DF score  $\geq 32$ ), which showed that PTX could reduce the development of hepatorenal syndrome and the mortality, in comparison to those receiving placebo. These findings were confirmed in 2000 by Akriavidis *et al*<sup>[6]</sup> in a double-blind placebo-controlled trial, which showed that 24% of PTX-treated patients and 46.1% of control patients died during hospitalization. The survival benefit of PTX was found to be related to a significant reduction in the development of hepatorenal syndrome. Among the patients who died, hepatorenal syndrome developed in 50% of PTX-treated patients and in 91.7% of placebo-treated patients. The study by De *et al*<sup>[1]</sup> is the first to compare PTX and corticosteroids head to head in a randomized controlled manner. The results of this study, demonstrating the advantage of PTX over corticosteroids, raise the question of the use of PTX as a standard treatment modality for severe alcoholic hepatitis.

A second issue we would like to comment on is the fact that the advantage of PTX in survival of patients with severe alcoholic hepatitis is clearly related to the prevention of hepatorenal syndrome<sup>[1,5,6]</sup>. The available data do not show the evident mechanism underlying this beneficial effect of PTX and only speculations could be made on this matter. The use of PTX in treatment of alcoholic hepatitis is based on its ability to inhibit the synthesis of tumor necrosis factor (TNF)- $\alpha$ , which is considered a pivotal mediator of alcohol-induced liver injury<sup>[6,7]</sup>. Although the authors did not assess in this study the immunological and inflammatory status (e.g. TNF- $\alpha$ ) of their patients, it has been previously reported that the prevention of hepatorenal syndrome and survival advantage in patients with severe alcoholic hepatitis after treatment with PTX are not associated with decreased circulating TNF- $\alpha$  levels or improved

liver function<sup>[6]</sup>. These findings give an alternative explanation for the positive effect of PTX on renal function of alcoholic hepatitis patients, which is the beneficial action of PTX on renal microcirculation and hemodynamics. This potential primary protective effect of PTX on renal function and its repeatedly confirmed efficacy on prevention of hepatorenal syndrome in severe alcoholic hepatitis patients (in this study, PTX prevented the development of hepatorenal syndrome) tempt us to speculate that it could potentially be used in the prevention and/or treatment of hepatorenal syndrome complicating other forms of advanced liver disease. To the best of our knowledge, this possibility has not been investigated up to now and appears to be an attractive new field for experimental and clinical research, given the current difficulties in the management of patients with hepatorenal syndrome.

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1179 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gasteroesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome, liver biology/pathobiology, liver failure, growth and cancer, liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systematically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Articles: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; (13) Guidelines: To introduce Consensuses and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice in gastroenterology and hepatology.

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjgwjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjgnet.com](mailto:submission@wjgnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive

foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

### Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g.  $6.92 \pm 3.86$  vs  $3.61 \pm 1.67$ ,  $P < 0.001$ ; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, □, ▲, △, etc., in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

## Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub>, not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23243641.

The format for how to accurately write common units and quanta can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first

mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *argI*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

## Editorial Office

### World Journal of Gastroenterology

Editorial Department: Room 903, Building D,  
Ocean International Center,  
No.62 Dongsihuan Zhonglu,  
Chaoyang District, Beijing 100025, China  
Telephone: +86-10-59080039  
Fax: +86-10-85381893  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>

## Language evaluation

The language of a manuscript will be graded before it is sent for revision.  
(1) Grade A: priority publishing; (2) Grade B: minor language polishing;  
(3) Grade C: a great deal of language polishing needed; (4) Grade D:  
rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Volume 15 Number 26 July 14, 2009

### INTRODUCTION

*World Journal of Gastroenterology* is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

### EDITORS FOR THIS ISSUE

Responsible Assistant Editor: *Xiao-Fang Liu*  
Responsible Electronic Editor: *De-Hong Yin*  
Proofing Editor-in-Chief: *Lian-Sheng Ma*

Responsible Science Editor: *Lai-Fu Li*  
Proofing Editorial Office Director: *Jian-Xia Cheng*

#### NAME OF JOURNAL

*World Journal of Gastroenterology*

#### RESPONSIBLE INSTITUTION

Department of Science and Technology of Shanxi Province

#### SPONSOR

Taiyuan Research and Treatment Center for Digestive Diseases, 77 Shuangta Xijie, Taiyuan 030001, Shanxi Province, China

#### EDITING

Editorial Board of *World Journal of Gastroenterology*, Room 903, Building D, Ocean International Center, No.62 Dongsihuan Zhonglu, Chaoyang District, Beijing 100025, China  
Telephone: +86-10-59080039  
Fax: +86-10-85381893  
E-mail: wjg@wjgnet.com

## INTRODUCTION

Anorectal complaints are very common and are caused by a variety of mostly benign anorectal disorders. Many anorectal conditions may be successfully treated by primary care physicians in the outpatient setting, but patients tend not to seek medical attention due to embarrassment or fear of cancer. As a result, patients frequently present with advanced disease after experiencing significant decreases in quality of life. A number of patients with anorectal complaints are referred to gastroenterologists. However, gastroenterologists' knowledge and experience in approaching these conditions may not be sufficient. This article can serve as a guide to gastroenterologists to recognize, evaluate, and manage medically or non-surgically common benign anorectal disorders, and to identify when surgical referrals are most prudent. A review of the current literature is performed to evaluate comprehensive clinical pearls and management guidelines for each topic. Topics reviewed include hemorrhoids, anal fissures, anorectal fistulas and abscesses, and pruritus ani.

## Abstract

Anorectal complaints are very common and are caused by a variety of mostly benign anorectal disorders. Many anorectal conditions may be successfully treated by primary care physicians in the outpatient setting, but patients tend not to seek medical attention due to embarrassment or fear of cancer. As a result, patients frequently present with advanced disease after experiencing significant decreases in quality of life. A number of patients with anorectal complaints are referred to gastroenterologists. However, gastroenterologists' knowledge and experience in approaching these conditions may not be sufficient. This article can serve as a guide to gastroenterologists to recognize, evaluate, and manage medically or non-surgically common benign anorectal disorders, and to identify when surgical referrals are most prudent. A review of the current literature is performed to evaluate comprehensive clinical pearls and management guidelines for each topic. Topics reviewed include hemorrhoids, anal fissures, anorectal fistulas and abscesses, and pruritus ani.

## HEMORRHOIDS

The estimated prevalence rate of symptomatic hemorrhoids in the United States is 4.4% of the adult population; more than one million individuals annually are affected by hemorrhoidal conditions<sup>[1,2]</sup>. Hemorrhoids are cushions of nonpathologic vascular tissue in the anal canal, which microscopically are sinusoids because they do not have any muscle as do veins<sup>[3]</sup>. Hemorrhoidal tissue is thought to contribute to anal continence because 15%-20% of resting anal pressure derives from these cushions. Hemorrhoids may protect the sphincter during defecation, and could operate as plugs to permit the anus to completely close while at rest. Three main cushions are found in the left lateral, the right anterolateral, and the right posterolateral portions of the anal canal. The symptoms of hemorrhoidal disease are caused by pathologic and dilated changes in hemorrhoidal tissue.

## Etiology

Proposed etiologic factors include vascular congestion and mucosal prolapse<sup>[4]</sup>. Vascular congestion could derive from prolonged straining or increased intra-abdominal pressure due to ascites, obesity, or pregnancy. Mucosal prolapse may develop secondary to derangement of the internal sphincter or through aging causing the anatomic structures supporting the muscularis submucosa to weaken, leading to prolapse of the hemorrhoidal tissue<sup>[5]</sup>. Multiple studies have shown elevated anal resting pressure in patients with hemorrhoids<sup>[1,6]</sup>. Whether the elevated resting pressure is caused by or is due to enlarged hemorrhoids is unknown, but resting tone does become normal after a hemorrhoidectomy.

## Symptoms

Patients often self-refer with symptoms of itching, pain, or bleeding per the rectum. To the general population, anything problematic around the anus is suspected to be hemorrhoids. Internal hemorrhoids may prolapse or bleed, but rarely become painful unless they develop thrombosis or necrosis. Thus, anal pain usually suggests other pathology and mandates closer investigation. As many as 20% of patients with hemorrhoids have concomitant anal fissure(s). Usually, painless bright red bleeding that stains the water in the toilet occurs from internal hemorrhoids. This bleeding is arterial, from presinusoidal arterioles, and is mostly associated with bowel movements where the stool is itself brown. If rectal bleeding is not typical for hemorrhoidal bleeding as described, a prompt and thorough medical evaluation is warranted. Thrombosed external hemorrhoids may cause significant pain because the anoderm is richly innervated which is exactly why external hemorrhoids should not be ligated or excised without adequate local anesthetics. Skin tags are often confused with symptomatic hemorrhoids. A skin tag is redundant fibrotic skin at the anal verge, often persisting as the residual of a thrombosed external hemorrhoid. It is important to note that there is no increased risk of cancer in hemorrhoids.

## Classification

Hemorrhoidal conditions are classified according to their location. External hemorrhoids are situated distal to the dentate line and are covered by anoderm that is sensitive to touch, temperature, and stretch because of innervation by somatic nerves. The dentate line is the junction of ectoderm and endoderm, and therefore represents an important mark between two distinct origins of venous and lymphatic drainage, nerve supply, and epithelial lining. Internal hemorrhoids are covered by columnar or transitional epithelium, are located proximal to the dentate line, and are graded based on the degree of the prolapse<sup>[7,8]</sup>. First-degree hemorrhoids may bleed and may bulge into the anal canal and may prolapse beyond the dentate line on straining. Second-degree hemorrhoids prolapse through the anus but spontaneously reduce. Third-degree hemorrhoids

prolapse through the anal canal and require manual reduction. Fourth-degree hemorrhoids prolapse, but are irreducible, and thus are at risk for strangulation. However, most hemorrhoids are a combined type of internal and external hemorrhoids. Prognosis and treatment are mostly based on the classification.

## Diagnosis

Patients who complain of hemorrhoids need a careful evaluation to exclude other conditions. Either the prone or the left lateral decubitus position can be used to evaluate the anal area, although the lateral position is easier for pregnant patients and those patients with severe chronic obstructive pulmonary disease. Digital, anoscopic, and sigmoidoscopic examination are important initial evaluations. A thorough examination of the anorectal area is required. Inspection is performed by gentle retraction of the buttocks. The color or condition of the skin should be examined for findings such as swelling, induration, fissure, draining sinuses, or mass. The sacrococcygeal region and the perianal skin should be examined. Palpation with a lubricated gloved index finger begins at the anal orifice, and then proceeds circumferentially around the anal canal through the lower rectum to identify any abscesses, tumors, or sphincter defects. Also, evaluating resting and/or squeezing anal pressures by asking the patient to squeeze will provide more information on the anal sphincter and the puborectalis muscle. Internal hemorrhoids are generally difficult to palpate unless thrombosed or very large. An anoscopy is done to visualize internal hemorrhoids, which bulge into the lumen of the anoscope when the patient strains. A full examination of the colon with a barium enema or colonoscopy is considered if there are no compatible findings of hemorrhoidal disease, especially in patients older than 40 years.

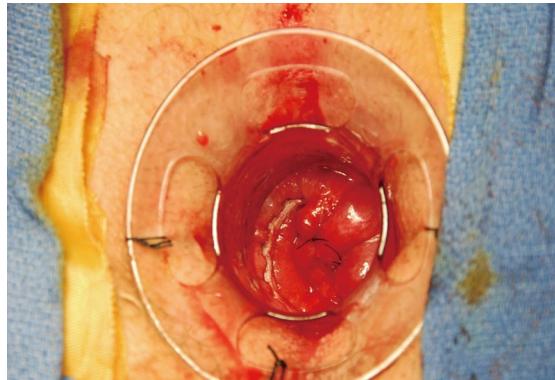

## Treatment

Because hemorrhoids are a normal part of anorectal anatomy, treatment is only indicated if they become symptomatic. However, in the general management of hemorrhoids, colorectal surgeons agree that all painful thrombosed hemorrhoids (Figure 1) should be excised. Some patients present at a time after thrombosis when symptoms have actually begun to subside. Excision is not mandatory in these cases, especially in the absence of erosion or significant tenderness to touch. Initial medical management is recommended for all but the most advanced cases. As a conservative treatment, the almost-universal recommendations are to add dietary fiber<sup>[9]</sup>, avoid straining during defecation, and to utilize sitz baths two to four times a day<sup>[10]</sup>. Although the available evidence to support the benefits of high fiber intake to manage and prevent hemorrhoids is limited, the use of high fiber is commonly recommended in clinical practice. Since fiber consumption can induce problems with abdominal bloating and pain, patients should start at a low dose of the fiber supplement and slowly increase the amount until reaching at least 20-30 g/d. Patients should be educated to

**Figure 1 Thrombosed hemorrhoids.**

drink plenty of water with fiber. Over-the-counter topical agents and suppositories have been used as the empirical treatment and can reduce some hemorrhoidal symptoms, but data supporting their effectiveness are lacking. Hemorrhoids that fail to respond to medical management may be treated with rubber band ligation, sclerosis, and thermotherapy by using infrared beam, electric current, CO<sub>2</sub> laser, or ultrasonic energy. These local techniques induce scarring and fixation of the hemorrhoids to the underlying tissues. These procedures are usually performed in the office setting, do not require anesthesia, and are mostly applied for second degree and some third-degree prolapsed hemorrhoids. Infrared photocoagulation works well on small bleeding hemorrhoids, but is less effective on large or bulky hemorrhoids. Infrared radiation, generated by a tungsten-halogen lamp, creates heat and thus leads to inflammation and later scarring of the tissue. Most authors report only infrequent complications to infrared treatments. Rubber band ligation has been demonstrated to be the most effective method to treat symptomatic internal hemorrhoids that have failed to respond to conservative management<sup>[11-14]</sup>. Controversy exists as to how many hemorrhoidal bundles can be effectively and safely banded at one time<sup>[15]</sup>. Complications associated with this procedure are not frequent (< 2%) and include vasovagal response, anal pain, bleeding from early dislodgment, and pelvic sepsis<sup>[16,17]</sup>. Operative hemorrhoidectomy is reserved for the large third- and fourth-degree hemorrhoids, mixed hemorrhoids with a prominent external component, and incarcerated internal hemorrhoids requiring urgent intervention. The hemorrhoidal tissue is excised, and the mucosal and skin defect may be left open as an open hemorrhoidectomy, may be partially closed, or may be closed with a running suture. Several randomized trials have compared different types of hemorrhoidectomies with a variety of open<sup>[18-20]</sup> and closed techniques with inconsistent results<sup>[20,21]</sup>. Similarly, a variety of techniques have been introduced to reduce postoperative pain. The stapled hemorrhoidopexy, also called Procedure for Prolapse and Hemorrhoids (PPH, Figure 2), is a technique that reduces the prolapse of hemorrhoidal tissue by using an intraluminal circular stapling device to remove a ring of redundant mucosa and submucosa from the upper anal canal, thereby reducing the prolapsing hemorrhoidal tissue back into the anal

**Figure 2 Procedure for prolapsing hemorrhoids (PPH).**

canal and fixing it into position. The hemorrhoidal inflow that transverses the excised segment is also interrupted, thus decreasing vascularity. Compared to conventional hemorrhoidectomy, PPH affects few nerve endings, which results in less post-operative pain. The ultrasonic scalpel hemorrhoidectomy and the bipolar sealing and cutting device have also been reported to produce less postoperative pain than conventional excisional hemorrhoidectomy<sup>[18,19,22,23]</sup>. However, long-term efficacy needs to be determined<sup>[21,24]</sup>.

## ANAL FISSURES

An anal fissure is a cut or split in the epithelial lining of the anal canal distal to the dentate line. A chronic anal fissure is usually categorized when the fissure fails to heal within 6-8 wk. Chronic fissures develop ulceration and heaped-up edges with exposure of the internal anal sphincter fiber at the base of the ulcer. There is often an associated external skin tag and/or an internal hypertrophied anal papilla. The vast majority of anal fissures occur in the posterior midline, while 10% to 15% occur in the anterior midline<sup>[25]</sup> and less than 1% of fissures occur in lateral positions.

### Differential diagnosis

If an anal fissure develops in atypical locations, one must consider other diseases. Crohn's disease is the most common cause of anal fissures associated with atypical locations, although other inflammatory bowel diseases, syphilis, tuberculosis, leukemia, cancer, and human immunodeficiency virus (HIV) are also known causes<sup>[26,27]</sup>.

### Symptoms

Anal fissures are the most common causes of severe anorectal pain. Characteristic symptoms include tearing pain with defecation and hematochezia that is usually present as blood on the toilet paper. Patients may also complain of a sensation of intensely painful anal spasms lasting for several hours after a bowel movement.

### Diagnosis

Anal fissures can be diagnosed through history and physical examination.

**Figure 3** Anal fissure.

**Figure 4** Anal fistula.

Gentle spreading of the buttocks to expose the perianal area may facilitate the examination. The fissure is easily seen in the anal canal (Figure 3). Some patients may experience extreme physical discomfort during examination and may require anesthesia. Digital or anoscopic examination may be poorly tolerated on the initial visit.

### **Pathophysiology**

Although the etiology of this condition is uncertain, the main hypothesis is that the posterior midline area may have decreased blood flow due to the configuration of the vessels of the anus<sup>[28]</sup>. Also, spasm of the internal anal sphincter may cause further reduction in blood flow to the posterior anal canal. Trauma from such factors as hard stools can aggravate the condition, and then eventually cause fissures. Once a tear occurs, it begins a cycle of pain, with increased contraction of the internal anal sphincter, thereby increasing pressure in the anal canal, which results in ischemia<sup>[29]</sup>. This cycle contributes to the development of a poorly healing wound that becomes a chronic fissure. Patients with chronic anal fissures also appear to have increased resting pressure in the anus per anal manometry<sup>[29,30]</sup>.

### **Treatment**

Medical therapy leads to healing in the vast majority of patients with acute anal fissures, and almost half of the patients with chronic fissures<sup>[31]</sup>. Therapy focuses on breaking the cycle of pain, spasm, and ischemia thought responsible for the development of the fissure. Initial conservative measures have consisted of three components: relaxation of the internal sphincter; institution and maintenance of atraumatic passage of stool; and pain relief. These goals can be accomplished with bulk agents and stool softeners, and warm sitz baths following bowel movements to relax the sphincter<sup>[32,33]</sup>. Warm sitz baths (not to exceed 120°F) may ease the acute pain in the anal area. The patient should undergo two to three sitz baths a day, especially after bowel movements, for about 10-15 min each session in a warm bath. After a sitz bath, the anal area should be carefully dried with a towel or a hair dryer with cool air. A significant reduction in anal pressure after soaking in warm water has been reported<sup>[34]</sup>. Based on the theory

that anal fissures are caused by ischemia through a spastic internal sphincter, pharmacological agents including glyceryl trinitrate (GTN)<sup>[35-37]</sup>, diltiazem<sup>[35,38-40]</sup>, and botulinum toxin may be useful. These agents have been employed to reduce the resting anal canal pressure and to improve blood flow, and as an alternative to surgical sphincterotomy for chronic fissures. GTN ointment applied two to four times per day to the anus has been the most extensively studied, resulting in various healing rates and the identification of a major side effect in dose-related headaches<sup>[36]</sup>. A randomized, controlled trial has shown that 0.2% nitroglycerin ointment applied twice daily healed chronic ulcers (68% compared with 8% in the placebo group) with evidence of a reduction in resting anal pressure and an increase in anoderm blood flow after eight weeks of treatment<sup>[37]</sup>. Diltiazem ointment (2%) appears to have similar efficacy to GTN, but may cause fewer side effects (headaches and gastrointestinal side effects) than GTN. Diltiazem maybe associated with the development of pruritus. Both diltiazem and GTN would be first-line therapies, while botulinum toxin is used as rescue treatment<sup>[41-44]</sup>. Botulinum toxin causes temporary muscle paralysis by preventing acetylcholine release from presynaptic nerve terminals, thereby decreasing the pressure in the internal sphincter<sup>[41,45]</sup>. The healing rate of anal fissures ranges from 60%-70% after a single injection of 15 or 20 U of the toxin<sup>[45,46]</sup>. One prospective randomized study showed that botulinum toxin had a better healing rate compared to 0.2% GTN ointment<sup>[47]</sup>. It may be beneficial to repeat the injection of botulinum toxin for patients with recurrent fissures<sup>[48,49]</sup>. There is no conclusion on the optimal dose of the toxin, the number of injections, or the precise site of injection. Despite relatively good efficacy, medical therapy has some limitations with poor compliance, unpleasant side effects, and recurrence of the fissure<sup>[35,43,50,51]</sup>. Surgical treatment is generally reserved for fissures that have failed medical therapy. A recent meta-analysis of four randomized, controlled trials revealed superior fissure healing rates with lateral internal sphincterotomy compared with topical nitroglycerin<sup>[52]</sup>. Lateral internal sphincterotomy is the procedure of choice for the majority of surgeons<sup>[53]</sup>. The aim of this procedure is to decrease spasms of the internal sphincter by dividing a portion of the

muscle. Depending on the preference of the surgeon, approximately 30% of the internal sphincter fibers are divided laterally by using either open or closed techniques. Although healing is achieved in more than 95% of patients and most patients experience immediate pain relief with overall satisfaction, most surgeons are reluctant to use this treatment as first-line therapy for chronic anal fissures due to possible postoperative incontinence. Persistent minor incontinence, which generally does not have a major impact on quality of life, has been reported as occurring in 1.2% to 35% in various studies<sup>[25,52,54-57]</sup>. However, several studies have also demonstrated no significant difference in minor fecal incontinence between sphincterotomy and topical nitroglycerin treatments<sup>[52,58,59]</sup>. A prospective randomized controlled trial with long-term follow-up and a large number of patients will be required to support lateral internal sphincterotomy as a first-line therapy.

## ANAL FISTULAS AND ANAL ABSCESES

“Fistula” means pipe or tube in Latin. An anal fistula is an abnormal connection between two epithelial-lined spaces of the anus and rectum, creating the appearance of a pipe or tube. Anal abscesses and fistulas are the acute and chronic manifestations of the same perirectal pathogenic process. The majority of these conditions originate from infected anal glands. Anal fistulas are classified by Parks and colleagues<sup>[60]</sup>, as intersphincteric, trans-sphincteric, suprasphincteric, and extrasphincteric fistula-in-ano. An in-depth understanding of anorectal anatomy is essential to successfully treat an anorectal abscess or fistula.

### Symptoms

The patient may complain of drainage, bleeding, pain with defecation or sexual activity, swelling, or diarrhea. Fistulas may be related to other diseases such as Crohn’s disease, proctitis, or anorectal cancer.

### Diagnosis

Physical examination may reveal the external opening as a protrusion or an induration, which drains pus. The importance of accurately characterizing the fistula tract (Figure 4) prior to therapy can not be overemphasized. The risk of incomplete healing, a recurrent fistula, or even inadvertent sphincter injury is increased if fistula anatomy is incorrectly delineated or an occult abscess is missed. Several imaging modalities are available to evaluate perianal fistulas and abscesses. Although correlation varies in the literature between 45%-95%, according to Goodsall’s rule, an imaginary transverse line should be drawn across the anus. External lesions seen anterior to this line run directly from the anal canal. If the external opening is detected posterior to this line, the fistula is more complex and tracks laterally around the anus prior to a midline posterior opening. Bidigital examination, with the index finger in the anal canal and the thumb exterior to it, may enable identification of the fistulous track as a cord-like lesion under the skin.

Endoscopy may detect the internal opening. Other methods include; passing a probe; injection of a dye such as hydrogen peroxide ( $H_2O_2$ ), milk, or methylene blue; fistulography; anal ultrasound with  $H_2O_2$  injection; and magnetic resonance imaging (MRI). Several studies have concluded that MRI and anorectal endosonography (EUS) are accurate means of delineating anatomy in relation to a fistula<sup>[61]</sup>. EUS is easily performed and less expensive than MRI, but it is not appropriate for the patient with severe anal pain or an anatomical stricture. Adopting endoanal coils and phased array imaging has contributed to the evolution of using MRI to evaluate anorectal disease<sup>[61-64]</sup>. The exact choice of which modality to use depends on local expertise, cost, and the available equipment.

### Management

The principal management is surgery. Anal abscesses should always be drained in a timely manner. Delayed or inadequate treatment may occasionally cause extensive or life-threatening suppuration with massive tissue necrosis and septicemia.

Thus, an early referral to a specialist is recommended. The goals of surgical therapy are to remove the fistula tract while preserving fecal continence. The surgical approach depends upon the type of fistula. Simple intersphincteric fistulas can be treated by fistulotomy (opening of the fistula tract). High transsphincteric and suprasphincteric fistulas are more safely treated by initial placement of a seton<sup>[65]</sup>. The seton is a foreign material placed through the fistula tract which is tightened at regular intervals until it eventually cuts through the sphincter. There are different types and seton techniques used in anorectal surgery<sup>[66-70]</sup>. The slow division of the anal sphincter with the simultaneous fibrosis allows the fistula tract to be more superficial and to re-establish continuity of the anorectal ring while preventing wide separation of the anal sphincter<sup>[66,71]</sup>. The literature has reported a 2%-8% recurrence rate following treatment with cutting setons. The rate of fecal incontinence following this procedure has been reported to be about 60%, but it is mostly minor incontinence to flatus; major incontinence to solid stool is 2%-3%. An anorectal advancement flap has been advocated for complicated and multiple fistulas including for patients with inflammatory disease and high transsphincteric or suprasphincteric fistulas<sup>[72,73]</sup>. Anal sphincter injury is the main morbidity after surgical management of anal fistulas. Fibrin glue has been used for the eradication of fistulas to reduce complications following surgical procedures<sup>[74-76]</sup>. However, fibrin glue should only be used as second or third line treatment because of the conflicting success rate of closing the fistulas (range = 30%-85%) and a high recurrence rate of up to 59%<sup>[77]</sup>. Its advantages as an acceptable alternative to conventional surgery are low morbidity, simplicity, and repeatability, especially in treating complex fistulas<sup>[78,79]</sup>. A relatively new treatment using a biodegradable “collagen plug” has been adopted to treat complex, high, and recurrent anorectal fistulas. Although the fistula

**Table 1 Etiologies of pruritus ani**

Anorectal disease	Anal fistula, fissure, skin tags, hemorrhoids, rectal prolapse, anal papillomas, rectal and anal carcinoma, fecal incontinence, hidradenitis
Systemic disease	Diabetes mellitus, chronic renal failure, iron deficiency, thyrotoxicosis, myxedema, Hodgkin's lymphoma, jaundice, leukemia, aplastic anemia
Dermatologic conditions	Psoriasis, erythrasma, seborrheic dermatitis, atopic dermatitis, intertrigo
Infections	Virus, bacteria, fungi, parasites
Gynecologic conditions	Vaginitis, endocervicitis
Neoplasms	Extramammary Paget's disease, squamous cell carcinoma, cloacogenic carcinoma, Bowen's disease
Hygiene	Poor cleansing or overaggressive cleansing with rubbing or excessive soap use
Diet	Coffee, chocolate, citrus, spicy foods, tea, beer, sodas containing caffeine, fat substitutes, milk and milk products
Local irritants	Obesity, excessive hair, tight-fitting clothing, anal creases, perfumed or dyed toilet paper, anal creams
Diarrheal states	Ulcerative colitis, crohn's disease, irritable bowel syndrome
Radiation	Postirradiation changes
Psychogenic	Anxiety, neuroses, psychoses
Drugs: Idiopathic	Quinidine, colchicine, antibiotics, ointments that may contain alcohol

**Table 2 Instructions for patients**

Do not scratch or rub the anal area
Wash the anal area with only water. Do not use soap or salt when you wash the anal area. Dry the area well after cleaning, by patting the skin with a soft towel or using a hair dryer with cool air
Make sure to clean the anal area after each bowel movement as instructed. Avoid the use of toilet paper that may be abrasive
When you shower or bathe, use unscented soap
Apply a thin cotton pledge directly in the anal crease in the morning and at bedtime, and change the pledge as needed if it becomes moist
Wear loose underwear
Soak the anal area in a warm sitz bath for 10 to 15 min two to three times a day. Do not add soaps, salt, oil, or skin softners to the water, and dry the anal area as above
Maintain a soft, large and nonirritating stool by having bulking agents such as psyllium or methylcellulose in 8-12 oz of water. Start at a low dose of the fiber supplement and slowly increase the amount of fiber until reaching at least 20-30 g/d
Eat a high fiber diet that includes 8-10 glasses of water a day
Avoid foods that include colas, spicy foods, citrus foods, coffee, beer, nuts, dairy products, tomatoes
You may apply 0.5% or 1% hydrocortisone ointment to the itch area, but only if directed by your doctor, and antihistamine tablets may be helpful for nighttime symptoms
Don't be despondent when recurrence occurs because it is common. Reconsult your doctor so that appropriate management can be applied

closure rate was inconsistent, the collagen plug might be a promising alternative for complex and high anorectal fistulas because it is minimally invasive and can be used repeatedly without damaging the anal sphincter<sup>[80,81]</sup>. However, large randomized controlled trials with long-term follow up are required to assess the value of this treatment.

Anal fistulas complicated by Crohn's disease are challenging because surgical treatment is associated with poor and delayed wound healing and the high risk of incontinence. Therefore, anal fistulas in this group should be initially managed with medical therapy that includes sitz baths, metronidazole, or IV infliximab, a tumor necrosis factor- $\alpha$  inhibitor<sup>[82]</sup>.

## PRURITUS ANI

Pruritus ani is a symptom complex, not a disease. It is a common but socially embarrassing condition. The word "pruritus" originated from the Latin word *prurire*, which means "to itch," and refers to an unpleasant cutaneous sensation. Thus, patients develop a nearly uncontrollable desire to scratch<sup>[83]</sup>. Excessive rubbing or scratching of the skin results in maceration, superinfection, and a decrease in thickness of the fatty skin layer, which

exacerbates the problem and leads to hypertrophy of the epidermis and lichenification. Pruritus ani affects 1%-5% of the adult population<sup>[83]</sup>, not uncommonly occurs in adolescents and the elderly, and is more prevalent in men than women<sup>[84]</sup>.

### Etiology

Pruritus ani is classified when it has an identifiable etiology that may include numerous anorectal diseases, other systemic diseases, transient internal sphincter relaxation, an exaggerated rectoanal inhibitory reflex, poor hygiene, overaggressive cleansing, and local irritants (Table 1)<sup>[85-90]</sup>. However, in more than one half of patients with pruritus ani the cause is categorized as idiopathic.

### Diagnosis

A variety of possible etiologic factors challenge the physician to approach the correct diagnosis and institute the appropriate management. A detailed history and close physical examination can often help in the identification of pruritus. Inspection, palpation, and anoscopic examination should be performed on the initial visit. Scrapings to exclude fungal and yeast infection may be helpful. Perianal skin biopsy may be useful in

suspicious skin lesions or severe cases. Some publications recommend sigmoidoscopy or colonoscopy to evaluate inflammatory bowel disease and colorectal neoplasms<sup>[88]</sup>.

### Treatment

Management is nonsurgical, thus should be aimed at the underlying cause; there is very rarely any reason for surgical referral. Appropriate follow-up care is necessary for therapeutic success. The goal to achieve success with patients who have no identifiable etiology is to maintain the perianal skin clean, dry, and slightly acidic. However, aggressive cleaning of the perianal area with alkaline soaps leads to chronic pruritus<sup>[88]</sup>. The vast majority of patients with pruritus ani can be treated by conservative management<sup>[89,91]</sup>. Instructions for patients, well described by Hicks and colleagues (Table 2)<sup>[88]</sup>, are removal of irritants, improving perianal hygiene<sup>[92]</sup>, avoiding scratching, wearing loose cotton underwear, adjusting the diet by adding a bulking agent to induce soft and non-irritating stools, and discontinuing offending agents, such as coffee, tea, cola, beer, chocolate, and tomatoes<sup>[88]</sup>. Hydrocortisone ointment 0.5 to 1.0% can provide symptomatic relief of idiopathic pruritus ani, but should not be used for prolonged periods of time because of dermal atrophy. Skin barriers such as topical zinc oxide, can also provide some relief. Nighttime sedating antihistamines or tricyclic antidepressants may be helpful. Refractory patients with intractable symptoms should be referred to a dermatologist<sup>[91]</sup>. Various therapies have been used with inconsistent results or insufficient data to judge efficacy, such as injection of methylene blue, surgical debridement, radiation therapy, ultraviolet phototherapy, cryotherapy, and intralesional corticosteroids<sup>[93-96]</sup>.

### CONCLUSION

Although most anorectal conditions are benign, knowledgeable and skilled physician intervention is often required. Understanding the pathophysiology of anorectal disease guides treatment selection. Initiating early appropriate treatments should lead to prompt symptomatic resolution in a cost-effective manner. A subgroup of patients who persistently present with symptoms despite applicable conservative or non-surgical management should be referred to a colorectal surgeon.

### ACKNOWLEDGMENTS

We thank Ms. Heather Dean from Cleveland Clinic Florida for her contribution to the editing and compilation of this publication. All the figures were provided by Badma Bashankaev (MD, Colorectal Department, Cleveland Clinic Florida), and reprints were not permitted without permission.

### Abstract

Hepatocellular carcinoma (HCC) still remains a considerable challenge for surgeons. Surgery, including liver transplantation, is the most important therapeutic approach for patients with this disease. HCC is frequently diagnosed at advanced stages and has a poor prognosis with a high mortality rate even when surgical resection has been considered potentially curative. This brief report summarizes the current status of the management of this malignancy and includes a short description of new pharmacological approaches in HCC treatment.

### INTRODUCTION

Hepatocellular carcinoma (HCC) is the third leading cause of cancer-related death and accounts for as many as 500 000 deaths annually being a considerable challenge for surgeons<sup>[1]</sup>. The incidence of HCC varies by geographic location from a relatively rare tumour, like those found in North America and Europe, to a very common and highly malignant tumour as occurs in sub-Saharan Africa and Southeast Asia. HCC has been found to account for 80% of all primary liver cancers, being the fifth most common cancer worldwide<sup>[1,2]</sup>. Most patients with HCC also suffer from coexisting cirrhosis, which is the major clinical risk factor for hepatic cancer and is correlated to hepatitis B virus or hepatitis C virus (HCV) infection<sup>[3]</sup>. However, cirrhosis from non-viral causes such as alcoholism, hemochromatosis and primary biliary cirrhosis are also associated with an elevated risk of HCC. Furthermore, concomitant risk factors such as HCV infection in addition to alcoholism, tobacco use, diabetes or obesity increase the relative risk of HCC development, as numerous studies in humans and animal models have shown<sup>[4-10]</sup>. The incidence of HCC varies by geographic area worldwide. Research has shown that Southeast Asia and sub-Saharan Africa have an incidence rate of HCC that ranges from 150 to 500 per 100 000 population, primarily because of the endemic nature of hepatitis B and C in those regions<sup>[11-13]</sup>.

HCV accounts for almost 90% of all cases of HCC in Japan, and in China, hepatitis B infection is diagnosed in about 80% of patients with HCC<sup>[12-14]</sup>. In Europe and North America, however, despite a significantly lower incidence rate of 3 to 4 per 100 000 population, a distinct increase in cases of HCC has been reported as a result of intravenous drug use, unsafe sexual practices, and other causes<sup>[15-17]</sup>. Because of a lack of effective HCV vaccination, underlying HCV infection is largely responsible for that increase. As a result of the interval between the onset of infection and the development of liver cirrhosis, the incidence of HCV-related HCC will continue to increase over the next few years<sup>[18]</sup>. In contrast to Asian populations, the percentage of Western patients with HCC but without underlying cirrhosis is considerable, and the development of HCC in cirrhotic individuals in the West is associated with a wider spectrum of underlying diseases. In the West, the percentage of virally engendered cirrhosis is lower than that in Asian regions, but alcohol-toxic or cryptogenic hepatic dam-

age is observed more frequently in Western countries<sup>[14]</sup>. Thus, the etiologic pattern of HCC in Western regions of low risk for that disease differs appreciably from that in Southeast Asia and sub-Saharan Africa.

Surgery, including liver transplantation (LT), still remains the most important therapeutic approach for patients with HCC. Over the past few decades, considerable progress has been made in the diagnosis and surgical treatment of HCC. In fact, tumors are now often identified at an early stage<sup>[19,20]</sup>, surgery is safer with an acceptable overall mortality rate (in cirrhotic patients < 5%), being characterized by a good long-term survival<sup>[21,22]</sup> and results of LT have steadily improved because of careful patient selection<sup>[23]</sup>.

However, HCC is still associated with a high rate of mortality and prognosis of this tumour is poor even when treatment has been considered potentially curative<sup>[24,25]</sup>.

This brief report summarizes the current status of the management of this disease and includes a short description of a new pharmacological approach in HCC treatment.

## STAGING

Various classification systems are available for HCC. The Barcelona Clinic Liver Cancer (BCLC) classification has emerged during recent years as the standard classification that is used for trial design and clinical management of patients with HCC<sup>[26,27]</sup>. This classification has been approved by EASL and the AASLD<sup>[24,28]</sup> and has subsequently been corroborated in clinical studies<sup>[29,30]</sup>. The BCLC staging system was constructed on the basis of the results obtained in the setting of several cohort studies and randomized controlled trials by the Barcelona group.

The main prognostic factors of this staging system are related to tumour status (defined by the number and size of nodules, the presence or absence of vascular invasion, and the presence or absence of extrahepatic spread), liver function (defined by the Child-Pugh score system, serum bilirubin and albumin levels, and portal hypertension), and general health status [defined by the Eastern Cooperative Oncology Group (ECOG), classification and presence of symptoms]. On the other hand, aetiology is not an independent prognostic factor. The BCLC classification links stage stratification with a recommended treatment strategy and defines standard of care for each tumour stage (Figure 1).

Patients with very early HCC (stage 0) are optimal candidates for resection. Patients with early HCC (stage A) should be considered for radical therapy [resection, LT, or local ablation *via* percutaneous ethanol injection (PEI) or radiofrequency (RF) ablation]. Patients with intermediate HCC (stage B) have been found to benefit from transarterial chemoembolization (TACE). Patients with advanced HCC, defined as the presence of macroscopic vascular invasion, extrahepatic spread, or cancer-related symptoms (ECOG performance status 1 or 2) (stage C), have recently been found to benefit from Sorafenib

treatment<sup>[31,32]</sup>. Patients with end-stage disease (stage D) will receive symptomatic treatment.

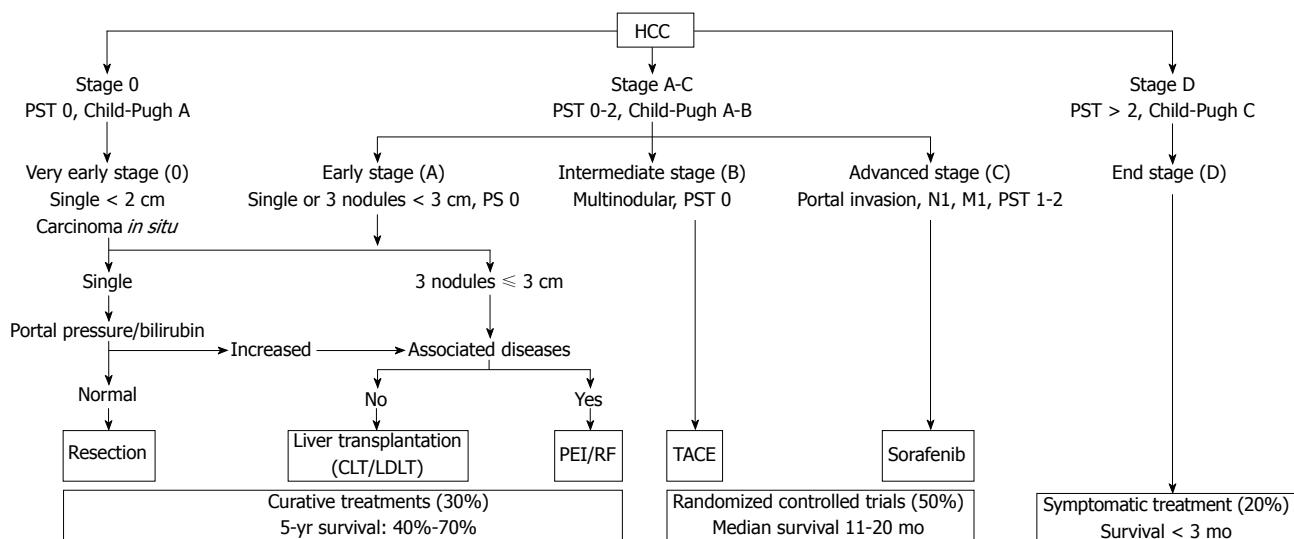

Treatment strategy will transition from one stage to another on treatment failure or contraindications for the procedures.

## HCC TREATMENT OPTIONS

### Liver resection

Pre-treatment imaging studies such as computed tomography and magnetic resonance imaging, either with or without angiography, can be used to match patients with their most appropriate treatment. Positron emission tomography is also useful in the identification of extrahepatic metastases which considerably influence clinical decision-making. These types of studies aid in detecting intrahepatic and extrahepatic disease as well as vascular invasion. Knowledge about the relation of the tumour to regional anatomic structures such as large vessels is crucial because it provides valuable information about resectability. Furthermore, volumetric studies can be used to define the residual parenchyma exactly. The determination of hepatic reserve is also significant when resection is considered. The healthy liver has a great capacity for regeneration and adjusts to the metabolic requirements of the host after liver resection due to hypertrophy of the residual liver. Partial hepatectomy usually ensures a safety margin of at least one centimeter and is associated with an operative mortality rate of less than 5%<sup>[33,34]</sup>. For patients with inadequate or borderline remnant parenchyma, hypertrophy of the prospective liver remnant can be induced by preoperative portal vein embolization<sup>[35]</sup>. However, the use of portal vein embolization to induce compensatory hypertrophy of healthy liver before major resection is controversial. Uncontrolled tumour progression as a result of the proliferation of malignant cells stimulated by this method and the risk of variceal bleeding resulting from acute portal hypertension should be carefully considered and for that reason this procedure raises some concerns<sup>[36]</sup>. In certain circumstances, an unfavourable location of the tumour and involvement of the confluence of the three hepatic veins and either the caval vein or the retrohepatic caval vein can render resection by conventional techniques impossible. In these rare cases, special techniques such as *in situ* or *ante situm* resection can be used<sup>[37]</sup>.

The overall long-term results after resection are favourable. However, only 20% to 30% of patients with HCC are eligible for resection because of advanced or multifocal disease or inadequate functional hepatic reserve<sup>[38]</sup>. In patients with solitary lesions of less than 5 cm, no vascular invasion, and a negative surgical margin of at least 1 cm, the 5-year survival rate after resection has been reported to be greater than 70%<sup>[39]</sup>. In a series consisting of 68 patients with HCC and non-cirrhotic liver, an overall 5-year survival rate of 40% was achieved even when extensive resection had been performed<sup>[40]</sup>. Similar results were observed in a large series in which patients with HCC and non-cirrhotic liver demonstrated a survival rate of 58% after 3 years and 42% after 5 years<sup>[41]</sup>.

**Figure 1** Barcelona Clinic Liver Cancer staging classification and treatment schedule<sup>[27]</sup>.

Despite earlier detection, safer surgical procedures and more aggressive treatment of HCC, recurrence, as a result of multicentric carcinogenesis or intrahepatic metastases from the primary tumour may occur. In selected patients, repeat resection provides good long-term benefits and is an option for those with solitary peripheral tumors that can be treated with segmental or atypical resection. In patients with adequate functional reserve capacity and no extrahepatic tumour growth, the 5-year survival rate after repeat resection has been reported to be as high as 86%<sup>[42]</sup>.

## LT

LT is one of the best treatment approaches for HCC in patients who fulfil the selection criteria (solitary tumors of less than 5 cm and up to three tumour nodules, each of which is smaller than 3 cm)<sup>[23]</sup>. First, it removes the tumour with the widest margin together with any intrahepatic metastasis. Second, it cures the underlying cirrhosis that is responsible for both hepatic decompensation and metachronous tumour after partial hepatectomy. Finally, it allows the histologic examination of the entire liver explant for the most accurate pathologic staging.

Study results have generally shown a significantly higher probability of survival in patients with incidentally discovered tumors, no vascular invasion, a negative nodal status, a tumour size of less than 5 cm, and a tumour of lower histologic grade<sup>[43-48]</sup>. The 5-year reported survival rate is around 26% after resection and 69% after transplantation in cirrhotic patients with HCC<sup>[43]</sup>. The decisive prognostic factor for patients with HCC is vascular invasion, which no system of medical imaging can accurately demonstrate at this time<sup>[49]</sup>. Therefore, the pre-operative prognosis is still based on the number and size of tumour nodes demonstrated, due to the evidence that vascular invasion has been found to be correlated to tumour size and number<sup>[44]</sup>. Because of the present lack of organs available, an accurate estimation of the patient's prognosis is important and not every patient with HCC

and cirrhosis can be treated with LT. Thus the need to obtain the optimal benefit from the limited number of organs available has prompted adherence to strict selection criteria, so that only those patients with early HCC and the highest likelihood of survival after transplantation are listed to undergo that procedure (Figure 1).

Excellent 5-year post-transplant patient survival of at least 70% has been reported from many centres<sup>[50,51]</sup>. In another study, excellent results were achieved in patients with solitary lesions of a maximum diameter of 6.5 cm, patients with a maximum of three lesions (the largest of which was no larger than 4.5 cm), and those who had no more than 8 cm in diameter in all tumour nodes. The 1-year and 5-year survival rates of these patients were as high as 90% and 72%, respectively<sup>[52]</sup>.

Even if the selection criteria for LT to treat HCC could be expanded, the current shortage of liver grafts and the lack of data defining the new limits for LT in patients with HCC makes the attempt to expand the listing criteria a very controversial issue. As a result of expanded listing criteria, the inclusion of patients with more advanced cancer may result in a higher dropout rate that in turn leads to poor survival rates in an intent-to-treat analysis<sup>[53,54]</sup>.

In their recent publication, Mazzaferro and colleagues<sup>[55]</sup> developed a new prognostic model that could be used to expand the Milan criteria and help identify patients whose odds of survival could be improved by having a liver transplant. Using the "up-to-seven" criteria, where seven is the maximum number obtained by adding the size of the largest tumour (in centimeter) to the total number of tumors, the report indicates that the 5-year survival in patients without microvascular invasion was 71.2%, similar to patients who met the Milan criteria. The researchers conclude: more patients with HCC could be candidates for transplantation if the current dual (yes/no) approach to candidacy, based on the strict Milan criteria, was replaced with a more precise estimation of survival contouring individual tumour characteristics and use of the up-to-seven criteria.

Therefore, the ultimate therapeutic choice should always result from the analysis of each individual case and should be based on the experience and judgment of the transplant team and not just on the statistical results derived from the literature.

The wait for a graft to become available still presents the greatest challenge. Methods of neoadjuvant therapy (PEI, RF, TACE) may be used to provide tumour control in patients on a waiting list for LT.

Patients can reach a prognostically unfavourable stage because of tumour progression with subsequent deterioration of their clinical profile while waiting and may no longer fulfil the criteria for LT<sup>[52]</sup>. As a result, these patients should be removed from the waiting list, indeed about 50% of HCC patients who were initially candidates for LT will become ineligible for transplantation if the median waiting period exceeds 1 year<sup>[53,56]</sup>.

Strategies to increase the donor pool and diminish the tumour progression rate have become a priority in many centres. In the United States, the United Network for Organ Sharing proposed a new system to allocate patients on the list according to the Model for End-Stage Liver Disease score<sup>[57]</sup>. This change gives priority to patients to minimize drop-out rates and has improved the access to timely liver transplant for patients with HCC<sup>[58]</sup>.

Recent advances in adult living-donor liver transplantation (LDLT) may produce a drastic change in the role of transplantation surgery for HCC. This option enables patients to avoid the long waiting time before transplantation and consequently to reduce the dropout rate. The keynote of living donation in patients with HCC and cirrhosis is supported by these factors: (1) Better graft function, because each graft is obtained from a healthy person; (2) Better clinical condition of the patient at the time of transplantation; (3) Optimal organ harvest, conservation, and reduced cold ischemia time; (4) A significantly reduced waiting time.

Whether LDLT is indicated in patients with HCC that exceeds the Milan criteria remains controversial<sup>[59,60]</sup>. A recent survey of transplant surgeons from North America, Europe, and Asia revealed that 41% of the respondents favoured LDLT for use in patients with HCC that exceeds the Milan criteria<sup>[61]</sup>. Patients who no longer fulfil the criteria because of tumour size or the number of tumour nodes may still retain the option of LDLT. Because a potential 5-year survival rate of around 50% in patients whose LT is justified by extended criteria has been described<sup>[53]</sup>, transplantation would offer a better chance of survival than would all other therapeutic options.

However, evidence-based universal guidelines for this important issue have not been established. Primary graft failure and the risk to the donor present ethical concerns that cannot be disregarded. Donor deaths and other complications, such as insufficiency of the donor's remaining liver (which required subsequent transplantation), have been reported<sup>[62]</sup>. Furthermore, some data also suggest the need to have a better evaluation of the donor, including liver histology<sup>[63]</sup>. The complication rate for LT in North America and Europe ranges between

9.2% and 40% for the donor, and the mortality risk in donors is still 0.3% to 0.61%<sup>[64,65]</sup>. In contrast, data in Japan showed a complication rate of 12% with no perioperative deaths in living liver donors<sup>[66]</sup>. Meticulous surgical techniques and perioperative management, lean body mass in individual Japanese donors, and genetic factors were given as possible explanations for the zero transplant-related mortality rate in Japan. In general, however, morbidity after living liver donation strongly correlates with the expertise of the staff of the transplant centre. Therefore, a combination of surgical expertise and thorough, individualized medical and psychological evaluations is vital to ensure the lowest morbidity rate and best outcome, not only in the recipient, but also in the donor.

### **Locoregional procedures and chemotherapy**

**Percutaneous ablation:** For patients who are not candidates for liver resection or transplantation, percutaneous ablation offers the best treatment option. However, to our knowledge, there are no randomized controlled clinical trials that have compared the results of this treatment option with those of surgical therapy for HCC, and none of the ablation techniques have been shown to offer a definitive survival advantage. The principle of ablation is based on the destruction of tumour cells by the application of chemical substances, such as ethanol, or by using RF or laser to modify the temperature in the tumour *via* the delivery of heat. Of all those techniques, PEI has been the most investigated<sup>[67]</sup>. In individuals who do not fit the optimal surgical profile, PEI is as effective as surgery and is associated with a 5-year survival rate as high as 72% if the accurate selection of patients is performed<sup>[68,69]</sup>. The low rate of procedure-related complications and the low cost of PEI are additional advantages. The main drawback of this technique is the need for repeated injections in separate sessions and the inability to achieve complete necrosis in larger tumors. In that regard, RF ablation has been shown to be more effective in achieving complete necrosis in tumors larger than 2 cm and to require fewer treatment sessions<sup>[70]</sup>. RF ablation involves the delivery of energy created by RF waves to tumors to induce thermal damage and coagulative necrosis. Study results have shown that RF ablation is superior to PEI in terms of causing complete tumour necrosis (90% *vs* 80%) and in the number of required treatments (1.2 *vs* 4.8)<sup>[71]</sup>. However, RF ablation causes more complications such as pleural effusion, bleeding, and tumour seeding than does PEI<sup>[71,72]</sup>. In addition, the effectiveness of RFA decreases as the tumour size exceeds 3 cm.

**Chemoembolization:** This approach can be used before liver resection to improve resectability, as a bridge to LT while awaiting organ availability, or as a palliative treatment, and it may offer patients with preserved liver function and no evidence of ascites a survival advantage<sup>[73]</sup>. Chemoembolization is based on the principle of arterial obstruction (obstruction of the hepatic artery during angiography *via* the use of agents such as an ab-

sorbable gelatin sponge, alcohol, *etc*; to induce ischemic tumour necrosis). This technique is effective because the growth of HCC depends primarily on the hepatic artery blood supply, but the healthy hepatic parenchyma has a dual blood supply (85% is supplied by the portal vein, and the remainder is supplied by the hepatic artery). The injection of a chemotherapeutic agent [usually cisplatin, doxorubicin hydrochloride (Adriamycin), or mitomycin C] before arterial obstruction (transcatheter arterial embolization) results in TACE, a method by which regionally elevated levels of these agents in the liver can be achieved while concomitant systemic toxicity is avoided. When compared with controls, patients treated with TACE exhibited a decrease in tumour size of 16% to 61% and a 1-year survival advantage as high as 82%<sup>[74-77]</sup>.

### **Systemic treatment**

A number of systemic chemotherapies have been evaluated in many clinical trials. Unfortunately, no single agent or combination of agents given systemically leads to reproducible response rates that show beneficial effect of systemic chemotherapy on survival rates<sup>[78]</sup>. Tamoxifen, octreotide, interferon, and interleukin-2 have not been shown to be effective in treating HCC in randomized controlled clinical trials<sup>[79,80]</sup>. The increasing knowledge in the molecular structure of HCC as well as the introduction of molecular targeted therapies in oncology have created an encouraging trend in the management of this disease<sup>[81]</sup>. These targeted molecular therapies are aimed at growth factors and their receptors, intracellular signal transduction and cell cycle control. Recent positive results from a preliminary study of the receptor tyrosine kinase inhibitor, sorafenib, have been reported in the treatment of HCC<sup>[31,52]</sup>. This oral multikinase inhibitor action of several kinases (VEGF, PDGF, c-kit receptor, Raf) involved in both tumour cell proliferation (tumour growth) and angiogenesis (tumour blood supply).

### **CONCLUSION**

Novel treatment options based on an improved understanding of the molecular pathogenesis of HCC have been proposed. Nonetheless a substantial improvement in the outcomes of intermediate and advanced stage HCC is expected with the advent of these targeted therapies, used in combination with surgical or locoregional therapies.

LT still remains an important treatment approach for HCC and is a well-documented and proven treatment modality for this disease. However, early unsatisfactory results have emphasized that only a highly selected patient population would benefit from transplantation. Pretransplantation therapies and the development of novel agents to prevent progression of HCC in patients awaiting LT are needed. Promotion of organ donation is necessary, the role of new systemic therapy is now becoming a new and interesting option in the treatment of patients with HCC, but LDLT as the dominant strategy will continue to escalate.

## INTRODUCTION

Liver masses are increasingly being identified due to the widespread use of imaging modalities such as ultrasonography (US), computed tomography (CT), and magnetic resonance imaging. The majority of these lesions are detected incidentally in asymptomatic patients. An accurate history and physical examination are essential to the diagnosis and treatment of solid liver masses. For example, the use of oral contraceptives or anabolic steroids might be related to hepatic adenoma (HA)<sup>[1]</sup>; alcohol use and occupational exposure are associated with angiosarcoma<sup>[2]</sup> and primary sclerosing cholangitis, liver fluke, Caroli's disease, and choledochal cysts are associated with cholangiocarcinoma<sup>[3]</sup>. Physical examination should look for liver tenderness, stigmata of chronic liver disease, or general deterioration signs (fever, weight loss). High alkaline phosphatase, high lactate dehydrogenase (LDH), low albumin, high prothrombin time, and iron overload are non-specific but might suggest an underlying chronic hepatitis, cirrhosis or an infiltrative process<sup>[4]</sup>. A history of hepatitis B, C or liver cirrhosis might point to hepatocellular carcinoma (HCC). A previous neoplasm or history of chemotherapy increases the suspicion of metastatic liver disease.

## CURRENT KNOWLEDGE

In the majority of patients, a proper diagnosis can be

**Table 1 Clinical differential diagnosis of the most common liver masses**

	<b>Cirrhotic liver</b>	<b>Common lesions</b>	<b>Non-cirrhotic liver</b>	<b>Common lesions</b>
Malignant mass	Hepatocellular carcinoma	a,d	Metastasis	a,b
	Cholangiocarcinoma		Well differentiated HCC	
	High grade dysplastic nodule		Fibro lamellar HCC	a,b,c,g
	Lymphoma		Cholangiocarcinoma	
	Metastasis (exceptional)		Hemangio-Endothelioma	
Benign mass	Low grade dysplasia	d	Lymphoma	g
	Focal fatty liver		Melanoma	
	Hemangioma		Neuroendocrine tumor	
	Hepatic adenoma	g	Sarcoma (angiosarcoma,leiomyosarcoma)	
			Hemangioma	
			Focal nodular hyperplasia (FNH)	a,b
			Hepatic adenoma (HA)	a,b
			Nodular regenerative hyperplasia	b,f
			Partial nodular transformation	e,f
			Focal fatty infiltration	c,e
			Bile duct adenoma	

a: Hyper vascular liver tumor; b: Tumors that are extremely rare in cirrhosis but relatively frequent in healthy normal liver; c: Tumors frequent in the left lobe; d: Mainly in cirrhosis; e: Equally found in cirrhotic and non cirrhotic; f: Clinically mimics cirrhosis; g: Extremely rare tumors.

made based on the characteristics on imaging modalities (Lesions size < 1.0 cm are usually benign). For diagnostic purposes, liver masses should be divided into those occurring with and without cirrhosis. A liver mass in a cirrhotic liver should be viewed as HCC until proven otherwise. Multiple liver masses in a cirrhotic liver indicate diffuse HCC, high-grade dysplastic nodules or, on rare occasions, hepatic lymphoma<sup>[5]</sup>. Benign liver lesions are found in more than 20% of the general population<sup>[6]</sup>, including haemangioma (4%), focal nodular hyperplasia (FNH, 0.4%) and hepatic adenomas (0.004%). Multiple liver lesions in a normal liver usually indicate liver metastasis (most commonly from adenocarcinoma of the colon, stomach, lung or prostate), but could be cysts or hemangiomas<sup>[7]</sup>. Liver metastasis is a rare finding in a cirrhotic liver<sup>[8]</sup> (Table 1). Multiple liver lesions of a benign nature such as hemangiomas or focal nodular hyperplasia are not uncommon in a normal liver.

Calcifications have no diagnostic utility but might suggest fibro-lamellar carcinoma or colorectal adenocarcinoma, whereas hemorrhage within the lesion suggests adenoma<sup>[9]</sup>. The initial strategy in cirrhosis should be the measurement of  $\alpha$ -fetoprotein (AFP) followed by ultrasound, contrast CT or magnetic resonance imaging (MRI)<sup>[10,11]</sup>. Fine needle core biopsy (FNCB) might be required, but biopsy of potentially operable lesions should be avoided. This review discusses the various characteristics of the most common solid liver lesions and recommends a practical approach for diagnostic workup.

## DIAGNOSTIC VALUE OF TUMOR MARKERS

AFP, PIVKA 2 (< 0.1 U/mL), desgamma-carboxy prothrombin and CA 19-9 (< 37 U/mL) are tumor markers for HCC. AFP is the first choice when diagnosing HCC and 10 ng/mL is the cut-off level. The formula (Ca 19-9 + CEA × 40) provides an index accuracy of 86%

in diagnosis of cholangiocarcinoma<sup>[12]</sup>. AFP values > 400 ng/mL are indicative of HCC. 30% of patients with HCC < 2 cm have normal AFP, 20% of HCCs produce no AFP, and levels from 20-250 are frequently seen in regenerating nodules or viral cirrhosis. An increase in AFP over time is virtually diagnostic of HCC<sup>[13]</sup>. Globally, the serum level of at least one of the tumor markers was elevated in 88% of patients with proven malignancy. Elevation was marked in 57%. No tumor marker alterations were detected in patients with benign lesions. Early lesions may have elevated tumor markers in fewer than 30% of cases<sup>[12]</sup>.

## IMAGING TECHNIQUES (TABLE 2)

A single imaging modality might suffice in cases that show interval development or progression, such as metastasis. Hemangiomas are often diagnosed by a single dynamic contrast enhanced imaging modality (MDCT). When further imaging techniques are necessary, CT angiography, MRI, and contrast enhanced-CT are performed to plan a surgical strategy. If this is not available on site, the patient and physician should decide whether the patient should undergo a biopsy or be referred for additional imaging. The key features of imaging techniques in the diagnosis of liver mass are shown in Table 3. Imaging tools for tumor assessment include: (1) Angiogram, RBC scintigraphy, contrast-enhanced CT, Porto-angiography CT, color Doppler ultrasound, contrast ultrasound, and gadopentetate dimeglumine-enhanced MRI; (2) MD-DPD enhanced MRI imaging, Gd-Balta-enhanced MRI imaging, EOB DTPA (to assess hepatocyte function and biliary excretion); (3) Plain film, US, CT scan (to assess tumor calcifications); and (4) US, contrast US, enhanced CT, MRI (utilized to assess capsule formation). US and CT are indicated for diagnosis of biliary obstruction or gallbladder diseases and for differentiation of cysts from solid liver lesions. Intraoperative ultrasound detects small liver lesions (< 5 mm). Endoscopic US assesses the left

**Table 2 Accuracy and key features of imaging techniques in the diagnosis of most common liver masses**

	<b>US-US doppler, contrast ultrasound</b>	<b>Triphasic CT</b>	<b>MRI</b>	<b>PET SCAN</b>	<b>CT-angiography</b>
Hemangioma (1-10 cm)	++ Hyperechoic Doppler: low flow, low index, absence of spectral broadening	+++ Peripheral puddles, fill in from periphery, enhancement on delayed scan	++++ Peripheral enhancement centripetal progression Hyperintense on T2, hypo intense on T1 SS > 95%, SP 95%	No uptake	+++ Cotton wool pooling of contrast, normal vessels without AV shunt, persistent enhancement Normal finding
Focal fatty liver	++ Hyper echoic, no mass effect, no vessel displacement	++ Sharp interface Low density (< 40 u)	+++	No uptake	
FNH (< 3 cm)	+ Homogenous iso, hypo, or hyper echoic, central hyper echoic area Central arterial signal Doppler: high flow, spectral broadening	++ Homogeneous enhance strongly with hepatic arterial phase Isodense with liver; Central low density scar	++++ Hyper vascular +Gd Isodense T1 Hyper intense scar T2 SS > 95%; SP > 95%	No uptake	+++ Hyper vascular 70% centrifugal supply
Adenoma (5-10 cm)	++ Heterogeneous Hyper echoic If haemorrhage: anechoic center In doppler: variable flow, spectral broadening	++ Homogenous > Heterogeneous, Peripheral feeders filling in from periphery	++ Capsule, Hyper intense in T1 (intra lesional fat)	No uptake uptake if degeneration to HCC	++ Hyper vascular Large peripheral Vessel Central scar if haemorrhage
HCC	++ Hypo or hyper echoic Doppler: hyper vascular Doppler: index and flow high, spectral broadening	+++ Hyper vascular, often irregular borders Heterogeneous > Homogeneous abnormal internal vessel Hallmark is venous washout SS 52%-54%	+++ Hyper vascular Poor different: Hypo intense T-1, Hyper intense T2 Well different: Hyper intense T-1, Iso intense T-2 SS 53%-78%	++ Increased uptake, but many HCCs show no uptake at PET	++++ Hyper vascular Av shunting Angiogenesis
Cholangiocarcinoma	Bile duct dilatation if major ducts are involved. Intra-hepatic CCC: no bile dilatation	Hypo dense lesion. Delayed enhancement	Hyper intense T1 Hyper intense T2 MRCP is useful	Uptake ++	Hypervascular
Metastasis	+ SS 40%-70% hypo to hyper echoic; doppler: low index and flow; presence of spectral broadening	+++ SS 49%-74 % complete ring enhancement	+++ SS 68%-90 % Low intensity T-1 High intensity T-2	+++++ SS 90%-100%	++++ SS 88%-95% hyper vascular

<sup>1</sup>Intraoperative ultrasound, contrast ultrasound and EUS are highly sensitive to detect liver mass; +: Degree of accuracy; SS: Sensitivity; SP: Specificity; MRI: Magnetic resonance imaging; CT: Computed tomography; HCC: Hepatocellular carcinoma.

**Table 3 Immunohistochemical staining in the evaluation of hepatic tumors**

<b>Tumor</b>	<b>Recommended immunostaining</b>
HCC	Polyclonal CEA Cytokeratin 8/18 pair (+/+ staining) Cytokeratin 7/20 pair (-/- staining) Hep Par 1, AFP
Cholangiocarcinoma	Cytokeratin 7/19 pair (+/+ staining) Cytokeratin 7/20 pair (+/- staining) B-HCG, CEA, Mucin-1
Epithelioid hemangioendothelioma	CD34 CD31 Factor VIII
Angiomyolipoma	HMB-45, smooth muscle actin
Metastatic carcinoma	
Neuroendocrine	Chromagrin, synaptophysin, neural enolase
Pancreas	Cytokeratin 7/20 pair (+/+ staining)
Colorectal	Cytokeratin 7/20 pair (-/+ staining)
Breast	Cytokeratin 7/20 pair (+/- staining)
Lung	Cytokeratin 7/20 pair (+/- staining)

liver lobe and the gastrohepatic ligament lymph nodes, and can help perform FNA. Doppler US evaluates blood

vessels patency and portal hypertension<sup>[14]</sup>.

The gold standard for detection and location of focal lesions is MRI or triple phase dynamic spiral CT<sup>[15]</sup>. Conventionally, a triple phase CT scan includes unenhanced, arterial and venous phases. The fourth phase is a delayed venous scan quadruple phase MDCT<sup>[16]</sup>. This is required only for small lesions thought to be HCC or cysts and hemangiomas. CT portography is one of the most sensitive imaging modalities for secondary lesions, but it is an examination that is performed in highly selected cases only, in few institutions and not for all types of liver lesions<sup>[16,17]</sup>. FDG PET CT scan is not very useful for HCC and therefore is not the best imaging modality to distinguish benign from malignant lesions<sup>[18]</sup>. A nuclear scan with Tc-99m-sulfur colloid shows increased uptake in FNH. MIBG and octreotide scintigraphy detect neuroendocrine tumors<sup>[19]</sup>. Hepatic Tc-99m red blood cell scan diagnoses hemangiomas > 2.5 cm (most university centers do not use this method and prefer contrast enhanced US, CT, and MRI)<sup>[20]</sup>. Ultrasound contrast agents and MRI using iron or gadolinium contrast better detect smaller lesions, satellite lesions or distant metastasis<sup>[21-23]</sup>.

Radiographic characteristics favoring HCC include the presence of a capsule bulging beyond the normal hepatic contour or a lesion with different densities. Contrast injection produces an immediate enhancement of most hepatomas.

## FINE NEEDLE ASPIRATION AND CORE BIOPSY (FNAB)

FNAB is safe, accurate and cost effective. Its specificity approaches 100% and its sensitivity is 67%-100%<sup>[24,16]</sup>. FNAB under CT or US in an appropriate location is the method of choice. FNAB is superior to FNCB; however, the methods are complementary, i.e. FNAB and FNCB have an accuracies of 78% separately and 88% when considered in combination<sup>[25,26]</sup>. However, many pathologists state that core biopsies are much preferred over needle biopsies for diagnosis of hepatic masses, because well differentiated HCCs cannot be separated from normal liver. Complications (mostly hemorrhages) are rare, with 0.5% minor complications and 0.05% major complications<sup>[27-30]</sup>. Another concern is the possible seeding of a tumor. Blind FNAB is diagnostic in > 50% of cases<sup>[31]</sup>, which increases to 65% when performing a second pass. An additional 5%-10% of tumors will be recognized if a cell block is obtained. Cohn's cytological criteria help to distinguish HCC from non-neoplastic lesions (81% of HCC show at least two criteria)<sup>[32]</sup>, e.g. increased nuclear/cytoplasmic ratio, trabecular pattern, and atypical naked hepatocyte nuclei. Some key features of immunohistochemical staining in the evaluation of hepatic tumors are shown in Table 3.

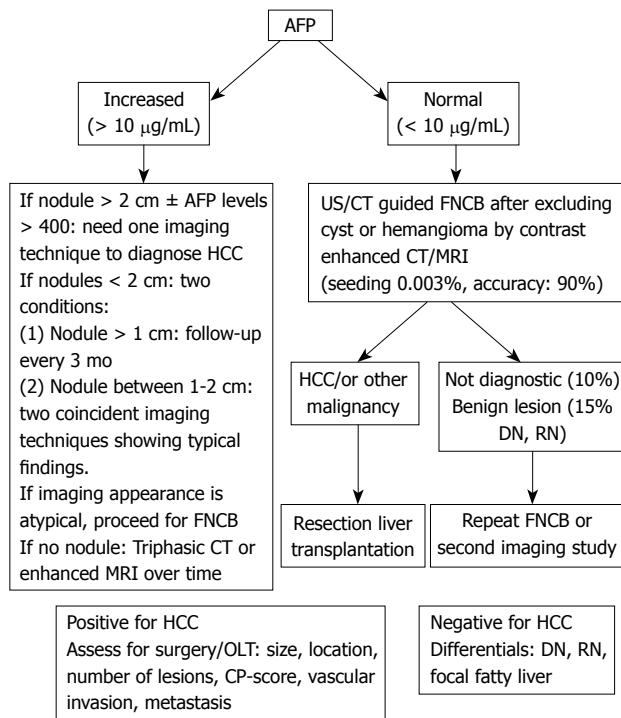

## GENERAL APPROACH TO LIVER MASSES IN CIRRHOTIC LIVERS (TABLE 1, FIGURE 1)

### Mass > 2 cm

Enhancement in the arterial phase and washout in the portal venous phase is essential for the diagnosis of a liver lesion > 2 cm in a cirrhotic liver. More than 80% of masses > 2 cm in a cirrhotic liver are HCC<sup>[33,34]</sup>. An elevated AFP confirms the diagnosis. If AFP is normal, further imaging will be diagnostic (triphasic CT, MRI)<sup>[13]</sup>. If there is still doubt, FNCB might be indicated (Figure 1).

### Mass < 2 cm

Seventy-five percent of masses < 2 cm in a cirrhotic liver are HCCs<sup>[35]</sup>. AFP levels and imaging might secure the diagnosis. If still in doubt, repeated imaging that detects enlargement of the lesion, or FNAB/FNCB might be indicated. Due to the risk of tumor seeding, biopsy should be avoided if surgical resection is possible<sup>[36]</sup>. A small nodule can be preneoplastic or benign. The American Association for the Study of Liver Diseases (AASLD) distinguishes lesions < 1 cm from those > 1 cm but < 2 cm. They suggest performing two imaging techniques from among US, CT, and MRI with IV contrast injection. If two techniques display typical

**Figure 1 Algorithm for the investigation of a liver mass in a cirrhotic liver.** Some hepatologists consider biopsy to be unnecessary for a mass in a cirrhotic liver even if the  $\alpha$ -fetoprotein (AFP) < 10; FNCB: Fine needle core biopsy; MRI: Magnetic resonance imaging.

imaging criteria, it is possible to diagnose HCC. Larger nodules should be diagnosed and small lesions should be surveyed every three months<sup>[37]</sup>. Caturelli showed that 69% of new nodules in a cirrhotic liver are malignant. Moreover, liver cell dysplasia is found in 60% of cirrhotic livers containing HCC and in only 10% of non-cirrhotic livers<sup>[38]</sup>.

### AFP is increased without a liver mass

In this case, repeated dynamic CT or MRI every three months is the rule<sup>[39]</sup>. An elevated AFP does not necessarily diagnose HCC, especially in patients with HCV who commonly have modest elevation of AFP without HCC. A marked AFP is helpful, but modest elevations would certainly not be an indication for OLT in the absence of a liver mass.

**HCC:** HCC is a common malignancy with an incidence of 1%-6% among cirrhotic patients<sup>[13,40-42]</sup>. Risk factors include cirrhosis, alcohol, HBV, HCV, metabolic liver diseases, environmental carcinogens, hormonal treatments and smoking<sup>[43,44]</sup>. Ninety to ninety five percent of HCCs arise in cirrhotic livers. Autopsy studies indicate that 20%-40% of patients with cirrhosis have HCC. Tumor size and severity of liver disease influence the survival rate. Patients with tumors < 5 cm have a survival of 80% at one year and 20% at three years. New abdominal pain, recent hepatomegaly, hemoperitoneum, persistent fever or weight loss in a cirrhotic patient should raise suspicion of HCC. Laboratory results that characterize HCC include a sudden increase in alkaline phosphatases, an increased ratio AST/ALT, an erythrocytosis, persistent leukocytosis,

recurrent hypoglycemia, hypercholesterolemia and hypercalcemia. The last four findings are paraneoplastic manifestations<sup>[45]</sup> together with ectopic hormonal syndrome, hypertrophic osteoarthropathy and porphyria cutana tarda<sup>[46]</sup>. Complications of HCC include obstructive jaundice<sup>[47]</sup>, and rupture of HCC (60%-90% mortality).

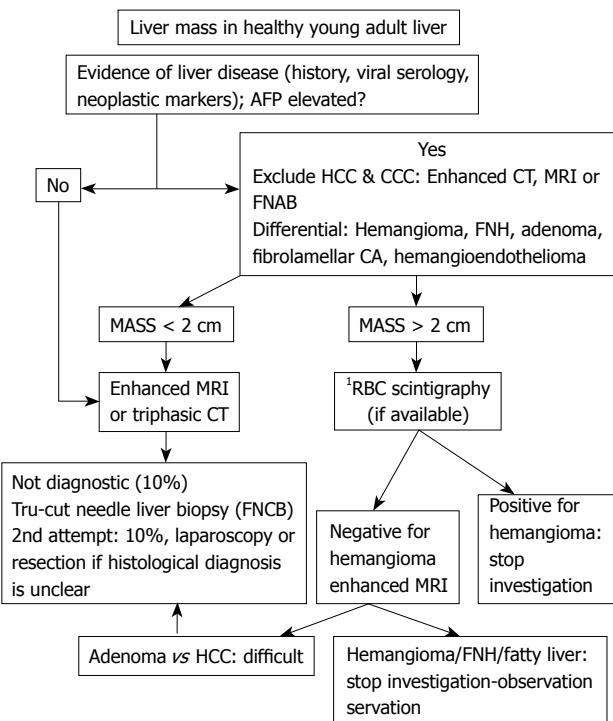

Screening for HCC includes US + AFP levels every six months. The AASLD guidelines recommend US only. AFP is of little additional value. Lesions > 2 cm need just one imaging technique showing typical findings (arterial hypervascularization) or one imaging technique and AFP levels > 400 in order to make a non-invasive diagnosis of HCC<sup>[13]</sup>. Lesions < 2 cm are divided into larger and smaller than 1 cm. Nodules > 1 cm but < 2 cm (1-2 cm) need diagnostic workup with two coincident or serial imaging techniques, rather than just proceeding with a biopsy. Nodules < 1 cm need screening follow up every three months. Nine to thirty seven percent of HCC are resectable at diagnosis<sup>[48]</sup>. Contraindications to resection include decompensated cirrhosis, extra-hepatic metastases, involvement of hepatic nodes or inferior vena cava (IVC), or bilobar extension<sup>[45]</sup>. The histological variants in cirrhotic livers include trabecular (65%), mixed (15%), compact (12%), pseudo glandular (5%) fibro lamellar (1.5%), and scirrhouous 0.5%<sup>[49]</sup>.

**Regenerative nodules:** Dysplastic nodules often occur within regenerative cirrhotic nodules. They can show low- or high-grade dysplasia. A progression from regenerative nodule with low-grade dysplasia to high-grade dysplasia, in well differentiated and poorly differentiated HCC, is possible<sup>[50-51]</sup>. MRI best differentiates this iso- or hypo-intense lesion from hyper intense HCC. In difficult cases, histology is required after liver resection or liver transplant. If HCC cannot be confirmed, the investigation must be repeated later. Over time, high-grade dysplastic nodules can become malignant, suggesting preventive ablation by ethanol<sup>[7]</sup>.

## GENERAL APPROACH TO LIVER MASSES IN NON-CIRRHOTIC LIVERS (TABLE 1, FIGURE 2)

Liver masses present with fever, pain, abdominal discomfort, or accidentally without overt symptomatology. Benign masses include hemangioma, FNH, nodular regenerative hyperplasia (NRH), and HA. The most frequent malignancy is gastrointestinal, urogenital, lung or breast carcinoma metastasis. Liver primary malignancy includes fibrolamellar carcinoma, cholangiocarcinoma, hepatic lymphoma and angiosarcoma<sup>[52,53]</sup>.

Elevated AFP diagnoses HCC<sup>[54]</sup>, otherwise, further imaging is required. US or CT classifies cysts, metastases and hemangioma. MRI identifies focal fatty liver, FNH, HA and hemangioma<sup>[55]</sup>. When the diagnosis remains uncertain, FNAB or follow up imaging is considered. Resection is indicated for large (> 5 cm) or growing adenomas.

**Figure 2 Algorithm for the management of a liver mass in a non-cirrhotic liver.** <sup>1</sup>Most centers do not use RBC scintigraphy to diagnose hemangioma due to their use of cross sectional imaging such as contrast enhanced ultrasonography (US)/CT/MRI.

### Benign lesions

**Hemangiomas:** Hemangiomas are found in 20% of the general population, more commonly in women<sup>[56,57]</sup>. The majority are asymptomatic. Giant hemangiomas (> 4 cm) are symptomatic in 40% of cases. Symptoms are rare and can include abdominal pain, early satiety, anorexia, and nausea<sup>[58]</sup>. Tc-99m labelled RBC Spect is the best and least expensive modality (specificity 100%) for lesions > 2.5 cm and MRI for lesions < 2 cm<sup>[59,60]</sup>. University centers rarely require RBC Spect for diagnosis of hemangiomas due to the use of cross sectional imaging. Histology of liver hemangiomas is blood-filled vascular sinusoids separated by connective tissue septa (peliosis lacks endothelial layer and fibrous trabeculae)<sup>[61]</sup>. The risk of rupture is minimal and does not justify resection. Other complications include thrombosis, sclerosis, and calcification. Liver hemangiomas can grow during pregnancy or oral contraception. Kasabach-Merritt syndrome (consumption coagulopathy) and Bornman-Terblanche-Blumgart syndrome (fever and abdominal pain) constitute uncommon complications<sup>[61]</sup>.

**FNH:** Focal nodular hyperplasia is found more often in women 20-50 years of age (80%). The pathogenesis is unknown, but includes vascular injury. The lesion is usually < 3 cm, asymptomatic and discovered accidentally. The main difficulty for the physician is differentiating FNH from adenoma or fibrolamellar carcinoma by imaging techniques. However, fibrolamellar carcinomas enhance heterogeneously, wash out, and have central calcifications and enlarged lymph nodes. These features are very rarely

found in FNH. Lack of symptoms, normal liver enzymes and no use of oral contraceptives argue in favour of FNH. Recent literature suggests that MRI has 70% sensitivity and 98% specificity for FNH (homogeneous hypervascular lesion with central scar)<sup>[62,63]</sup>. If radiology is unequivocal, most hepatologists advocate a "wait and see" attitude. Otherwise, image guided percutaneous biopsies are performed, one in the tumoral tissue and the other in the normal liver tissue. The histology resembles inactive cirrhosis with proliferating hepatocytes around a normal prominent central artery with a central fibrous scar<sup>[62]</sup>. The natural history of FNH is variable (stable, regressive or progressive over time), but resection is not necessary because it does not progress to malignancy. Complications are rare and include hepatic vein thrombosis or Kasabach-Merritt syndrome<sup>[63,64]</sup>.

**HA:** Adenoma occurs in women with oral contraception use > 5 years<sup>[65]</sup> or in diabetic patients. Multiple adenomas are associated with glycogen storage disease type I and type III<sup>[66]</sup>. Adenomatosis (> 10 adenomas) is observed with anabolic or androgenic steroids consumption<sup>[67]</sup>. Abdominal discomfort is common<sup>[68]</sup>. The lesion is hypo- to hyper-echoic on US and hypo- to hyper-dense on CT. MRI is not specific<sup>[69,70]</sup>. The lesions are often < 8 cm but can be > 15 cm microscopically; they appear as monotonous sheets of normal or small hepatocytes with no bile duct, portal tract or central vein. Five percent of hepatic adenomas transform to HCC<sup>[71]</sup>.  $\beta$ -catenin immunostaining might be useful for diagnosis. Spontaneous rupture and hemoperitoneum occur in 10% of cases, especially during menstruation, pregnancy or post partum. Most hepatologists advocate resection and discontinuation of oral contraception<sup>[72,73]</sup>.

**NRH and partial nodular transformation (PNT):** NRH (large regenerative nodule) is associated with Behcet's disease, rheumatic diseases, myeloproliferative disorders, chronic venous congestion, metastatic neuroendocrine tumors, Budd-Chiari syndrome, and various drugs (steroids, contraceptives, antineoplastics, anticonvulsives, and immunosuppressives)<sup>[74]</sup>. Some lesions present with portal hypertension and cholestasis. A diagnostic open liver biopsy is rarely required<sup>[75]</sup>. NRH shows diffuse hyperplastic nodules with thickened liver cell plates without fibrosis. Reticulin changes are characteristic. Portal vein thrombosis could lead to NRH by parenchymal atrophy and compensatory hyperplasia. Portal vein thrombosis has also been invoked in the pathogenesis of PNT<sup>[76]</sup>.

**Focal fatty infiltration of the liver:** In 10% of patients with fatty liver, fat accumulates focally or shows focal sparing, usually in the anteromedial segment of the left lobe. These patients usually have diabetes, hyperlipidemia, obesity, drink alcohol or take steroids<sup>[77]</sup>. On US, fat is hyper echoic. On CT, it has low attenuation. Focal fatty liver does not displace intrahepatic vessels. The gold standard imaging technique is MRI with increased signal on T1 sequence<sup>[78]</sup>. Fat suppression techniques are also very promising.

### Other rare benign tumors

**Hepatobiliary cyst adenoma:** This lesion is rare, occurs predominantly in middle-aged women and causes abdominal pain. It differs from benign cyst by having thick septated wall. Up to 25% become malignant (cystadenocarcinoma), therefore surgical excision is indicated<sup>[79]</sup>.

**Bile duct adenoma (cholangioma):** Bile duct adenomas are solitary sub capsular nodules measuring 1-20 mm described in patients with  $\alpha$ -1-antitrypsin deficiency. The bile ducts are smaller and do not contain bile.

**Biliary papillomatosis:** Only 50 cases have been described worldwide<sup>[80]</sup>. It is a tumor of middle age, leading to biliary obstruction by tumor shedding, mucus and lithiasis, cholangitis and hemobilia. Diagnosis is made by endoscopic retrograde cholangiopancreatography (ERCP), which shows typical mucinous discharge from a dilated ampulla, multiple filling defects and stenosis. Hepatectomy can effect a cure.

**Mesenchymal and neural tumors:** This category includes lipomas, myolipomas, angiomyolipomas, schwannomas, neurofibromas and chondromas.

**Inflammatory pseudotumor:** This is a rare, benign inflammatory condition of middle-aged men. Patients might present fever, weight loss, leukocytosis and elevated ESR. If the diagnosis can be made on biopsy, there should be no need for resection; rather the primary source should be treated<sup>[81]</sup>.

**Pseudo-lesions:** A pseudo-lesion is a non-diseased area of different signal intensity, attributable to focal alteration in hemodynamics or parenchymal metabolism<sup>[82]</sup>. Pseudo-lesions seen in cirrhotic and non-cirrhotic livers include arterio-portal shunts, regenerating nodules, confluent fibrosis, and abnormal blood inflow.

### Malignant lesions

**Liver metastasis:** The liver is the most common site of metastasis from the gastrointestinal tract, pancreas, breast, and lung<sup>[41]</sup>. Multiple defects in the liver imaging suggest a metastatic process. Only 20% of liver metastases present as solitary lesions. Generally, both hepatic lobes are involved. On CT-scan, colorectal metastases appear as low attenuation lesions, often with irregular margins and necrotic centres<sup>[14]</sup>. During the early vascular phase of dynamic CT, metastasis appears with increased enhancement. The sensitivity of CT (85%) can be augmented by CT arterial portography<sup>[83]</sup>. Intraoperative US has excellent sensitivity and specificity for colorectal adenocarcinoma metastasis<sup>[84]</sup>. The most promising imaging modality is PET CT with FDG that accumulates in cells with hypermetabolism. Colon, lung and breast cancers can be staged with PET CT with sensitivity of 92%-100% and specificity of 85%-100%<sup>[85]</sup>. The hypervascularity of neuroendocrine tumors is often evident on dynamic CT<sup>[86]</sup>. Somatostatin receptor

scintigraphy can localize 90% of neuroendocrine tumors (gastrinoma)<sup>[87]</sup>.

In metastatic colorectal carcinoma, the prognosis is improved following surgical resection. Contraindications to resection include: N > 4 liver metastases, extrahepatic spread and involvement of hepatic lymph nodes. Metastatic liver tumors that might calcify include colon, leiomyosarcoma, osteogenic sarcoma, rhabdomyosarcoma, chondrosarcoma, ovarian cystadenocarcinoma, melanoma, pleural mesothelioma, neuroblastoma, and testis tumors. Calcified metastases from stomach, pancreas, lung and breast to the liver are extremely rare. Guided FNA will help identify the primary lesion<sup>[88]</sup>.

**HCC (see previous section on HCC):** Almost all patients with HCV related HCC have cirrhosis, whereas patients with HCC related to HBV are less likely to have cirrhosis. The absence of cirrhosis makes this tumor more amenable to surgical resection<sup>[34]</sup>.

**Fibrolamellar carcinoma:** The fibrolamellar variant is a distinctive subtype of HCC but is not associated with classic risk factors for HCC. It occurs at a mean age of 26 years, presenting as a large, solitary painful mass usually located in the left lobe. The AFP level is normal<sup>[89]</sup>. The term "fibrolamellar" characterizes the microscopic appearance of the lesion: thin layers of fibrosis separate the neoplastic hepatocytes<sup>[90]</sup>. A fibrous central scar may be seen on imaging studies<sup>[91]</sup>. 50% of lesions are resectable at the time of diagnosis<sup>[90]</sup>.

**Intrahepatic cholangiocarcinoma:** Cholangiocarcinoma accounts for 20% of primary liver tumors and arises as adenocarcinoma or papillary or mucinous carcinomas<sup>[92]</sup>. Risk factors include cirrhosis, primary sclerosing cholangitis (PSC, 10%), bile duct adenoma, choledochal cysts, biliary papillomatosis, Caroli's disease, and liver fluke<sup>[93-95]</sup>. Jaundice is the most common clinical presentation<sup>[96]</sup>, and rapidly increasing bilirubin associated with weight loss predicts cholangiocarcinoma. Tumor markers CEA, CA-19-9 or AFP might be elevated. CA 19-9 level > 100 has 89% sensitivity and 86% specificity<sup>[97]</sup>. There are three anatomic subtypes: Peripheral intrahepatic 15%, perihilar central (Klatskin tumor) 60%, and distal common bile duct 25%. Peripheral cholangiocarcinoma resembles HCC without cirrhosis. The central hilar and distal types are associated to sclerosing cholangitis, inflammatory bowel disease, or other chronic biliary disease. US and CT show marked intrahepatic duct dilatation<sup>[98]</sup>. An abrupt change in the calibre of the bile duct suggests malignancy<sup>[99]</sup>. Digital image analysis and fluorescent in situ hybridization are more sensitive than routine standard brush cytology in the diagnosis of cholangiocarcinoma. ERCP, percutaneous transhepatic cholangiography (PTC) and magnetic resonance cholangiopancreatography (MRCP) assess the resectability of the tumor.

PET CT stages these tumors with a sensitivity of 93%. The suggested screening includes US, CEA and CA 19-9 every six months, ERCP and brush cytology if there

is biliary stenosis. Combined HCC-cholangiocarcinoma shows features of both hepatocellular and biliary epithelial differentiation<sup>[100]</sup>.

**Epithelioid hemangioendothelioma:** This low-grade malignancy affects individuals between 20-80 years of age. It is associated with oral contraception and exposure to polyvinyl<sup>[101]</sup>. Epithelioid hemangioendothelioma presents with abdominal pain, hepatomegaly, low fever and normal liver enzymes. Endothelial cells stain for CD34, CD31 and factor VIII. The prognosis is good with surgical resection or liver transplantation<sup>[102,103]</sup>.

**Cystadenocarcinoma:** Usually in the right lobe, cystadenocarcinoma is multicytic and contains bile-stained material. It presents as abdominal pain with weight loss<sup>[104]</sup> and prognosis is good<sup>[105]</sup>.

**Lymphomas and leukemia:** Liver involvement is common in Hodgkin's disease including lymphoma infiltration (diffuse small nodules or large masses), drugs, viral hepatitis, and sepsis. Cholestasis is uncommon and vanishing bile duct syndrome has been described<sup>[106]</sup>. The differential diagnosis includes reactive infiltrate and T-cell lymphomas.

Primary hepatic lymphoma is rare and can present as solitary or multiple masses, as a diffuse hepatic involvement with hepatomegaly, or as hepatic failure with elevated LDH<sup>[107]</sup>. Peripheral gamma delta T cell lymphomas with massive hepatic sinusoidal infiltration and splenic involvement have also been described<sup>[108]</sup>. The liver might be diffusely or locally infiltrated by multiple myelomas or leukemia (chronic lymphoid leukemia, hairy cell leukemia)<sup>[109-113]</sup>.

**Neuroendocrine tumors:** Neuroendocrine tumors originating in the gastrointestinal tract frequently metastasize to the liver<sup>[114]</sup>. Liver metastases can be resected<sup>[115]</sup>. Traditional chemotherapy is not effective.  $\alpha$ -interferon has been associated with tumor response. The use of somatostatin analogs in the carcinoid syndrome improves symptoms. Liver transplant remains an option<sup>[116]</sup>.

**Angiosarcoma:** Angiosarcoma is associated with exposure to vinyl chloride<sup>[117]</sup>. Most patients are not amenable to surgery. Usually both hepatic lobes are involved and rapid tumor growth and tendency to metastasize contribute to its dismal prognosis. Chemotherapy and radiotherapy have no role, and ligation of the hepatic artery might permit palliation.

**Undifferentiated sarcoma of the liver:** This rare tumor mainly affects children. The clinical features are fever and a liver mass with recurrent hypoglycemia. The median survival is two months. Imaging shows a solid and cystic lesion with multiple loculi<sup>[118]</sup>.

**Other mesenchymal cell malignancies:** Rhabdomyosarcoma is the most common tumor of the biliary tree in young children. The tumor can mimic a choledocal

cyst<sup>[119]</sup>.

Fibrosarcoma presents as a hepatic mass with recurrent hypoglycemia that will resolve after resection. Serum IGF-2 is elevated<sup>[120]</sup> and Leiomyosarcoma presents with general deterioration and right upper quadrant pain. Angiograms or CT-angiography show a hypervascular tumor. Liver transplantation is possible<sup>[121]</sup>.

## LIVER BIOPSY VERSUS LIVER MASS RESECTION

Before hepatic resection, lesions should be measured, counted and localized to the Couinaud segments. Their relationship to major anatomical structures (portal vein, hepatic artery, inferior vena cava, and hepatic vein) should be detailed<sup>[122-125]</sup>. If malignancy is obvious, biopsy should be avoided because of possible dissemination<sup>[30,44,126]</sup>. Liver histology by true cut needle biopsy is much more profitable than fine needle aspiration and cytological examination but has several disadvantages. If the tumor is small (< 3 cm), a second attempt should be made in 20% of cases<sup>[127]</sup>, bleeding is mild in 1% and severe in 0.1%. In 10% of cases, a firm diagnosis is not established and resection should be performed.

The Child Pugh score helps select which patients should undergo hepatic resection<sup>[128]</sup>. Survival depends on the regenerative potential and the presence of cirrhosis<sup>[129]</sup>. Traditionally, cirrhosis is a contraindication to hepatic resection because of the high mortality rate (20%). A dilemma arises when patients with cirrhosis require a hepatic resection. The problem is that 10%-20% of patients with cirrhosis have primary hepatic malignancy. Moreover, 80%-90% of patients with HCC and 10%-20% of patients with cholangiocarcinoma have cirrhosis. The operative mortality of extensive hepatic resection in patients without cirrhosis is 10%<sup>[130]</sup>.

Treatment modalities include radiofrequency ablation (RFA), percutaneous ethanol injection, cryoablation, hepatic arterial chemoembolisation (TACE), and laparoscopic liver resection. Patients with compensated cirrhosis might benefit from liver resection, RFA or TACE, but patients with decompensated cirrhosis would probably experience no survival benefit<sup>[131]</sup>. In highly selected patients with incidental, central or multifocal tumors, hepatic transplantation might be more beneficial.

## CONCLUSION

In the diagnostic strategy of liver masses, two scenarios are examined: (1) incidentally discovered solid lesions or masses in a cirrhotic patient. The most likely diagnosis is HCC, followed by high and low-grade dysplastic nodule. Lesions > 2 cm are diagnosed by imaging techniques, lesions of 1-2 cm require histology if imaging modalities are atypical, and lesions < 1 cm require US follow-up every three months; (2) incidentally discovered solid lesions or masses in a non cirrhotic patient. The most prevalent lesion is hemangioma. FNH and adenoma should be ruled out in young women with contraceptive treatment. If the lesion is found at

staging or follow up of a known primary malignancy, histology is required when the lesion is doubtful. The most common liver metastases are from adenocarcinoma of colon, stomach, lung, prostate, or breast.

### INTRODUCTION

Colorectal cancer (CRC) is the second most common cause of cancer mortality in the developed countries with increasing prevalence in developing countries due to the changing life style and eating habits<sup>[1]</sup>. More than 940 000 new cases of CRC and nearly 500 000 related deaths are reported each year worldwide.

CRCs are almost primary adenocarcinomas. Neovascularization is considered as an initial triggering event in colorectal tumor growth and dissemination<sup>[2]</sup>. The main mechanisms inciting neovascularization are angiogenesis, the growth of new blood vessels by budding or sprouting from the existing vasculature and vasculogenesis which is the de novo vascular formation from precursor endothelial cells known as angioblasts. Neovascularization arises early in the adenoma-carcinoma sequence via upregulation of various angiogenic factors including vascular endothelial growth factor<sup>[3]</sup>. Thus, the *in vivo* imaging techniques that assess the microvasculature play an immense role in the management of patients with CRC.

Functional imaging techniques including perfusion computed tomography (CT) have emerged as new dimensional tools in the evaluation of blood supply and kinetics in the oncological as well as non oncological aspect of medical fields. A definite radiological preoperative staging is mandatory for adequate management because the treatment protocols need to be standardized based on tumor invasion depth, status of the regional lymph nodes, and distant metastases. Although perfusion CT has been used for a while in the arena of neurological science, it has gained momentum recently in cancer management. In the field of oncology, perfusion CT is emerging as a novel technique applied in the diagnosis, staging, grading, prognostic evaluation based on tumor vascularity, and therapeutic response monitoring. Although many other promising imaging techniques allow for tissue perfusion measurement, CT is particularly ideal for various reasons such as its

### Abstract

Perfusion computed tomography (CT) has emerged as a novel functional imaging technique with gradually increasing importance in the management of colorectal cancer (CRC). By providing the functional tumor microvasculature, it also helps the assessment of therapeutic response of anti-angiogenic drugs as it may reflect tumor angiogenesis. Perfusion CT has been applied in clinical practice to delineate inflammatory or neoplastic lymph nodes irrespective of their size, identify micro-metastases and to predict metastases in advance of their development. It is of increasing significance for preoperative adjuvant therapies and avoidance of unnecessary interventions. Despite controversies regarding the techniques employed, its validity and reproducibility, it can be advantageous in the management of CRCs in which the prognosis is dependent on preoperative staging. With recent advances in the perfusion CT techniques, and incorporation to other modalities like positron emission tomography, perfusion CT will be a novel tool in the overall management of CRCs. This article aims at reviewing the existing clinical applications and recent advances of perfusion CT with a reference to future development in the management of CRCs.

widespread availability, affordability, prevalence of better experience, routine availability of commercial software and readily incorporation of perfusion software for vascular measurements into existing CT protocols<sup>[4,5]</sup>.

## PERFUSION CT PRINCIPLES AND PROTOCOLS IN CRCs

The basic principle governing perfusion CT is the temporal changes in the tissue enhancement following intravenous administration of iodinated contrast media<sup>[6,7]</sup>. Compartmental and deconvolution analyses are the two commonly used analytical methods to quantify vascular physiology from the data acquired from the dynamic CT. In the compartmental modeling technique, analysis can be done by one compartment method which assumes the intravascular and extravascular compartment as a single compartment and allows measurement of tissue perfusion based on Fick's principle during the first pass of contrast, and by double compartment method which assumes the intravascular spaces as two compartments and estimates capillary permeability and blood volume (BV) by Patlak analysis which denotes the passage of contrast into the extravascular space from the intravascular space<sup>[6]</sup>. The deconvolution model on the other hand is based on determining the impulse reside function for the targeted tissue which applies to the arterial and tissue concentration-time curves.

A general perfusion CT technique typically requires a baseline unenhanced image acquisition, followed by a series of images acquired over a time period after an intravenous bolus injection of iodinated contrast media<sup>[8,9]</sup>. The unenhanced CT acquisition primarily provides a wide coverage to the targeted organ, thus serving as a localizer to select the appropriate tissue area to be covered in the following dynamic CT acquisition range. A large coverage area of about 8-16 cm in the dynamic acquisition scan providing increased sample volume has become possible with the recent advances in the scanner technology, although a 2-cm or 4-cm coverage area is still in practice in majority of the institutions. For perfusion measurement, the first pass study includes the images acquired during the initial phase for a total of approximately 40-60 s. By the compartment method, the acquisition of images is done every 3-5 s whereas by deconvolution method, images are acquired every 1 s<sup>[8,9]</sup>. For permeability measurement, second-phase images are acquired, ranging 2-10 min after the first pass study. By compartmental method, the images are obtained every 10-20 s whereas by deconvolution method every 10 s for 2 min after the first pass study<sup>[9,10]</sup>.

Special considerations have to be taken while performing the perfusion studies in CRC. Patients are usually kept on 4-6 h of fasting before water soluble contrast material is given for ingestion to assist in opacifying the small intestine. Image misregistration and errors in estimation of perfusion values due to the respiratory as well as abdominal motions during image acquisition must be avoided. Although respiratory

gating may not be so practicable, it is worthwhile instructing patients for minimal respiratory efforts. Abdominal gating is useful for proper assessment of the tumor physiology. Use of abdominal straps to curtail anterior abdominal wall excursion has been routinely performed. To overcome the bowel peristalsis during perfusion examination of colorectal region, spasmolytic drugs such as hyoscine butyl bromide or glucagon are recommended<sup>[11-14]</sup>. Besides, the use of water or saline to distend the lumen of colorectal region is advantageous for the optimal delineation of the tumor and accurate assessment of the bowel wall thickness<sup>[15]</sup>. Various fallacies do exist while selecting the region of interest, thus mandating careful judgment to avoid attenuation artifacts from various prosthesis as well as misregistration in areas prone to motion. Besides, the proper selection of arterial input is necessary to avoid errors in perfusion value measurement<sup>[7]</sup>.

## APPLICATIONS OF PERFUSION CT IN CRC

Perfusion CT has been applied increasingly in the diagnosis, differentiation, staging, grading and prognosis of CRC and for identification of occult malignancies and local or regional metastases and relapse, and prediction of tumor activity and monitor of treatment response to antiangiogenic drugs and chemoradiotherapy as well.

Henderson *et al*<sup>[16]</sup> noted that perfusion CT enables characterization of the tumor status based on extrapolating the physiological vascular parameters, thus allowing *in vivo* quantification of the microvasculature of the tumor. It has been considered that the gross morphological changes in tumor pathology occur at a later time period than the associated functional vascular profile alteration, precluding accurate and early quantification. Perfusion CT has therefore of a substantial value in assessing the tumor physiology, which is superior to other earlier performed methods<sup>[17-19]</sup>.

### **Validation and correlation with microvessel density (MVD) in CRC**

Perfusion CT exploits the enhancement characteristics of the tissue following contrast which heralds the vascular physiologic changes. Thus, perfusion CT which reflects the tumor physiology can be regarded as an indirect imaging biomarker for the *in vivo* evaluation of angiogenesis. MVD on the other hand represents the number of tumor blood vessels, varied in different tumor types, which may not reflect the angiogenic activity or angiogenic dependence of the tumor.

Dynamic contrast enhanced CT has been regarded as an appropriate non-invasive technique for assessment of angiogenesis, and positive correlations between CT parameters and immunohistologic measures, such as MVD, have also been noted<sup>[20]</sup>. Although Li *et al*<sup>[21]</sup> in their study revealed that there was no significant correlation in perfusion parameters between CRC and MVD, later observations by Goh *et al*<sup>[22,23]</sup> suggested

that BV and permeability surface area product (PS) measurement reflects angiogenesis and that perfusion CT is an appropriate technique for assessing tumor vasculature. CT perfusion imaging may be considered more valid for assessing tumorigenesis in CRC compared with the histological MVD<sup>[21]</sup>.

### **Value in diagnosis of CRC**

White *et al*<sup>[24]</sup> reported that MVD progressively increases from normal colonic mucosa through adenomas to CRC. However, MVD was not related to the Dukes' stage and appeared to decrease slightly with increasing Dukes' stage or tumor differentiation<sup>[21]</sup>. Bossi *et al*<sup>[25]</sup> reported that angiogenesis is an initial prerequisite in colorectal tumorigenesis. Goh *et al*<sup>[22]</sup> observed that CRC has high blood flow (BF), BV, PS and low mean transit time (MTT) values as compared with diverticular disease, which helps differentiate cancer from colonic thickness due to diverticulitis. Li *et al*<sup>[21]</sup> found that superficial invasive carcinomas are capable of eliciting neovascularization comparable to those with distant metastases. Rectal cancer demonstrated higher BF and shorter MIT than normal rectum. In their initial study, Bellomi *et al*<sup>[26]</sup> also found that BF, BV and PS are significantly higher in rectal cancer than in the normal rectal wall. Sahani *et al*<sup>[15]</sup> observed a significant difference in BF and MTT between rectal tumor and normal rectum. However, there was no significant difference in the BV and PS. Perfusion CT has not been found to be correlated with the tumor stages, depth of invasion, and lymph node metastasis in various studies in CRC. However, Li *et al*<sup>[21]</sup> observed that perfusion measurement had a negative correlation with increasing Duke's stage.

### **Value in prognosis of CRC**

Besides a diagnostic value in CRC, perfusion CT has also been employed to assess various treatment modalities and predict the tumor response to those therapies<sup>[15,20]</sup>. Controversies exist while taking MVD as prognostic indicator because of incoherent results and various practical limitations. Bossi *et al*<sup>[25]</sup> indicated that MVD did not provide significant prognostic information in CRC. Pietra *et al*<sup>[27]</sup> observed that MVD in CRC without lymph nodes involvement has no correlation with conventional prognostic factors and provides no significant prognostic information. Sahani *et al*<sup>[15]</sup> observed that poor prognosis was more likely in tumors with high BF and low MIT possibly due to the increased angiogenic activity of the tumor cells. Bellomi *et al*<sup>[26]</sup>, however, found that rectal cancers with high baseline BF and BV showed good response to chemoradiotherapy.

### **Value in metastases and treatment monitoring in CRC**

Leggett *et al*<sup>[28]</sup> observed that increased arterial perfusion appeared to be an indicator of liver metastases in patients with CRC. It was also noted that progressive disease may be indicated by a reduction in the portal perfusion. Irrespective of the presence of focal liver lesions, there are alterations in the microvasculature and perfusion values

in CRC, it is not ideal to employ the same enhancement protocols in patients with liver metastases<sup>[27]</sup>.

Perfusion CT has played an increasing role in monitoring therapeutic response to antiangiogenic drugs and chemoradiation as it may reflect tumor angiogenesis and provide insight of the functional tumor microvasculature<sup>[15,20,26]</sup>. However, there have been few studies to predict subsequent relapse in CRC. Goh *et al*<sup>[29]</sup> prospectively studied the vascular measurements in patients with rectal cancer to determine if it can predict subsequent metastatic relapse. It was observed that there was a significant difference in the vascularity of the tumors in patients who will subsequently develop metastases despite of curative surgery. Vascular parameter such as MTT was significantly high whereas tumor BF and permeability surface area product were low in patients who developed metastases. It was also noted that PS measurements were significantly higher in patients who already had evidence of metastatic disease compared with patients who subsequently developed metastatic disease<sup>[29]</sup>.

Perfusion CT definitely has an implied role in the monitoring and prediction of treatment response to chemotherapy and radiation therapy in rectal cancers<sup>[26]</sup>. Sahani *et al*<sup>[15]</sup> observed that after completion of chemoradiotherapy, rectal cancer showed a consistent decrease of BF and an increase of MIT. Bellomi *et al*<sup>[26]</sup> observed similar results with decrease in BF, BV and PS after chemoradiation in rectal cancer. In a clinical trial of patients with rectal cancer treated with antiangiogenic therapy (bevacizumab), Willett *et al*<sup>[20]</sup> observed that CT perfusion helped monitor antiangiogenic changes within 2 wk of treatment and its characteristics are correlated with tumor MVD, which presented with decrease in MVD and other surrogate markers of angiogenesis.

## **CONCLUSION**

Perfusion CT is strengthening its role as a preferred functional imaging technique in the management of CRC. Despite various limitations, perfusion CT has substantially influenced the imaging and treatment aspect in the management of CRC patients, particularly as a biomarker for monitoring the response of various treatment modalities, which may have further clinical usefulness in the staging of the disease and prognostic value as well. With the advancement in perfusion software and the development of new generation of scanners having a wider cine acquisition, it has allowed single or even multiple organ perfusions with the advantage of decreased radiation exposure and motion artifacts. Moreover, the integration of positron emission tomography (PET)-CT systems with FDG-PET data represents an exciting new innovative technology that has a wide range of clinical application as a single examination while minimizing the image misregistration. Development of new contrast agents which retain longer in intravascular compartment may also overcome some of the complexities of physiological modeling

required for conventional contrast agents that exhibit two-compartment pharmacokinetics. Perfusion CT which was primarily introduced as a research tool has now emerged as a definitive functional technique in the management of CRC.

## Abstract

**AIM:** To evaluate radiofrequency thermal ablation (RTA) for treatment of cystic echinococcosis in animal models (explanted organs).

**METHODS:** Infected livers and lungs from slaughtered animals, 10 bovine and two ovine, were collected. Cysts were photographed, and their volume, cyst content, germinal layer adhesion status, wall calcification and presence of daughter or adjacent cysts were evaluated by ultrasound. Some cysts were treated with RTA at 150 W, 80°C, 7 min. Temperature was monitored inside and outside the cyst. A second needle was placed inside the cyst for pressure stabilization. After treatment, all cysts were sectioned and examined by

histology. Cysts were defined as alive if a preserved germinal layer at histology was evident, and as successfully treated if the germinal layer was necrotic.

**RESULTS:** The subjects of the study were 17 cysts (nine hepatic and eight pulmonary), who were treated with RTA. Pathology showed 100% success rate in both hepatic (9/9) and lung cysts (8/8); immediate volume reduction of at least 65%; layer of host tissue necrosis outside the cyst, with average extension of 0.64 cm for liver and 1.57 cm for lung; and endocyst attached to the pericystium both in hepatic and lung cysts with small and focal *de novo* endocyst detachment in just 3/9 hepatic cysts.

**CONCLUSION:** RTA appears to be very effective in killing hydatid cysts of explanted liver and lung. Bile duct and bronchial wall necrosis, persistence of endocyst attached to pericystium, should help avoid or greatly decrease *in vivo* post-treatment fistula occurrence and consequent overlapping complications that are common after surgery or percutaneous aspiration, injection and repiration. *In vivo* studies are required to confirm and validate this new therapeutic approach.

## INTRODUCTION

Cystic echinococcosis is a helminthic zoonosis that can occasionally affect human beings. The organs most frequently involved are the liver and the lungs<sup>[1,2]</sup>. Viability and pathogenicity of the cyst are conditioned by the integrity of its germinal membrane. For many years elective treatment has been surgery (organ resection, cysto-pericystectomy)<sup>[3,4]</sup>. Recently percutaneous aspiration, injection and reaspiration (PAIR), using hypertonic saline or ethanol, has become a valid alternative option, principally for the liver<sup>[5,6]</sup>. This is now widely advocated in the treatment of uncomplicated fluid-filled liver cysts because of lower recurrence and complication rates<sup>[3,7,8]</sup>. There are, however, few reports in the literature on PAIR treatment of pulmonary echinococcosis<sup>[9,10]</sup>. Chemotherapy with albendazole can be used in combination with interventional procedures, but is seldom effective alone<sup>[3,11-13]</sup>. Both surgery and PAIR can result in post-procedure complications, namely, biliary or bronchial fistulae promoted by endocyst detachment<sup>[14-16]</sup>; chemical cholangitis or pneumonia due to passing of hypertonic saline or ethanol into the biliary or bronchial tree through a pre-existing communication<sup>[9,10,17,18]</sup>; and infection or abscess on the cyst cavity<sup>[3,7,10]</sup>. Chemical cholangitis is a frightful complication since it invariably requires liver transplantation<sup>[17]</sup>. Radiofrequency thermal ablation (RTA) is currently used for treatment of neoplasms, primarily hepatocellular carcinoma<sup>[19-21]</sup>.

To our knowledge, there is no controlled study in the literature on possible treatment of hydatid cyst with RTA. The aim of our study was to evaluate RTA for treatment of cystic echinococcosis of liver and lung in animal models (explantated organs). The primary end point was to evaluate efficacy in killing the parasite. The secondary end-points were to evaluate germinal layer adhesion status after the procedure and the effect of radiofrequency (RF) on host organ tissue outside the cyst.

## MATERIALS AND METHODS

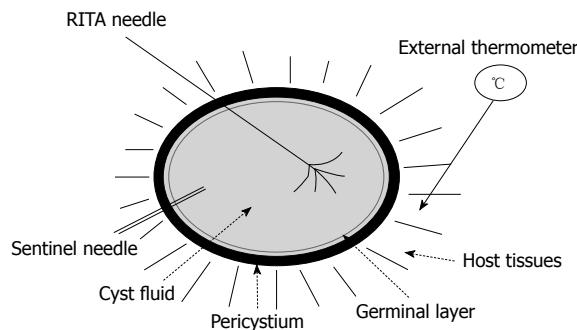

### Material

Cystic echinococcosis is an endemic zoonosis in Sicily<sup>[22,23]</sup>. To perform our study we used infected livers and lungs from slaughtered animals, 10 bovine and two ovine. Samples were provided by the Veterinary Service of the Region of Sicily within 12 h of their collection. By using slaughtered animals with endemic zoonosis, our study had minimal economic costs and raised no ethical concerns.

### Procedure

Each cyst was photographed and evaluated by ultrasound (US). Cyst volume was calculated with the ellipsoid volume formula ( $4/3 \pi abc$ ;  $abc$  = cyst hemidiameters). Cyst content, germinal layer adhesion status, presence of wall calcification and presence of daughter or adjacent cysts were also evaluated by US.

The *ex-vivo* approach, large size and superficial place

**Figure 1** Schematic description of radiofrequency thermal ablation (RTA) on echinococcal cyst.

of the cysts made US evaluation easy in the lung as well as the liver.

Each cyst was placed on a RITA® dispersive electrode and, under US guidance, a 9-tip expandable needle (RITA® StarBurst TM XL, RITA Medical Systems) was inserted into the cyst, expanded and connected to a RF generator (RITA Medical System 1500 X). Temperature inside the cyst was monitored by RITA needle tip temperature transducers. Under US guidance a thermometer (bimetal thermometer 0 + 120°C, probe length: 110 mm - Ø 4 mm, dial Ø 45 mm) was also placed outside the cyst, up to 1 cm from its wall, for external temperature monitoring. Both internal and external temperature was monitored throughout the procedure and for the following 20 min.

In addition to the RITA needle, a second needle, which we named "sentinel needle," was also placed inside the cyst in order to stabilize internal cyst pressure during the procedure (Figure 1). In fact, during pre-study sessions of the treatment that we preliminarily performed in order to optimize the technical aspects of the procedure, we observed that while reaching target temperature, endocytic pressure quickly increases and invariably causes cyst rupture unless pressure stabilization is obtained. The increase in endocytic pressure is likely due to gas formation (water vapor, CO<sub>2</sub>) at the interface of the fluid/needle because of the high local temperature.

The RTA parameters we used were: 150 watts, 80°C, 7 min. Treated cysts were then sectioned and a pathology examination was performed. Histology on the samples evaluated the germinal layer, the presence of scolices, the pericystium, parenchymal cells, blood vessels, biliary ducts (liver) and the bronchial walls (lung).

All the data were stored in an Excel database and used for statistics. In addition to the treated cysts, there were also some untreated parasitic cysts randomly examined with US and histology, using the same criteria as that used for treated cysts, as an addendum to the study.

### Viability definition

Alive cyst: histological evidence of preserved germinal layer; killed cyst: necrotic endocyst at histology.

### Statistical analysis

By definition, pilot studies are conducted on a small

number of cases, which makes reliable statistical correlations difficult to establish. Nevertheless, we performed a statistical analysis of our data in an attempt to identify significant trends. All values were expressed as a mean, and the Mann-Whitney *U*-test was used for comparison among groups. All *P* values were two-sided, and *P* < 0.05 was considered statistically significant. The Pearson test was used to investigate the linear relationship between two groups of data.

## RESULTS

A total of 28 cysts, 16 hepatic and 12 pulmonary, were evaluated. Seventeen, treated with RTA, were the object of our study (Table 1). In addition, 11 untreated cysts, seven hepatic and four pulmonary, were randomly evaluated. All of them were unilocular with anechoic content, no wall calcification, germinal membrane adherence were observed at US, and all were alive at pathology.

### Treated cysts

Seventeen cysts were treated with RTA: nine hepatic, average volume 40.5 mL (range, 8.3-61.6 mL), and eight pulmonary, average volume 158.7 mL (range, 4.2-471 mL). Baseline US showed the endocyst was attached to the pericystium in 100% (9/9) of liver and 75% (6/8) of lung cysts, and focally detached in 25% (2/8) of lung cysts. Average time to reach the target temperature inside the cyst was 6.3 min for the liver (range, 3-14 min) and 9.5 min for the lung (range, 3-19 min). During RF administration the internal temperature remained stable at target temperature

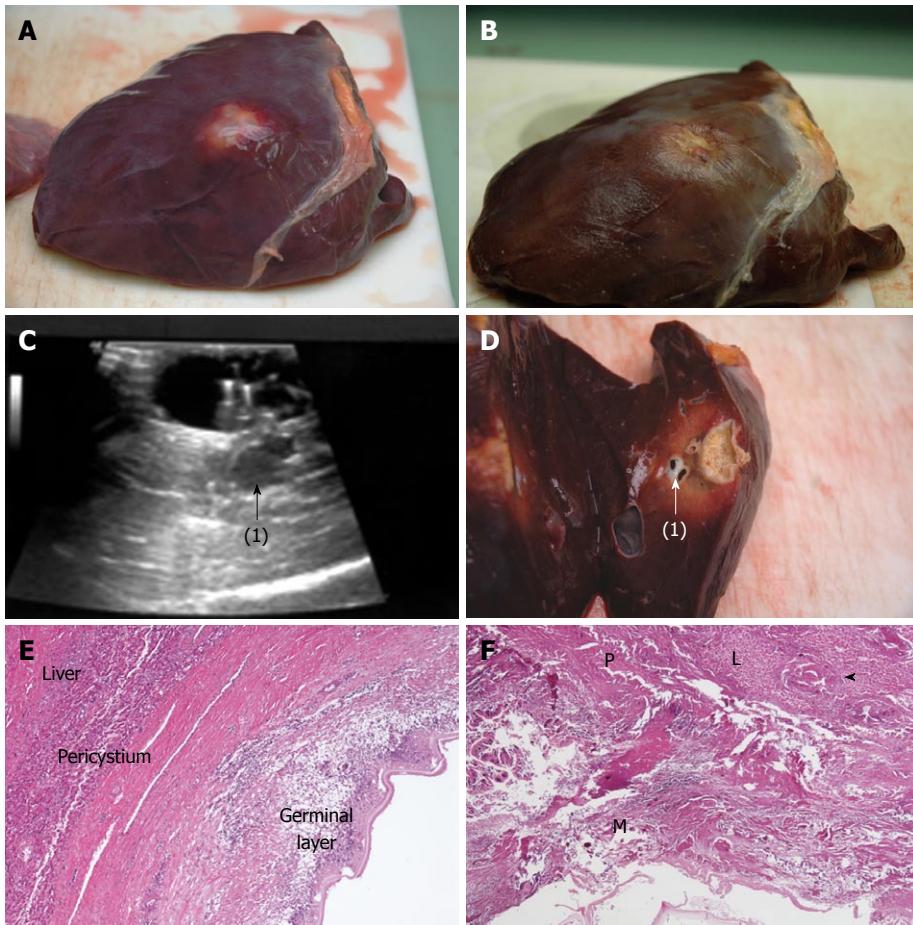

**Figure 2 Cyst volume before and after RTA in liver (A) and lung (B).** All treated cysts showed a strong and immediate reduction in volume.

in all treated cysts.

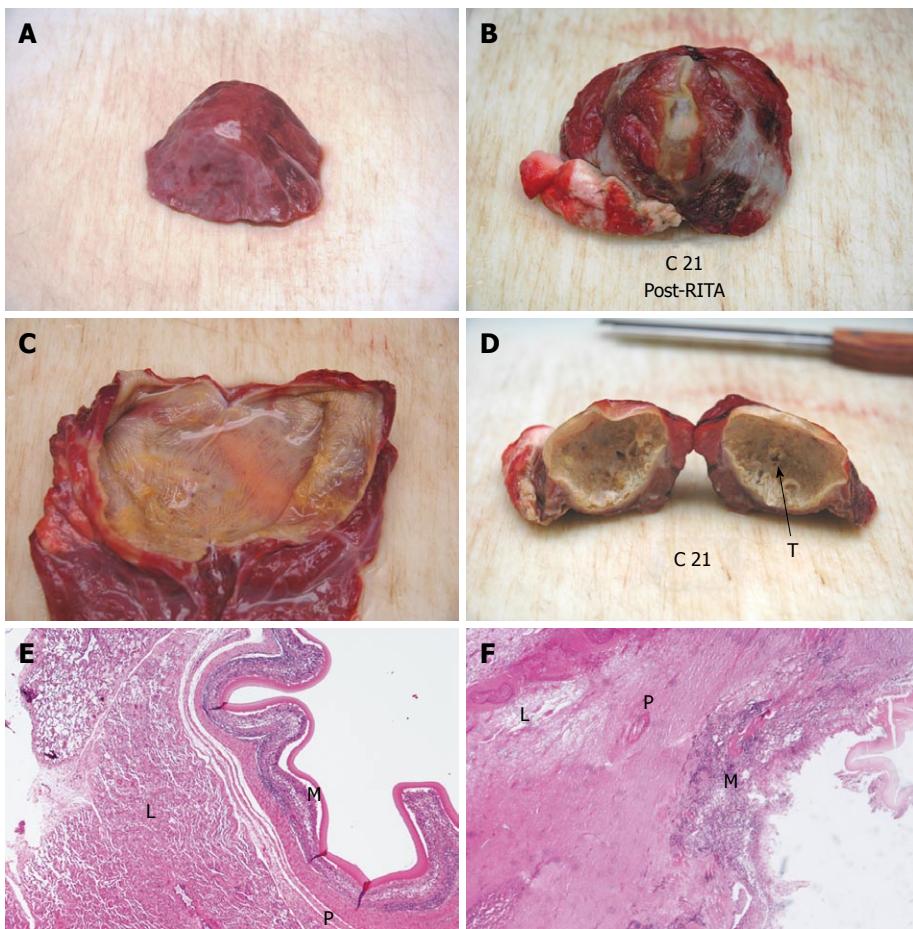

After RTA, 100% of the cysts had volume reduction. For the liver, the cyst volume average decreased from 40.5 mL before to 14.9 mL after RTA (*P* = 0.004). For the lung, the cyst mean volume decreased from 158.7 to 57.1 mL (*P* = 0.13). Hence, immediate reduction of mean volume for liver and lung cysts was 65% and 69%, respectively (Figure 2).

Compared with baseline, the endocyst remained attached to the pericystium after RTA in hepatic and lung cysts. We observed just a small and focal (i.e. few millimeters) *de novo* endocyst detachment in three hepatic cysts. Histology showed a 100% success rate in both hepatic (9/9) and lung cysts (8/8). A coagulative necrosis of the endocyst and the pericystium was observed, as well as a concentric area of host organ tissue necrosis, variable in size, with an average extension of 0.64 cm (range, 0-2 cm) for liver, and 1.57 cm (range, 0.8-2.5 cm) for lung (Figures 3-6). Possible correlation between cyst volume and size of pericyst necrosis was evaluated. For the liver, an inverse correlation of 68% was observed between pre-RTA volume and pericyst necrosis extension (*P* = 0.044). For lung cysts this correlation was 30% (*P* = 0.471). It is worth noting that within the necrotic area, parenchymal cells, blood vessels, bile ducts (liver) and bronchial walls (lung) were all necrotic in all treated cysts. Organ samples taken from areas far from the treated cysts showed normal histology in all cases.

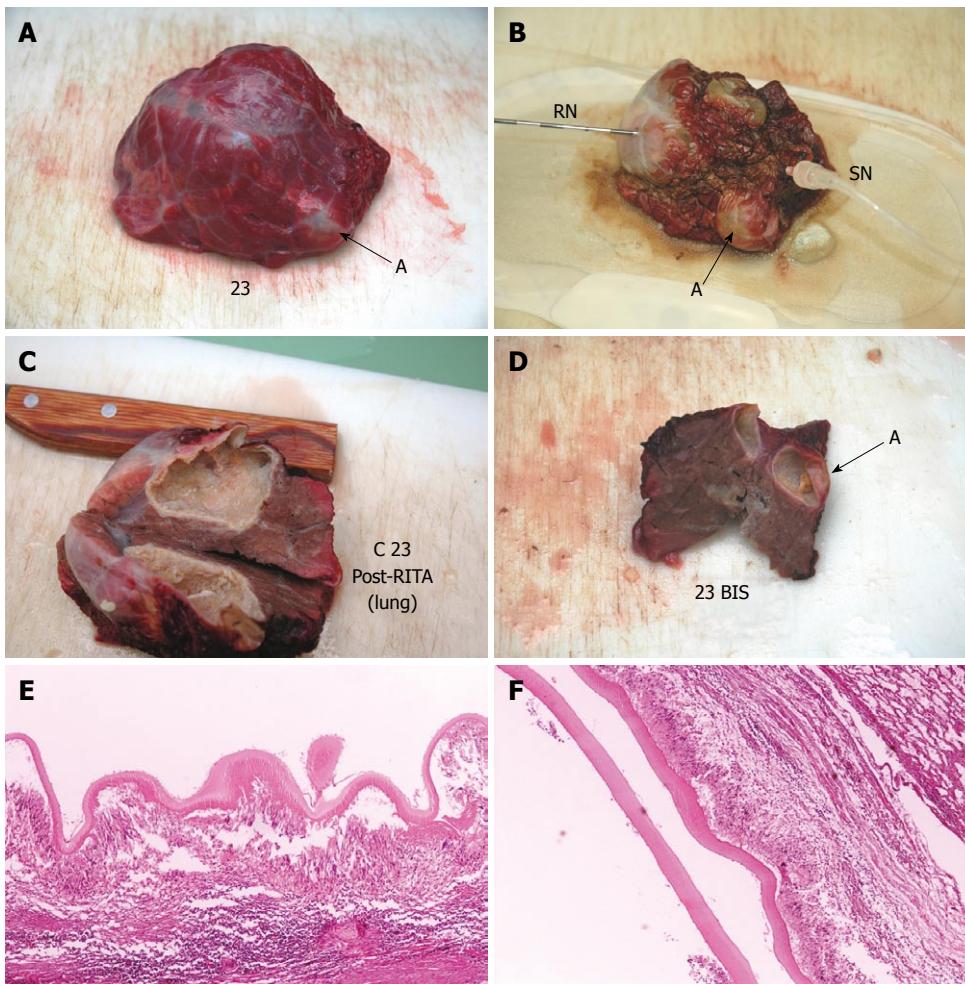

Two cysts, hepatic and pulmonary, respectively,

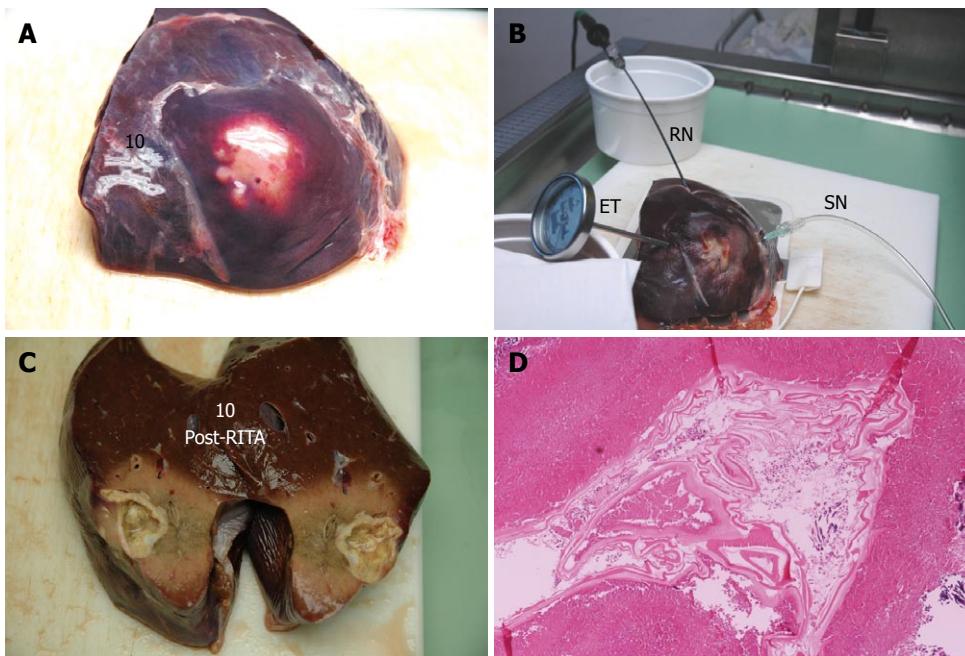

**Figure 3 Hydatid cyst of the liver treated with RITA.** The upper panel shows the surface of the liver before (A) and after (B) RITA. The procedure caused cyst retraction. The middle panel shows pre-procedure ultrasound (C) and post-RTA section (D) of the cyst. A transverse US scan shows the RITA needle expanded inside the cyst and a smaller adjacent cyst (1) situated within the necrotic area surrounding the treated cyst. Histology showed the smaller cyst was necrotic and killed despite no direct treatment. In the lower panel, histology (HE stain,  $\times 4$ ) of an untreated cyst (E) is compared with that of the treated one (F). In the former, all structures are well recognizable, while in the latter the cyst layers are totally necrotic. M: Germinal membrane; P: Pericystium; L: Liver parenchyma. Arrow tips indicate necrotic portal tracts. 1: Adjacent cyst.

**Figure 4 Hydatid cyst of the lung.** Untreated (left) and treated (right) cysts are compared. External surface (upper panel), findings after sectioning (middle panel), and  $4 \times$  HE stained histology (lower panel) are shown. Untreated cyst shows normal surface, flaccidity after sectioning, thin and translucent endocyst and well preserved cyst layers at histology. Treated cyst looks dehydrated, rigid, has a thick and papyraceous-like endocyst and is totally necrotic at histology. T: RITA-needle tract; M: Germinal membrane; P: Pericystium; L: Lung parenchyma.

**Figure 5** *Echinococcus* cyst of the lung before (A) and after (B-D) RITA. External surface of the cyst (upper panel), findings after sectioning (middle panel), and histology (lower panel). After treatment (B) the cyst looks shrunken, rigid and dehydrated. Post-RITA section of the cyst (C) shows the endocyst is thick, papyraceous-like and attached to pericystium. Histology (HE stain,  $\times 4$ ) shows complete necrosis of the cyst wall (E). An adjacent cyst (indicated by arrow A in slides A, B, D) was necrotic and killed at histology (F) despite no direct treatment. RN: RITA needle; SN: Sentinel needle.

**Figure 6** *Echinococcus* cyst of the liver treated with RITA. The upper panel shows the surface of the liver before (A) and after (B) RITA. Procedure caused cyst retraction. RITA needle, sentinel needle and external thermometer, still in place, can be seen (B). The left lower panel shows post-RITA section (C) of the cyst. Histology of a paramedian section (right lower panel, HE stain,  $\times 2$ ) shows cyst walls and surrounding liver closest to the cyst are totally necrotic and with granular amorphous aspect (D). RN: RITA needle; SN: Sentinel needle; ET: External thermometer.

adjacent ( $< 1$  cm) to the ones treated were killed despite no direct treatment (Figures 3 and 5). Another cyst, an external daughter lung cyst not directly treated, was partially alive at histology, though the procedure on the mother cyst was non-optimal because the cyst ruptured early.

Temperature curves detected inside and outside the cysts during the entire procedure had similar courses, but with clearly lower values in the host tissue near the cysts (data not shown). The highest temperature gradient ( $T_{\max}$  internal -  $T_{\max}$  external) ranged between  $11.9^{\circ}\text{C}$  and  $58.3^{\circ}\text{C}$  (mean,  $38.0^{\circ}\text{C}$ ) in liver cysts and between  $16.9^{\circ}\text{C}$

and 38.7°C (mean, 27.7°C) in the lung. The external temperature peak was never above 70°C, and in 88% of the samples was below 55°C.

## DISCUSSION

Our primary goal was to investigate whether RTA can kill *Echinococcus granulosus* cysts in explanted livers and lungs. We observed that RF (1) warmed the hydatid cyst fluid and caused endocyst necrosis in both hepatic and lung cysts in 100% of cases; (2) maintained endocyst attachment to the pericystium; (3) caused a layer of host tissue damage outside the cyst; (4) gave lower temperature values outside the cyst than inside it; and (5) resulted in a post-procedure volume reduction average of more than 65%.

From a review of the literature we found only two case reports on using RTA for treatment of cystic lesions in humans. No controlled study on RTA treatment of hydatid cysts is reported. Rhim *et al*<sup>[24]</sup> successfully treated a simple cyst of the liver, though this differs from the hydatid cyst from biological and pathological points of view. Brunetti *et al*<sup>[25]</sup> reported treatment with RTA on a single patient with cystic echinococcosis of the liver. However, here, the assessment of treatment efficacy was based solely on disappearance of scolices upon post-procedure microscopic examination of cyst fluid. This is not sufficient for assessing the definitive killing of the cyst if long term clinical follow-up is lacking, though the ideal procedure is microscopic verification of permanent damage to the germinal membrane, as mentioned by Brunetti *et al*<sup>[25]</sup> themselves in their comments on Khuroo's paper<sup>[26]</sup>. In this regard, we would like to underscore that in our study a microscopic examination with methylene blue stain on cyst fluid collected through the sentinel needle just before, during, and soon after the RF administration was initially performed on a limited number of cysts, looking for scolices and their viability. This was discontinued in the study because of its total lack of sensitivity (no scolex was seen in the centrifuged fluid, even though they were present later at histology). Finally, Brunetti *et al*<sup>[25]</sup> in their case report say nothing of pressure stabilization to avoid cyst rupture.

Actually, in our pre-study sessions of treatment, all the cysts we treated invariably "exploded" a few minutes after the start of the procedure, independently of their baseline volume. That no longer happened after we started placing a "sentinel needle" inside the cyst. We also observed that ruptured cysts, despite reaching the target internal temperature faster, were still alive and often contained well preserved scolices on pathology examination. This suggests that RTA kills the parasite by using its own fluid, which assures homogeneous and sustained values of high temperature inside the whole cyst. If there is a rupture of the cyst and its fluid is released, RF causes only focal damage, probably where the needle tips are in contact with the cyst wall.

It has been demonstrated that during PAIR on cystic echinococcosis, the germinal membrane usually detaches entirely and collapses inside the cyst<sup>[3,9,14-16]</sup>. This always

occurs, by definition, during peri-cystectomy. Endocyst detachment can cause the appearance of biliary or bronchial fistulae inside the cyst cavity. This is more likely if a pre-existing virtual communication between the parasitic cyst and the biliary or bronchial tree is present<sup>[9,10,27,28]</sup>. The biliary fistula is one of the most frequent complications after surgery or percutaneous treatment of liver hydatid cysts<sup>[15,29-31]</sup>, though at lower rates after PAIR<sup>[3,32]</sup>. It often evolves into infected collection and abscess, thus increasing hospital length of stay, economic costs and patient discomfort<sup>[32]</sup>. The heat-related coagulative necrosis we obtained with RTA can explain both the killing effect on the parasite and also why the endocyst remained attached to the pericystium. Based on that, it seems reasonable to suppose a low (if not lack of) incidence of fistula occurrence after RTA *in vivo*. Furthermore, the layer of host tissue necrosis we observed outside the treated cysts, whether thinner or thicker, could further increase the killing effect (by stopping *in vivo* blood vessel supply) and decrease the incidence of post-procedure fistula occurrence (by causing bile duct or bronchial wall necrosis). This, of course, must still be proven by controlled *in vivo* studies. Nevertheless, an indication of this possibility emerged in a recently published case report by Thanos *et al*<sup>[33]</sup>, who successfully treated a post-surgical biliocystic communication and cystocutaneous fistula with RF.

Based on our results we expect that *in vivo* blood flow would have no significant effect on the intra-cystic killing power of RTA. In fact, data on treatment of hepatocellular carcinoma and other hepatic tumors show how RTA can cause *in vivo* necrosis of vascularized nodules up to 5 cm in size<sup>[19,20]</sup>, and up to 8.5 cm in size if associated with occlusion of tumor blood supply<sup>[21]</sup>. This should occur even more on a hydatid cyst that has no internal blood flow (and therefore no internal heat sink effect), that is full of fluid and that has a relatively thick wall that creates a physical barrier from the outside, as also demonstrated by the gradient we calculated between the temperature inside the cysts and outside. In any case, only *in vivo* controlled studies can definitively answer this question.

Several studies report a volume reduction of the cyst of 65% or more after PAIR or pericystectomy, and such rates are described usually 6-19 mo after the treatment<sup>[16,31,34,35]</sup>. In our study, compared with baseline, we observed this level of volume reduction immediately after treatment. This is probably due to necrosis and dehydration of the cyst wall and the surrounding host tissues (Figures 5 and 6). The volume decrease after RTA and correlation of cyst volume with extension of pericyst necrosis were significant for the liver but not for the lung. This is probably due to different tissue characteristics (liver is solid, while lung has some air inside); to the small number of cases analyzed; and, lastly, to the fact that the lung cysts provided were larger and mainly exophytic compared with the hepatic cysts. An optimal statistical investigation of such correlations would require larger numbers.

With respect to our goals, we believe the results of

our pilot study are very interesting, particularly the 100% success rate we observed despite different baseline cyst volumes and types of organs treated.

Potential advantages expected with *in vivo* RTA on cystic echinococcosis as follows: (1) While PAIR sometimes requires more sections to assure definitive killing of the cyst, RTA can kill a hydatid cyst in a single section, since the entire cyst wall is made necrotic by a heat-related mechanism; (2) Given that RTA avoids the use of chemical media there is no risk of chemical cholangitis related to its accidental passing into the biliary tree. Hence, pre-existence of cysto-biliary communication is no longer a contraindication to percutaneous treatment; (3) Compared with PAIR or surgery, persistence of endocyst attachment to pericystium in a high percentage of cases should help avoid or greatly decrease post-RTA fistula occurrence, and consequent overlapping complications.

The results, and the experimental hypothesis raised by our study, must be confirmed by *in vivo* study.

## COMMENTS

### Background

Treatment of cystic echinococcosis is surgery or percutaneous aspiration, injection and reaspiration (PAIR) using hypertonic saline or ethanol, and it is aimed to cause permanent damage to the endocyst. Surgery and PAIR can result in biliary or bronchial fistulae, prompted by endocyst detachment; chemical cholangitis or pneumonia, due to passing of hypertonic saline or ethanol into the biliary or bronchial tree; and infection or abscess on residual cyst cavity. Radiofrequency thermal ablation (RTA) is currently used for treatment of neoplasms, primarily hepatocellular carcinoma.

### Research frontiers

Features of an ideal therapy for hydatid cysts should include the following: (1) certainty of killing the parasite; (2) avoidance of post-procedure fistulae and consequent overlapping complications; (3) mini-invasive approach. The authors experimented with the use of RTA trusting in its heat-related killing power as well as on the possibility that, after heat-related coagulative necrosis of cyst wall, the parasitic endocyst could have remained attached to the pericystium. This approach is unlike surgery or PAIR, which invariably cause endocyst detachment.

### Innovations and breakthroughs

The research showed that radiofrequency is able to warm and irreversibly damage hydatid cysts in a single section, since the entire cyst wall is made necrotic by a heat-related mechanism. Avoiding the use of chemical media, there is no risk of chemical cholangitis. Unlike PAIR, the existence of cysto-biliary communication would no longer be a contraindication to percutaneous treatment of the hydatid cyst. The persistence of endocyst attachment to pericystium should help avoid or greatly decrease post-RTA fistula occurrence and consequent overlapping complications.

### Applications

This pilot study suggests that a new therapeutic approach in treatment of hydatid cyst is possible and, indeed, very effective. The *ex vivo* model is expected to be predictive of what would be the *in vivo* effect of RTA, since cystic lesions have no internal blood vessels. *In vivo* blood flow would not have a significant impact, particularly in view of the fact that HCCs of several cm can be currently ablated with RTA despite being vascularized (heat sink effect), and that RTA power is increased by occlusion of tumor blood supply. The study also seems to suggest that RTA could potentially be used to attempt treatment of other types of cystic lesions (symptomatic treatment in polycystic disease,

cystic neoplasms, pancreatic pseudocysts, etc).

### Terminology

*Cystic echinococcosis* is a helminthic zoonosis that can affect human beings, most frequently involving the liver or the lungs, where it causes expansive cystic lesions. Endocyst or *prolifera* membrane is the thin, delicate, and translucent inner membrane that produces the cyst fluid and generates new larval elements able to expand the infestation.

### Peer review

This is an *ex vivo* pilot study on RFA in cystic echinococcosis in a relatively small animal sample size. The authors report 100% success rate in treating cysts and several innovative technical aspects. Results and literature data reported in the paper discussion suggest that this technique is very promising.

## Abstract

**AIM:** To investigate the possible protective effects of carnosol on liver injury induced by intestinal ischemia reperfusion (I/R).

**METHODS:** Rats were divided randomly into three experimental groups: sham, intestinal I/R and carnosol treatment ( $n = 18$  each). The intestinal I/R model was established by clamping the superior mesenteric artery for 1 h. In the carnosol treatment group, surgery was performed as in the intestinal I/R group, with intraperitoneal administration of 3 mg/kg carnosol 1 h before the operation. At 2, 4 and 6 h after reperfusion, rats were killed and blood, intestine and liver tissue samples were obtained. Intestine and liver histology was investigated. Serum levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT) and interleukin (IL)-6 were measured. Liver tissue superoxide dismutase (SOD) and myeloperoxidase (MPO) activity were assayed. The liver intercellular adhesion molecule-1 (ICAM-1)

and nuclear factor  $\kappa$ B (NF- $\kappa$ B) were determined by immunohistochemical analysis and western blot analysis.

**RESULTS:** Intestinal I/R induced intestine and liver injury, characterized by histological changes, as well as a significant increase in serum AST and ALT levels. The activity of SOD in the liver tissue decreased after I/R, which was enhanced by carnosol pretreatment. In addition, compared with the control group, carnosol markedly reduced liver tissue MPO activity and serum IL-6 level, which was in parallel with the decreased level of liver ICAM-1 and NF- $\kappa$ B expression.

**CONCLUSION:** Our results indicate that carnosol pretreatment attenuates liver injury induced by intestinal I/R, attributable to the antioxidant effect and inhibition of the NF- $\kappa$ B pathway.

## INTRODUCTION

Intestinal ischemia reperfusion (I/R) is one of the most common types of cell injury, which is caused by many factors, such as acute blood loss, shock, ileus and multiple trauma. Intestinal I/R not only leads to intestinal damage itself, but also causes severe destruction of remote organs<sup>[1-3]</sup>. The liver is the first distant organ involved after intestinal I/R<sup>[4,5]</sup>. Although the detailed mechanism of liver injury induced by intestinal I/R remains to be elucidated, a variety

of inflammatory mediators including intracellular adhesion molecule-1 (ICAM-1) and cytokines, as well as infiltration of neutrophils have been implicated in this process<sup>[6-8]</sup>.

Nuclear factor κB (NF-κB) is one of the most important transcriptional factors, which consists of p50 and p65 subunits. In quiescent cells, it exists as a latent cytoplasmic complex bound to an inhibitor protein, I-κB. In response to an activation signal, I-κB is phosphorylated and degraded through the proteosomal pathway. The free NF-κB complex is then able to translocate into the nucleus and induce expression of various target genes that are critical for cell survival, inflammation and immunity<sup>[9,10]</sup>. NF-κB is also activated and plays a major role during the local and systemic inflammatory response following intestinal I/R<sup>[11]</sup>. Thus, modulating the NF-κB pathway is a new concept and therapeutic option to attenuate intestinal I/R-induced local and remote organ injury<sup>[11-13]</sup>.

Carnosol, a major component of rosemary, is a phenolic diterpene that has potent antioxidant and anti-inflammatory activities<sup>[14-16]</sup>. Carnosol has been found to suppress NO production and inducible nitric oxide synthase gene expression by inhibiting NF-κB activation<sup>[17]</sup>.

In this study, we investigated the effects of carnosol on liver injury following intestinal I/R and explored the mechanism of its protective action.

## MATERIALS AND METHODS

### Animals

Male Wistar rats (Animal Center of Dalian Medical University, Dalian, China) weighing 190-220 g were used in this study, which was approved by the Institutional Ethics Committee. All rats were fed with standard laboratory chow and water, and housed in accordance with institutional animal care guidelines.

### Experimental design

Rats were assigned randomly into three experimental groups: control, intestinal I/R and carnosol pretreatment groups ( $n = 18$  in each group). The rats in the control group underwent surgical preparation including isolation of the superior mesenteric artery (SMA) without occlusion; the intestinal I/R group was subjected to 1 h intestinal ischemia and various times of reperfusion after the SMA was isolated and occluded<sup>[18]</sup>. In the carnosol pretreatment group, surgery was performed as in the intestinal I/R group with intraperitoneal administration of 3 mg/kg carnosol (Cayman Chemical Company, Ann Arbor, MI, USA) 1 h before the operation. Carnosol was dissolved in 3% DMSO before administration. The dose of carnosol administered was determined according to a previous study<sup>[19]</sup>, with modification from our preliminary experiments. The rats in the control and intestinal I/R group were treated with an equal volume of 3% DMSO when needed. At each of the indicated time points (2, 4 and 6 h after reperfusion), six rats were

killed randomly from each group, and blood, intestine and liver tissue samples were obtained for further analysis.

### Intestine and liver morphological assessment

The isolated intestine and liver tissues were harvested and fixed in 10% formalin. After being embedded in paraffin, the tissues were stained with hematoxylin and eosin for light microscopy.

### Measurement of serum aspartate aminotransferase (AST), alanine aminotransferase (ALT) and interleukin (IL)-6 levels

The serum levels of AST and ALT were measured with an OLYMPUS AU1000 automatic analyzer (AusBio Laboratories Co., Ltd. Beijing, China). The serum levels of IL-6 were determined using a radioimmunoassay kit (Radioimmunity Institute of PLA General Hospital, Beijing, China) following the manufacturer's instructions.

### Liver superoxide dismutase (SOD) and myeloperoxidase (MPO) activity assay

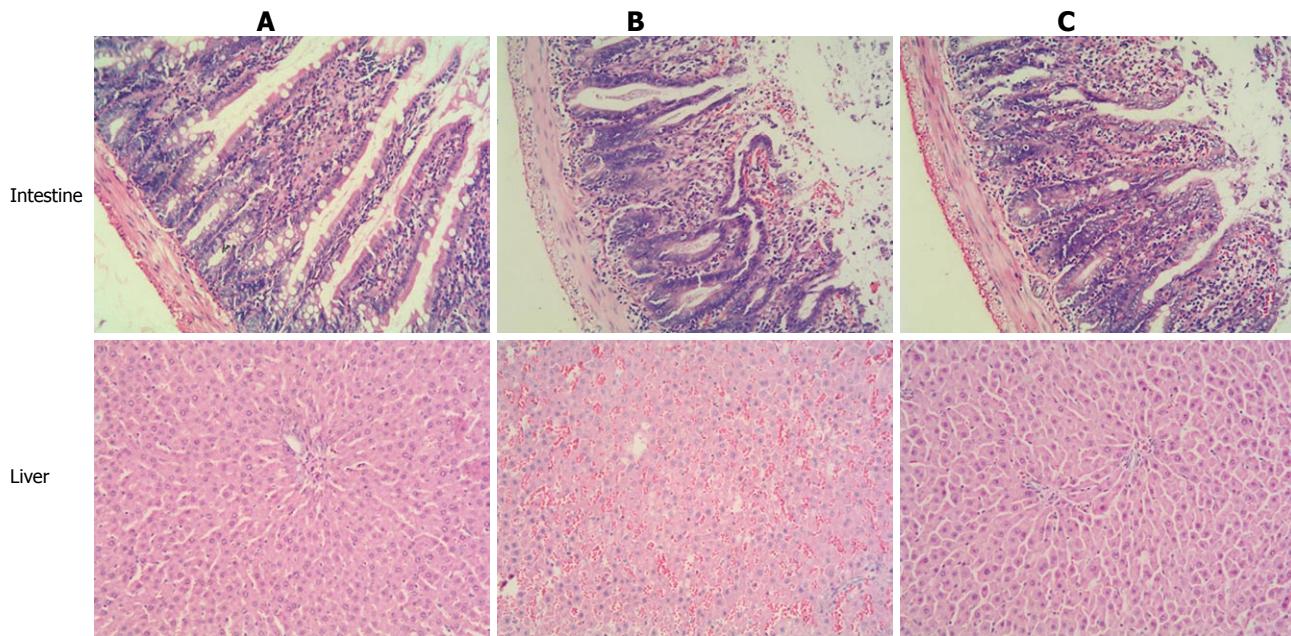

The liver tissues were harvested and homogenized immediately on ice in five volumes of normal saline. The homogenates were centrifuged at 1200 r/min for 10 min. The SOD and MPO activity in the supernatant was determined using an assay kit (Nanjing Jincheng Corp., China), according to the manufacturer's recommendations.

### Liver NF-κB immunohistochemical analysis

Formalin-fixed, paraffin-embedded liver tissue sections of 4-μm thickness were stained with SP immunohistochemistry technique for NF-κB. After being dewaxed or washed in PBS, tissue sections were cultured in 3% hydrogen peroxide to eliminate intrinsic peroxidase, and quenched in normal goat serum for 30 min. The sections were then incubated overnight at 4°C with polyclonal rabbit anti-rat NF-κB antibody (NeoMarkers Corp, Jingmei Biotech, Shenzhen, China), followed by addition of anti-rabbit immunoglobulin and streptavidin conjugated to horseradish peroxidase (HRP). Finally, slides were stained with 3,3'-diaminobenzidine (DAB), and hematoxylin was used for counter staining. Brown staining in cytoplasm and nucleus were considered as positive.

### Liver ICAM-1 and NF-κB western blotting

Cellular plasma and nuclear protein were extracted from frozen live tissue with a protein extraction kit (Pierce, Rockford, IL, USA). The protein was separated by 10% SDS-PAGE and then electroblotted onto nitrocellulose membranes (Millipore, Bedford, MA, USA) for 30 min. The membranes were then incubated overnight at 4°C with rabbit polyclonal antibody ICAM-1 (Boster Corp, Ltd. Wuhan, China) and NF-κB against rat. The membranes were incubated for 1 h at 37°C with an anti-rabbit IgG conjugated with HRP. The signals were visualized by a DAB assay kit (Fuzhou Maixin Biological

**Figure 1 Changes in histology of intestine and liver tissues ( $\times 200$ ) in the control (A), intestinal I/R (B) (1 h ischemia and 4 h reperfusion) and carnosol pretreatment (C) groups.** A: Normal structure of intestine and liver; B: Edema, hemorrhage and neutrophil infiltration were observed in intestinal mucosa and liver tissue; C: Relatively normal histology of intestine and liver with less inflammatory cell infiltration.

Technology Co., Ltd, Fuzhou, China) and analyzed with a gel imaging system (Kodak System EDAS120, Japan).

#### Statistical analysis

All data were expressed as mean  $\pm$  SD. The *F* test was used to evaluate statistical significance using SPSS 10.0 statistical software (Chicago, IL, USA).  $P < 0.05$  was considered statistically significant.

## RESULTS

#### Effect of carnosol on intestinal I/R-induced liver injury

Intestinal I/R induced apparent intestine and liver injury at all the time points (2, 4 and 6 h) after reperfusion, manifested as histological changes in the intestine and liver with edema, hemorrhage and neutrophil infiltration, as well as a significant increase in serum AST and ALT level ( $P < 0.01$ ,  $P < 0.05$ ) when compared with the control group. Compared with the I/R group, the intestine and liver pathological damage was improved in the carnosol pretreatment group (Figure 1). In addition, there was a significant difference in liver function between the intestinal I/R and carnosol pretreatment groups ( $P < 0.05$ , Figure 2), which indicates that carnosol significantly attenuated the intestinal I/R-induced liver injury.

#### Effect of carnosol on liver SOD activity

Compared with the control group, liver tissue SOD level in the I/R group reduced significantly ( $P < 0.01$ ). SOD level was elevated markedly in carnosol pretreatment ( $P < 0.05$ , Figure 2).

#### Effect of carnosol on liver neutrophil infiltration

Liver neutrophil infiltration was determined by MPO

activity. Compared with the control group, liver tissue MPO activity increased significantly after intestinal I/R ( $P < 0.01$ ). Administration of carnosol reduced MPO activity in liver tissue significantly ( $P < 0.05$ , Figure 2).

#### Effect of carnosol on serum IL-6 level

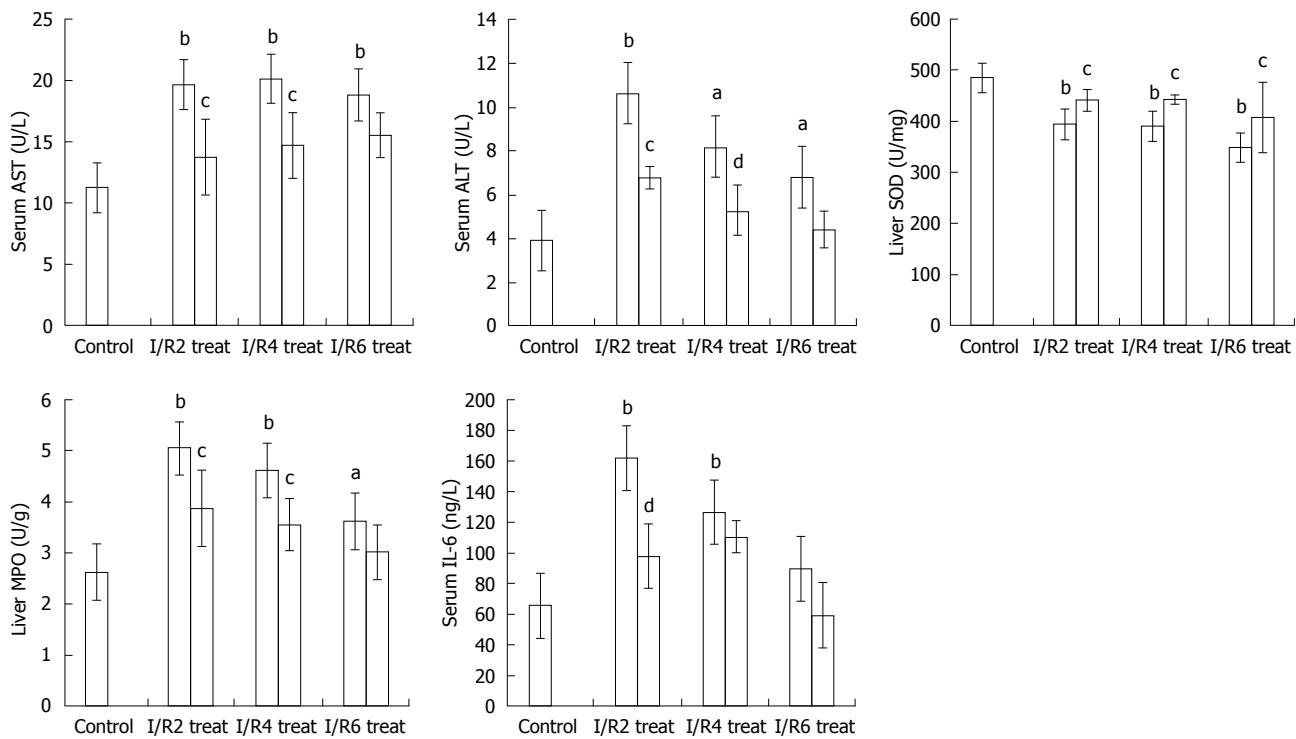

Compared with the control group, there was a marked increase in serum IL-6 level in the intestinal I/R group at 2 and 4 h of reperfusion ( $P < 0.01$ ), however carnosol pretreatment decreased serum level of IL-6 significantly at 2 h of reperfusion when compared with the I/R group ( $P < 0.01$ , Figure 2). This indicated that carnosol was sufficiently effective to suppress the increase of IL-6 level at early times after reperfusion.

#### Effect of carnosol on liver NF- $\kappa$ B p65 expression

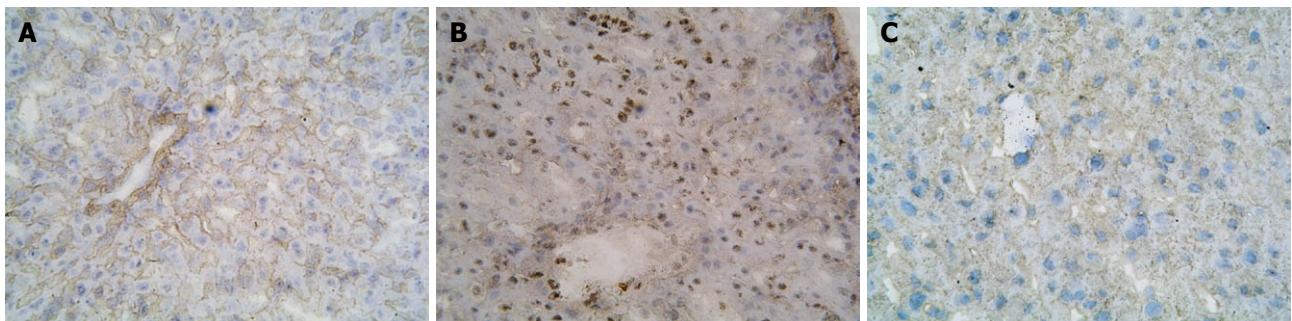

The immunohistochemical study showed that there was little staining of NF- $\kappa$ B p65 in the control group. In comparison, the strong positive expression of NF- $\kappa$ B p65 as brown staining was observed in the nucleus and cytoplasm in the intestinal I/R group. While the positive staining of NF- $\kappa$ B p65 expression was weakened markedly in the carnosol pretreatment group (Figure 3), western blotting showed weak staining for liver NF- $\kappa$ B p65 in the control group. Compared with the control group, IOD level of NF- $\kappa$ B p65 increased markedly in the intestinal I/R group ( $P < 0.05$ ). After pretreatment with carnosol, the IOD level of NF- $\kappa$ B p65 decreased significantly ( $P < 0.05$ , Figure 4A).

#### Effect of carnosol on liver ICAM-1 expression

Western blotting showed weak positive staining for ICAM-1 in the liver in the control group. However, a significant ICAM-1 protein signal was observed in the

**Figure 2 Activity of serum AST (U/L), serum ALT (U/L), liver tissue SOD (U/mg), liver tissue MPO (U/g) and serum IL-6 (ng/L) in different groups.** After 1 h intestinal ischemia and 2, 4 and 6 h reperfusion, the serum was assayed for AST, ALT and IL-6 activity. The liver tissue was assayed for SOD and MPO level. Data are expressed as mean  $\pm$  SD. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs control group; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs I/R group.

**Figure 3 Immunohistochemical staining of liver NF-κB p65 ( $\times 400$ ) in the control (A), I/R (B) (1 h ischemia and 4 h reperfusion) and carnosol pretreatment (C) groups (carnosol 3 mg/kg intraperitoneal administration).**

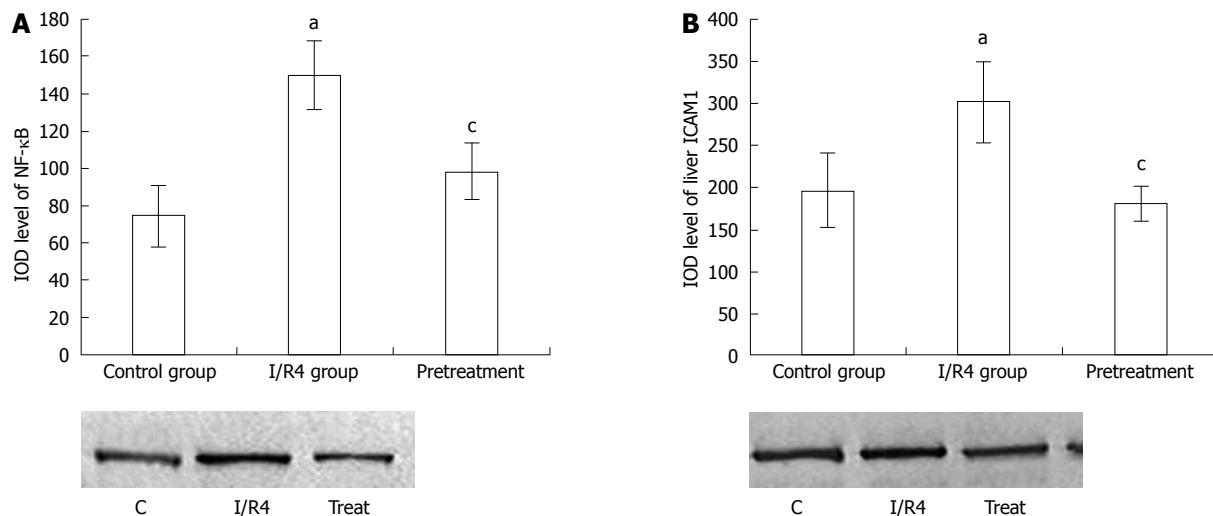

intestinal I/R group. Compared with the control group, IOD level of ICAM-1 increased markedly ( $P < 0.05$ ). This decreased markedly after pretreatment with carnosol ( $P < 0.05$ , Figure 4B).

## DISCUSSION

Intestinal I/R is not only necessary to the intestine itself, but involves severe distant tissue dysfunction. Liver is particularly vulnerable to the negative consequences of intestinal I/R because its vasculature is coupled in series with that of the intestine<sup>[20]</sup>. Although the precise mechanisms of intestinal I/R-induced liver injury have not been elucidated fully, previous research has shown that liver injury associated with intestinal I/R appear to be dependent on leukocyte adhesion and activation. Intestine- and/or liver-derived mediators, such as oxygen

radical species, IL-6 and tumor necrosis factor- $\alpha$ , have been suggested as participants in the I/R-induced, leukocyte-mediated liver responses<sup>[5,7,21]</sup>.

Recent studies have implied that the NF-κB pathway is involved in this process. A multitude of signaling factors, including oxidants, inflammatory cytokines, immune stimuli and viruses, can activate the transcriptional factor NF-κB<sup>[11,12,21]</sup>. In the early stage of intestinal I/R, the gut barrier function is damaged progressively, and bacteria, endogenous endotoxin, bacteriotoxin and reactive oxygen species invade the circulation and induce expression of NF-κB<sup>[10]</sup>. Since NF-κB activation requires nuclear translocation of the Rel/p65 subunit of NF-κB, nuclear NF-κB p65 level was examined to assess the activation of NF-κB. In the present study, intestinal I/R-induced liver injury manifested as pathological liver injury, significantly

**Figure 4** IOD level of western blotting analysis of liver NF-κB p65 (A) and ICAM-1 (B) in the control, intestinal I/R (1 h ischemia and 4 h reperfusion) and carnosol pretreatment groups (carnosol 3 mg/kg intraperitoneal administration). Data are expressed as mean  $\pm$  SD. <sup>a</sup> $P < 0.05$  vs control group; <sup>c</sup> $P < 0.05$  vs I/R group.

increased serum ALT and AST levels, and alterations in the biochemical indicators of oxidative stress in the liver. These changes were parallel to the increased level of serum IL-6 and liver NF-κB p65 expression, which suggests that activation of the NF-κB pathway plays an important part in the pathogenesis of intestinal I/R-induced liver injury. The above observation is also consistent with our previous study<sup>[12,13]</sup>.

Extracts of *Rosmarinus officinalis* L. have been used widely as a preservative in the food industry because of the antioxidant activity of their constituents such as carnosol and carnosic acid<sup>[22-24]</sup>. Carnosol and carnosic acid are good scavengers of peroxyl radicals and are able to block the formation of the hydroxyl radical generated in non-lipid systems<sup>[25]</sup>. They have been shown to inhibit non-enzymatic-induced lipid peroxidation in liver microsomes when incubated in the presence of FeCl<sub>3</sub><sup>[25]</sup> or Fe(NO<sub>3</sub>)<sub>3</sub><sup>[23]</sup>. Carnosol has also been shown to suppress the formation of proinflammatory leukotrienes in rat leukocytes<sup>[26]</sup>. In addition, inhibition of activation of transcription factor NF-κB has been proposed as one of the important underlying mechanisms of action of carnosol<sup>[16,17]</sup>. Therefore, it is reasonable to postulate that carnosol may exert protective effects in intestinal I/R-induced liver injury.

As expected, the present study showed that pretreatment with carnosol considerably attenuated intestinal I/R-induced liver injury, including reduced liver morphological injury and oxidative stress, as well as decreased serum ALT and AST activity. In addition, carnosol pretreatment resulted in significant down-regulation of the proinflammatory factor IL-6, which in turn, limited activation of circulation leukocytes in the microcirculation of the liver and other tissues. This led to reduced inflammation-mediated tissue injury. Moreover, endothelial adhesion molecules expressed on the surface of endothelial cells, such as ICAM-1, which play an important role in mediating firm adhesion and emigration of activated leukocytes in postcapillary

venules, were attenuated after carnosol treatment. The down-regulation of IL-6 and ICAM-1 was consistent with the decreased expression of NF-κB, which indicated that the protective effect of carnosol on intestinal I/R-induced liver injury may be related partly to the inhibition of NF-κB activation.

In conclusion, we showed pretreatment with the natural antioxidant carnosol attenuated liver injury induced by intestinal I/R, attributable to the antioxidant effect and inhibition of the NF-κB pathway.

## COMMENTS

### Background

Carnosol is a phenolic diterpene that has potent antioxidant and anti-inflammatory activities. There have been no reports about its effect on liver injury induced by intestinal ischemia/reperfusion (I/R). The present study investigated the preconditioning effects of carnosol on liver injury induced by intestinal I/R and confirmed the hypothesis that the protective effect of carnosol is mediated via inhibition of nuclear factor κB (NF-κB) activity.

### Research frontiers

Recently, it has been found that NF-κB plays a major role during the local and systemic inflammatory response following I/R. This study attempted to confirm that modulating the NF-κB pathway is a novel concept and therapeutic strategy for attenuating liver injury caused by intestinal I/R.

### Innovations and breakthroughs

The study showed pretreatment with the natural antioxidant carnosol attenuated liver injury induced by intestinal I/R, attributable to the antioxidant effect and inhibition of the NF-κB pathway.

### Applications

This study indicated that carnosol pretreatment protects liver injury induced by intestinal I/R. The protective effects may be associated with inhibition of NF-κB activation. This may represent a novel and attractive approach to prevent intestinal I/R injury.

### Terminology

NF-κB proteins are a family of transcriptional factors that control the expressions of many genes in immune and acute phase inflammatory responses, cell adhesion, differentiation, oxidative stress responses and apoptosis. Recently, it has been found that NF-κB plays an important role during intestinal I/R.

### Peer review

The authors demonstrated that carnosol attenuated liver injury induced by intestinal I/R in rats. The study is very interesting and the results are sound.

and the level of fibronectin, collagen I and  $\alpha$ -smooth muscle actin (SMA). The pro-apoptotic effect of anti-IGFBP-7 antibody was determined by flow cytometry.

**RESULTS:** Immunocytochemistry and Western blotting revealed that the expression of IGFBP-7 in TGF- $\beta_1$  treated HSC was significantly up-regulated compared to that in the control group. In addition, fibronectin, collagen I and  $\alpha$ -SMA also showed enhanced expression in accordance with the transdifferentiation process in a dose-dependent manner to some extent. Moreover, flow cytometry suggested that anti-IGFBP-7 antibody induced apoptosis of activated HSC, which is responsible for the development of liver fibrosis, and may represent a novel pathway and target for therapeutic intervention.

**CONCLUSION:** IGFBP-7 showed increased expression in activated HSC and played an important role in the activation and transdifferentiation process of HSC. Anti-IGFBP-7 antibody may ameliorate liver fibrogenesis.

## Abstract

**AIM:** To investigate the role of insulin-like growth factor binding protein-7 (IGFBP-7) in the activation and transdifferentiation of hepatic stellate cells (HSC) *in vitro*.

**METHODS:** Rat HSC-T6 cells were cultured in separate dishes and treated with various concentration of transforming growth factor (TGF)- $\beta_1$ , IGFBP-7 or anti-IGFBP-7 antibody for 24 h. The supernatant or a cytoplasm suspension was obtained from cultured HSC, followed by transfer of cells to form cell-coated dishes. Immunocytochemistry and Western blotting were used to analyze the expression of IGFBP-7 induced by TGF- $\beta_1$

## INTRODUCTION

Hepatic fibrosis and cirrhosis are characterized by excessive fibrosis attributable to hepatic stellate cell (HSC) proliferation and activation<sup>[1]</sup>, resulting in excessive production of extracellular matrix (ECM), including fibrin-forming collagens I and III, proteoglycans, fibronectins

and hyaluronic acid<sup>[2]</sup>. The occurrence of hepatic fibrosis is also a common response to most chronic liver injuries such as viral hepatitis, parasitic infection, metabolic or autoimmune diseases, congenital abnormalities, and alcohol abuse<sup>[1,3]</sup>. However, the pathogenesis of hepatic fibrosis is still unknown<sup>[4]</sup>. In recent studies, HSC were the primary source of excess ECM assembly in liver fibrosis<sup>[5]</sup>. During the development of liver fibrosis, HSC undergo a process of activation, resulting in the expression of ECM, reduced retinoid storage capability and transdifferentiation to a myofibroblast-like phenotype which is characterized by expression of  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA)<sup>[6]</sup>. Fibrotic changes result in structural changes and lead to reconstruction of hepatic lobules, dysfunction of liver bioactivity, and even death. At present, there is no effective treatment to halt the progression of liver fibrosis and cirrhosis. The only current life-prolonging intervention is liver transplantation. Thus, HSC play an important role in the pathogenesis of liver fibrosis.

HSC activation process is very complicated and is the result of a complex interplay between different hepatic cell types such as inflammatory cells and secreted cytokines, chemokines and growth factors<sup>[7]</sup>. The cellular transformation that develops gradually *in vitro* can be mimicked *in vitro* by short term culture of HSC on plastic, providing a model to study the intra- and extra-cellular determinants that regulate the transformation/activation process. Excessive cellular proliferation and an abundant ECM protein production that is not counteracted by increased ECM protein degradation have been shown to be the specific hallmark of HSC activation<sup>[8]</sup>. Another major feature of the activation process is the responsiveness of HSC to cytokines, resulting in the up-regulation of the platelet-derived-growth factor (PDGF) and members of the transforming growth factor (TGF)- $\beta$  family. PDGF appears to a major mitogen for stellate cells, and members of the TGF- $\beta$  family are the primary fibrogenic cytokines<sup>[9,10]</sup>. Boers *et al*<sup>[11]</sup> have detected a significant change in expression of insulin-like growth factor binding protein (IGFBP)-7 as a novel marker for hepatic fibrosis.

IGFs play an important role in the regulation of metabolism, development and growth of HSC<sup>[12]</sup>. The capacity of IGFs to exert their biological effects *via* interactions with specific cell surface receptors is modulated by the presence of a family of structurally related IGF-binding proteins. So far, 6 distinct IGFBPs have been identified and differ in molecular mass, binding properties for IGFs and posttranslational modifications as well as tissue and development regulated expression<sup>[13]</sup>. In addition, low affinity binders termed IGFBP-rPs have been found. IGFBP-7, the first protein proven to be functionally related to IGFBPs, called IGBP-rP1, is one of these low affinity binders to IGF-I and is expressed relatively more highly upon HSC activation, especially in the end stage<sup>[11]</sup>.

The aim of the present study was to investigate whether IGFBP-7, at different concentrations, may induce the activation and perpetuation of HSC. Our initial experiments demonstrated that expression of IGFBP-7 was up-regulated in patients with liver fibrosis

and cirrhosis. We examined roles of IGFBP-7 in different stages of HSC by exposure of HSC to exogenous cytokines. The involvement of IGFBP-7 was evaluated in activated HSC and increased ECM was detected. IGFBP-7 also induced the differentiation of HSC from a quiescent to an activated phase, whereas the specific antibody of IGFBP-7 can induce apoptosis of activated HSC. The data suggest that IGFBP-7 is sufficient to initiate the activation of HSC in conjunction with or prior to observation, which strongly implicates IGFBP-7 in the pathogenesis of hepatic fibrosis. In addition, overexpression of IGFBP-7 provides a novel cellular model to study the pathogenesis of human hepatic fibrosis.

## MATERIALS AND METHODS

HSC-T6 lines were a generous gift from Scott L Friedman of the Mount Sinai School of Medicine (NY, USA). Briefly, samples were washed and transferred into 25 cm<sup>2</sup> culture dishes (Orange Scientific, Belgium) for culture under standard conditions in a normoxic atmosphere of 16% O<sub>2</sub>, 5% CO<sub>2</sub>, and 79% N<sub>2</sub> (by volume) in RPMI1640 medium (Gibco, USA) containing 10% fetal calf serum (FCS), 100 U/mL penicillin, 100 g/mL streptomycin and 3.57 g/L HEPES at 37°C. HSC were kept in secondary culture (partially “activated” HSC) and were passaged once every 2 to 3 d. Briefly, for cells in secondary culture, 10<sup>5</sup> cells/well were seeded into 12-well plates supplemented with RPMI1640 (Gibco) without FCS, or 10 cells/well were transferred to 96-well plates. After allowing HSC to attach overnight, cultures were incubated with TGF- $\beta$ 1 (Peprotech, UK) or IGFBP-7 (R&D, US), or anti-IGFBP-7 antibody (R&D, US), in different concentrations or in combination for 24 h before each experimental manipulation.

### Immunocytochemistry

After 24 h in cell culture to allow cells to attach, cell-coated dishes were obtained, fixed with 1% paraformaldehyde for 10 min, and washed by PBS. Endogenous peroxidases and biotins were then quenched using an endogenous peroxidase blocking kit and biotin blocking kit, respectively. The sections were blocked with 3% FCS (Roche, US) and incubated with one of the following antibodies: polyclonal anti- $\alpha$ -SMA/monoclonal anti-collagen I (Abcam, UK), and polyclonal anti-fibronectin (Santa Cruz, US). Sections were washed and incubated with biotinylated secondary antibody (Santa Cruz, US and Jackson, US). Bound secondary antibody was detected using the UltraSensitive™ SP kit (DAKO, US) according to the manufacturer's instructions. For modeling negative controls, the primary antibodies were substituted with PBS. The reaction products were visualized by diaminobenzidine tetrahydrochloride (DAB) (DAKO, US). Stained sections were viewed under a Nikon Eclipse 800 microscope and IOD (integrated optical density) or IA (integrated absorption) of the positive brown particles determined semiquantitatively by examining 5 fields randomly at  $\times 200$  magnification in each slice.

### Western blotting

Culture supernatant and cellular lysates were obtained from a cultured HSC-T6 line according to the standard protocol. In brief,  $2 \times 10^5$ /mL active cells were cultured in 12-well plates in the absence or presence of TGF- $\beta$ 1 at different concentrations. Cultures were harvested after 12 h of incubation, supernatants were extensively dialyzed, and the remaining cells were trypsinized, then centrifuged, lysed, and finally cellular lysates were attained. Thirty microliter of cellular lysates were separated on 15% sodium dodecyl polyacrylamide gels (SDS-PAGE) under reducing conditions and then transferred onto PVDF membranes (SABC, US). After blocking with TBST (TBS and 0.1% Tween) for 3 h, the membranes were incubated with anti-IGFBP-7 antibody as the primary antibody overnight then washed with PBS. Secondary antibodies were conjugated with horseradish peroxidase for 3 h. The signals were visualized by DAB. The relative signal intensities of the bands were quantitated using Molecular Analyst software, and the results were normalized to levels of  $\beta$ -actins (Santa Cruz, US) in each sample. In selected experiments, the secretion of collagen I to the media was determined by ELISA (R&D, US) following incubation of confluent cultures of HSC-T6 with TGF- $\beta$ 1 (Peprotech, UK) or anti-IGFBP-7 antibody in different concentrations and combinations for up to 24 h, in accordance with the manufacturer's instructions.

### Flow cytometry

HSC-T6 lines were maintained under standard conditions as mentioned before, and then were transferred to 12-well dishes. After 24 h in culture, serum-free media was added containing anti-IGFBP-7 antibody in concentrations of 0.25 mg/L, 0.50 mg/L and 1.00 mg/L. Following another 14 h in culture, supernatants were discarded, and 500 g of cells were centrifuged. The remaining cells were washed with PBS, followed by centrifugation again for 5 min at 500 g at 4°C. Then, cell pellets were resuspended in ice-cold binding buffer to  $1 \times 10^6$  cells/mL, with tubes on ice. Both 5  $\mu$ L of annexin-V and 2.5  $\mu$ L of propidium iodide (PI) (Beckman Coulter, US) were added to 100  $\mu$ L of cell suspensions. Tubes were kept on ice for 10 min in the dark, and then another 100  $\mu$ L of binding buffer was added to the preparations and mixed gently. Quantitative analysis of the preparations was performed after

**Table 2 ELISA determination of collagen I (mean  $\pm$  SD)**

	n	Collagen I (ng/mL)
Control	6	36.61 $\pm$ 1.28

TGF $\beta$ 1 2 ng/mL + Anti-IGFBP-Pr1 antibody 1 $\mu$ g/mL	6	33.95 $\pm$ 3.27 <sup>c</sup>
TGF $\beta$ 1 2 ng/mL + Anti-IGFBP-Pr1 antibody 2 $\mu$ g/mL	6	34.59 $\pm$ 3.97 <sup>c</sup>
TGF $\beta$ 1 4 ng/mL + Anti-IGFBP-Pr1 antibody 0.1 $\mu$ g/mL	6	40.24 $\pm$ 3.46 <sup>e</sup>
TGF $\beta$ 1 4 ng/mL + Anti-IGFBP-Pr1 antibody 1 $\mu$ g/mL	6	32.61 $\pm$ 4.86 <sup>e</sup>

Relative expression of collagen I was measured by ELISA; after HSC incubated for 24 h, supernatant was obtained and analyzed. Statistical analysis was done by the SNK-q test. <sup>a</sup>P < 0.05, compared with the control group; <sup>c</sup>P < 0.05, compared with the TGF $\beta$ 1 2 ng/mL; <sup>e</sup>P < 0.05, compared with TGF $\beta$ 1 4 ng/mL.

30 min by flow cytometry. Meanwhile, following the 14 h culture, 20  $\mu$ L MTT and 100  $\mu$ L PBS were added to each well at 37°C in 5% CO<sub>2</sub> atmosphere (by volume) for 4 h. Supernatants were discarded, and 150  $\mu$ L DMSO was added and mixed gently. After incubation with chromogenic substance for 10 min, absorbance (A) at 490 nm was measured in samples to measure the value of A under different concentrations of anti-IGFBP-7 antibody.

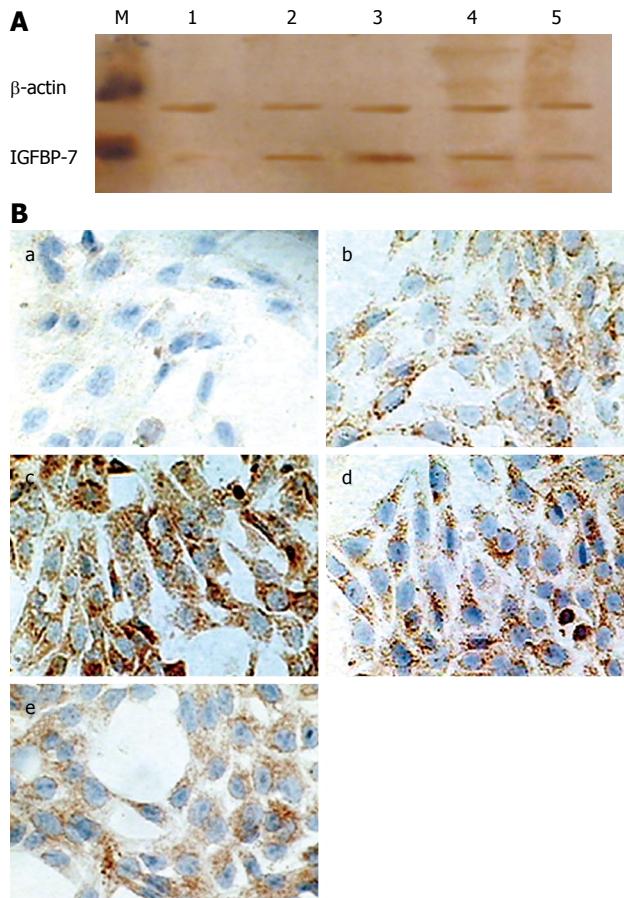

### Statistical analysis

Data are presented as the mean  $\pm$  SD, and all calculations were made using SPSS11.5. Statistical comparisons were performed using an ANOVA correlation analysis. Paired comparisons were done using the SNK-q test. Significance was set at a value of P < 0.05.

## RESULTS

### In vitro expression of IGFBP-7 in HSC

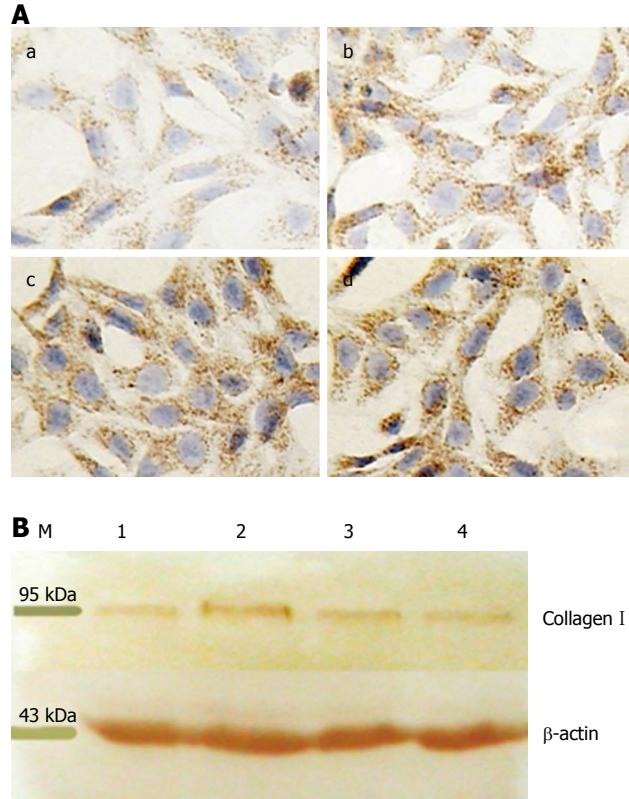

Differences in absorbance between TGF- $\beta$ 1-treated cells and controls are shown in Table 1. Expression of IGFBP-7 was up-regulated by TGF- $\beta$ 1 of 2, 4, 8 and 16  $\mu$ L/L, as detected in the cytoplasm of HSC by Western blotting analysis of cellular lysates (Figure 1A). Immunohistochemistry also demonstrated an increased expression of IGFBP-7 in TGF- $\beta$ 1-treated HSC on cell-coated dishes. As shown in Figure 1B, in the TGF- $\beta$ 1-treated groups, the amount of positive brown staining was abundant and the value of IOD of positively stained particles increased significantly (Table 1), as compared with the control group in which only a few cells were positively stained. The expression in cells treated with 4  $\mu$ L/L of TGF- $\beta$ 1 was stronger than most other groups. Perhaps this effect is the reason that the autocrine expression of TGF- $\beta$ 1 is strengthened, and exogenous TGF- $\beta$ 1 expression decreases the secretion of IGFBP-7.

**Figure 1** *In vitro* expression of IGFBP-7 in HSC. A: Detection of IGFBP-7 by Western blotting. Cultured HSC were incubated with TGF- $\beta$ 1; lysates were harvested after 24 h, and analyzed by Western blotting for IGFBP-7.  $\beta$ -actin was managed as a loading control. Each experiment was replicated 6 times. M: Marker; 1: Control group; 2, 3, 4, 5 represent 2  $\mu$ g/L, 4  $\mu$ g/L, 8  $\mu$ g/L and 16  $\mu$ g/L TGF- $\beta$ 1, respectively; B: Expression of IGFBP-7 in activated HSC. Expression of IGFBP-7 was examined on HSC-coated dishes after treatment with TGF- $\beta$ 1 at different concentrations for 24 h (a-d indicated control, 2  $\mu$ g/L, 4  $\mu$ g/L, 8  $\mu$ g/L and 16  $\mu$ g/L TGF- $\beta$ 1, respectively). IGFBP-7 was detected by immunocytochemistry, and the level of the expression of IGFBP-7 was enhanced in a dose-dependent manner to some extent compared with the control group. Original magnification:  $\times 200$ .

#### Quantitation of collagen I deposition in HSC

To analyze the *in vitro* effects of IGFBP-7 on HSC secretion of collagen I, supernatant was collected and the amount of collagen I was analyzed by ELISA following a standard protocol according to the manufacturer's instructions. As shown in Table 2, the secretion of collagen I was prominent in the TGF- $\beta$ 1-treated groups, compared with the control group and the anti-IGFBP-7-treated groups. However in the wells treated with 2 or 4 ng/mL TGF- $\beta$ 1 and 0.1, 1 or 2  $\mu$ g/mL anti-IGFBP-7 antibody, the amount of collagen I was significantly decreased, as compared with the groups treated with TGF- $\beta$ 1 alone. We further performed immunohistochemistry to determine the expression of collagen I in HSC. As shown in Figure 2A, positive brown collagen I staining in IGFBP-7-treated HSC obviously increased compared with the controls in a dose-dependent manner to some extent. Western blotting analysis was also used to characterize the amount of collagen I protein in the cytoplasm of HSC. As shown

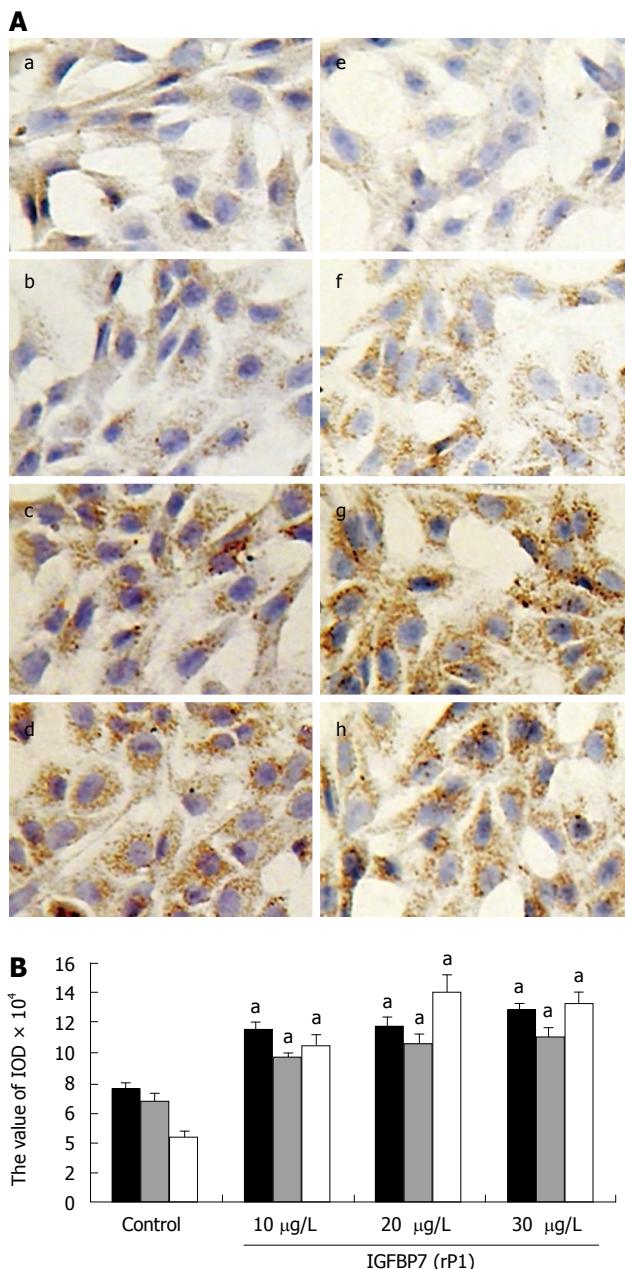

**Figure 2** Quantitation of collagen I deposition in HSC. A: Immunocytochemical detection of collagen I. Expression of collagen I was examined on HSC-coated dishes after treatment with IGFBP-7 at different concentrations for 24 h (a-d indicated control, 10  $\mu$ g/L, 20  $\mu$ g/L, and 30  $\mu$ g/L IGFBP-7, respectively). Collagen I was examined by immunocytochemistry and the level of the expression of collagen I was enhanced in a dose-dependent manner in sequence compared with the control group. Original magnification:  $\times 200$ ; B: Detection of collagen I by Western blotting. Cultured HSC were incubated with IGFBP-7 for 24 h, and then lysates of HSC were harvested and analyzed by Western blotting for collagen I.  $\beta$ -actin was used as a loading control. Each experiment was replicated 6 times. M: Marker; 1: Control group; 2, 3, 4 represent 10  $\mu$ g/L, 20  $\mu$ g/L, 30  $\mu$ g/L.

in Figure 2B, the protein was prominently synthesized in accordance with HSC activation. The differences in absorbance between IGFBP-7-treated groups at different concentrations and the control group in sequence were  $0.7663 \pm 0.0412$ ,  $0.7439 \pm 0.0720$ ,  $0.7039 \pm 0.0889$ , and  $0.6402 \pm 0.0475$ , respectively ( $P < 0.05$ ).

#### Comparison of fibronectin levels and fibroblast phenotype

The deposition of fibronectin was examined by immunohistochemistry. As shown in Figure 3A (a-d), fibronectin was detected in the cytoplasm of HSC. In the control group, only a few brown particles were detected although the amount of staining was higher in the IGFBP-7-treated groups, also in a dose-dependent manner. To characterize the HSC phenotype,  $\alpha$ -SMA expression was examined. As shown in Figure 3A (e-h),  $\alpha$ -SMA-positive HSC were more abundant in IGFBP-7-treated cells than in the control group, and the increase was in a dose-dependent manner. The comparison and analysis of IOD of fibronectin and  $\alpha$ -SMA was performed and presented in Figure 3B. A significant difference was seen between each IGFBP-7-treated group at different concentrations and the control group. Thus,

**Figure 3 Comparison of fibronectin levels and fibroblast phenotype.** A: Characterization of  $\alpha$ -SMA and fibronectin. Immunocytochemistry was performed on HSC after incubation with IGFBP-7 at different concentrations (0, 10  $\mu$ g/L, 20  $\mu$ g/L and 30  $\mu$ g/L) for 24 h.  $\alpha$ -SMA (a-e) and fibronectin (f-h) were examined by immunocytochemistry. The amount of the expression of  $\alpha$ -SMA (b-d) and fibronectin (f-h) were enhanced in a dose-dependent manner in sequence compared with the control group (a, e). Original magnification:  $\times 200$ . B: Comparison of the expression of collagen I, fibronectin and  $\alpha$ -SMA at different concentrations. The expression of collagen I, fibronectin and  $\alpha$ -SMA was detected through immunocytochemistry, and the value of IOD of the positive-brown particles was calculated. The black, gray and white bars represents the IOD value of  $\alpha$ -SMA, collagen I and fibronectin, respectively. Statistical analysis was done using the SNK-q test.  $^aP < 0.05$ .

IGFBP-7 induced an increased expression and deposition of fibronectin, which led to the transformation of HSC into a myofibroblastic phenotype.

#### Anti-IGFBP-7 antibody-induced HSC apoptosis

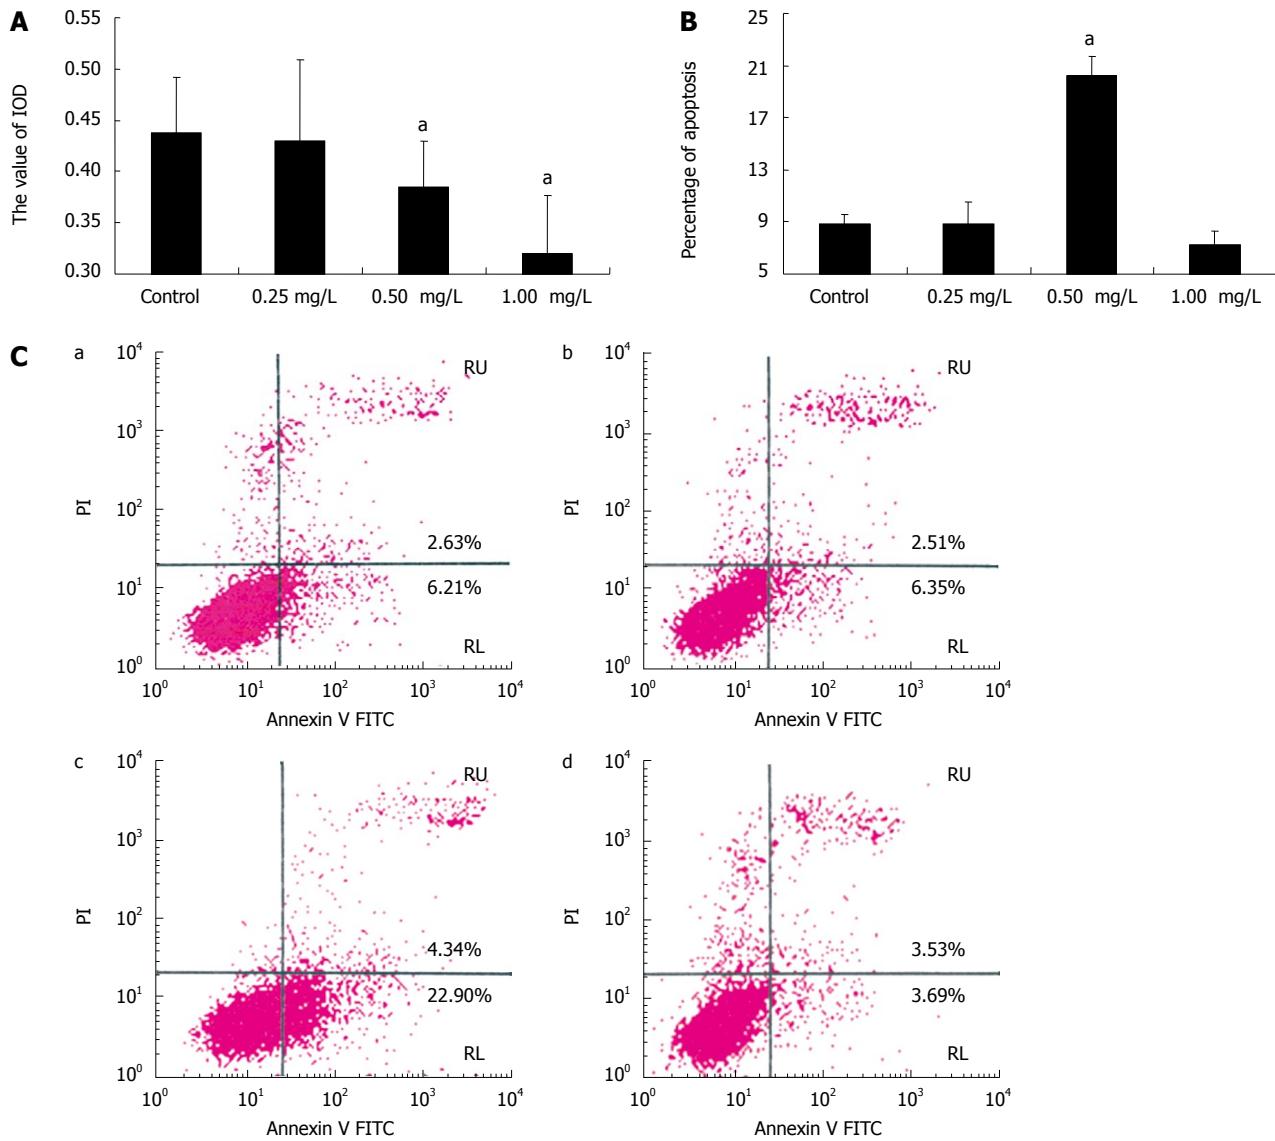

We further examined the effect of anti-IGFBP-7 antibody on activated HSC. To characterize the inhibitory effect of

anti-IGFBP-7 antibody on activated HSC, MTT assays were performed. As shown in Figure 4A,  $A$  decreased after anti-IGFBP-7 antibody treatment, compared with the control group. Also, treatment with 0.50 mg/L and 1.00 mg/L of antibody could significantly reduce the value of  $A$ . To determine the proportion of apoptotic cells to all activated cells, flow cytometry with annexin/PI was used. As shown in Figure 4B, the ratio of apoptotic cells was prominent in the 0.50 mg/L anti-IGFBP-7 antibody treatment group, as compared with the control group. The difference between 0.25 mg/L, 1.00 mg/L and the control was not significant (Figure 4). Statistical analysis of these results is shown in Figure 4C.

## DISCUSSION

HSC are the main source of ECM, which contributes to the occurrence and development of liver fibrosis<sup>[14]</sup>. We previously reported increased IGFBP-7 protein levels in patients with liver fibrosis and cirrhosis. In this study, expression and function of IGFBP-7 were studied in cultured HSC which were administered different reagents. The object was to define the bioactivity and function of IGFBP-7 in such a model of HSC in different stages of activation and transdifferentiation. For this purpose, we used TGF- $\beta$ 1 as the profibrotic cytokine to activate HSC from quiescent to partially activated and ultimately completely transdifferentiated HSC. Then, the expression of IGFBP-7 was analyzed in cell-coated dishes. The resulting stained-cell dishes revealed that the expression of IGFBP-7 was significantly increased in TGF- $\beta$ 1-treated HSC ("activated" HSC). It has been demonstrated that the IGFBP-7 showed enhanced expression and could work as a novel marker in the pathogenesis of HSC<sup>[11]</sup>. Our observations further confirmed this statement. HSC could be considered to be one of the principal effectors involved in fibrogenesis. In response to liver injury as well as other cytokines, HSC are considered to undergo a phenotypic transformation from a quiescent to a myofibroblast-like phenotype, characterized by DNA synthesis, motility, contractility and synthesis of ECM<sup>[15,16]</sup>. TGF- $\beta$ 1 is the best-known primary fibrogenic cytokine<sup>[9,10]</sup>, whereas it is not clear which specific gene is responsible for the fibrotic response.

IGFBPs showed high expression together with other markers of HSC activation, especially in the end stage. The liver is the major producer of IGFBPs, mainly IGFBP-1 and -3<sup>[17]</sup>. The present study mainly focused on the function and distribution of IGFBP superfamily members among different organs and tissues. IGFBPs are the binding proteins of IGF-1 and -2; they regulate the interaction of IGF-1 and -2 with their receptors, and modulate the growth-promoting and metabolic activities of IGF-1 and -2 by affecting the downstream signal transduction of IGFR<sup>[18]</sup>. *In vitro*, the proliferation of HSC is enhanced by IGF-1<sup>[19,20]</sup>. *In vivo*, however, production of IGF-1 by HSC has recently been reported to attenuate hepatic cirrhosis<sup>[17]</sup>. Furthermore, IGF-1 replacement therapy seems to benefit patients with hepatic cirrhosis<sup>[21]</sup>.

**Figure 4** Anti-IGFBP-7 antibody induces HSC apoptosis. **A:** HSC viability assay. The activated HSCs had anti-IGFBP-7 antibody of different concentrations added, and the absorbance (A) of each treated group was analyzed by the MTT cell viability assay to investigate the bioactivity of cultured cells. Statistical analysis was done using the SNK-q test.  $^aP < 0.05$ ; **B:** Percentage of apoptosis in all treated cells. Activated HSCs were divided into 4 groups, and then each group was treated with anti-IGFBP-7 antibody at different concentrations of 0 mg/L, 0.25 mg/L, 0.50 mg/L and 1.00 mg/L, and analyzed after 24 h culture, using flow cytometric assay. Statistical analysis was done using the SNK-q test.  $^aP < 0.05$ ; **C:** Flow cytometry assay. Cultured cells were treated with anti-IGFBP-7 body at different concentrations of 0 mg/L, 0.25 mg/L, 0.50 mg/L and 1.00 mg/L. After 24 h incubation, flow cytometry was used to analyze the pro-apoptotic effect of anti-IGFBP-7 antibody.

Because of the binding activity of IGFBPs, the induction of these binding proteins may affect hepatic cirrhosis. An *in vitro* study revealed that IGFBPs could display intrinsic bioactivities that are dependent on or independent of binding of IGF-1 and -2, in the process of hepatocyte growth, differentiation and activity<sup>[22]</sup>. So far, 6 distinct IGFBPs have been identified, which differ in molecular mass and binding affinities for IGF-1 and -2<sup>[13]</sup>. Moreover, low affinity IGF binders termed IGFBP-rPs have been found. IGFBP-7, also called IGFBP-rP1, is one of these low affinity binders of IGF-1. In the transcription of activated human HSC, expression of 5 IGFBP family members was detected. The most prominent was the extremely high expression of IGFBP-5, which is known to be the most abundantly expressed protein in activated HSC. In addition, IGFBP-7 is obviously detected in these cells, whereas a smaller induction is seen for IGFBP-4,

-6 and -3<sup>[6]</sup>. The growth-promoting and metabolic activities of IGF-1 and -2 are modulated by the family of IGFBPs<sup>[23]</sup>. In certain pathological conditions, IGFBP-1 through -6 all may inhibit the growth of cells. IGFBP-1 and -3 may destroy glucose equilibrium in humans; IGFBP-1, -5, and -6 may also disturb this capability<sup>[24]</sup>, whereas IGFBP-7 (rP1) could modulate proliferation, cohesion of cells, the regeneration of blood vessel and biosynthesis of prostacyclin<sup>[25]</sup>. IGFBP-8 (rP2) is considered to be a key cytokine in the fibrogenesis of tissues and organs<sup>[13]</sup>. Since modulation of IGF activity is very complex and varied, their differences may be important factors in determining the local autocrine and paracrine activities of IGFs. The striking up-regulation of IGFBP-7 predicted that it is a good marker of HSC activation and is also a promising target for therapeutic intervention in hepatic fibrosis.

Increased collagen and fibronectin deposition were detected in IGFBP-7-treated HSC, demonstrating that IGFBP-7 can activate and induce ECM production and fibrosis *in vitro*. Moreover,  $\alpha$ -SMA-expressing cells increased among TGF- $\beta$ 1-treated cells, suggesting that they acquired a myofibroblastic phenotype<sup>[26]</sup>. Taken together, our findings indicate that superexpression of IGFBP-7 induces the deposition of ECM through the transformation of HSC into myofibroblastic cells which then contribute to the resulting fibrosis. We have shown that myofibroblastic changes are induced *in vitro* by IGFBP-7. In patients with liver fibrosis and cirrhosis, HSC are mainly responsible for the excessive deposition of ECM, many of which may have the phenotypic characteristics of myofibroblasts. A myofibroblast is strictly defined by electromicroscopic findings as a cell that is vimentin- and/or  $\alpha$ -SMA-positive, with prominent rough endoplasmic reticulum, a modestly developed periphery, with focal densities, and producing collagen, granules, gap, and actin-filament-based junctions<sup>[27]</sup>. However, most of the present studies are restricted to an immunohistochemical determination without electron microscopy, such as spindle-shaped cells expressing  $\alpha$ -SMA<sup>[28]</sup>. Thus,  $\alpha$ -SMA-expressing cells in our model undergo a myofibroblastic change, and this *in vitro* phenomenon can also be triggered by exogenous IGFBP-7 applied to human stellate cells. In humans, HSC are mainly located at the sinusoid within the subendothelial space of Disse in close contact with the hepatocytes. They comprise roughly one-third of the nonparenchymal cell population or about 5%-8% of total liver cells<sup>[29]</sup>. During the development of liver fibrosis, HSC undergo a process of activation, resulting in a reduced retinoid storage capability and transformation to a myofibroblastic phenotype that is characterized by expression of  $\alpha$ -SMA. In fact, the myofibroblast-like phenotype is not limited to liver, but also is a prominent feature of fibrosis in other tissues including pancreas, kidney, lung and skin<sup>[30]</sup>.

Apoptosis of activated HSC is significantly detected when anti-IGFBP-7 antibody is administered to the medium. Flow cytometric analysis is a novel, specific and exact way to detect and measure apoptosis, based on the new parameters appearing on the surface of cells such as phospholipids that become exposed at the cell surface and form one of the specific signals for recognition and removal of apoptotic cells by macrophages. The anti-IGFBP-7 antibody acts as a proapoptotic factor, having great impact on the survival and proliferation of HSC. We predict that the anti-IGFBP-7 antibody also performs this function *in vivo*, which will be investigated in subsequent studies.

In summary, we have shown that IGFBP-7 plays a pivotal role in the pathogenesis of HSC activation and has profibrotic activities *in vitro*. IGFBP-7 induces the production of ECM via activation of HSC and the development of a myofibroblastic phenotype in HSC. The over-expression of IGFBP-7 *in vitro* also provides a new model to study the pathogenesis of HSC activation. The inhibitory effect of anti-IGFBP-7 antibody on

activated HSC provides a promising intervention for liver fibrosis.

## ACKNOWLEDGMENTS

The authors thank the other technicians in the laboratory of the key medical laboratory of the First Teaching Hospital, including Yan Guo and Hai-Yan Zhang. The excellent technical assistance of the Department of Pathophysiology is gratefully acknowledged, especially the teacher, Yuan-Chang Zhao.

## COMMENTS

### Background

Hepatic stellate cells (HSC) are the main source of extracellular matrix (ECM), and thus play an important role in the occurrence and development of liver fibrosis. Insulin-like growth factor binding protein (IGFBP)-7 is a novel protein, which may be relevant to the activation of HSC.

### Research frontiers

IGFBP-7 expression has been detected significantly during fibrogenesis, but how this protein is related to liver fibrosis is largely unknown. In this study, the authors demonstrated that IGFBP-7 could activate HSC in accordance with the transdifferentiation process in a dose-dependent manner to some extent.

### Innovations and breakthroughs

Recent studies have highlighted the importance of IGF-I and IGFBP-3 in the liver tissues and the roles they play in fibrogenesis. This is the first study to report that expression of IGFBP-7 is also enhanced in this process and IGFBP-7 could activate HSC *in vitro*. Furthermore, this protein may be the main mediator of HSC bioactivity.

### Applications

By understanding how IGFBP-7 is relevant to liver fibrosis, this study may represent a new strategy for therapeutic intervention in the treatment of patients with liver fibrosis.

### Terminology

HSC are specific cells located in the hepatic lobules, and are the primary source of excess ECM assembly during liver fibrosis. The activation of HSC is regulated by known and unknown cytokines. IGFBP-7 is one member of the IGFBP superfamily, which is thought to work as a potential activator of HSC.

### Peer review

The paper by Liu *et al* is an interesting one, not only because of its findings, but also because of the quality of the presented data.

Thermal hyperalgesia was present in both groups of IBS patients relative to controls, with IBS patients reporting significantly lower pain threshold and pain tolerance at both test sites. Cluster analysis revealed the presence of subgroups of IBS patients based on thermal hyperalgesia. One cluster (17% of the sample) showed a profile of heat pain sensitivity very similar to that of healthy controls; a second cluster (47% of the sample) showed moderate heat pain sensitivity; and a third cluster (36% of the sample) showed a very high degree of thermal hyperalgesia.

**CONCLUSION:** A subset of IBS patients had thermal hypersensitivity compared to controls, who reported significantly lower HPTh and HPTo. All IBS patients had a higher score on the FBDSI than controls. Interestingly, the subset of IBS patients with high thermal sensitivity (36%) had the highest FBDSI score compared to the other two groups of IBS patients.

### Abstract

**AIM:** To characterize thermal hypersensitivity in patients with constipation- and diarrhea-predominant irritable bowel syndrome (IBS).

**METHODS:** Thermal pain sensitivity was tested among patients with diarrhea-predominant IBS (D-IBS) and constipation-predominant IBS (C-IBS) compared to healthy subjects. A total of 42 patients (29 female and 13 male; mean age  $27.0 \pm 6.4$  years) with D-IBS; 24 patients (16 female and eight male; mean age  $32.5 \pm 8.8$  years) with C-IBS; and 52 control subjects (34 female and 18 male; mean age  $27.3 \pm 8.0$  years) participated in the study. Thermal stimuli were delivered using a Medoc Thermal Sensory Analyzer with a 3 cm  $\times$  3 cm surface area. Heat pain threshold (HPTh) and heat pain tolerance (HPTo) were assessed on the left ventral forearm and left calf using an ascending method of limits. The Functional Bowel Disease Severity Index (FBDSI) was also obtained for all subjects.

**RESULTS:** Controls were less sensitive than C-IBS and D-IBS (both at  $P < 0.001$ ) with no differences between C-IBS and D-IBS for HPTh and HPTo.

### INTRODUCTION

Irritable bowel syndrome (IBS) is one of the most common gastrointestinal disorders encountered by gastroenterologists. Patients classically present with chronic abdominal pain associated with an alteration in bowel habits. Even though the pathophysiology of the IBS is unclear, visceral hypersensitivity is a common clinical marker of the disorder<sup>[1,2]</sup>. Visceral hypersensitivity may account for symptoms of

abdominal pain, urgency, and bloating experienced by many patients with this disorder.

Although visceral hypersensitivity is considered a hallmark feature of IBS, conflicting evidence exists regarding somatic hypersensitivity in this patient population. Somatic pain conditions, such as fibromyalgia and migraine headaches show significant comorbidity with IBS, which suggests that somatic hypersensitivity characterizes at least a subpopulation of IBS patients<sup>[2,3]</sup>. Several investigators have found no evidence for heightened somatic pain sensitivity in IBS patients. For example, two studies reported that IBS patients showed lower sensitivity to painful electrocutaneous stimuli compared to healthy controls<sup>[4,5]</sup>. Also, others have reported similar cold pressor pain tolerance in IBS patients and controls<sup>[6,7]</sup>. In contrast, our recent studies using hot water immersion have shown widespread somatic hyperalgesia associated with IBS<sup>[2,8,9]</sup>, and others using the cold pressor test have demonstrated somatic hypersensitivity in IBS patients compared with healthy controls<sup>[3,10]</sup>.

These conflicting findings may result from differing somatic pain testing procedures. Alternatively, patient sampling may be a contributing factor, given that there may be subgroups of IBS patients who differ in their somatic sensitivity. For example, somatic hypersensitivity may be present only in a subset of patients based on IBS subtype [i.e. diarrhea-predominant IBS (D-IBS) vs constipation-predominant IBS (C-IBS)], symptom severity and/or psychological profile.

Previous studies have explored the correlates of visceral hypersensitivity among patients with IBS<sup>[11-16]</sup>. For example, depression is correlated with rectal pain thresholds only in patients who alternate between constipation and diarrhea. Others have reported no association of psychological factors with rectal sensitivity; however, hypersensitivity to rectal distention is associated with increased IBS symptom severity assessed by daily diary<sup>[11]</sup>. Similarly, other investigators have found that rectal pain sensitivity is correlated positively with clinical symptoms among IBS patients<sup>[12-14]</sup>, while others have reported no such association<sup>[15,16]</sup>. However, the association of somatic hypersensitivity with clinical symptoms in IBS has not been evaluated.

To further evaluate somatic hyperalgesia among patients with IBS, we evaluated thermal pain sensitivity among patients with D-IBS and C-IBS compared with healthy subjects. The aims of the present study were: (a) to compare the spatial distribution and magnitude of thermal hyperalgesia between D-IBS and C-IBS patients and controls; and (b) to compare the spatial distribution and magnitude of thermal hyperalgesia among IBS patients as a function of symptom severity.

## MATERIALS AND METHODS

### Participants

A total of 42 patients (29 female and 13 male; mean age  $27.0 \pm 6.4$  years) with D-IBS; 24 patients (16 female and eight male; mean age  $32.5 \pm 8.8$  years) with C-IBS; and 52

**Table 1 Demographic variables for IBS patients and controls**

	D-IBS (n = 42)	C-IBS (n = 24)	Controls (n = 52)
Age (mean $\pm$ SD)	$27.0 \pm 6.4$	$32.5 \pm 8.8$	$27.3 \pm 8.0$
Sex (female), n (%)	29 (69)	16 (67)	34 (64)
FBDSI	62.8 (23.2)	68.4 (25.3)	2.1 (4.9)
Self-reported race/ethnicity n (%)			
White	33 (79)	15 (63)	43 (83)
Black	3 (7)	6 (25)	3 (6)
Hispanic	3 (7)	1 (4)	3 (6)
Asian	3 (7)	2 (8)	3 (6)

D-IBS: Diarrhea-predominant irritable bowel syndrome; C-IBS: Constipation-predominant irritable bowel syndrome. Columns may not sum to 100%, because values were rounded to the nearest 1%. Scores on the Functional Bowel Disorder Severity Index (FBDSI) that share a superscript are different at  $P < 0.01$ .

control subjects (34 females and 18 male; mean age  $27.3 \pm 8.0$  years) participated in the study. The demographics of the participating subjects are presented in Table 1. IBS subjects and healthy controls were recruited via advertisements posted at the University of Florida and the Ohio State University. The study was approved by the University of Florida, the North Florida/South Georgia Veterans Health System, and the Ohio State University Institutional Review Boards. All subjects signed informed consent prior to the start of the study.

None of the control subjects had any evidence of acute or chronic somatic/abdominal pain or IBS based on a questionnaire and complete physical examination by an experienced gastroenterologist. Also, controls were free of any systemic medical disease or psychological conditions that could affect sensory responses. All IBS subjects had symptoms for at least 5 years. The diagnosis of IBS was made by the same gastroenterologist who examined patients based on the ROME III criteria and exclusion of organic disease<sup>[17]</sup>. All subjects with IBS were examined for fibromyalgia (FM) using the 1990 American College of Rheumatology criteria for FM<sup>[18]</sup>. None of the patients were diagnosed as having FM. None of the IBS or control subjects were taking analgesics, serotonin uptake inhibitors, serotonin antagonists, or tricyclic antidepressants for a period of at least 3 wk prior to the study.

All subjects underwent experimental psychophysical testing during a single session. All sessions were conducted between 9 AM and 6 PM to control for circadian rhythm effects. Subjects were instructed to refrain from the use of any analgesic medication for 48 h and from caffeine for 4 h before their sessions. Prior to each session, participants received a reminder concerning the restrictions on analgesic medication and caffeine use.

Female subjects participated during the follicular phase of their cycles (i.e. 4-9 d post onset of menses). This cycle phase was chosen because it is characterized generally by the least sensitivity to pain and by minimal menstrual cycle related symptoms<sup>[19]</sup>. The menstrual cycle has been reported to alter pain perception in women, and IBS symptoms have also been reported to fluctuate across the menstrual cycle<sup>[20]</sup>. In addition, the follicular phase was chosen because some female

subjects would have been using oral contraceptives (OCs), and the follicular phase is the cycle phase during which women who use OCs and normal cycling women are the most similar in their responses to experimental pain<sup>[21]</sup>.

### **Psychophysical measures**

Multiple psychological factors have been related to pain responses in a number of studies, and these factors may mediate partially group differences in pain sensitivity. Therefore, all participants completed psychological questionnaires that assessed coping style, anxiety, depression, and hyper-vigilance prior to the first experimental session. In addition, a measure of current affective state was administered prior to each experimental session. These measures were used as control variables (as further described in the data analysis section) to determine whether group differences in pain sensitivity remain significant after controlling for the influence of psychological variables.

The Coping Strategies Questionnaire (CSQ) consists of 44 items that are related to how individuals cope with pain<sup>[22]</sup>. It yields seven subscales based on the pain coping strategies: diverting attention, catastrophizing, praying and hoping, ignoring pain sensations, reinterpreting pain sensations, increasing behavioral activity, and coping self-statements. The CSQ also provides measures of subjects' perceived ability to control and decrease pain. It has been used widely with various pain populations, and has been modified for use with healthy pain-free subjects, by having individuals respond to the instrument based on how they cope typically with day-to-day aches and pains<sup>[23]</sup>. Responses on the CSQ have previously been related to experimental pain responses<sup>[24]</sup>, as well as clinical pain, including IBS<sup>[25-27]</sup>. We have used this scale in previous psychophysical and clinical research<sup>[28-30]</sup>.

The Kohn reactivity scale consists of 24 items that assess an individual's level of reactivity or central nervous system arousability. It has been used recently as a measure of the construct of hypervigilance<sup>[31]</sup>. This measure has been shown to correlate negatively with pain tolerance<sup>[31,32]</sup> and has been reported to have adequate internal consistency, ranging from an  $\alpha$  value of 0.73 to 0.83<sup>[33]</sup>.

The State-Trait Anxiety Inventory (STAXI) consists of 20 items that assess dispositional (i.e. trait) anxiety<sup>[34]</sup>. This is a well-validated and widely used instrument for assessing general anxiety.

The Beck Depression Inventory (BDI) is a widely used, 21-item, self-report measure that assesses common cognitive, affective and vegetative symptoms of depression. Research that has evaluated the psychometric properties of the BDI has suggested that it shows excellent reliability and validity as an index of depression<sup>[35]</sup>. Since chronic pain patients often endorse somatic symptoms assessed by the BDI, which may artificially inflate their scores<sup>[36]</sup>, the BDI has been separated into a 13-item cognitive affective subscale and an eight-item somatic-performance subscale<sup>[37]</sup>.

The Profile of Mood States-bipolar Form (POMS-BI) consists of 72 mood-related items, and subjects

indicate the extent to which each item describes their current mood<sup>[38]</sup>. This questionnaire assesses positive and negative affective dimensions. The POMS-BI has been well validated with other mood measures and is sensitive to subtle differences in affective state. We have used this measure in previous psychophysical studies<sup>[28]</sup>. This mood measure was administered to determine the current affective state at the beginning of each sensory testing session.

Functional Bowel Disorder Severity Index (FBDSI) comprises three variables: current pain (by visual analog scale), diagnosis of chronic abdominal pain, and number of physician visits in the past 6 mo<sup>[39]</sup>. The FBDSI is sufficiently sensitive to distinguish among the different groups, from healthy controls, through non-IBS patients, to patients with IBS only and, finally, IBS patients with concomitant FM. Severity is rated as none (0 points, controls), mild (1-36 points, non-IBS patients), moderate (37-110 points, IBS patients), and severe ( $> 110$  points, IBS and FM). All IBS patients that participated in the study were characterized with this index.

### **Thermal procedures**

Thermal stimuli were delivered using a computer-controlled Medoc Thermal Sensory Analyzer (TSA-2001; Ramat Yishai, Israel). This is peltier-element-based stimulator with a 3 cm  $\times$  3 cm surface area. Temperature levels were monitored by a contactor-contained thermistor, and returned to a preset baseline of 32°C by active cooling at a rate of 10°C/s. Heat pain threshold (HPT<sub>h</sub>) and heat pain tolerance (HPT<sub>o</sub>) were assessed on the left ventral forearm and left calf using an ascending method of limits. The cutoff temperature (to avoid tissue damage) for all trials was 52°C. Subjects were assigned randomly within each group (controls, C-IBS, D-IBS) to receive thermal nociceptive stimulation to the left ventral forearm versus the left calf in a random order that was counterbalanced across all groups.

From a baseline of 32°C, probe temperature increased at a rate of 0.5°C/s until the subject responded by pressing a button on a handheld device. This slow rate of rise preferentially activates C-fibers and diminishes artifacts associated with reaction time.

### **HPT<sub>h</sub>**

For HPT<sub>h</sub>, subjects were informed via digitally recorded instructions to press the button when the sensation first became painful. Four trials of HPT<sub>h</sub> were performed at each site (ventral forearm and calf). The average of the four trials at each site was computed for HPT<sub>h</sub>. The position of the thermode was altered slightly between trials in order to avoid either sensitization or habituation of cutaneous receptors. In addition, interstimulus intervals of at least 30 s were maintained between successive stimuli. Four trials of HPT<sub>h</sub> were presented followed by a 15-min rest period, and then four trials of HPT<sub>o</sub> were performed.

### **HPT<sub>o</sub>**

For HPT<sub>o</sub>, subjects were instructed to press the button

when the sensation was no longer tolerable. Four trials of HPTo were performed at each site (ventral forearm and calf). The average of the four trials at each site was computed for HPTo. The position of the thermode was altered slightly between trials in order to avoid either sensitization or habituation of cutaneous receptors. In addition, interstimulus intervals of at least 30 s were maintained between successive stimuli.

### Statistical analysis

The primary analyses involved one between- and two within-subject variables, and consequently, the repeated measures command within the General Linear model module of SPSS was used. In the first primary analysis, differences between controls and D-IBS and C-IBS patients for HPTh and HPTo at the forearm and calf were tested. In the second primary analysis, associations between IBS symptom severity and HPTh and HPTo at the forearm and calf were tested. A series of one-way ANOVAs were used to test for group differences in psychological inventories. As a result of the number of statistical tests performed, a Bonferroni correction was used to maintain family-wise type 1 error rate at  $P < 0.05$ .

## RESULTS

### Samples

A total of 118 participants were studied, which included 42 patients (29 female and 13 males; mean age  $27.0 \pm 6.4$  years) with D-IBS; 24 patients (16 female and eight male; mean age  $32.5 \pm 8.8$  years) with C-IBS; and 52 control subjects (34 female and 18 males; mean age  $27.3 \pm 8.0$  years) (Table 1). There was no difference in age or sex between the groups (controls, D-IBS and C-IBS). FBDSI score was higher in the D-IBS ( $62.8 \pm 23.2$ ) and C-IBS ( $68.4 \pm 25.3$ ) patients than the controls ( $2.1 \pm 4.9$ ), but did not differ between the patient groups.

### HPTh and HPTo

HPTh and HPTo (mean  $\pm$  SD) at both sites for C-IBS, D-IBS, and controls are presented in Table 2. We found significant effects for site, pain measure, and group (all at  $P < 0.001$ ). Pair-wise comparisons supported the hypothesis that controls were less sensitive than C-IBS and D-IBS patients (both at  $P < 0.001$ ), with no differences between C-IBS and D-IBS. Two-way interactions for pain measure  $\times$  group ( $P = 0.002$ ) and site  $\times$  pain measure ( $P < 0.001$ ) were also significant. Pair-wise comparisons revealed that controls had higher HPTh and HPTo than C-IBS and D-IBS (both at  $P < 0.001$ ) on the forearm and the calf. There was no difference in HPTh or HPTo between C-IBS and D-IBS patients.

A group effect emerged for Kohn scores ( $P = 0.004$ ), with C-IBS ( $78.8 \pm 9.9$ ) having higher scores than D-IBS ( $70.8 \pm 10.8$ ) and controls ( $70.1 \pm 11.1$ ) (collapsed across groups,  $72.1 \pm 11.2$ ). There were no differences in the BDI ( $3.4 \pm 3.7$ ), STAXI ( $28.0 \pm 4.8$ ), POMS positive ( $53.2 \pm 15.7$ ), POMS negative ( $29.8 \pm 16.3$ ) or any of the subscales of the CSQ (distracting attention,  $10.0 \pm 6.1$ ; cognitive

**Table 2** HPTh and HPTo for the arm and leg

Groups (n)	Threshold (HPTh)		Tolerance (HPTo)	
	Forearm	Calf	Forearm	Calf
Controls (n = 52)	43.2 $\pm$ 1.8	45.1 $\pm$ 1.7	48.0 $\pm$ 1.8	48.1 $\pm$ 1.4
Diarrhea (n = 42)	39.1 $\pm$ 3.3	41.1 $\pm$ 4.0	44.7 $\pm$ 3.8	44.9 $\pm$ 2.1

### Differences as a function of IBS symptoms

We found significant effects for site, pain measure, and symptom severity (all at  $P < 0.001$ ). The site by symptom severity interaction was not significant; however, the 3-way interaction (site  $\times$  pain  $\times$  symptoms) was significant ( $P < 0.01$ ). To interpret this interaction involving an internal level variable (IBS symptom severity) and two nominal variables, we examined scatter plots for HPTh and HPTo at the leg and arm by FBDSI scores. The results suggest a naturally occurring gap between scores of 72 and 82 that was associated with pain sensitivity; therefore, two groups were formed based on FBDSI scores, with a cutoff at 80. Demographic variables for the two symptom severity groups are presented in Table 3. HPTh and HPTo at both sites for the two IBS symptom severity groups are presented in Table 2 and Figure 1. The IBS symptom subgroups did not differ for Kohn, BDI, STAXI, POMS, or CSQ scores.

## DISCUSSION

Overall, our findings indicate thermal hyperalgesia for IBS-C and IBS-D patients relative to controls, with IBS patients reporting significantly lower pain threshold and pain tolerance at both test sites. These findings add further

**Figure 1** HPT and HPTo for IBS pain subgroups.

support to the notion that IBS patients show somatic hyperalgesia. A unique finding of our study is that we detected a strong relationship between heat pain measures and FBDSI scores. IBS patients with high FBDSI scores had the highest thermal pain sensitivity compared to IBS patients with low to moderate FBDSI scores.

In contrast to our current findings, several previous studies have indicated lack of somatic hyperalgesia among IBS patients relative to controls<sup>[6,7]</sup>, with some studies actually showing higher pain threshold among IBS patients relative to controls<sup>[4,5]</sup>. One possible explanation for this is differences in the painful stimulus, as previous studies have used electrical stimuli, mechanical pressure, and cold immersion, but none has used contact heat. Also, Chang and colleagues<sup>[40]</sup> have reported that female IBS patients showed significantly higher pressure pain threshold than female controls in response to a randomly administered series of fixed stimuli, but no group differences emerged for threshold assessed using ascending stimuli. Randomly administered stimuli are thought to reduce response bias, which is likely driven by psychological factors such as hypervigilance. Since we used ascending stimuli in the present study, it is possible that response bias contributed to our results. However, this seems unlikely given the lack of correlations between psychological factors, including anxiety and hypervigilance, and heat pain responses. Differences in the nature of the patient population may present another explanation for the differences between our findings and those of previous studies. Most prior investigations<sup>[4-7]</sup> recruited IBS patients from clinical settings, typically in tertiary care centers, whereas our IBS sample was recruited from the community, using print and postal advertisements. This community-based recruitment approach yielded a psychologically healthy IBS population, which was similar to the controls for most psychological measures. Moreover, most previous studies have included a female-only population, while we included women and men in both the IBS and control samples. Thus, differences in the experimental pain stimulus and patient population may have contributed to the differing pattern of results.

Consistent with the present findings, other investigators have reported somatic hyperalgesia in IBS patients, using cold pain<sup>[3,10]</sup>, and we have shown similar results

with heat immersion<sup>[2,8]</sup>. However, to the best of our knowledge, this is the first report of an association between somatic pain sensitivity and clinical symptoms among patients with IBS. Wilder-Smith and colleagues<sup>[10]</sup> have reported a strong association between somatic and visceral hypersensitivity. However, there is mixed evidence regarding the association between visceral hypersensitivity and clinical symptoms in IBS<sup>[11,13,15,16,41]</sup>. In our study, the association of somatic hyperalgesia with FBDSI score suggests that central mechanisms contribute to the severity of patients' clinical symptoms. This has potentially important treatment implications, as one might speculate that patients exhibiting somatic hypersensitivity may benefit from treatments that alter central processes, rather than those that are restricted to peripheral targets.

Several limitations of this study should be mentioned. First, somatic pain testing was limited to HPT and HPTo and did not include other stimuli. Thus, it is not possible to determine whether these findings are specific to heat pain. Second, we did not assess sensitivity to visceral stimuli, and it would be interesting to know whether heat pain sensitivity is associated with visceral sensitivity. However, given our relatively large sample size, visceral testing was not feasible. Finally, based on the current design, we were unable to identify the mechanisms that underlie heat hyperalgesia and its association with clinical symptoms. Despite these limitations, the relatively large sample size, the use of heat pain measures designed to activate C-fibers, and the strong association between heat pain sensitivity and IBS symptom severity represent unique and valuable features of our study.

## CONCLUSION

Our study indicates somatic hypersensitivity for both groups of IBS patients relative to controls, with IBS patients reporting significantly lower thermal pain threshold and tolerance. Moreover, somatic pain sensitivity was associated with IBS symptoms, such that patients with high FBDSI scores showed significantly greater pain sensitivity compared to those with low to moderate FBDSI scores. Further studies are warranted to evaluate somatic hypersensitivity as a predictor of clinical symptoms in IBS.

## COMMENTS

### Background

Irritable bowel syndrome (IBS) is one of the most common gastrointestinal disorders encountered by gastroenterologists. Patients present classically with chronic abdominal pain associated with an alteration in bowel habits. Even though the pathophysiology of IBS is unclear, visceral hypersensitivity is a common clinical marker of the disorder. Visceral hypersensitivity may account for symptoms of abdominal pain, urgency, and bloating experienced by many patients with this disorder.

### Research frontiers

Although visceral hypersensitivity is considered a hallmark feature of IBS, conflicting evidence exists regarding somatic hypersensitivity in this patient population. Somatic pain conditions, such as fibromyalgia and migraine headaches show significant comorbidity with IBS, which suggests that somatic hypersensitivity characterizes at least a subpopulation of IBS patients. Several

recent studies using hot water immersion have shown widespread somatic hyperalgesia associated with IBS, and others using the cold pressor test have demonstrated somatic hypersensitivity in IBS patients compared with healthy controls.

### Innovations and breakthroughs

Overall, the findings indicate thermal hyperalgesia for constipation- and diarrhea-dependent IBS relative to controls, with IBS patients reporting significantly lower pain threshold and tolerance at both test sites. These findings add further support to the notion that IBS patients show somatic hyperalgesia. A unique finding of this study is that the authors detected a strong relationship between heat pain measures and Functional Bowel Disease Severity Index (FBDSI) scores. IBS patients with high FBDSI scores had the highest thermal pain sensitivity compared to those IBS patients with low to moderate FBDSI scores.

### Applications

This study suggests that a subset of IBS patients has evidence of somatic hypersensitivity that may relate to extra-intestinal symptoms.

### Peer review

This is an elegant study that evaluated systematically thermal hypersensitivity in a large number of IBS patients. The results are novel and interesting and may lead to new therapy in a subset of IBS patients with somatic hypersensitivity.

Published online: July 14, 2009

During May, there was a tendency for fewer subjects, (76.2% vs 95.2%,  $P = 0.078$ ) to report runny nose, while during June, fewer subjects, 11.1% vs 33.3%, reported nasal blocking in the probiotics group ( $P = 0.101$ ). Concomitantly, fewer subjects in the probiotic group had infiltration of eosinophils in the nasal mucosa compared to the placebo group, 57.1% vs 95% ( $P = 0.013$ ). Eye symptoms tended to be slightly more frequent in the probiotic group, 12.5 d [interquartile range (IQR) 6-18] vs 7.5 d (IQR 0-11.5) ( $P = 0.066$ ) during May. Fecal IgA was increased in the placebo group during the pollen season; this increase was prevented by the probiotics ( $P = 0.028$ ).

**CONCLUSION:** Birch pollen allergy was shown to be associated with changes in fecal microbiota composition. The specific combination of probiotics used was shown to prevent the pollen-induced infiltration of eosinophils into the nasal mucosa, and indicated a trend for reduced nasal symptoms.

### Abstract

**AIM:** To investigate whether birch pollen allergy symptoms are linked with gut microbiota changes and whether probiotics have an effect on these.

**METHODS:** Forty seven children with confirmed birch pollen allergy were randomized to receive either a probiotic combination of *Lactobacillus acidophilus* (*L. acidophilus*) NCFM™ (ATCC 700396) and *Bifidobacterium lactis* (*B. lactis*) BI-04 (ATCC SD5219) or placebo in a double-blind manner for 4 mo, starting prior to onset of the birch pollen season. Symptoms were recorded in a diary. Blood samples were taken for analysis of cytokines and eosinophils. Fecal samples were analysed for microbiota components, calprotectin and IgA. Nasal swabs were taken for analysis of eosinophils.

**RESULTS:** The pollen season induced a reduction in *Bifidobacterium*, *Clostridium* and *Bacteroides* which could not be prevented by the probiotic intervention. During the intervention, significantly higher numbers of *B. lactis*  $11.2 \times 10^7 \pm 4.2 \times 10^7$  vs  $0.1 \times 10^7 \pm 0.1 \times 10^7$  bacteria/g feces ( $P < 0.0001$ ) and *L. acidophilus* NCFM™  $3.5 \times 10^6 \pm 1.3 \times 10^6$  vs  $0.2 \times 10^6 \pm 0.1 \times 10^6$  bacteria/g feces ( $P < 0.0001$ ) were observed in the probiotic group compared to the placebo group.

### INTRODUCTION

Allergic rhinitis and asthma are common chronic conditions, with a recently reported annual symptom prevalence of 15% for both diseases in young teenagers in Western Europe<sup>[1]</sup>. Allergic rhinitis is often seasonal and caused by exposure to environmental allergens. It has been shown that, in allergic rhinitis, nasal allergen

provocation induces an inflammatory response not only in nasal but also in bronchial mucosa<sup>[2]</sup>, and *vice versa*<sup>[3]</sup>, emphasizing the importance of the airways as a single anatomic-functional unit. Furthermore, chronic allergic rhinitis is known to be an independent risk factor of asthma<sup>[4]</sup>. Allergic rhinitis is frequently accompanied by allergic conjunctivitis, characterized by decreased conjunctival epithelial integrity and repair mechanisms even outside the pollen season<sup>[5]</sup>.

Probiotics are live microorganisms which, when administered in adequate amounts confer a health benefit on the host<sup>[6]</sup>. Specific probiotic strains have been shown to be effective in the prevention<sup>[7-9]</sup> and treatment<sup>[10]</sup> of atopic eczema, alleviating allergic inflammation both locally and systemically. The evidence of probiotic efficacy against allergic rhinitis and immunological sensitization predisposing to asthma is insufficient and contradictory at present. The previously studied probiotic strains or combinations of these may not have targeted airway allergies, or the populations studied may not have been responsive to immune modulation<sup>[9]</sup>.

We hypothesized that allergic rhinitis can be alleviated by the use of specific probiotics selected to both modify the intestinal microbiota and to confer immune effects, which can be demonstrated in the intestinal tract prior to an allergic reaction. We assumed that the nasal mucosa is the most vulnerable structure of the airways, allowing the greatest inhalational allergen penetration. Thus we chose to study the effects of selected probiotic bacteria in allergic rhinitis in children during the birch pollen season. The specific strains used in this study were selected based on their anti-inflammatory properties and an expected effect in promoting a Th1 type of immune response<sup>[11,12]</sup>. The study population was chosen to cover subjects with confirmed birch pollen allergy. By selecting children, we hypothesized that there would be more opportunity to modify the immune responses.

## MATERIALS AND METHODS

### Patients

Forty-seven children with clinically and immunologically documented and physician-verified birch pollen allergy were enrolled in the study. All had previously had symptoms of allergic rhinitis confined to the birch pollen season, and the specific test result to birch pollen had been positive, either with skin prick testing (positive result if the mean wheal diameter for birch pollen allergen was greater than 3 mm) or demonstration of specific IgE antibody in serum (according to the manufacturer's reference values, the level for positivity was a specific IgE more than 0.35 kU/L). The symptoms of the patients during the previous pollen season included sneezing and runny or blocked nose, and the nasal symptoms were often associated with allergic eye symptoms, such as itching and redness of the conjunctiva. Patients with diagnosed asthma, habitual use of probiotics and/or prebiotics and recent use of antibiotics were excluded from the study.

The study was approved by the Ethics Committee

of the Hospital District of South-Western Finland and informed, written consent was received from the participants and their parents. The study was registered at [www.clinicaltrials.gov](http://www.clinicaltrials.gov) under the identifier NCT00746226.

### Study material

The study material consisted of capsules containing  $5 \times 10^9$  CFU of a combination of 25% *Lactobacillus acidophilus* (*L. acidophilus*) NCFM™ (ATCC 700396) and 75% *Bifidobacterium lactis* (*B. lactis*) Bl-04 (ATCC SD5219), Danisco Cultures, Madison, USA. The strains were selected based on their anti-inflammatory properties and Th1-type immune stimulating effects and their ratio was chosen to optimize these functions. The viability of the study material was determined at monthly intervals during the study by Danisco Cultures, Madison. This laboratory was not involved in the study, and no significant reduction in viability was observed (results not shown). The placebo consisted of identical capsules containing microcrystalline cellulose. The study material was randomized at the site of production by a person not involved in the study. The volunteers, researchers and biostatisticians remained blinded for the duration of the study and the analyses. The code was broken after completion of the statistical analyses.

### Study design

Eligible subjects were assigned to receive one of the individually coded test products. The subjects or their parents were instructed to consume one capsule daily or to suspend its contents in a suitable liquid.

The patients attended the study unit 3 times during spring 2006 (Figure 1). The first visit was in March before the birch pollen season, and consumption of the study material started after this visit. The second visit was at the end of April-beginning of May during the birch pollen season and the third visit was in June at the end of the season, when consumption of the study product was finished.

Clinical examination of the patients was carried out at each study visit. At each visit, nasal smears were taken from both nostrils by gently rubbing the middle or inferior turbinate with a cotton covered stick, followed by fixing and staining with eosin and methylene blue. Eosinophil counts were determined semiquantitatively by microscope as follows: -, no eosinophils in any of the fields of view; +, a few scattered eosinophils at least in some fields of view; ++, eosinophils easily found in every field of view; and +++, every field of view abundant in eosinophils. Venous blood samples were drawn at each study visit. At the first and third visit, the blood eosinophil count was determined by automated blood cell counter (Advia 120, Bayer Health Care, Germany), and allergen-specific IgE antibodies in serum were measured by an immunofluorometric assay (ImmunoCAP™, Phadia AB, Uppsala, Sweden). All samples were initially screened using a mix of inhalation allergens (Phadiatop ImmunoCAP). The samples which were positive at screening were subsequently tested for

birch pollen-specific IgE.

The concentrations of the cytokines interleukin (IL)-4, IL-5, IL-6, IL-10 and tumor necrosis factor (TNF)- $\alpha$  were measured by multiplex flow cytometric assay using a commercial Human Th1/Th2 Cytokine Kit (BD Immunocytometry Systems and BD Biosciences Pharmingen). The concentrations of transforming growth factor (TGF)- $\beta$ 2 were measured at the first and second visit and soluble CD-14 (sCD-14) at the first and third visit using commercial sandwich ELISA specific for these molecules (R&D Systems Europe Ltd., Abingdon, UK).

The presence of blocked or runny nose, respiratory difficulty, coughing, eye symptoms or eczema was recorded by the parents on the diary cards throughout the study. The number of days with each symptom during each of the study months was reported.

#### **Analysis of gut microbiota by fluorescent in situ hybridization (FISH)**

The major groups of fecal bacteria were analyzed using the FISH method as previously described<sup>[13]</sup>. In brief, fecal samples were suspended in PBS and homogenized. Bacteria were fixed with paraformaldehyde and hybridized with Cy3 indocarbocyanin-labeled oligonucleotide probe. Probes included Bac303 (5'-CCAATGTGGGGACCTT-3') for the *Bacteroides-Prevotella* group, Bif164 (5'-CAT CGGCATTACCACCC-3') for bifidobacteria, His150 [5'-TTATGCGGTATTAATCT (C/T) CCTTT-3'] for clostridia of the *C. histolyticum* group and MUC-1437 (5'-CCTTGCAGGTGGCTTCAGAT-3') for *Akkermansia muciniphila*-like bacteria<sup>[14]</sup>, total cells were enumerated using an EUB338 (5'-GCTGCCTCCGTAGGAGT-3')-fluorescein (FITC)-labelled probe<sup>[15,16]</sup>.

Flow-cytometric analyses were performed using a BD<sup>TM</sup> LSR II flow cytometer (Becton, Dickinson and Co., USA) equipped with 4 lasers (355, 405, 488 and 635 nm). We used the 488 nm laser at 15 mW. This standard instrument is equipped with 2 light scatter detectors which measure forward (FSC) and side scatter (SSC) and 4 fluorescence detectors detecting appropriately filtered light at green (FL1, 525 nm), yellow (FL2, 575 nm), orange (FL3, 620 nm), and red (FL4, 675 nm) wavelengths. To avoid cell coincidence, the flow rate was kept at the lowest setting (data rate 200-300 events per second). At least 30 000 events were recorded for each sample and all experiments were conducted in duplicate. Data were stored as list-mode files and analyzed off-line using the BD FACSDiva<sup>TM</sup> software version 4.1.1 (Becton, Dickinson and Co., USA).

Immediately prior to analysis, Flow-Count fluorospheres (Beckman Coulter, USA) were added to each sample. Absolute bacterial cell counts were determined following the manufacturer's instructions, using the ratio of positive bacteria to fluorospheres counted using the following formula: cells/ $\mu$ L = [(cells counted)/(fluorospheres counted)]  $\times$  fluorospheres/ $\mu$ L. To avoid loss of the signal intensity of hybridized cells, they were kept in the dark on ice at 4°C until the flow

cytometry assay. Results were expressed as the numbers of cells hybridizing with the specific group-Cy3 probe and total bacteria EUB 338-FITC probe.

#### **Analysis of microbiota by quantitative real-time PCR (qRT-PCR)**

DNA extractions from pure cultures of the different microorganisms and fecal samples were extracted using the QIAamp DNA stool Mini kit (Qiagen, Hilden, Germany) following the manufacturer's instructions. qPCRs were conducted as previously described<sup>[10,11]</sup>. For characterization of the fecal microbiota PCR primers were designed targeting *B. lactis* according to Gueimonde and co-workers<sup>[17]</sup>. *L. acidophilus* NCFM<sup>TM</sup> was quantified using primers as described by Ouwehand and co-workers<sup>[18]</sup>. The oligonucleotides were purchased from the Thermo Electron Corporation (Thermo Biosciences, Ulm, Germany). Briefly, PCR amplification and detection were performed with an ABI PRISM 7300-PCR sequence detection system (Applied Biosystems, UK). Each reaction mixture of 25  $\mu$ L was composed of SYBR<sup>®</sup> Green PCR Master Mix (Applied Biosystems, UK.), 1  $\mu$ L of each of the specific primers at a concentration of 0.25  $\mu$ mol/L, and 1  $\mu$ L of template DNA. The fluorescent products were detected at the last step of each cycle. A melting curve analysis was made after amplification to distinguish the targeted PCR product from the non-targeted PCR product.

#### **Microbial activity**

Microbial activity was determined by measurement of lactic acid, short chain fatty acids: acetic, butyric, lactic and propionic acids, and branched chain fatty acids: valeric, isobutyric, 2-methylbutyric and isovaleric acid. These were determined by gas chromatography as described previously by Holben *et al*<sup>[19]</sup>. The results were expressed in mmol/kg.

#### **Determination of intestinal immune responses**

Changes in the immunological status of the intestine were monitored by measuring the concentrations of IgA and calprotectin from the soluble fraction of feces. For IgA measurements the frozen samples were thawed and extracted with BSA as described previously and stored at -20°C before analysis<sup>[20]</sup>. Concentrations of IgA were then determined with the ELISA according to the manufacturer's instructions (E80-102, Bethyl Laboratories, Inc., Montgomery, TX, USA). The concentrations of calprotectin were determined with ELISA following the manufacturer's instructions (Calpro AS, Oslo, Norway). The results were expressed as  $\mu$ g per g fresh weight.

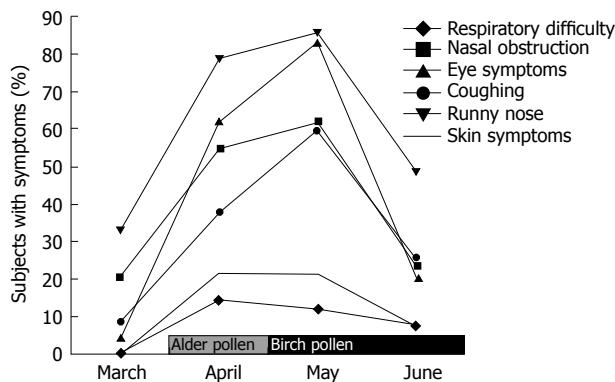

#### **Statistical analysis**

Differences between the treatment groups were analysed using the Mann-Whitney U test. Differences within the treatment groups between the different time points were analyzed using the Wilcoxon signed rank test. Correlations between the level of fecal colonization of *B. lactis* or *L. acidophilus* NCFM<sup>TM</sup> and immune or

**Table 1** The clinical characteristics of the study subjects

	Probiotic	Placebo	P-value
N	24	23	
Drop-outs	2	1	$P > 0.99$
Age (yr)	9.0 (4.2-11.9)	8.9 (6.1-12.9)	$P = 0.845$

Length (cm)	135.2 (107.3-156.5)	133.6 (113.8-152.5)	$P = 0.50$
Weight (kg)	31.0 (11.9-47.4)	32.4 (20.2-45.3)	$P = 0.80$

Data are expressed as mean (range).

**Figure 1** Percentage of subjects with specific symptoms of birch pollen allergy among allergic children. The gray bar represents the alder pollen season and the black bar the birch pollen season in Turku (Finland) during the study period ( $> 100$  pollen/m $^3$ ).

microbiological variables in the probiotic group during the second visit were determined with the Spearman rank correlation test. To determine differences between the groups and over time, the data was analyzed with a linear mixed effects model, having effects for time, group, and their joint effect. Individual baseline differences were taken into account by including the first time point as a covariate in the model. P-values below 0.05 were considered significant.

## RESULTS

### Clinical characteristics

Baseline clinical characteristics of the 2 groups are presented in Table 1. Twenty patients in the probiotic and 21 in the placebo group completed the study. Three patients, 2 in the probiotic group and 1 in the placebo group, were excluded during the study because of newly developed asthma. Three patients, 2 in the probiotic group and 1 in the placebo group, decided to drop out of the study. The mean duration of breast-feeding was 7.5 mo (range 0-18 mo), there being 2 patients whom were not breast-fed.

### Impact of the birch pollen season on allergy

The impact of the onset of the birch pollen season on allergy symptoms in the two study groups is depicted in Figure 1. The peak period of birch pollen exposure, April and May, resulted in specific symptoms such as nasal obstruction and runny nose. All the recorded

**Table 2** Number of subjects with nasal eosinophilia n (%)

Month	Placebo	Probiotic
March	14 (63.6)	17 (70.8)
April/May	19 (95.0)	12 (57.1) <sup>1</sup>
June	12 (60.0)	12 (60.0)

<sup>1</sup>P = 0.013 compared to placebo group.

symptoms increased during April and May (the height of the pollen season in Turku, Finland), and decreased again in June ( $P < 0.001$ ).

At the start of the study, there was no difference in the observed symptoms between the 2 study groups. Runny nose tended ( $P = 0.078$ ) to be reported in May by fewer subjects in the probiotic group (76.2%) than in the placebo group (95.2%). During June, fewer subjects reported nasal blocking in the probiotics group (11.1%) than in the placebo group (33.3%). This did not, however, reach statistical significance ( $P = 0.101$ ). Concomitantly with the differences in nasal symptoms, the number of subjects with infiltration of eosinophils in the nasal mucosa increased in the placebo group during the April/May visit but an increase was not observed in the probiotic group ( $P = 0.013$ ), where the fraction of subjects with nasal eosinophil infiltration remained unchanged (Table 2).

During May, the subjects in the probiotic group reported more days with eye symptoms, 12.5 d (interquartile range (IQR) 6-18 d), than subjects in the placebo group, 7.5 d (IQR 0-11.5 d),  $P = 0.066$ . In June, this difference was no longer detectable.

### Impact of intervention on immunological parameters

In addition to the increase in symptoms over the season, concentrations of birch pollen-specific IgE also increased in both groups from March to June,  $P = 0.0015$  and  $P = 0.0002$  for placebo and probiotic respectively (Table 3). Likewise, blood eosinophil numbers increased in both placebo ( $P = 0.03$ ) and probiotic groups ( $P = 0.002$ ), from March to June (Table 3). Concentrations of IL-6 decreased in both groups from March to April/May,  $P = 0.0004$  and  $P = 0.0002$  in placebo and probiotic groups, respectively (Table 3). Concentrations of IL-10 were reduced in the placebo group from March to April/May,  $P = 0.0495$ . For both groups, concentrations of TNF- $\alpha$  decreased from March to April/May,  $P = 0.0007$  and  $P = 0.0005$  in placebo and probiotic groups, respectively. Concentrations of TNF- $\alpha$  were higher in the placebo group at the start of the study,  $P = 0.0062$ , however, at the April/May visit no difference was observed,  $P = 0.17$ . Concentrations of interferon- $\gamma$  and IL-2 were below the detection limit for both groups at all 3 time points tested. No differences in the concentrations of TGF- $\beta$ 2, IL-4, IL-5 and CD14 were detected (Table 3).

Concentrations of fecal IgA and calprotectin exhibited great individual variance ( $P < 0.0001$  and  $P = 0.015$ , respectively). Because of this significant variation, the data were analyzed taking the baseline

<sup>1</sup>Significantly different from previous time point;  $P < 0.01$ . <sup>2</sup>Significantly different from previous time point;  $P < 0.05$ . <sup>3</sup>Significantly different from placebo;  $P < 0.01$ . <sup>4</sup>Determined by fluorescent *in situ* hybridization (FISH). <sup>5</sup>Determined by quantitative real-time PCR. Data are expressed as mean (SE), microbes/g feces.

level into account. Neither the probiotic treatment, nor pollen season had any significant effects on the fecal calprotectin concentrations. However, fecal IgA concentrations were increased in the placebo group during April/May ( $P = 0.028$ ), which was prevented by the probiotic intervention. In the latter group, the concentration remained stable during the entire study period, Table 4.

#### Impact of probiotics on the gut microbiota

Administration of *B. lactis* Bl-04 and *L. acidophilus* NCFM™ led to a significant increase in the fecal numbers of *B. lactis* ( $P = 0.0032$ ) and *L. acidophilus* NCFM™ ( $P = 0.0036$ ), from March to April/May and numbers remained high until the end of the intervention in June, indicating good compliance by the subjects (Table 5). The differences were also significant compared to the placebo group during April/May; *B. lactis* ( $P < 0.0001$ ) and *L. acidophilus* NCFM™ ( $P = 0.0002$ ), and June; *B. lactis* ( $P < 0.0001$ ) and *L. acidophilus* NCFM™ ( $P <$

0.0001), Table 5.

A general decrease in numbers of the major bacterial groups *Eubacterium*, *Bifidobacterium*, *Bacteroides* and *Clostridium* accompanied the birch pollen season in both study groups (Table 5). This may not be explained by the increase in fecal numbers of *B. lactis* and *L. acidophilus* as the decrease in fecal numbers was manifested in both probiotic and placebo groups. In the placebo group, concentrations of 2-methylbutyric acid were reduced from April/May to June,  $P = 0.0501$ . However, no differences in concentrations of other measured fecal organic acids were observed between the 2 groups for any of the time points (Table 6).

#### DISCUSSION

Probiotics have been used to reduce the risk of atopic eczema, frequently the first allergic symptom to manifest itself. Previous intervention studies showing risk reduction for eczema have failed to reduce the risk of

<sup>1</sup>Significantly different from previous time point;  $P = 0.05$ . Data are expressed as mean  $\pm$  SE.

respiratory allergies. This may be due to strain and host specific characteristics. However, a recent study with a combination of *Lactobacillus rhamnosus* (*L. rhamnosus*) GG and *B. lactis* Bb-12, achieved for the first time, a reduction in risk of both eczema and later sensitization, but only in a high-risk population<sup>[21]</sup>. Nevertheless, we need to acknowledge that a more profound understanding of the complex nature of atopy and atopic disease is needed, as it is likely that there are distinct etiological factors and pathogenetic mechanisms underlying the heterogeneous manifestations of the disorder. Thus, one mode of prevention or treatment may not suffice to target the plethora of allergic disease.

In the present study, we observed in the probiotic group a reduction of nasal eosinophil infiltration, an objective marker of allergic rhinitis. The degree of eosinophil infiltration of the respiratory mucosa is known to directly correlate with the intensity of the disease<sup>[22]</sup>. Indeed, trends for less runny nose during the peak of the pollen season and reduced nasal blocking towards the end of the season were observed in the current study. Earlier trials with probiotics and pollen allergy have shown that *L. rhamnosus* GG was not effective in relieving birch pollen allergy symptoms<sup>[23]</sup>. Likewise, *Lactobacillus casei* Shirota, was not found to be effective in reducing symptoms of Japanese cedar pollen allergy<sup>[24]</sup>, although the strain did reduce serum concentrations of IL-5, IL-6, interferon- $\gamma$  and specific IgE in subjects with allergic rhinitis<sup>[25]</sup>. A recent study showed, however, that *B. longum* BB536 was able to relieve eye symptoms in subjects suffering from Japanese cedar pollen allergy<sup>[26,27]</sup>, likewise *L. rhamnosus* GG and *L. gasseri* TMC0356 reduced nasal symptoms of Japanese cedar pollen allergy<sup>[28]</sup>.

Interestingly, our results indicate that gut microbiota are involved in regulating the inflammatory processes also in airway allergies. The fecal levels of bifidobacteria, clostridia and *Bacteroides* were reduced at the peak of the birch pollen season. As the change occurred in both treatment groups, it is not likely to be a consequence of the intervention, but may rather relate to the birch pollen season or possibly, but unlikely, to the concomitant antihistamine medication. Changes in fecal microbiota composition, a decrease in *Bacteroides fragilis* levels, in response to cedar pollen challenge have previously been

reported<sup>[29]</sup>. The underlying reasons for the temporary reduction of the numbers of the major phyla of the microbiota can only be speculated. Despite the change in the composition of the fecal microbiota, only a small change in 2-methylbutyric acid concentrations was observed, and no other changes in the determined intestinal microbial metabolites were detected.

The probiotic strains used in the current study were selected on the basis that they had either anti-inflammatory properties or could be expected to have a Th1 response-promoting effect<sup>[11,12]</sup>. Their ratio was chosen to optimize these 2 effects. The probiotic intake was reflected in temporary colonization of the gut by the study probiotics and in their enhanced numbers in fecal samples from the study children. This indicates that the study subjects had good compliance to the treatment and the study procedure. Furthermore, fecal *L. acidophilus* NCFM™ numbers correlated positively with fecal acetic acid concentrations ( $R = 0.612$ ,  $P = 0.0116$ ), fecal propionic acid concentrations ( $R = 0.449$ ,  $P = 0.0642$ ) and fecal butyric acid concentrations ( $R = 0.519$ ,  $P = 0.0323$ ). These observations may suggest that the presence of, in particular, *L. acidophilus* NCFM™ increases microbial fermentation in the colon. However, the consumption of the probiotic strains did not prevent changes in the colonization pattern when compared to the placebo group.

The study population was chosen to cover subjects with confirmed birch pollen allergy. The subjects selected suffered from significant symptoms of birch pollen allergy; this may have exceeded the potential effect of the intervention. Furthermore, all subjects were allowed to use oral antihistamines prophylactically. Also this has undoubtedly reduced the possibility of observing a treatment effect. Notwithstanding these limitations, positive influences could be observed on established clinical markers of pollen allergy, particularly in mucosal responses, where the increases in nasal eosinophil infiltration and increases in fecal IgA were prevented. Inhibition of increased Th2 type reactivity in the gut during the birch pollen season in the probiotic group may indicate that the shift to Th2 responses which has been associated with the development of allergy can be relieved by supplementation with this particular probiotic combination.

In conclusion, our study showed that consumption of a combination of *L. acidophilus* NCFM™ and *B. lactis* Bl-04 could positively influence markers of respiratory allergy, especially in the mucosae, and also resulted in a tendency for a reduction in reported nasal symptoms.

## COMMENTS

### Background

Pollen allergies are increasing in affluent societies. This is thought to be related to a reduced microbial exposure. Probiotics could provide a safe form of microbial exposure possibly through modulation of the intestinal microbiota.

### Research frontiers

Studies have shown that selected probiotics may modulate the immune response and contribute to the relief or primary prevention of atopic dermatitis. Few studies have, however, investigated the potential of probiotics on pollen allergies. The present study indicates a potential for the specific combination of *Lactobacillus acidophilus* (*L. acidophilus*) NCFM and *Bifidobacterium lactis* (*B. lactis*) Bl-04 in the alleviation of birch pollen allergy in children.

### Innovations and breakthroughs

The present randomized, placebo-controlled, double-blind study showed that the intestinal microbiota changes during the birch pollen season, and the combination of *L. acidophilus* NCFM and *B. lactis* Bl-04 was not able to counteract this change. Despite the prophylactic use of antihistamines, the probiotic combination did reduce an objective marker of pollen allergy (nasal eosinophilia) and indicated a trend for a reduction in subjective markers, nasal blocking and runny nose.

### Applications

Probiotics may provide an alternative or complementary treatment for pollen allergies. A future study could investigate whether this would lead to a reduced use of antihistamines.

### Terminology

Probiotics are live microorganisms which, when administered in adequate amounts confer a health benefit on the host. Specific strains of probiotics have been observed to modulate the immune system and the composition and activity of the intestinal microbiota.

### Peer review

The study addresses an interesting and relevant issue on which data is scarce, and the findings may contribute to our understanding of the role of probiotics in allergic rhinitis.

was observed. Lesions were mostly hypoechoic and mixed, solitary or multiple. Some of the patients presented with dilated splenic veins and hepatofugal blood flow. A pulse wave was registered in the centre and at the margins of lymphoma. The average velocity of the pulse wave was higher at the margins ( $P > 0.05$ ). A continuous venous wave was found only at the margins of lymphoma. There was no linear correlation between lymphoma size and velocity of pulse and continuous wave ( $r = 390$ ,  $P < 0.01$ ). HPI was significantly lower in patients with lymphomas than in controls ( $P < 0.05$ ), pointing out increased arterial perfusion in comparison to portal perfusion.

**CONCLUSION:** Color Doppler ultrasonography is a sensitive method for the detection of neovascularization in Hodgkin's hepatic lymphoma and estimation of its intensity. Hepatic radionuclide angiography can additionally help in the assessment of vascularisation of liver lesions.

### Abstract

**AIM:** To estimate the characteristics of Color Doppler findings and the results of hepatic radionuclide angiography (HRA) in secondary Hodgkin's hepatic lymphoma.

**METHODS:** The research included patients with a diagnosis of Hodgkin's lymphoma with metastatic focal lesions in the liver and controls. Morphologic characteristics of focal liver lesions and hemodynamic parameters were examined by pulsed and Color Doppler in the portal, hepatic and splenic veins were examined. Hepatic perfusion index (HPI) estimated by HRA was calculated.

**RESULTS:** In the majority of patients, hepatomegaly

### INTRODUCTION

The first choice technique for the investigation of

liver lesions, including Hodgkin's hepatic lymphoma, is ultrasound<sup>[1]</sup>. The diagnosis of this type of lymphoma can be made by non-specific sonographic signs, such as hepatomegaly, irregularity of liver margins, number and appearance of the lesions, echogenicity, enlarged retroperitoneal lymph nodes<sup>[2]</sup>, presence of pleural effusion or ascites, etc. Biopsy of focal lesions of the liver controlled by ultrasound in patients with malignant lymphomas is a reliable technique which can replace lymphography and other imaging procedures such as CT and nuclear magnetic resonance. Thrombosis of the portal and splenic vein has been described as a real rare complication of secondary hepatic lymphoma. The use of Color Doppler (CD) in the investigation of vascularisation of focal lesions in the liver brings about new possibilities in differential diagnostics of focal hepatic lesions<sup>[2]</sup>.

In the pre-evaluation and diagnosis of patients with liver tumors, after ultrasonography and Doppler-US and contrast enhanced ultrasonography (CEUS), significant nuclear medicine methods are used: radiocolloids, blood pool, hepatobiliary scintigraphy, angioscintigraphy with radiolabeled microspheres and "first pass" radionuclide angiography<sup>[3-6]</sup>. These methods precede selective angiography and other invasive methods. CT and nuclear magnetic resonance, although used mainly for the morphological examination of the liver, can be also performed in hepatic blood flow studies<sup>[7,8]</sup>. Recently, positron emission tomography has also been included, in combination with other imaging modalities. Nuclear medicine methods are basically founded on the analysis of hepatic radionuclide angiography (HRA), obtained after the "first pass" of the radioactive bolus and registered activity over the liver and other abdominal organs after intravenous injection of <sup>99m</sup>Tc. As well as methods based on the assessment of total liver blood flow and assessment of shunts the technique of radionuclide angiography and determination of the hepatic perfusion index (HPI) proposed by Sarper<sup>[9]</sup> is a noninvasive method providing additional information on portal blood flow.

The aim of our examination within this study was the evaluation of characteristics of Color Doppler findings and the results of HRA in secondary Hodgkin's hepatic lymphoma. Another aim was the estimation of reliability of CD ultrasound (US) in respect of neovascularization and level of intensity of vascularisation of the focal liver change.

## MATERIALS AND METHODS

The study included 25 patients with a diagnosis of Hodgkin's lymphoma who had secondary focal lesions in the liver and 30 controls. Controls were patients with different complaints, examined in the Clinical Center of Serbia, who underwent, among other investigations, nuclear medicine examinations (radionuclide ventriculography or another study which required iv injection of <sup>99m</sup>Tc pertechnetate) and abdominal and cardiology US. All the results, including laboratory analysis were physiological, and showed that they did not

have any disease or disorders. All controls were informed that their results would be included in the study.

Focal hepatic lesions had histopathological findings that correlated with our ultrasonographic studies. The ATL Ultramark9 system, and a convex probe with pulsed Doppler and CD of 2.5 MHz (WF50 Hz) were used for ultrasonographic examination. Hemodynamic parameters examined by pulsed Doppler and CD in the portal, hepatic and splenic vein were: diameter, flow, respiratory dependence of flow and collaterals. Examination of vascularisation of the focal hepatic lesion involved detection and measurement of blood flow in the centre of the focal lesion, as well as at its margin and periphery. Counting and recording for each specific focal change was performed by detection of the CD signal at a certain depth of scanning per cm<sup>2</sup>. The CD signal was created by reflection of an ultrasonic beam from the small blood vessels. Examination was repeated several times for every focal lesion, since the number of CD signals varied while breathing or changing the angle of the ultrasonic beam. An average of 5 planes of scanning were used for every hepatic change. Flow at the margins and in the center of every focal lesion was measured by combination of Color and pulsed Doppler. The results were statistically analyzed using Wilcoxon's, Kruskal-Wallis and  $\chi^2$  tests.

HRA was performed in patients with Hodgkin's hepatic lymphoma and controls after bolus injection of 740 MBq <sup>99m</sup>Tc-pertechnetate, (1 min, 1f/s), using a ROTA scintillation camera and MicroDelta computer. The arterial-hepatic and portal-venous phase of HRA were separated at the moment when maximal activity over the left kidney region of interest (ROI) was registered. The HPI was calculated according to Sarper's method<sup>[9]</sup>. Thus, the HPI reflects the value of the relative portal contribution to the liver blood flow. As well as the mean values (mean) and standard deviation (SD), statistical analyses included *t* tests, *U* tests, one and two way analysis of variance and a multiple range test.

The final diagnoses were based on the clinical findings, results of the functional and laboratory analysis, US and Doppler US, angiography, biopsy with histopathology and other clinical examinations. Consent was obtained from each patient, and the study protocol conformed to the established ethical guidelines. Written consent was obtained from all patients, according to the regulations of the School of Medicine Ethical Committee.

## RESULTS

Hepatomegaly existed in 23 patients (91%). Hyperechoic appearance of node was present in 11% of cases, hypoechoic in 55% and heterogeneous mixed echoic structure in 34%. Solitary tumor nodes were found in the liver in 19 patients (48%) and multiple nodes existed in 16 patients (52%). The smallest tumor node was 1.5 cm, and the biggest was 14 cm. There was a diffuse infiltration of the liver in 2 patients. Solitary tumor knots were most frequently localized in the right lobe (36%),

**Table 1** The values of hemodynamic parameters (Doppler-US)

Hemodynamic parameters	Statistical parameters					
	Unit	n	Mean	SD	CV	Med
Patients with secondary Hodgkin's hepatic lymphoma						
Diameter portal vein	cm	25	1.7	0.4	26	1.7
Velocity portal vein	cm/s	25	18.0	22.0	18	13.0
Volume of blood flow portal vein	mL/min	25	859.0	574.0	69	643.0
Velocity hepatic artery	cm/s	25	40.0	16.0	38	40.0
Control group						
Diameter portal vein	cm	30	1.0	0.1	10	1.0
Velocity portal vein	cm/s	30	17.0	2.0	13	17.0
Volume of blood flow portal vein	mL/min	30	781.0	164.0	23	763.0
Velocity hepatic artery	cm/s	30	38.0	5.0	14	36.0

US: Ultrasound; CV: Coefficient of variation; Med: Median.

between right and left lobe (53%) and in the left lobe of liver (11%). The position at the right liver lobe was frequently followed by irregular margins of the liver and pleural effusion at the right side. Ascites was present in 4 patients (16%). Retroperitoneal lymph nodes were found in 16 patients (64%). Splenomegaly was detected in 16 (64%). The spleen consisted of heterogeneous echoes with bigger or smaller knots in 10 patients (40%).

Dilated splenic veins were present in 40% of cases and hepatofugal blood flow in 32%. Hepatofugal flow in the splenic vein was observed in 16% of the patients, while the others had normal hepatopetal flow. A spontaneous splenorenal shunt and collateral blood flow was detected in 12% of patients with mass splenomegaly. A hepatofugal direction of flow existed in the portal vein in 50% of patients. Hemodynamic parameters in patients with lymphomas and controls are presented in Table 1. Thus, the diameter of the portal vein was significantly ( $P < 0.05$ ) bigger than standard values and ranged from 1.1-2.4 cm. However, the average flow velocity in the portal vein was not significantly different ( $P > 0.05$ ) from that in the controls. The volume of blood flow through the portal vein was 600-1200 mL/min which was not significantly different from normal values ( $P > 0.05$ ). Flow velocity in the hepatic artery was 15-55 cm/s, which was significantly different from the values in the control group ( $P < 0.05$ ).

In 3 patients without nodules in the liver visible on US examination, slight perfusion disorders were detected by Doppler-US. The volume of portal blood flow was slightly increased (1000-1200 mL/min), without any impact on the statistical calculation.

Two types of spectral curved lines were found: pulse-arterial wave and continuous venous wave, and velocities are presented in Table 2. A pulse wave was registered in the centre and at the margins of lymphoma and its velocity ranged from 80-140 cm/s. The average velocity of the pulse wave at the margins was a little higher ( $P > 0.05$ ) than in the center of the lesion. A continuous venous wave was found only at the margins of the lymphoma and its maximum velocity was 35 cm/s. There was no linear correlation between lymphoma size

**Table 2** Average velocities of the pulse and continuous waves in the center and at the margins of lymphoma

Wave	Tumor center			Tumor margin		
	Mean	SD	Med	Mean	SD	Med
Pulse (cm/s)	80	23	84	84	25	88

Lymphoma patients	25	0.27	0.22	73	0.35

and velocity of pulse and continuous waves ( $r = 390$ ,  $P < 0.01$ ).

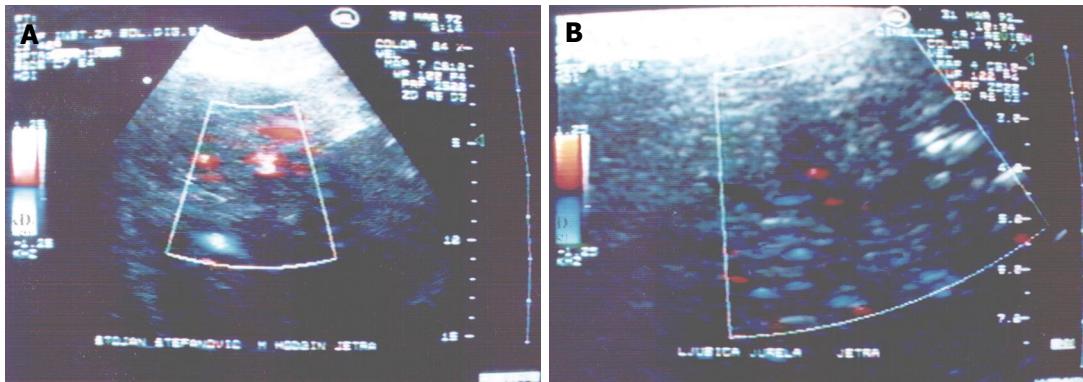

The CD signal could not be found within the parts of the focal lesion where there was no flow in small blood vessels or where the flow could not be detected by the CD system. The CD signal in hypoechoic lesions varied from 0.5-0.9 of blood vessels/cm<sup>2</sup>. Maximum values of the number of CD signals were noticed in lesions 3-5 cm in size and they ranged from 1-3 blood vessels/cm<sup>2</sup> of area in hypoechoic zones. In the case of hyperechoic lesions the result was 0.5-0.6 vessels/cm<sup>2</sup>. Comparing number of CD signals *in vivo* to number of blood vessels in histological tissue, we could not find any relevant differences between these two methods ( $P > 0.05$ ) (Figure 1).

Results of HRA in patients with secondary Hodgkin's hepatic lymphoma (Table 3), showed that HPI was significantly lower in patients with lymphomas than in controls ( $P < 0.05$ ). Thus, arterial hepatic perfusion was increased in patients with secondary hepatic lymphomas, while the venous component of hepatic perfusion was decreased.

## DISCUSSION

Most of the patients with Hodgkin's hepatic lymphoma had hepatomegaly, mainly with hypoechoic or heterogenous mixed echoic structures, while in a small number of patients it was hyperechoic. The lesions were solitary or multiple, of various sizes. Solitary tumor knots were most frequently localized between the lobes or in the right lobe and the rarest lesions were in the left lobe. Some patients had irregular liver margins with pleural effusion at the right side, while some had ascites. Most of them had enlarged retroperitoneal lymph nodes.

Our results regarding the morphology of lesions, are in accordance with the literature data<sup>[1,2]</sup>, where the non-specific sonographic sign in the majority of secondary hepatic lymphomas is hepatomegaly with irregular, cogged like liver margins. According to our results, secondary hepatic lymphomas appear in solitary or multinodular shapes or as diffuse hepatic infiltration. A rarer echoic structure is the shape of the target lesion, or

**Figure 1** Color doppler ultrasonography. A: Intense-central neovascularization in the focal liver lesion; B: Intense peripheral neovascularization in the focal liver lesion.

mixed echoic structure<sup>[2]</sup>. The appearance of secondary hepatic lymphoma is associated with enlarged spleen, or with retroperitoneal lymphadenopathy or pleural effusion in a great number of cases<sup>[1]</sup>. Ascites is also very often a finding in patients with secondary hepatic lymphoma<sup>[1]</sup>.

Splenomegaly was detected in half of the patients. Splenic lesions were heterogeneous with bigger or smaller knots in nearly half of the patients. Because of the higher vascular pressure, dilated splenic veins were often present with hepatofugal blood flow in a third of the patients. In some patients, blood flow was in 2 directions. A spontaneous splenorenal shunt and collateral blood flow could be detected in patients with mass splenomegaly. In patients with liver Hodgkin's lymphomas, changes in the diameter of the splenic vein were due to changes in resistance in the portal vascular system, hilar adenopathy and splenomegaly.

Changes in venous vessels of the portal system in patients with liver Hodgkin's lymphomas included dilated portal veins ( $P < 0.05$ ) and changes in flow direction (hepatofugal in 50%) ( $P < 0.05$ ). However, no significant changes in volume of blood flow or blood flow velocity through the portal vein ( $P > 0.05$ ) were observed. However, significant differences in blood flow velocity through the hepatic artery were seen ( $P < 0.05$ ). In 3 patients without nodules in the liver visible on US examination, slight perfusion disorders were detected by Doppler-US. The volume of portal blood flow was slightly increased because of the increased inflow through the portal vein due to splenomegaly. This fact could enable early further investigation and detection of lymphomas in the liver, before the obvious changes in liver tissue occur. These values were not statistically significant.

A pulse wave was registered in the center and a little higher ( $P > 0.05$ ) at the margins of lymphoma. A continuous venous wave was found at the margins of lymphoma. There was no linear correlation between lymphoma size and velocity of pulse and continuous waves ( $r = 390$ ,  $P < 0.01$ ). Our results show intense neovascularization of the focal lesions in the center, as well as on the periphery, which differentiate those tumors from other secondary deposits. The highest pulse wave velocities correspond to arteriovenous shunts.

The CD signal could not be found within the parts

of focal lesions with no flow in small blood vessels or where flow could not be detected by the current CD system. The CD signal in hypoechoic lesions varied from 0.5-0.9 of blood vessels/cm<sup>2</sup>. Estimation of CD signals *in vivo* in these tumors corresponds to the number of blood vessels in histological tissue. HPI values were significantly lower in patients with lymphomas than in controls ( $P < 0.05$ ). Thus, arterial hepatic perfusion was increased in patients with secondary hepatic lymphomas, while the venous component of hepatic perfusion was decreased which is usual for malignant lesions.

Various literature results prove the value in Doppler-US in the estimation of characteristics of liver tumors that could help in the early diagnosis, differential diagnosis and appropriate choice of therapy. Although there is much literature data about Doppler-US characteristics and possibilities of differential diagnosis of malignant and benign liver tumors, not many of them deal with hepatic metastases of Hodgkin's lymphoma. According to Tcelepi *et al*<sup>[10]</sup>, detecting and characterizing focal liver lesions is one of the most difficult challenges in imaging emphasizing the main strengths being in its ability to definitively characterize common benign lesions (cysts and hemangiomas), safety, low cost, and its ability to guide biopsy. Disadvantages include its inability to image the entire liver in many patients and its inferiority to CT as a means of detecting extrahepatic malignant disease. Sonography is less sensitive than CT or MRI in detecting focal lesions. However, US contrast agents can improve liver lesion detection and characterization. Tscelepi indicated that intraoperative US is the most sensitive imaging modality in detecting focal liver lesions. However, some authors obtained better results with CEUS. Thus, Ernst *et al*<sup>[11]</sup> with a new US contrast agent showed that metastatic liver lesions had previously undetected blood flow in the rim of the tumor; hepatocellular carcinoma displayed enhanced signal intensity in the vessels of the rim and in the center of the tumor, while adenoma and focal nodular hyperplasia showed signal enhancement in the central area of the tumor. No signal enhancement was observed in hemangiomas, a focal fatty lesion, or in a carcinoid metastatic lesion. Thus, enhanced CD flow study may aid in the detection of flow signals or sonographic differentiation of hepatic tumors. Also, some authors, after the study of patients with malignant

diseases (hepatocellular carcinoma, cholangiocellular carcinoma, metastasis and lymphoma) and those with benign lesions, with color stimulated acoustic emission in the late phase of Levovist enhancement showed a high specificity and sensitivity for differentiation between benign and malignant focal liver lesions<sup>[12]</sup>.

Results of HPI show that arterial hepatic perfusion in Hodgkin's lymphoma is dominant and that venous-portal inflow is reduced in comparison with standard values. Although there are no precise data from the literature concerning metastatic lymphoma in the liver, the results of other authors regarding the flow in malignant lesions in general are in accordance with our findings. Thus, according to Petrović *et al*<sup>[13]</sup> HPI is a sensitive indicator of the presence of malignant liver tumors, but is within normal range in patients with hepatic hemangioma. The results of Dragoteanu *et al*<sup>[14]</sup> showed that malignant tumors (primitive or metastases) increase the arterial supply of the liver and decrease the portal flow. However, benign tumors do not change the portal/arterial liver blood flow ratio. However, recently, according to Robinson<sup>[15]</sup> the sensitivity of US, CT and magnetic resonance techniques for detecting liver metastases assessed in comparison with surgical inspection, intraoperative US and pathological examination, are of uncertain accuracy in detecting very small lesions. With current imaging technology, even with optimum imaging, it is possible to detect only about one-half of metastatic nodules < 1 cm in patients undergoing liver resection and pathological correlation. Robinson emphasized that micrometastases produce alterations in blood flow that may be recognized by radionuclide or Doppler perfusion methods in the very early phase.

Currently, use of CT and MRI to detect hepatic lymphoma as well as its perfusion has been employed. Generally speaking, CT reveals Hodgkin's lymphoma as homogeneously hypodense clearly delineated nodules. After contrast application the lesions appear hypodense, although a weak enhancement may be detected. However, in the case of the infiltrative form, a diffusely decreased attenuation may be seen, without the possibility of distinguishing it from fatty infiltration. MRI reveals focal hepatic lymphomas are homogeneously hypointense in comparison to the normal liver parenchyma on unenhanced T1-weighted images. However, dynamic imaging after gadolinium contrast application reveals hypointensity on arterial phase images followed by homogeneous delayed enhancement on portal venous phase imaging. However, it is still difficult to differentiate lymphoma, metastases and hepatocellular carcinoma.

Thus, according to Liu *et al*<sup>[16]</sup>, a plain CT scan identified hypodense lesions which did not display marked enhancement on arterial phase and portal venous phase scans. On delayed phase scan, the border of the lesions became clear, and slight enhancement was observed in the periphery and some partitions of the lesions. According to Vinnicombe *et al*<sup>[17]</sup>, CT accurately depicts nodal enlargement above and below the

diaphragm, has variable sensitivity for intra-abdominal visceral involvement and is generally outstanding in depicting the extent of disease, especially extranodal extension. Despite the advances in CT technology, there are still areas where CT performs less well, even when using an intravenous contrast medium. The results of Earl *et al*<sup>[18]</sup> show that although CT scan could occasionally demonstrate disease in nodes, its value was limited by its inability to detect involvement of nodes which were not significantly enlarged. However, CT scan would appear to be the investigation of choice in patients with suspected abdominal relapse because of the more frequent presence of disease in sites not seen on lymphography. Gossman *et al*<sup>[19]</sup> emphasized that fast MRI has considerably reduced imaging time, and it is now considered to be as diagnostic as CT for staging Hodgkin's disease. The excellent soft-tissue contrast and the lack of exposure to ionizing radiation are the main advantages of MRI imaging, especially with the application of newly developed lymphotropic contrast agents. In addition, Hoane *et al*<sup>[20]</sup> concluded that MRI and CT may be equivalent imaging modalities in the detection of nodal involvement, and that MRI has an advantage in its ability to diagnose marrow involvement. According to MRI findings in primary lymphoma of the liver, on T1-weighted imaging the tumor was isointense in one and homogeneously hypointense to the liver parenchyma in the other. On T2-weighted imaging both tumors were homogeneously hyperintense. In one case the margin of the tumor was poorly defined, and portal branches were identified within the tumor, an unusual finding in other liver neoplasms. Additionally, according to Hori *et al*<sup>[21]</sup> it is possible to investigate the morphological, hemodynamical and functional nature of focal hepatic lesions and correctly establish a diagnosis of liver tumors based on those findings using dynamic CT and MRI with extracellular contrast material or MRI with liver-specific contrast material.

Some recent papers employ positron emission tomography for the assessment of tumor perfusion. Growth of malignant tumors is dependent on sufficient blood supply, an enhanced microvessel density is seen as part of these reactions and this is associated with increased perfusion as measured by PET<sup>[22]</sup>. Some authors used PET and CT in the investigation of liver tumor blood flow and metabolism<sup>[23]</sup>.

In comparison to other metastatic liver tumors, Hodgkin's lymphoma has increased vascularization which we have seen only in primary hepatocellular carcinoma, which can help in differentiating it from other metastatic tumors. The significant impact on assessment of microvascularization can be obtained using contrast enhanced US. The absence of splenomegaly and retroperitoneal lymph nodes can further help in differentiation of hepatocellular carcinoma from lymphoma. In that case, further investigation is needed. Firstly, laboratory analysis can be employed (tumor marker levels, the absence of hepatotropic viruses B and C), as well as estimation of the age group, and anamnestic data (alcohol abuse and former cirrhosis).

For an exact diagnosis, radionuclide methods, as well as MDCT and MRI, can be also used.

Liver metastases of different tumors have different flow patterns. According to our results, a special characteristic of Hodgkin's disease is the demonstration of continuous venous flow at the periphery and pulsed arterial flow both at the margins and at the center of the lesion. Increased vascularization has also been obtained in metastases of carcinomas of the kidneys and suprarenal gland. In the center of the lesion, pulse waves did not register at all, while those registered at the good vascularized tumor margin had slightly lower velocities (68-78 cm/s) in comparison to Hodgkin's lymphoma. In metastases of colorectal adenocarcinomas, there was no pulse wave registered in the center, while it was registered at the margin in only 50% of patients, with obviously decreased velocities in comparison to Hodgkin's lymphoma (27 cm/s). A continuous wave registered on the edges in all the patients, which showed decreased velocities (19 cm/s). Metastases of pancreatic and gallbladder adenocarcinomas showed pulse wave velocity on the tumor margin was slightly decreased in comparison to Hodgkin's lymphoma (65-75 cm/s), while continuous wave velocity in the tumor margins registered in all patients had a similar velocity (28-40 cm/s) to that in Hodgkin's lymphoma<sup>[24]</sup>. Another type of lymphoma (secondary non-Hodgkin's) shows a similar echo type, but different vascular characteristics. Arteriovenous shunts in this type of lymphoma are localized on the edges of the tumor, and thus, the pulse waves registered in this area with CD showed lower values (50-60 cm/s). No continuous wave on the periphery was registered in any patient with non-Hodgkin's lymphoma, and when registered, velocities were also lower (10-26 cm/s)<sup>[24]</sup>.

However, in order to perform prompt and adequate therapy, diagnosis and monitoring of malignant liver disease should be improved. According to our results, as well as the above mentioned data of other authors, contemporary diagnostic imaging methods mainly provide morphological data about the tissue while perfusion imaging of the liver can improve this limitation. According to some authors<sup>[7]</sup> liver flow scintigraphy and flow quantification at Doppler US have focused on characterization of global abnormalities. CT and MRI imaging can provide regional and global parameters. However, some shortcomings of these methods need to be overcome (by reduction of radiation doses associated with CT perfusion imaging, improvement of spatial and temporal resolution at MR imaging, accurate quantification of tissue contrast material at MR imaging, and validation of parameters obtained from fitting enhancement curves to biokinetic models, applicable to all perfusion methods).

In conclusion, CD US is a useful method for detection of vascularization in Hodgkin's hepatic lymphoma and estimation of its intensity. Thus, it could help in the early diagnosis and differential diagnosis of malignant liver lesions, including hepatic Hodgkin's lymphoma. In comparison to other metastatic liver tumors, Hodgkin's lymphoma has

increased vascularization which we have seen only in primary hepatocellular carcinoma, which can help in differentiating it from other metastatic tumors. A significant impact on assessment of microvascularization can be obtained using contrast enhanced US. The presence of splenomegaly and retroperitoneal lymph nodes can further help in differential diagnosis. However, in most cases, further investigation (such as laboratory analysis, estimation of the age group and anamnestic data) is needed. For a more reliable diagnosis, radionuclide methods, MDCT and MRI can be also used.

## COMMENTS

### Background

The aim of the paper was to estimate the characteristics of Color Doppler findings and the results of hepatic radionuclide angiography (HRA) in secondary Hodgkin's hepatic lymphoma, in order to try to distinguish these entities from other hepatic tumors without using more advanced diagnostic methods.

### Research frontiers

Possibility of distinguishing liver involvement by Hodgkin's hepatic lymphoma by estimation of the morphology of the liver by US, as well as estimation of typical flow patterns (pulse and continuous flow) at the center and margins of the lymphoma.

### Innovations and breakthroughs

"It seems that a peculiar characteristic of Hodgkin's disease is the demonstration of continuous venous flow at the periphery and pulsed arterial flow both at the margins and at the center of the lesions. This is interesting and merits further investigation (reviewer's opinion)".

### Applications

By carefully examining the liver, one can, using easily available methods, differentiate benign from malignant lesions, as well as suspect Hodgkin's hepatic lymphoma.

### Peer review

This paper evaluated of characteristics of Color Doppler finding and the results of radionuclide angiography in secondary Hodgkin's hepatic lymphoma. This is interesting and merits further investigation.

### Abstract

**AIM:** To explore the impact of fecal incontinence (FI) on quality of life (QOL) of patients attending urogynecology and colorectal clinics (CCs).

**METHODS:** Cross-sectional study of 154 patients (27 male) with FI, who attended the clinics at a regional hospital in North Queensland, Australia in 2003 and 2004, and completed the Fecal Incontinence Quality of Life Scale (FIQL: 1 = very affected; 4 = not affected).

**RESULTS:** More than 22% of patients had their QOL affected severely by FI. Patients reported that they had not previously been asked about FI by a medical practitioner nor did they voluntarily disclose its presence. The median FIQL scores for all participants were: lifestyle = 3.24; coping = 2.23; depression = 2.42; and embarrassment = 2.33. Increasing frequency of soiling had a negative effect on all four FIQL scales ( $P < 0.001$ ) as did the quantity of soiling ( $P < 0.01$ ). Female CC patients had poorer FIQL scores than urogynecology clinic patients for lifestyle ( $P = 0.015$ ), coping ( $P = 0.004$ ) and embarrassment ( $P = 0.009$ ), but not depression ( $P = 0.062$ ), despite having experienced FI for a shorter period.

**CONCLUSION:** Failure to seek treatment for FI degrades the quality of patients' lives over time. FI assessment tools should incorporate the quantity of fecal loss.

### INTRODUCTION

Fecal incontinence (FI) is the involuntary discharge of liquid or solid stools. FI severity has been described as a combination of the frequency and type of stools, the severity of urgency, and frequency of pad usage<sup>[1,2]</sup>. This problem affects both men and women, irrespective of social, employment or financial status<sup>[3,4]</sup>. The prevalence of FI increases with age<sup>[5,6]</sup> and Australian studies have reported some of the highest rates in the world<sup>[5,7,8]</sup>.

People with mild fecal loss such as staining are unwilling to admit to themselves that they have an FI problem<sup>[9]</sup>. As the problem worsens and patients inevitably accept that they have FI, they are reluctant to disclose the problem to others<sup>[9-15]</sup>, with only 5%-27% seeking help from their doctors<sup>[15]</sup>. Lack of disclosure may be to the result of embarrassment, the erroneous belief that FI is a normal part of aging, or the perception that no treatment is available. Doctors may fail to comprehend patient hints about diarrhea and FI<sup>[15]</sup> or may be reluctant to ask about fecal leakage, perhaps because of their own embarrassment or the perception that FI is a trivial concern<sup>[16]</sup>.

FI can range from causing mild embarrassment to becoming an insidious burden on the person's quality of life (QOL)<sup>[17-21]</sup>. Tools used to measure the impact of FI on QOL have been under development for 20 years and include lifestyle components in summary scales, generic measures, disease-specific measures, utility measures, and more recently, direct questioning of objective measures<sup>[1]</sup>. The Fecal Incontinence Quality Of Life (FIQL) questionnaire, a disease-specific tool, was designed to

evaluate the impact of FI on four aspects of patients' QOL: lifestyle; coping behavior; depression or self perception; and level of embarrassment. Each aspect is described as a score measured on a scale between 1 and 4, where 1 is very affected and 4 is not affected<sup>[22]</sup>. Validity and reliability of the FIQL have been established and it has been recommended as a useful tool to assess FI<sup>[23]</sup>.

This study was designed to explore the impact of FI on the QOL of patients attending urogynecology and colorectal surgical outpatient clinics at a publicly funded regional hospital with a large rural catchment<sup>[24]</sup>.

## MATERIALS AND METHODS

### Participants

Participants were consecutive patients attending the colorectal clinic (CC) and urogynecology clinic (UC) at The Townsville Hospital, in North Queensland Australia, between January and June 2003 and August and November 2004. Ethical approval was obtained from the ethics committees of Townsville Hospital and James Cook University.

### Study procedure

The study procedure has been described previously<sup>[5,9]</sup>. Briefly, a cross-sectional survey was conducted among patients at the CC and UC. On arrival, all patients attending these clinics were invited to participate in the study. Exclusion criteria included children (under 18 years), pregnancy, terminal illness, mental illness, or gastrointestinal stoma. Eligible subjects completed a patient consent form. Participants were then given a self-administered questionnaire that contained questions about patient demographics, alcohol consumption, preexisting medical conditions, and prior surgical history; all known risk factors for FI. Patients who answered "yes" to the question "do you ever accidentally soil your clothes or underclothes with feces?" proceeded to questions relating to the frequency, severity and management of FI, and the 29 question FIQL survey tool<sup>[22]</sup>. The physicians of participating patients also surveyed them using the Cleveland Clinic Florida Fecal Incontinence Score<sup>[25]</sup>, which was compared with the self-administered survey tool results to investigate disclosure problems<sup>[9]</sup>. Here, we report information about the QOL questions from the self-administered questionnaire.

### Statistical analysis

Mean and SD were used to describe age. Medians and interquartile ranges were used as measures of central tendency and estimates for dispersion for duration of FI and FIQL scales. FIQL scales were calculated in accordance with the developers recommendations<sup>[26]</sup>. For bivariate testing of categorical variables, exact versions of  $\chi^2$  tests were conducted for nominal items, while exact trend tests were used for ordinal variables. Multiple linear regressions were used to investigate relationships between FIQL scales and clinics, basic severity (type  $\times$  frequency) and duration of FI among

female participants, and FIQL scales and components of severity<sup>[2]</sup>, with and without quantity of fecal loss, in all participants. Potential components were initially considered separately and were then combined. As FIQL scales were not distributed normally, they were transformed by taking the square root. As no major differences between transformed and untransformed regression results were found, the untransformed regression data have been presented. Results of linear regression analyses are presented by regression coefficients ( $\beta$ ) with 95% CIs and/or  $P$  values. A significance level of 0.05 was adopted *a priori*.

## RESULTS

The recruitment methodology and tools used were the same in 2003 and 2004. There were no differences in age ( $P = 0.603$ ), sex ( $P = 0.149$ ) or prevalence of FI ( $P = 0.076$ ) in participants between the two recruitment periods, thus the data were combined for analysis.

### Response rate

A total of 769 patients (451 in 2003 and 318 in 2004) were invited to participate. Of these, 423 women attended the UC and 146 men and 200 women attended the CC, with 93.4% ( $n = 718$ ) of the eligible patients completing the self-administered FI questionnaire. As 43 patients completed the survey more than once, the initial responses were used and duplicate data were removed from the combined database, which left a total of 675 unique entries.

### Prevalence

Of the 675 patients in the study 154 (22.8%; 95% CI: 19.6%-26.0%) reported having accidentally soiled their clothes or underclothes with feces and answered the FIQL questions. There were 27 men from the CC, and 127 women, 52 from the CC and 75 from the UC, with FI. The mean age (SD) of the participants with FI was 56.2 (14.3) years. There was no age difference between sexes ( $P = 0.281$ ) or clinics ( $P = 0.82$ ), or the women attending the two clinics ( $P = 0.87$ ).

### Etiology

Patients reported the following etiological risk factors for FI. There were 27 participants who reported having bowel disease (25 from CC, nine male), with 14 of them (all from CC, two male) having been diagnosed with colorectal cancer. Twenty seven women (eight from CC) had undergone vaginal repair surgery, whilst 51 women (16 from CC) reported difficult vaginal births using forceps, vacuum extraction or long second-stage labor. Twenty-one participants (11 from CC, two male) reported rectal prolapse; 23 (20 from CC, nine male) had undergone surgery for hemorrhoids, anal fissures or fistulas; 101 (39 from CC, 10 male) had urinary incontinence; 11 (six from CC, four male) had anal injuries; 18 (10 from CC, four male) had diabetes; six (four from CC, two male) reported spinal cord disease; three (one from CC, one male) had neurological disease; 39 (21

from CC, seven male) reported chronic constipation; and 17 women (five from CC) had psychiatric problems that required medication. Some patients had multiple factors.

### Duration

Patients attending the UC documented having FI for a significantly longer period (median: 24 mo, IQR: 12-60), than those attending the CC [12 (6-24),  $P = 0.001$ ]. Similarly, women in the UC clinic had FI for longer than those in the CC clinic [UC = 24 (12-60); CC = 12 (6-24),  $P = 0.002$ ].

### Frequency

More than half (55.8%) of the participants admitted to soiling at least once per month: 17% (25) of patients reported soiling daily, 24% (35) weekly, 15% (22) monthly, and 44% (65) less than once a month. There was no difference in the frequency of incontinent episodes between sexes ( $P = 0.678$ ). However, women who attended the CC reported more frequent leakage, with 27.5% soiling daily compared with 11.0% of those in the UC ( $P = 0.037$ ), possibly as a result of their bowel condition.

### Type

In the CC, significantly more men (79%) disclosed liquid bowel leakage than women (46%), whilst fewer men reported solid (8%) and combined solid/liquid (13%) leakage than women (solid = 18%, combined = 36%;  $P = 0.008$ ). There was no significant difference between women attending the CC or UC with regard to type of leakage (UC: liquid bowel leakage, 46%; solid bowel leakage, 28%; combined solid/liquid bowel leakage, 25%,  $P > 0.05$ ). More women attending the CC reported passive leakage (80%) than those attending the UC (62.5%,  $P = 0.037$ ) or men (48%,  $P = 0.026$ ). There were no differences between sexes or clinics for fecal urgency or quantity of fecal soiling.

### QOL impact

The median (IQR) results of the FIQL scales (range: 1-4; 4 = not affected) for all participants were: lifestyle = 3.24 (2.22-3.80); coping = 2.23 (1.60-3.00); depression = 2.42 (1.95-3.33); and embarrassment = 2.33 (1.67-3.58) (Table 1). Participants who attended the CC had significantly poorer scores than those who attended the UC for lifestyle ( $P = 0.005$ ), coping ( $P = 0.003$ ) and embarrassment ( $P = 0.024$ ) but not depression ( $P = 0.056$ ).

There were no significant differences in any of the FIQL scales between sexes when compared in total or within the CC (Figure 1). Women who attended the CC had lower scores on all scales compared with those who attended the UC (lifestyle:  $P = 0.015$ ; coping:  $P = 0.004$ ; depression:  $P = 0.062$ ; embarrassment:  $P = 0.009$ ; Figure 1). The four multiple linear regression analyses [FIQL = clinic + duration + basic FI severity (type  $\times$  frequency) + error] used to investigate the relationships between QOL of women by clinic, FI type/frequency and duration determined that the poorer QOL results in the CC with regard to clinic and type/frequency

**Table 1** FIQL of patients attending CCs and UCs in North Queensland

Scale <sup>3</sup>	n <sup>1</sup>	Missing	Mean (range) <sup>2</sup>	SD	Median (IQR)
Scale 1: lifestyle	119	35	2.99 (1.0-4.0)	0.899	3.24 (2.22-3.80)
Scale 2: coping	130	24	2.36 (1.0-4.0)	0.884	2.23 (1.60-3.00)
Scale 3: depression	128	26	2.57 (1.0-4.0)	0.806	2.42 (1.95-3.33)
Scale 4: embarrassment	124	30	2.53 (1.0-4.0)	0.990	2.33 (1.67-3.58)

FIQL, Rockwood *et al*<sup>[22]</sup>; <sup>1</sup>Patients who consented to participate in the 2003 and 2004 studies and answered yes to ever soiling with feces,  $n = 154$ ; <sup>2</sup>QOL scale of 1 represents very low functional status and 4 is not affected by FI; <sup>3</sup>Scales calculated as per letter to the editor, Rockwood<sup>[26]</sup>.

remained significant (all  $P < 0.05$ ), whilst duration of soiling remained significant for the lifestyle, depression and embarrassment scales (all  $P < 0.05$ ) but not for the coping scale ( $P = 0.103$ , Table 2).

Increasing frequency and quantity of soiling had a significant negative effect across all four QOL scales (frequency,  $P < 0.001$ ; quantity,  $P < 0.01$ ). QOL was poorer in participants with greater urgency and passive soiling, whilst those participants who documented both solid and liquid bowel leakage had poorer QOL than those with either alone. Not all scales reached significance (Table 3). When comparing QOL between female participants who attended the CC and UC, the scores for frequency, quantity, type and fecal urgency were significantly poorer across all FIQL scales for female participants in the CC ( $P < 0.05$ ). Women who reported passive FI in the CC had poorer QOL scores than those in the UC for lifestyle ( $P = 0.040$ ), coping ( $P = 0.020$ ), depression ( $P = 0.181$ ), and embarrassment ( $P = 0.019$ ).

The model (FIQL = frequency + type + urgency + pad use + error) used to investigate the relationships between the four FIQL scales and the components of severity showed that the significant components that affected QOL were frequency and fecal urgency with regard to lifestyle and coping (all  $P < 0.05$ ); and frequency and type with regard to depression and embarrassment (all  $P < 0.05$ ). As a result of the low rate of pad usage (36% wore pads), passive leakage (68% reported) was included in the model, and the quantity of fecal loss was also investigated. This amended model (Table 4) showed: daily, solid, and large losses of stool to be significant factors for lifestyle ( $P < 0.05$ ); monthly and daily leakage, urgency, pad wearing and large quantities of fecal loss to be significant factors for coping ( $P < 0.05$ ); frequent and major leakage of both solid and liquid stool were significant factors for depression ( $P < 0.05$ ); whilst frequent, solid and liquid, and passive stool loss significantly affected embarrassment ( $P < 0.05$ ).

## DISCUSSION

The major findings of this study were that more than 22% of patients who attended the UC and CC in 2003 and 2004 for matters other than FI had their QOL severely affected by FI, with the QOL of participants who

attended the CC being poorer than that of those from the UC. Furthermore, the negative impact on participants'

lives worsened with the loss of both solid and liquid stool and the increased frequency and quantity of soiling.

**Figure 1** Association of FIQL scales with sex and CC and UC. FIQL, Rockwood *et al*<sup>[22]</sup>; Box and whisker demonstrates median, IQR, minimum and maximum. *P* values calculated by unpaired Wilcoxon test (Mann-Whitney); QOL score of 1 represents very low functional status and 4 is not affected by FI; FIQL scales calculated as per letter to the editor, Rockwood<sup>[26]</sup>.

In this study of the impact on QOL of FI in rural and regional north Queensland, our overall FIQL results for lifestyle (3.24), coping (2.23), depression (2.42) and embarrassment (2.33) were within the range of comparable clinic-based studies in other countries<sup>[21,27-31]</sup>, and closely reflected the scores found in a similar study

conducted at a Pelvic Floor Center in Minnesota, USA<sup>[21]</sup> and baseline scores from two Victorian (Australia) clinical studies that investigated injectable material for FI<sup>[32,33]</sup>.

The QOL of patients who attended the CC was more severely affected than that of participants from the UC, even though they had reported FI for a shorter duration. There were no significant differences between those who had a diagnosis of bowel disease and those who did not. Thus the poorer QOL in CC participants may be a direct result of recent colorectal surgery, in which the sudden and unexpected onslaught of FI was more devastating than for the UC participants who may have learnt to cope with their progressive FI over an extended time period. These CC FIQL results are comparable with previously published results from a pouch, non-pouch study<sup>[29]</sup>, but the participants in our study were less able to cope, and were more depressed and embarrassed, although this did not affect their lifestyle to the same degree.

The UC patients' QOL scores were lower than those in a similar study in Texas, USA<sup>[30]</sup> but higher than in the study in Minnesota, USA<sup>[21]</sup>, for lifestyle, coping and embarrassment, but not depression. This difference may have been caused by a longer duration with FI in the older cohorts in our study and the Minnesota study, (mean age 56 years), compared with the younger cohort in the Texas study (mean age 39 years). This suggests that older women with FI had poorer QOL than younger affected women, which implies that delaying treatment for this condition results in poorer QOL over time.

This study investigated the relationship between FI severity and the FIQL scales individually and collectively. A negative impact was found on patients' lives, which increased with frequency of soiling. This was evident on all scales of the FIQL, but there was little difference in each of the FIQL scales between weekly and monthly incontinent episodes. This lack of difference may be because an incontinent episode that occurs infrequently is unexpected, and hence, would be similarly distressing.

The data collected for pad wearing was dichotomous, which may explain why only significant results for the coping scale were obtained. If, in addition, the number of pads worn per day had been assessed, the embarrassment scale may also have reached significance.

The type of soiling affected participants' QOL differently. Patients with both solid and liquid soiling reported a poorer QOL than those with either solid or liquid only incontinent episodes. This is consistent with the Texas study in which a liquid component of anal incontinence was reported to have a greater impact upon QOL of participants than either flatus or non-liquid incontinence<sup>[30]</sup>.

The association between quantity of fecal loss and FIQL scales was found to be highly significant. Patients with the most soiling, i.e. those who soiled furniture, had the lowest possible FIQL score for coping and embarrassment, and performed only marginally better on the lifestyle and depression scales. There are few reports of the relationship between quantity of fecal loss and QOL, however, a Japanese study investigating the QOL of patients following total proctocolectomy and ileal J-pouch-anal anastomosis determined that greater soiling resulted in higher levels of frustration, which is an anxiety measure calculated using a Japanese translation of Cattell's anxiety scale<sup>[34]</sup>. When quantity was included in the FIQL/severity regression model, it was found to be significant ( $P < 0.05$ ) for the lifestyle, coping and depression scales, but did not reach significance for the embarrassment scale ( $P = 0.065$ ). Given this relationship between the FIQL scales and quantity of fecal soiling, it is suggested that the definition of FI severity should include quantity of fecal loss as well as frequency, type, urgency and pad wearing.

In conclusion, to the best of our knowledge, this is the first study to measure the effect of FI on QOL of people in rural and regional Australia. More than 22% of the patients attending the UC and CC in North Queensland, for matters other than FI, had their QOL severely affected by this condition. Patients reported that they had not been asked about FI by their general practitioners or hospital physicians, nor did they voluntarily disclose its presence<sup>[9]</sup>. Women who have obstetric-injury-related FI suffer in silence, and their QOL deteriorates as they age. The definition of FI severity should include quantity of fecal loss<sup>[35]</sup>. Further community-based research in Australia is warranted in regard to the impact of FI on QOL of people who suffer with this complaint.

## ACKNOWLEDGMENTS

We thank Dr. Rane AJ for facilitating access to the patients in his UCs.

## COMMENTS

### Background

As many as one in seven adults suffer with fecal incontinence (FI), which can have a devastating effect on the lifestyle of people with frequent, ad hoc or large amounts of fecal seepage. These people often fail to seek treatment due to embarrassment, believing the problem is uniquely theirs, or because they are unaware of the existence of available treatments.

### Research frontiers

Patients referred to urogynecology and colorectal surgical clinics, for other reasons, have a high incidence of FI. They do not seek assistance whilst attending these clinics from physicians who can recommend or refer for treatment. In this study, the authors demonstrated the impact that FI had on these patients' quality of life (QOL).

### Innovations and breakthroughs

Recent reports have highlighted the impact conservative treatments, such as biofeedback, and more invasive treatments, such as injectable bulking agents, sacral nerve stimulation, artificial bowel sphincter and dynamic graciloplasty, have had on the QOL of patients with FI. This study reports that despite these improvements many people continue to suffer unaware of such advances.

### Applications

By understanding more than one in five patients attending colorectal and urogynecological clinics have their QOL severely affected by FI, attending physicians can enable access to treatment by directly asking patients about this problem.

### Terminology

FI is the involuntary discharge of solid or liquid stools.

### Peer review

FI severity, including the quantity of stool loss, can have a severe negative impact on QOL. This is an interesting and relevant study that deals with a demanding subject.

subjected to ERCP within 3 d of MRCP to check for the presence of stones.

**RESULTS:** No stones were detected by ERCP in any patient, confirming the results of MRCP.

**CONCLUSION:** When clinical symptoms improve, blood biochemical parameters have normalized, and MRCP shows there are no stones in the common bile duct, it can be considered the stone has spontaneously passed and thus ERCP is not necessary.

### Abstract

**AIM:** To investigate the usefulness of magnetic resonance cholangiopancreatography (MRCP) and the need for endoscopic retrograde cholangiopancreatography (ERCP) in cases of suspected spontaneous passage of stones into the common bile duct.

**METHODS:** Thirty-six patients with gallbladder stones were clinically suspected of spontaneous passage of stones into the common bile duct because they presented with clinical symptoms such as abdominal pain and fever, and showed signs of inflammatory reaction and marked rise of hepatobiliary enzymes. These symptoms resolved and they showed normalized values of blood biochemical parameters after conservative treatment without evidence of stones in the common bile duct on MRCP. All these patients were

### INTRODUCTION

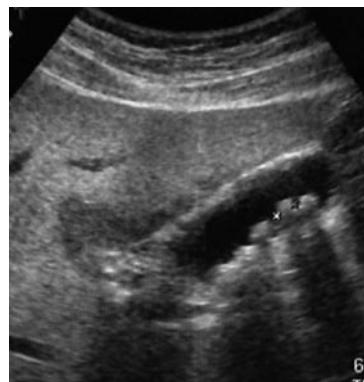

Magnetic resonance cholangiopancreatography (MRCP) is a relatively new imaging technique developed for the diagnosis of patients with pancreaticobiliary disease. The signal of structures filled with static or slowly moving fluid, such as the bile and pancreatic ducts, is greatly increased on T2-weighted images, resulting in an increased duct-to-background contrast. Recent studies have shown that MRCP is as useful as endoscopic retrograde cholangiopancreatography (ERCP) regarding the diagnosis of extrahepatic bile duct and pancreatic duct abnormalities such as common bile duct stones<sup>[1-4]</sup>,

malignant obstruction of the bile and pancreatic ducts<sup>[1,2,5]</sup>, congenital anomalies<sup>[1,6,7]</sup>, and chronic pancreatitis<sup>[8-10]</sup>. In some institutions, MRCP is becoming the first-choice technique for imaging the biliary system, with ERCP being reserved for therapeutic indications. In recent studies, MRCP showed extremely high performance in visualizing bile duct stones with both a sensitivity and a specificity of 90% or higher in most cases<sup>[11-17]</sup>. In the false negative cases, all stones were as small as 3-5 mm and were present near the duodenal papilla. Thus, MRCP is very useful for the diagnosis of bile duct stones and the determination of a therapeutic strategy. Since ERCP involves the risk of complications such as acute pancreatitis<sup>[18-21]</sup>, it should be performed only when absolutely necessary. In some patients clinically suspected of choledocholithiasis, ERCP shows a cleavage at the duodenal papilla, but does not detect the stones in the common bile duct. These findings suggested that stones in the common bile duct had probably passed spontaneously. In fact, it was reported that three-fourths of common bile duct stones passed spontaneously before cholecystectomy<sup>[22]</sup>, indicating that many patients with bile duct stones may not need ERCP. There are reports on the clinical course of patients suspected of spontaneous passage of bile duct stones after MRCP alone<sup>[23,24]</sup>. However, since ERCP was not performed, it was not clear whether the stones were actually present. Presence of bile duct stones could cause acute cholangitis, which, if aggravated, may be fatal. Consequently, we investigated the usefulness of MRCP and the need for diagnostic ERCP in patients suspected of spontaneous passage of stones.

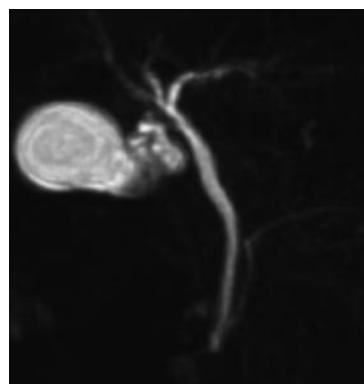

## MATERIALS AND METHODS

From April 2007 to January 2009, 36 patients suspected of spontaneous passage of bile duct stones were prospectively evaluated. There were 26 men and 10 women and the mean age of the patients was 62.1 years (range: 33-82 years). The mean observation period was 6.7 mo (1-9 mo). After blood sampling the patients were subjected to ultrasound examination (Power Vision 6000; TOSHIBA Tochigi Japan) to assess the presence of stones in the gallbladder and common bile duct. The patients had gallbladder stones and were clinically suspected of spontaneous passage because they presented with clinical symptoms that included abdominal pain and fever, and showed signs of inflammatory reaction as well as a marked rise of hepatobiliary enzymes. These symptoms resolved and patients showed normalized values of blood biochemical parameters after conservative treatment, without evidence of stones in the common bile duct on MRCP. Patients who had originally had intrahepatic cholestasis were considered as "improved" if the level of hepatobiliary enzymes had normalized. The US, MRCP and ERCP images of typical cases are shown in Figures 1-3, respectively.

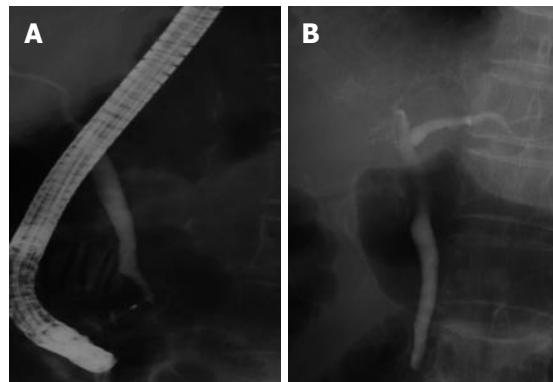

In this study, the need for urgent drainage was assessed first. Accordingly, blood was collected from

**Figure 1** A 56-year-old man. Several gallbladder stones measuring about 5-10 mm were detected by abdominal ultrasonography.

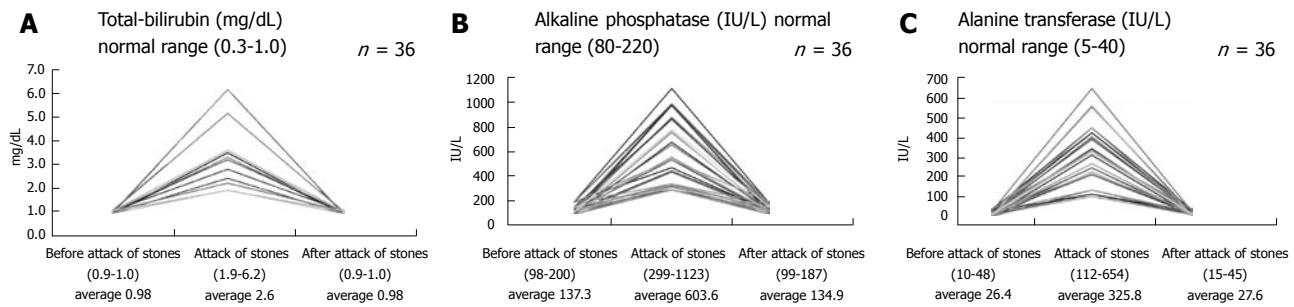

**Figure 2** No translucency indicative of stones in the bile duct was shown by magnetic resonance cholangiopancreatography.

**Figure 3** No translucency indicative of stones in the bile duct was shown by endoscopic retrograde cholangiopancreatography (A). After withdrawal of the fiber, the posture was changed and the bile duct was imaged again. However, no translucency was observed (B).

the patients on arrival at the hospital for the assessment of acute cholangitis. Patients with moderate to severe acute cholangitis<sup>[25]</sup> that did not respond to the initial medical treatment, were excluded from this study and were subjected to emergency ERCP with biliary drainage. When a patient presented symptoms of acute cholangitis during follow-up, ERCP was conducted provided the patient had given his/her informed consent prior to the examination. Patients with symptoms of acute pancreatitis were excluded from this study. Even

**Figure 4** Changes in serum. A: Total-bilirubin; B: Alkaline phosphatase; C: Alanine transferase.

if a marked increase in hepatobiliary enzymes was detected before arrival at the hospital, we waited for an improvement in clinical symptoms and blood test values if cholangitis was mild, before performing MRCP followed by ERCP.

MRCP was performed using a 1.5T GE CV/I scanner and a phased-array torso coil (General Electric Medical Systems, Milwaukee, WI). The radiographic conditions were as follows: thin-section MRCP images were obtained in the coronal plane using half Fourier single-shot fast spin echo (SSFSE) imaging at a slice thickness of 4.0 mm, 34FOV, 256 × 256 matrix, and a TE of 180. Thick-slab SSFSE MRCP images were obtained in the plane using a matrix of 256X256 and a maximum TE. Imaging in the coronal and axial planes was done using a fast 3D spoiled gradient echo sequence with a TR of 3.9 TE minutes, 2.4 mm slice thickness (interpolated to 1.2 mm), and a 256 × 192 matrix. Images were reviewed on an Advantage Windows workstation (General Electric Medical Systems) that allowed 3D reconstruction. MRCP images were read after evaluating clinical symptoms and hematological findings to examine the common bile duct for the presence of stones. First, a radiologist with more than 20 years of experience examined the MRCP images and if there were no bile duct stones, the same MRCP images were subsequently examined by a gastroenterologist with more than 15 years of experience. Only after the absence of stones was confirmed by these 2 specialists, was the case defined as spontaneous passage of stones. MRCP was conducted after the clinical symptoms and blood test findings had sufficiently improved. ERCP was conducted within 4 d of MRCP to check for the presence of stones. ERCP images were read only by the gastroenterologist who had examined the MRCP images. As a measure against complications, the duration of ERCP was strictly limited to within 15 min. This prospective study was conducted after obtaining informed consent from the patients. Furthermore, the protocol of this study was discussed and approved by the Institutional Review Board of Funabashi Central Hospital.

## RESULTS

ERCP was successfully conducted in all 36 patients after MRCP confirmed the absence of stones in each of them. The ERCP procedure was completed within 15 min in all these cases. Mild acute pancreatitis,

assessed according to Cotton's criteria<sup>[21]</sup>, occurred as a complication after ERCP in 1 (2.8%) of the 36 patients. Cannulation was difficult in this patient and pancreatitis was assumed to be caused by pancreatography, which was performed 3 times during ERCP. However, remission was attained after conservative treatment. No other complications occurred. Both the radiologist and the gastroenterologist who read MRCP images ruled out the presence of bile duct stones in the 36 patients ( $K = 1.0$ ) (Figures 2 and 3).

MRCP showed the bile duct had a mean diameter of 6.6 mm (range, 4.8-8.3 mm). Biochemical average (and range) data were total bilirubin 2.6 (1.9-6.2) mg/dL (Figure 4A), alkaline phosphatase (ALP) 603.6 (299-1123) IU/L (Figure 4B), and alanine transferase (ALT) 325.8 (112-654) IU/L (Figure 4C) at the time of common bile duct obstruction while the normal range values were total bilirubin 0.3-1.0 g/dL; ALP 80-220 IU/L and ALT 5-40 IU/L. Subsequently, 6 patients underwent cholecystectomy. During the observation period, none of the 36 patients experienced a second spontaneous passage of stones. At the time of registration for this study, the clinical symptoms of 6 patients suspected of spontaneous passage of stones were already showing a tendency towards remission. Yet these patients were not registered for the study because they had moderate cholangitis. Accordingly, urgent ERCP was conducted without MRCP. The result indicated no bile duct stone in any of the 6 cases.

## DISCUSSION

MRCP can detect bile duct stones with a high rate of accuracy and sensitivity. In the present study, ERCP detected no stones in any of the patients suspected of spontaneous passage of stones and confirmed by the MRCP conducted after the clinical symptoms had improved and blood test values had normalized or returned to baseline levels. Nevertheless, the possible presence of small stones undetectable by ERCP cannot be denied. Intraductal ultrasonography (IDUS), which can be used following ERCP, is a valuable tool for the imaging of tiny stones. IDUS is likely to detect very small bile duct stones more accurately than ERCP alone<sup>[26]</sup>. Bile duct stones have, however, been reported to pass spontaneously in most cases<sup>[22]</sup>. Although the aggressive use of IDUS may increase the detection of

bile duct stones, prolonged ERCP practice may result in accidental events. Thus, this procedure was not included in the study design.

The presence or absence of small stones is a matter of controversy. However, it is basically reasonable to assume a spontaneous passage of stones if MRCP has detected no stones in the patients whose clinical symptoms improved and whose blood test values normalized or returned to the baseline levels. Today, most reports conclude that MRCP is comparable to ERCP in the diagnosis of biliary stones. Institutions with high-magnetic-field MRI make it a rule not to perform diagnostic ERCP in patients who have no stones identified by MRCP. The possibility that the present study would be useful in considering indications for use of ERCP was suggested. The results of this study indicate the feasibility of diagnosis of spontaneous passage of stones in the common bile duct based on clinical symptoms, blood biochemistry, US, and MRCP without exposure to X-ray, thus reducing such exposure for medical personnel responsible for conducting ERCP<sup>[27]</sup>, and avoiding the potential complications of ERCP.

US is a simple examination tool for imaging bile duct stones but is less satisfactory for the detection of stones<sup>[26]</sup>. However, it provides information on the gallbladder and important information on the diameter of the bile duct considering the presence of bile duct stones and thus it is a very useful examination. Given the higher performance of MRCP, diagnosis employing US or MRCP rather than diagnostic imaging will become more common when bile duct stones are suspected. However, the patients with spontaneous passage of stones included in this study presented with mild cholangitis. In patients with moderate or severe cholangitis, drainage of the biliary tract that allows the detection of stones more rapidly than MRCP, may prove very useful<sup>[25]</sup>. When clinical symptoms improve, blood biochemical parameters have normalized, and MRCP shows there are no stones in the common bile duct, it can be considered that the stone has spontaneously passed and thus ERCP would not be necessary.

## COMMENTS

### Background

Magnetic resonance cholangiopancreatography (MRCP) is a relatively new imaging technique developed for the diagnosis of patients with pancreaticobiliary disease. Recent studies have shown that MRCP is as useful as endoscopic retrograde cholangiopancreatography (ERCP) for the diagnosis of extrahepatic bile duct and pancreatic duct abnormalities such as common bile duct stones.

### Innovations and breakthroughs

When clinical symptoms improve, blood biochemical parameters have normalized, and MRCP shows there are no stones in the common bile duct, it can be considered the stone has spontaneously passed and thus ERCP would not be necessary.

### Peer review

This is a prospective, non-controlled study from a single center. The observation is made that ERCP is not helpful when a passed stone is suspected and MRCP is negative.

Lam ETP, Lam CLK, Lai CL, Yuen MF, Fong DYT. Psychometrics of the chronic liver disease questionnaire for Southern Chinese patients with chronic hepatitis B virus infection. *World J Gastroenterol* 2009; 15(26): 3288-3297 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3288.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3288>

## INTRODUCTION

Chronic hepatitis B (CHB) virus infection remains a major global health problem. It is estimated that 350 million people worldwide are chronically infected, of whom one third (120 million) are Chinese<sup>[1]</sup>. The prevalence is higher in southern China (> 10%) than Northern China (6%-10%)<sup>[2]</sup>. Up to 25% of patients may die from CHB complications, such as cirrhosis-related complications or hepatocellular carcinoma (HCC), posing a threat to both mental and physical health, leading to impairment of health-related quality of life (HRQOL).

HRQOL has become an important outcome measure in clinical and health policy settings in the last two decades. Disease-specific measures are often needed to complement generic measures to give a more comprehensive evaluation of the HRQOL of patients with specific diseases. Several HRQOL measures have been developed specifically for chronic liver disease (CLD), such as the Chronic Liver Disease Questionnaire (CLDQ)<sup>[3]</sup>, the Hepatitis Quality of Life (HQLQ)<sup>[4]</sup>, the Liver Disease Quality of Life<sup>[5]</sup> and the Liver Disease Symptom Index (LDSI)<sup>[6]</sup>. The CLDQ developed by Younossi *et al*<sup>[3]</sup> was the first and is the most widely used. The other liver disease-specific HRQOL measures are not commonly used because they are either too long, or the validity data are limited<sup>[4-8]</sup>.

## Abstract

**AIM:** To test the psychometric properties of a Chinese [(Hong Kong) HK] translation of the chronic liver disease questionnaire (CLDQ).

**METHODS:** A Chinese (HK) translation of the CLDQ was developed by iterative translation and cognitive debriefing. It was then administered to 72 uncomplicated and 78 complicated chronic hepatitis B (CHB) patients in Hong Kong together with a structured questionnaire on service utilization, and the Chinese (HK) SF-36 Health Survey Version 2 (SF-36v2).

**RESULTS:** Scaling success was ≥ 80% for all but three items. A new factor assessing sleep was found and items of two (Fatigue and Systemic Symptoms) subscales tended to load on the same factor. Internal consistency and test-retest reliabilities ranged from 0.58-0.90 for different subscales. Construct validity was confirmed by the expected correlations between the SF-36v2 Health Survey and CLDQ scores. Mean scores of CLDQ were significantly lower in complicated compared with uncomplicated CHB, supporting sensitivity in detecting differences between groups.

The CLDQ consists of 29 items which are grouped into 6 subscales: abdominal symptoms (AS), fatigue (FA), systemic symptoms (SS), activity (AC), emotional function (EF) and worry (WO). It is applicable to all types of liver diseases including CHB. It has been shown to have adequate internal reliability, validity and sensitivity. Test-retest reliability was more variable with intra-class correlation (ICC) ranging from 0.23 to 0.72 for different subscales<sup>[3]</sup>. Previous studies showed that the CLDQ is more responsive than a generic measure to detect a change in patients with CLD<sup>[3,9]</sup>. It has been translated and validated in different languages<sup>[9-13]</sup>, supporting its potential for cross-cultural adaptation. However, most of the psychometric data of the CLDQ have been derived from patients with hepatitis C virus (HCV) infection and Western populations. There are few data on its applicability for Southern Chinese CHB patients despite the fact that China has the world's largest population suffering from CLD.

Recently, the CLDQ has been translated into Mandarin Chinese but this Chinese (Mainland) version may not be applicable to Southern Chinese who speak Cantonese, a dialect that has significant differences in the usage of words and terms from Mandarin. In addition, information on the validity, reliability and other psychometric properties of the Chinese (Mainland) CLDQ version is limited. The aim of this study was to test the psychometric properties of a Chinese [Hong Kong (HK)] translation of the CLDQ for Southern Chinese CHB patients. This would enable the evaluation of the impact of CHB infection and assess the effect of anti-viral drug treatments on HRQOL in the world's largest population of CHB patients.

The objectives of this study were: (1) To develop a Chinese (HK) CLDQ that is semantically equivalent to the original; (2) To test the scaling assumptions and factor structure of the Chinese (HK) CLDQ; (3) To assess the psychometric properties in terms of reliability, construct validity, and sensitivity of the Chinese (HK) CLDQ; (4) To determine whether any modification of the CLDQ can improve its psychometric properties for Southern Chinese CHB patients.

## MATERIALS AND METHODS

### Ethics

This research project was approved by the Institutional Review Board of the University of Hong Kong/Hospital Authority Hong Kong West Cluster (IRB reference No., UW 06-089 T/1114 and trial registration No., HKC-TR-151).

### Development of the Chinese (HK) CLDQ

The Chinese (HK) translation of the CLDQ was developed by iterative translations, expert panel review and cognitive debriefing, as recommended guidelines by experts<sup>[14,15]</sup>. The original CLDQ was translated into Chinese by two independent professional translators. Reconciliation of the forward translations into a single forward translation was carried out by a bilingual expert in HRQOL measures (Lam CLK) and the translators. The reconciled Chinese translation was back-translated into English by another professional translator. The back

translation was reviewed by the original author and the bilingual expert to identify any non-equivalence in the Chinese translation, which was then revised. The first draft of the Chinese (HK) CLDQ was evaluated by cognitive debriefing interviews with six Southern Chinese patients with CHB infection and further revision was made to ensure item clarity and equivalence to become the final Chinese (HK) CLDQ (used in this study on psychometrics properties).

### Subjects

Patients with complicated CHB were recruited from out-patient hepatitis clinics of a regional hospital and patients with uncomplicated CHB were randomly selected from the computerized registers of three public primary care clinics serving over 100 000 people in one of five regions in Hong Kong. Patients aged 18 years or older who were hepatitis B surface antigen-positive for more than six months were included in the study. Patients were excluded if they could not communicate in Cantonese; had cognitive impairment shown by the patient's inability to understand the study to give consent; were co-infected with HIV, HCV or hepatitis D virus; had undergone liver transplantation or had end-stage non-hepatitis B-related illnesses; were currently taking excessive alcohol (> 30 U/wk) or illegal drugs; or refused to give consent. Each patient completed the Chinese (HK) CLDQ, the Chinese (HK) SF-36v2 Health Survey and a structured questionnaire on morbidity and socio-demographics, administered by a trained interviewer. Each patient was asked if he/she had ever been diagnosed by a registered practitioner for more than four weeks to have hypertension, diabetes mellitus, heart disease, stroke, chronic lung disease, arthritis, psychological illness (i.e. depression, anxiety, neurasthenia or psychosis) or any other chronic diseases. Chronic co-morbidity was measured by the total number of diseases (summation of positive responses to the questions) and the presence of a specific diagnosis. Clinical data related to the CHB infection including Child's staging for patients with cirrhosis and the biomarkers of liver disease (alanine aminotransferase, aspartate aminotransferase,  $\alpha$ -fetoprotein and total bilirubin) in each patient were retrieved from medical records. Socio-demographic data including age, gender, education, marital status, occupation, household income and family history of liver disease were also collected.

The Chinese (HK) CLDQ was re-administered to the 46 subjects with uncomplicated CHB, whose condition was expected to be stable, by telephone two weeks from the first administration, in order to assess the test-retest reliability of the Chinese (HK) CLDQ. Sixty one percent of the repeat interviews were carried out by the same interviewer.

### Instruments

The Chinese (HK) CLDQ consists of 29 items measuring six subscales as described above. Each item is rated on a 7-point (1 = all of the time to 7 = none of the time) Likert scale. Scores for each of the six domains are calculated by the mean of the item scores within the subscale. A summary score is calculated by the mean of all subscale scores. The scores range from 1 to 7 with a higher score indicating better HRQOL.

The Chinese (HK) SF-36v2 Health Survey is a generic HRQOL measure that has been translated, validated and normed on the general Chinese population in Hong Kong<sup>[16,17]</sup>. It measures eight domains of HRQOL on physical functioning (PF), role-physical (RP), bodily pain (BP), general health (GH), vitality (VT), social functioning (SF), role-motional (RE) and mental health (MH). Summations of item scores of the same domain give the domain scores, which are transformed into a range from 0 to 100. A higher score indicates better HRQOL. The eight domain scores are summarized to form the physical component (PCS) and mental component (MCS) summary scores.

### **Statistical analysis**

All data analysis was carried out in SPSS for Windows 15.0. Statistical significant levels were set at  $P$  values less than 0.05.

### **Scaling assumptions**

The CLDQ item and subscale scores were calculated and tested against the following scaling assumptions: (1) Items should be substantially linearly correlated to the hypothesized subscale score with a coefficient of 0.4 or above by Spearman rank correlation test, to show the item is a significant indicator for the subscale concept. (2) An item should have a stronger correlation with its hypothesized subscale than other subscales indicating scaling success<sup>[18]</sup>. This is a test of item discriminant validity. The difference between correlations is statistically significant if it is greater than two standard errors (1 divided by the square root of sample size).

### **Construct validity**

**Factor analysis:** Exploratory factor analysis using principal components with varimax rotation was performed to evaluate the factor structure of the Chinese (HK) CLDQ. The criterion for factor extraction was an eigenvalue greater than one. The highest factor loading was identified for each item. The scree plot was also used to determine the number of factors.

**Convergent validity:** Construct validity was also tested by convergent validity determined by Spearman correlations between corresponding CLDQ and SF-36v2 Health Survey domain scores. It was hypothesized that moderate ( $r = 0.4$  to  $0.7$ ) to strong ( $r > 0.7$ ) correlations should exist between CLDQ FA and SF-36v2 VT; between CLDQ SS and SF-36v2 BP; between CLDQ AC and SF-36v2 PF, RP and RE; and between CLDQ EF and SF-36v2 MH scores.

### **Sensitivity**

The mean CLDQ scores were compared between two CHB patient groups, and the difference was tested by independent  $t$  to evaluate its sensitivity in detecting a difference between patients with complicated and uncomplicated infections. The sensitivity of the CLDQ was also assessed by the effect size (difference between group mean scores/overall standard deviation). According to Cohen<sup>[19]</sup>, effect sizes of 0.3, 0.5 and 0.8 were considered small, medium and large differences, respectively. An effect size of less than 0.3 was considered not significant.

### **Reliability**

Different methods were used to assess reliability, including internal consistency and test-retest reliability. Internal consistency was measured by Cronbach's  $\alpha$ , which is a measure of the extent to which items in a questionnaire are homogeneous (correlated) in supporting the same concept<sup>[20]</sup>. Test-retest reliability refers to the stability of an instrument over time<sup>[21]</sup>, which was measured by the intra-class correlation (ICC) between the two-week test-retest results. Reliability coefficients  $\geq 0.7$  and 0.9 are usually expected for group comparisons and individual comparisons, respectively<sup>[21]</sup>.

## **RESULTS**

### **Translational equivalence of the Chinese (HK) CLDQ**

All items except item 11 (level of energy) were found to be understood by 6 patients. Three out of six patients did not understand item 11. Five patients (83%) interpreted the meaning of all except four items (11, 13, 19 and 28) correctly. Four out of six patients misinterpreted the meaning of item 11 with three interpreting it as decreased physical strength. Two patients (33.3%) had difficulty in differentiating the meaning of "sleepy" and "drowsy"; and did not seem to have interpreted the words "mood swings" (item 19). Two out of six patients did not include the meaning of "worried about never feeling better" (item 28) in their interpretation. The Chinese (HK) translation was revised based on the results of cognitive debriefing and the revised questionnaire was then field tested on 23 CHB patients before this study. The final Chinese (HK) CLDQ was formed and its back-translation is shown in the appendix.

### **Subjects**

One hundred and eighty four CHB patients were identified; 6 patients were excluded (3 had hepatitis B infection less than 6 mo, 2 had communication problems and 1 had co-infection with HCV) and 28 patients refused to participate in this study. One hundred and fifty Chinese adults consisting of 72 uncomplicated (normal liver function defined as liver enzymes persistently within the normal range and without any history of cirrhosis or HCC) and 78 complicated (cirrhosis or HCC) completed the study, giving a response rate of 84.3% (150/178). Table 1 shows their characteristics, overall and by disease severity groups. There were 8 patients in the complicated CHB group who had HCC without any cirrhosis and had normal liver function. There were no statistical differences in demographics between the uncomplicated and complicated CHB groups, except age and sex ( $P < 0.001$ ). Complicated CHB patients were older and there were more men than those in the uncomplicated group which was expected because CHB complications were more common in men than in women and the median age for the development of complications was 57.2 years<sup>[22,23]</sup>.

### **Score distribution**

Table 2 shows the distribution of the Chinese (HK) CLDQ and SF-36v2 scores. There was practically no

Child C		15 (19.2)	15 (10.0)

CHB: Chronic hepatitis B; HCC: Hepatocellular carcinoma; LF: Liver function. Data are no. (%) of patients, unless otherwise indicated.

<sup>1</sup>Significant difference between uncomplicated and complicated CHB groups by independent sample *t* or Fisher's exact test, *P* < 0.05. Socio-demographic variables are recoded as binary categorical variables for performing Fisher's exact test: male vs female; no schooling vs any formal education; living with spouse vs other marital status; managers, administrators and professional vs other occupations.

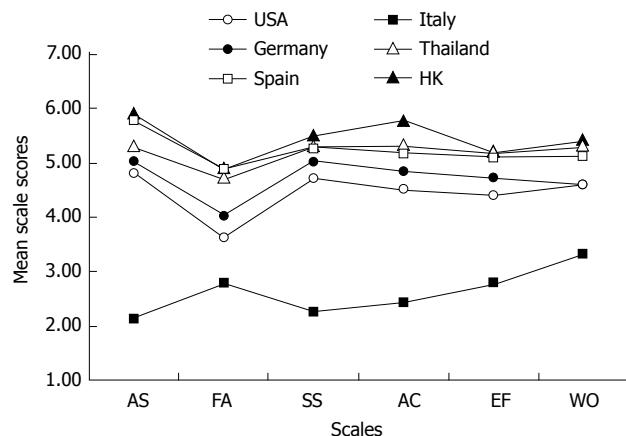

floor effect but there were significant ceiling effects in the Chinese (HK) CLDQ AS, AC and WO subscales, more so in the uncomplicated than the complicated group. Significant ceiling effects were also found in most SF-36v2 Health Survey scales. Sub-group analysis showed that the mean Chinese (HK) CLDQ scores were significantly lower in the complicated group than the uncomplicated group in all subscale and overall scores.

Figure 1 compares the distribution of the Chinese (HK) CLDQ scores with those from other countries. The distribution pattern of the Chinese (HK) CLDQ subscale scores was very similar to those of other countries<sup>[3,9,11,13]</sup>, except Italy, supporting cross-cultural conceptual equivalence.

### Scaling properties

Table 3 shows the mean item scores and standard deviation of the 29 CLDQ items grouped under their hypothesized subscales. All correlations between items and their hypothesized subscales score exceeded the standard of 0.4.

All but six items had a higher correlation with its hypothesized subscale than other subscales, i.e. 100% scaling success. Four items of the SS subscale and two items of the AC subscale correlated more highly with some other subscales than their own. Scaling success was the lowest in item 3 "bodily pain", which correlated more highly with four other subscales than with the SS subscale, with the highest found for EF, but the differences were not statistically significant. Items 6 "shortness of breath", 23 "dry mouth", 27 "itching", 7 "not able to eat as much as you

**Figure 1** The Chinese (HK) CLDQ scores by countries. AS: Abdominal Symptoms; FA: Fatigue; SS: Systemic Symptoms; AC: Activity; EF: Emotional Function; WO: Worry.

would like" and 9 "trouble in lifting or carrying heavy objects" correlated higher with one to three other subscales than its own, but the differences in the correlations were not statistically significant.

The overall scaling success rate on discriminant validity was 100% for four scales (AS, FA, EF and WO), but it was 73% for the AC subscale and 64% for the SS subscale.

### Factor analysis

Table 4 illustrates the rotated factor loadings between the

AS: Abdominal Symptoms; FA: Fatigue; SS: Systemic Symptoms; AC: Activity; EF: Emotional Function; WO: Worry; PF: Physical Functioning; RP: Role Physical; BP: Bodily Pain; GH: General Health; VT: Vitality; SF: Social Functioning; RE: Role Emotional; MH: Mental Health; PCS: Physical Component Summary; MCS: Mental Component Summary; ES: Effect Size. <sup>1</sup>The Chinese (HK) CLDQ score range 1-7 and SF-36v2 score range 0-100; higher scores indicate better health-related quality of life; <sup>2</sup>Uncomplicated CHB are patients who had no cirrhosis or hepatocellular carcinoma (HCC) and normal liver function; Complicated CHB refers to those with cirrhosis or HCC; <sup>3</sup>% floor: Percentage of CHB patients at the lowest possible score; <sup>4</sup>% ceiling: Percentage of CHB patients at the highest possible score; <sup>5</sup>Effect size was calculated as the difference between uncomplicated and complicated mean score, divided by the overall SD. <sup>a</sup>Significant difference between uncomplicated and complicated CHB patients by independent sample *t* (*P* < 0.05); <sup>b</sup>Significant difference between CHB groups and HK norm by independent sample *t* (*P* < 0.05).

29 items and 6 factors with eigenvalue > 1. The six factors explained 70.1% of total variance. The factor loadings of the items were not entirely consistent with the scaling hypothesis. Items of the FA and SS subscales, except bodily pain (item 3), decreased strength (item 8) and decreased energy (item 11), seemed to load on the same factor (factor 3). Two FA subscale items (8 “decreased energy” and 11 “decreased strength”) loaded more strongly on AC than its hypothesized factor. A new factor (factor 6) was found with the highest loading from two items assessing sleep (items 16 and 20). The items of EF, WO, AS and AC subscales loaded nicely on their hypothesized factors.

### Construct validity

Table 5 shows the correlations between the scores of the CLDQ and SF-36v2 Health Survey. As hypothesized, moderate to strong correlations were found between CLDQ FA and SF-36v2 VT scores; and between CLDQ SS and the SF-36v2 BP scores. The CLDQ AC score correlated significantly with all SF-36v2 Health Survey domain scores and the strongest was found with the SF-36v2 RP and SF scores. The CLDQ EF score correlated strongly not only with the SF-36v2 MH score but moderately with the SF-36v2 VT, RE, RP and GH scores.

### Sensitivity

As shown in Table 2, the CLDQ overall and subscale mean scores were all significantly higher in the uncomplicated than the complicated CHB group. The effect sizes of the group differences in the CLDQ scores all exceeded 0.4 (range 0.4-0.6). Only three of the eight SF-36v2 domain scores (PF, RP and SF) and the PCS

score detected a significant difference between the uncomplicated and the complicated groups. However, the greatest effect size difference between the two groups was found in the SF-36v2 RP score.

### Reliability

Across all subscales, the Cronbach's  $\alpha$  coefficients of the internal consistency reliability were higher than the recommended value of 0.7 (Table 5). ICC coefficients measuring the two-week test-retest reliability exceeded 0.7 in all but the AS (0.58) and AC (0.66) subscales. The reliability coefficients were comparable to those of the SF-36v2 Health Survey.

Table 5 also shows that the correlations (range 0.50-0.87) between the CLDQ subscales were smaller than the subscale internal reliability coefficients for all subscales, showing that each subscale measures a distinct concept. The overall CLDQ scores correlated strongly with all CLDQ subscale scores.

### DISCUSSION

The mean scores of the CLDQ found in our population were generally higher than those found in other countries. This might be the result of a sampling difference, in that over half of our subjects had uncomplicated CHB infection and most of the other studies included patients with more serious diseases and patients with HCV who tend to have more impairment in HRQOL than patients with CHB infection<sup>[24]</sup>. The other reason for a difference in the absolute HRQOL scores between different populations is a difference in the sociocultural norms. A comparison

<sup>1</sup>Spearman correlation between item and its hypothesized subscale corrected for overlap (relevant item removed from its subscale for correlation); <sup>2</sup>Level of scaling success, item-subscale correlation is higher for hypothesized subscale than competing subscale; <sup>3</sup>Item-subscale correlation is lower for hypothesized subscale than for competing subscale, but not statistically significant at the cutoff point of two standard errors (0.16).

with the population norms of generic HRQOL measures such as those of the SF-36 Health Survey will provide a more meaningful interpretation on the impact of CHB on HRQOL between different populations. Our study found that uncomplicated CHB patients had significant impairment in the SF-36v2 RP, BP, SF and RE domains, and complicated CHB patients had significantly lower SF-36v2 scores in six domains (PF, RP, BP, GH, SF and RE) than the norms of the HK population (Table 2)<sup>[25,26]</sup>. The findings suggested that CHB infection affected HRQOL only modestly unless complications develop. Surprisingly, there was no difference in the MH score between CHB patients and the HK population norm. It was unlikely that a potentially lethal chronic infection had no effect on mental health, the SF-36v2 Health Survey was probably not sensitive enough to detect the difference.

The high ceiling effects in the AS, AC and WO subscales in patients with uncomplicated CHB were

expected since they were usually asymptomatic. A pattern that was similar to that found in a Spanish population<sup>[9]</sup>. A high ceiling effect was also observed among patients with complicated CHB which was unexpected, this was probably because most of our subjects with complicated CHB were under anti-viral treatment that might have improved their HRQOL, or perhaps some patients had adjusted to their illnesses. On the whole, the CLDQ had a lower ceiling effect than the SF-36v2 Health Survey, suggesting that this disease-specific HRQOL measure would be more responsive than the generic measure in detecting improvements with treatment, which needs to be confirmed by prospective studies. The lack of floor effect indicates that the Chinese (HK) CLDQ would be able to capture any deterioration in patients' QOL as the disease progresses.

The item-subscale correlations and factor analysis results supported the scaling structure of the Chinese (HK)

<sup>1</sup>All analyses were performed with the total sample of 150 patients, except for the Intra-class Correlation Coefficient (ICC), which was based on the results from 46 uncomplicated CHB patients.

CLDQ in general. However, the scaling success rates of items 3 (bodily pain), 23 (dry mouth) and 9 (trouble in

lifting or carrying heavy objects) seemed too low to be acceptable, raising the question whether they should be

**Table 6** Psychometric properties of the revised Chinese (HK) CLDQ subscales

Revised subscales	Mean	SD	% floor	% ceiling	Scaling success	Cronbach's $\alpha$	ICC
AS	5.9	1.3	0.0	37.3	100.0	0.84	0.58

SL	4.8	1.7	1.3	17.3	100.0	0.78	0.79
Overall Scores	5.4	1.1	0.0	0.7	NA	0.89	0.85

grouped under other subscales than the originally hypothesized. It is interesting to note that bodily pain correlated the most with the EF subscale score and loaded the strongest on the EF factor (Table 4). It is a common observation that emotional state has a strong influence on pain perception and *vice versa*. Although the items on dry mouth or trouble in lifting or carrying heavy objects correlated more strongly with other subscales than their own, they should probably remain in the hypothesized subscale because the differences in the item-subscale correlations were not significant and the item-hypothesized subscale correlations were greater than 0.4. Furthermore, the factor loading results were not consistent with the results of the item-subscale correlations. The item "dry mouth" correlated most strongly with WO subscale score but the loading was the highest on the SS factor (0.48). The item "trouble in lifting or carrying heavy objects" correlated highest with the SS score but factor analysis showed that it loaded most strongly on the factor of EF.

The factor structure of the Chinese (HK) CLDQ version was almost identical to the original CLDQ in four subscales (EF, WO, AS and AC). The new factor of Sleep found in our Chinese population was also found in the Spanish, Italian and German population<sup>[9,10,27]</sup>. CHB patients may have sleep difficulties due to reasons other than emotional problems, such as pain and other symptoms. The items of the FA and SS subscales, except items 3, 8 and 11, loaded on one single factor since they all measure symptoms. Items 8 and 11 of the FA subscale loaded on the AC factor. Factor analysis with promax rotation was also performed to cross-validate the factor structure obtained by the varimax rotation, and it showed similar results with a new factor assessing sleep and items of the FA subscale loaded mostly on the AC factor instead of a separate factor.

An alternative scaling structure for the Chinese (HK) CLDQ based on the factor loading results could be formed. Items 16 (difficulty in sleeping) and 20 (difficulty in falling asleep at night) were grouped into a new Sleep subscale. Items 8 (decreased strength) and 11 (decreased energy) were grouped into the AC subscale. Items 2, 4 and 13 of the original FA subscale are grouped with items of the SS subscale to form the new SS subscale. Item 3 (bodily pain), although loaded most strongly and correlated the most with EF factor, remains in the SS subscale because this has better face validity. The psychometric properties of the revised Chinese (HK) CLDQ subscales with regrouping of the items are shown in Table 6. It can be seen that the new subscale structure greatly improves the scaling success rates of the SS and AC items, although it

reduces the success rate of the EF subscale slightly. The new scaling structure also reduced the ceiling effects of the SS and AC subscales. Further studies are needed to determine whether the revised subscale structure will translate into better sensitivity and responsiveness in clinical applications. Until such data are available, the original subscale structure of the CLDQ is recommended to allow better international comparability.

The expected correlations between the CLDQ and SF-36v2 Health Survey domains were observed confirming convergent construct validity. The correlation with the SF-36v2 RE domain was higher in the CLDQ EF than the AC subscale because conceptually the SF-36v2 RE measures the effect of emotional problems on daily activities.

The CLDQ subscales of AS and WO address domains that are not assessed by the generic measure (SF-36v2 Health Survey) and detected significant differences between the two groups of CHB patients. There were significant differences in the WO and EF subscales of the CLDQ between the CHB groups although this was not found in most of the mental-health related domains (RE, MH and MCS) of the SF-36v2 Health Survey, suggesting that the Chinese (HK) CLDQ was more sensitive than the generic measure in detecting the emotional impact of CHB. It is worth noting that although more domains in the CLDQ showed a significant difference between the complicated and uncomplicated CHB groups, the largest effect size difference was found in the SF-36v2 RP domain indicating that a disease-specific measure may not always be more sensitive than a generic measure. The two types of HRQOL measures should complement each other in the evaluation of the HRQOL of CHB patients.

Internal consistency and test-retest reliability were acceptable for all subscales. Test-retest reliability (ICC) of the AS subscale was relatively low (0.58) probably because these symptoms could fluctuate from day to day and pain intensity might vary noticeably in a relatively short period of time. Reliability of the CLDQ in our study was generally higher than those found in other studies (0.46-0.95)<sup>[9,12]</sup>. The SS subscale had very good test-retest reliability (ICC 0.86) in our population. The very low ICC (0.23) found in the US study was likely the result of an inappropriately long retest interval of six months<sup>[3]</sup>.

Our study administered the Chinese (HK) CLDQ using an interviewer since our populations had a relatively low literacy level. The performance of the instrument by self-completion will need to be confirmed by further studies. The responsiveness of the Chinese (HK) CLDQ in detecting changes with disease progression or anti-viral treatment will also need to be determined.

The Chinese (HK) CLDQ was validated in content and construct. It had satisfactory psychometric properties in terms of factor structure, scaling assumption, construct validity, reliability and sensitivity in Southern Chinese patients with CHB infection. It was more sensitive than the SF-36v2 Health Survey in detecting the impact of CHB on mental-health and symptom related HRQOL. The Chinese (HK) CLDQ should be applicable to all Cantonese-speaking Chinese in HK and other parts of Southern China. It is also likely to be applicable to the majority of Chinese populations in Australia, North America, and Europe who are mostly emigrants from HK. There was good equivalence in the score distribution pattern across several cultures indicating that it can be used as a cross-cultural HRQOL measure in multiethnic populations or global studies. Some modifications of the scaling structure of the CLDQ may improve its psychometric properties for CHB patients, which need to be explored by further clinical studies.

#### Appendix: Back-translation of Chinese (HK) CLDQ

##### Original Wording

This questionnaire is designed to find out how you have been feeling during the last 2 wk. You will be asked about you symptoms related to your liver disease, how you have been affected in doing activities, and how your mood has been. Please complete all of questions and select only one response for each question.

1 How much of the time during the last 2 wk have you been troubled by a feeling of abdominal bloating?

All of the time

Most of the time

A good bit of the time

Some of the time

A little of the time

Hardly any of the time

None of the time

2 How much of the time have you been tired or fatigued during the last 2 wk?

3 How much of the time during the last 2 wk have you experienced bodily pain?

4 How often during the last 2 wk have you felt sleepy during the day?

5 How much of the time during the last 2 wk have you experienced abdominal pain?

6 How much of the time during the last 2 wk has shortness of breath been a problem for you in your daily activities?

7 How much of the time during the last 2 wk have you not been able to eat as much as you would like?

8 How much of the time in the last 2 wk have you been bothered by having decreased strength?

9 How often during the last 2 wk have you had trouble lifting or carrying heavy objects?

10 How often during the last 2 wk have you felt anxious?

11 How often during the last 2 wk have you felt a decreased level of energy?

##### Backward Translation

The purpose of this questionnaire is to understand how you felt in the past 2 wk.

The questions are about the symptoms resulting from your liver illness and how these symptoms affect your participation in activities, and your emotions.

Please answer all questions. You can only choose one answer for each question.

1 In the past 2 wk, how much time you have been bothered by your bloating problem?

All the time

Most of the time

Quite Often

Sometimes

A Short Time

Hardly Any

Never

2 In the past 2 wk, how much time did you feel tired or exhausted?

3 In the past 2 wk, how much time did your body ache?

4 In the past 2 wk, how often did you feel sleepy during the daytime?

5 In the past 2 wk, how much time did you have abdominal pain?

6 In the past 2 wk, how much time were your daily activities affected by your shortness of breath?

7 In the past 2 wk, how much time were you unable to eat as much as you want?

8 In the past 2 wk, how much time have you been bothered by the decline in your physical energy?

9 In the past 2 wk, how often did you find it difficult when you were lifting or carrying heavy objects?

10 In the past 2 wk, how often did you feel anxious?

11 In the past 2 wk, how often did you find your energy level decreasing?

12 How much of the time during the last 2 wk have you felt unhappy? 12 In the past 2 wk, how much time did you feel unhappy?

13 How often during the last 2 wk have you felt drowsy? 13 In the past 2 wk, how often did you feel sleepy?

14 How much of the time during the last 2 wk have you been bothered by a limitation of your diet? 14 In the past 2 wk, how much time have you been bothered by your restricted diet?

15 How often during the last 2 wk have you been irritable? 15 In the past 2 wk, how often did you become irritable?

16 How much of the time during the last 2 wk have you had difficulty sleeping at night? 16 In the past 2 wk, how much time did you find it difficult to sleep at night?

17 How much of the time during the last 2 wk have you been troubled by a feeling of abdominal discomfort? 17 In the past 2 wk, how much time have you been bothered by your abdominal discomfort?

18 How much of the time during the last 2 wk have you been worried about the impact your liver disease has on your family? 18 In the past 2 wk, how much time did you worry that your liver illness will affect your family?

19 How much of the time during the last 2 wk have you had mood swings? 19 In the past 2 wk, how much time did your emotions fluctuate?

20 How much of the time during the last 2 wk have you been unable to fall asleep at night? 20 In the past 2 wk, how much time were you unable to sleep until sunrise?

21 How often during the last 2 wk have you had muscle cramps? 21 In the past 2 wk, how often did your muscle cramp?

22 How much of the time during the last 2 wk have you been worried that your symptoms will develop into major problems? 22 In the past 2 wk, how much time did you worry that your symptoms will become a serious problem?

23 How much of the time during the last 2 wk have you had a dry mouth? 23 In the past 2 wk, how much time did you have dry mouth?

24 How much of the time during the last 2 wk have you felt depressed? 24 In the past 2 wk, how much time did you feel depressed?

25 How much of the time during the last 2 wk have you been worried about your condition getting worse? 25 In the past 2 wk, how much time did you worry that your condition will deteriorate?

26 How much of the time during the last 2 wk have you had problems concentration? 26 In the past 2 wk, how much time did you find it hard to concentrate?

27 How much of the time have you been troubled by itching during the last 2 wk? 27 In the past 2 wk, how much time have you been bothered by itchiness?

28 How much of the time during the last 2 wk have you been worried about never feeling any better? 28 In the past 2 wk, how much time did you worry that your health condition will not improve?

29 How much of the time during the last 2 wk have you been concerned about the availability of a liver if you need a liver transplant? 29 In the past 2 wk, how much time have you worried that you could not get a liver if you have to undergo a liver transplant?

#### ACKNOWLEDGMENTS

We thank Ms Fong Nga Po and Ms Cara Chan Yuen Yee for their assistance in data collection and entry, and the staff of the Division of Hepatobiliary/Pancreatic Surgery & Liver Transplantation and Gastroenterology & Hepatology Specialist Outpatient Clinics, Queen Mary Hospital for their help in patient recruitment.

#### COMMENTS

##### Background

Chronic hepatitis B (CHB) virus infection remains a global problem and a public health threat. CHB patients may suffer or die from liver-related complications, posing a threat to both mental and physical health, leading to impairment of quality of life.

##### Research frontiers

Health-related quality of life (HRQOL) outcomes should supplement traditional clinical outcomes in the evaluation of the impact and the effectiveness of treatment for patients with CHB infection.

### Innovations and breakthroughs

The Chronic Liver Disease Questionnaire (CLDQ) had been applied mainly to patients with hepatitis C virus infection in Western countries. This study was the first to show that a Chinese (Hong Kong) translation of the CLDQ was valid, reliable and sensitive for Southern Chinese patients with CHB infection. The CLDQ can be applied to millions of Southern Chinese CHB patients to evaluate their HRQOL. Some modifications might further improve its validity, reliability and sensitivity.

### Applications

The Chinese (Hong Kong) CLDQ can be used to evaluate the impact of CHB virus infection and assess the effectiveness of anti-viral drug treatments in Cantonese-speaking Southern Chinese. The CLDQ can be used as a cross-cultural HRQOL measure in international studies that include Southern Chinese.

### Terminology

CHB virus infection refers to those who are hepatitis B surface antigen-positive for more than six months. Validity is defined as the extent to which a test measures what it is intended to measure. Reliability refers to the consistency or stability of the measurement process across time, patients or observers.

### Peer review

The authors validated and tested the psychometric properties of a Southern Chinese translation of the CLDQ and determined that their questionnaire was valid, reliable, and sensitive for southern Chinese patients with hepatitis B virus infection. The study was well done and used appropriate methodology to validate and test the questionnaire.

## Abstract

**AIM:** To study the liver and spleen volume variations in hepatic fibrosis patients at different histopathological stages.

**METHODS:** Multidetector computed tomography (MDCT) scan was performed in 85 hepatic fibrosis patients. Liver volume (LV) and spleen volume (SV) were measured. Fifteen healthy individuals served as a control group (S0). The patients were divided into stage 1 (S1) group ( $n = 34$ ), stage 2 (S2) group ( $n = 25$ ), stage 3 (S3) group ( $n = 16$ ), and stage 4 (S4) group ( $n = 10$ ) according to their histopathological stage of liver fibrosis.

**RESULTS:** The LV and standard LV (SLV) had a tendency to increase with the severity of fibrosis, but no statistical difference was observed in the 5 groups (LV:  $F = 0.245$ ,  $P = 0.912$ ; SLV:  $F = 1.902$ ,  $P = 0.116$ ). The SV was gradually increased with the severity of fibrosis, and a statistically significant difference in SV was observed among the 5 groups ( $P < 0.01$ ). The LV/SV ratio and SLV/SV ratio were gradually decreased with the aggravation of hepatic fibrosis, and statistically significant differences in both LV/SV and SLV/SV were found among the 5 groups ( $P < 0.01$ ).

**CONCLUSION:** The absence of obvious LV reduction in patients with chronic liver disease may be a

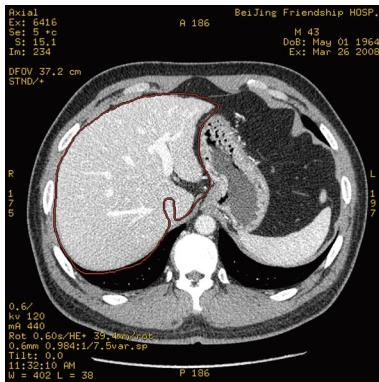

## INTRODUCTION

Hepatic fibrosis is an important histopathological stage of chronic liver disease, and can progress to hepatocirrhosis. Studies have shown that hepatic fibrosis can be reversed<sup>[1,2]</sup>. Therefore, hepatic fibrosis can be halted if it is early diagnosed and treated with intervention therapy. Liver biopsy is the golden diagnosis standard for hepatic fibrosis and cirrhosis, but it cannot be used widely and repeatedly due to its invasive nature. This study was to observe the liver volume (LV) and spleen volume (SV) variations in patients with hepatic fibrosis by 64-row multidetector computed tomography (MDCT).

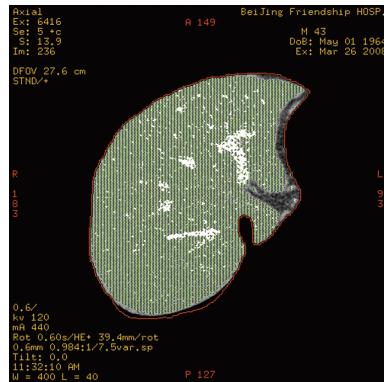

## MATERIALS AND METHODS

### Patients

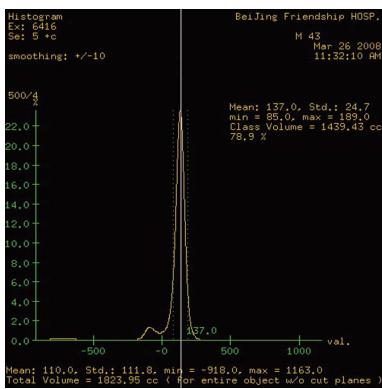

Eighty-five patients (66 males and 19 females, mean age 41 years) with liver fibrosis in our hospital between November 2007 and September 2008 were included in this study. All of them had chronic hepatitis B. The patients were divided into stage 1 (S1) group ( $n = 34$ ),

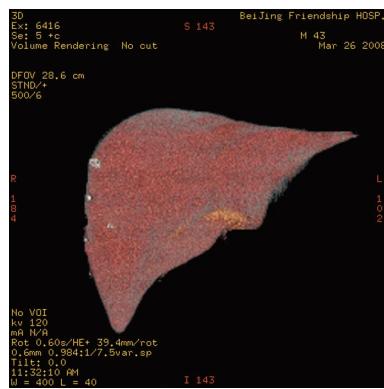

**Figure 1** Profile of the liver with an interval of several sections for the separation of liver from other organs and their tissues around.

**Figure 2** Regulation of threshold value for exclusion of gallbladder, main liver blood vessels and fat.

**Figure 3** Measurement of liver volume.

**Figure 4** Volume rendering image of liver after reconstruction.

stage 2 (S2) group ( $n = 25$ ), stage 3 (S3) group ( $n = 16$ ), and stage 4 (S4) group ( $n = 10$ ) according to their histopathological stage of fibrosis. The patients had no liver and spleen tumor. Fifteen patients (10 males and 5 females, mean age 35.5 years) with no history of liver and spleen disease served as a control group (S0). They underwent abdominal computed tomography (CT) scan for liver disease. Routine abdominal CT scanning showed no liver, bile and spleen disease. Liver test was normal and antigen test was negative for hepatitis B and C.

#### Diagnostic method

All patients with chronic hepatitis B were diagnosed according to the results of pathological examination of liver biopsy. The patients were divided into four groups according to the diagnostic criteria for virus hepatitis as previously described<sup>[3]</sup>.

#### Imaging parameters

Abdominal CT scan was performed with a 64-row MDCT scanner (GE LightSpeed VCT). Protocols included a non-enhancement scan and an enhancement scan of the upper abdomen from the dome of diaphragm to the entire liver and spleen (5 mm thickness, 80-120 mAs, and 120 kVp). All patients received an injection of 100 mL iopromide (300 mg I/mL; Ultravist, Schering) through a peripheral vein (generally an

antecubital vein) at a flow rate of 4.0 mL/s. The arterial phases were tracked with a scanning monitor and a time delay of 25 s after arterial phases was applied in all patients for the venous phases. Bolus-injection technique was used to administer contrast material with a power injector. All patients underwent CT scan at a supine position during a single breath.

#### Measurement of LV and SV

After scanning, 5 mm portal vein phase reconstruction images obtained from the raw data were divided (0.625 mm) and transferred to an interactive workstation (AW4.2 or AW4.3) to measure LV and SV. The profile of liver was outlined manually to exclude the inferior vena cava with an interval of several sections. Gallbladder, main liver blood vessels and fat were excluded by regulating the threshold value. The enclosed liver parenchymal area was then calculated automatically<sup>[4,5]</sup> and expressed as the LV (Figures 1-4).

Body weight (BW) and body height (BH) recorded at the time of CT examination were used to calculate the body surface area (BSA) following the equation:  $BSA (m^2) = [0.0071 \times BH (cm) + 0.0133 \times BW (kg) - 0.1971]$ . LV is significantly related with BW, BH, and BSA as described elsewhere<sup>[6,7]</sup>. Therefore, standard liver volume (SLV) was measured following the equation:  $SLV (cm^3/m^2) = LV (cm^3)/BSA (m^2)$ .

The measurement of SV and LV was similar. Since

**Table 1 Comparison of related volumes in patients with liver fibrosis and healthy controls (mean  $\pm$  SD)**

Group	Patients ( <i>n</i> )	Liver volume (cm <sup>3</sup> )	Standard liver volume (cm <sup>3</sup> )	Spleen volume (cm <sup>3</sup> )	Liver/spleen volume ratio	Standard liver/spleen volume ratio
Control	15	1133.39 $\pm$ 131.84	637.98 $\pm$ 65.93	190.94 $\pm$ 70.37 <sup>b,d</sup>	6.70 $\pm$ 2.56 <sup>b,d</sup>	3.81 $\pm$ 1.62 <sup>b,d,e</sup>

<i>F</i> value		0.245	1.902	12.383	9.702	9.784
<i>P</i> value		0.912	0.116	0.000	0.000	0.000

<sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 vs S3; <sup>c</sup>*P* < 0.05, <sup>d</sup>*P* < 0.01 vs S4; <sup>e</sup>*P* < 0.05 vs S2.

SV does not correlate with BW, BH and body mass index (BMI)<sup>[8-10]</sup>, it is not necessary to make the SV standard.

Then, the LV/SV ratio and SLV/SV ratio were calculated.

### Statistical analysis

Results were expressed as mean  $\pm$  SD. One way analysis of variance(ANOVA) was used for multiple mean comparisons. Bonferroni correction was used for comparison of two samples. If heterogeneity of variance was found, a log transformation was used to normalize the data distribution, and ANOVA was run with an equal variance. *P* < 0.05 was considered statistically significant. Statistical analysis was performed using SPSS (version 14.0, SPSS).

## RESULTS

The total LV and SLV were 1133.39  $\pm$  131.84 cm<sup>3</sup> and 637.98  $\pm$  65.93 cm<sup>3</sup> in the control group. The LV (*F* = 0.245) and SLV (*F* = 1.902) in patients with hepatic fibrosis tended to increase with the severity of fibrosis, but no statistically significant difference was observed among the 5 groups (Table 1).

A log transformation was used to normalize the data distribution and ANOVA was run with an equal variance due to the heterogeneity of variance in SV. The SV was larger in patients with liver fibrosis than in control group and increased gradually with the severity of fibrosis (Table 1). There was a significant difference among the 5 groups (*F* = 12.383, *P* = 0.000). Statistically significant differences were observed between S3, S4 and other groups(S0, S1 and S2, *P* < 0.01).

The LV/SV ratio and SLV/SV ratio decreased gradually with the severity of fibrosis (Table 1). The differences in LV/SV (*F* = 9.702, *P* = 0.000) and SLV/SV (*F* = 9.784, *P* = 0.000) were significant among the 5 groups. Statistically significant differences in LV/SV were observed between S3 and S0, S1, and between S4 and S0, S1, S2 (*P* < 0.01). There were statistically significant differences in SLV/SV between S3 and S0, S4 and S0, S1 (*P* < 0.01), and between S2 and S0, S3 and S1, S4 and S2 (*P* < 0.05).

## DISCUSSION

Measurement of LV and SV is a mature technique<sup>[4,5,10-12]</sup>.

The method, which combines profile outline and threshold value regulation, is convenient with a good veracity and repeatability<sup>[5]</sup>. Liver and spleen vary in size among different individuals<sup>[13,14]</sup>. LV is obviously related with BW, BH, and BSA in normal persons<sup>[15-17]</sup>. BSA is calculated according to BW and BH, and therefore can equalize the difference in BW and BH. It is more reasonable to choose SLV (per BSA volume) to analyze LV change in hepatic fibrosis patients at different histopathological stages. Because SV does not correlate with BW, BH, and BMI<sup>[8-10]</sup>, there is no need to make the spleen volume standard.

Reports are available on LV changes in patients with hepatic fibrosis<sup>[18,19]</sup>. Chen *et al*<sup>[18]</sup> reported that the left, right and caudate lobe volumes tend to increase with the aggravation of inflammatory activity and the severity of fibrosis, with significant changes in vertical diameter and volume index of the left lobe but no obvious change in the right and caudate lobe volume. Tarao *et al*<sup>[19]</sup> reported that the LV is significantly larger in grade 2 alcoholic liver fibrosis patients than in grade 1 alcoholic liver fibrosis patients and healthy controls, and the LV is larger in grade 3 alcoholic liver fibrosis patients than in grade 2 alcoholic liver fibrosis patients, suggesting that LV in patients with alcoholic liver fibrosis increases gradually with the severity of fibrosis. The results of this study show that the LV and SLV in patients with liver fibrosis tended to increase with the severity of fibrosis from S1 to S3, but decrease in S4, indicating that LV tends to increase gradually with the severity of chronic liver diseases or fibrosis. Since the number of hepatic cells accounts for 70%-80% of the liver parenchyma, and the reserved liver function is closely related to the total functional hepatic cells, LV measurement can partly show changes in hepatic cells and stages of liver fibrosis or cirrhosis, and thus can be used as an indicator of liver function. It has been shown that LV significantly correlates with Child-Pugh classification of cirrhosis<sup>[5,20,21]</sup>. In this study, LV and SLV changes were observed in patients with fibrosis (*P* > 0.05), which may be attributed to the limited number of cases. On the other hand, it may indicate that hepatic fibrosis has not yet led to obvious liver volume reduction and the decrease of hepatic cellular components.

It has been reported that changes in SV are related to the severity of fibrosis<sup>[19,22,23]</sup>. Tarao *et al*<sup>[19]</sup> showed that SV is significantly larger in grade 3 hepatic fibrosis

patients than in grade 1 and 2 hepatic fibrosis patients and healthy controls, indicating that SV in patients with hepatic fibrosis at an early stage is inconspicuously changed, but conspicuously at the advanced stage. Hoefs *et al*<sup>[22]</sup> reported that different percentages of SV above the upper normal limits can be noted in patients with histologically proven liver disease: no fibrosis (10%), or mild- moderate fibrosis (36.7%), early liver cirrhosis (52%), and advanced liver disease (75%), indicating that SV is closely related with the severity of liver fibrosis and cirrhosis. Ding *et al*<sup>[23]</sup> reported that SV is closely correlated with the histopathological stage of hepatic fibrosis and cirrhosis. In their study, the SV increased gradually in patients with hepatic fibrosis compared with normal subjects, and the differences between S3,S4 and the others were significant ( $P < 0.01$ ).

In our study, the SV was larger in patients with liver fibrosis and increased gradually with the severity of fibrosis, and statistically significant differences were seen between S3, S4 and other groups ( $P < 0.01$ ), suggesting that SV in patients with advanced fibrosis increases obviously compared with normal persons and patients with early fibrosis.

The underlying mechanism may be that extensive fibrosis with formation of fibrous septum occurs at the advanced stages of fibrosis, thus leading to portal congestion and hypertension, obstruction of spleen vein and splenomegaly.

It has been shown that the SV/LV ratio and SLV/SV ratio are significantly different between normal individuals and liver cirrhosis patients. The SV/LV ratio is considered a better index for the diagnosis of liver cirrhosis due to its minor coefficient of variation<sup>[11]</sup>. It was reported that the SV/LV ratio is of prognostic importance in patients with primary biliary cirrhosis<sup>[24]</sup>. The SV/LV ratio and SLV/SV ratio, calculated in this study, were  $6.70 \pm 2.56$  and  $3.81 \pm 1.62$ , respectively in the control group, and decreased gradually with the aggravation of fibrosis in the other groups. The differences in LV/SV between S3 and S0, S1, and between S4 and S0, S1, S2 were statistically significant ( $P < 0.01$ ). The differences in SLV/SV between S3 and S0, between S4 and S0, S1 and between S3 and S1, S4, S2 were statistically significant ( $P < 0.01$ ), indicating that the SV/LV ratio and SLV/SV ratio are smaller in patients with advanced hepatic fibrosis than in patients with early hepatic fibrosis and normal persons, which may contribute to the diagnosis of advanced fibrosis.

Liver biopsy is the golden standard for the differential diagnosis of liver fibrosis from cirrhosis. However, some CT image findings may be useful in pathologic staging of liver fibrosis and cirrhosis. Studies have shown that LV is smaller in cirrhosis patients than in normal individuals<sup>[5,11,20,21]</sup>. Since this study showed that there was no statistical difference in LV between the fibrosis and control groups, no obvious LV reduction in patients with chronic liver disease may be a morphological and predictive index for the absence of liver cirrhosis. However, its accuracy needs to be further evaluated.

The SV range is wide in normal cases<sup>[12]</sup>, and can be easily influenced by factors, such as venous congestion and disorders of the hematological system. Therefore, using SV as a dependable index for the severity of liver fibrosis needs to be further studied. However, SV can be used as a reference index based on the fact that changes in SV are related to the severity of liver fibrosis. The significance of changes in LV/SV ratio and SLV /SV ratio is similar to that of SV, because variations in LV/SV ratio and SLV/ SV ratio mainly depend on the increased SV.

When the LV and SV are measured, some other parameters, such as main portal and spleen vein diameter, and collateral circulation of portal vein, can be detected and evaluated, all of which are the indirect signs of liver disease and portal hypertension. However, changes in LV are a direct sign of the severity of chronic liver disease.

## COMMENTS

### Background

Hepatic fibrosis is an important histopathological stage of chronic liver disease, and can progress to liver cirrhosis. Its diagnosis and staging remain difficult.

### Research frontiers

Liver biopsy is considered the golden diagnosis standard for hepatic fibrosis and cirrhosis, but it is an invasive procedure. Changes in liver volume (LV) and spleen volume (SV) are the morphological index of chronic liver disease.

### Innovations and breakthroughs

Eighty-five cases of liver fibrosis underwent 64-row multidetector computed tomography (MDCT) scanning, and their LV and SV were measured. The results showed that the LV was not obviously reduced in liver fibrosis and cirrhosis patients, indicating that which may be a morphological and predictive index for the absence of liver cirrhosis.

### Applications

Measurement of LV and SV with a 64-row MDCT is a noninvasive method to display the morphological changes in liver fibrosis and can contribute to the clinical diagnosis and treatment of chronic liver disease.

### Peer review

The measurement of LV and SV with MDCT is a noninvasive method to estimate the severity of chronic liver disease, and is of potential usefulness in differentiating liver fibrosis from cirrhosis and in staging of liver fibrosis. Further study is needed to evaluate its accuracy.

Pathologically, 54.5% of the intussusceptions had a tumor, of which 27.3% were malignant. 9.1% comprised nontumorous polyps. Four intussusceptions had a gastrojejunostomy with intestinal intubation, and four intussusceptions had no organic lesion.

**CONCLUSION:** CT is the most effective and accurate diagnostic technique. Colonoscopy can detect most lead point lesions of non-enteric intussusceptions. Intestinal intubation should be avoided.

### Abstract

**AIM:** To optimize the preoperative diagnosis and surgical management of adult intussusception (AI).

**METHODS:** A retrospective review of the clinical features, diagnosis, management and pathology of 41 adult patients with postoperative diagnoses of intussusception was conducted.

**RESULTS:** Forty-one patients with 44 intussusceptions were operated on, 24.4% had acute symptoms, 24.4% had subacute symptoms, and 51.2% had chronic symptoms. 70.7% of the patients presented with intestinal obstruction. There were 20 enteric, 15 ileocolic, eight colocolonic and one sigmoidorectal intussusceptions. 65.9% of intussusceptions were diagnosed preoperatively using a computed tomography (CT) scan (90.5% accurate) and ultrasonography (60.0% accurate, rising to 91.7% for patients who had a palpable abdominal mass). Coloscopy located the occupying lesions of the lead point of ileocolic, colocolonic and sigmoidorectal intussusceptions. Four intussusceptions in three patients were simply reduced. Twenty-one patients underwent resection after primary reduction. There was no mortality and anastomosis leakage perioperatively. Except for one patient with multiple small bowel adenomas, which recurred 5 mo after surgery, no patients were recurrent within 6 mo.

### INTRODUCTION

Intussusception is defined as the telescoping of a segment of the gastrointestinal tract into an adjacent one. Intussusception is uncommon in adults compared with the pediatric population. It is estimated that only 5% of all intussusceptions occur in adults and approximately 5% of bowel obstructions in adults are the result of intussusception<sup>[1]</sup>. Adult intussusception (AI) often presents with nonspecific symptoms. Preoperative diagnosis remains difficult and the extent of resection, and whether the intussusception, should be reduced remains controversial<sup>[1]</sup>. The present study reviews our experience of AI, and discusses the optimal preoperative diagnosis and surgical management techniques.

### MATERIALS AND METHODS

The medical records of 41 adult patients (18 years of age and older) with a postoperative diagnosis of intussusception at the First Affiliated Hospital, China Medical University, from January 2001 to August 2008, were collected. The clinical features, diagnosis,

management and pathology of the 41 patients were reviewed.

An intussusception that involved only the jejunum or ileum was considered an enteric intussusception. An intussusception that involved the ileum and the colon was designated an ileocolic intussusception. An intussusception that involved only the colon was considered a colocolonic intussusception and one that involved the sigmoid colon and rectum was considered a sigmoidorectal intussusception<sup>[1]</sup>. A proximal segment of the bowel telescoped into the lumen of the adjacent distal segment was defined as antegrade intussusception. A distal segment of the bowel telescoped into the lumen of the adjacent proximal segment was defined as retrograde intussusception<sup>[2]</sup>.

Acute symptoms were defined as < 4 d, subacute symptoms were defined as 4–14 d, and chronic symptoms were defined as > 14 d<sup>[3]</sup>.

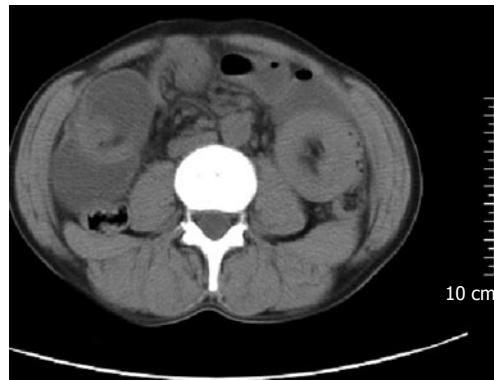

Intussusception was preoperatively diagnosed by abdominal ultrasonography with the target and doughnut signs on transverse view and the pseudokidney sign in the longitudinal view<sup>[1]</sup>. Intussusception was preoperatively diagnosed by multi-slice spiral computed tomography (CT) scans with the characteristic target or sausage sign, edematous bowel wall and mesentery in the lumen<sup>[4,5]</sup>.

## RESULTS

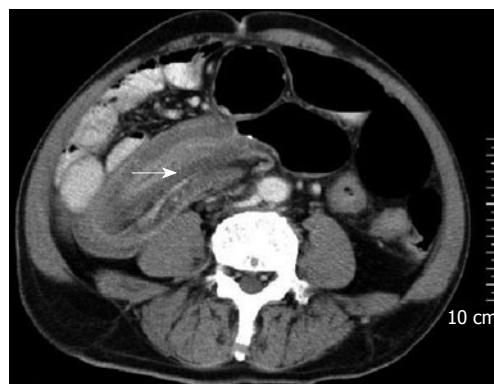

Of all the 41 patients, there were 18 males with an average age of 41.3 (15–71) and 23 females with an average age of 47.0 (18–87). The male:female ratio was 1:1.3. Three (7.3%) patients had two intussusceptions. In all, 44 intussusceptions were diagnosed, of which 20 were enteric intussusceptions (45.5%), 15 were ileocolic intussusceptions (34.1%), eight were colocolonic intussusceptions (18.2%) and one was a sigmoidorectal intussusception (2.3%). Forty-three intussusceptions were antegrade (97.7%) and only one enteric intussusception was retrograde (2.3%) (Table 1).

Of the 41 patients, 95.1% (39/41) had abdominal pain, 26.8% (11/41) had bloody stool, and 34.1% (14/41) had a palpable abdominal mass. This classic pediatric presentation triad was only seen in 9.8% (4/41). 70.7% (29/41) presented with intestinal obstructions of various extents. The duration of the symptoms varied from six hours to three years; 24.4% (10/41) with acute symptoms, 24.4% (10/41) with subacute symptoms, and 51.2% (21/41) with chronic symptoms.

Of the 41 patients, 65.9% (27/41) were preoperatively diagnosed with intussusception. Thirty patients had ultrasonography, of which 18 were diagnosed with intussusception (60.0% accuracy). However, the preoperative diagnostic accuracy of the patients who had palpable abdominal masses was 91.7% (11/12). Twenty-one patients had helical CT scans, of which 19 were diagnosed with intussusception (90.5% accuracy) (see Table 1, Figures 1–4). None of the patients who had experienced gastrojejunostomy and underwent an upper gastrointestinal water-soluble contrast study, were

**Figure 1** A 44-year-old man with two enteric intussusceptions due to multiple adenoma carcinomas. The intussusceptions appear as round target-shaped masses with a hypodense area of fat density close to its centre, the mesenteric fat. The beam is perpendicular to the axis of the intussusceptions.

**Figure 2** A 64-year-old man with an ileocolic intussusception due to a ileum B cell malignant lymphoma. A sausage-shaped mass with high density soft tissue above represents the edematous bowel wall of the intussuscipiens and the intussupceptum, with fat density below, representing mesenteric fat. The higher linear density within the mesenteric fat (arrow) is mesenteric blood vessels. This appearance is caused by the axis of the intussusception being parallel with the computed tomography (CT) beam.

diagnosed intussusception. One patient who had a small intestinal lipoma and underwent capsule endoscopy was diagnosed with regional mucosa puffiness. Eight patients underwent a colonoscopy. The etiologies were found in most of them by colonoscopy (Table 2).

Four intussusceptions in three patients, including two patients who had undergone gastrojejunostomy with an intestinal tube, and one patient with a retrograde idiopathic enteric intussusception, were simply reduced. One patient with a mobile cecum underwent appendectomy and cecum immobilization after primary reduction. Eighteen patients underwent segmental resection of the small bowel, 17 underwent a right hemicolectomy, one underwent a left hemicolectomy, and one patient with a sigmoidorectal intussusception underwent a segmental sigmoidectomy. One patient with multiple small and large intestinal adenomas underwent segmental resection of the small and large bowel. Of the 41 patients, 21 underwent resection after primary reduction (Table 1).

Of the 20 enteric intussusceptions, four of them (20%) underwent a simple reduction, nine (45%) had a

segmental resection with primary reduction, four (20%) failed in reduction, and three (15%) had segmental resection without reduction.

Of the 15 ileocolic intussusceptions, nine (60%) were reduced successfully. Due to the reduction, five patients had limited resection with preservation of the antireflux ileocecal valve. Reduction failed in three patients (20%). Three of them (20%) had a right hemicolectomy without reduction.

Of the eight colocolic intussusceptions, three of them were reduced successfully before resection.

The other five had resection without reduction. The sigmoidorectal intussusception was reduced and had a segmental sigmoidectomy.

There was no perioperative mortality and anastomosis leakage. Except for one patient with multiple small bowel adenomas recurrent 5 mo after surgery, none of them were recurrent within 6 months postoperatively.

Pathological examinations of the 44 intussusceptions showed that a tumor occupied 54.5% (24/44), with 27.3% (12/44) malignant, 25.0% (11/44) benign, and

**Table 2** Coloscopy results for intussusceptions

Intussusception type	Etiology	Coloscopy diagnosis	
		Diagnosis of intussusception	Etiological diagnosis
Enteric	Intestinal inflammatory disease	No	Intestinal inflammatory disease

**Figure 3** Efferent loop intussusception with a tube. A 70-year-old woman underwent Billroth II gastrectomy and efferent loop intubation for enteral nutrition. One month postoperatively, CT at the level of the lower abdomen shows a round, target-shaped mass in the left abdomen. The mass consists of a hyperdense tube (arrow), a "half-moon" shaped hypodense area medial to it, the intussuscepted mesenteric fat and a soft tissue rim representing the opposing walls of the intussuscipiens and the intussusceptum.

2.3% (1/44) borderline. 9.1% (4/44) were nontumorous polyps. 4.5% (2/44) were due to intestinal inflammatory disease. Meckel's diverticulum and mobile cecum accounted for 4.5% (2/44). Apart from three cases (four intussusceptions), who had already undergone a gastrojejunostomy, no organic lesion was found in four intussusceptions by pathology or exploration, one of which one was the only retrograde intussusception (see Tables 1 and 3).

## DISCUSSION

Intussusception is the leading cause of intestinal obstruction in children and ranks second only to

**Figure 4** An 87-year-old woman with a colocolonic intussusception due to ascending colon carcinoma.

appendicitis as the most common cause of acute abdominal emergency in children. AI is distinct from pediatric intussusception in that it is rare, accounting for only 5% of all cases of intestinal obstructions, and about 90% of it is secondary. The exact mechanism is still unknown. However, it is believed that any lesion in the bowel wall or irritant within the lumen that alters normal peristaltic activity is able to initiate an invagination. Ingested food and subsequent peristaltic activity of the bowel produces an area of constriction above the stimulus and relaxation below, thus telescoping the lead point through the distal bowel lumen<sup>[1,3,4]</sup>.

Similar to the results of Zubadi *et al*<sup>[1]</sup>, enteric type intussusception is the most common type in our series. However, in the report of Goh *et al*<sup>[4]</sup> of 60 cases of AI, ileocolic (25%) and ileocecal-colic (13.3%) types were the most common. Their enteric type occupied 26.7%. Similar to our results, their colocolic and sigmoidorectal

types were the least common types.

Most patients present with subacute (24.4%) or chronic (51.2%) symptoms; therefore the characteristic pediatric presentation triad of abdominal pain, palpable abdominal mass and bloody stool was only seen in 9.8% of cases. It is one of the reasons why preoperative diagnosis is difficult.

Ultrasound is apt to be masked by gas-filled loops of bowel, and most AIs present with intestinal obstruction<sup>[6]</sup>. The preoperative diagnosis accuracy (60.0%) of ultrasonography is not satisfying. However, the preoperative diagnosis accuracy of the 12 patients who had palpable abdominal mass was 91.7%, indicating that in cases of palpable abdominal mass, the diagnostic accuracy of ultrasonography would increase significantly.

Recently, with the signs of target or sausage, mesenteric fat and vessels, abdominal CT scan has been reported to be the most useful imaging technique, with a diagnostic accuracy is 58%-100%<sup>[3-5,7,8]</sup>. Recent studies have demonstrated the superiority of CT in revealing the site, level, and cause of intestinal obstructions and in demonstrating threatening signs of bowel nonviability<sup>[9,10]</sup>. As was shown in our study, the majority of AIs presented with partial or complete intestinal obstruction. Moreover, 90.5% (20/22) of AIs were diagnosed by CT in our series. One case of AI that was not diagnosed by CT, however, was correctly diagnosed as having an intestinal occupying lesion. In contrast to ultrasound, CT is not affected by the presence of gas in the bowel and will clearly demonstrate the intussusception, whether in the small bowel or in the colon. Additional valuable information, such as metastasis or lymphadenopathy, is readily obtained by CT and may point to an underlying pathology<sup>[3]</sup>. Therefore, we suggest that all patients presenting with an intestinal obstruction should have an abdominal CT scan as a regular diagnostic test.

Wang *et al*<sup>[3]</sup> considered that most lesions lead distally, can easily be seen by coloscopy, and intraoperative coloscopy might help to distinguish benign from malignant lesions before reduction of intussusceptions. Using the results of a coloscopy, limited surgical management by appendectomy, polypectomy or diverticulectomy might be performed in specific situations, resulting in an uncompromised bowel after reduction<sup>[3]</sup>. In our study, all lesions of the lead points of ileocolic, colocolic or sigmoidorectal intussusceptions were found in the seven patients who had a colonoscopy. Moreover, all the adenoma and adenocarcinomas were diagnosed pathologically through colonoscopy. However, some lesions, such as lymphoma and lipoma, which were not in the mucosa, were not diagnosed pathologically. Therefore, we think that the pathological diagnosis of most of the lead points of ileocolic, colocolic and sigmoidorectal intussusceptions, which locate in the mucosa, could be made by coloscopy. Perhaps some lesions, such as appendicitis and polyps, could be diagnosed by coloscopy to avoid undue surgery.

It is reported that 8%-20% of AIs are idiopathic and are more likely to occur in the small intestine<sup>[6]</sup>. In

our series, there were four [9.1% (4/44)] patients whose etiologies were not found by surgical exploration and/or pathology. One of them occurred in the colon (see Tables 1 and 3). Three of them had intestinal necrosis with bleeding. Segments of intestine had to be resected. The only retrograde intussusception found in our patients was cured by simple reduction.

Most AIs have underlying pathological lesions; therefore, most authors agree that laparotomy is mandatory. However, whether or not the intussusception should be reduced before resection remains controversial. The theoretical objections to reductions are intraluminal seeding and venous dissemination of malignant cells, possible perforation during manipulation and increased risk of anastomotic complications in the face of edematous and inflamed bowel<sup>[11]</sup>.

Although only 30% (6/20) of the etiologies of our enteric intussusceptions were malignant, borderline leiomyoma is potentially malignant. Therefore, reduction before resection would be more prudent. We suggest that if the underlying etiology and/or the lead point is suspected to be malignant, or if resected area required without reduction is not massive, an en bloc resection of the intussusception should be considered.

There were only three cases (37.5%) of colocolic intussusceptions caused by a malignant tumor—adenocarcinoma in our series, but most authors report malignant pathology presents in 69%-100%<sup>[3,4]</sup>. Only one case of ileocolic intussusception had a malignant organic lesion (terminal ileum B cell malignant lymphoma) in our series. Wang *et al*<sup>[3]</sup> reported 5/12 patients had malignant lesions in this type of intussusception. They think intraoperative colonoscopy might help to distinguish benign from malignant lesions before reduction. This technique can identify benign lesions of the ileum and be used to perform limited resection with preservation of the antireflux ileocecal valve. Moreover, appendectomy, polypectomy or diverticulectomy might be performed in specific situations to produce an uncompromised bowel after reduction, when definitively diagnosed by coloscopy<sup>[3]</sup>. Our colonoscopies found all (7/7) of the lead point lesions and diagnosed all of the adenoma and adenocarcinomas of non-enteric intussusceptions. In our study, the lesions of appendicitis, benign tumors and polyps might have been diagnosed by coloscopy; organic lesion might have been excluded on the patient who had undergone appendectomy before exploration for intussusception. If coloscopy had been undertaken, unnecessary surgery could have been avoided. Therefore, we consider that in ileocolic, colocolic and sigmoidorectal intussusceptions, coloscopy is necessary, either preoperatively or intraoperatively.

The sigmoidorectal intussusception caused by villous and tubular adenoma of the sigmoid colon in our study was successfully reduced before partial resection of the sigmoid colon and the patient was spared a Miles operation. Zubaidi *et al*<sup>[11]</sup> considered that even if an intussusception of this type is secondary to a carcinoma, to avoid an abdominoperineal resection and a permanent colostomy, reduction should be performed first.

There were three patients in our study who underwent gastrojejunostomy and nasojejunal intubation for enteral nutrition and had efferent loop intussusceptions. All of them were misdiagnosed as gastropexia initially. The tube had been intubated together with a nasogastric tube into the stomach. During the operation, before completion of the gastrojejunostomy, a candy ball enveloped with a perturbed surgery glove finger end, which was tied on the tip of the tube, was put into the efferent loop, then the candy ball was drawn from the outside of the efferent loop more than 40 cm distally to the anastomosis. Gayer et al<sup>5</sup> and Erkan et al<sup>6</sup> also consider intestinal intubation in the etiology of intussusception. However, they did not illuminate the mechanism of it. It is well known that the mucosal and seromuscular layers of the intestine connect loosely with each other. We think that when the candy ball on the tip of the tube is drawn distally, because of friction, the proximal mucosa will be pushed, folded and prolapsed distally. If the muscularis of mucosa is injured, then the distally pushed mucosa will not be able to recover by itself. As a result, the mucosa could prolapse distally and protrude into the intestinal lumen like a ring shaped tumor, and then an intussusception could occur.

In conclusion, AI is an infrequent problem. Most AIs present with subacute and chronic symptoms have intestinal obstructions to various extents. CT is the most effective and accurate diagnostic technique. In the case of a palpable abdominal mass, ultrasonography is also helpful for diagnosis. Enteric intussusception should be reduced when the underlying etiology is suspected to be benign or the resection is massive without reduction. Most lead point lesions of the ileocolic, colocolic or sigmoidorectal intussusceptions can be found by coloscopy. For these types of intussusceptions, coloscopy might provide information allowing the avoidance of unnecessary surgery. Intestinal intubation is the main cause of iatrogenic intussusception and should be avoided.

## COMMENTS

### Background

Intussusception is uncommon in adults. It is estimated that only 5% of all intussusceptions occur in adults and approximately 5% of bowel obstructions in adults are the result of intussusception. Adult intussusception (AI) often presents with nonspecific symptoms. Preoperative diagnosis remains difficult. The extent of resection and whether the intussusception should be reduced remains controversial.

### Research frontiers

Recent researches are focused on accurate preoperative diagnosis and proper treatment of it.

### Innovations and breakthroughs

According to their data, the authors found computed tomography (CT) is the most effective and accurate diagnostic technique. In case of a palpable abdominal mass, ultrasonography is also helpful for diagnosis. Enteric intussusception should be reduced when the underlying etiology is suspected to be benign or the resection is massive without reduction. Most lead point lesions of the ileocolic, colocolic or sigmoidorectal intussusceptions can be found

by coloscopy. For these types of intussusception, coloscopy might provide information that allows avoidance of unnecessary surgery. Intestinal intubation is the main cause of iatrogenic intussusception and should be avoided. They also propose a hypothesis for the occurrence of this kind of intussusception.

### Applications

The authors suggest that all patients presenting with an intestinal obstruction or the patients who are suspected intussusception, have an abdominal CT scan as a regular diagnostic test. In cases with a palpable abdominal mass, ultrasonography should be applied. If non-enteric intussusception is suspected, coloscopy might provide information allowing the avoidance of unnecessary surgery. Enteric intussusception should be reduced when the underlying etiology is suspected to be benign or the resection is massive without reduction. Intestinal intubation should be omitted unless very necessary or carried out very gently or with lubrication.

### Terminology

Intussusception: defined as the telescoping of a segment of the gastrointestinal tract into an adjacent one; enteric intussusception: an intussusception involved only jejunum or ileum is considered an enteric intussusception; ileocolic intussusception: an intussusception that involves the ileum and the colon is designated an ileocolic intussusception; colocolonic intussusception: an intussusception involving only the colon is considered a colocolonic intussusception; sigmoidorectal intussusception: involving the sigmoid colon and rectum; non-enteric intussusception: including ileocolic, colocolonic and sigmoidorectal intussusceptions. Acute symptoms: defined as < 4 d; Subacute symptoms: defined as 4-14 d. Chronic symptoms: defined as > 14 d. Antegrade intussusception: the proximal segment of the bowel telescoped into the lumen of the adjacent distal segment is defined as antegrade intussusception. Retrograde intussusception: the distal segment of the bowel telescoped into the lumen of the adjacent proximal segment is defined as retrograde intussusception.

### Peer review

The authors reviewed 41 cases of adult intussusception. The article is well written and worthy of publication.

## Abstract

Echinococcosis is a cyclozoanosis characterized by cystic lesions usually situated inside or outside the liver. We discuss the case of a 77-year-old woman with a recurrent hydatidosis with a cyst arising from the liver, growing through the lateral right abdomen wall, and reaching the subcutaneous tissue of the lumbar region. In the literature, rare subcutaneous or muscular localizations of hydatid cysts are described, however, there is no mention of a cyst growing over the abdominal wall muscles, shaped like an hourglass, partially in the liver and partially in the subcutaneous tissue, as in our case. We have not found any pathogenetic explanation for this growth pattern which is not typical of the biological behaviour of a hydatid cyst.

## INTRODUCTION

Hydatid disease is a cyclozoanosis caused by *Echinococcus granulosus* or *Echinococcus multilocularis*, and is characterized by cystic lesions usually situated in the liver. These lesions can be asymptomatic for a long time, or cause an ache, however, there are no specific local or general symptoms and signs are related to size, location or complications of the cyst. The case of recurrent hydatidosis in a 77-year-old woman is discussed where the cyst, probably arising from the liver, grew through the lateral right abdomen wall and reached the subcutaneous tissue of the lumbar region.

## CASE REPORT

A 77-year-old woman was evaluated due to of the growth of an aching mass in the right lumbar region. Three years previously surgery was performed for hydatidosis of the mesentery. Objective examination revealed a painful swelling mass in the right lumbar region about 7-8 cm in diameter and mobile with respect to the upper and lower layers, which had distinct margins and a smooth surface (Figure 1). On palpating the abdomen the patient had pain in the right upper abdominal quadrant. CT of the abdomen showed a voluminous low-density mass (74 cm × 58 mm) in the low-external side of the VI liver segment. The mass was pedunculated, growing over the right posterior abdominal wall muscles and reaching the subcutaneous tissues (Figure 2).

Surgical treatment confirmed that the voluminous cyst was connected to the VI liver segment by a peduncle. Growing sideways and then behind, this mass reached the muscular layer arriving at the subcutaneous tissue of the right lumbar region. The mass was removed from the perihepatic side of the peduncle, 2-3 cm inside the liver, and from the abdominal external oblique muscle and the latissimus dorsi up to the subcutaneous tissue of the lumbar region (Figure 3). The post-operative period was problem-free, and the patient was discharged after 1 wk on anti-helminthic therapy. Histology confirmed the suspicion of hydatid cyst.

## DISCUSSION

Hydatid disease is caused by *Echinococcus granulosus*, an endemic infection in several mediterranean countries, or by *Echinococcus multilocularis*. Hydatid cysts can

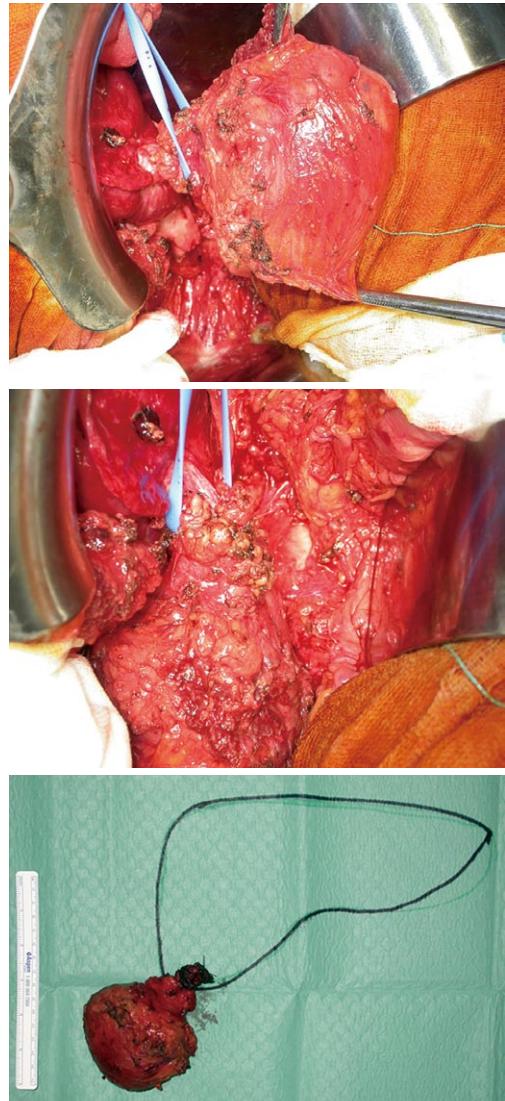

**Figure 1** Mass in the right lumbar region.

**Figure 2** CT. The mass and the peduncle which connected it to the liver, as shown by the scheme with the surgical specimen.

be observed in all parts of the body, but are more frequent in the liver (50%-70%), lung (20%), and spleen (5%-8%)<sup>[1]</sup>, while rare localizations are the kidneys, adrenal glands<sup>[2]</sup>, spleen, soft tissues and brain<sup>[3]</sup>.

Echinococcosis may be asymptomatic, detected only when imaging scans of the liver are carried out for different reasons, but it may cause pain or lead to complications. Cysts can rupture into the peritoneum, resulting in anaphylaxis or peritonitis<sup>[4]</sup>, or into the biliary tract, causing cholangitis or cholestasis, and into the bronchi, causing bronchial fistula, or the cysts may become infected and form liver abscesses. Compression of the bile duct, portal vein, and hepatic veins can cause cholestasis, portal hypertension, and Budd-Chiari syndrome, respectively<sup>[5]</sup>.

**Figure 3** Pedunculated mass arising from the sixth liver segment and growing over the posterior abdominal wall muscles and reaching the subcutaneous tissue.

The diagnosis of hydatid cysts relies on epidemiologic data (geographical location and profession) clinical manifestations, serologic tests and radiologic imaging.

The treatment of choice is surgery. Chemotherapy (albendazole and mebendazole) is currently indicated in patients who cannot undergo major operations or for the prevention of secondary echinococcosis after surgery<sup>[6]</sup>, but is contraindicated for large, superficially situated, or infected cysts, which are prone to rupture<sup>[7,8]</sup>.

Our case shows some particular features that deserve closer examination. Usually the hydatid cyst grows in the liver in every direction, both inside the hepatic parenchyma and outside towards the peritoneal cavity. In our case, the cyst was connected to the liver by a peduncle 3-4 cm inside the liver. The surgeon who operated on our patient three years previously informed us of two hydatid cysts (diameter 9 cm and 12 cm) located in the mesocolon, which were connected by a peduncle, making it easy to remove them without spreading the disease. The hypothesis that the cyst we treated could have been a secondary echinococcosis due to spillage

of cystic fluid and seeding during the first operation<sup>[5]</sup> has been denied. In the literature, rare subcutaneous or muscular localizations of hydatid cysts have been described<sup>[9]</sup>, however, a cyst growing over the abdominal wall muscles, shaped like an hourglass, partially in the liver and partially in the subcutaneous tissue, as in our case has never been described. This growth pattern is not typical of the biological behaviour of a “benign tumor” such as a hydatid cyst, and seems to be more similar to the behaviour of an infiltrating malignant neoplasm. The only plausible explanation is that it could be related to seeding during the first surgery through drainage, however, the only drainage after the first surgery was located in the right lower abdominal quadrant, far away from the lumbar localization of the cyst we treated.

In the literature, Parmar *et al*<sup>[10]</sup> reported a case showing some similarities to our patient: a hepatic hydatid cyst which had ruptured into the subcutaneous tissue of the anterior abdominal wall. While the superficial and subcutaneous localization of the mass was similar, its connection with the right lobe of the liver was different. In Parmar's case the right lobe of the liver was almost entirely occupied by the cyst, in our case the cyst was connected only by a peduncle. Parmar did not suggest any pathogenetic explanation, but just describes the kind of rupture that can involve a hydatid cyst.

In conclusion, we have not found any evidence in the literature for a pathogenetic explanation for the growth of the hydatid cyst over the abdominal wall muscles, shaped like an hourglass, partially in the liver and partially in the subcutaneous tissue. A similar growth pattern may occur in cysts found in the liver cupola where they can damage the diaphragm through inflammatory processes. The cysts then grow towards the pleural opening to the bronchial tubes, resulting in an uncommon and severe complication,

a hydatid bronchobiliary fistula. In this situation the pathogenetic mechanism is clearly caused by the infective process resulting in adhesions in the diaphragm. In our case no infective process was present, the cyst was connected to the liver by a peduncle which was easily removed from the transverse colon and from the muscles.

### INTRODUCTION

Proteus syndrome is an extremely rare disorder characterized by postnatal overgrowth of multiple tissues derived from different cell lineage<sup>[1-3]</sup>. The patient with Proteus syndrome described in this paper experienced constipation, nausea, vomiting, and abdominal pain due to the encasement and pressure of the intestinal tract by a large fatty mass which had developed in the left abdominal wall. The excision of this mass improved the symptoms.

### CASE REPORT

A 4-year-old female underwent a resection of a soft mass in her left inguinal area. This mass was pathologically diagnosed to be a lipoma. She was sent to the Department of Orthopedic Surgery because the lesion recurred and spread to the surrounding area. The recurrent tumors in her left inguinal area, left thigh and knee increased in size, and additional excisions were performed when the patient was 8- and 11-years-old. The pathological diagnosis was an infiltrating lipoma. She was diagnosed to have Proteus syndrome based on the diagnostic criteria reported<sup>[2-4]</sup>. The neoplasm increased in size gradually, and produced hemihypertrophy of the left lower extremity and trunk, and spread to the left abdominal wall and the retroperitoneum. Since the increasing abdominal mass encased and pressed the digestive organs, she gradually developed constipation. Bowel movements occurred about once a week at the time of presentation. A bowel obstruction caused symptoms including constipation, nausea, vomiting and abdominal pain. She had two healthy sisters and the rest of her family were also healthy. She had iron-deficient anemia with hypermenorrhea and she had a

### Abstract

Proteus syndrome is an extremely rare congenital disorder that produces multifocal overgrowth of tissue. This report presents a surgical case of a large lipoma in the abdominal wall of a patient with Proteus syndrome. She was diagnosed with Proteus syndrome based on certain diagnostic criteria. The neoplasm increased in size gradually, producing hemihypertrophy of her left lower extremity and trunk, and spread to her retroperitoneum and her left abdominal wall. She experienced gradually progressive constipation, nausea, vomiting, and abdominal pain. Computed tomography (CT) of the abdomen demonstrated a large mass in the subcutaneous adipose tissue of the left lower abdominal wall which measured 12 cm × 8 cm × 6 cm in diameter and encased the left colon. This mass in the abdominal wall was excised. The weight of the excised mass was 1550 g. The histopathological diagnosis of this mass was lipoma. After surgery, the encasement of the left colon was improved, and the patient was able to move her bowels twice per day. The excision of the large lipoma in the abdominal wall contributed to the improved bowel passage in this patient with Proteus syndrome.

**Key words:** Proteus syndrome; Lipoma; Bowel obstruction; Abdominal wall; Bowel passage

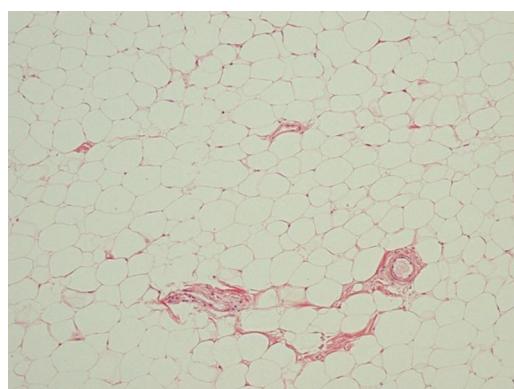

**Figure 1 Clinical findings of the abdomen.** There was a child-head sized mass at the left lower abdomen (arrows).

**Figure 2 A preoperative plain abdominal X-ray examination indicated that colon gas in the left colon (arrows) was shifted to the upper right side.**

**Figure 3 Preoperative computed tomography (CT) of the abdomen.** A large mass in the subcutaneous adipose tissue in the left lower abdominal wall was identified (arrows) and this encased the peritoneal organs to the right side.

**Figure 4 Histopathological findings of the excised mass.** Lobular arrangement of mature adipocytes diffusely infiltrating into the skeletal muscle was observed.

transfusion history. On physical examination, she had a temperature of 36.4°C, and blood pressure of 120/70 mmHg. A large mass with unclear margins was found in the left lower quadrant of her abdominal wall (Figure 1). She showed hemihypertrophy and deformity of her left lower extremity. There were large and bizarre skin tumors on her left lower extremity.

Laboratory data showed a white blood cell count of 4800 cells/mm<sup>3</sup>, hemoglobin 7.7 g/dL, hematocrit 25%, platelets 321 000 cells/mm<sup>3</sup>, normal electrolytes and blood urea nitrogen, and the liver function was normal.

A plain abdominal X-ray examination indicated scoliosis and deformity of the pelvic bone. Colon gas in the left colon shifted to the right upper side (Figure 2). Computed tomography (CT) of the abdomen demonstrated a large mass in the subcutaneous adipose tissue at the left lower abdominal wall which was 12 cm x 8 cm x 6 cm in diameter and encased the peritoneal organs to the right side (Figure 3). An upper gastrointestinal series revealed a mass encasing the stomach toward the upper side and the small intestine toward the right upper side (data not shown).

The mass in the abdominal wall was excised in 1997. The weight of the excised mass was 1550 g. A histopathological examination revealed a lobular arrangement of mature adipocytes (Figure 4), and these cells diffusely invaded into the skeletal muscle.

These findings indicated the diagnosis of a non-malignant lipoma.

The postoperative course was uneventful, the encasement of the left colon was improved, and she left the hospital on the 15th postoperative day. At present, she continues to receive medical treatment on an outpatient basis. Postoperatively, bowel movement occurred twice a day. A postoperative plain X-ray examination indicated that the shift of the left colon gas was improved (Figure 5). Postoperative CT also revealed reduced encasement of the peritoneal organs (Figure 6).

## DISCUSSION

Wiedermann *et al*<sup>[2]</sup> proposed diagnostic criteria for Proteus syndrome: (1) gigantism of the hands and/or feet, (2) pigmented nevus, (3) hemihypertrophy, (4) subcutaneous tumors, (5) skull anomalies, (6) accelerated growth and (7) visceral abnormalities. Recently, the main diagnostic criteria for Proteus syndrome are that it is sporadic, mosaic and has a progressive course<sup>[3]</sup>. The current case presented with lipomatosis, severe hemihypertrophy of the left trunk and left lower extremity, scoliosis, endometriosis and huge bizarre-shaped body tumors. Consequently, this patient was diagnosed to have Proteus syndrome based on the above-mentioned diagnostic criteria<sup>[5]</sup> and was the 6th

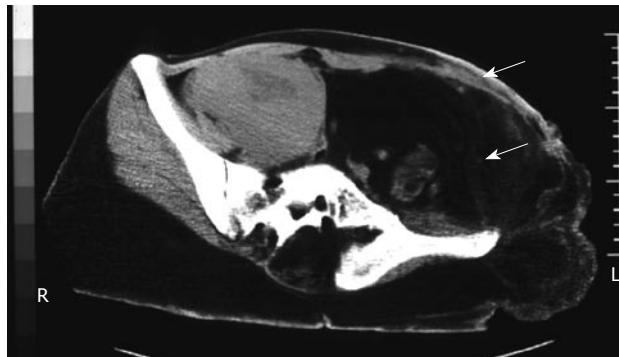

**Figure 5** A postoperative plain abdominal X-ray examination indicated that the shift of the left colon gas (arrows) was improved as compared to the preoperative state.

Japanese case described in the English literature<sup>[5-9]</sup>.

This syndrome is caused by the germline loss of functional mutations in PTEN<sup>[10]</sup> and is an overgrowth syndrome<sup>[11]</sup>. PTEN acts as a negative regulator of PI3-kinase signaling by catalyzing the dephosphorylation of PIP3<sup>[12,13]</sup>. This case was diagnosed based on the previous criteria for Proteus syndrome<sup>[2-4]</sup>, and the germline mutation in PTEN was not examined.

Lipomatosis of the colon complicating Proteus syndrome was reported previously<sup>[14]</sup>. A 12 year-old boy with Proteus syndrome presented with gross abdominal distension and severe intractable constipation. Magnetic resonance imaging showed adipose tissue widely spread throughout the abdomen and pelvis. A laparotomy revealed a huge infiltrating lipomatosis encasing the left colon, including the rectum. On the other hand, the symptoms of bowel obstruction in the current case may have been caused by the encasement and pressure of the intestinal tract by a child-head sized lipoma that developed in the left abdominal wall. This lipoma was excised from the abdominal wall and removal of this huge lipoma produced the improvement in the patient's symptoms.

Proteus syndrome is a complex disorder associated with varied, disproportionate, asymmetric overgrowth of many body parts and unregulated adipose tissue. The overgrowth seen in Proteus syndrome is progressive and difficult to manage. Patients with Proteus syndrome require repeated treatment for the progressive overgrowth of tissue over a long period. Aggressive treatment may cause severe functional and cosmetic consequences, so surgical intervention is often delayed until it is absolutely necessary<sup>[15]</sup>. In the current case, other sites of the lipomatosis, such as the left extremity and back, were excised when it affected the patient's quality of life. This report presented an extremely rare case of bowel obstruction due to a large lipoma in the abdominal wall. The excision of this large mass improved the bowel passage in a patient with Proteus syndrome.

**Figure 6** Postoperative CT of the abdomen. The encasement of the peritoneal organs was improved as compared to the preoperative state (arrows).

## INTRODUCTION

### Abstract

A granular cell tumor (GCT) is a benign neoplasm of unclear histogenesis that is generally believed to be of nerve sheath origin. GCT is not common and most often affects the tongue, skin and soft tissue, although it may occur anywhere in the body. We experienced a case of GCT that arose in the cecum of a 55-year-old man. The GCT was removed by laparoscopic resection. In addition to the tumor, endoscopic examination revealed the presence of a 5-mm-polyp in the descending colon and multiple tiny polyps in the sigmoid colon and rectum. Histological examination demonstrated a cecal tumor 1.5 cm × 1.0 cm × 0.7 cm with a hard consistency; in cut sections, mixed cells with yellowish and whitish portions were seen. The tumor was located between the mucosa and subserosa, and was composed of plump histiocyte-like tumor cells with abundant granular eosinophilic cytoplasm, which were immunoreactive for S-100 protein, vimentin, neuron-specific enolase, inhibin- $\alpha$  and calretinin. The tumor showed extensive hyalinization and focal dystrophic calcification. Immunohistochemical profiles did not confirm any particular cell type for the histogenetic origin of the GCT, including a nerve sheath origin. Extensive hyalinization and calcification showing involution of tumor cells suggest benign clinical behavior of GCT.

## CASE REPORT

A 56-year-old man was admitted to the Gastroenterology Department of Chosun University Hospital with a 2-mo history of abdominal pain and diarrhea. Colonoscopy

**Figure 1** Endoscopic examination revealed an approximately 2-cm-sized protruding mass in the cecum.

revealed a protruding mass approximately 2 cm in diameter, with central umbilication in the cecum (Figure 1), as well as a 5-mm polyp and tiny sized multiple polyps in the descending colon and rectum, respectively.

A polyp in the descending colon was removed by snare polypectomy, and the polyp was diagnosed histologically as tubular adenoma. The cecal mass was resected by laparoscopic myotomy. Grossly, the mass was 1.5 cm × 1.0 cm × 0.7 cm, yellowish-white in color, and hardly palpable. Microscopically, the well-circumscribed mass was located mainly between the submucosa and subserosa, with partial involvement of the mucosa (Figure 2A). The mass was composed of round to polygonal cells with abundant granular eosinophilic cytoplasm. Characteristically, much of the tumor showed extensive hyalinization and focal dystrophic calcification (Figure 2B and C). There was no tumor necrosis, spindling and vesicular nuclei with large nucleoli, increased mitotic activity, a high nuclear to cytoplasmic ratio, and pleomorphism. The tumor was seen as a small, well-circumscribed mass, but with no infiltrative growth pattern; findings that favor a benign rather than a malignant lesion. Immunohistochemical analysis demonstrated that the tumor cells were reactive for S-100 protein (Figure 2D), neuron-specific enolase (NSE), vimentin, calretinin and inhibin (Figure 3). The tumor cells were non-reactive for smooth muscle actin (SMA), c-kit (CD117) and CD34. Based on the morphological and immunohistochemical findings, the resected tumor was diagnosed as a benign GCT that occurred in the cecum.

## DISCUSSION

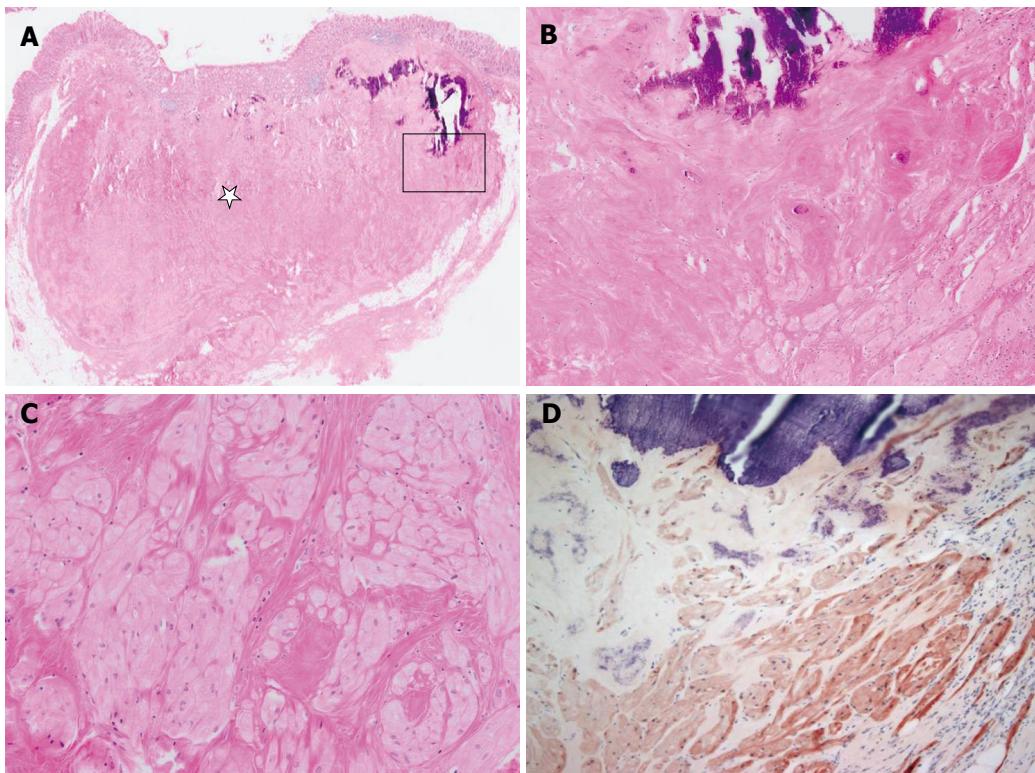

GCT is diagnosed only rarely, based on macroscopic and endoscopic examinations, as a result of its small size and shape that resemble a diminutive polyp<sup>[12]</sup>. Recently, endoscopic ultrasonography (EUS) has been used more frequently to determine the depth of tumor invasion in the gastrointestinal wall, and, it is useful for evaluating gastrointestinal tract submucosal tumors<sup>[13]</sup>. However, EUS cannot sufficiently distinguish a benign submucosal tumor from other tumors such as malignant neoplasia<sup>[14]</sup>.

The final diagnosis of GCT is dependent on the pathological findings. The histological markers for GCT are plump histiocyte-like, bland-looking neoplastic cells

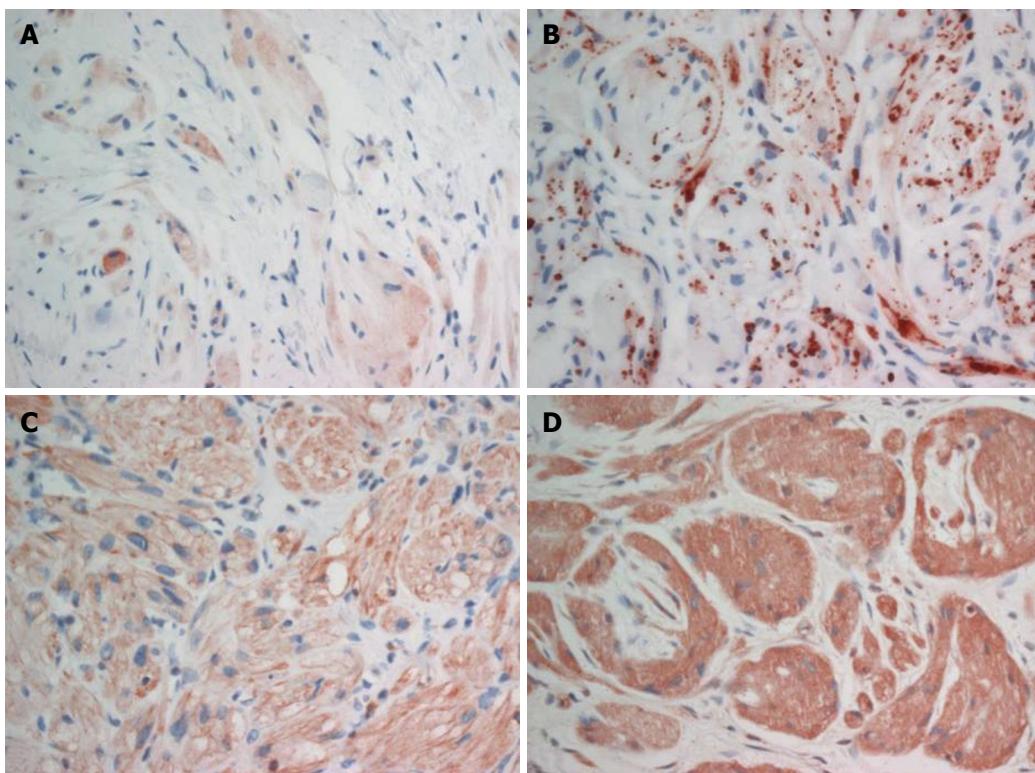

with abundant granular eosinophilic cytoplasm, which contains acidophilic, periodic acid-Schiff-positive, diastase-resistant granules. The cells contain small, uniform nuclei where mitotic figures are absent and neural markers, including S-100 protein or NSE, are expressed uniformly<sup>[15,16]</sup>.

The histogenesis of GCT has remained enigmatic in spite of a vast number of immunohistochemical and ultrastructural studies<sup>[7]</sup>. Neural origin or differentiation, in particular of the Schwann cell type, is currently in favor. However, recent findings have cast doubt on the neural origin of these tumors<sup>[7]</sup>. Vered *et al*<sup>[7]</sup> have suggested that immunoreactivity of the granular cells to a broad panel of antibodies including S-100 protein, CD68, vimentin, calretinin, NKI/C3, protein gene product 9.5, nerve growth factor receptor and inhibin- $\alpha$  that characterize different tissue do not confirm any particular cell type for the histogenesis of GCT. In the present case, tumor cells were reactive for S-100 protein, NSE, calretinin, vimentin, and inhibin- $\alpha$ , which agrees with a previous study<sup>[7]</sup>.

In most cases of colonic GCT, the tumor was less than 2 cm and well separated from the muscularis propria<sup>[17]</sup>. Since this tumor is considered as benign, and no patients with recurrence or metastasis have been documented, it is usually accepted that endoscopic tumor excision may be the best treatment for GCT in the gastrointestinal tract<sup>[14]</sup>. However, Nakachi *et al*<sup>[14]</sup> have suggested that GCT in the gastrointestinal tract is usually small and asymptomatic, and the tumor tends to be found incidentally during endoscopy performed for other reasons. Observation of these GCTs with the use of endoscopy and EUS is indicated unless the patient is symptomatic, or the tumor is larger than 2 cm or demonstrates atypical EUS or histological features. In the present case, there was extensive hyalinization and focal dystrophic calcification of tumor cells, which indicated a long-standing tumor with no atypical changes, which supports the above description. Vered *et al*<sup>[7]</sup> have advocated that GCT can be regarded as a lesion that reflects local metabolic or reactive changes rather than a true neoplasm. In the large series of GCTs evaluated by Vered *et al*<sup>[7]</sup>, lesions displayed three main architectural patterns, including small and well-circumscribed nodules, larger and poorly circumscribed lesions, and an impressive infiltrative pattern with remote satellite nodules. The pattern of small and well-circumscribed nodules may represent benign mesenchymal tumors that have undergone extensive or complete granular cell change, and the remaining patterns may be compatible with a diffuse process of metabolically induced cytoplasmic granular changes in mesenchymal cells. Most lesions with an infiltrative pattern and positive margin almost never recur, whereas for a definite tumor, recurrent lesions are expected. It has been suggested that the lesions may be metabolic or reactive in nature and not neoplastic. The present case displayed extensive hyalinization and calcification in between granular cells, which suggestss a long duration; findings that favor GCT with reactive changes, or a true neoplasm.

**Figure 2** Microscopically and immunohistochemically, the appearance of the tumor was compatible with that of granular cell tumor. A: The tumor was located mainly between the submucosa and the subserosa. Much of the tumor showed extensive hyalinization (star) and dystrophic calcification. B and C: A high magnification view (square of A) showed dystrophic calcification, hyalinization and some viable tumor cell nests in the peripheral portion of the tumor. The tumor cells were composed of round to polygonal cells with abundant granular eosinophilic cytoplasm. D: Immunohistochemically, tumor cells were reactive for S-100 protein.

**Figure 3** Tumor cells of the granular cell tumor were immunoreactive for inhibin- $\alpha$  (A), calretinin (B), vimentin (C) and NSE (D).

Several GCTs with adjacent benign or malignant tumors have been reported previously. In 2006, Eriksen *et al*<sup>[18]</sup> reported the first case of a synchronous adenoma

and GCT, and Sarsik *et al*<sup>[19]</sup> also observed a tubular adenoma in the vicinity of a GCT. Caltabiano *et al*<sup>[20]</sup> reported a GCT covered by squamous cell carcinoma

of the tongue. The present case also had adjacent multiple polyps, including tubular adenoma. Based on these findings, it is suggested that GCT shows reactive granular cell changes in the process of spontaneous regression of a preceding tumor. The coincidence of the adjacent tumor can be regarded as favoring a non-neoplastic or reactive process. However, to date, there is no evidence of any association or disposing factors between GCT in the colon and colonic adenoma or other malignancy<sup>[18]</sup>.

In summary, we experienced a 1.5 cm × 1.0 cm × 0.7 cm cecal GCT that showed extensive hyalinization and focal dystrophic calcification with synchronous tubular adenoma in the descending colon. Immunohistochemical profiles did not confirm any particular cell type for the histogenesis of GCT. Endoscopists and pathologists should consider the possibility of this tumor in the gastrointestinal tract. When a patient is asymptomatic, and unless the tumor is larger than 2 cm or shows atypical features, observation of this tumor with the use of endoscopy and EUS is indicated.

### INTRODUCTION

Hemangiomas of the large intestine are relatively

uncommon benign tumors which can occur anywhere in the gastrointestinal tract<sup>[1]</sup>. These are clinically important vascular malformations because of the possibility of massive bleeding. Although a variety of histological and clinical types of hemangioma exist, the cavernous and capillary subtypes are most commonly encountered. Recent advances in colonoscopic techniques have led to successful endoscopic resection in selected cases<sup>[2-4]</sup>, but most large lesions have been treated surgically<sup>[5,6]</sup>. We report the case of a large cavernous hemangioma in the cecum with pericolic infiltration which was removed successfully using minimally invasive surgery.

### CASE REPORT

A 37-year-old woman was referred to her local hospital because of intermittent rectal bleeding. Colonoscopy revealed a blue polypoid lesion with a nodular surface in the cecum (Figure 1). A hemangioma was suspected. She was transferred to our hospital for further evaluation and surgical treatment.

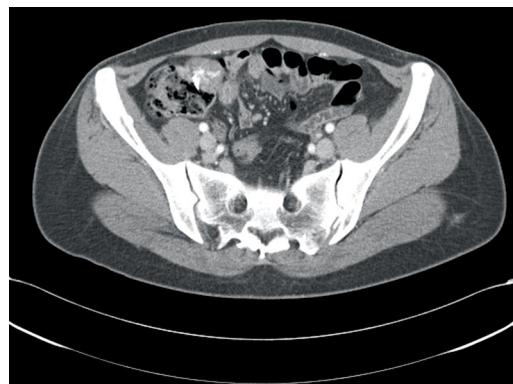

The physical examination revealed no specific signs. Abdominopelvic computed tomography (CT) showed a lesion in the cecum protruding extraluminally with heterogeneous enhancement (Figure 2). The operative findings suggested a tumor involving the cecum and extending into the pericolic fat. Laparoscopic-assisted ileocecal resection and side-to-end ileo-ascending colon anastomosis were carried out. Macroscopically, the surgical specimen was a 5.8 cm × 4.2 cm cavernous hemangioma involving the entire wall of the colon and extending into the pericolic fat (Figure 3). Microscopically, the tumor consisted of large, dilated, blood-filled vessels lined by flattened endothelium. The vascular walls were thickened focally by adventitial fibrosis (Figure 4). Postoperatively, the patient has recovered well with no recurrence of symptoms.

### DISCUSSION

Hemangiomas are rare lesions of the colon, but vascular malformations of the gastrointestinal tract have been reported since 1839<sup>[7]</sup>. According to the literature, these lesions originate from embryonic sequestrations of mesodermal tissue<sup>[8]</sup>. Histologically, hemangiomas are distinct from telangiectasias and angiomyolipomas, and most colonic hemangiomas are the capillary or

**Figure 1** Colonoscopy of the cecum showing a bluish nodular lesion.

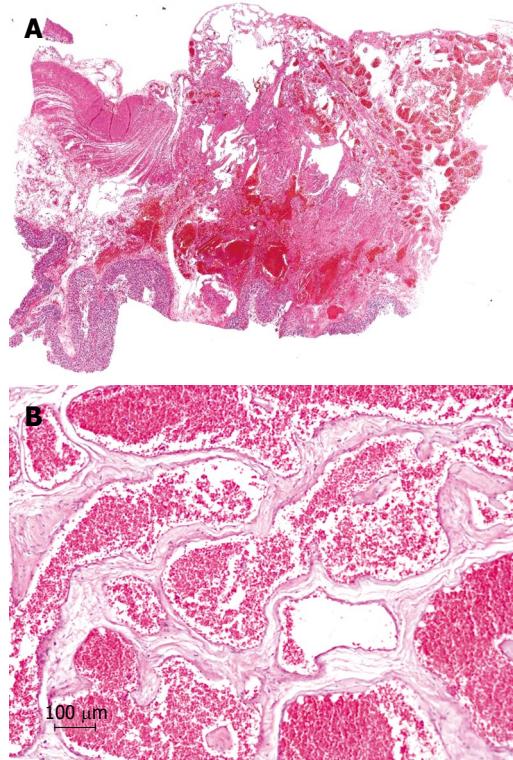

**Figure 2** Abdominopelvic computed tomography showing a lesion in the cecum protruding extraluminally with heterogeneous enhancement.

**Figure 3** Macroscopically, the surgical specimen was a cavernous hemangioma.

cavernous subtype. Capillary hemangiomas consist of a proliferation of small capillaries composed of thin-walled spaces lined by endothelial cells, while cavernous hemangiomas consist of large spaces lined by single or multiple layers of endothelial cells<sup>[9]</sup>. The capillary subtype is usually solitary and causes no symptoms, while the cavernous subtype presents with bleeding (60%-90%), anemia (43%), obstruction (17%), and, rarely, with platelet sequestration, although approximately 10% of patients remain asymptomatic<sup>[10]</sup>. The endoscopic findings of hemangiomas of the colon vary. Grossly, hemangiomas appear as soft, compressible bluish or deep red submucosal lesions, with dilated, engorged veins in the rectal wall<sup>[5]</sup>. However, they can be difficult to diagnose in some cases, especially if the hemangioma has an unusual color or is covered. A histological diagnosis before treatment may be difficult because of the risk of uncontrollable bleeding following a biopsy<sup>[1,4]</sup>. Hence, these lesions should not be biopsied. Abdominal CT can provide useful information about the size of the lesion and its extension to adjacent organs. Visceral angiography may also be useful in excluding coexisting hemangiomas at other sites in the gastrointestinal tract<sup>[5]</sup>.

Complete surgical resection is the best treatment for large or diffuse lesions<sup>[5]</sup>, although endoscopic resection has sometimes been recommended for hemangiomas that are pedunculated, polypoid, small, and limited

**Figure 4** HE staining of the hemangioma. A: Histological section showing large, dilated, blood-filled vessels lined by flattened endothelium (HE,  $\times 1$ ); B: The vascular walls were thickened focally by adventitial fibrosis (HE,  $\times 100$ ).

to the submucosal layer according to endoscopic ultrasonography<sup>[4]</sup>. Polypoid hemangiomas sometimes involve the entire wall of the colon, extending through the mesocolon and mesentery, as in our case<sup>[5]</sup>. In summary, we performed laparoscopic resection of a large cavernous hemangioma in the cecum. Although these lesions are rare, a better understanding of these lesions should help to obtain a definite diagnosis and devise an appropriate treatment plan.

### TO THE EDITOR

Hepatic retransplantation (HR) is a major challenge due to inferior results when compared to primary transplantation, ethical questions related to the use of a limited resource, major economic costs, and more demanding surgical techniques<sup>[1,2]</sup>. Arterial revascularization of a graft can be challenging, especially if hepatic artery thrombosis or vascular abnormalities are present<sup>[3,4]</sup>.

The chronic shortage of cadaveric livers has led surgeons to alternative approaches, namely split-liver<sup>[5]</sup> and living-related transplantation<sup>[6]</sup>, which are now routinely performed, but almost exclusively for primary liver transplantation.

According to UNOS data, of the HRs performed between 1996 and 2007, only 8.7% were done using right or extended right grafts from deceased donors, and 14.3% using right grafts from live donors<sup>[7]</sup>.

In our institute, as well as in most European centers, both the right lobe from a living donor and the right extended graft from the deceased donor are procured with only the right branch of the hepatic artery for arterial supply. When a right partial graft is transplanted, the need to use the right branch of the hepatic artery instead of the entire hepatic artery, or the celiac trunk, or the aortic patch, can discourage surgeons from considering the possibility of an interposition graft.

Here we report our experience with 5 HRs in which right partial grafts resulting from conventional *in situ* extended right graft split livers (ERSL), and one right lobe resulting from an adult-to-adult living-related transplant (LRLT) were used.

For arterial reconstruction, we used, in the first case, an end-to-end anastomosis between the right branch of the ERSL and the recipient proper hepatic

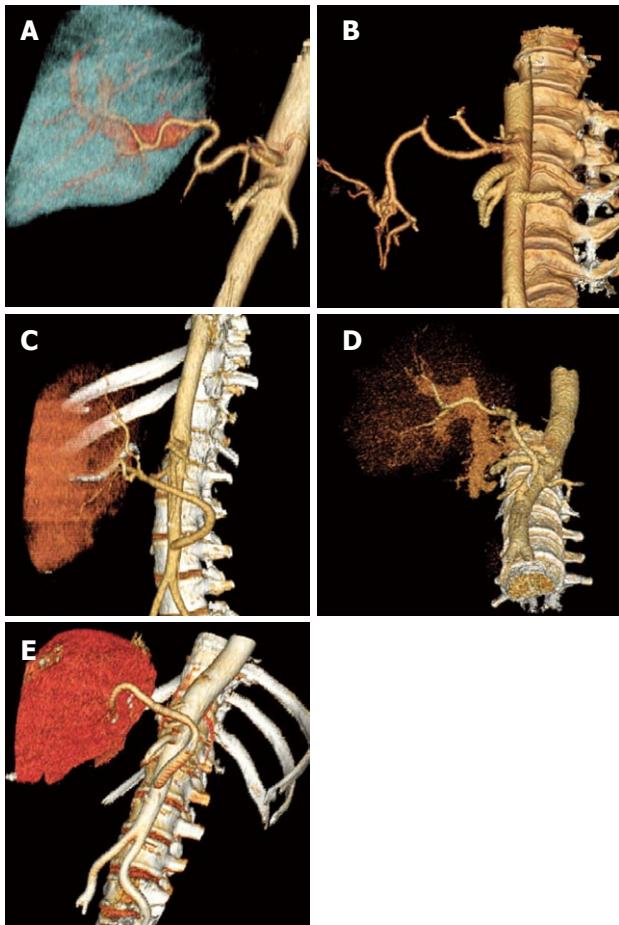

### Abstract

Though split-liver and living-related transplantation are routinely performed, they are done almost exclusively for primary liver transplantation because of potential surgical difficulties. These difficulties are generally related to arterial revascularization, particularly if there is hepatic artery thrombosis. According to UNOS data, of the hepatic retransplantations performed between 1996 and 2007, only 8.7% were done using right or extended right grafts from deceased donors, and 14.3% using right grafts from live donors. Here we report our experience with 5 hepatic retransplantations in which right partial grafts resulting from conventional *in situ* splits, and one right lobe resulting from an adult-to-adult living-related transplant, were successfully used with different modalities of graft arterialization.

**Figure 1 Arterial Reconstruction.** A: End-to-end anastomosis between the right branch of the extended right graft split livers (ERSL) and the recipient proper hepatic artery in a patient who needed retransplantation after living-related transplant (LRLT); B: End-to-end anastomosis between the right branch of the ERSL and recipient splenic artery in a patient transplanted because of hepatic artery thrombosis after LRLT; C: Cadaveric donor iliac interposition graft between the infra renal aorta and the right branch of the LRLT in a patient who had hepatic artery thrombosis after the standard primary transplant; D: Arterial revascularization using a cadaveric donor iliac interposition graft between the infra renal aorta and the right branch of the ERSL; E: Cadaveric donor iliac interposition graft between the infra renal aorta and the right branch of the ERSL.

artery in a patient who needed retransplantation after LRLT (Figure 1A). In the second case, we performed an end-to-end anastomosis between the right branch of the ERSL and the recipient splenic artery in a patient transplanted because of hepatic artery thrombosis after LRLT (Figure 1B). In the third case, a living-related transplant involving a patient who had hepatic artery thrombosis after the standard primary transplant, the arterial reconstruction was obtained using a cadaveric donor iliac interposition graft between the infra renal aorta and the right branch of the right lobe (Figure 1C). In the fourth case, an ERSL was used to re-transplant a patient having undergone a standard primary liver transplant. In this case, arterial revascularization was obtained using a cadaveric donor iliac interposition graft between the infra renal aorta and the right branch of

the ERSL (Figure 1D). In the last case, after the failure of an LRLT, an ERSL was used, with the need again for a cadaveric donor iliac interposition graft between the infra renal aorta and the right branch of the ERSL (Figure 1E). All the patients here reported received a mean follow-up of 28 mo (3-42) and are alive and free of biliary complications, or required relaparotomy due to graft loss.

The HR rate in our center is 8.6% out of a total of 580 liver transplants performed since 1999. Recipients are considered candidates for HR if they fit our listing criteria for primary transplantation. During HR, from a technical stand point, we always perform the standard technique with the use of veno-venous bypass. Portal vein and hepatic artery reconstruction are realized according to the vascular anatomy of each single patient. Vessel mismatch is not problematic when a wider iliac graft, which does not require spatulating or modifying in any way the larger artery, is used.

In regions like ours, with a rate of 9.3 cadaveric donor pmp, the chance of using right partial graft gave us the possibility to re-transplant patients that otherwise could not be cured. Although the surgical technique of arterial reconstruction here described is not a novelty, it should be emphasized that right partial grafting for HR achieves good results and allows optimization of a limited resource.

## Meetings

### Events Calendar 2009

January 12-15, 2009  
Hyatt Regency San Francisco, San Francisco, CA  
Mouse Models of Cancer

January 21-24, 2009  
Westin San Diego Hotel, San Diego, CA  
Advances in Prostate Cancer Research

February 3-6, 2009  
Carefree Resort and Villas, Carefree, AZ (Greater Phoenix Area)  
Second AACR Conference  
The Science of Cancer Health Disparities in Racial/Ethnic Minorities and the Medically Underserved

February 7-10, 2009  
Hyatt Regency Boston, Boston, MA  
Translation of the Cancer Genome

February 8-11, 2009  
Westin New Orleans Canal Place, New Orleans, LA  
Chemistry in Cancer Research: A Vital Partnership in Cancer Drug Discovery and Development

February 13-16, 2009  
Hong Kong Convention and Exhibition Centre, Hong Kong, China  
19th Conference of the APASL  
<http://www.apasl2009hongkong.org/en/home.aspx>

February 27-28, 2009  
Orlando, Florida  
AGAI/AASLD/ASGE/ACG Training Directors' Workshop

February 27-Mar 1, 2009  
Vienna, Austria  
EASL/ AASLD Monothematic: Nuclear Receptors and Liver Disease  
[www.easl.ch/vienna2009](http://www.easl.ch/vienna2009)

March 13-14, 2009  
Phoenix, Arizona  
AGAI/AASLD Academic Skills Workshop

March 20-24, 2009  
Marriott Wardman Park Hotel  
Washington, DC  
13th International Symposium on Viral Hepatitis and Liver Disease

March 23-26, 2009  
Glasgow, Scotland  
British Society of Gastroenterology (BSC) Annual Meeting  
Email: bsg@mailbox.ulcc.ac.uk

April 8-9, 2009  
Silver Spring, Maryland  
2009 Hepatotoxicity Special Interest Group Meeting

April 18-22, 2009  
Colorado Convention Center, Denver, CO  
AACR 100th Annual Meeting 2009

April 22-26, 2009  
Copenhagen, Denmark  
the 44th Annual Meeting of the European Association for the Study of the Liver (EASL)  
<http://www.easl.ch/>

May 17-20, 2009  
Denver, Colorado, USA  
Digestive Disease Week 2009

May 29-June 2, 2009  
Orange County Convention Center Orlando, Florida  
45th ASCO Annual Meeting  
[www.asco.org/annualmeeting](http://www.asco.org/annualmeeting)

May 30, 2009  
Chicago, Illinois  
Endpoints Workshop: NASH

May 30-June 4, 2009  
McCormick Place, Chicago, IL  
DDW 2009  
<http://www.ddw.org>

June 17-19, 2009  
North Bethesda, MD  
Accelerating Anticancer Agent Development

June 20-26, 2009  
Flims, Switzerland  
Methods in Clinical Cancer Research (Europe)

June 24-27 2009  
Barcelona, Spain  
ESMO Conference: 11th World Congress on Gastrointestinal Cancer  
[www.worldgicancer.com](http://www.worldgicancer.com)

June 25-28, 2009  
Beijing International Convention Center (BICC), Beijing, China  
World Conference on Interventional Oncology  
<http://www.chinamed.com.cn/wcio2009/>

July 5-12, 2009  
Snowmass, CO, United States  
Pathobiology of Cancer: The Edward A. Smuckler Memorial Workshop

July 17-24, 2009  
Aspen, CO, United States  
Molecular Biology in Clinical Oncology

August 1-7, 2009  
Vail Marriott Mountain Resort, Vail, CO, United States  
Methods in Clinical Cancer Research

August 14-16, 2009  
Bell Harbor Conference Center, Seattle, Washington, United States  
Practical Solutions for Successful Management  
<http://www.asge.org/index.aspx?id=5040>

September 23-26, 2009  
Beijing International Convention Center (BICC), Beijing, China  
19th World Congress of the International Association of Surgeons, Gastroenterologists and Oncologists(IASGO)  
<http://iasgo2009.org/en/index.shtml>

September 27-30, 2009  
Taipei, China  
Asian Pacific Digestive Week  
<http://www.apdwcongress.org/2009/index.shtml>

October 7-11, 2009  
Boston Park Plaza Hotel and Towers, Boston, MA, United States  
Frontiers in Basic Cancer Research

October 13-16, 2009  
Hyatt Regency Mission Bay Spa and Marina, San Diego, CA, United States  
Advances in Breast Cancer Research: Genetics, Biology, and Clinical Applications

October 20-24, 2009  
Versailles, France  
Fifth International Conference on Tumor Microenvironment: Progression, Therapy, and Prevention

October 30-November 3, 2009  
Boston, MA, United States  
The Liver Meeting

November 15-19, 2009  
John B. Hynes Veterans Memorial Convention Center, Boston, MA, United States  
AACR-NCI-EORTC Molecular Targets and Cancer Therapeutics

November 21-25, 2009  
London, UK  
Gastro 2009 UEGW/World Congress of Gastroenterology  
[www.gastro2009.org](http://www.gastro2009.org)

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1179 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gasteroesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome, liver biology/pathobiology, liver failure, growth and cancer, liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systematically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Articles: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; (13) Guidelines: To introduce Consensuses and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice in gastroenterology and hepatology.

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, Index Medicus, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, PubMed Central, Digital Object Identifier, CAB Abstracts and Global Health. ISI, Thomson Reuters, 2008 Impact Factor: 2.081(32/55 Gastroenterology and Hepatology).

### Published by

The WJG Press and Baishideng

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjgwjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjgnet.com](mailto:submission@wjgnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive

foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

### Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g.  $6.92 \pm 3.86$  vs  $3.61 \pm 1.67$ ,  $P < 0.001$ ; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, □, ▲, △, etc., in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

## Books

*Personal author(s)*

- 10 **Sherlock S**, Dooley J. Diseases of the liver and biliary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

*Chapter in a book (list all authors)*

- 11 **Lam SK**. Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

*Author(s) and editor(s)*

- 12 **Breedlove GK**, Schorfheide AM. Adolescent pregnancy. 2nd ed. Wieczorek RR, editor. White Plains (NY): March of Dimes Education Services, 2001: 20-34

*Conference proceedings*

- 13 **Hardden P**, Joffe JK, Jones WG, editors. Germ cell tumours V. Proceedings of the 5th Germ cell tumours Conference; 2001 Sep 13-15; Leeds, UK. New York: Springer, 2002: 30-56

*Conference paper*

- 14 **Christensen S**, Oppacher F. An analysis of Koza's computational effort statistic for genetic programming. In: Foster JA, Lutton E, Miller J, Ryan C, Tettamanzi AG, editors. Genetic programming-EuroGP 2002: Proceedings of the 5th European Conference on Genetic Programming; 2002 Apr 3-5; Kinsdale, Ireland. Berlin: Springer, 2002: 182-191

**Electronic journal** (list all authors)

- 15 Morse SS. Factors in the emergence of infectious diseases. *Emerg Infect Dis* serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

**Patent** (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc, assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express  $t$  test as  $t$  (in italics),  $F$  test as  $F$  (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as  $r$  (in italics), degree of freedom as  $v$  (in Greek), sample number as  $n$  (in italics), and probability as  $P$  (in italics).

## Units

Use SI units. For example: body mass,  $m$  (B) = 78 kg; blood pressure,  $p$  (B) = 16.2/12.3 kPa; incubation time,  $t$  (incubation) = 96 h, blood glucose concentration,  $c$  (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration,  $p$  (CEA) = 8.6 24.5  $\mu$ g/L;  $CO_2$  volume fraction, 50 mL/L  $CO_2$ , not 5%  $CO_2$ ; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23243641.

The format for how to accurately write common units and quanta can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first

mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities:  $t$  time or temperature,  $c$  concentration,  $A$  area,  $l$  length,  $m$  mass,  $V$  volume.

Genotypes:  $gyrA$ ,  $argI$ ,  $cmyc$ ,  $c fos$ , etc.

Restriction enzymes: *Eco*RI, *Hind*II, *Bam*HI, *Kbo*I, *Kpn*I, etc.

Biology: *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

## Editorial Office

### World Journal of Gastroenterology

Editorial Department: Room 903, Building D,  
Ocean International Center,  
No.62 Dongsihuan Zhonglu,  
Chaoyang District, Beijing 100025, China  
Telephone: +86-10-59080039  
Fax: +86-10-85381893  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>

## Language evaluation

The language of a manuscript will be graded before it is sent for revision.  
(1) Grade A: priority publishing; (2) Grade B: minor language polishing;  
(3) Grade C: a great deal of language polishing needed; (4) Grade D:  
rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee. EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

### INTRODUCTION

*World Journal of Gastroenterology* is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

## Abstract

Bile acids are implicated as etiologic agents in cancer of the gastrointestinal (GI) tract, including cancer of the esophagus, stomach, small intestine, liver, biliary tract, pancreas and colon/rectum. Deleterious effects of bile acid exposure, likely related to carcinogenesis, include: induction of reactive oxygen and reactive nitrogen species; induction of DNA damage; stimulation of mutation; induction of apoptosis in the short term, and selection for apoptosis resistance in the long term. These deleterious effects have, so far, been reported most consistently in relation to esophageal and colorectal cancer, but also to some extent in relation to cancer of other organs. In addition, evidence is reviewed for an association of increased bile acid exposure with cancer risk in human populations, in specific human genetic conditions, and in animal experiments. A model for the role of bile acids in GI carcinogenesis is presented from a Darwinian perspective that offers an

explanation for how the observed effects of bile acids on cells contribute to cancer development.

## INTRODUCTION

Although it was proposed that bile acids are carcinogens as early as 1939 and 1940, there was little evidence at that early time that bile acids act as carcinogens in the gastrointestinal (GI) tract (reviewed in<sup>[1]</sup>). Since then, however, evidence has accumulated that exposure of cells of the GI tract to repeated high physiologic levels of bile acids is an important risk factor for GI cancer. Here we review the substantial evidence, much of it obtained in the last few years, for a role of bile acids in cancers of the esophagus, stomach, small intestine, liver, biliary tract, pancreas and colon/rectum. High exposure to bile acids may occur in a number of settings, but, most importantly, is prevalent among individuals who have a high dietary fat intake<sup>[2]</sup>. A rapid effect on cells of high bile acid exposure is the generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS). Increased production of ROS/RNS, can lead to increased DNA damage and then increased mutation. The production of ROS/RNS following bile acid exposure likely occurs through multiple pathways involving disruptions of the cell membrane and mitochondria<sup>[1]</sup>. For each organ of the GI tract, we

review evidence, where available, on deleterious effects of bile acids, including the induction of ROS/RNS, induction of DNA damage, mutation and apoptosis, and the development of reduced apoptosis capability upon chronic exposure. Reduced ability to undergo apoptosis is important because apoptosis is a beneficial process that rids the body of cells with unrepaired DNA damage that can cause mutation. Reduced apoptosis capability has been linked to increased mutagenesis<sup>[3-5]</sup>. We also review epidemiologic evidence and results of animal experiments indicating that long-term exposure to elevated levels of bile acids increases GI cancer risk.

The annual world-wide number of deaths due to cancer is about 7.6 million, and among these about 2.8 million (36%) are due to cancers of the GI tract<sup>[6]</sup>. A recent prospective study was carried out on red and processed meat in relation to cancer incidence in a cohort of approximately half a million men and women<sup>[7]</sup>. Individuals in the highest quintile of red meat intake, compared with those in the lowest, had a statistically significant elevated risk of esophageal, colorectal and liver cancer. Also, for processed meat, the risk of colorectal cancer was elevated. Both types of meat are sources of saturated fat and iron, which have independently been associated with carcinogenesis. In addition, processed meats contain nitrates and nitrites, precursors of N-nitroso mutagenic compounds.

## ESOPHAGUS

The estimated yearly number of deaths world-wide from esophageal cancer is 300 034 for men and 142 228 for women<sup>[6]</sup>, making it the sixth leading cause of cancer deaths among men and women combined. There are two principal histologic types of esophageal cancer, adenocarcinoma and squamous cell carcinoma. In the United States, the incidence of adenocarcinoma has increased four-fold between 1973 and 2002, whereas squamous cell carcinoma has declined 30% over the same period, making adenocarcinoma the predominant form of esophageal cancer<sup>[8]</sup>. Barrett's metaplasia of the esophagus is an important predisposing condition for the development of esophageal adenocarcinoma<sup>[9]</sup>. Barrett's esophagus (BE) is a metaplastic lesion of the distal esophagus, characterized by the replacement of the normal squamous epithelium by columnar intestinal epithelium containing goblet cells. BE is associated with increased duodeno-gastro-esophageal reflux<sup>[10,11]</sup>, which causes increased exposure of the esophagus to bile acids from the duodenum and acidity (gastric acidity) from the stomach. Individuals with esophageal adenocarcinoma experience even greater exposure to bile than persons with uncomplicated BE<sup>[12]</sup>. Expression of bile acid transporter proteins is increased in BE tissues, suggesting that the development of BE metaplasia may be an adaptation to protect cells from bile acids<sup>[13]</sup>. Thus progression to BE and to adenocarcinoma may be strongly influenced by bile acid exposure. As discussed next, evidence indicates that short-term exposure of esophageal cells to bile acids induces oxidative stress, DNA damage, mutation and apoptosis; and among surviving cells selects over the long-run for resistance to apoptosis and ultimately cancer.

Five studies have shown that bile acids cause increased production of ROS in esophageal cells, including those from BE metaplasia. A cocktail of five bile acids designed to mimic the bile acids present in gastroesophageal reflux was used to test whether reflux induces ROS<sup>[14]</sup>. The five bile acids were glycocholic acid (GCA), taurocholic acid (TCA), glycdeoxycholic acid (GDCA), glycochenodeoxycholic acid (GCDC) and deoxycholic acid (DCA). This cocktail induced ROS in biopsies from human BE metaplastic tissue. The bile acid cocktail also induced ROS in cultured SV40-transformed squamous esophageal epithelial cells (HET1-A). DCA induced ROS in cultured human esophageal adenocarcinoma cells (OE33) and squamous cell carcinoma cells (KYSE-30)<sup>[15]</sup>. GCDC in acidic media induced ROS in cultured esophageal squamous cell lines derived from patients with gastroesophageal reflux disease (GERD) with BE, or without BE<sup>[16]</sup>. When mice were fed a zinc deficient diet containing a DCA supplement, ROS production was increased and BE-like lesions developed<sup>[17]</sup>.

Six studies showed that bile acids induce DNA damage in esophageal cells (Table 1), and five of these reported evidence for oxidative DNA damage.

The findings that bile acids induce DNA damage suggest that bile acids may also increase the frequency of mutation, since replication of a damaged DNA template strand often results in a replication error and thus a mutation.

Esophagoduodenostomies were performed on Big Blue F1 *lacI* transgenic rats to surgically increase duodeno-gastro-esophageal reflux<sup>[21]</sup>. The frequency of *lacI* mutant cells proved to be significantly higher in the esophageal mucosa of the surgically altered rats than in the unaltered control rats, indicating that components of refluxate, such as bile acids, increase mutation. Forty-six percent of the mutant cells were altered at CpG dinucleotide sites, and the majority of these mutations (61%) were C to T or G to A transitions. This pattern of mutation is similar to that in human esophageal adenocarcinoma, suggesting that reflux is not only mutagenic, but also carcinogenic. Consistent with these findings, it was found that DCA treatment of cultured esophageal cells cause an increase in the frequency of GC to AT mutations in the *p53* gene<sup>[15]</sup>. In addition, increased duodeno-gastro-esophageal reflux was observed to increase mutagenesis using a surgical model in Big Blue mice (rather than rats)<sup>[22]</sup>.

Bile acids induce apoptosis in esophageal cells, perhaps through the mediation of damaging ROS. DCA induced apoptosis in esophageal biopsies from normal human squamous epithelium<sup>[23]</sup>. Also, five different bile acids [GCDC, GDCA, TCA, taurochenodeoxycholic acid (TCDC) and taurodeoxycholic acid (TDCA)] individually, and also in a mixture, induced apoptosis of cultured human normal esophageal mucosal epithelial cells<sup>[24]</sup>.

Although a short-term effect of high bile acid exposure is induction of apoptosis, a longer-term effect of repeated high exposure to apoptosis-inducing agents, such as bile acids, appears to be selection for apoptosis resistant cells. When tissue samples from patients with normal esophagus, esophagitis, BE lesions and

**Table 1** Bile acids induce DNA damage in cells of the esophagus

Cells/tissues	Bile acids that induce DNA damage	Assay for damage	Ref.
Cultured SV40-transformed, squamous esophageal epithelial cells (HET1-A) and Barrett's associated adenocarcinoma cells (FLO-1)	DCA; also cocktail containing GCA, TCA, TCDCA	Comet assay <sup>1</sup> for strand breaks	[18]
Cultured SV40-transformed, squamous esophageal epithelial cells (HET1-A)	DCA	Comet assay for strand breaks; evidence for oxidative mechanism involving nitric oxide	[19]
Cultured human adenocarcinoma cells (OE33)	DCA	Micronuclei assay; induction of micronuclei by DCA, reduced by antioxidants	[15,20]
Biopsies from human Barrett's esophageal metaplastic tissue	Cocktail containing DCA, GCA, TCA, GDCA, GCDCA	8-OHdG, an oxidized form of the DNA base guanine; assayed by IHC	[14]
Mouse model of esophagitis and Barrett's esophagus	DCA (as dietary supplement; also zinc deficiency)	8-OHdG assayed by IHC	[17]

<sup>1</sup>Comet assay, also known as the single cell gel electrophoresis assay; 8-OHdG: 8-hydroxydeoxyguanosine; IHC: Immunohistochemical assay.

adenocarcinomas were studied for apoptosis capability, it was found that apoptosis is inhibited early in the dysplasia-carcinoma sequence of BE by over-expression of the anti-apoptotic protein, Bcl-2<sup>[25]</sup>, presumably as a result of chronic gastroesophageal reflux containing bile acids. BE cells have high levels of the anti-apoptotic proteins IL-6, Bcl-xL and Mcl-1<sup>[26]</sup>. Studies of tissues obtained from patient biopsies, indicated that BE cells are resistant to apoptosis induction by DCA compared to esophageal squamous epithelium and normal colon epithelium<sup>[23]</sup>. Reduced apoptosis competence may arise by mutation in genes encoding proteins necessary for apoptosis. Since cells resistant to apoptosis have a growth advantage in the presence of agents that ordinarily induce apoptosis, such as bile acids, these cells will tend to proliferate to form a field of apoptosis resistant cells<sup>[27]</sup>. Within such a defective field, repeated encounters with bile acids in reflux would cause further DNA damage. Such DNA damage, leading to further mutation, may give rise to malignancy.

Considerable evidence indicates an association of bile acid exposure with esophageal cancer. In rats, reflux of duodenal or gastro-duodenal contents, that include bile acids, induced esophageal carcinoma in the absence of exogenous carcinogen<sup>[28]</sup>. Rat surgical models with increased duodenal reflux into the esophagus, but without added carcinogen, caused esophagitis, BE-like lesions and adenocarcinomas<sup>[29-32]</sup>. Persons with BE were found to have increased duodenoesophageal reflux and increased exposure to bile acids in their refluxate, suggesting that the BE premalignant lesion is linked to bile acid exposure<sup>[10,11]</sup>. In a rat duodenal-contents reflux model, a high animal-fat intake changed the bile acid composition of bile juice and increased the development of BE and esophageal adenocarcinoma<sup>[33]</sup>.

In summary, evidence indicates that, in esophageal cells and tissues, bile acids have the short-term effect of inducing oxidative stress, oxidative DNA damage, mutation and apoptosis. Over a longer period, bile acids are implicated in the development of apoptosis resistance and eventually the development of adenocarcinoma.

## STOMACH

The estimated yearly number of deaths world-wide from gastric cancer is 511 549 for men and 288 681 for women<sup>[7]</sup>,

making it the second leading cause of cancer deaths among men and women combined. Infection by the bacterium *Helicobacter pylori* is the major etiologic risk factor in gastric carcinogenesis. However, gastroesophageal reflux appears to have an important role in the development of gastric cardia adenocarcinoma<sup>[34,35]</sup> which may have an etiology similar to that of esophageal adenocarcinoma<sup>[34]</sup>.

Exposure of cultured gastric carcinoma cells (St23123) to TCDCA increased production of ROS<sup>[36]</sup>. DCA induced apoptosis in cultured human gastric epithelial cells<sup>[37]</sup>. In rats, TCA increased stomach tumorigenesis induced by the carcinogen N-methyl-N'-nitro-N-nitrosoguanidine<sup>[38]</sup>. Carcinoma in the gastric stump (generated in rats by surgical gastrectomy) was increased by dietary fat intake and increased bile acid output<sup>[39]</sup>. Gastric adenocarcinomas were found to develop in a rat surgical model of duodenal reflux<sup>[40]</sup>. Gastroesophageal reflux in humans is implicated in adenocarcinoma of the gastric cardia<sup>[34,35,41]</sup>. Thus, elevated bile acid exposure is associated with increased ROS, induction of apoptosis and increased development of cancer of the gastric cardia.

## SMALL INTESTINE

Small intestinal cancer is relatively infrequent compared to other cancers of the GI tract. In the United States, only 0.2% of all cancer deaths are due to cancer of the small intestine. Elevated risk of carcinoid tumor of the small intestine is associated with saturated fat intake<sup>[42]</sup>, consistent with an etiologic role of bile acids. Fifty-three percent of adenocarcinomas of the small intestine arise in the duodenum, although the length of the duodenum is only 4% of the entire length of the small intestine. In addition, 57% of these duodenal cancers arise in the 6-7 cm segment that includes the outlet (Ampulla of Vater) of the common bile duct where bile (including bile acids) and pancreatic secretions empty into the small intestine<sup>[43]</sup>. Most adenomas and carcinomas of the small intestine and extrahepatic bile ducts arise in the region of the Papilla of Vater (which includes the Ampulla of Vater)<sup>[44]</sup>. Patients who have undergone a cholecystectomy are at increased risk of cancer of the small intestine, a risk that declines with increasing distance from the common bile duct<sup>[45]</sup>. These findings indicate that exposure to high levels of bile might be the

**Table 2** Bile acids induce apoptosis in liver cells

underlying cause of carcinomas of the small intestine.

Individuals with familial adenomatous polyposis (FAP) have an increased risk of developing adenomas and cancer of the small and large intestine. In the small intestine, these lesions arise mostly near the outlet of the common bile duct, where their distribution parallels bile acid exposure<sup>[46,47]</sup>. In a mouse model of FAP (*Apc*<sup>min/+</sup>), higher dietary fat intake was associated with an increase in small intestinal tumors<sup>[48]</sup>. Administration of CDCA in this FAP mouse model increased duodenal tumors, suggesting that unconjugated bile acids contribute to periampullary tumor formation in the setting of an *Apc*<sup>min/+</sup> genotype<sup>[49]</sup>.

The farnesoid X receptor (FXR) is a member of the nuclear receptor superfamily, and bile acids are endogenous ligands of FXR. FXR is necessary for maintaining bile acid homeostasis, and activation of FXR induces the expression of ileal bile acid binding protein (IBAB) and ileal bile acid transporters. In *Apc*<sup>min/+</sup> mice, FXR deficiency led to an increase in the size of small intestine adenocarcinomas<sup>[50]</sup>. Taken together, these results indicate that bile acids play a central role in cancer of the small intestine.

## LIVER

The estimated yearly number of deaths world-wide from liver cancer is 474 215 for men and 205 656 for women<sup>[6]</sup>, making it the third leading cause of cancer deaths among men and women combined. The majority of liver cancers world-wide arise as a result of chronic infection by hepatitis B or C virus, or from exposure to aflatoxin B1, a carcinogenic food contaminant. Excessive alcohol consumption is another risk factor. However, the risk of hepatocellular carcinoma is elevated in individuals with late stage primary biliary cirrhosis, a possible autoimmune disease<sup>[51]</sup>. Liver cancer can also arise in children with a defect in the bile acid export pump<sup>[52]</sup>. Thus bile acids are implicated in at least some cases of liver cancer.

Several studies have shown that bile acids induce ROS in cells of the liver. TCDCA induced ROS in isolated rat hepatocytes<sup>[53,54]</sup>. ROS were also induced in rat hepatocytes by GCDCA<sup>[55-57]</sup> and by DCA<sup>[58]</sup>. Taurolithocholate-3-sulfate induced ROS both in rat hepatocytes and a human hepatoma cell line (HuH7)<sup>[59]</sup>.

Treatment of human hepatoma cells (HepG2) with DCA activated the *gadd153 promoter*<sup>[60]</sup>. This promoter is activated by DNA damage, suggesting that DCA induces

DNA damage in hepatoma cells.

DCA is a promoter of preneoplastic lesions (hyperplastic nodules) in hepatocellular carcinogenesis<sup>[61,62]</sup>. Evidence has also been presented that DCA, given as a dietary supplement in rats, possess initiating activity for hepatocarcinogenesis<sup>[63]</sup>. At least 12 studies have shown that bile acids induce apoptosis in liver cells. These are listed in Table 2. Apoptosis induced in liver cells by hydrophobic bile acids is likely caused by oxidative stress<sup>[59]</sup>.

Four studies indicated that bile acid-induced apoptosis in liver cells is mediated by ROS. A lazaroid antioxidant (U83836E) inhibited induction of apoptosis in isolated rat hepatocytes<sup>[55]</sup>. The antioxidants  $\alpha$ -tocopherol, ebselen or idebenone (a coenzyme Q analogue) inhibited apoptosis of isolated rat hepatocytes by GCDCA and GCA<sup>[57]</sup>. Also in isolated rat hepatocytes, the antioxidants  $\beta$ -carotene and  $\alpha$ -tocopherol inhibited GCDCA induced apoptosis<sup>[67]</sup>. LCA and CDCA activated the antioxidant responsive element Nrf2 in human hepatoma-derived cells (HepG2), mouse hepatoma-derived cells (Hepa1c1c7) and primary human hepatocytes<sup>[72]</sup>. Nrf2 activation inhibits apoptosis, and the target genes of activated Nrf2 include the genes that encode the rate-limiting enzyme in glutathione biosynthesis and thioredoxin reductase 1. The general finding that induction of apoptosis in liver cells by bile acids can be reduced by anti-oxidants implies that this induction is mediated by ROS.

The bile salt export pump conveys bile acids from the hepatocyte cytoplasm into bile canaliculi. Mutations in the *ABCB11* gene cause a deficiency in the bile salt export pump, leading to intrahepatic accumulation of toxic bile salts. Children with such mutations have an increased incidence of hepatocellular carcinoma<sup>[52,73]</sup>. Mice lacking the farnesoid X receptor, which controls the synthesis and export of bile acids, have increased hepatic bile acids. These mice have a high incidence of liver tumors<sup>[74,75]</sup>. Such findings led to the suggestion that in cholestatic liver disease, chronic exposure to bile acids may play an important role in hepatocellular carcinogenesis<sup>[51]</sup>.

## BILIARY TRACT

Cholangiocarcinoma (CC) is an adenocarcinoma that arises from the bile duct epithelium. The CCs that occur within the liver are referred to as intrahepatic CCs. Those that occur at the confluence of the left and right hepatic duct are termed hilar CCs. The CCs that arise between the hepatic hilum and the duodenal papilla (or

Ampulla of Vater) are called extra hepatic CCs<sup>[76]</sup>.

The gallbladder and bile duct are exposed to high concentrations of bile acids. The bile acids excreted from the liver into the gall bladder are at a concentration of approximately 100 mmol/L<sup>[77]</sup>. The lifetime risk for developing cholangiocarcinoma in patients with primary sclerosing cholangitis is estimated at 7%-13%<sup>[78]</sup>, and it was suggested that chronic exposure to bile acids may play an important role in cholangiocellular carcinogenesis<sup>[51]</sup>. Two children with progressive familial intrahepatic cholestasis and cholangiocarcinoma were found to have an absence of bile salt export pump expression and mutations in the *ABCB11* gene<sup>[79]</sup>. Loss of a functional bile salt export pump may cause cholangiocarcinoma through intracellular accumulation of bile acids. Incubation of immortalized mouse cholangiocytes with GCDC resulted in the generation of ROS and an increase the percentage of cells with oxidative DNA damage (8-OHdG), suggesting that the a long-term effect of excessive exposure of the biliary tract to GCDC may be carcinogenesis<sup>[80]</sup>.

## PANCREAS

The estimated yearly number of deaths world-wide from pancreatic cancer is 137 206 for men and 122 185 for women<sup>[6]</sup>, making it the eighth leading cause of cancer deaths among men and women combined. Most adenocarcinomas of the pancreas occur in the head of the gland, which is in close proximity to bile<sup>[81]</sup>. In a hamster surgical model, bile reflux into the pancreatic duct was shown to induce development of intraductal papillary carcinomas of the pancreas<sup>[82]</sup>, suggesting that bile acid may be an etiologic agent in pancreatic cancer. Consistent with this idea, epidemiological studies found a positive correlation between ingestion of a western style high fat diet and the incidence of pancreatic cancer<sup>[83-85]</sup>. Treatment of human pancreatic cancer cell lines with bile acids (CDCA, DCA or TCDCA) induced cyclooxygenase-2 (COX-2) expression<sup>[81]</sup>. Since COX-2 is overexpressed in human pancreatic adenocarcinomas, these results also suggest a possible role for bile acids in pancreatic carcinogenesis.

## COLON AND RECTUM

The estimated yearly number of deaths world-wide from cancer of the colon and rectum is 318 798 for men and 284 169 for women<sup>[6]</sup>, making it the fourth leading cause of cancer deaths among men and women combined. Although both inherited mutations, environmental factors (e.g. smoking) and dietary factors are involved in colorectal cancer development, sporadic colorectal cancer appears to be caused predominantly by dietary factors.

The association of risk of colorectal cancer and consumption of red meat and processed meat was assessed in a meta-analysis of 15 prospective studies on red meat and 14 studies on processed meat<sup>[86]</sup>. The results showed consistent associations between high consumption of red and of processed meat and risk of colorectal cancer. In another recent study, a dose-dependent positive

Rat colonic mucosa	DCA (ROS)	[118]
Mouse colonic mucosa	DCA (ROS, RNS)	[119]

association between saturated fat intake and localized colorectal cancer was found in women, but not in men<sup>[87]</sup>. In earlier work, a positive association between dietary fat consumption and cancer incidence was reported<sup>[88-93]</sup>. Dietary total fat intake and saturated fat intake, but not polyunsaturated fat intake, are positively associated with colon cancer incidence<sup>[94]</sup>. In cancer prone *Apc*<sup>min/+</sup> mice, a high fat diet results in a significant increase in tumors<sup>[48]</sup>. A Western-style diet, containing elevated lipids and decreased calcium and vitamin D, induced colonic tumors in normal CB7Bl/6 mice<sup>[95-97]</sup>. Taken together, these studies implicate dietary fat (primarily from red and processed meat) in the etiology of human colorectal cancer.

Dietary intake of high-fat and high-beef foods results in a significantly higher excretion of fecal secondary bile acids, mainly DCA and LCA<sup>[98]</sup>. Presumably the increase in DCA and LCA reflects increased production of bile acids in order to emulsify the increased level of dietary fat. Epidemiologic studies have also found that fecal bile acid concentrations are increased in populations with a high incidence of colorectal cancer<sup>[99-106]</sup>. The most significant bile acids with respect to human colorectal cancer appear to be the secondary bile acids, DCA and LCA<sup>[99]</sup>.

Although repeated exposure of the colorectal epithelium to high physiological concentrations of bile acids appears to be the major etiologic factor in colorectal carcinogenesis, other factors may also be significant. Intake of dietary heme iron is associated with increased risk of colorectal cancer<sup>[107]</sup>, suggesting that iron catalyzed formation of ROS may play a role. The risk of colorectal cancer is also increased by smoking<sup>[108]</sup>. Bile acids and nicotine from smoking can interact synergistically in colon cells to increase oxidative stress and DNA damage<sup>[109]</sup>.

Twelve studies have reported that bile acids induce production of ROS or RNS in colon cells (Table 3).

Fourteen studies showed that bile acids induce DNA damage in colon cells (Table 4), of which a component is likely oxidative DNA damage. Defective repair of oxidative DNA damage is linked to increased risk of colon cancer. The base excision repair pathway deals with oxidative damages in DNA caused by ROS. 8-OHdG is a major oxidative damage in DNA that can mispair with adenine causing G:C to T:A transversion mutations, unless the mispair is corrected. MUTYH is a mammalian DNA glycosylase that initiates base excision repair by excising adenine opposite 8-OHdG. Genetic

defects in MUTYH cause multiple polyps<sup>[120]</sup> and greatly increased risk of colorectal cancer<sup>[121]</sup> in humans.

The numerous studies showing that bile acids induce DNA damage in colon cells suggest that bile acids may also induce mutation and genomic instability. In a model system for inducing tumors in the rat using the carcinogen azoxymethane, DCA not only increased the incidence of colon tumors, but also increased the incidence of tumors with *K-ras* point mutations<sup>[132]</sup>, suggesting that DCA may induce *K-ras* mutations. Hydrophobic bile acids cause aneuploidy and micronuclei formation, indicators of genomic instability, in a variety of cell types including colon epithelial cells<sup>[133]</sup>. Persistent exposure of cultured colon epithelial cells to DCA results in alterations in expression of chromosomal maintenance/mitosis-related genes that might give rise to the observed genomic instability<sup>[133]</sup>.

The 27 studies listed in Table 5 indicate that hydrophobic bile acids induce apoptosis in colon cells. Exposure of colon epithelial cells to DCA causes induction of growth arrest and DNA damage-inducible genes *GADD34*, *GADD45* and *GADD153*, probably in

response to the DNA damage caused by DCA<sup>[131]</sup>. DCA induced expression of *GADD153* is essential for DCA induction of apoptosis<sup>[130]</sup>. These findings suggest that induction of DNA damage by DCA results in apoptosis. Induction of apoptosis by DCA may protect against the survival of cells with damaged template DNA that upon replication might undergo mutation leading to cancer<sup>[134]</sup>.

Repeated long-term exposure of colonic epithelial cells to high physiologic concentrations of bile acids appears to select for cells that are resistant to induction of apoptosis by bile acids. Such apoptosis-resistant cells might arise and clonally expand through the processes of mutation (or epimutation) and natural selection. Several studies of colon cancer patients have shown that epithelial cells in areas of the colonic mucosa that do not contain the cancer itself have increased resistance to induction of apoptosis by DCA<sup>[115,135,137-139]</sup>. The expression of anti-apoptotic protein Bcl-xL is elevated in the colorectal mucosa adjacent to colorectal adenocarcinomas<sup>[157]</sup>. These findings suggest that tumors may often arise in a field of apoptosis-resistant epithelial cells. A variant of ileal bile acid binding protein (IBABP), termed IBABP-L,

is upregulated in colorectal cancer and is necessary for survival of HCT116 colon cancer cells in the presence of physiologic levels of hydrophobic bile acid<sup>[158]</sup>. This finding suggests that IBABP-L is a key factor in the development of resistance to bile acids in colon cancer cells. Furthermore, repeated long-term exposure of HCT-116 human colonic epithelial cells in culture to sublethal concentrations of DCA selects for cells that have further increased resistance to DCA-induced apoptosis<sup>[159]</sup>. These observations suggest a link between development of resistance to bile acid-induced apoptosis and colon cancer.

In summary, evidence indicates that, in colonic epithelial cells and tissues, bile acids have the short-term effect of inducing oxidative stress that causes DNA damage leading to mutation and apoptosis. Over a longer period, repeated exposure to high levels of bile acid may select for the development of apoptosis resistant fields of cells and eventually to the development of adenocarcinoma.

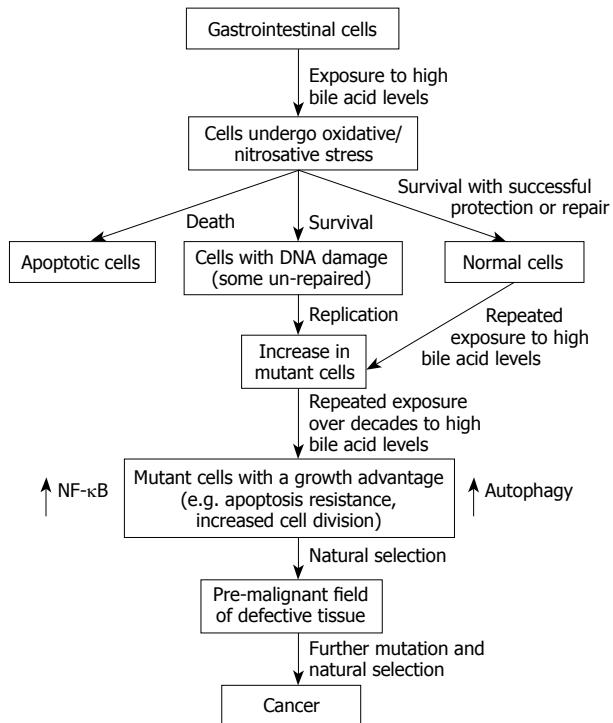

### DNA DAMAGE COUPLED WITH RESISTANCE TO CELL DEATH DRIVES TUMORIGENESIS

We have emphasized, above, the role of bile acids in inducing ROS/RNS and DNA damage in cells of the GI tract. These stresses, if excessive, can overwhelm cellular defenses resulting in cell death<sup>[139,160-163]</sup>. However, we have also shown that bile acids can activate two major cell survival pathways, NF-κB<sup>[115,124]</sup> and autophagy<sup>[164]</sup> (Figure 1). Both of the pathways are known to be activated by ROS<sup>[165,166]</sup>. Results from our laboratory indicate that the activation of both pathways by DCA can be attenuated by the use of antioxidants<sup>[113,115,124,164]</sup>. We have also shown that the NF-κB and autophagy pathways contribute to the stable apoptosis resistance that characterizes cell lines persistently exposed to DCA<sup>[159,164]</sup>. The sensitization to DOC-induced cell death after interfering with these pathways was documented using antisense oligonucleotides against the p65 subunit of NF-κB<sup>[159]</sup> and pharmacologically through the use of 3-methyladenine<sup>[164]</sup>, an inhibitor of autophagy.

The induction of persistent DNA damage in apoptosis-resistant cells is a dangerous situation that can lead to further mutation and ultimately cancer (Figure 1). An increase in Bcl-2 (an anti-apoptotic protein), for example, may also downregulate Ku DNA binding activity, thereby further amplifying genomic instability through interference with the non-homologous end-joining pathway of DNA repair<sup>[167]</sup>. The cross-talk between anti-apoptotic proteins and DNA repair proteins is a current area of investigation.

### NUCLEAR BILE ACID RECEPTORS FXR, VDR AND PXR/SXR

Recently, it has become apparent that nuclear bile acid receptors FXR, VDR and PXR/SXR play an

**Figure 1** The role of bile acids in the sequence of events leading to gastrointestinal cancer.

important role in protecting against carcinogenic effects of bile acids. FXR, a member of the nuclear receptor superfamily, responds to bile acids as physiological ligands<sup>[168-170]</sup>. FXR has a key role in activating pathways that maintain bile acid homeostasis<sup>[50]</sup>. FXR protects against intestinal tumorigenesis, possibly by a mechanism involving induction of apoptosis<sup>[50,171]</sup>.

The vitamin D receptor (VDR) functions as a receptor for the secondary bile acid lithocholic acid, and has a key role in activating a pathway that detoxifies lithocholic acid<sup>[172]</sup>. Similarly, the human xenobiotic receptor SXR (steroid xenobiotic receptor) and its rodent homolog PXR (pregnane X receptor) are bile acid receptors that, when activated, induce a response that detoxifies bile acids<sup>[173,174]</sup>. PXR promotes bile acid detoxification by activating bile acid metabolizing enzymes and transporters. In both human colon cancer cells and normal mouse colon epithelium PXR/SXR protects against bile acid induced apoptosis<sup>[149]</sup>.

### CONCLUSION

In Figure 1, we suggest a possible general pathway for bile acid induced carcinogenesis based on evidence reviewed above. An immediate effect on cells of the GI tract to exposure to a high physiologic level of bile acids is the induction of ROS/RNS. This can lead to DNA damage and apoptosis in some cells. Among surviving cells, some may remain normal by successfully employing protective and repair mechanisms. Other surviving cells, however, may retain unrepaired DNA damage. When such cells undergo DNA replication using a damaged strand as template, mutations will likely arise. Over years of frequently repeated exposure to high

levels of bile acids many mutations will occur, and some of these mutations may provide a growth advantage to the cell in which they occur. The growth advantage may involve apoptosis resistance, and increased and/or aberrant proliferation. Such cells will tend to expand clonally at the expense of neighboring cells to form a field of defective cells. Further repeated exposure to high levels of bile acids will lead to additional mutations. Should some of these mutations arise within a defective field and also provide additional growth advantages, a secondary field will spread within the first field by natural selection. Repetition of this "mutation-and-selection" process over many years, perhaps decades, will lead to a pre-malignant field and eventually to cancer.

### Abstract

Diarrhoea is an alteration of normal bowel movement characterized by an increase in the water content, volume, or frequency of stools. Diarrhoea needs to be classified according to the trends over time (acute or chronic) and to the characteristics of the stools (watery, fatty, inflammatory). Secretory diarrhoeas, mostly acute and of viral aetiology in more than 70% of cases, are by far the most important subtype of diarrhoeas in terms of frequency, incidence and mortality (over 2.5 million deaths/year in developing countries). Natural and synthetic opiates such as morphine, codeine, and loperamide which react with endogenous opiates (enkephalins, beta-endorphins, dynorphins) mainly act on intestinal motility and slow down transit. An antidiarrhoeal drug developed in recent years, racecadotril, acts as an enkephalinase inhibitor. Clinical studies have shown that it is just as effective as loperamide in resolving acute diarrhoea but with greater reduction in pain and abdominal distension. Some studies have explored the prevalence of diarrhoea in old age. An epidemiological study carried out in Italy by 133 General Practitioners on 5515 elderly outpatients reported a prevalence of diarrhoea, defined according to the Rome criteria, of 9.1%. Infectious diseases (19%) and drug use (16%) were the most common causes of diarrhoea in old age. Regardless of the cause, the treatment of elderly patients with diarrhoea must include rehydration and nutritional support. Every year, more than 50 million tourists travel from industrialized countries to places where hygiene levels are poor. At least 75% of those travelling for short periods mention health problems, and in particular traveller's diarrhoea.

### INTRODUCTION

A decrease in consistency (i.e. soft or liquid) and an increase in frequency of bowel movements to > 3 stools per day has often been used as a definition of diarrhoea for epidemiological investigations. Diarrhoea is an alteration of normal bowel movement characterized by an increase in the water content, volume, or frequency of stools. Intestinal water balance results from a complex regulation involving inflammatory mediators (prostaglandins, leukotrienes, bradykinin, nitric oxide), hormones, neuropeptides, integrity of the intestinal wall, efficiency of the circulatory system and of the enteric nervous system<sup>[1]</sup>.

From a clinical point of view, diarrhoea needs to be classified taking into account certain characteristics such as trends over time (acute or chronic, using a limit of 4 wk to separate the two conditions) and the characteristics of the faeces (watery, fatty, inflammatory, etc)<sup>[2]</sup>. Using all these characteristics, a doctor can better understand the diarrhoea symptom and decide upon diagnosis and therapy more rationally. The duration of diarrhoea is important, because acute forms are usually due to some infectious agent, intoxication, or food allergy. However, acute diarrhoea may be a symptom of the onset of chronic organic or functional disease. Also important is a chemical/physical examination of the stools. Watery diarrhoea is a symptom of some defect in the re-absorption of water due to an imbalance between the secretion and absorption of electrolytes (secretory diarrhoea) or to the ingestion of substances which the intestine has failed to absorb (osmotic diarrhoea).

Excessively fatty diarrhoea may be due to low intestinal absorption of lipids, which may be due in turn to poor digestion thereof, and inflammatory diarrhoea, if there is mucus and pus. The distinction between secretory and osmotic diarrhoea may be made clinically by trying to eliminate the various causes of osmotic diarrhoea, which are relatively few. The latter is due to the ingestion of salts (magnesium sulphate or phosphate) or polysaccharides (mannitol, sorbitol) which are not readily absorbed, or to some enzyme defect in the intestinal mucosa (e.g. a lack of lactase). Osmotic diarrhoea stops when the patient fasts, or when substances which cannot be readily absorbed are no longer ingested; secretory diarrhoea, however, continues even when the patient has stopped eating. Secretory diarrhoea may be caused by several factors, either endogenous or exogenous, which determine an imbalance between the absorption and secretion of electrolytes. Among the causes of secretory diarrhoea there are also intestinal motility abnormalities, both primitive and secondary to systemic neuro-endocrine or metabolic diseases. A significant proportion - usually about one third - of patients with irritable bowel syndrome (IBS) have diarrhoea as their main symptom. The clinical characteristics of this type of diarrhoea, called "functional," are its periodicity, its occurrence solely during the day, after meals, and faecal urgency or incontinence. The pathogenic mechanisms most often seen in these patients are stress (*via* central or peripheral mediators, the most important of which is serotonin), food factors (allergies) and hormones (oestrogen, prostaglandin)<sup>[3]</sup>.

## ETIOLOGICAL FACTORS OF THE ACUTE DIARRHOEA IN ADULT AGE

Secretory diarrhoeas, mostly acute and due to infections (bacteria, viruses, parasites), are by far the most important subtype of diarrhoeas in terms of frequency, incidence and mortality (over 2.5 million deaths/year). In developing countries, they represent the primary cause of child mortality, whereas in developed and developing countries alike secretory diarrhoeas are an important cause of hospitalisation and health expenditure. It is estimated that about 200-300 million new cases occur yearly in the USA with 900 000 hospital admissions and an overall expenditure of about 23 million dollars<sup>[4]</sup>. Despite these numbers, the true prevalence of infectious diarrhoea is probably underestimated since the pathogen may not be searched for in stool samples or the patient may not seek medical or hospital attention<sup>[5]</sup>. A Canadian study showed that only 22% of patients with diarrhoea seek medical attention and only 5% of these has a stool examination<sup>[5]</sup>. Infectious diarrhoeas are of viral aetiology in more than 70% of cases. Rotavirus is the major cause of infantile gastroenteritis and each year causes 600 000-800 000 deaths worldwide<sup>[6]</sup>. The virus infects the mature enterocytes of the villus tip of the small intestine and induces watery diarrhoea. Rotavirus impairs activities of intestinal disaccharidases and Na<sup>+</sup>-solute transport and inhibits water reabsorption through

the production of NSP4 enterotoxin. An additional secretion component is due to activation of the enteric nervous system, producing an increased chloride secretory response. The other viral etiologic agent is Norovirus which exerts a direct action on the activity of enzymes of the brush border<sup>[7]</sup>.

Bacterial aetiology occurs in 1.5%-5.6% of cases. The most frequently identified bacteria are *Campylobacter* (2.3%), *Salmonella* (1.8%), *Shigella* (1.1%) or *Escherichia Coli* (0.4%). Symptoms such as fever and bloody diarrhoea are strongly suggestive of the presence of an invasive bacterium (*Shigella spp*, *Salmonella spp*, *Camp. jejuni*, *Clostridium difficile*). These orally ingested micro-organisms overtake immune defences and adhere to the intestinal wall. Subsequently they alter the metabolism of the cell by penetrating the cell, either directly or through the production of toxins. Both toxins and bacteria cause cell death and can invade bloody circulation with systemic symptoms such as fever, chills, hypotension, nausea and vomiting. Depending on the pathogenetic mechanism, infectious bacterial diarrhoeas can be divided in cytotoxic (pathogens stimulate secretory function by activating intracellular enzymes without damaging the epithelial layer e.g. *Vibrio cholerae*, some strains of *E. coli*, *Bacillus cereus*) and cytotoxic (pathogens damage directly epithelial cell e.g. *Shigella*, *C. perfringens*, *C. difficile*, *Staphylococcus aureus*, *Salmonella* and *Campylobacter*)<sup>[8]</sup>.

A striking example of infectious diarrhoea of bacterial origin is that caused by *V. cholerae*, a Gram-negative bacterium causing a severe acute watery diarrhoea burdened with a 25%-50% mortality rate<sup>[9]</sup>. Every year, more than 100 000 cholera cases and 2000-3000 deaths are officially reported to WHO. Cholera toxin activates adenylate cyclase and elevated intracellular cAMP levels provoke loss of water and electrolytes which is manifested as the typical diarrhoea. The massive outpouring of electrolyte-rich isotonic fluid into the bowel can lead to volume depletion and shock, followed by renal and cardiac failure. Rehydration therapy, either intravenous or oral, considerably decreases the number of deaths from 25%-50% to less than 1%<sup>[9]</sup>.

*E. coli*, a normal saprophyte of the gastrointestinal tract, is another important cause of acute infectious diarrhoea<sup>[10]</sup>. According to pathogenetic mechanisms, as well as clinical syndromes, 5 strains can be distinguished (enterotoxigenic *E. coli*, enteropathogenic *E. coli*, enterohaemorrhagic *E. coli*, enteroinvasive *E. coli*, enteroaggregative *E. coli*). Transmission is *via* the orofaecal route or *via* direct person-to-person contact.

Shigellosis is a major cause of diarrhoea-related morbidity and mortality, especially in developing countries, with an estimated annual incidence of 165 million cases and 1 million deaths<sup>[11]</sup>. Transmission usually occurs *via* contaminated food and water or through person-to-person contact. Shigella bacteria multiply within colonic epithelial cells causing inflammation, mucosal ulceration, and bleeding. The symptoms of shigellosis include diarrhoea and/or dysentery with frequent mucoid bloody stools, abdominal cramps and tenesmus. The severity of the clinical picture is directly related to the infecting strain; *Sh. sonnei* causes mild diarrhoea, whereas *Sh. dysenteriae* and

*Sh. flexneri* usually cause mucoid bloody diarrhoea<sup>[12]</sup>.

*C. difficile* is an important nosocomial pathogen and the most frequently diagnosed cause of infectious hospital-acquired diarrhoea<sup>[13]</sup>. The causative organism is acquired by the oral route from an environmental source or by contact with an infected person or a health care worker who serves as a vector. Disruption of the bowel microflora, generally by antibiotics (clindamycin, cephalosporine and chinolones) creates an environment that allows *C. difficile* to proliferate. Toxigenic strains usually produce toxin A and toxin B, which cause intense inflammation of the colonic mucosa with fluid and electrolyte secretion<sup>[14]</sup>. The syndrome that results includes severe watery diarrhoea, fever, abdominal pain, and leukocytosis, sometimes complicated by toxic megacolon.

Salmonella species are Gram-negative aerobic/anaerobic bacilli that cause substantial morbidity, mortality and burden of disease globally. Salmonella can colonize both the small bowel and colon causing different clinical pictures. Typhoid fever (*S. typhi* and *S. paratyphi*) and enteritis (*S. enteritidis* and *S. typhimurium*) are the most common disease syndromes. Typhoid fever is particularly frequent in under-developed countries. In year 2000, a total of 21.6 million cases occurred with more than 216000 deaths<sup>[15]</sup>. Intestinal parasitic infections account for 20%-25% of infectious diarrhoeas, which are mostly chronic and endemic in developing countries<sup>[6]</sup>. *Giardia lamblia* is the most frequent cause of parasitic diarrhoea in immunocompetent patients. Giardiasis is common in developing countries but also in industrialized countries e.g. endemic areas in Russia<sup>[16]</sup>. *G. lamblia*, the cause of human giardiasis, is among the most common intestinal protozoa worldwide. Human infection may range from asymptomatic shedding of giardial cysts (60% of cases) to symptomatic giardiasis, causing abdominal cramps, nausea, acute or chronic diarrhoea, with malabsorption and failure of children to thrive. Factors affecting different clinical manifestations include virulence of the strain, amount of parasites ingested, and host immune response. Quite interestingly, giardiasis does not induce leukocytosis or eosinophilia.

Amoebiasis is the second leading cause of death from parasitic disease worldwide. The causative protozoan parasite, *Entamoeba histolytica*, is a potent pathogen infecting about 50 million people and resulting in 40 000 deaths per year<sup>[17]</sup>. The infection prevails in developing countries, particularly India, Africa, Mexico and South America. People at risk of infection include immigrants, travellers returning from countries of high endemicity, and men who have sex with men. Clinical manifestations range from asymptomatic carriage to invasive disease (bloody diarrhoea), to extraintestinal disease with liver abscess.

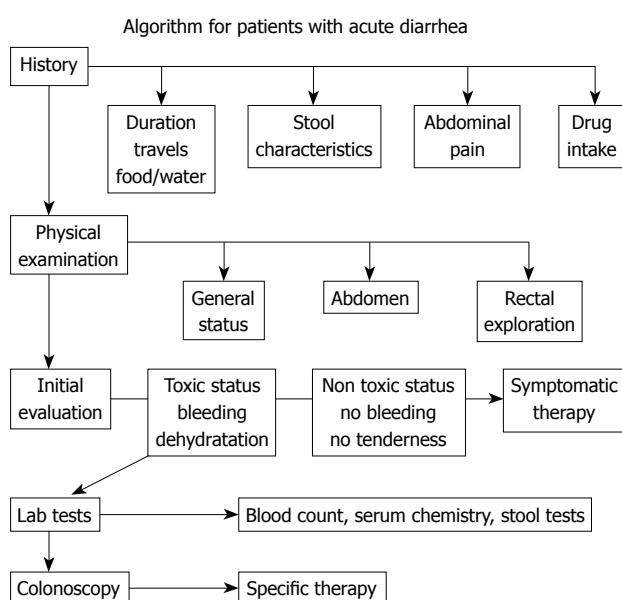

Acute infectious diarrhoea is among the most common illnesses worldwide, particularly in developing countries, and its associated morbidity and mortality are greatest among those at the extremes of age.

The presence of leukocytes in the stools is extremely important for the differential diagnosis of infectious diarrhoea. Faecal leukocytes are present in patients with diarrhoea caused by *Shigella*, *Campylobacter*, enteroinvasive *E. coli*, and absent in cases of infection by *V. cholerae*,

enterotoxigenic *E. coli*, *Rotavirus*, *Norovirus*, *G. lamblia*, *Entamoeba histolytica*, *Staph. aureus*, *Clostridium*.

## RATIONAL APPROACH TO DIAGNOSIS AND TREATMENT

Clinical classification of diarrhoea and an understanding of the main pathogenic mechanisms that bring it about are vital for a diagnostic and therapeutic approach. The initial diagnostic strategy (Figure 1) in patients with acute diarrhoea is mainly based upon a proper collection of medical history and an evaluation of the patient's clinical condition. This first diagnostic step often allows a good empirical therapy to be prescribed, whereas in patients with a poor general condition, or in those that do not respond to treatment, laboratory tests and, if required, an endoscopic examination of the intestine, must be undertaken. In both adults and children, rehydration is essential in managing patients with acute diarrhoea. Millions of lives have been saved thanks to the introduction of oral re-hydration therapy but this therapeutic approach, although essential in correcting dehydration, does not resolve the process that is at the base of diarrhoea and does not change the volume of faeces and evacuation frequency. In patients where the diagnosis leads to ascertainment of the cause of diarrhoea, therapy is usually aimed at removing the identified cause or aetiological agent. In many patients, therapy must begin before all the diagnostic tests have been exhausted (empirical therapy), since acute diarrhoea can greatly affect the quality of a patient's life and may compromise the health of children and elders. Anti-diarrhoeal therapy, known as symptomatic therapy, may be adopted alongside an aetiological therapy to improve the patient's clinical condition. The rational basis for an empirical or symptomatic therapy is determined by the main pathogenetic mechanism, that is the inability of the intestine to re-absorb water. Table 1 lists drugs for treatment of diarrhoea. The most widely used drugs in treating the symptoms of diarrhoea are those containing substances which react with endogenous opiates. These are peptides present not only in the central nervous system but also in the EC cells and the nervous plexus of the intestinal wall. There are three main types of endogenous peptide opiates: (1) enkephalins, which are found in the epithelial cells of the intestine; when they bind with delta receptors, they reduce cAMP levels and thus reduce the secretion of water and electrolytes; (2)  $\beta$ -endorphins, which bind with the mu receptor and mostly act by blocking gastrointestinal motility; (3) dynorphins, which bind with kappa receptors and lower nociceptive sensitivity. Natural and synthetic opiates such as morphine, codeine, and loperamide, are ineffective as antidiarrhoeal drugs; however, they mainly act on intestinal motility and slow down transit. This is why they have some side-effects, such as secondary constipation and abdominal bloating, which, together with some effects on CNS, contraindicate their use in children and in the elderly. An understanding of the molecular and cellular mechanisms causing intestinal

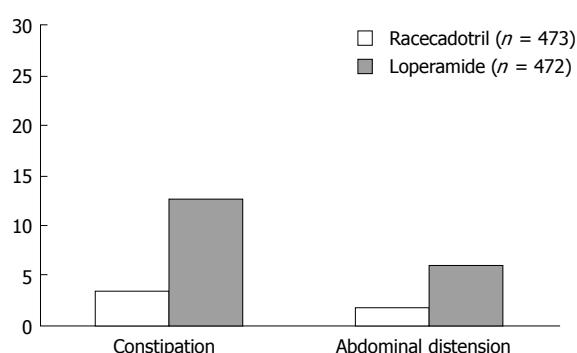

**Figure 1** Algorithm for patients with acute diarrhoea (modified from Schiller LR. Diarrhea. *Med Clin North Am* 2000; 84: 1259).

**Table 1** Symptomatic therapy of diarrhea

Opiates	Drug	Dose
μ-receptor agonists	Diphenoxylate	2.5–5 mg qid
	Loperamide	2–4 mg qid
	Codeine	15–60 mg qid
	Morphine	2–20 mg qid
Enkephalinase inhibitor δ-receptor	Racecadotril	1.5 mg/kg tid
Adrenergic agonists	Clonidine	0.1–0.3 mg tid
Somatostatin analogue	Octreotide	30–250 μg tid
Bile acids binding substances	Cholestyramine	4–16 g/die
Fibers	Psyllium	10–20 g/die

secretion has brought about developments in substances which can act selectively as anti-secretory drugs. Pharmacological research has recently been mainly oriented on enkephalins, which are endogenous opiates and are fairly widespread in the enteric nervous system. Enkephalinergic nerves reach the basolateral membrane of enterocytes where, *via* the delta receptors, they inhibit the action of adenylyl cyclase thus blocking the secretion of water and chloride. Enkephalins are rapidly broken down by a specific enzyme, enkephalinase, which determines the biological half-life of these peptides. In this context, racecadotril is an antidiarrhoeal drug developed in recent years. Racecadotril acts as an enkephalinase inhibitor thus promoting the anti-secretory action of enkephalins at the gastrointestinal level. After ingestion racecadotril is rapidly absorbed and becomes an active metabolite (Tiorfan). The anti-diarrhoeal action of this substance has been studied many times in pre-clinical and clinical trials, and it has been shown that it is purely anti-secretory. In fact, this drug has no effect on intestinal motility. Clinical studies<sup>[18–21]</sup> have shown that it is just as effective as loperamide in resolving acute diarrhoea but with greater reduction in pain and abdominal bloating and less secondary constipation (Table 2, Figure 2). Racecadotril

**Figure 2** Treatment-related adverse events associated with antidiarrhoeal therapy (from Prado et al<sup>[20]</sup>).

**Table 2** Comparison of Racecadotril (100 mg *tid*) and Loperamide (1·6 mg/die) in the treatment of acute diarrhea in adults

NS: Not significant.

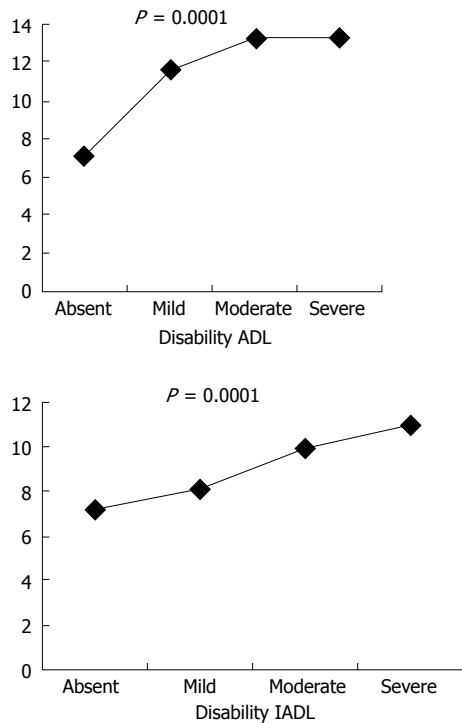

therefore represents a safe and rational therapy for acute diarrhoea, and is easy to use either alone or together with an aetiological therapy. The particular features of this drug make it very effective and suitable for use in children as well as in geriatric age groups.

Other drug categories include: (1) somatostatin analogues (octreotide), which are used in carcinoid syndrome or in other endocrinous diarrhoeas; (2) adrenergic agonists, such as clonidine, which affect intestinal motility and transport; (3) chelating agents, such as colestyramine, which are used with diarrhoea caused by bile acids, such as in post-cholecystectomy or maldigestion syndromes; (4) dietary food supplements, such as psyllium, which increase stool consistency and are useful for patients with incontinence.

## ACUTE DIARRHOEA IN THE ELDERLY

### Epidemiology

Some studies have explored the prevalence of diarrhoea in old age but the data does not give homogeneous results. A previous study performed in 328 non-institutionalized elderly subjects from U.S.<sup>[22]</sup> reported a prevalence of diarrhoea of 14.2%. More recently, a cross-sectional survey carried out in Australia, Canada, Ireland and the U.S. reported a prevalence of diarrhoea of 3.9% in elderly subjects aged 65 years or more<sup>[23]</sup>. Differences in the definitions of diarrhoea and the methodology of study recruitment may explain the discrepancies in the results. Indeed, in the first study, collection of data was made through a mailed self-administered questionnaire and patients with diarrhoea included in the survey were determined according to the Rome criteria for functional

**Figure 3** Prevalence of diarrhoea and disability according to ADL and IADL. 423 patients with diarrhea (GSRS score  $\geq 2$ ), M = 178, F = 245, mean age =  $75.0 \pm 6.3$  years, range = 65-100 years.

diarrhoea, i.e. both “the subjects with a stool frequency of more than three stools per day” and “the subjects who passed loose or watery stool and/or with urgent need for defecation”. In the second study, diarrhoea was defined according to the World Health Organization definition as three loose stools or bowel movements in any 24 h period during the 4 wk before the interview. In this study, moreover, data were collected by telephone call, thus excluding persons who did not have access to a fixed line telephone in their home and therefore probably the older and more disabled elderly people.

Very recently an epidemiological study carried out in Italy by 133 General Practitioners on 5515 elderly outpatients, reported a prevalence of diarrhoea, defined according to the Rome criteria, of 9.1%; the prevalence of diarrhoea significantly increased with an increase of both age and the grade of disability as evaluated by the ADL and the IADL (Figure 3). The study, moreover, demonstrated that, in the past 6 mo, elderly patients with diarrhoea underwent a significantly higher number of gastroenterological visits and instrumental examinations of the gastrointestinal tract such as barium X-ray, colonoscopies, abdominal ultrasound and CT than elderly subjects without diarrhoea. This finding is indirectly in agreement with previous studies supporting the concept that diarrhoea in old age may significantly impair the quality of life and functional status of affected individuals<sup>[24]</sup> and it may be a cause of morbidity and complications leading to a severe burden in hospitalized elderly patients<sup>[25]</sup>.

### Etiology

A previous study carried out in the U.S. in hospitalized patients aged 70 years and over reported that infectious

diseases (19%) and drug use (16%) were the most common causes of diarrhoea in old age. Gastrointestinal disorders, such as ischaemic colitis, malabsorption, diverticular disease, IBS and tumors of the colon and/or the small intestine accounted for about 15% of cases. Over 20% of diarrhoea observed in this population, however, was associated with the presence of constipation, and diarrhoea was a clinical expression of faecal incontinence in the presence of coprostasis<sup>[26]</sup>.

**Infectious diarrhoea:** A study from the U.S. reported that *Salmonella* (16.1 cases/100 000 persons), *Campylobacter* (13.4 cases/100 000 persons), *Shigella* (10.3 cases/100 000 persons) and *E. coli* O157:H7 (1.7 cases/100 000 persons) were the pathogens most frequently associated with diarrhoea. *Vibrio*, *Yersinia*, *Listeria* and *Cyclospora* were found in less than one case per 100 000 subjects<sup>[8]</sup>. A positive stool culture was found in 1.5%-5.6% of cases when performed three days before the beginning of symptoms. After 72 h from the beginning of diarrhoea, the diagnostic accuracy of the stool culture was less than 0.8%. Thus the microbiologic evaluation of hospitalized patients or those with recent exposure to antibiotics in whom diarrhoea develops should focus on the diagnosis of toxigenic *C. difficile*, the most common cause of nosocomial diarrhoea. Testing for other pathogens in patients who have been hospitalized for more than 72 h is discouraged, except in elderly patients 65 years of age or older with comorbidity, patients with Human Immunodeficiency Virus infection, patients with neutropenia and patients with suspected systemic spread of enteric infection<sup>[27]</sup>.

In elderly patients who have taken antibiotics the most frequent cause of infectious diarrhoea is *C. difficile*. Hospitalization and institutionalization are independent risk factors for *C. difficile* infection; indeed, in these settings the infection may be observed in 30% of subjects, even if asymptomatic in over 2/3 of subjects, with a high rate (10%-20%) of relapses. In elderly subjects *C. difficile* infection may have a nonspecific clinical presentation, including hyperpyrexia, abdominal pain or leukocytosis, and is sometimes complicated by toxic megacolon and sepsis.

**Drug-related diarrhoea:** Diarrhoea is a relatively frequent adverse event, accounting for about 7% of all drug adverse effects<sup>[28]</sup>. More than 700 drugs have been implicated in causing diarrhoea. Several mechanisms have been reported to be involved in inducing drug-related diarrhea, such as altered gastrointestinal defences, mucosal damage of the small and large intestine and/or disruption of normal pathophysiological processes of fluid and electrolyte absorption and secretion; sometimes more than one mechanism may be involved<sup>[29]</sup>.

A recent epidemiological survey carried out in Italy demonstrated that elderly patients with diarrhoea were taking a significantly higher number of drugs than patients without diarrhoea. Moreover, a significant increase in the prevalence of diarrhoea occurred in patients who were treated with a progressively higher number of drugs, reaching a prevalence of 11.0% in patients who were taking 3-5 drugs and a prevalence of 11.7% in patients who were taking 6 drugs or more.

In this elderly population of outpatients, the drugs significantly associated with the presence of diarrhoea were antibiotics, proton pump inhibitors, allopurinol, psycholeptics, selective serotonin reuptake inhibitors and the antihypertensive angiotensin II receptor blockers.

### **Approaches to therapy**

**Rehydration and nutrition:** Regardless of the cause, the treatment of elderly patients with diarrhoea must include rehydration and nutritional support. Patients should be encouraged to drink fluids and take salts both in liquids and in crackers. If necessary i.v. electrolyte solutions may be used.

**Antimicrobials:** Since in over 90% of cases of diarrhoea the pathogen may not be identified, the clinical benefit of an empiric antibiotic treatment should be evaluated taking into account the risk of adverse event reactions and the risk of harmful eradication of normal flora. In elderly patients with community-acquired diarrhoea with fever, dysentery and severe clinical conditions, and in whom diarrhoea is not thought to be attributable to fluoroquinolone-resistant bacteria, empirical treatment with an agent such as a fluoroquinolone is reasonable. Alternatively, treatment in severely ill elderly patients may include macrolides such as erythromycin or azithromycin<sup>[8]</sup>. The treatment of *C. difficile*-associated diarrhoea usually includes cessation of the initiating antibiotic. The choice to immediately re-treat the patient with another antibiotic is poor, supported by currently available evidence. Oral metronidazole is effective; vancomycin has been tested but it is more prone to serious adverse drug reactions. Recent evidence suggest that teicoplanin is better than vancomycin for bacteriological cure and that it has borderline greater efficacy in reducing symptomatology<sup>[30]</sup>.

**Symptomatic therapy:** Over 300 over-the-counter products are currently used for their antidiarrhoeal properties; of these, only loperamide, bismuth subsalicylate and kaolin have been tested in controlled studies. Curiously, none of these studies have been carried out in elderly patients. Recently, a multicenter study carried out on 945 outpatients, reported that racecadotril, a potent inhibitor of enkephalinase which exerts an anti-hypersecretory effect without increasing intestinal transit time, was as effective as loperamide in reducing diarrhoea with a significantly lower prevalence of side effects such as constipation, anorexia and abdominal pain than loperamide<sup>[20]</sup>.

Because of its characteristics, racecadotril can be an effective pharmacologic option in the treatment of diarrhoea in elderly patients; however, further studies are needed to extensively evaluate the role of racecadotril in the treatment of diarrhoea in elderly patients.

## **TRAVELLER'S DIARRHOEA**

Every year, more than fifty million tourists travel from industrialized countries to places where hygiene levels are poor. At least 75% of those travelling for short

periods mention health problems - mostly mild - but occasionally they require help from a doctor (7%) or even admission to a hospital (1%).

Traveller's diarrhoea (TD) is the most frequent of these problems; it occurs during or immediately after a trip to a less hygienic country, lasts for 3-4 d, and is characterised by the elimination of watery or soft faeces.

TD is usually brought about by eating contaminated water or foodstuffs, and affects 20%-50% of those travelling to countries with poor hygiene standards. In certain geographical areas, up to 60% of tourists can be affected if they stay for longer than 2 wk.

Based on hygiene conditions, there are 3 risk levels in the world: high risk [most of Asia, the Middle East, Turkey, Africa - except South Africa - Central America, and part of Latin America (20%-56%)], average risk (Eastern Europe, South Africa, some countries in Latin America, and some Caribbean islands) and low risk (Western Europe, the U.S., Canada, Australia, and Japan (4%-8%) (Figure 4).

The risk of contracting TD depends very closely upon the hygiene conditions in the country, and is very high for tourists from low-risk countries travelling to other countries (Table 3).

### **Aetiology**

TD aetiology is varied, and includes viruses, bacteria, protozoans, and mycetes. The main aetiological agents of secretory diarrhoea are *E. coli* (enteropathogenic, enteroadhesive, enterotoxic), *V. cholerae*, *C. difficile*, *Rotavirus* or *Norwalk astrovirus*, and for dysentery-related diarrhoea they are *E. coli* (enteroinvasive, enterohaemorrhagic), *Shigella spp*, *Camp. jejuni*, *S. typhi*, *S. paratyphi*, other salmonellas, *Aeromonas spp*, *Yersinia enterocolitica*, non-cholera bacilli, *Entamoeba histolytica*, *G. lamblia*, *Cryptosporidium*, *Cyclospora*.

### **Prevention**

Risk depends greatly upon the foodstuffs consumed (Table 4). The place in which food is prepared is also essential: in fact, the risk increases from private homes to restaurants, to food purchased at the road side.

When assessing risk, due account must be kept of certain variables which affect TD. Among the various predisposing factors are the type of trip, so an adventure holiday is more risky than one in a five-star hotel. Young people who do not eat at the table, especially children, seem to be at much greater risk than adults. There may also be certain genetic factors which might explain why some people are more easily affected by TD than others. Some conditions such as hypochlorhydria and achlorhydria should not be neglected: gastric acidity is an important barrier against pathogens. People with genetic or food-based hypochlorhydria, or who have had stomach surgery and need to take proton pump inhibitors, have a higher risk of TD<sup>[31]</sup>.

Indeed, it is interesting to notice that a trip to a high-risk area less than 6 mo after a previous trip there has a much lower risk of TD. This may be due to some sort of immunity to gastroenteral pathogens developed since the previous visit.

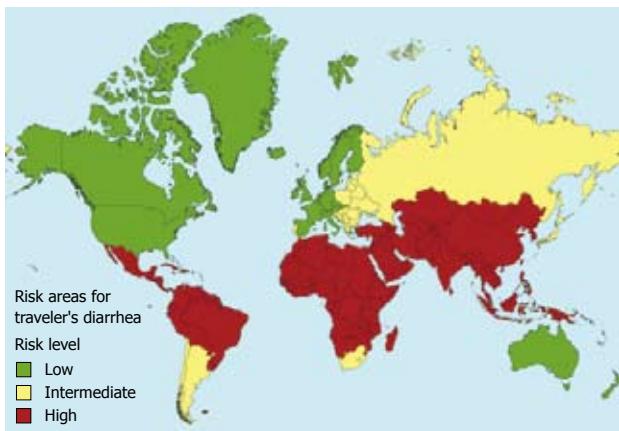

Figure 4 TD risk areas (Health Information for International travel, CDC 2005-2006).

Table 3 TD risk according to country and destination

Country of origin	Country of destination (%)		
	Low	Average	High
Low	2-4	10-20	20-40
Average	2-4	Indeterminate	90 <sup>1</sup>
High	2-4	ND	8-18

<sup>1</sup>Selected groups (e.g. Nile Cruises); ND: Not available.

Table 4 Food risk scale

Low risk (increasing)	High risk (decreasing)
Coffee, tea (served hot)	Puddings (> with unbaked creams)
Foods served at > 60°C	Tap water, ice
Fruit peeled by consumer	Cooked shellfish
Freshly-squeezed fruit	Cheese
Soft drinks in general	Cold collation
Bread	Spicy sauces
Bottled mineral water	Salads and raw vegetables
Butter	Milk

TD prevention is based on: suitable treatment of food, vaccination, and good personal hygiene, especially washing one's hands properly.

**Treatment of food:** To reduce the risk of TD as much as possible, one must take care when choosing food and drink, and avoid as far as possible any which do not appear to have been prepared properly.

These choices are extremely simple, but are very often ignored. Indeed, only a tiny fraction of all travellers take any notice of them. An inquiry carried out at big European airports<sup>[32]</sup> found that only 5.5% of travellers were willing to do anything about food safety.

**Vaccinations:** Anti-typhus, anti-hepatitis A, and anti-cholera vaccines can be effective against certain levels of TD. (1) Anti-typhus. There are two types of vaccines: tablets and injections. The first requires three tablets to be taken every other day. It is effective in 75% of cases, and provides protection for 2-3 years. The second type of

vaccine requires a single injection, and is 77% effective for three years. The oral vaccine must not be taken if one is taking malaria tablets, because it reduces the effectiveness of both. The injection, however, can be given along with other vaccinations (including malaria). In the oral and injected forms, efficacy is 55%-80% for three years (Levine, 2001); (2) Anti-hepatitis A. A subcutaneous injection can be given, and it becomes very effective two weeks thereafter; it will continue to provide protection for up to 20 years. The vaccination requires two injections: the second is given 6-12 mo after the first; (3) Anti-cholera. Two types of oral vaccine are given against *V. cholerae*: live but weakened, genetically a sub-unit A (CVD 103 HgR), and inactive cells deactivated using a sub-unit B mix (WC/rBS). The latter, designed to protect travellers against cholera, has been proven effective against TD caused by enterotoxic *E. coli*, the most frequent cause of this type of disease. Protection against TD can reach 80%<sup>[33,34]</sup>.

### Therapy

Rest must be taken for 2-3 d, and only water drunk. If symptoms persist, intestinal disinfectants can be given. To reduce the risk of dehydration and the duration of diarrhoea, antidiarrhoeal drugs can be used. Loperamide is effective but has side effects such as constipation and meteorism and/or abdominal swelling, which may cause intestinal occlusion, especially in elderly patients<sup>[35,36]</sup>. Racecadotril, recently made available in Italy, is equally effective as loperamide and does not cause any of these problems.

The General Medical Council in Italy has designed a solution to be taken by mouth, made up as follows: sodium chloride (3.5 g/L), potassium chloride (1.5 g/L), glucose (20.0 g/L), and sodium citrate (2.9 g/L). A solution using 2.5 g/L of sodium bicarbonate has a shorter half-life but is physiologically equivalent and can be found in most countries. Alternatively, the following solution can be used: 6 tsp. of sugar, 1 tsp. of kitchen salt, 2 pts. of drinking water<sup>[37,38]</sup>.

Antibiotics should only be given in serious cases, and where a specific bacterial aetiology is suspected.

### CONCLUSION

In summary, diarrhoea is an alteration of normal bowel movement characterized by an increase in the water content, volume, or frequency of stools. Secretory diarrhoeas, mostly acute and due to infections (bacteria, viruses, parasites), are by far the most important subtype of diarrhoeas in terms of frequency, incidence and mortality. Clinical classification of diarrhoea and an understanding of its main pathogenic mechanisms are fundamental for a diagnostic and therapeutic approach. A symptomatic anti-diarrhoeal therapy may be adopted alongside an aetiological therapy to improve the patient's clinical conditions and among the anti-diarrhoeal drugs racecadotril represents a safe and rational therapy. Acute diarrhoea is frequently reported in old age with a prevalence of 3.9%-14.2%. The treatment of elderly patients with diarrhoea, regardless of the cause, must include rehydration and nutritional support. TD may

represent a relevant problem since every year more than fifty million tourists travel from industrialized countries to places where hygiene levels are poor and at least 75% of those travelling for short periods mention health problems.

## Abstract

Pancreatic cancer is ranked fifth among cancer-related deaths worldwide with a 5-year survival rate of less than 5%. Currently, surgery is the only effective therapy. However, most patients are diagnosed in the late stage and are not suitable for receiving curative surgery. Moreover, pancreatic cancer doesn't respond well to traditional chemotherapy and radiotherapy, leaving little effective treatment for advanced pancreatic cancer cases.  $1\alpha,25$ -dihydroxyvitamin  $\text{D}_3$  [ $1\alpha,25(\text{OH})_2\text{D}_3$ ], the biologically active form of vitamin  $\text{D}_3$ , was originally identified during studies of calcium and bone metabolism, though it is now recognized that it exerts biological effects in almost every tissue in the body. Abundant evidence has shown that  $1\alpha,25(\text{OH})_2\text{D}_3$  has antiproliferative, apoptotic, pro-differentiation and antiangiogenesis effects in many types of cancer cells *in vivo* and *in vitro*, including breast, prostate, and colon. Similarly, the antitumor growth effect of  $1\alpha,25(\text{OH})_2\text{D}_3$  on pancreatic cells has been demonstrated. The clinical use of  $1\alpha,25(\text{OH})_2\text{D}_3$  is impeded by the lethal side effects of hypercalcemia and hypercalciuria. Therefore,  $1\alpha,25(\text{OH})_2\text{D}_3$  analogs, which are either equipotent or more potent than  $1\alpha,25(\text{OH})_2\text{D}_3$  in inhibiting tumor cell growth but with fewer hypercalcemic and hypercalciuric side effects, have been developed for the treatment of different cancers. Recently, a pre-clinical study demonstrated that a less calcemic analog of  $1\alpha,25(\text{OH})_2\text{D}_3$ , 19-nor- $1\alpha,25(\text{OH})_2\text{D}_2$  (Paricalcitol), is effective in inhibiting tumor growth *in vitro* and *in vivo*, *via* upregulation of p21 and p27 tumor suppressor genes. Studies on the anti-tumor effects of a more potent analog of Paricalcitol are underway.

## INTRODUCTION

Pancreatic adenocarcinoma is one of the most lethal human malignancies. It ranks as the fourth most common cancer-related mortality in the Western world and fifth most common worldwide<sup>[1]</sup>. There were 37 680 new cases of pancreatic cancer and 34 290 deaths due to this disease in 2008 in the United States alone<sup>[2]</sup>. The overall 5-year survival rate of pancreatic cancer is estimated to be around 1%-4%, which is attributed to its aggressive growth behavior, such as early local spread and metastasis, and resistance to radiation and most systemic chemotherapies<sup>[1]</sup>. The poor prognosis is also due to the lack of effective early diagnosis. Consequently, most patients have been diagnosed with late stage disease. Currently, surgery remains the cornerstone of treatment. After resection, the 5-year survival rate is 10%-29%<sup>[3-5]</sup>, but only 10%-15% of pancreatic cancer patients are suitable candidates for resection. For the non-operable pancreatic cancer cases, the most frequently used treatment methods include radiation and chemotherapy with 5-fluorouracil, cisplatin or gemcitabine<sup>[6-8]</sup>, or a combination of these modalities<sup>[9-11]</sup>. Growing evidence supports neoadjuvant therapy to downstage some pancreatic cancer patients from borderline resectable to resectable disease<sup>[12,13]</sup>,

but its impact on long-term survival still needs further examination<sup>[14]</sup>. With this bleak background, there is an urgent need to develop novel treatments for pancreatic cancer.

## SOURCES AND METABOLISM OF VITAMIN D

The production of vitamin D<sub>3</sub> depends on solar ultraviolet B radiation (wavelength between 290–315 nm), which converts 7-dehydrocholesterol stored in the skin to previtamin D<sub>3</sub>. Previtamin D<sub>3</sub> is then thermoisomerized to vitamin D<sub>3</sub>, which then enters the bloodstream and is bound to the vitamin D binding protein. Very little food naturally contains vitamin D. The cutaneous synthesis of vitamin D<sub>3</sub> is normally responsible for over 90% of our vitamin D requirement<sup>[15]</sup>. Vitamin D (including both vitamin D<sub>2</sub> and vitamin D<sub>3</sub>) obtained from sunlight or dietary sources is then converted to 25-hydroxyvitamin D [25(OH)D], catalyzed by vitamin D-25-hydroxylase in the liver. 25(OH)D is the major circulating form of vitamin D and is widely accepted as an index of vitamin D status in humans. However, it is biologically inert until it is hydroxylated in the kidney to form 1 $\alpha$ ,25-dihydroxyvitamin D [1 $\alpha$ ,25(OH)<sub>2</sub>D]. 1 $\alpha$ ,25(OH)<sub>2</sub>D is a lipid-soluble hormone that interacts with the vitamin D receptor (VDR) to exert a variety of functions, including genomic and non-genomic actions.

## VITAMIN D AND CANCER

1 $\alpha$ ,25(OH)<sub>2</sub>D, the biologically active form of vitamin D, was originally discovered because of its effects on calcium and bone metabolism. It is now recognized that the hormone has activities in almost every tissue in the body. 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> implements this effect through binding to the nuclear VDR and then binding to a specific DNA sequence, the vitamin D response elements (VDREs)<sup>[16]</sup>. *Via* this genomic pathway, 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> can modulate gene expression in a tissue-specific manner, mainly leading to inhibition of cellular proliferation, induction of differentiation and apoptosis, which in turn, protect cells from malignant transformation and repress cancer cell growth.

However, the use of vitamin D to treat cancers has been impeded by lethal hypercalcemia induced by systemic administration of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>. To overcome this drawback, analogs of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>, exhibiting more potent growth inhibition but less calcemic effects, have been developed as anticancer drugs<sup>[17]</sup>, and some of them have shown great results in pre-clinical studies. For example, Akhter *et al*<sup>[18]</sup> demonstrated that a 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> analog, EB 1089, exhibited an antiproliferative effect on colon cancer in a xenograft animal model. Abe-Hashimoto *et al*<sup>[19]</sup> showed that another 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> analog, OCT, displayed an antitumor effect on a xenograft model using MCF-7, a

breast cancer cell line, in combination with tamoxifen. Furthermore, Polek *et al*<sup>[20]</sup> showed that another analog, LG190119, possessed antiproliferative activity when tested in an LNCaP prostate cancer cell xenograft model.

There are some limited clinical trials that show 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> and its analogs have antitumor effects in humans when used alone or in combination with other chemotherapy drugs. For example, Beer *et al*<sup>[21]</sup> conducted a phase II clinical trial in which they showed the combination of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> and docetaxel could induce > 50% decline in PSA, a prostate cancer tumor marker, and improve survival of prostate cancer patients. However, most of the clinical trials only confirmed the less- or non-calcemic effect of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> or its analog when used alone or in combination with other chemotherapy drugs without prolonging the survival of cancer patients. There are still many ongoing clinical trials attempting to demonstrate the antitumor effect of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> and its analogs in humans. More effort is required in order to fully appreciate the clinical utilities of vitamin D-based therapies in treating human diseases, including cancers.

## MECHANISMS OF VITAMIN D ACTIONS FOR CANCER TREATMENT

Vitamin D reduces the risk of cancer through its biologically active metabolite, 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>, which regulates cellular proliferation and differentiation, inhibits angiogenesis, and induces apoptosis.

Stumpf *et al*<sup>[22]</sup>, in 1979, reported that the VDR existed not only in the intestine, bone and kidney, but in almost all tissues in the body. Suda *et al*<sup>[23]</sup> (1982) first noted that 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> caused a marked inhibition of cell growth on VDR-positive M-1 leukemic cells. In the same year, Tanaka *et al*<sup>[24]</sup> reported that 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> showed the same effect on HL-60 leukemic cells, which had the VDR. Since then, many VDR-containing cancer cell lines, including prostate, colon, breast, lung, and melanoma, have shown growth inhibition when exposed to 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub><sup>[15,25-27]</sup>.

The antiproliferative effects of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> are mainly due to alterations in several key regulators of the cell cycle, culminating in dephosphorylation of retinoblastoma protein and arrest of cells in G<sub>0</sub>/G<sub>1</sub><sup>[28]</sup>. Progression of the cell cycle is regulated by cyclins and their associated cyclin dependant kinases and cyclin dependant kinase inhibitors (CKIs). The CKI genes, such as p21 and/or p27, have VDRE within their promoter regions, and are genomic targets of the 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>/VDR complex in many cell types, which in turn, induces G<sub>1</sub> cell-cycle arrest and withdrawal from the cell cycle<sup>[29-31]</sup>. However, some genes are transcriptionally affected by 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> but lack VDREs in their promoter regions, which suggests that 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> induces indirect effects on cell-cycle regulation through another signaling pathway.

For example,  $1\alpha,25(\text{OH})_2\text{D}_3$  could downregulate the expression of estrogen, epidermal growth factor, insulin-like growth factor 1, and keratinocyte growth factor and upregulate inhibitory growth factors, such as transformation growth factor- $\beta$ <sup>[32-35]</sup>.

$1\alpha,25(\text{OH})_2\text{D}_3$  can also induce differentiation to control tumor cell proliferation through the pathways of phosphatidylinositol 3-kinase, which is VDR dependent<sup>[36]</sup>, and by suppression of interleukin 12 protein secretion<sup>[37]</sup>, which is VDR independent.

Induction of apoptosis is another important function of  $1\alpha,25(\text{OH})_2\text{D}_3$ , which represses the expression of the antiapoptotic protein, BCL<sub>2</sub>, and prosurvival protein, BCL-X<sub>L</sub>.  $1\alpha,25(\text{OH})_2\text{D}_3$  also enhances the expression of proapoptotic proteins such as BAX and BAD<sup>[38]</sup>. In addition to the BCL<sub>2</sub> family,  $1\alpha,25(\text{OH})_2\text{D}_3$  can activate the caspase effector molecules directly to induce apoptosis<sup>[38]</sup>. Furthermore, it has been shown that  $1\alpha,25(\text{OH})_2\text{D}_3$ , in combination with radiation or chemotherapeutic agents, causes an additive effect on cancer cell death<sup>[39-42]</sup>.

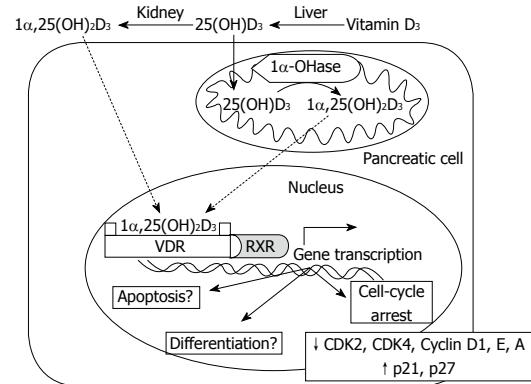

Inhibition of angiogenesis is also an important anticancer mechanism of  $1\alpha,25(\text{OH})_2\text{D}_3$ .  $1\alpha,25(\text{OH})_2\text{D}_3$  can repress endothelial cell growth *in vitro* and reduce angiogenesis *in vivo*<sup>[43-45]</sup>. The anti-angiogenic effects of  $1\alpha,25(\text{OH})_2\text{D}_3$  might subsequently lead to the inhibition of metastasis, as demonstrated in murine prostate and lung models treated with  $1\alpha,25(\text{OH})_2\text{D}_3$ <sup>[46,47]</sup>.

The precise anticancer mechanisms of  $1\alpha,25(\text{OH})_2\text{D}_3$ , including VDR-dependent and VDR-independent pathways are not fully understood. For the further use of  $1\alpha,25(\text{OH})_2\text{D}_3$  and its analogs in the treatment of cancers, there should be more studies addressing this issue to pave the way for the development of more potent  $1\alpha,25(\text{OH})_2\text{D}_3$  analogs.

## ASSOCIATION OF VITAMIN D AND PANCREATIC CANCER-EPIDEMIOLOGICAL EVIDENCE

Epidemiologic studies have shown that vitamin D status, influenced by living at high or low latitude, solar UV exposure and dietary intake of vitamin D, was inversely associated with the incidence of some cancers such as prostate, colon and breast<sup>[48-50]</sup>. It was also reported that the risk of developing prostate, breast and colon cancer was decreased by 30%-50% if the serum concentration of  $25(\text{OH})\text{D}$  exceeded 50 nmol/L<sup>[51,52]</sup>. Tangpricha *et al*<sup>[53]</sup> demonstrated that vitamin D deficiency enhanced the growth of MC-26 colon cancer xenografts in BALB/c mice, which supported the hypothesis that vitamin D sufficiency could reduce the proliferation of tumor cells *in vivo*.

To date, there have been only two epidemiological studies discussing the vitamin D status and the incidence of pancreatic cancer. One was conducted by Skinner *et al*<sup>[54]</sup> on U.S. nurses and health professionals, which demonstrated that higher dietary intake of vitamin D could be associated with lower incidence of pancreatic

**Figure 1 Mechanisms of Vitamin D<sub>3</sub> action on pancreas cells.** Both  $1,25(\text{OH})_2\text{D}_3$  and  $25(\text{OH})\text{D}_3$  can enter pancreas cells, where  $25(\text{OH})\text{D}_3$  can be converted to  $1,25(\text{OH})_2\text{D}_3$  by  $1\alpha$ -OHase.  $1,25(\text{OH})_2\text{D}_3$  can bind the VDR and further combine with the retinoid X receptor (RXR) to form a heterodimer, VDR-RXR. The VDR-RXR heterodimer binds to specific vitamin D response elements located in the promoter region of vitamin D-responsive genes, which in turn induces gene transcription. So far, in terms of pancreas cells, inhibition of CDK2, CDK4, Cyclin D1, Cyclin E, Cyclin A and upregulation of p21 and p27 have been demonstrated, leading to a block in the cell cycle at G<sub>0</sub>/G<sub>1</sub>. Regarding induction of differentiation, apoptosis and other anticancer mechanisms, further studies are required.

cancer. The other report, however, conducted in the observational cohort of the Finnish Alpha-Tocopheral Beta-Carotene (ATBC) trial, showed a discrepancy in results compared to the report by Skinner *et al*<sup>[54]</sup>. The ATBC data suggested that a higher serum concentration of  $25(\text{OH})\text{D}$  in male smokers was associated with a higher incidence of pancreatic cancer<sup>[55]</sup>. The reason behind these contradictory results was not clear, but they employed different measures of dietary intake of vitamin D *versus*  $25(\text{OH})\text{D}$ , and the participants in the ATBC trials were all male smokers, which might have contributed to the different conclusions in the two studies. To clarify this, more studies addressing the relationship between vitamin D status and incidence of pancreatic cancer are required.

## VITAMIN D AND PANCREATIC CANCER-BIOCHEMICAL EVIDENCE

While the precise anticancer mechanisms, including VDR-dependent and VDR-independent actions, induced by  $1\alpha,25(\text{OH})_2\text{D}_3$  still require further investigation, it is known that in pancreatic cancer cells,  $1\alpha,25(\text{OH})_2\text{D}_3$  induces the expression of p21 and p27 and inhibits the production of cyclins (D<sub>1</sub>, E and A) and cyclin dependent kinases 2 and 4, which in turn, elicit cell cycle arrest in G<sub>0</sub>/G<sub>1</sub> *in vitro*<sup>[56]</sup>. Similar effects have been observed with 19-nor- $1\alpha,25(\text{OH})_2\text{D}_2$  (Paricalcitol) in human pancreatic cancer cells *in vitro* and *in vivo* by upregulating the expressions of p21 and p27<sup>[57]</sup> (Figure 1).

Currently, very little is known about the mechanisms of vitamin D actions on pancreatic cancer cells. More emphasis in this area is needed, because very few efficient therapeutic options are available to benefit pancreatic cancer survival.

## POTENTIAL OF VITAMIN D ANALOGS FOR PANCREATIC CANCER TREATMENT

Since the VDR exists in almost every tissue of the body<sup>[22]</sup> and 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> exhibits growth inhibitory effects on many different types of cancer cells, several studies have been performed to investigate the anticancer effect of vitamin D and its analogs on pancreatic cancer cells during the past two decades. For example, Kawa *et al*<sup>[56]</sup> reported that 22-oxa-1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>, a 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> analog, caused growth inhibition in three pancreatic cancer cell lines and inhibited the growth of a BxPC-3 tumor in a xenograft nude mice model<sup>[58]</sup>. Colston *et al*<sup>[59]</sup> demonstrated that another 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> analog, EB 1089, exhibited more potent antitumor effects than 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> on the GER cell line, a human pancreatic cancer cell line, *in vitro* and *in vivo*. Pettersson *et al*<sup>[60]</sup> also reported that EB 1089 induced greater tumor growth inhibition than 9-cis-retinoic acid *in vitro*. These two pre-clinical studies therefore suggested that EB 1089 might be a promising vitamin D analog for further clinical trials in pancreatic cancer patients. However, in a phase II clinical trial, which is also the only clinical trial studying the use of vitamin D analogs against pancreatic cancer, EB 1089 given once daily orally failed to significantly improve patient survival, although most patients tolerated the daily orally dose of 10-15  $\mu$ g of the drug well, without causing hypercalcemia<sup>[61]</sup>.

With the knowledge that 19-nor-1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>2</sub> (Paricalcitol) is a Federal Drug Administration approved drug for the treatment and prevention of secondary hyperparathyroidism associated with chronic kidney disease<sup>[62]</sup>, and this analog has comparable growth inhibitory effects as 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> in human prostate cancer cells *in vitro*<sup>[63]</sup>, Schwartz *et al*<sup>[57]</sup> studied the same analog in human pancreatic cancer cells *in vitro* and demonstrated that it also inhibited the proliferation of these cells. Given the fact that Paricalcitol has been shown to be less calcemic than 1 $\alpha$ ,25(OH)<sub>2</sub>D and few therapeutic options for pancreatic cancer patients are available, it is worth further exploration as an anticancer drug for pancreatic cancer.

In addition to using synthetic 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> analogs to treat pancreatic cancer in an effort to avoid hypercalcemia, another strategy is the employment of inactive prohormone 25(OH)D<sub>3</sub> (Figure 1). This is based on the finding that many normal and cancerous cells, including prostate cell lines and primary cultures of prostate cells, possess 25(OH)D-1 $\alpha$ -hydroxylase (1 $\alpha$ -hydroxylase or CYP27b1), the enzyme responsible for the conversion of 25(OH)D<sub>3</sub> to 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub><sup>[26]</sup>, and CYP27b1 has been proposed as a tumor suppressor<sup>[64]</sup>. Furthermore, it has been demonstrated that 25(OH)D<sub>3</sub> had a comparable tumor growth inhibitory effect to 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> on primary cultures of prostate cells<sup>[63,65]</sup>. These findings led to a subsequent study demonstrating that CYP27b1 activity was also expressed in pancreatic cancer cells and the growth of these cancer cells was

inhibited in the presence of 25(OH)D<sub>3</sub><sup>[66]</sup>. Given the fact that the conversion of 25(OH)D<sub>3</sub> to 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> occurs within the cell, and the 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> formed acts in an autocrine/paracrine fashion<sup>[26,63-65]</sup>, systemic administration of 25(OH)D<sub>3</sub> might greatly minimize the risk of hypercalcemia. 25(OH)D<sub>3</sub> has been approved by the Federal Drug Administration to treat vitamin D deficiency in humans; therefore, 25(OH)D<sub>3</sub> could be another attractive candidate for clinical trials in pancreatic cancer patients.

## CONCLUSION

Abundant evidence indicates that 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> has antiproliferative, pro-differentiative, apoptotic and antiangiogenic activities in different types of tumor cells. In different cancer cell types, 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> can induce the expression of various molecular markers to regulate cell growth. Even in the same tissue, different cell types might exhibit heterogeneous responses to the addition of 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>. It is known that 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> and its analogs can inhibit pancreatic cancer cell growth *in vitro*<sup>[56,59]</sup> via activation of p21 and p27, which in turn influence cell cycle progression and arrest cells in G<sub>0</sub>/G<sub>1</sub>. So far, the only pancreatic cancer clinical trial using a 1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub> analog, EB 1089<sup>[61]</sup>, did not show significant prolongation of survival. However, a preclinical study with 19-nor-1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>2</sub> (Paricalcitol) in pancreatic cancer cells<sup>[60]</sup> has provided some encouraging results and might lead to further clinical trials. Moreover, given the fact that pancreatic cancer cells possess 1 $\alpha$ -hydroxylase (CYP27b1) activity and can convert the prohormone 25(OH)D, which has a low risk of inducing hypercalcemia even at high concentrations, into 1 $\alpha$ ,25(OH)<sub>2</sub>D within the cells and thereby inhibiting pancreatic cancer cell growth in an autocrine/paracrine fashion<sup>[26,63-65]</sup>, prohormone 25(OH)D-based therapy might be another attractive treatment strategy for pancreatic cancer in the future.

## Abstract

**AIM:** To investigate the functional significance of insulin-like growth factor binding protein-5 (IGFBP-5) overexpression in pancreatic cancer (PaC).

**METHODS:** The effects of IGFBP-5 on cell growth were assessed by stable transfection of BxPC-3 and PANC-1 cell lines and measuring cell number and DNA synthesis. Alterations in the cell cycle were assessed by flow cytometry and immunoblot analyses. Changes in cell survival and signal transduction were evaluated after mitogen activated protein kinase and phosphatidylinositol 3-kinase (PI3K) inhibitor treatment.

**RESULTS:** After serum deprivation, IGFBP-5 expression increased both cell number and DNA synthesis in BxPC-3 cells, but reduced cell number in PANC-1 cells. Consistent with this observation, cell cycle analysis of IGFBP-5-expressing cells revealed accelerated cell cycle progression in BxPC-3 and G2/M arrest of PANC-1 cells. Signal transduction analysis revealed that Akt activation was increased in BxPC-3, but reduced in PANC-1 cells that express IGFBP-5. Inhibition of PI3K with LY294002 suppressed extracellular signal-regulated kinase-1 and -2 (ERK1/2) activation in BxPC-3, but enhanced ERK1/2 activation in PANC-1 cells that express IGFBP-5. When MEK1/2 was blocked, Akt activation remained elevated in IGFBP-5 expressing PaC cells; however, inhibition of

## INTRODUCTION

Pancreatic cancer (PaC) is the fourth leading cause of cancer deaths in the United States. Annually, the incidence of PaC almost equals the number of deaths related to this disease, and these numbers have begun to increase<sup>[1]</sup>. Pancreatic tumors are highly chemoresistant, so chemotherapy rarely leads to eradication of the malignancy. Even with chemo- and radiation therapy, median survival for patients who have undergone resection is less than two years<sup>[1]</sup>. Therefore, a better understanding of aberrant signaling pathways that promote tumor growth is necessary to identify inhibitors to potentially enhance the response of current chemotherapeutics.

Insulin-like growth factors (IGFs) regulate cellular growth, differentiation, and apoptosis<sup>[2]</sup>. In non-malignant cells, IGF-binding proteins (IGFBPs) modulate the activity of IGF-I and -II, and their affinity for IGFs can be altered by proteolysis, phosphorylation, and adherence to cell-surface or extracellular matrix proteins<sup>[3]</sup>. Insulin-like growth factor

binding proteins (IGFBPs) can also act independently of IGF to either stimulate or inhibit growth of various cell types. Both IGF-I and the IGF-I receptor (IGF-I R) are expressed in pancreatic tumors and cell lines<sup>[4-6]</sup>, and IGFBP-1, -3, and -5 have been associated with pancreatic cancer<sup>[7-9]</sup>.

We found that IGFBP-5 is expressed at higher levels in pancreatic tumors than in non-malignant pancreatic tissues<sup>[9]</sup>. The role of IGFBP-5 in cancer cell growth and proliferation, however, is not fully understood and has not been studied in pancreatic cancer. In this study, therefore, we investigated the functional significance of IGFBP-5 overexpression in pancreatic cancer by stable transfection of the *IGFBP-5* cDNA into two pancreatic cancer cell lines to better represent the heterogeneous genetic background of pancreatic tumors. We examined the effects of IGFBP-5 on cell proliferation and on cell cycle distribution and the status of key cell cycle regulators. We also investigated the mechanism of IGFBP-5-mediated growth effects by assessing the activation status of Akt and extracellular signal-regulated kinase-1 and -2 (ERK1/2) and the effects of inhibition of the phosphatidylinositol 3-kinase (PI3K) and mitogen activated protein kinase (MAPK) pathways after serum deprivation. These studies show that IGFBP-5 can enhance pancreatic cancer cell growth by altering the expression and activity of cell cycle regulators and the activation of key signaling intermediates.

## MATERIALS AND METHODS

### *Cell lines, cloning, and stable transfection*

Human pancreatic cancer cell lines BxPC-3 and PANC-1 were obtained from the American Type Culture Collection (Manassas, VA). PANC-1 cells were grown in DMEM and BxPC-3 cells were grown in RPMI 1640, both media were supplemented with 100 mL/L fetal bovine serum.

The full-length cDNA encoding human *IGFBP-5* was synthesized by reverse transcription polymerase chain reaction from pancreatic tumor cDNA. The amplified product spanned 822 bp (nt 749-1570) of the published human *IGFBP-5* mRNA, covering the start (752) and stop codons (1568) (GenBank, NM\_000599). The primers used were as follows: 5'-CACCAAGATGGTGTGCTC-3' (sense) and 5'-TCACTCAACGTTGCTGCTGTCGAA-3' (antisense). The sense primer included sequences to facilitate TOPO cloning (underlined). The amplified product was cloned into the pENTR/SD TOPO vector (Invitrogen, Carlsbad, CA) and the sequence of the *IGFBP-5* insert was confirmed by sequencing.

The full-length human *IGFBP-5* cDNA was transferred into the expression vector pIRESpuro3GW<sup>[10]</sup> using Invitrogen's Gateway cloning technology and cells were stably transfected using LipofectAMINE (Invitrogen). IGFBP-5 transfectants (/IGFBP-5) and vector controls (/Vec) were selected in medium containing puromycin (2 µg/mL PANC-1 and 1.5 µg/mL BxPC-3). Individual clones were expanded and successful

transfection was confirmed by immunoblot analysis of conditioned medium concentrated using Microcon YM 10 filter devices after 24 h growth in serum-free medium (SFM) and detected with α-IGFBP-5 antibodies (R&D Systems, Minneapolis, MN). Two clones were selected per cell line, one that expressed low levels of IGFBP-5 (IGFBP-5L) and one that expressed high levels (IGFBP-5H).

### **Growth studies**

Stable transfectants were seeded ( $3.5 \times 10^4$  cells/well) in 24-well plates in the appropriate growth medium for 24 h. The medium was then removed, cells were washed with phosphate-buffered saline (PBS), and fresh growth medium or SFM was added to the cells. Cells were either cultured continuously in the same medium or SFM changed every 24 h. Growth was assessed based on cell number and [<sup>3</sup>H]-thymidine incorporation at various times in the above culture conditions.

### **Cell number**

The number of cells in each well was determined by harvesting the cells with trypsin-EDTA solution and counting cells in an aliquot using a Z1 Particle Counter (Beckman-Coulter) in duplicate.

### **[<sup>3</sup>H]-thymidine incorporation**

At the end of incubations, medium was removed, cells were washed with PBS, and then 2 µCi/mL [<sup>3</sup>H-methyl]-thymidine in SFM was added for the last 4 h of each growth period at 37°C. After the labeling period, cells were precipitated with ice-cold methanol: acetic acid (3:1, v/v) at 4°C overnight. The cells were washed with a solution of 800 mL/L methanol in water, and DNA was dissolved by adding 0.5 mol/L NaOH (300 µL) for 30 min. Radioactivity contained in 100 µL aliquots was determined by scintillation counting.

### **Cell cycle analysis**

Cells were seeded ( $3.5 \times 10^5$  PANC-1 cells/well or  $4 \times 10^5$  BxPC-3 cells/well) in 6-well plates in the appropriate growth medium for 24 h. The medium was removed, cells were washed with PBS, and either fresh growth medium or SFM was added. After 48 h, cells were trypsinized and aliquots of  $1 \times 10^6$  cells were fixed overnight in 700 mL/L ethanol at 4°C. Fixed cells were washed and suspended in 1 mL of 50 µg/mL propidium iodide, 1 mg/mL RNase A, and 1 g/L BSA in PBS for 30 min in the dark at room temperature. Using a FACSCalibur flow cytometer (Becton Dickinson, San Jose, CA), cell cycle analysis was performed on 10000 cells for each sample. Quantitation of cell cycle distribution was performed using CellQuest software (Becton Dickinson).

### **Immunoblot analysis**

For immunoblots, equivalent amounts of protein were resolved by SDS-PAGE and blotted onto PVDF membrane (Invitrogen), followed by blocking with 50 g/L nonfat milk powder in 10 mmol/L Tris, pH 7.6,

100 mmol/L NaCl, and 1 mL/L Tween 20. Immunoblots were incubated with the following primary antibodies:  $\alpha$ -IGFBP-5 (R&D Systems);  $\alpha$ -phospho-ERK1/2,  $\alpha$ -ERK1/2,  $\alpha$ -phospho-Akt (Ser 473),  $\alpha$ -Akt (Cell Signaling Technology, Danvers, MA);  $\alpha$ -GAPDH (Ambion, Austin, TX); and  $\alpha$ -cyclin D1,  $\alpha$ -CDK4,  $\alpha$ -cyclin B1,  $\alpha$ -cdc2,  $\alpha$ -cyclin E,  $\alpha$ -CDK2,  $\alpha$ -p21,  $\alpha$ -p27,  $\alpha$ -actin (Santa Cruz Biotechnology, Santa Cruz, CA). Antigen-antibody complexes were detected using the appropriate secondary antibody linked to horseradish peroxidase and visualized using ECL Plus chemiluminescent reagent (Amersham Biosciences, Piscataway, NJ).

#### Cyclin-dependent kinase assays

CDK activity assays were performed essentially as described previously<sup>[11]</sup> using histone H1 and Rb<sub>773-928</sub> (Upstate Biotechnology) as substrates for CDK2 and CDK4, respectively. Reaction products were resolved by SDS-PAGE and visualized by autoradiography.

#### Cell viability and proliferation

3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assays (Roche, Indianapolis, IN) were performed to evaluate cell growth and viability of IGFBP-5 expressing cell lines after treatment with LY294002 or U0126 (Calbiochem, San Diego, CA). Cells were seeded ( $0.9 \times 10^4$  cells/well PANC-1 and  $1 \times 10^4$  cells/well BxPC-3) in 96-well plates in the appropriate growth medium. After 24 h the medium was removed, cells were washed with PBS, SFM was added, cells were incubated for 24 h, and inhibitors (LY294002, U0126, or vehicle) were then added to the medium. After 48 h, MTT assays were performed according to the manufacturer's protocol. The viable cells were expressed as a percentage of the optical absorbance relative to the optical absorbance of the corresponding control or untreated cells.

#### Analysis of effect of IGFBP-5-conditioned medium on signaling

IGFBP-5 transfected or vector transfected PANC-1 and BxPC-3 cells were seeded in 10 cm plates in the appropriate growth medium. After 24 h the medium was removed, cells were washed with PBS, SFM was added, and cells were incubated for 48 h. Conditioned medium was then collected and centrifuged at 1500 r/min for 10 min. PANC-1 and BxPC-3 cells were seeded in 6-well plates in the appropriate growth medium. After 24 h the medium was removed, cells were washed with PBS, SFM was added, and the cells were incubated for 24 h. PANC-1 and BxPC-3 cells were then treated for 15 min, 24, 48 and 72 h with conditioned medium from IGFBP-5 or vector-transfected controls. Cells were lysed and samples were prepared for immunoblot analysis.

#### Statistical analysis

Data are expressed as the mean  $\pm$  SE or a percentage. Statistical analyses of data were performed using a two-way analysis of variance (ANOVA) and Bonferroni post-

test (GraphPad Software; San Diego, CA). For data normalized to the vector transfected control, variables were log transformed prior to statistical analysis.  $P < 0.05$  was considered significant.

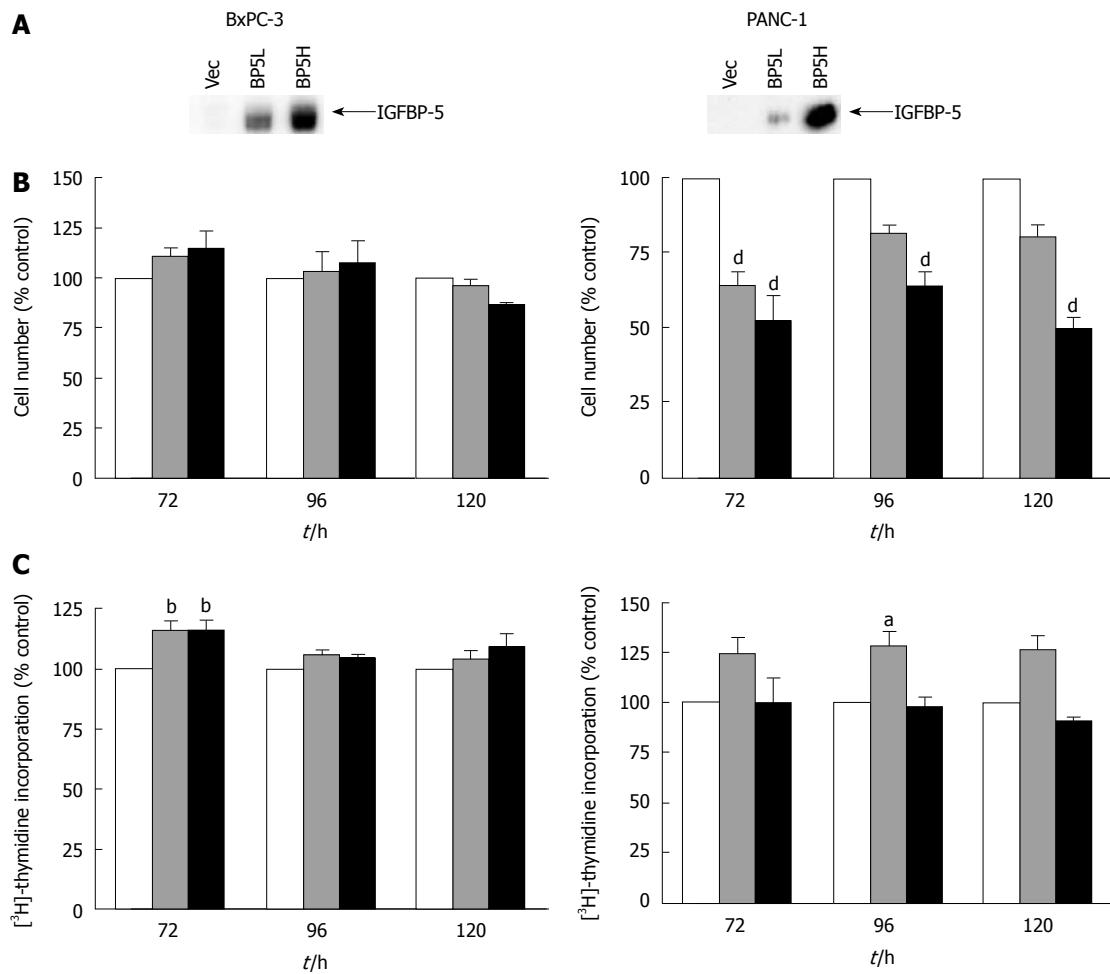

## RESULTS

#### *IGFBP-5 overexpression promotes BxPC-3 cell growth after serum deprivation*

The stable expression of IGFBP-5 in transfected PaC cells was verified by immunoblot analysis after 24 h growth in serum-free conditions and concentration of conditioned medium (Figure 1A). To examine dose-dependent effects and to obviate insertion effects resulting from the generation of the stable transfectants, growth effects were assessed by analyzing cell number and thymidine incorporation using cell lines expressing different levels of IGFBP-5 designated as low (IGFBP-5L) and high (IGFBP-5H). In serum-containing medium, cell numbers were significantly lower in PANC-1 cells expressing IGFBP-5 than in vector transfected control cells (Figure 1B). Although the decrease in PANC-1 cell number corresponded to the increase in IGFBP-5 expression, a similar association in DNA synthesis and IGFBP-5 expression was not observed (Figure 1C). These results suggest that IGFBP-5 inhibits growth of PANC-1 cells cultured in the presence of serum. In contrast, no growth effects were observed in BxPC-3 cells grown in serum-containing medium.

IGFBP-5 has been shown to have both growth factor-dependent and -independent growth and survival effects in both normal and cancer cells<sup>[3]</sup>. Therefore, we hypothesized that IGFBP-5 may aid growth of PaC cells when the bioavailability of growth factors is low. To investigate this, we examined IGFBP-5-mediated growth effects in the absence of exogenous growth factors. As IGFs are present in FBS, we performed these studies in the absence of serum as has been done previously to elucidate IGF-dependent and -independent effects<sup>[5,12-14]</sup>. Consistent with our hypothesis, both cell number and DNA synthesis increased significantly in BxPC-3 cells expressing high levels of IGFBP-5 in SFM (Figure 2A and B, respectively). In contrast, high levels of IGFBP-5 significantly reduced the number of PANC-1 cells (Figure 2A). Interestingly, low levels of IGFBP-5 significantly elevated thymidine incorporation in PANC-1 cells, similar to the effects observed in cells grown in serum-containing medium, though the increase was less dramatic in the presence of high levels of IGFBP-5 (Figure 2B). These data suggest that, in the absence of exogenous growth factors, IGFBP-5 promotes growth of BxPC-3 cells but inhibits growth of PANC-1 cells.

Growth factors and their receptors are upregulated and associated with increased tumorigenicity in pancreatic cancer<sup>[15]</sup>. Additionally, in PaC cells the overexpression of autocrine growth factors has been shown to allow cell proliferation in the absence of serum<sup>[16,17]</sup>. In the previous experiments, PaC cells were grown without replenishing SFM for 120 h. Thus,

**Figure 1 Effect of IGFBP-5 expression on PaC cells grown in the presence of serum.** Stable transfectants (empty vector /Vec-white bar, low /IGFBP-5L-gray bar, high/IGFBP-5H-black bar) were seeded in growth media. (A) IGFBP-5 expression was verified by immunoblot analysis of secreted IGFBP-5 after 24 h growth in SFM and concentration of conditioned medium. Cell counts (B) and thymidine incorporation (C) were determined at 72, 96 and 120 h post-seeding. Data shown represent the mean  $\pm$  SE of IGFBP-5-transfected cell growth relative to vector-transfected controls (100%) from 3-5 separate experiments performed in duplicate.  $^aP < 0.05$ ,  $^bP < 0.01$ ,  $^dP < 0.001$ .

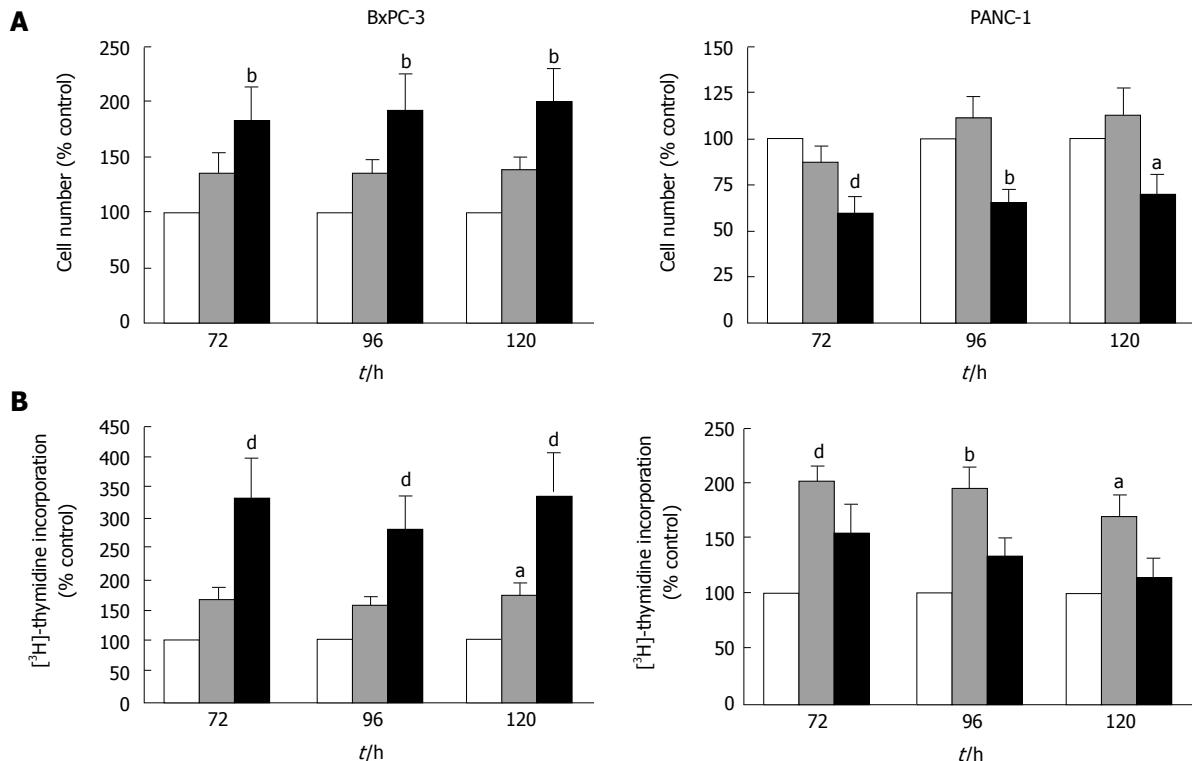

to determine whether IGFBP-5 confers a growth advantage in the absence of endogenously produced growth factors, cells were grown with SFM changed daily. In BxPC-3 cells cultured with frequent medium changes, IGFBP-5 expression was associated with significantly elevated thymidine incorporation and cell number (Figure 3). In contrast, significantly reduced cell numbers were observed in PANC-1 cells expressing high levels of IGFBP-5 grown with frequent changes of SFM (Figure 3A). Therefore, even in the absence of growth factors, IGFBP-5 enhanced BxPC-3 cell proliferation but inhibited PANC-1 cell growth, and these effects were exacerbated by frequent changes of SFM.

#### **IGFBP-5 expression is associated with cell cycle dysregulation in serum-containing growth conditions**

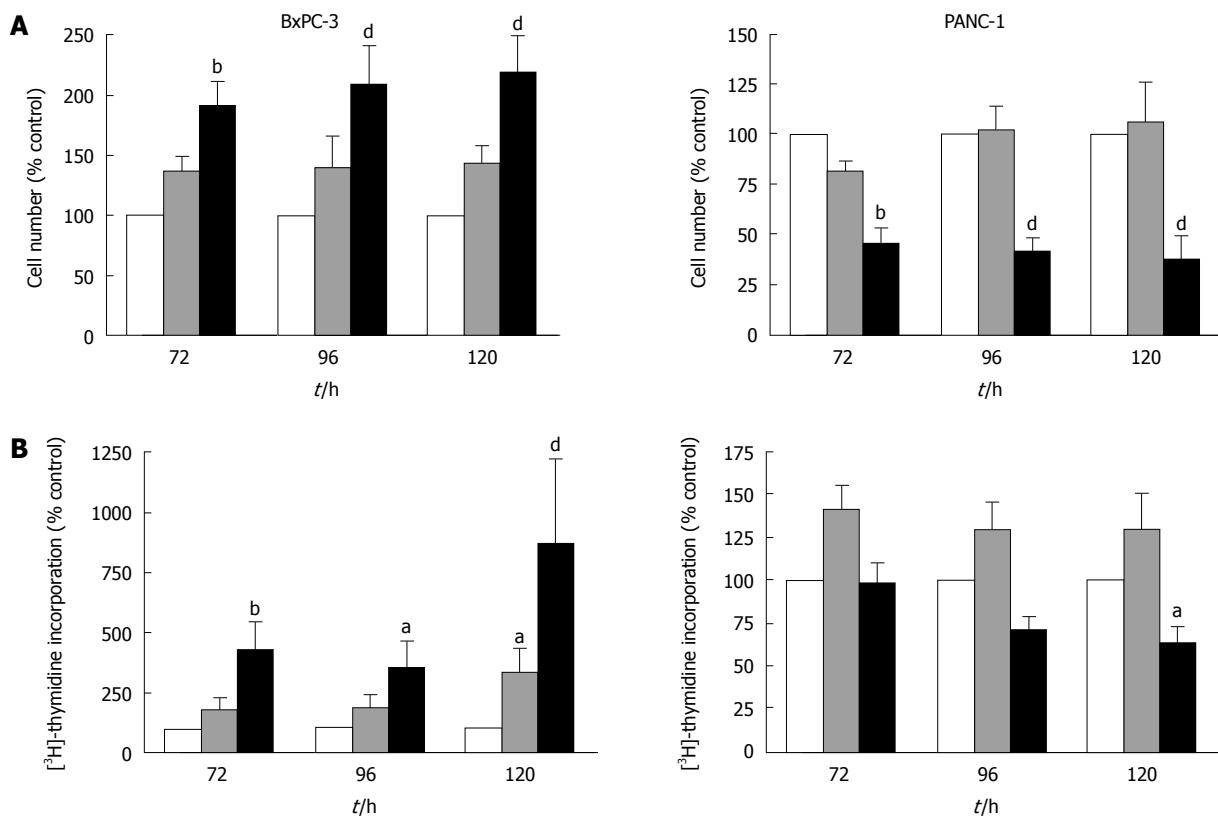

In the growth studies, PANC-1 cells that overexpress IGFBP-5 had lower cell numbers but more DNA synthesis than control cells. These data suggest a possible block in the cell cycle at the G2/M transition. In contrast, BxPC-3 cells expressing high levels of IGFBP-5 exhibited higher cell numbers and thymidine incorporation, indicating accelerated progression

through the cell cycle. While IGFBP-5 expression has different effects on growth of the two cell lines, these data indicate that the effects might result from a common overall process-cell cycle dysregulation.

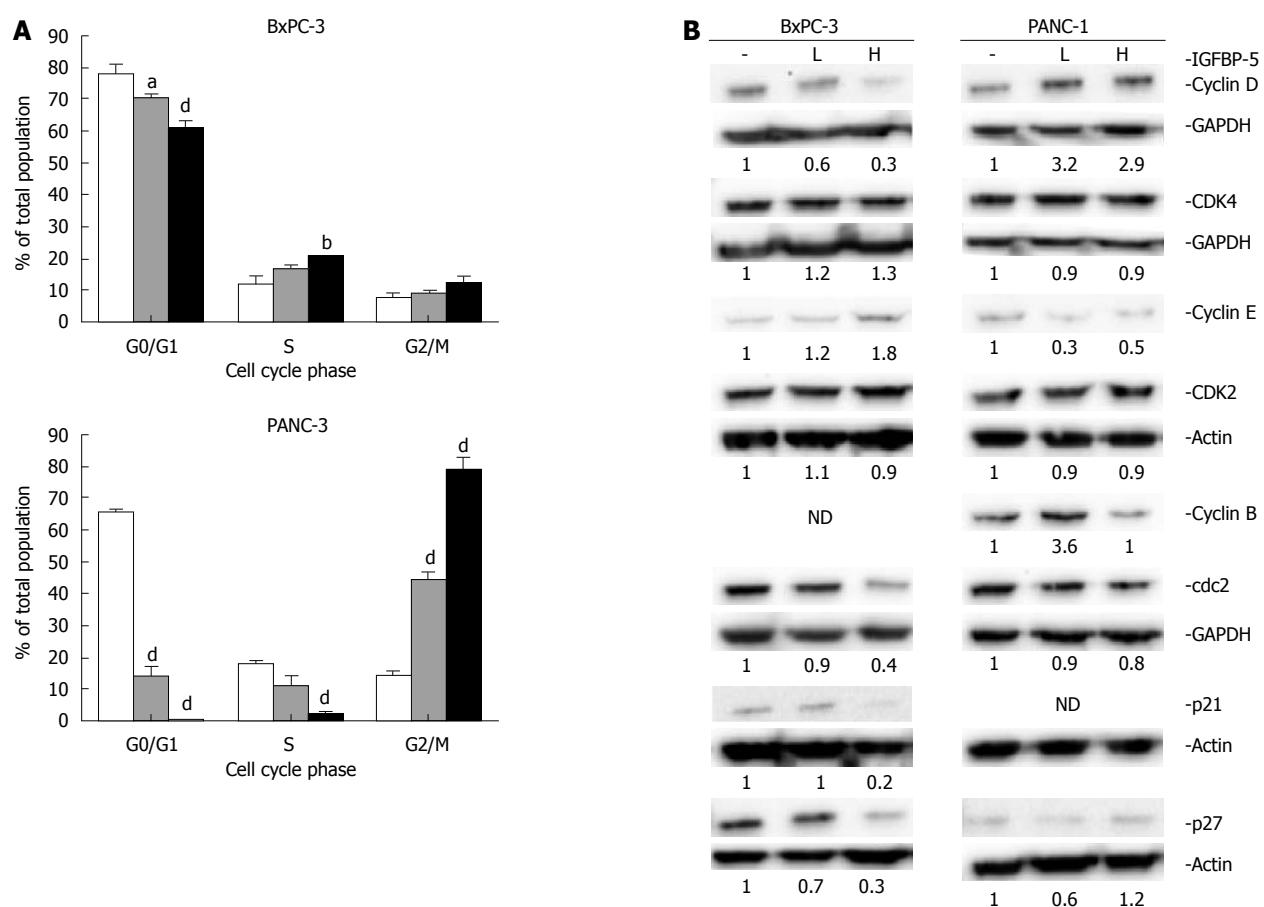

Therefore, we examined the cell cycle distribution and status of key cell cycle regulators of G1/S (cyclin D/CDK4, cyclin E/CDK2, p21<sup>Cip1</sup>, and p27<sup>Kip1</sup>) and G2/M (cyclin B/cdc2) transitions in transfected cell lines in the presence (Figure 4) and absence (Figure 5) of serum. The examination of cell cycle distribution by propidium iodide staining and FACS analysis revealed that IGFBP-5 expression in BxPC-3 cells grown in the presence of serum resulted in significantly fewer cells in G1 phase and an increased percentage of cells in S phase (Figure 4A). In contrast, in PANC-1 cells grown in the presence of serum, IGFBP-5 expression was associated with significantly fewer cells in G1 and S phases and an accumulation of cells in G2/M phase (Figure 4A). To identify the cell cycle components responsible for these effects, the expression of key cell cycle regulators was determined in the same growth conditions used for analyzing cell cycle distribution. In BxPC-3 cells, IGFBP-5 overexpression was associated with markedly

**Figure 2 Effect of IGFBP-5 expression on PaC cells grown in the absence of serum.** Stable transfectants (empty vector/Vec-white bar, low/IGFBP-5L-gray bar, high/IGFBP-5H-black bar) were seeded in growth media for 24 h then switched to serum-free medium (SFM) for the remainder of the growth period. Cell counts (A) or thymidine incorporation (B) were determined at 72, 96 and 120 h post-seeding. Data shown represent the mean  $\pm$  SE of IGFBP-5-transfected cell growth relative to vector-transfected controls (100%) from 3-5 separate experiments performed in duplicate.  $^aP < 0.05$ ,  $^bP < 0.01$ ,  $^dP < 0.001$ .

**Figure 3 Effect of IGFBP-5 expression on PaC cells grown with daily changes of SFM.** Stable transfectants (empty vector/Vec-white bar, low/IGFBP-5L-gray bar, high/IGFBP-5H-black bar) were seeded in growth media for 24 h and switched to SFM, which was replaced every 24 h for the remainder of the growth period. Cell counts (A) and thymidine incorporation (B) were determined at 72, 96 and 120 h post-seeding. Data shown represent the mean  $\pm$  SE of IGFBP-5-transfected cell growth relative to vector-transfected controls (100%) from 3-5 separate experiments performed in duplicate.  $^aP < 0.05$ ,  $^bP < 0.01$ ,  $^dP < 0.001$ .

**Figure 4 Cell cycle distribution of PaC cells that overexpress IGFBP-5 grown in the presence of serum.** Stable transfectants (empty vector/Vec-white bar, low/IGFBP-5L-gray bar, high /IGFBP-5H-black bar) were seeded in growth media. After 24 h, the medium was removed and replaced with fresh growth media for 48 h. (A) Cell cycle distribution was determined by propidium iodide staining and FACS analysis. Data shown represent the mean  $\pm$  SE from 3 experiments performed in duplicate. (B) Cell lysates were prepared for immunoblot analysis of cell cycle regulators and their expression was detected using the appropriate antisera. Membranes were subsequently stripped and reprobed for actin or GAPDH as a load control. Analyses of cyclin E/cdk2 and cyclin B/cdc2 expression were performed simultaneously, therefore, only a single load control, actin or GAPDH, respectively, is shown for each pair. Quantitation of band density represents the level of IGFBP-5-associated expression relative to vector-transfected controls (1.0) normalized to the expression level of actin. ND: Not detected. The results are representative of 3 experiments. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ , <sup>d</sup> $P < 0.001$ .

lower levels of cyclin D, cdc2, p21<sup>Cip1</sup>, and p27<sup>Kip1</sup> but elevated levels of cyclin E (Figure 4B). In contrast, in PANC-1 cells overexpression of IGFBP-5 resulted in elevated levels of cyclin D but reduced levels of cyclin E (Figure 4B). Expression of cyclin B in BxPC-3 and p21 in PANC-1 cells was not detected.

#### IGFBP-5 expression is associated with cell cycle dysregulation during serum starvation

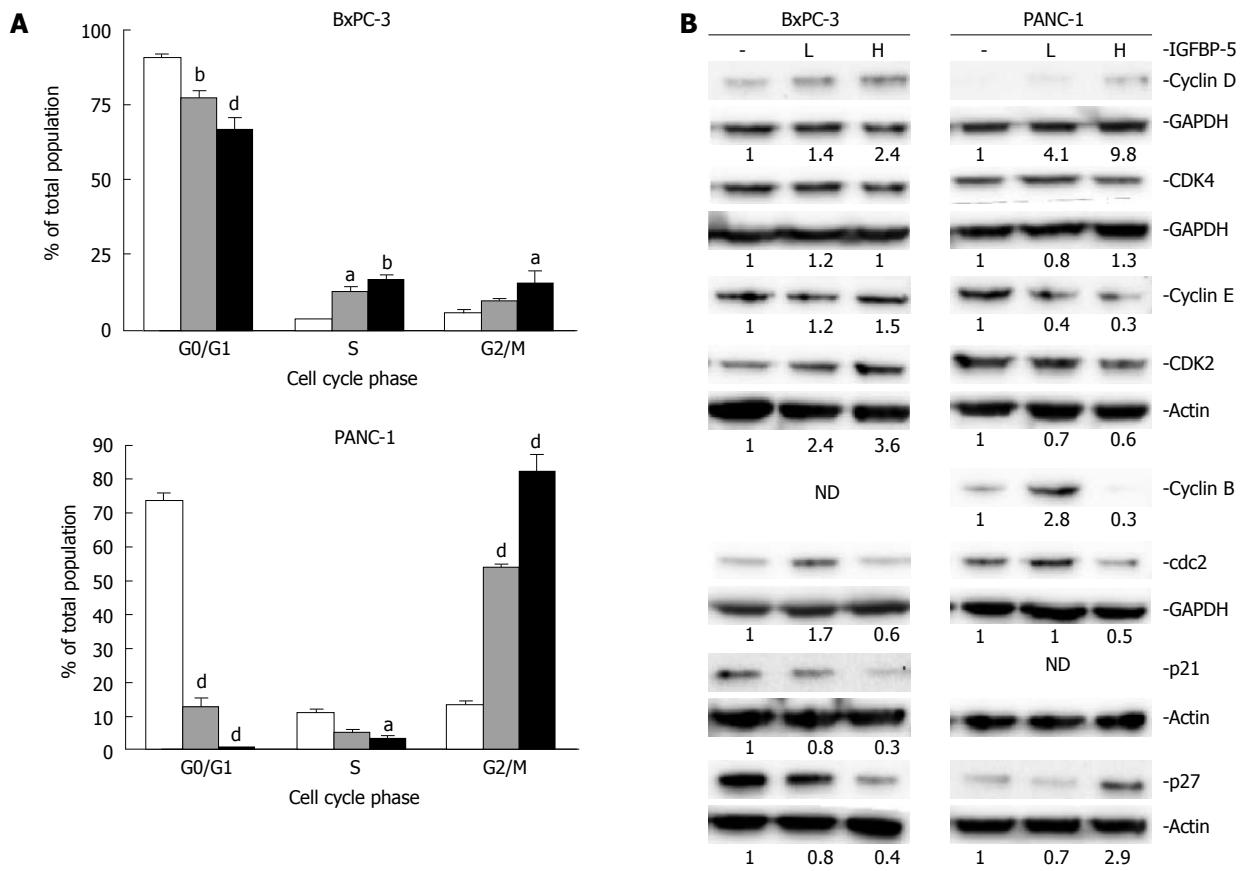

In the absence of serum, IGFBP-5 expression resulted in marked alterations in cell proliferation, particularly in BxPC-3 cells; therefore, the cell cycle was analyzed in serum-starved cells. Serum deprivation exacerbated the effects of IGFBP-5 expression on cell cycle distribution that were observed in serum-containing growth conditions. In BxPC-3 cells, the percentage of IGFBP-5-expressing cells was reduced in G1 phase but elevated in both S and G2/M phases (Figure 5A). In PANC-1 cells, IGFBP-5 expression was associated with a reduced percentage of cells in G1 and S phases and an increased percentage of cells in G2/M phase (Figure 5A).

To determine whether serum starvation changes

expression profiles of cell cycle regulators in cells that express IGFBP-5, we assessed the expression in cells grown in SFM. With IGFBP-5 expression, BxPC-3 cells showed prominent increases in the levels of cyclin D and CDK2, and to a lesser extent, cyclin E, which is consistent with enhanced cell proliferation. However, the levels of the G1/S transition inhibitors p21<sup>Cip1</sup> and p27<sup>Kip1</sup> were reduced (Figure 5B). IGFBP-5 expression in PANC-1 cells in the absence of serum produced increased levels of p27<sup>Kip1</sup> and cyclin D and reduced levels of cyclin E and CDK2 (Figure 5B), which reflects the observed growth arrest and accompanying enhanced thymidine incorporation (Figure 2). Similar to PaC cells grown in the presence of serum, cyclin B expression in BxPC-3 and p21 expression in PANC-1 cells was not detected.

#### PI3K signaling is required for IGFBP-5-enhanced growth of BxPC-3 cells

To investigate the mechanism of IGFBP-5-enhanced cell growth after serum deprivation, we examined the PI3K and MAPK pathways, which have been shown to

**Figure 5 Cell cycle distribution of PaC cells that overexpress IGFBP-5 grown in the absence of serum.** Stable transfectants (empty vector/Vec-white bar, low/IGFBP-5L-gray bar, high /IGFBP-5H-black bar) were seeded in growth media. After 24 h, the medium was changed to SFM for 48 h. A: Cell cycle distribution was determined by propidium iodide staining and FACS analysis. Data shown represent the mean  $\pm$  SE from 3 separate experiments performed in duplicate; B: Cell lysates were prepared for immunoblot analysis of cell cycle regulators and their expression was detected using the appropriate antisera. Membranes were subsequently stripped and reprobed for actin or GAPDH as a load control. Analyses of cyclin E/cdk2 and cyclin B/cdc2 expression were performed simultaneously, therefore, only a single load control, actin or GAPDH, respectively, is shown for each pair. Quantitation of band density represents the level of IGFBP-5 associated expression relative to vector-transfected controls (1.0) normalized to the expression level of actin. ND: Not detected. The results are representative of 3 experiments. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ , <sup>c</sup> $P < 0.001$ .

enhance proliferation and survival of pancreatic cancer cells<sup>[18-21]</sup>. Immunoblot analysis of the PI3K signaling intermediate Akt revealed a 3.5-fold increase in the level of phosphorylated Akt in BxPC-3 cells expressing IGFBP-5, but Akt phosphorylation was reduced in PANC-1 cells expressing IGFBP-5 (Figure 6A). When cells were treated with a PI3K inhibitor, LY294002, IGFBP-5 no longer conferred a growth advantage in BxPC-3 cells (Figure 6B). These results indicate that PI3K signaling is necessary for IGFBP-5-enhanced growth of BxPC-3 cells.

#### MAPK signaling is required for IGFBP-5-enhanced growth of pancreatic cancer cells

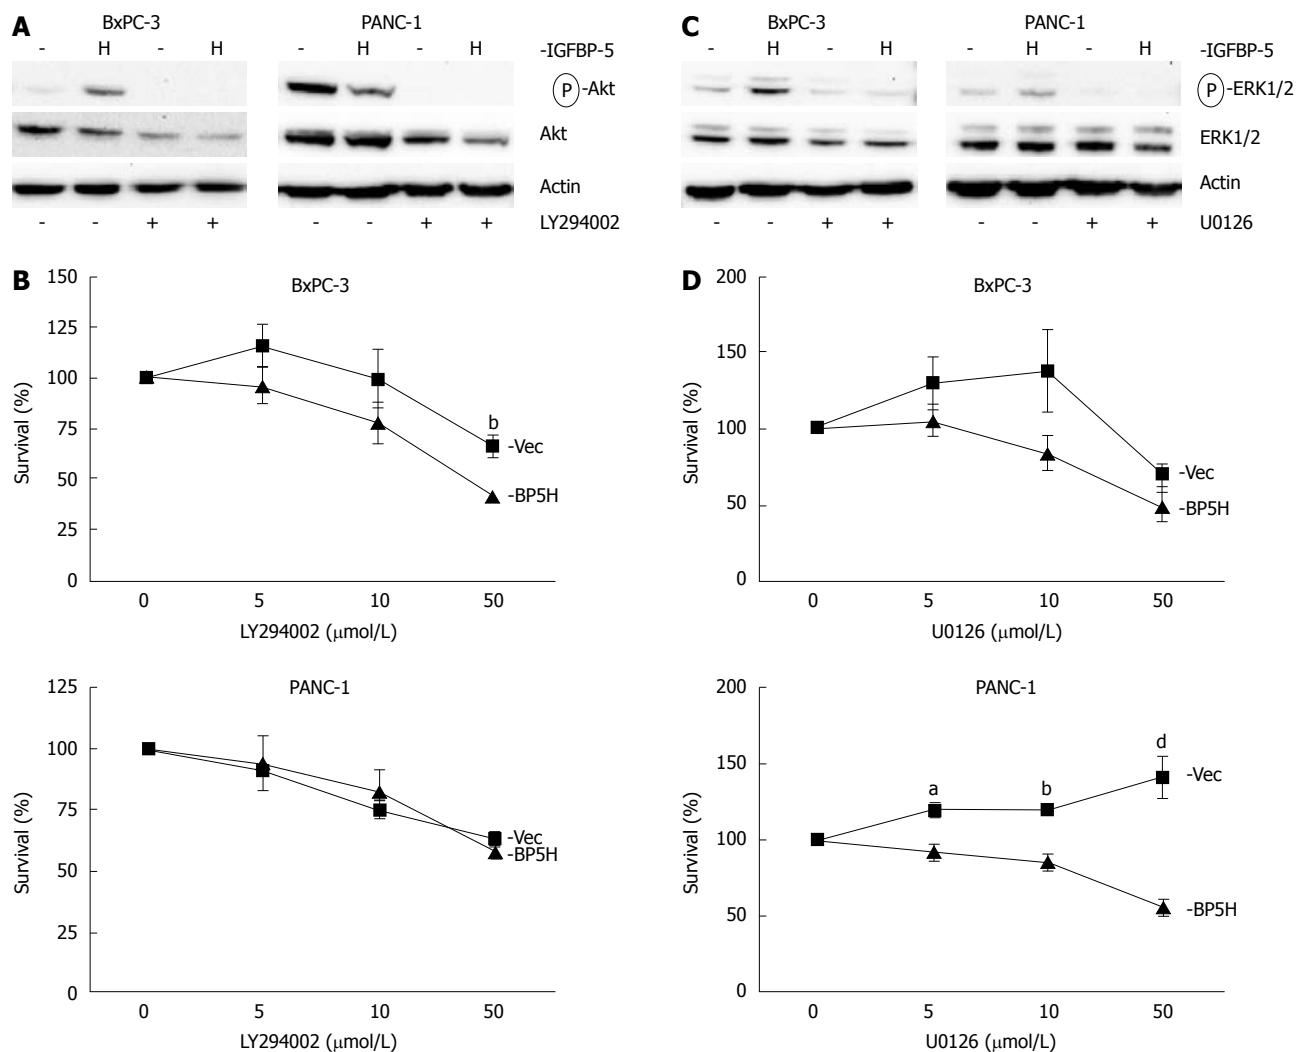

To determine whether IGFBP-5 mediates cell growth via MAPK signaling in PaC cells, the survival studies were repeated with U0126, a MEK1/2 inhibitor. Immunoblot analysis revealed that ERK1/2 activation (phosphorylation) is 2.6-fold greater in BxPC-3 cells expressing IGFBP-5 (Figure 6C) and IGFBP-5-mediated growth is abrogated when the MAPK pathway is blocked with U0126 treatment (Figure 6D). Similarly, ERK1/2 activation is 2-fold greater in PANC-1 cells that express IGFBP-5 (Figure 6C) and significantly fewer IGFBP-

5-expressing cells survive when the MAPK pathway is blocked (Figure 6D). These studies suggest that the MAPK pathway is necessary for IGFBP-5-enhanced cell growth after serum deprivation.

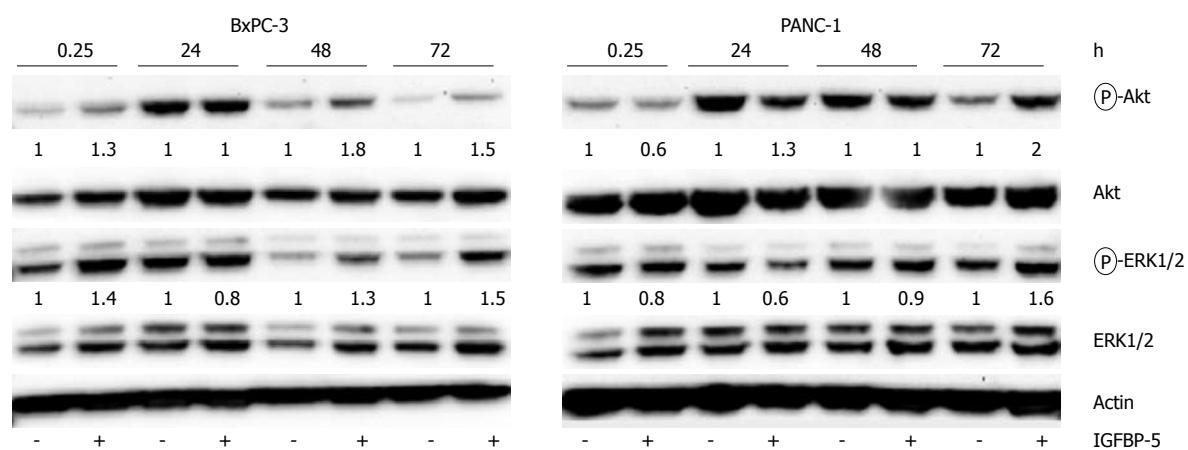

#### Effect of IGFBP-5-conditioned medium on signaling in PaC cells

To determine whether IGFBP-5 induced changes in Akt and ERK1/2 activation through an autocrine pathway, we applied conditioned medium from IGFBP-5-transfected cells to PaC cells and examined the effect on Akt and ERK1/2 activation. Consistent with our expression studies, BxPC-3 cells treated with IGFBP-5-conditioned medium increased activation of Akt and ERK1/2 compared with cells treated with conditioned medium from vector transfected cells (Figure 7). Similar levels of phosphorylated protein were observed in cells exposed to vector-transfected or IGFBP-5-conditioned medium at 24 h, however, only PaC cells exposed to IGFBP-5-conditioned medium had a prolonged induction of Akt and ERK1/2 activation (72 h).

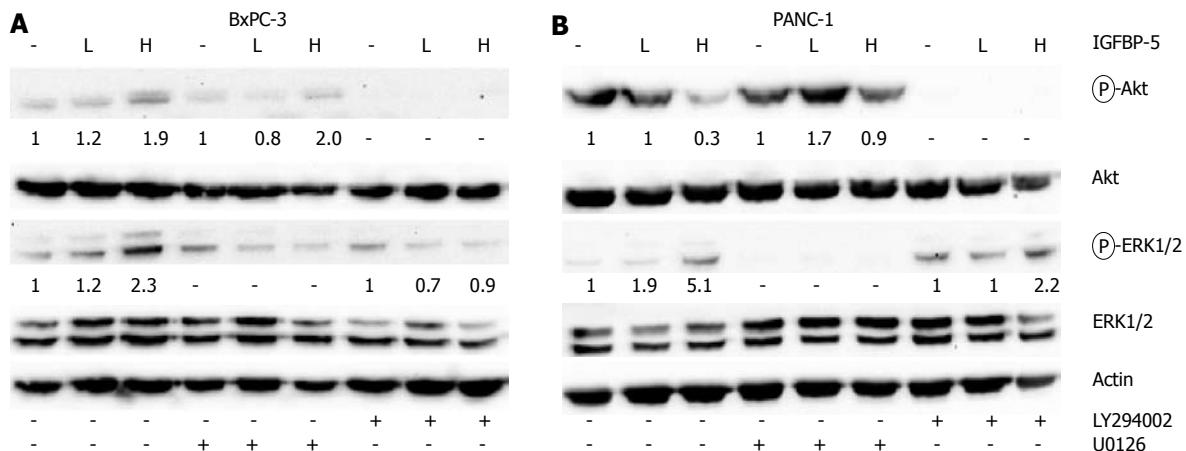

The effect of IGFBP-5 conditioned medium on ERK1/2 activation in PANC-1 cells was similar to the results observed in cells expressing IGFBP-5. After

**Figure 6** PI3K or MEK1/2 inhibition decreases IGFBP-5-enhanced growth of serum-starved PaC cells. Stable transfectants (empty vector/Vec-closed square or high /BP5H-closed triangle) were seeded in growth media. The serum-containing medium was changed to SFM 24 h post-seeding. After 24 h in serum-free conditions, a PI3K inhibitor (LY294002, A and B) or MEK1/2 inhibitor (U0126, C and D) was added to the medium. After 48 h, an MTT assay (B and D) was performed to assess cell viability. Cell lysates were prepared at this time for immunoblot analysis of Akt or ERK1/2 activation (A and C, respectively) using phospho-specific antibodies. For immunoblots, cells were treated with 25  $\mu$ mol/L LY294002 or 10  $\mu$ mol/L U0126, as indicated. Membranes were subsequently stripped and reprobed for total Akt or ERK1/2 (A and C, respectively). Actin level was monitored to normalize protein loading. Data shown represent the mean  $\pm$  SE from 4 separate experiments performed in triplicate. The percentage of viable cells was determined relative to control-treated cells (100%). <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ , <sup>d</sup> $P < 0.001$ .

**Figure 7** IGFBP-5-conditioned medium enhances activation of Akt and ERK1/2 in PaC cells. IGFBP-5- (+) or vector-transfected (-) control cells were grown for 48 h in SFM. Conditioned medium was collected and applied to BxPC-3 or PANC-1 cells for indicated times. Cell lysates were prepared and immunoblot analysis of phosphorylated Akt or ERK1/2 was performed. Membranes were subsequently stripped and reprobed for total Akt or ERK1/2. Actin level was monitored to normalize protein loading. Quantitation of band density represents the level of IGFBP-5-associated expression relative to vector-transfected controls (1.0) normalized to the expression level of total Akt or ERK1/2. Results are representative of three independent experiments.

**Figure 8** Effect of IGFBP-5 on signaling in serum-starved PaC cells. BxPC-3 (A) and PANC-1 (B) stable transfectants [empty vector (-), low IGFBP-5-L, or high IGFBP-5-H] were deprived of serum for 24 h then incubated in the presence of vehicle (DMSO), LY294002, or U0126 (10  $\mu$ mol/L) for an additional 48 h. Cell lysates were prepared for immunoblot analysis of Akt or ERK1/2 activation using phospho-specific antibodies. Membranes were subsequently stripped and reprobed for total Akt or ERK1/2. Actin level was monitored to normalize protein loading. Quantitation of band density represents the level of IGFBP-5-associated expression relative to vector-transfected controls (1.0) normalized to the expression level of total Akt or ERK1/2. Results are representative of three independent experiments.

exposure of PANC-1 cells to IGFBP-5-conditioned medium, Akt and ERK1/2 activation levels were slightly reduced after 15 min, reached control levels by 48 h, and were elevated by 72 h (Figure 7). Interestingly, in PANC-1 cells that express IGFBP-5, activation of Akt was reduced whereas in cells exposed to IGFBP-5-conditioned medium Akt activation was elevated (2 fold). To determine if the IGFBP-5-mediated growth effects observed in PaC cells that express IGFBP-5 could be replicated by application of conditioned medium, PANC-1 and BxPC-3 cell growth was examined. The cell number and level of DNA synthesis observed in cells exposed to IGFBP-5-conditioned medium compared to controls in these growth conditions were not significantly different (data not shown). These results suggest that enhanced activation of Akt and ERK1/2 in IGFBP-5 expressing PaC cells is due to an autocrine pathway.

#### Effect of IGFBP-5 on Ras-mediated cross-talk

After serum deprivation of PANC-1 cells, Akt activation is reduced whereas ERK1/2 activation is elevated in cells expressing IGFBP-5. In BxPC-3 cells that express IGFBP-5, Akt and ERK1/2 phosphorylation is elevated. Previously, it has been shown that Ras- and PI3K-mediated pathways exhibit cross-talk in breast cancer cells<sup>[22]</sup>. Therefore, we sought to determine whether the differential effects observed between the PaC cells which express wild-type K-Ras (BxPC-3) or harbor mutated K-Ras (PANC-1) were a result of cross-talk between these pathways. Serum-deprived PaC cells were exposed to either U0126 or LY294002 and activation of ERK1/2 and Akt was examined by immunoblot analysis. After MEK1/2 inhibition in serum-starved BxPC-3 cells, Akt activation is decreased, however IGFBP-5 expressing cells maintain a level of Akt activation that is 2-fold greater than vector-transfected cells (Figure 8A). Inhibition of the PI3K pathway suppresses IGFBP-5-enhanced activation of ERK1/2 in serum-deprived

BxPC-3 cells. These results suggest that Akt activation is necessary for enhanced activation of ERK1/2 associated with IGFBP-5. In contrast, inhibition of MEK1/2 does not completely block IGFBP-5-enhanced Akt activation, therefore, ERK1/2-independent pathways must contribute to increased Akt activation associated with IGFBP-5.

In PANC-1 cells, inhibition of PI3K signaling is associated with elevated levels of ERK1/2 activation in the presence of IGFBP-5 compared to vector controls (Figure 8B). Interestingly, IGFBP-5 is associated with an elevated level of Akt activation (1.7 to 3 fold) when MAPK signaling is blocked compared to that observed in the absence of MAPK inhibition (Figure 8). These results suggest that inhibition of either the MAPK or PI3K pathway in IGFBP-5 expressing PANC-1 cells may shift signaling to the other pathway.

## DISCUSSION

Previously, we determined that IGFBP-5 was differentially expressed in pancreatic tumors compared to non-malignant pancreatic tissue<sup>[9]</sup>. IGFBP-5 has been implicated in cell survival in muscle, prostate cancer, and breast cancer cells<sup>[23-25]</sup>, however, the role of IGFBP-5 in pancreatic cancer has not been investigated. In this study we have examined the effects of IGFBP-5 expression on two cell lines, BxPC-3 and PANC-1, both of which express the IGF-1 receptor and are responsive to IGF-1<sup>[26]</sup>. Growth of the cell lines in the presence of serum, used as a surrogate for IGF-1 and other growth factors<sup>[12-14]</sup>, revealed that IGFBP-5 reduced PANC-1 cell growth thus opposing the cell proliferative effects of IGF-1 and other growth factors. This result is similar to the growth inhibitory effects of IGFBP-5 observed in breast cancer cells<sup>[27]</sup>.

When tumors reach a certain size, their growth is limited by a lack of available growth factors; therefore, mechanisms that circumvent growth factor deprivation

and allow tumor growth are utilized. Consistent with this notion, we found that IGFBP-5 promotes cell growth after serum starvation. In the presence of IGFBP-5 after serum starvation, cell number and DNA synthesis are significantly elevated in BxPC-3 cells, with a clear dose-dependency reflected by increased cell growth with increased IGFBP-5 expression. In contrast, high levels of IGFBP-5 in PANC-1 cells inhibited growth. Interestingly, low levels of IGFBP-5 appeared to enhance DNA synthesis as measured by thymidine incorporation, but this effect was lost with higher IGFBP-5 expression, though the reason for these differences remains unclear. Intriguingly, the growth promoting effects of IGFBP-5 on BxPC-3 cells parallel those observed in prostate cells<sup>[24]</sup>.

The upregulation of oncogenes and downregulation of tumor suppressor genes contributes to the uncontrolled growth and survival of pancreatic cancer cells<sup>[28]</sup>. To determine if IGFBP-5 overexpression contributes to the dysregulation of pancreatic cancer cell growth, we analyzed cell cycle distribution and found that IGFBP-5 promotes progression through the cell cycle in BxPC-3 cells but leads to a G2/M cell cycle arrest in PANC-1 cells. These results are consistent with observed changes in cell number and DNA synthesis associated with IGFBP-5 expression. Other studies have shown that serum-starved BxPC-3 cells undergo cellular arrest and increased apoptosis. However, after serum stimulation cellular proliferation proceeds and apoptosis is reduced; both responses are dependent on PI3K activation<sup>[29]</sup>. Our study shows that serum-deprived BxPC-3 cells that express IGFBP-5 continue to proliferate and thus IGFBP-5 may mimic the effect of serum exposure and provide the mitogenic stimulus necessary for tumor growth when the bioavailability of growth factors is low. Thus, in this context IGFBP-5 can act similarly to, and in the absence of, IGF-I to enhance proliferation of pancreatic cancer cells.

Neuroblastoma cells exposed to increasing doses of IGFBP-5 dramatically increased proliferation in the presence of low levels of IGFBP-5 but returned to control levels at a higher dose<sup>[30]</sup>. For this study, we chose clones which express IGFBP-5 at either a low or high level to determine if IGFBP-5 affects pancreatic cancer cell growth in a dose-dependent manner. Indeed, the effects of IGFBP-5 on the growth of BxPC-3 and PANC-1 cells appeared to be dose-dependent; however, the effect was additive rather than inverse as observed in neuroblastoma cells. Low levels of IGFBP-5 promote progression of BxPC-3 cells through the cell cycle and this effect is exacerbated by high levels of IGFBP-5. PANC-1 cells that expressed low levels of IGFBP-5 had cell numbers similar to the control but two-fold increases in DNA synthesis; whereas cells with high levels of IGFBP-5 had reduced cell numbers but maintained or slightly exceeded control levels of DNA synthesis which may be due to elevated Cyclin D1 levels observed in these conditions (Figure 4). Both low and high levels of IGFBP-5 in PANC-1 cells led to cell cycle arrest at G2/M; however, when cells expressed high levels of IGFBP-5 a greater percentage

accumulated in G2/M phase. Overexpression of IGFBP-5 in breast cancer cells also resulted in G2/M cell cycle arrest as well as induction of apoptosis<sup>[27]</sup>, though we did not observe an increase in the percentage of cells with subG1 DNA content.

Our studies show that changes resulting in IGFBP-5-enhanced BxPC-3 cell growth are reflected by elevations in cyclins D and E and accompanying reductions in p21<sup>Cip1</sup> and p27<sup>Kip1</sup> CDK inhibitors, which may allow BxPC-3 cells that express IGFBP-5 to rapidly progress through the G1/S transition and result in enhanced cell growth observed in cell growth studies. In a survey of pancreatic tumors, CDK2 and CDK4 upregulation was observed to directly correlate with progression of pancreatic cancer; in contrast cyclin E upregulation was observed in 25% of high-grade intraepithelial neoplasia and 75% of ductal carcinoma and cyclin D1 had the lowest frequency of upregulation in late stage disease further demonstrating the deregulation of the G1/S transition in the early stages of PaC<sup>[31]</sup>. The progressive loss of p27<sup>Kip1</sup> expression has been correlated with tumor grade and clinical stage (i.e. positive immunohistochemical staining in well-differentiated, early stage tumors) and thus may be involved in the malignant progression of PaC<sup>[32,33]</sup>. In contrast to the growth effects of IGFBP-5 observed in BxPC-3 cells, PANC-1 cells expressing IGFBP-5 exhibited reduced levels of cyclin E and CDK2 and an elevated level of p27<sup>Kip1</sup>, which may explain the distinct G2/M arrest observed for this cell line. This likely protects cells from unfavorable conditions and allows cells to rapidly re-enter the cell cycle when conditions are favorable.

IGFBP-5-mediated growth effects are often associated with activation of the PI3K and MAPK pathways<sup>[24,30]</sup>. In PaC cells, it has been observed that Akt is constitutively activated at a high level in PANC-1 cells but not in BxPC-3 cells<sup>[34]</sup>, which our study confirms; whereas MAPK activity is not constitutively active in PANC-1 or BxPC-3 cells<sup>[5,12]</sup>. In this study, overexpression of IGFBP-5 elicited increased phosphorylation of Akt in BxPC-3 cells but reduced phosphorylation in PANC-1. Both cell lines, however, exhibited a modest increase in ERK1/2 phosphorylation with IGFBP-5 expression. Upon inhibition of either the PI3K or MAPK pathway, IGFBP-5 no longer enhanced growth of BxPC-3 or PANC-1 cells after serum deprivation. These data suggest, therefore, that IGFBP-5 promotes cell growth in BxPC-3 cells by enhancing PI3K-Akt signaling. Consistent with our findings, a conditionally active form of Akt has been shown to transform cells by promoting progression through S and G2/M phases of the cell cycle, decreasing expression of p27<sup>Kip1</sup>, and increasing activity of CDK2<sup>[35]</sup>, similar to our observations in BxPC-3 cells overexpressing IGFBP-5.

In this study, we have demonstrated that in BxPC-3 cells IGFBP-5 promotes proliferation *via* activation of the PI3K pathway; whereas it promotes growth arrest *via* activation of the MAPK pathway in PANC-1 cells. Although both cell lines employed in these studies were derived from pancreatic adenocarcinomas, they represent

different genetic backgrounds and reflect differences observed in human tumors. For example, both cell lines express the IGF-1R and are responsive to IGF-1<sup>[26]</sup>, however, BxPC-3 cells have wild-type K-ras and express lower levels of PTEN mRNA while PANC-1 cells express higher levels of PTEN mRNA and possess an activating K-ras mutation. Thus, while the opposing effects of IGFBP-5 on these two cell lines may not be satisfying to those expecting a uniform response from cells originating from the same tumor type, these results highlight the clinical challenge of treating a disease that does not actually represent a single entity. Tumors arising from the same organ may exhibit a great diversity in the signal transduction pathways they utilize and treatments will continue to fail if they do not account for these differences. In both cell lines employed in this study the predominant pathway stimulated by IGFBP-5 (i.e. Akt in BxPC-3 and ERK1/2 in PANC-1) is maintained, although at a lower level, in the presence of pharmacological inhibition of the other pathway, which may represent a novel mechanism by which IGFBP-5 promotes PaC cell growth and survival.

Pancreatic tumors are highly chemoresistant, thus treatment rarely leads to eradication of the malignancy. Since tumors are comprised of cells with heterogeneous genetic backgrounds they often do not respond uniformly to any specific treatment. This cellular complexity is underscored by the divergent characteristics of the two PaC cell lines used in our study. Our results, therefore, highlight the need to identify multiple chemotherapeutic targets for treating pancreatic cancer. Further studies aimed at identifying signaling intermediates involved in IGFBP-5-enhanced cell growth and survival within the diverse cellular population of pancreatic tumors may therefore elucidate potentially important therapeutic targets.

## COMMENTS

### Background

Pancreatic cancer (PaC) is the fourth leading cause of cancer deaths in the United States. Annually, the incidence of PaC almost equals the number of deaths related to this disease, and these numbers have begun to increase. Previously, insulin-like growth factor binding protein-5 (IGFBP-5) was demonstrated to be differentially expressed in pancreatic tumors compared to non-malignant pancreatic tissue. IGFBP-5 has been implicated in cell survival in muscle, prostate cancer, and breast cancer cells; however, the role of IGFBP-5 in pancreatic cancer has not been investigated.

### Research frontiers

IGFPB-5 is expressed at higher levels in pancreatic tumors than in non-malignant pancreatic tissues. The role of IGFBP-5 in cancer cell growth and proliferation, however, is not fully understood and has not been studied in pancreatic cancer. In this study, the authors demonstrate that IGFBP-5 can enhance pancreatic cancer cell growth by altering the expression and activity of cell cycle regulators and the activation of key signaling intermediates.

### Innovations and breakthroughs

In this study, the effects of IGFBP-5 expression were examined on two cell

lines, BxPC-3 and PANC-1, both of which express the IGF-I receptor and are responsive to IGF-I. In BxPC-3 cells IGFBP-5 promotes proliferation via activation of the PI3K pathway; whereas it promotes growth arrest via activation of the MAPK pathway in PANC-1 cells. The opposing effects of IGFBP-5 on these two cell lines highlight the clinical challenge of treating a disease that does not actually represent a single entity. Tumors arising from the same organ may exhibit a great diversity in the signal transduction pathways they utilize and treatments will continue to fail if they do not account for these differences.

### Applications

Pancreatic tumors are highly chemoresistant, thus treatment rarely leads to eradication of the malignancy. Since tumors are comprised of cells with heterogeneous genetic backgrounds they often do not respond uniformly to any specific treatment. The results of this study highlight the need to identify multiple chemotherapeutic targets for treating pancreatic cancer. Further studies aimed at identifying signaling intermediates involved in IGFBP-5-enhanced cell growth and survival within the diverse cellular population of pancreatic tumors may therefore elucidate potentially important therapeutic targets.

### Terminology

Insulin-like growth factors (IGFs) regulate cellular growth, differentiation, and apoptosis and IGF-binding proteins (IGFBPs) modulate the activity of IGFs. IGFBPs can also act independently of IGF to either stimulate or inhibit growth of various cell types. Both IGF-I and the IGF-I receptor (IGF-I R) are expressed in pancreatic tumors and cell lines, and IGFBP-1, -3, and -5 have been associated with pancreatic cancer.

### Peer review

The authors investigate the functional significance of IGFBP-5 overexpression in pancreatic cancer. The manuscript is interesting, with some novel aspects of the IGFBP-5 biology in pancreatic cancer cells disclosed.

findings of fibrosis and the severity of inflammation correlated with the MRI category in all cases.

**CONCLUSION:** Our findings suggest that SB CD can be grouped by the MRI findings and that these groups are associated with patients more likely to respond to continued medical therapy. The MRI categories also correlated with the presence and level of intestinal inflammation and fibrosis on surgical pathology, and may be of prognostic use in the management of CD patients.

Correlation of MRI-determined small bowel Crohn's disease categories with medical response and surgical pathology. *World J Gastroenterol* 2009; 15(27): 3367-3375 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3367.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3367>

## Abstract

**AIM:** To determine whether magnetic resonance imaging (MRI) can be used to categorize small bowel Crohn's disease (SB CD) into groups that correlate with response to medical therapy and surgical pathology.

**METHODS:** Data was collected from all patients with MRI evidence of SB CD without significant colonic disease over a 32-mo period. Two radiologists, blinded to clinical findings, evaluated each MRI and grouped them based on bowel wall thickness and wall enhancement. These categories were: (1) "fibrosis", (2) "mild segmental hyper-enhancement and mild wall thickening", (3) "mild segmental hyper-enhancement and marked wall thickening", (4) "marked segmental transmural hyper-enhancement". Patient response to additional medical therapy post-MRI was prospectively determined at 8-wk. Non-responders underwent endoscopy and were offered therapeutic endoscopy or surgery. Surgical pathology was assessed against the MRI category.

**RESULTS:** Fifty-five patients were included. Females and category "2" patients were more likely, and patients with luminal narrowing and hold-up less likely, to respond to medical therapy ( $P < 0.05$ ). Seventeen patients underwent surgery. The surgical pathological

## INTRODUCTION

Crohn's disease (CD) is a life-long, chronic, relapsing condition. Morbidity is high and its incidence and prevalence are increasing worldwide<sup>[1]</sup>. Despite the development of new medical therapies, there is little evidence that they alter the natural history of CD. Due to the transmural nature of CD, fibrosis, stenosis and obstruction often result<sup>[2]</sup>, with fibrosis and stricture formation still the most common reason for intestinal resection.

CD frequently involves the terminal ileum (TI) so investigation of the small bowel (SB) is of the utmost importance. Unfortunately, TI assessment by endoscopy is not optimal, with a significant proportion of colonoscopic examinations failing to reach the cecum<sup>[3]</sup>. The mainstay of SB investigation has been SB enterography or SB enteroclysis (SBE) that requires placement of a nasojejunal tube (NJT). More recently CT enteroclysis

(CTE), wireless capsule enteroscopy (WCE), double balloon enteroscopy, MR SB enteroclysis (MRE) and MR enterography have become available. Conventional radiology (SBE and SB enterography) only has a sensitivity of between 23% and 80% for the detection of typical CD radiological lesions<sup>[4-6]</sup>. It delivers ionising radiation and is suboptimal for the assessment of extra-intestinal involvement and complications. WCE on the other hand allows for excellent visualization of the SB mucosa, but its specificity is lower than other methods<sup>[6]</sup>, it does not clearly localise the lesions, histology cannot be taken, and there is a small but definite capsule retention rate contraindicating its use in SB strictures<sup>[7]</sup>.

CTE has been well described<sup>[8]</sup>, has good sensitivity (71%-95%) and impressive specificity (90%-98%) and is superior to conventional enteroclysis<sup>[9]</sup>. The use of ionising radiation in CTE in a generally young patient cohort, however, is not ideal. CTE also lacks functional information, has poor fluoroscopic control of SB filling and suboptimal soft tissue contrast<sup>[6,10-12]</sup>. MRI also has high sensitivity and specificity in the evaluation of CD<sup>[13]</sup> and while it does not provide as consistently good mucosal detail as conventional enteroclysis, it has a strong correlation with pathologic findings and does not use ionising radiation<sup>[14-16]</sup>. MRI also demonstrates good soft tissue contrast, subtle degrees of contrast enhancement and conveys functional information, while potentially differentiating active inflammation from fibrosis in preliminary studies<sup>[16,17]</sup>. A retrospective paper correlating CTE findings with surgical pathology in 36 patients accurately detected strictures, fistulas, abscesses and inflammatory masses in 94% of patients<sup>[18]</sup>. CTE was deemed to provide accurate preoperative diagnosis for SB CD. As MRI potentially has the ability to differentiate inflammation from fibrosis, the question arises as to whether MR imaging could be used to predict patient response to continued medical therapy and the need for surgery?

The hypothesis of this study was that SB enhancement, bowel wall thickness and other findings on MRI could categorise CD patients and that these categories could be used to identify patients who were more likely to respond to continuing medical therapy. It was also hypothesised that these categories would correlate with the presence and level of intestinal inflammation and fibrosis identified on surgical pathology.

## MATERIALS AND METHODS

All subjects were patients of the Centre for Inflammatory Bowel Diseases, Fremantle Hospital; a specialist inflammatory bowel disease (IBD) unit in a 450-bed tertiary institution. All patients had previously been confirmed as having CD on previous endoscopic examination with histological confirmation. Data was collected from all CD patients with SB disease undergoing MRI enterography or MRE over a 32-mo period. Any patient with a contraindication to the intravenous use of gadodiamide was excluded. Response to medical therapy was determined prospectively.

### ***MRI preparation***

All patients drank only clear fluids for 6 h prior to their MRI and were nil by mouth for 2 h. Patients either underwent MRE or MR enterography. Patients who underwent an MR enterography (including those patients where placement of the NJT failed for technical reasons or patient refusal) drank 1000 mL of the bowel contrast agent over 20 min. For an MRE, an NJT (Bilbao-Dotter, Cook, Australia) was placed under fluoroscopy. The bowel contrast agent used was a polyethylene glycol-water solution (Glycoprep-C, Pharmatek Fresenius Kabi, Australia), which was injected manually through the NJT (60 mL/min increasing to 120-150 mL/min). A total of 800-2000 mL was usually required to distend the SB to the TI. This varied depending on previous bowel resections.

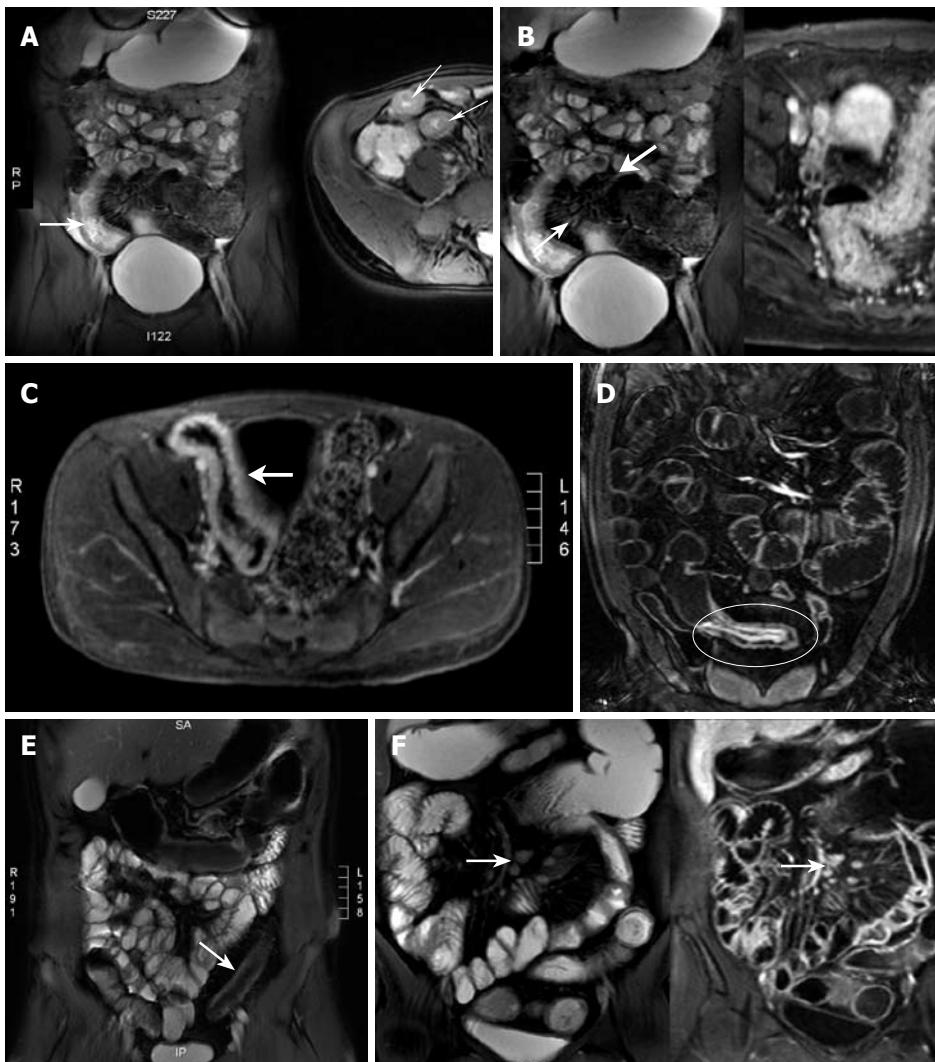

### ***MRI technique***

Patients were imaged supine using a 1.5T MRI system (Avanto SQ, Siemens Medical Solutions, Erlangen, Germany) with a surface array coil providing compression. In patients with an ileostomy, the stoma bag was emptied and a sponge placed between the surface coil and stoma.

A scout image was acquired to ensure adequate coverage and assess retrograde filling of the stomach. SB filling was dynamically assessed using a coronal 150 mm thick single slab T2-weighted (HASTE) fat saturated sequence acquired repeatedly without breath-holding to monitor for retrograde stomach filling and SB distension. These images were combined into a cine loop and used to assess stenotic lesions. If there was doubt as to TI contrast filling, a single breath-hold coronal T2-weighted sequence (HASTE) with a 6 mm slice thickness and 30% gap was obtained.

To reduce bowel peristalsis and prolong SB distension, 10 mg intravenous hyoscine butylbromide (Buscopan, Boehringer Ingelheim, Australia) was given if there were no contraindications. Once there was adequate SB filling, a coronal pre-contrast T1-weighted 3D gradient echo (VIBE) with a 2 mm slice thickness was obtained. Intravenous gadodiamide (Omniscan, Amersham, Australia) was injected (0.2 mL/kg) with post-contrast imaging commencing at 60 s. Post-contrast VIBE sequences were obtained in the coronal and axial planes. The axial plane required 2 overlapping sections covering the upper and lower abdomen.

Further imaging included a coronal steady-state free precession sequence (trueFISP) with a 6 mm slice thickness and 30% gap obtained with and without fat saturation, axial steady-state free precession sequence (trueFISP) with a 6 mm slice thickness and 30% gap obtained without fat saturation in 2 blocks of the upper and lower abdomen, coronal T2-weighted half Fourier single shot turbo spin echo (HASTE) sequence with 6 mm slice thickness and 30% gap, and axial T2-weighted HASTE sequence with a 5 mm slice thickness and 30% gap was obtained in 2 blocks of the upper and lower abdomen. If a site of pathology was identified at an overlap point on the axial images, then a further

**Figure 1 MRI characteristics of intestinal inflammation.** A: Bowel wall thickening. The distended bowel wall is normally 1-3 mm thick. An abnormal thickness is > 4 mm (arrowed); B: Mucosal hyperemia (thick arrow), engorged ileal vasa recta or the “comb sign” (thin arrow); C: Transmural enhancement (arrowed); D: Mucosal enhancement (circled); E: Fibrofatty infiltration (arrowed); F: Lymphadenopathy (arrowed).

set of targeted axial trueFISP and HASTE images were obtained.

For MR enterography, an initial single breath-hold coronal T2-weighted sequence (HASTE) with a 6 mm slice thickness and 30% gap was obtained. If there was adequate filling of the TI, buscopan was injected and routine imaging performed as above. With suboptimal filling of the TI, but sufficient bowel contrast proximally, reassessment occurred at 5-min intervals for 15 min. If there was still inadequate filling of SB loops, the patient drank a further 500 mL of contrast.

#### MRI assessment

Each MRI was evaluated by consensus of two radiologists (CW and PS) with experience in both gastrointestinal and MR imaging blinded to clinical findings. Image analysis was performed using a standardised worksheet. Diseased bowel was identified as abnormal bowel wall thickening and abnormal transmural or mucosal enhancement. Bowel wall thickness was assessed as normal (< 3 mm), mildly abnormal (3-6 mm) or markedly abnormal (> 6 mm)<sup>[19]</sup>. Mucosal enhancement was contrast enhancement localized to the inner layer of the intestinal wall and transmural enhancement was homogenous contrast enhancement of the whole wall. The degree of pathological bowel wall

contrast enhancement was assessed as none, mild (less than renal cortical enhancement) or marked (more than renal cortical enhancement) and classified as mucosal, transmural enhancement or both. The degree of enhancement was measured relative to the renal cortex on the coronal acquisition, and axial views were used for problem solving and cross-referencing of bowel loops.

Mesenteric hyperemia, fibrofatty proliferation, enlarged local lymph nodes and/or abnormally enhancing lymph nodes were assessed (Figure 1). Mesenteric nodes < 5 mm in short axis were considered physiological. Larger nodes, especially if clustered and contrast enhancing, were considered pathological<sup>[20]</sup>. The number of regional nodes and length of diseased segment were noted. Disease complications, including fistulas or abscesses, were recorded, as was free fluid, and stenoses with or without functional obstruction. Signs of functional obstruction were pre-stenotic dilatation and delayed contrast progression on the dynamic HASTE series.

#### MRI classification of fibrosis and inflammation

Based on the SB MRI findings, the CD patients were grouped into one of four categories; (1) “fibrosis”, (2) “mild segmental hyper-enhancement and mild wall thickening”, (3) “mild segmental hyper-enhancement

**Table 1 Grouping by MRI findings**

	Category 1	Category 2	Category 3	Category 4
Mucosal enhancement	Nil	Mild	Mild	Mild or marked
Transmural enhancement	Nil	Nil or mild	Nil or mild	Marked
Wall thickness (mm)	> 3	< 6	> 6	> 3

Patients were grouped on the basis of the SB wall thickness and mucosal or transmural enhancement. The 4 categories could also be described as (1) fibrosis, (2) mild segmental hyper-enhancement and mild wall thickening, (3) mild segmental hyper-enhancement and marked wall thickening, and (4) marked segmental transmural hyper-enhancement.

and marked wall thickening”, and (4) “marked segmental transmural hyper-enhancement” (Table 1). Studies were classified as “fibrosis” if there was bowel wall thickening without contrast enhancement. The diagnostic confidence of this was increased if the wall thickening had reduced signal intensity on T1- and T2-weighted images and if this region remained of constant calibre. “Marked segmental transmural hyper-enhancement” was diagnosed if there was marked transmural enhancement with increased bowel wall thickness.

“Mild segmental hyper-enhancement and mild wall thickening” was present if mucosal and/or transmural contrast enhancement was mild with only mild bowel wall thickening (3-6 mm). “Mild segmental hyper-enhancement and marked wall thickening” was present if there was mild mucosal and/or transmural contrast enhancement, but the bowel wall was > 6 mm.

### Response to medical therapy

Response to continued medical therapy was assessed prospectively. CD was diagnosed in accordance with previously established international criteria<sup>[21]</sup> exclusive of infective enterocolitis, Behcet’s disease and microscopic colitis. Response and remission to medical therapy was assessed by the Harvey Bradshaw index (HBI)<sup>[22]</sup>. A response was a reduction in the HBI of  $\geq 3$  and remission was defined as a HBI < 5. For patients who had undergone colectomy, physician assessment with endoscopy or imaging was used to assess response/remission. A response was determined after a further 8 wk of medical therapy. If medical therapy failed, then endoscopic or surgical options were offered. Correlation between the MRI findings and response to medical therapy was assessed, and for patients undergoing surgical resection the correlation between surgical pathology and the MRI was also assessed.

### Histological analysis

Specialist histopathologists reported on the macroscopic appearance and histology of the surgical specimens. They graded the degree of inflammation based on the bowel wall thickness, mesentery appearance, mesenteric lymph nodes, mucosal ulceration and the density and extent of both the acute and chronic inflammatory cell infiltrates, loss of goblet cells, crypt abscesses and

**Table 2 Characteristics of the CD patients prior to the MRI examination**

	CD (n = 52)
Gender: male	38.5% (20/52)
Age at diagnosis (yr)	38.9 ± 16.0 (14-79)
A1 ≤ 16	11.5% (6/52)
A2 17-40	55.8% (29/52)
A3 > 40	32.7% (17/52)
Crohn’s disease	
L1 Terminal ileum	78.8% (41/52)
L2 Colon	0% (0/52)
L3 Ileocolonic	19.2% (10/52)
L4 Upper GI	7.7% (4/52)
P Perianal	9.6% (5/52)
B1 Non-stricture	
Non-penetrating	75.0% (39/52)
B2 Stricture	19.2% (10/52)
B3 Penetrating	5.8% (3/52)
Colectomy	11.5% (6/52)
Terminal ileal resection	25.0% (13/52)
Proximal SB resection	1.9% (1/52)

architectural distortion. “Mild inflammatory infiltrates with scattered glandular architectural distortion and crypt branching” was termed mild inflammation. “Mucosal ulceration with marked glandular changes, dilated complex crypts, a transmural mixed cellular infiltrate and reactive changes in the mesentery” was termed severe. Fibrosis was determined by the presence of a stricture, the bowel wall thickness and assessment of collagen deposition in the bowel wall.

### Statistical analysis

Logistic regression was undertaken by a statistician (KM) and assessed wall enhancement, degree of enhancement, bowel wall thickness, abscess, fibro-fatty proliferation, fistula, free fluid, length of disease, mesenteric hyperemia, luminal narrowing with and without prestenotic dilatation, regional lymph nodes and enhancement, sex, and age. Variable selection was undertaken retaining effects significant at the 0.05 level, and the significant effects and odds ratios are presented, along with 95% confidence intervals.

## RESULTS

Data was collected over a 32-mo period on 55 CD patients who had abnormal SB-MRI findings consistent with SB CD without significant active colonic disease. Three of these patients were asymptomatic despite the abnormal MRI findings and were not included in any further analysis. Of the remaining 52 patients (Table 2), 38.5% were male (20/52) with an average age at diagnosis of 38.5 years (range 14-79 years). Forty-two patients (81%) had disease confined to the small intestine (one patient only suffered from proximal SB disease - L4) and 10 (19%) suffered from ileocolonic CD. Of these 10 patients, 6 had previously undergone a colectomy or proctocolectomy and had ongoing active disease confined to the SB. The remaining 4 patients had

5ASA: 5 aminosalicylic acid; AZA/6MP: Azathioprine/6 mercaptopurine; MTX: Methotrexate; N/A: Not applicable.

ileal inflammation and colonic inflammation confined to the cecum or right colon. A further 14 patients had previously undergone surgery for their CD. Thirteen underwent a terminal ileal resection and a limited right hemicolectomy, with 3 of these patients each having had a further 2 resections of the neoterminal ileum for stricturing disease. The final patient had 3 resections of the mid SB for stenosing CD.

Utilising a combination of the maximal SB wall thickness and level of mucosal/mural enhancement, patients were allocated into 1 of 4 categories (Table 1). All the patients in category "4" also demonstrated 2 or more extra-intestinal changes of inflammation (i.e. mesenteric hyperemia, fatty proliferation, enlarged regional lymph nodes, pathological lymph node enhancement or free fluid) indicating a more severe level of inflammation. MRI detection of bowel wall enhancement and its degree, level of bowel wall thickness, as well as the presence of an abscess, fibro-fatty proliferation, mesenteric hyperemia, a fistula, free fluid or enlarged regional lymph nodes are detailed in Table 3. The length of bowel involved and the presence of luminal narrowing with and without prestenotic dilatation, patient age and sex are also presented.

The medical therapies received by the patients included the use of steroids (prednisone, budesonide), 5-aminosalicylic acid (5ASA) azathioprine/6-mercaptopurine (AZA/6MP), methotrexate (MTX), antibiotics and anti-TNF alpha therapy (Table 4). Medical therapy was not standardized between patients, but was tailored to the individual patient. Twenty-seven of the 52

patients responded to medical therapy and 2 of these patients responded to conservative non-IBD related medical therapy. One patient refused to take any medical therapy prior to an endoscopic examination. If any patient failed to respond to the continued medical therapy, an endoscopic examination was offered to determine whether there was ongoing active inflammatory disease or if the inflammation was controlled and any stricture was amenable to endoscopic dilatation.

Twenty-five patients failed to respond to medical therapy (2/4 patients with ileal and right sided colonic disease, 3/6 with active SB disease post colectomy and 20/42 with SB disease). No significant differences were detected between the medical therapy received and the response/remission rates overall, or between any of the MRI categories (Table 4), suggesting that despite non-standardized medical therapy, the differences in the medical therapies were not primarily responsible for differences observed in the response rates.

Six patients had previously undergone total colectomy, so clinical response after a further 8 wk of medical therapy was determined by physician assessment and either endoscopic or radiological assessment. Of the remaining 46 patients, the average HBI was 8.7 (range 6-20) prior to medical therapy. Logistic regression identified that females were more likely to respond to medical therapy than males (OR = 5.46, 95% CI = 1.295-23.00, P = 0.021). Patients with intestinal narrowing and prestenotic dilatation with or without hold up were less likely to respond to medical therapy (OR = 7.85, 95% CI 1.73-35.6, P = 0.008). This was primarily due to the lack

**Table 5 MRI category, response to medical therapy in relation to luminal narrowing with and without hold up**

<b>MRI group</b>	<b>No narrowed lumen</b>	<b>Narrowed lumen no hold up</b>	<b>Narrowed lumen with hold up</b>			
1 n = 7	Response No response	0% (0/2) 100% (2/2)	Response No response	25% (1/4) 75% (3/4)	Response No response	0% (0/1) 100% (1/1)
2 n = 9	Response No response	100% (5/5) 0% (0/5)	Response No response	100% (4/4) 0% (0/4)	Response No response	N/A N/A
3 n = 16	Response No response	66.7% (2/3) 33.3% (1/3)	Response No response	66.7% (2/3) 33.3% (1/3)	Response No response	40% (4/10) 60% (6/10)
4 n = 20	Response No response	83.3% (5/6) 16.7% (1/6)	Response No response	57.1% (4/7) 42.9% (3/7)	Response No response	14.3% (1/7) 85.7% (6/7)
Total n = 52	Response No response	75.0% (12/16) 25.0% (4/16)	Response No response	61.1% (11/18) 38.9% (7/18)	Response No response	27.8% (5/18) 72.2% (7/18)

of response in patients with luminal narrowing and hold up, who were less likely to respond to medical therapy than either patients without luminal narrowing, or those with narrowing and no hold up ( $P < 0.0001$  and  $P = 0.007$  respectively, Table 5). Luminal narrowing was observed in 44.4% (4/9), 81.3% (13/16) and 70% (14/20) of patients in category "2" "3" and "4" respectively, while narrowing also occurred in 71.4% (5/7) of category "1" patients, suggesting that luminal narrowing can occur without the presence of inflammation detected by MRI. No significant differences were detected between response rates and age, the presence of mesenteric hyperemia, fibrofatty proliferation, enlarged local lymph nodes, nodal enhancement, free fluid, length of involved segment, or the presence of fistulas or an abscess.

No statistical difference was detected in response to continued medical therapy related to bowel wall thickness (Figure 1A,  $\leq 6$  mm vs  $> 6$  mm). Patients with mild or marked SB intestinal wall enhancement, however, were more likely to respond than those with SB wall abnormalities without enhancement (OR 33.0, 95% CI 2.56-426.7 and OR 15.0, 95% CI 1.22-184, respectively). There was no difference in patient response related to enhancement localized to the mucosal or mural layers compared to enhancement in both layers.

Regarding a separate analysis, controlling for sex, patients in category "2" were more likely to respond to medical therapy when compared to any of the other categories (OR 39.69,  $P = 0.0014$  compared with category "1"; OR 11.56,  $P = 0.023$  compared with category "3"; OR 8.98,  $P = 0.040$  compared with category "4") and more likely to go into remission compared to patients in category "1" ( $P = 0.021$ ), with border-line significance for category "3" ( $P = 0.050$ ), but not when compared to category "4" ( $P = 0.24$ ). This lack of significance was most likely secondary to low patient numbers. There were no other statistically significant differences between the other 3 groups. Controlling for the category type, females were still more likely to respond than males (OR = 5.91,  $P = 0.0071$ ).

#### Failure of medical therapy

Twenty-five patients failed to respond to medical therapy and were offered colonoscopic examination to determine whether there was ongoing active inflammatory disease or if there was intestinal stricturing without in-

flammation that would be amenable to endoscopic dilatation. Six (85.7%) of 7 patients failed medical therapy in category "1"; 1 patient refused colonoscopy and 1 went to surgery due to uncontrolled intestinal bleeding. The remaining 4 patients demonstrated no active colonic or terminal ileal inflammation at colonoscopy, but 3 had an ileal/anastomotic stricture that was endoscopically dilated with resolution of their symptoms. All category "2" patients responded to continued medical therapy. Nine of 16 (56.3%) category "3" patients failed to respond to continued medical therapy. Two of these patients demonstrated no inflammation at colonoscopy and underwent dilatation of an ileal/anastomotic stricture with resolution of their symptoms. A further 4 patients demonstrated inflammation of the ileum alone without a stricture identified and 3 patients did not demonstrate inflammation or stricture in either the colon or terminal ileum. These patients had been noted to have proximal SB CD on MRI. Ten of 20 patients (50%) in category "4" failed to respond to medical therapy. Six patients underwent colonoscopy and all demonstrated severe ileal inflammation. Among those remaining, two patients elected to go straight to surgery without a colonoscopic examination, one was not physically fit for an endoscopic procedure and one died from other causes unrelated to his IBD.

Seventeen patients went to surgery (16 after failure of medical therapy and 1 who relapsed after responding to medical therapy; Table 6). Specialist histopathologists assessed the macroscopic appearance and histology of the surgical specimens. The 2 patients in category "1" demonstrated fibrosis macroscopically and microscopically with only minimal or no inflammation detected histopathologically. In conjunction with the endoscopic assessment, 5 of the 6 non-responders in category "1" did not demonstrate histological or endoscopic inflammation, consistent with the MRI findings of fibrosis without active inflammation. The single category "2" patient undergoing surgery demonstrated no fibrosis macroscopically or histologically. Macroscopic and histological fibrosis, however, was present in all 7 category "3" patients undergoing surgery. This MRI category included those patients considered to have mild inflammation but intestinal fibrosis on MRI, and the findings of the surgical pathology indicated that this classification highly correlated with intestinal fibrosis. Of the 8 patients with

**Table 6 Correlation of MRI findings with surgical pathology**

No.	Sex	Age	MRI assessment		Surgical pathology		
			Group	Fistula	Inflammation	Fibrosis	Fistula
1	F	23	1	No	Minimal	Yes	No
2	M	45	1	No	No	Yes	No
3	F	39	2	Yes	Mild	No	Yes
4	M	17	3	No	Mild	Yes	No
5	F	59	3	No	Mild	Yes	No
6	F	31	3	No	Mild	Yes	No
7	M	18	3	No	Moderate	Yes	No
8	M	24	3	Yes	Mild	Yes	Yes
9	F	37	3	No	Mild	Yes	No
10	M	41	3	No	Mild	Yes	No
11	F	62	4	No	Florid	Yes	No
12	M	19	4	No	Florid	Yes	No
13	M	61	4	No	Florid	Yes	No
14	F	21	4	Yes	Florid	No	Yes
15	M	43	4	Yes	Florid	Yes	Yes
16	M	14	4	No	Florid	No	No
17	F	56	4	No	Florid	No	No

mild segmental hyper-enhancement on MRI (categories “2” and “3”), 7 demonstrated mild and 1 moderate SB inflammation histologically. Of the 7 category “4” patients undergoing surgery, 3 demonstrated fibrosis macroscopically and histologically. All 7 demonstrated florid SB inflammation. In one patient, the pathology described severe inflammation and fistulas, in combination with submucosal fibrosis without macroscopic fibrosis. All fistulas ( $n = 4$ ) identified by surgical pathology had previously been identified on SB MRI.

In summary, the surgical pathology confirmed the MRI assessment as to the presence or absence of fibrosis in all the category “1”, “2” and “3” patients (10/10) while confirming the presence of moderate to severe intestinal inflammation with or without fibrosis in all 7 of the category “4” patients. This suggests that the MRI categories are accurate in the classification of both inflammation severity and the presence of fibrosis.

## DISCUSSION

CD is a transmural disease that may result in obstructive symptoms secondary to intestinal inflammation and/or fibrosis. Fibrosis is not effectively treated by pharmaceutical agents and the presence of fibrotic strictures is one reason behind the high rate of surgical intervention<sup>[23]</sup>. Radiological investigations have undergone a revolution with both CTE and MRE demonstrating impressive specificity and sensitivity in the assessment of SB CD. CTE, however, delivers ionising radiation with concerns that even a single abdominal CT may increase the lifetime risk of malignancy<sup>[24]</sup>. This risk is even greater in the younger population<sup>[25]</sup>. MR, however, provides good soft tissue contrast that may differentiate between intestinal inflammation and fibrosis, and appears to be superior to CT scanning<sup>[16,17]</sup>. For long-term safety issues, as well as potentially better diagnostic capabilities, MR examination of the SB would appear to be preferable to CT.

TI attenuation is associated with histologically active

CD on CTE<sup>[26]</sup>. There are limited studies that compare MRI findings with SB inflammation, but they suggest that contrast enhancement intensity correlates with intestinal inflammation<sup>[27]</sup>. The level of bowel wall thickening on CTE, however, was not an independent risk factor for disease activity once attenuation was considered, similar to our MRI findings. MRI data that combines both bowel wall thickening and signal intensity has previously demonstrated greater accuracy in assessing disease severity<sup>[26,27]</sup>. In view of these observations patients in our study were classified on the basis of intestinal wall enhancement and bowel wall thickening on MRI.

Our findings suggest that the SB MRI findings can be used to categorise CD patients, and that these categories correlate with patient response to ongoing medical therapy and the histological findings at surgery. No significant differences were detected between the medical therapy regime used and the response/remission rates overall, or between any of the MRI categories, suggesting that the medical therapy was not primarily responsible for differences observed in the response rates. Overall females were more likely to respond to medical therapy than males. This may potentially be impacted by 7 of the 9 patients in category “2” being female, but reasons behind this observation are unclear. Controlling for sex, however, patients in category “2” were still more likely to respond to continued medical therapy than any of the other categories.

Macroscopic/histological fibrosis was present on surgical pathology in all the category “1” and “3” patients undergoing surgery. All category “4” patients undergoing surgery demonstrated florid inflammation on the surgical pathology. In contrast, no category “2” or “3” patients demonstrated florid inflammation on surgical pathology with all but one having only mild inflammation. These findings may explain why category “2” patients were more likely to respond to medical therapy as they only had mild inflammation and were yet to develop fibrotic changes, unlike patients with marked wall thickening which is associated with fibrosis and/or florid inflammation.

A further finding from this work was that patients with intestinal narrowing and prestenotic dilatation were less likely to respond to medical therapy. It has been suggested that narrowing can be differentiated by CTE into inflammatory and fibrostenotic lesions<sup>[28]</sup>. In our study it was noted that there was a similar percentage of patients with luminal narrowing with severe inflammation (70%, 14/20) compared to patients with fibrosis and mild inflammation (81.3%, 13/16) or fibrosis and no inflammation (71.4%, 5/7). Patients with narrowing and inflammation, however, were more likely to have narrowing with hold up (47.2% 17/36) than patients without inflammation (14.3%, 1/7), suggesting that MRI may also be able to differentiate inflammatory from fibrostenotic lesions.

MRI findings of marked wall thickening without bowel wall enhancement were observed to be negatively associated with a response to medical therapy, while minimal bowel wall thickening with mild wall enhance-

ment predicted a good response to continued medical therapy. As patient MR categories based on SB wall thickness and luminal wall enhancement appear to correlate with the response to continuing medical therapy as well as with the surgical pathology, our findings would support the use of SB MRI as a diagnostic and prognostic tool in the management of patients with SB CD.

## COMMENTS

### Background

Small bowel (SB) involvement is common in Crohn's disease (CD). The study aimed to determine whether magnetic resonance imaging (MRI) could predict response to medical therapy and correlate with surgical pathology in these patients.

### Research frontiers

Utilising a combination of the maximal SB wall thickness and level of mucosal/mural enhancement detected on MRI, patients were able to be grouped into 1 of 4 categories; (1) "fibrosis", (2) "mild segmental hyper-enhancement and mild wall thickening", (3) "mild segmental hyper-enhancement and marked wall thickening", and (4) "marked segmental transmural hyper-enhancement". This categorization was then used to determine a prognostic role for SB MRI in the management of CD.

### Innovations and breakthroughs

Category "2" patients were more likely to respond to medical therapy than any other category, as were females, while patients with intestinal narrowing and prestenotic dilatation with or without hold up were less likely to respond. The presence of marked wall thickening without bowel wall enhancement was negatively associated with a medical response. Surgical pathology confirmed the MRI assessment of inflammation severity and presence of fibrosis.

### Applications

The proposed MR categories appeared to correlate with response to continuing medical therapy and the surgical pathology, thereby supporting the use of SB MRI as a diagnostic and prognostic tool in the management of patients with SB CD.

### Terminology

CD is a chronic inflammatory condition of the intestine that frequently involves the terminal ileum with narrowing and fibrosis. Harvey Bradshaw index (HBI) is a means of measuring a clinical response in CD with a reduction in the HBI of  $\geq 3$  being a clinical response and remission defined as a HBI < 5 terminal ileum. MRI is a cross sectional imaging technique that does not utilize radiation and provides excellent tissue differentiation.

### Abstract

**AIM:** To evaluate the ultrasonography (EUS) features of gastric gastrointestinal stromal tumors (GISTs) as compared with gastric leiomyomas and then to determine the EUS features that could predict malignant GISTs.

**METHODS:** We evaluated the endoscopic EUS features in 53 patients with gastric mesenchymal tumors confirmed by histopathologic diagnosis. The GISTs were classified into benign and malignant groups according to the histological risk classification.

**RESULTS:** Immunohistochemical analyses demonstrated 7 leiomyomas and 46 GISTs. Inhomogeneity, hyperechogenic spots, a marginal halo and higher echogenicity as compared with the surrounding muscle layer appeared more frequently in the GISTs than in

the leiomyomas ( $P < 0.05$ ). The presence of at least two of these four features had a sensitivity of 89.1% and a specificity of 85.7% for predicting GISTs. Except for tumor size and irregularity of the border, most of the EUS features were not helpful for predicting the malignant potential of GISTs. On multivariate analysis, only the maximal diameter of the GISTs was an independent predictor. The optimal size for predicting malignant GISTs was 35 mm. The sensitivity and specificity using this value were 92.3% and 78.8%, respectively.

**CONCLUSION:** EUS may help to differentiate gastric GISTs from gastric leiomyomas. Once GISTs are suspected, surgery should be considered if the size is greater than 3.5 cm.

Is it possible to differentiate gastric GISTs from gastric leiomyomas by EUS? *World J Gastroenterol* 2009; 15(27): 3376-3381 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3376.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3376>

### INTRODUCTION

Mesenchymal tumors of the gastrointestinal tract are usually incidentally discovered as a firm, protruding submucosal lesion during upper gastrointestinal examinations for unrelated conditions, although the larger tumors may occasionally cause bleeding<sup>[1]</sup>. Pathologically, most of these tumors are composed of spindle cells and display smooth muscle differentiation. In recent years, with the advance of immunohistochemistry, it is known that most gastric and small bowel mesenchymal tumors are gastrointestinal stromal tumors (GISTs) that

are derived from the interstitial cells of Cajal<sup>[1-3]</sup>. The incidence of GISTs is 10-20 per million with the stomach being the most common location as 60% to 70% of GISTs arise in this organ<sup>[4]</sup>.

Endoscopic ultrasonography (EUS) is a valuable imaging tool for the diagnosis and evaluation of gastric GISTs. Gastric GISTs generally appear as round, hypoechoic lesions with a ground-glass echo texture, and these lesions are contiguous with the fourth layer of the stomach<sup>[5-7]</sup>. Several studies have attempted to differentiate benign and malignant stromal tumors on the basis of their EUS features<sup>[6-11]</sup>. However, most of these studies were performed before the concept of GISTs was introduced and they included non-gastric tumors in their study samples. In addition, little is known about differentiating GISTs and leiomyomas by EUS<sup>[11]</sup>.

Therefore, the aim of this study was to evaluate the EUS features of gastric GISTs in comparison with gastric leiomyomas, and we wanted to determine if the EUS features could predict the malignant potential of gastric GISTs according to the histological risk classification.

## MATERIALS AND METHODS

### Patients

From July 2005 to June 2008, the medical records of all patients with histopathologically proven gastric leiomyomas or GISTs who underwent EUS examination at our endoscopic unit were retrospectively reviewed. There were 53 patients (22 men and 31 women), with a mean age of 59 years (range 29-75 years). The histologic specimens were obtained by surgical resection in 50 patients (94.3%), by needle biopsy in two patients (3.8%), and by endoscopic resection in 1 patient (1.9%). This study was reviewed and approved by the Institutional Review Board at Pusan National University Hospital.

### Histopathology

The tumors were histopathologically proved to be gastric mesenchymal tumors and they were classified immunohistochemically as leiomyomas or GISTs<sup>[5]</sup>. In particular, the leiomyomas were defined as being desmin positive and c-kit (CD117) negative tumors and the GISTs were defined as being c-kit positive tumors. The GISTs were divided into 4 groups in accordance with the consensus meeting report at the National Institute of Health (Table 1)<sup>[12]</sup>. Then, the GISTs with a very low risk or low risk were defined as benign GISTs, and the GISTs with an intermediate risk or high risk were defined as malignant GISTs.

### EUS

EUS was performed with a radial scanning ultrasound endoscope (GF-UM2000; Olympus, Tokyo, Japan) using scanning frequencies of 7.5 and 12 MHz. All the examinations were performed under intravenous conscious sedation (midazolam with or without meperidine). Scanning of the tumor was performed after filling the stomach with 400-600 mL of deaerated water. About

**Table 1 Proposed approach for defining the risk of aggressive behavior in GISTs**

	<b>Size (cm)</b>	<b>Mitotic count</b>
Very low risk	< 2	< 5/50 HPF
Low risk	2-5	< 5/50 HPF
Intermediate risk	< 5 5-10	6-10/50 HPF < 5/50 HPF
High risk	> 5 > 10 Any size	> 5/50 HPF Any mitotic rate > 10/50 HPF

HPF: High-power field.

10-20 endosonograms were recorded for each patient, and these images were stored on magneto-optical disks. A review of the EUS photos was performed by a single experienced endosonographer (Kim GH) who was kept "blinded" to the final diagnosis, and this endosonography had previously performed more than 1000 examinations. The following EUS features were recorded for all the tumors: (a) the maximal diameter, (b) the presence of mucosal ulceration on endoscopy and/or EUS, (c) the echogenicity in comparison with the surrounding normal proper muscle layer (hyperechoic or isoechoic), (d) the homogeneity (homogenous or heterogenous), (e) the presence of a marginal halo and lobulation, (f) the presence of cystic spaces, hyperechogenic spots and calcification, (g) the regularity of the marginal border (regular or irregular) and (h) the pattern of tumor growth (inside or outside the gastric wall).

### Statistical analysis

The differences in gender and the EUS findings between leiomyomas and GISTs were assessed using the  $\chi^2$  test or Fisher's exact test, and the patient age and tumor size were assessed using the Student *t*-test. Calculation of the sensitivity, specificity and the positive and negative predictive values of each EUS feature and combinations of these features for differentiating GISTs from leiomyomas were carried out manually.

Univariate analyses using the  $\chi^2$  test or Fisher's exact test were performed to identify the EUS features that could predict malignant GISTs. Multivariate logistic regression analyses were performed to identify the independent predictors of malignant GISTs. The odds ratios and their 95% confidence intervals were used to predict malignant GISTs. Receiver operating characteristic (ROC) curve was applied to find the best sensitivity and specificity cut-off value of the tumor size for predicting malignant GISTs. A *P* value < 0.05 was considered statistically significant. The statistical calculations were performed using the SPSS version 12.0 for Windows software (SPSS Inc, Chicago, IL, USA).

## RESULTS

### EUS features differentiating GISTs from leiomyomas

Immunohistochemical analyses demonstrated that 7 cases were leiomyomas and 46 cases were GISTs. The baseline characteristics and endosonographic features are shown in

**Table 2 Baseline characteristics and EUS features of the patients with leiomyomas and GISTs of the stomach n (%)**

Variables	Leiomyomas (n = 7)	GISTs (n = 46)	P-value
Gender			0.686
Male	2 (28.6)	20 (43.5)

Absent	4 (57.1)	5 (10.9)	
Present	3 (42.9)	41 (89.1)	
Calcification			1.000
Absent	6 (85.7)	39 (84.8)	
Present	1 (14.3)	7 (15.2)	

Table 2. The tumor size and presence of ulceration were not different between the leiomyomas and the GISTs. A marginal halo appeared more frequently in the GISTs than in the leiomyomas ( $P = 0.002$ ). The echogenicity of all the leiomyomas was nearly similar to that of the surrounding normal proper muscle layer, but more than half of the GISTs showed higher echogenicity than that of the surrounding normal muscle layer (Figure 1) ( $P = 0.004$ ). Inhomogeneity of the tumor and hyperechogenic spots were observed more frequently in the GISTs than in the leiomyomas ( $P < 0.05$ ).

Table 3 shows the value of each EUS feature for differentiating GISTs from leiomyomas. Each criterion had a high positive predictive value, but limited sensitivity or specificity. The presence of at least two of these four features in a given tumor had a sensitivity of 89.1%, a specificity of 85.7%, a positive predictive value

**Table 3 Sensitivity, specificity and positive and negative predictive values of the EUS features that differentiate GISTs from leiomyomas in the stomach (%)**

EUS features	Sensitivity	Specificity	Positive predictive value	Negative predictive value
Echogenicity in comparison with the surrounding muscle echo	58.7	100	100	26.9
Homogeneity	80.4	85.7	97.4	40.0

of 97.6% and a negative predictive value of 54.5% for predicting GISTs.

### EUS features predicting malignant potential of GISTs

When the GISTs were classified into benign and malignant groups according to the histological risk classification, 33 cases were grouped as benign GISTs (very low risk, 11 cases; low risk, 22 cases) and 13 cases as malignant GISTs (intermediate risk, 8 cases; high risk, 5 cases). Except for the size and irregularity of the tumor border, most of the endosonographic features were not helpful in predicting the malignant potential of GISTs (Figure 1, Table 4). On the multivariate logistic regression analysis, only the maximal diameter of the GISTs was an independent predictor (OR, 9.3; 95% CI, 1.6-53.6) (Table 5). A ROC curve was created to identify the discriminative value of size for predicting the malignant potential of GISTs (Figure 2). The sensitivity was almost optimized when the critical value of the size was 35 mm. Of the 19 patients with a tumor size  $\geq 35$  mm, 12/19 (63.2%) were malignant GISTs. However, of the 27 patients with a size  $< 35$  mm, 26 (96.3%) were benign GISTs and 1 (3.7%) was a malignant GIST. Therefore, this model of prediction for malignant GISTs had a positive predictive value of 63.2% and a negative predictive value of 96.3%. This resulted in a sensitivity of 92.3% and a specificity of 78.8%.

## DISCUSSION

GISTs are rare neoplasms that account for less than 1% of all gastrointestinal malignancies. GISTs have the capability to become malignant and then metastasize, whereas leiomyomas are almost invariably benign<sup>[4]</sup>. In clinical practice, preoperative differentiation between GISTs and leiomyomas is usually difficult, even if EUS-guided fine-needle aspiration or trucut biopsy is performed<sup>[13-15]</sup>. Thus, if it were possible to differentiate GISTs from leiomyomas and then to predict the malignant potential of GISTs by EUS imaging, then this would be essential in the clinical management of gastrointestinal mesenchymal tumors. There have been

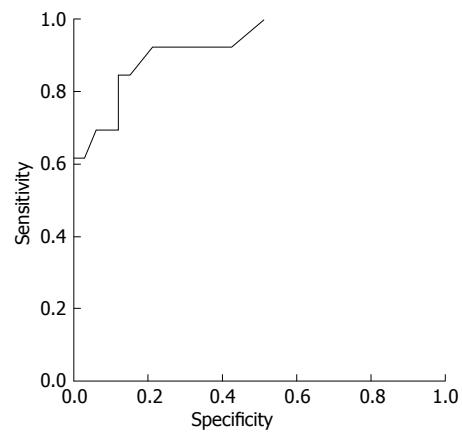

**Figure 1 EUS features of gastric mesenchymal tumors.** A: A gastric leiomyoma. The mass is homogenous and its echogenicity is similar to that of the surrounding normal muscle layer. It is 35 mm × 13 mm in size and a marginal halo is not observed; B: A gastric GIST with low risk potential. The mass is inhomogenous and its echogenicity is somewhat higher than that of the surrounding muscle layer. It is 25 mm × 18 mm in size. A marginal halo (arrow) and hyperechogenic spots are seen; C: A gastric GIST with high risk potential. The mass is inhomogenous and 82 mm × 76 mm in size. A marginal halo, hyperechogenic spots and irregular border (arrow head) are seen.

several studies that have attempted to differentiate benign from malignant stromal tumors based on their EUS features<sup>[2,5-11]</sup>. However, most of these studies did not differentiate the EUS features of GISTs and leiomyomas, and they did not characterize the EUS features of GISTs according to the histological risk classification. In addition, they did not restrict the study subjects to those with the gastric mesenchymal tumors.

Initially, we tried to find the EUS features that could

**Figure 2 Receiver operating characteristic (ROC) curve of the tumor size for predicting malignant GISTs in the stomach.**

**Table 5 Multivariate analysis of EUS features between benign and malignant GISTs of the stomach**

Variables	Odds ratio (95% CI)	P value

Cystic change	1.4 (0.1-19.5)	0.800

differentiate GISTs from leiomyomas. In a previous study<sup>[9]</sup>, the EUS features such as size greater than 4 cm, ulceration or cystic foci were almost exclusively seen in CD-117 positive tumors as compared with CD-117 negative tumors. In that study, immunohistochemical staining such as for desmin or S-100 was not performed, so the CD-117 negative tumors were not homogenous; i.e. they may have been leiomyomas or schwannomas. In the present study, we restricted the subjects to compare GISTs with only leiomyomas, and the latter are almost invariably benign. As a result, tumor size and the presence of ulceration and cystic changes in the tumor were not helpful for differentiating GISTs from leiomyomas in this study. Instead, inhomogeneity, hyperechogenic spots, a

marginal halo and higher echogenicity in comparison with the surrounding muscle layer were helpful for predicting GISTs. Especially, if at least two of these four features are present, then the sensitivity and specificity for predicting GISTs were 89.1% and 85.7%, respectively. This result is similar to the results of a previous report<sup>[11]</sup> that a marginal halo and the relatively higher echogenicity, as compared to the adjacent normal muscular layer on EUS, might suggest GISTs. In addition, the previous reports, which were carried out before the concept of GISTs was introduced, have suggested that inhomogeneity and hyperechogenic spots are the EUS features that are predictive of malignancy<sup>[6,7]</sup>.

A hypoechoic halo is a well known characteristic ultrasonographic sign of malignant liver tumors such as hepatocellular carcinoma<sup>[16]</sup>. A pseudocapsule of the collapsed surrounding tissues, which is the result of an expansively growing tumor, is thought to be the cause of the halo in malignant liver tumors<sup>[16]</sup>. A previous study showed that on pathologic examination, the tumor cells of GISTs were partially or completely circumscribed by the residual muscle tissues of the surrounding muscular propria and this formed a capsule-like structure<sup>[11]</sup>. In the present study, a marginal halo was found in 78.3% of GISTs, whereas this was seen in only 14.3% of leiomyomas.

In this study, higher echogenicity in comparison with the surrounding muscle layer was found in more than half of GISTs, whereas the echogenicity of the leiomyomas was nearly equal to that of the surrounding muscle layer. Pathologically, it is well known that the cellularity of leiomyomas is normal to moderate with eosinophilic cytoplasm, whereas GISTs show higher overall cellularity, which creates a basophilic appearance on hematoxylin and eosin staining<sup>[1-3]</sup>. It is assumed that the difference in echogenicity between GISTs and leiomyomas might reflect these pathologic differences of cellularity and the structural components of the tumors.

Second, we tried to find the EUS features that could predict the malignant potential of GISTs after dividing the GISTs into 2 groups (benign and malignant) according to the histological risk classification. Previous studies have suggested that a large size, exogastric growth, ulceration, cystic changes, hyperechogenic foci and irregularity of the margin favored a diagnosis of malignant gastrointestinal mesenchymal tumors<sup>[6,7,17,18]</sup>, but these studies were performed before the concept of GISTs had been introduced, as was mentioned earlier. In the present study, only tumor size and irregularity of the border were helpful in predicting the malignant potential of GISTs. Multivariate logistic regression analysis showed that only size was an independent predictor, which is consistent with a previous report that conducted multivariate analysis according to the histological risk classification of GISTs<sup>[10]</sup>. With the critical size of 35 mm, the sensitivity and specificity were 92.3% and 78.8%, respectively. This could be explained by the fact that tumor size, together with the mitotic count, is used to determine the histological classification system. Therefore, once we discriminate GISTs from leiomyomas, the size of the tumor ( $> 35$  mm) might be

the most reliable indicator of malignancy.

This study had several limitations. First, this was a retrospective study that compared the EUS features of gastric GISTs and leiomyomas. In addition, there might have been a potential bias when retrospectively reviewing the endosonographic photos. During the EUS examination, we took at least 10-20 endosonographic photos to determine EUS characteristics of gastric mesenchymal tumors. Therefore, this would compensate, to some degree, the limitation of this retrospective study. Second, although EUS examinations were performed, patients were selected for surgery or biopsy according to the clinical opinions and decisions of the medical doctors. Third, the number of leiomyomas included in this study was small relative to the number of GISTs. This limitation might be due to the fact that the most common mesenchymal tumors of the stomach are GISTs and other tumors, such as leiomyomas and schwannomas, are rarely encountered in clinics.

Gastric mesenchymal tumors are often asymptomatic, and they are usually incidentally discovered during upper gastrointestinal endoscopy for unrelated conditions. The main problem in the asymptomatic patient is to determine whether or not the tumors have a malignant potential. Because GISTs have a malignant potential, the gastric mesenchymal tumors, even if they are small, should not be ignored if EUS features are suggestive of GISTs. Further large prospective long-term studies are needed to validate our results for gastric mesenchymal tumors.

In conclusion, EUS is a useful method to diagnose gastric mesenchymal tumors and to predict the malignant potential of GISTs. The EUS features such as inhomogeneity, hyperechogenic spots, a marginal halo and higher echogenicity as compared with the surrounding muscle layer may help to differentiate GISTs from leiomyomas. Once GISTs are suspected by EUS, surgical treatment should be considered if the size of the tumor is greater than 3.5 cm.

## COMMENTS

### Background

Endoscopic ultrasonography (EUS) is a valuable imaging tool for the diagnosis and evaluation of gastric gastrointestinal stromal tumors (GISTs). Several studies have attempted to differentiate benign and malignant stromal tumors on the basis of their EUS features. However, most of these studies were performed before the concept of GISTs was introduced and they included non-gastric tumors in their study samples.

### Research frontiers

Most previous studies did not differentiate the EUS features of GISTs and leiomyomas, and they did not characterize the EUS features of GISTs according to the histological risk classification. In addition, they did not restrict the study subjects to those with gastric mesenchymal tumors. Therefore, we evaluated the EUS features of gastric GISTs in comparison with gastric leiomyomas, and tried to determine the EUS features that could predict the malignant potential of gastric GISTs according to the histological risk classification.

### Innovations and breakthroughs

To differentiate GISTs from leiomyomas by EUS, the following four features were helpful; inhomogeneity, hyperechogenic spots, a marginal halo and higher echogenicity as compared with the surrounding muscle layer. These features appeared more frequently in GISTs than in leiomyomas. The presence of at least two of these four features had a sensitivity of 89.1% and a specificity of 85.7% for predicting GISTs. Except for tumor size and irregularity of the border, most of the EUS features were not helpful in predicting the malignant potential of GISTs. On multivariate analysis, only the maximal diameter of the GISTs was an independent predictor. The optimal size for predicting malignant GISTs was 35 mm. The sensitivity and specificity using this value were 92.3% and 78.8%, respectively.

### Applications

EUS is a useful method to diagnose gastric mesenchymal tumors and to predict the malignant potential of GISTs. The EUS features such as inhomogeneity, hyperechogenic spots, a marginal halo and higher echogenicity as compared with the surrounding muscle layer may help to differentiate GISTs from leiomyomas. Once GISTs are suspected by EUS, surgical treatment should be considered if the size of the tumor is greater than 3.5 cm.

### Terminology

GISTs are mesenchymal tumors derived from the interstitial cells of Cajal. The incidence of GISTs is 10-20 per million and the stomach is the most common location of GISTs (60%-70%).

### Peer review

This is a relatively large single-center study aiming to evaluate the EUS features of gastric GISTs vs leiomyomas initially and subsequently focusing on GISTs to determine EUS-features associated with malignancy.

HBV DNA load was assessed by quantitative real-time polymerase chain reaction.

**RESULTS:** CD8<sup>+</sup> T-cells were significantly higher in patients at the immune-tolerant stage than in patients at the immune-active and -inactive carrier stages ( $36.87 \pm 7.58$  vs  $34.37 \pm 9.07$ ,  $36.87 \pm 7.58$  vs  $28.09 \pm 5.64$ ,  $P < 0.001$ ). The peripheral blood in patients at the immune-tolerant and immune active stages contained more CD8<sup>+</sup> T-cells than CD4<sup>+</sup> T-cells ( $36.87 \pm 7.58$  vs  $30.23 \pm 6.35$ ,  $34.37 \pm 9.07$  vs  $30.92 \pm 7.40$ ,  $P < 0.01$ ), whereas the peripheral blood in patients at the immune-inactive carrier stage and in normal controls contained less CD8<sup>+</sup> T-cells than CD4<sup>+</sup> T-cells ( $28.09 \pm 5.64$  vs  $36.85 \pm 6.06$ ,  $24.02 \pm 4.35$  vs  $38.94 \pm 3.39$ ,  $P < 0.01$ ). ANOVA linear trend test showed that CD8<sup>+</sup> T-cells were significantly increased in patients with a high viral load ( $39.41 \pm 7.36$ ,  $33.83 \pm 7.50$ ,  $31.81 \pm 5.95$  and  $26.89 \pm 5.71$ ,  $P < 0.001$ ), while CD4<sup>+</sup> T-cells were significantly increased in patients with a low HBV DNA load ( $37.45 \pm 6.14$ ,  $33.33 \pm 5.61$ ,  $31.58 \pm 6.99$  and  $27.56 \pm 5.49$ ,  $P < 0.001$ ). Multiple regression analysis displayed that log copies of HBV DNA still maintained its highly significant coefficients for T-cell subpopulations, and was the strongest predictors for variations in CD3<sup>+</sup>, CD4<sup>+</sup> and CD8<sup>+</sup> cells and CD4<sup>+</sup>/CD8<sup>+</sup> ratio after adjustment for age at HBV-infection, maternal HBV-infection status, presence of hepatitis B e antigen and HBV mutation.

**CONCLUSION:** Differences in peripheral T-cell subpopulation profiles can be found in different clinical stages of chronic HBV infection. T-cell impairment is significantly associated with HBV load.

## INTRODUCTION

Hepatitis B virus (HBV) infection is a dynamic process with variable biochemical, virological and histological profiles at different stages of chronic HBV infection depending on host and viral factors. Furthermore, the profiles may change at a variable pace over time<sup>[1-5]</sup>. Based on the virological and biochemical parameters, chronic HBV infection can be divided into three stages: immune-tolerant stage, immune active stage and immune-inactive carrier stage<sup>[5-7]</sup>. Patients at the immune-tolerant stage have no symptoms, but their serum hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) are detectable, and HBV DNA levels are high, while their serum aminotransferase level is normal or minimally elevated, and their histological activity is minimal. This stage often lasts decades in perinatal HBV infection patients. The serum HBV DNA level decreases, and the serum aminotransferase level increases, symptoms may appear and flares of aminotransferase may be observed in patients at the immune active stage. The time of this stage ranges months-years in patients with chronic HBV infection. Flares of aminotransferase are followed by HBeAg seroconversion in some patients. The immune-inactive carrier stage is characterized by a low HBV DNA level and a normal aminotransferase concentration. HBV clearance is closely associated with the appearance of a vigorous virus-specific T-cell response<sup>[3,4]</sup>. In contrast, HBV persistence and chronic hepatitis are associated with a markedly diminished HBV-specific T-cell response<sup>[4,8-11]</sup>. Interestingly, different profiles of chronic hepatitis B are also associated with different magnitudes of HBV-specific immune response<sup>[12]</sup>. Episodes of acute flares during chronic HBV infection are associated with the recovery of HBV-specific CD4<sup>+</sup> T cell response<sup>[13,14]</sup>. Increased HBV-specific CD8<sup>+</sup> T cell response has only been demonstrated in patients with a low HBV replication, irrespective of the inflammation degree<sup>[15-17]</sup>. These data have led to the hypothesis that the composition of T cell subpopulations is different in different clinical stages of chronic HBV infection, which may be related to the HBV load. Thus, characterization of T cell profiles is relevant to the improved understanding of chronic HBV infection and the design of antiviral therapy. This study was to characterize the different stages of chronic HBV infection by analyzing the composition of T cell subpopulations in peripheral blood and its correlation with HBV replication.

## MATERIALS AND METHODS

### Subjects

Four hundred and twenty-two consecutive chronic HBV infection patients were recruited from Department of Infectious Diseases of First Affiliated Hospital of

Kunming Medical University, Third Kunming People's Hospital, and Yunnan General Hospital of Chinese People's Armed Police Forces, between January 2006 and May 2007. The patients were diagnosed according to the criteria for viral hepatitis<sup>[5-7]</sup>.

All patients fulfilled the following criteria: positive HBsAg for at least 12 mo, no other concomitant causes of liver disease (hepatitis C and D, HIV infection and alcohol consumption of more than 60 g/d), relatively rare liver diseases (autoimmune hepatitis and metabolic liver disease), on immunosuppressive therapy or antiviral therapy for HBV-infection within the recent 12 mo before entry. None of the patients was a drug user, or exposed to hepatotoxin. All patients gave their informed consent to participate in the study. The study protocol, conforming to the guidelines of Declaration of Helsinki, was approved by the Ethics Committees of the Faculty of Medicine of Prince of Songkla University and the First Affiliated Hospital of Kunming Medical University.

One hundred healthy individuals (61 males, 39 females), with a mean age of 33.24 ± 10.28 years, served as controls.

### **Serological test of liver function and evaluation of HBVs markers**

Serum alanine aminotransferase (ALT), aspartate transaminase (AST) and total bilirubin levels were measured with routine automated techniques (upper limit: 40 U/L, 40 U/L and 17.1 μmol/mL, respectively). HBV markers (HBsAg, HBsAb, HBeAg, HBeAb, HBcAb, and anti-HBcAb IgM) were detected by enzyme-linked immunosorbent assay.

### **Detection of HBV DNA and HBV pre-core mutant**

Serum HBV DNA load in individuals was detected by real-time polymerase chain reaction (RT-PCR) using a Lightcycler PCR system (FQD-33A, Bioer) with a lower detection limit of approximately 1000 viral genome copies/mL with a reagent kit package insert (Shenzhen PG Biotech Co. Ltd.) following its manufacturer's instructions. The primer was provided with the kit, the reaction volume was 40 μL. PCR was performed at 37°C for 5 min and at 94°C for 1 min, followed by 40 cycles at 95°C for 5 s and at 60°C for 30 s. HBV pre-core A1896 mutant was detected by PCR (PE9600, Perkin Elmer Co., Ltd. USA) with the reagent kit package insert (Shanghai Haoyuan Biotech Co. Ltd) following its manufacturer's instructions.

### **Detection of peripheral blood T lymphocyte subsets**

The key compositions of cellular immune are T-lymphocytes and their subpopulations. CD3<sup>+</sup>, CD4<sup>+</sup> and CD8<sup>+</sup> cells are the major function subgroups of T cells and play an important role in response to HBV infection, which can reflect the cellular immune function and immunoregulation and are usually regarded as a valuable index of the changes in immunity of patients<sup>[3,4]</sup>. This index was used in our study to evaluate the cellular immune function of chronic HBV infection patients.

Blood samples were collected into heparinized vacuum tubes. Whole blood samples were analyzed using a Muti-Q-Prep processor (Coulter, USA) and an Epics-XL flow cytometer (Coulter, USA). Lymphocytes were analyzed using a gate set on a forward scatter *vs* a side scatter, and a three-color flow cytometry was used to combine CD3, CD4 and CD8. Anti-human monoclonal antibodies, CD3-PE-CY5/CD4-FITC/CD8-PE, were purchased from Immunotech, Ltd, USA. The detected peripheral blood T lymphocyte subsets in each sample were analyzed using the CellQuest software (Coulter, USA). The results were expressed as percentages of CD3<sup>+</sup>, CD3<sup>+</sup>/CD4<sup>+</sup> (short for CD4<sup>+</sup> below) and CD3<sup>+</sup>/CD8<sup>+</sup> (short for CD8<sup>+</sup> below) cells which were positive for the marker antigen in the total T cell population. The procedures were performed with the reagent kit package insert following its manufacturer's instructions.

#### **Maternal HBV infection status**

All medical records of mothers of the subjects were reviewed for previous HBV infection and those who were infected with HBV were identified. In addition, all of them were invited to undergo HBV-marker tests. For those with a positive result, a second set of tests were conducted three months after the first test to confirm their chronic HBV carrier status. If the mother was dead, the cause of death was investigated based on the medical records of HBV-related liver diseases, such as chronic hepatitis B, liver cirrhosis or hepatocellular carcinoma. If yes, the maternal HBV infection status was classified as positive.

#### **Age at HBV infection**

In the recent three decades, all children in China have been obligated to have a test for HBV markers when they first go to kindergarten and elementary school. Subsequent obligatory tests are made when they apply for entrance examination of university or for a job. Based on the results of these tests obtained from medical records and interview, we classified the age at the first positive test as < 8 years, between 8-20 years and > 20 years, respectively.

#### **Statistical analysis**

Initial calculation came up with a sample size of 50 patients with positive HBV DNA and 50 patients with negative HBV DNA, which could provide the study with a statistical power of 80% at the 0.025 level of significance to detect the difference in T-cell variation values of 33 and 38. However, to cover the potentially confounded problem due to other variables and to have enough subjects for stratifying the HBV DNA load to examine the dose-response relationship, we recruited 422 chronic HBV infection patients and 100 healthy controls.

Descriptive statistical analysis was used to examine the age, gender, serum HBV load, HBeAg status, age at HBV-infection and maternal HBV infection status.

The number of T-lymphocyte subpopulations in normal individuals (HBsAg-negative), which was expressed as mean  $\pm$  SD, served as a control reference. Effects of different independent demographic, clinical and serological variables on T-cell profiles were analyzed only in HBsAg-positive patients. Univariate analysis of these profiles broken down by individual independent variables was carried out. Independent *t* test was done for 2-level independent variables and one-way ANOVA for more than 2-level variables. The relationship between HBV replication level and peripheral T-lymphocyte subpopulation was analyzed by correlation analysis and ANOVA linear trend test. Finally, multiple linear regression models were employed in multivariate analysis for the assessment of independent effects of variables on peripheral blood T lymphocytes. Variables yielding a *P* value  $\leq 0.2$  in the univariate analysis were included in multivariate analysis, and the models were refined by backward elimination guided by the change in log likelihood of successive models. *P* < 0.05 was considered statistically significant. Computation was carried out with the aid of R Software version 2.5.1<sup>[18]</sup>.

## **RESULTS**

#### **Characteristics of patients at different stages of chronic HBV infection**

The demographic, virological, serological, and clinical characteristics of patients are summarized in Table 1. The mean age of 422 chronic HBV infection patients (males accounted for 63.5%) was 30.59  $\pm$  10.40 years. Over half of the patients' mothers were HBV positive. Two fifths of the patients were infected with HBV before the age of 8 years. Two thirds of the patients had detectable HBV DNA load and the majority of them (62.8%) had over  $10^7$  copies of HBV DNA per milliliter, more than half of them were HBeAg positive (51.7%) and nearly one third of them were infected with HBV pre-core region mutant.

Based on the predefined virological and biochemical parameters, all patients were divided into different stages of chronic HBV infection. A total of 112 patients were assigned to the immune-tolerant stage with a mean ALT level of 25.37  $\pm$  12.56 IU/L, a mean viral load of 7.88  $\pm$  1.54 log<sub>10</sub> copies of HBV DNA/mL, while 106 patients had more than  $10^5$  copies of HBV DNA/mL, six patients with positive HBeAg had  $10^5$  copies of HBV DNA/mL. Of the 112 patients, all with HBeAg positive and 37 had HBV DNA pre-C mutations. The patients at the immune-tolerant stage had a higher maternal HBV infection rate (83.0%) and a younger age (< 8 years) at HBV infection (55.4%). Two hundred and twenty-two patients were assigned to the immune active stage with a mean ALT level of 161.42  $\pm$  139.26 IU/L, a mean HBV load of 5.94  $\pm$  2.21 log<sub>10</sub> copies/mL. Of the 222 patients, 96 were HBeAg positive, 71 had HBV DNA pre-C mutations, and 57 had a serum HBV load of less than  $10^3$  copies/mL, but no other reasons for the elevated aminotransferase level. Eighty-eight patients at the immune-inactive carrier stage had a mean

<sup>1</sup> $\chi^2$  test; <sup>2</sup>t-test.

ALT level of 31.15  $\pm$  19.67 IU/L, a mean HBV load of 3.11  $\pm$  0.37 log<sub>10</sub> copies/mL. Eighty patients had undetectable serum HBV DNA, and 8 patients with negative HBeAg had a serum HBV load of less than 10<sup>5</sup> copies/mL. Ten patients had positive HBeAg and undetectable HBV DNA, and 14 patients had HBV pre-core mutant infection. Patients at the immune-inactive carrier stage also had a low maternal HBV infection rate (28.4%) and an older age (> 20 years) at HBV-infection (54.5%). All parameters had a statistically significant difference in patients at the three stages of chronic HBV infection. Profess from immune tolerance to chronic

HBV infection was significantly associated with HBV replication status including a higher HBV load, HBeAg expression, and HBV pre-core mutation ( $P < 0.001$ ).

The characteristics of patients with a high HBV load (HBV DNA  $>$  10<sup>7</sup> copies/mL) and a low HBV load (HBV DNA  $<$  10<sup>7</sup> copies/mL) at the immune-tolerant and -active stages are summarized in Table 2. Patients with a high HBV load had a higher maternal HBV infection rate (91.7%) and a higher positive HBV pre-C mutation rate (42.9%) than those with a lower HBV load at the immune-tolerant stage ( $P < 0.001$ ). A similar pattern was observed in patients at the immune active

**Table 3** Peripheral T-cell subsets broken down by various factors in normal controls and chronic HBV infection patients (mean  $\pm$  SD)

Groups	Patients (n)	CD3 <sup>+</sup>	CD4 <sup>+</sup>	CD8 <sup>+</sup>	CD4 <sup>+</sup> /CD8 <sup>+</sup> ratio

8-20	127	57.17 $\pm$ 12.27	33.05 $\pm$ 5.90	33.39 $\pm$ 7.91	1.07 $\pm$ 0.41
> 20	103	61.42 $\pm$ 11.89	36.02 $\pm$ 7.27	28.86 $\pm$ 7.89	1.35 $\pm$ 0.49
Unknown	26	62.25 $\pm$ 14.39	34.93 $\pm$ 6.34	31.78 $\pm$ 7.58	1.19 $\pm$ 0.45

Effects of various independent demographic, clinical and serological variables on T-cell profile of HBsAg positive individuals were analyzed. <sup>b</sup>P < 0.001 vs measurement of each T-cell parameter; <sup>c</sup>P < 0.01, <sup>d</sup>P < 0.001 vs ANOVA linear trend test.

stage. Furthermore, patients with a high HBV load had a younger age at HBV infection and a higher HBeAg expression level than those with a low HBV load at the immune active stage.

#### Composition of peripheral blood T lymphocyte subpopulations

The composition of T lymphocytes in peripheral blood of all chronic HBV infection patients is summarized in Table 3. Univariate analyses showed that T-cell impairment was significantly associated with both clinical stages of chronic HBV infection and higher HBV loads, serum HBeAg expression, HBV pre-C region mutation, history of maternal HBV infection, and younger age at HBV-infection. The linear dose-response relationship between T-lymphocyte subpopulations and HBV DNA copies was highly significant (linear trend test,  $P < 0.001$ ). The number of CD3<sup>+</sup> and CD4<sup>+</sup> cells and CD4<sup>+</sup>/CD8<sup>+</sup> ratio were negatively correlated with the serum HBV load in chronic HBV infection patients ( $r = -0.67, -0.58, -0.69, P < 0.0001$ ), while the number of CD8<sup>+</sup> cells was positively correlated with the HBV load ( $r = 0.64, P < 0.0001$ ).

The composition of peripheral blood T-lymphocytes in patients at different immune stages of chronic HBV infection is shown in Figure 1. The number of peripheral blood CD8<sup>+</sup> T-cells was higher in patients at the immune-tolerant stage than in patients at the immune-active and -inactive carrier stages, whereas the number of CD4<sup>+</sup> T cells was lower in patients at the immune-tolerant stage than in patients at the immune-inactive carrier stage ( $P < 0.001$ ), suggesting that patients

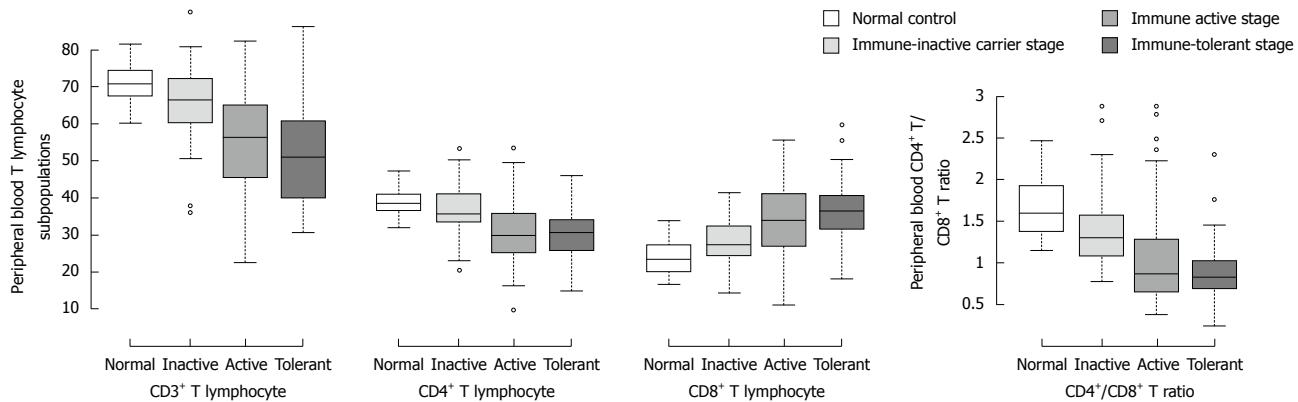

at the immune-tolerant stage have the highest number of peripheral blood CD8<sup>+</sup> T-cells and the lowest number of peripheral blood CD4<sup>+</sup> T-cells and ratio between CD4<sup>+</sup>/CD8<sup>+</sup> cells than those at the immune-active and -inactive carrier stages. The peripheral blood contained more CD8<sup>+</sup> T-cells than CD4<sup>+</sup> T-cells in patients at the immune-tolerant and -active stages, whereas the peripheral blood contained more CD4<sup>+</sup> T-cells than CD8<sup>+</sup> T-cells in patients at the immune-inactive carrier stage and normal controls ( $P < 0.01$ ).

The proportion of CD3<sup>+</sup>, CD4<sup>+</sup> and CD8<sup>+</sup> T-cells in peripheral blood of patients at the immune-tolerant stage is summarized in Figure 2A. The mean percentage of CD3<sup>+</sup> and CD4<sup>+</sup> T-cells was higher, whereas the mean percentage of CD8<sup>+</sup> T-cells was lower in patients with a low HBV load than in patients with a high HBV load ( $P < 0.001$ ). A similar pattern was also observed between patients with a high HBV load and those with a low HBV load at the immune active stage ( $P < 0.001$ , Figure 2B).

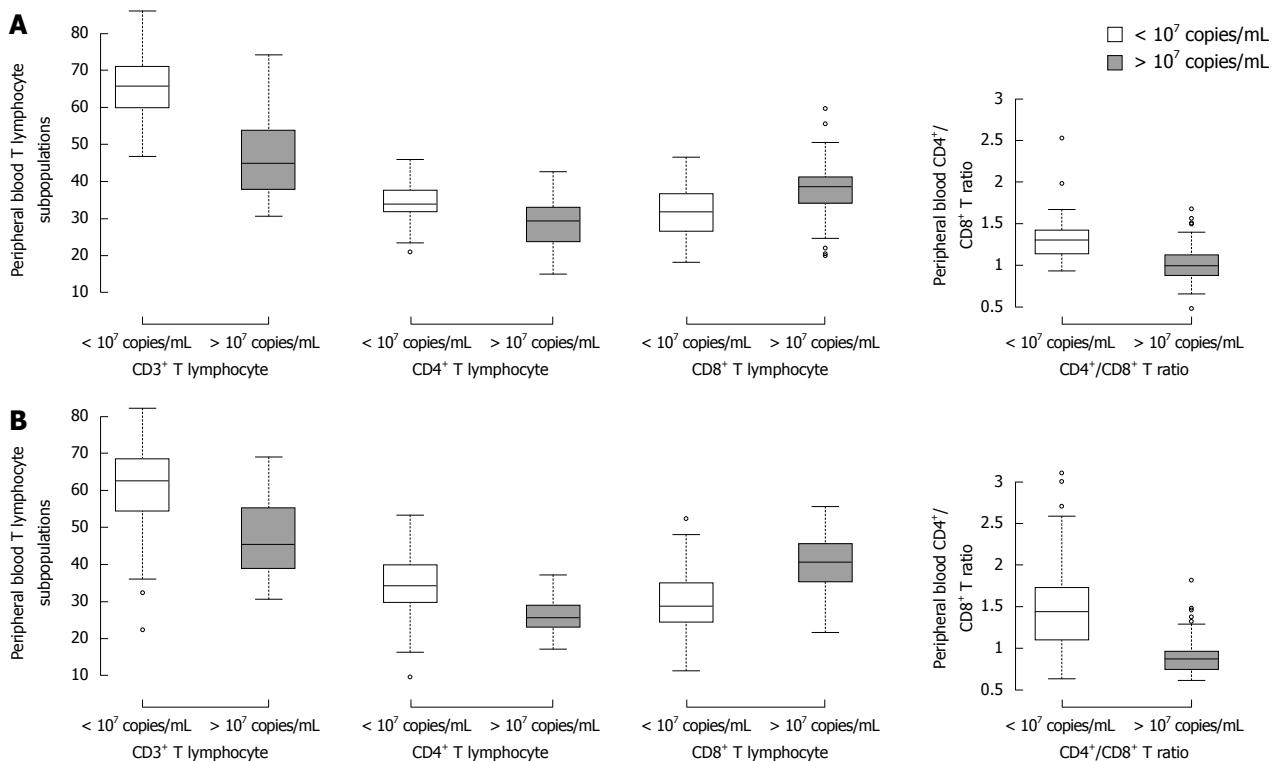

The mean percentage of CD3<sup>+</sup> and CD4<sup>+</sup> T-cells was higher in patients with negative HBeAg than in those with positive HBeAg at the immune active stage, whereas CD8<sup>+</sup> T-cells was lower in patients with negative HBeAg than in those with positive HBeAg ( $P < 0.001$ , Figure 3B). A similar pattern was observed between patients with negative HBeAg and those with positive HBeAg at the immune-tolerant stage ( $P > 0.05$ , Figure 3A).

#### Linear regression predicting peripheral blood T lymphocyte subpopulation

Linear regression models of CD3<sup>+</sup>, CD4<sup>+</sup> and CD8<sup>+</sup>

**Figure 1** Peripheral blood T-lymphocyte subpopulations in patients at different clinical stages of chronic HBV infection. The mean percentages of CD3<sup>+</sup>, CD4<sup>+</sup> and CD8<sup>+</sup> T cells and CD4<sup>+</sup>/CD8<sup>+</sup> ratio were shown in patients at the different stages and control. Top of the box represents the 75%, the bottom of the box represents the 25%, the solid line in the middle of the box represents the median. Whiskers above and below the box indicate the 90% and 10%, while filled circles represent outliers. A statistically significant difference in T cells but not in CD4<sup>+</sup> cells was observed between chronic HBV infection patients and normal control ( $P < 0.01$ ). In the peripheral blood of patients at the immune-tolerant and immune-active stages, CD8<sup>+</sup> T-cells were the dominant lymphocytes compared to CD4<sup>+</sup> T-cells, whereas in the peripheral blood of patients at the immune-inactive carrier stage and normal controls, CD4<sup>+</sup> T-cells were the dominant lymphocytes compared to CD8<sup>+</sup> T-cells.

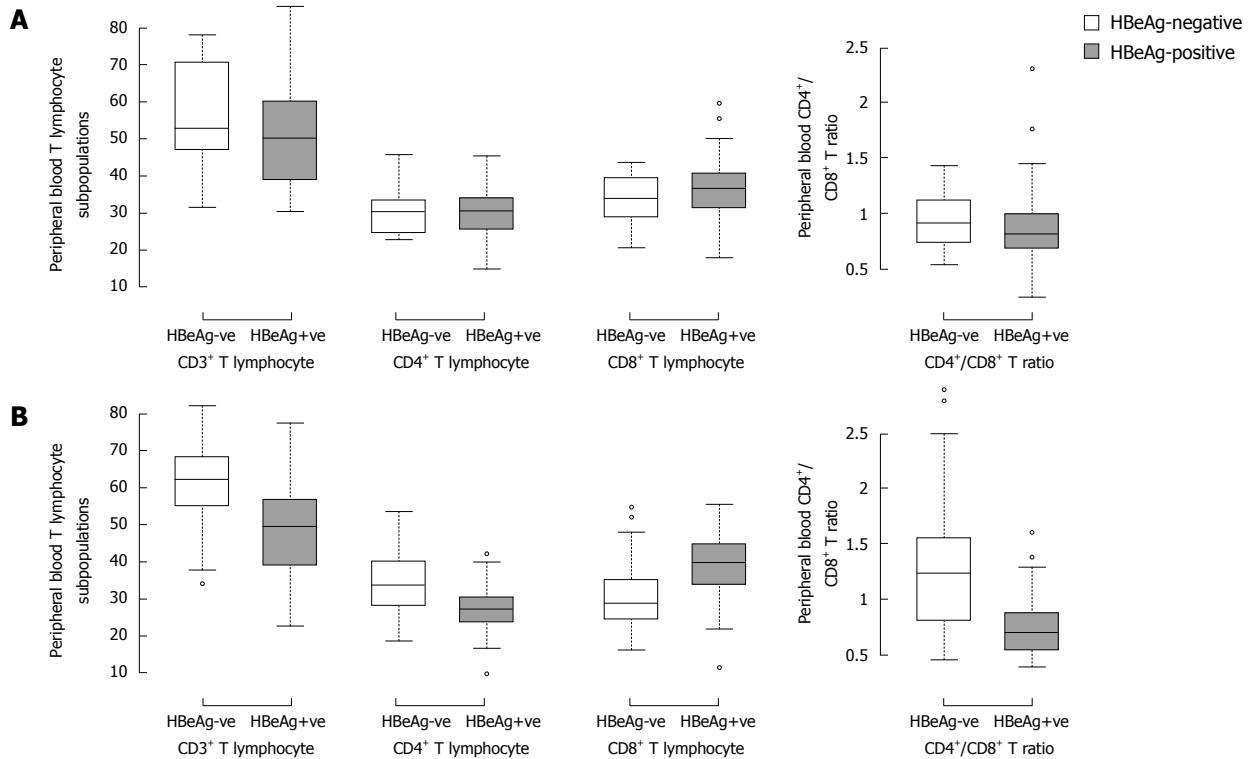

**Figure 2** Mean percentages of CD3<sup>+</sup>, CD4<sup>+</sup> and CD8<sup>+</sup> T-cells in patients at immune-tolerant stage (A) and immune active stage (B) of chronic HBV infection. Patients were divided into two groups based upon HBV DNA load. The proportion of CD8<sup>+</sup> T-cells was significantly higher in patients with a high HBV load than in patients with a low HBV load at the immune-tolerant stage ( $38.66 \pm 7.11$  vs  $31.50 \pm 6.40$ ,  $P < 0.001$ ) and at the immune active stage ( $40.07 \pm 7.55$  vs  $30.11 \pm 7.69$ ,  $P < 0.001$ ). The percentage of CD4<sup>+</sup> T-cells was significantly higher in patients with a low HBV load than in patients with a high HBV load at the immune-tolerant stage ( $33.77 \pm 5.81$  vs  $29.05 \pm 6.11$ ,  $P < 0.001$ ) and at the immune active stage ( $34.41 \pm 7.23$  vs  $26.25 \pm 4.52$ ,  $P < 0.001$ ). Significant differences were found in CD3<sup>+</sup> T-cells and CD4<sup>+</sup>/CD8<sup>+</sup> ratio between patients with a high HBV load and a low HBV load at the immune-tolerant stage ( $45.90 \pm 10.69$  vs  $65.40 \pm 8.70$ ,  $0.78 \pm 0.21$  vs  $1.11 \pm 0.32$ ,  $P < 0.001$ ) and at the immune active stage ( $46.82 \pm 9.25$  vs  $62.01 \pm 10.52$ ,  $0.69 \pm 0.23$  vs  $1.24 \pm 0.47$ ,  $P < 0.001$ ). CD8<sup>+</sup> T-cells were predominant compared with CD4<sup>+</sup> T-cells in patients with a high HBV load, whereas CD4<sup>+</sup> T-cells were predominant compared with CD8<sup>+</sup> T-cells in patients with a low HBV load.

cells and CD4<sup>+</sup>/CD8<sup>+</sup> ratio as dependent variables are listed in Table 4. After adjustment for all independent variables, serum HBV load was the key predictor for T-cell profiles. The number of CD3<sup>+</sup> and CD4<sup>+</sup> T lymphocytes was significantly reduced, the number of CD8<sup>+</sup> T cells was increased, and the CD4<sup>+</sup>/CD8<sup>+</sup> ratio was decreased in patients at the immune-tolerant stage. Those with chronic HBV infection at a younger age

had less CD4<sup>+</sup> T cells and a lower CD4<sup>+</sup>/CD8<sup>+</sup> ratio than those with chronic HBV infection at an older age. HBeAg expression, HBV pre-C mutation, and maternal HBV-infection status also had partial independent effects on T-lymphocyte profiles.

The relationship between T-lymphocyte subpopulations and HBV load stratified by age at HBV infection is shown in Figure 4A. No significant difference of T-cell

**Figure 3 Mean percentages of CD3<sup>+</sup>, CD4<sup>+</sup> and CD8<sup>+</sup> T-cells in peripheral blood of patients at the immune-tolerant stage (A) and immune active stage (B).** Patients were divided into two groups based upon the HBeAg status. The proportion of CD8<sup>+</sup> T-cells was significantly higher in HBeAg positive patients than in HBeAg negative patients at the immune active stage ( $39.24 \pm 8.05$  vs  $30.66 \pm 8.01$ ,  $P < 0.001$ ). The percentage of CD4<sup>+</sup> T-cells was significantly higher in HBeAg negative patients than in HBeAg positive patients at the immune active stage ( $33.60 \pm 7.41$  vs  $27.39 \pm 5.75$ ,  $P < 0.001$ ). Significant differences were found in CD3<sup>+</sup> T-cells and CD4<sup>+</sup>/CD8<sup>+</sup> ratio between HBeAg positive and negative patients ( $48.99 \pm 11.06$  vs  $60.48 \pm 11.22$ ,  $0.74 \pm 0.25$  vs  $1.21 \pm 0.50$ ,  $P < 0.001$ ). CD8<sup>+</sup> T-cells were predominant compared with CD4<sup>+</sup> T-cells in patients with a high HBeAg expression level, whereas CD4<sup>+</sup> T-cells were predominant compared with CD8<sup>+</sup> T-cells in patients with a low HBeAg expression level. In immune-tolerant-patients, no significant difference was observed in parameters of T-cell profile between HBeAg negative and positive patients ( $P > 0.05$ ).

The linear regression model was employed in multivariate analysis to assess the independent effects of variables on peripheral blood T lymphocyte subpopulation.  $\beta$ : Coefficients from the model; SE: Standard error; <sup>1</sup>Continuous variable; <sup>2</sup>Reference group with positive HBeAg; <sup>3</sup>Reference group without pre-C mutation; <sup>4</sup>Reference group at tolerant stage; <sup>5</sup>Reference group with the age < 8 years at HBV infection; <sup>6</sup>Reference group without maternal HBV infection status.

subsets was found in patients at different HBV infection ages after adjustment for serum HBV load. A similar pattern of the relationship between T-lymphocyte subpopulations and HBV load stratified by maternal HBV carrier status was also observed in patients with chronic HBV infection (Figure 4B). No significant difference was found in T-cell subsets between patients in maternal HBV carrier status after adjustment for serum HBV load.

## DISCUSSION

This study demonstrated that there were clear differences of peripheral T cell subpopulation profile in patients at different clinical stages of chronic HBV infection. An impaired balance of T-cell subsets was related to an increased proportion of CD8<sup>+</sup> T lymphocytes, a decreased proportion of CD4<sup>+</sup> T lymphocytes and a

**Figure 4 Correlation between T-cell subsets and HBV load stratified by age at HBV infection (A) and maternal HBV infection status (B).** Three regression lines (with different slopes) were drawn for patients at different ages of HBV infection. The coefficient of the interaction term "HBVDNA: age-at-HBV-infection" was not statistically significant for each parameter of T lymphocyte subpopulations ( $P > 0.05$ ). A similar pattern was seen when stratified by maternal HBV infection status.

decreased ratio between CD4<sup>+</sup> and CD8<sup>+</sup> cells. T-cell impairment had a linear dose-response relationship with the HBV DNA load.

The composition of T-cell subpopulations in

peripheral blood was significantly different in patients at different clinical stages of chronic HBV infection, indicating that patients at the immune-tolerant stage have the highest number of CD8<sup>+</sup> T-cells, the lowest number

of CD4<sup>+</sup> T-cells, and lowest ratio between CD4<sup>+</sup> and CD8<sup>+</sup> cells than those at the immune-active and inactive carrier stages. It has been reported that the composition of peripheral blood lymphocyte populations in patients at different stages of chronic HBV infection with research subject sample sizes ranging from 29 to 47<sup>[19,20]</sup>, which are different from our study and is, thus, unable to detect any significant difference of T-cell subsets in patients at different clinical stages of chronic HBV infection. Using a larger sample size that covered a wide range of different stages of chronic HBV infection in this study, we showed the discrimination power of the composition of T cell profile in peripheral blood.

An impaired balance of T-cell subsets is related to an increased proportion of CD8<sup>+</sup> T lymphocytes, a decreased proportion of CD4<sup>+</sup> T lymphocytes, and decreased ratio between CD4<sup>+</sup> and CD8<sup>+</sup> cells during chronic HBV infection<sup>[21-27]</sup>. However, the results of previous studies are controversial results<sup>[28-32]</sup>. The fact that chronic hepatitis B represents a dynamic disease state may explain such divergent results. Therefore, any analysis of the composition of peripheral blood lymphocyte populations needs to be viewed within the context of disease progression. In this study, we attempted to correlate the trend in HBV infection, diseases progression, and stages of HBV infection with the T-cell phenotypes based on the virological and biochemical profiles (Figure 1). Our results revealed that T-cell impairment was significantly associated with the HBV replication level, indicating that serum HBV load is a strong predicting factor for T-lymphocyte subpopulations. Interestingly, our results are consistent with previous findings<sup>[19]</sup>. It has been reported that the proportion of CD8<sup>+</sup> T-cells and CD4<sup>+</sup> T-cells in liver is increased, respectively, in patients with a high HBV load and in those with a low HBV load at the immune-clearance stage<sup>[19]</sup>. Pham *et al*<sup>[33]</sup> also reported that the CD4<sup>+</sup>/CD8<sup>+</sup> ratio in liver-derived lymphocytes is correlated with HBV replication in patients with chronic hepatitis B. The decreased proportion of CD4<sup>+</sup> T-cells and CD4<sup>+</sup>/CD8<sup>+</sup> ratio in chronic HBV infection patients with a high HBV load and HBeAg expression may be a consequence but not the cause of a high HBV DNA load<sup>[3-5,12]</sup>. The impact of HBV load on antiviral T-cell responses has been precisely characterized in animal models of virus infections (like LCMV), showing that the sustained presence of viral antigens leads to a progressive functional decline of virus-specific CD8<sup>+</sup> T-cell responses and ultimately virus-specific T-cell deletion<sup>[34-36]</sup>. Similarly, the frequency and function of circulating and intrahepatic HBV-specific CD8<sup>+</sup> T cells are inversely proportional to the HBV DNA load in HBV-infected patients<sup>[37-39]</sup>. High HBV loads are associated with the ablation of CD8<sup>+</sup> T cell responses and IL-2 production impaired by virus-specific CD4<sup>+</sup> T cells<sup>[35]</sup>. Matloubian *et al*<sup>[40]</sup> demonstrated that CD4<sup>+</sup> T cells are required to sustain the CD8<sup>+</sup> T cell responses during chronic HBV infection. Furthermore, Lamivudine treatment can transiently restore the efficient antiviral T cell responses in patients

with chronic hepatitis B and alleviate their viremia<sup>[41-44]</sup>, indicating that HBV load plays an important role in the pathogenesis of T cell hypo-response in chronic HBV infection patients.

Although no information on the proportion of T-cell profile in liver was provided in this study, Pernollet *et al*<sup>[45]</sup> demonstrated that intrahepatic lymphocyte subsets are correlated with peripheral lymphocyte subsets and there is an exchange between intrahepatic and peripheral compartments. Similarly, two recent works have shown that the same specific T lymphocytes can be isolated from either the liver compartment or the PBL of chronically HCV-infected patients<sup>[46,47]</sup>. For this reason, the authors of one of these works proposed a characterization of the lymphocyte response to HCV in the peripheral blood instead of in the liver compartment<sup>[46]</sup>. We can also hypothesize that T lymphocytes leave the liver after encountering antigen there, although it has recently been shown that the majority of activated CD8<sup>+</sup> T cells entering the liver undergo apoptosis within the liver<sup>[48,49]</sup>. On the other hand, it has been reported that peripheral blood mononuclear cells can be infected with HBV<sup>[50,51]</sup>. Nuti *et al*<sup>[52]</sup> suggested that intrahepatic lymphocytes do not undergo clonal expansion within the liver but migrate from extrahepatic sites to the chronically infected liver, where they display the function of effector cells and subsequently die, implying that maintenance of the intrahepatic lymphocyte pool depends on continuous immigration of lymphocytes.

Multivariate multiple regression analysis in our study demonstrated a partial independent effect of HBeAg and pre-core mutant infection on T-cell profile, which is supported by previous studies<sup>[53-69]</sup>. It is well known that factors including HBeAg<sup>[53-59]</sup> and viral mutations<sup>[60-69]</sup> may contribute to the outcome and pathogenesis of HBV infection by inducing tolerance to specific T cells, reducing their potential to kill cells, inhibiting antigen processing and presentation, thereby decreasing the visibility of infected hepatocytes in the immune system. In addition, our results indicate that there was no significant difference of the proportion of T-cell subsets in patients at different ages of HBV infection and in patients of maternal HBV carrier status after adjustment for serum HBV load. In our study, patients with a maternal carrier history were usually infected with HBV at a younger age (Table 1) and a higher HBV load was detected in most of them, suggesting that HBV infection from the mother and/or at a younger age predisposes to tolerance to HBV infection and, thus, has a higher BHV load.

The differences of peripheral T cell subpopulation profile in patients at different clinical stages of chronic HBV infection and the strong relationship between peripheral T-lymphocyte subpopulations with a HBV load were observed in this study. Unfortunately, no information on the proportion of virus-specific T-cell subpopulations was provided in this study. Whether the increased CD8<sup>+</sup> T cells contain an increment of virus-specific CD8<sup>+</sup> T cells and the decreased CD4<sup>+</sup> T cells include a decrement of HBV-specific CD4<sup>+</sup> T cells

remains unclear. Further studies are needed to confirm their relationship and the correlation between intrahepatic and peripheral lymphocyte subsets.

In conclusion, HBV viral load in patients at the immune-tolerant and immune active stages contributes to the variations in peripheral T cell subpopulation profile, which is relevant to the design of individualized new anti-viral strategies. Further study is required to better understand the complex host-virus interaction that determines the persistence and outcome of HBV infection.

## ACKNOWLEDGMENTS

The authors would like to express their sincere appreciation to Professor Tawesak Tanwandee at Division of Gastroenterology, Department of Medicine, Faculty of Medicine, Siriraj Hospital, Mahidol University, Bangkok, Thailand, and Professor Ming-Qing Chen, Dean of the First Clinical Medical College of Kunming Medical University, China, for their excellent constructive and valuable advice and technical assistance for this study. The gratitude is also given to the staff at Department of Hepatology, Third Kunming People's Hospital; Department of Infectious Diseases of Yunnan General Hospital, Chinese People's Armed Police Forces; Epidemiology Unit, Faculty of Medicine, Prince of Songkla University for participating in the research project. The authors sincerely thank all participants for their cooperation in the study.

## COMMENTS

### Background

Hepatitis B virus (HBV) infection is a serious public health problem worldwide and a major cause of chronic hepatitis, liver cirrhosis, and hepatocellular carcinoma. The pathogenesis of persistent HBV infection and hepatitis B is very complex and has not been clarified until now. HBV infection, a dynamic process with variable biochemical, virological and histological profiles at its different stages, depends on host and viral factors. Furthermore, the profiles may change at a variable pace over time. Based on the virological and biochemical parameters, chronic HBV infection patients can divided into immune-tolerant stage, immune active stage, and immune-inactive carrier stage.

### Research frontiers

Outcome of HBV infection and the pathogenesis of liver disease are determined by immune-mediated host-virus interaction, which is difficult to fully elucidate because the host range of HBV is limited to human beings and chimpanzees. The pathogenesis of liver disease and interaction between virus and host remain the hotspots in this field.

### Innovations and breakthroughs

The pathogenesis of cellular immune disorder and viral replication remains unknown. In the present study, peripheral T-lymphocyte subpopulations in chronic HBV infection patients were detected by flow cytometry and HBV load was determined by real-time polymerase chain reaction. The results suggest that differences in the peripheral T cell subpopulation profile were observed in patients at different clinical stages of chronic HBV infection. HBV load in patients at the immune-tolerant and immune active stages contributes to the variations in peripheral T cell subpopulation profile. The substantial linear dose-response relationship and strong independent predictive effect of HBV load on T-lymphocyte subpopulations suggested a close proximity of the causal pathway between them, indicating that HBV load plays an important role in the pathogenesis of T-cell impairment in chronic HBV infection patients.

### Applications

The results, which suggest that a high HBV load contributes to the impaired balance of T-cells in chronic HBV infection patients, have practical implications

because understanding of the immune response to HBV infection is useful in developing appropriate therapeutic strategies for controlling viral hepatitis and disease progression, improving current knowledge about the prognosis of persistent HBV infection. In addition, a high HBV load can predict the variations in peripheral blood T-lymphocyte subpopulations of chronic HBV infection patients.

### Terminology

CD4<sup>+</sup> T cells, classically referred to helper T cells that are required for the efficient effector cytotoxic/suppressor CD8<sup>+</sup> T- and B-cell antibody production, play an important role in HBV infection by secreting Th1 cytokines that down-regulate HBV replication, and by promoting CD8<sup>+</sup> T- and B-cell responses. CD8<sup>+</sup> T cells go on to clear HBV-infected hepatocytes through cytolytic and non-cytolytic mechanisms, thus reducing the circulating virus level, while B-cell antibody production neutralizes free viral particles, thus preventing (re) infection. CD3<sup>+</sup>, CD4<sup>+</sup> and CD8<sup>+</sup> cells are the major function subgroups of T cells and play an important role in the response to HBV infection, which can reflect the cellular immune function and immunoregulation and are usually regarded as a valuable index of the changes in immunity of patients.

### Peer review

This is a descriptive study of the peripheral T cell sub-populations in chronic hepatitis B based in a large cohort of patients.

### Abstract

**AIM:** To assess the use of topical negative pressure (TNP) in the management of severe peritonitis.

**METHODS:** This is a four-year prospective analysis from January 2005 to December 2008 of 20 patients requiring TNP following laparotomy for severe peritonitis.

**RESULTS:** There were 11 males with an average age of  $(59.3 \pm 3.95)$  years. Nine had a perforated viscus, five had anastomotic leaks, three had iatrogenic bowel injury, and a further three had severe pelvic inflammatory disease. TNP and the VAC® Abdominal Dressing System were initially used. These were changed every two to three days. Abdominal closure was achieved in 15/20 patients within  $4.53 \pm 1.64$  d. One patient required relaparotomy due to residual sepsis. Two patients with severe faecal peritonitis due to perforated diverticular disease received primary anastomosis at second look laparotomy, as sepsis and their general condition improved. In the remaining 5/20 cases, the abdomen was left open due to bowel oedema and or abdominal wall oedema. Dressing was switched to TNP and VAC® GranuFoam®. Three of the five patients returned a few months later for abdominal wall reconstruction and restoration of intestinal continuity. Two patients developed intestinal fistulae. All 20 patients survived.

**CONCLUSION:** The use of TNP is safe. Further studies

### INTRODUCTION

The principles of managing peritonitis have not changed for decades. They include elimination of the septic focus, removal of necrotic tissue, and drainage of purulent material<sup>[1]</sup>. Despite advances in antibiotics therapy and intensive care support, mortality and morbidity remain high<sup>[2]</sup>. In certain cases of severe peritonitis, the surgeon may feel that a further look is required to achieve these goals<sup>[1]</sup>. This can be achieved by leaving the abdomen open at the index operation<sup>[3]</sup>. While this concept of a planned second look following major abdominal trauma is well recognised<sup>[4]</sup>, its use following abdominal catastrophe due to severe peritonitis remains controversial<sup>[3]</sup>. Several different techniques have been tried to facilitate a second look<sup>[4-6]</sup>. Recently, topical negative pressure (TNP) with the VAC® Abdominal Dressing System was introduced<sup>[3,7]</sup>. However, concerns were raised about its safety<sup>[8-10]</sup>. We report our experience using TNP in managing patients with advanced peritonitis.

### MATERIALS AND METHODS

This is a four-year prospective analysis from January 2005 to December 2008 of 20 patients who developed severe peritonitis and whose abdomens were left open requiring TNP to allow a second look laparotomy. This

decision was taken independently by the operating surgeon. Patients' demographics, type and cause of peritonitis were noted. APACHE II scoring<sup>[11]</sup> and hospital mortality probability were calculated independently by critical care staff. Morbidity, mortality and delayed abdominal closure were recorded. TNP and the VAC® Abdominal Dressing System (Kinetic Concepts Inc., San Antonio, Texas, USA) were initially used to allow further exploration of the abdomen every 48 to 72 h. The TNP was set at 125 mmHg continuous. Once the abdomen was judged to be clean, and if delayed abdominal closure was not possible due to bowel oedema and or abdominal wall oedema, the dressing was switched to TNP and a VAC® GranuFoam® dressing with a non-adherent silicone dressing underneath. Tissue viability staff could carry this out in the ward. Dressing techniques are described elsewhere<sup>[3,7]</sup>. All data are presented as mean  $\pm$  SE.

## RESULTS

There were 11 males and 9 females with an average age of ( $59.3 \pm 3.95$ ) years. Seven patients developed severe peritonitis following elective surgery and 13 were initially admitted as emergencies. 10/20 patients required TNP from the onset and the remaining half after they developed a complication requiring further surgical intervention. Nine patients developed faecal peritonitis, four had a perforated stomach or duodenum, another four developed severe peritonitis due to small bowel perforation, and the remaining three patients had severe pelvic sepsis. Peritonitis was due to perforated viscus in nine patients, five had an anastomotic leak, three sustained an iatrogenic bowel injury, and in a further three patients peritonitis was due to severe pelvic inflammatory disease. The APACHE II scoring was ( $16.7 \pm 1.9$ ) and the hospital mortality probability was ( $37.2\% \pm 5.2\%$ ). The length of stay in the critical care unit (level III and level II) was ( $19.8 \pm 4.48$ ) d. The VAC® Abdominal Dressing System and TNP were initially used in all patients, with a change of dressing every two to three days in theatre (Table 1).

Abdominal closure was achieved in 15/20 patients within ( $4.53 \pm 1.64$ ) d. This required ( $2.35 \pm 1.81$ ) dressings. Two of those fifteen patients required a biological mesh to assist in abdominal wall closure. One patient required relaparotomy due to residual sepsis. In two patients who had severe faecal peritonitis due to perforated diverticular disease, primary anastomosis was possible at second look laparotomy because sepsis and their general condition improved. No covering stoma was required and they made an uneventful recovery.

For the remaining five cases, the abdomen was left open due to bowel and or abdominal wall oedema and the dressing was switched to TNP and a VAC® GranuFoam® dressing with a non-adherent silicone dressing underneath. This was carried out in the ward. Two patients developed intestinal fistulae. In the first patient, a small bowel anastomosis broke down on the fifth postoperative day, which was converted to an end ileostomy. The second patient had multiple enterotomies,

**Table 1** Details of the patients included in this study (mean  $\pm$  SE)

Male/female	11/09
Age (yr)	$59.3 \pm 3.95$
APACHE II scoring	$16.7 \pm 1.9$
4-9	3 patients
10-25	14 patients
26-35	3 patients
Hospital mortality probability (%)	$37.2 \pm 5.25$
Peritonitis: type	
Faecal peritonitis	9 patients
Perforated stomach/duodenum	4 patients
Small bowel perforation	4 patients
Pelvic sepsis	3 patients
Underlying problem	
Perforated viscus	9 patients
Anastomotic leak	5 patients
Iatrogenic bowel injury	3 patients
Pelvic sepsis	3 patients
No. of changes of dressings in theatre	$2.35 \pm 1.81$
Delayed primary closure	15/20
Complications	
Fistulae	2/20
Residual collection	1/20
Mortality	0/20

of which two leaked on the ninth postoperative day and these were treated conservatively. These two patients and a further third patient returned a few months later for abdominal wall reconstruction and restoration of intestinal continuity. One patient underwent surgery after 6 mo and the remaining two around 12 mo from their initial surgery. One patient is awaiting reversal of a stoma and abdominal wall reconstruction.

## DISCUSSION

Surgery is the cornerstone of treatment of abdominal sepsis<sup>[12]</sup>. It is every surgeon's desire to achieve this goal with a single operation, but this is not always possible<sup>[11]</sup>. The concept of a planned relaparotomy was suggested<sup>[12]</sup>. When some authors found that one extra laparotomy was not enough the concept of the open abdomen was developed<sup>[13]</sup>. A randomised study of 232 patients from the Dutch peritonitis study group<sup>[14]</sup> failed to show any advantage of "planned relaparotomy" compared to "laparotomy on demand". A further randomised study by Robledo *et al*<sup>[11]</sup> comparing open with closed "on demand" management of severe peritonitis was terminated after the inclusion of 40 patients because of a mortality disadvantage for the open abdomen group (55 vs 30%). However in this study, the "open abdomen" was managed with a non-absorbable polypropylene mesh.

Billing *et al*<sup>[15]</sup> in a case control study found no advantage of planned relaparotomy, but for a subgroup analysis of patients in whom source control was not achieved during the index operation, a lower mortality rate was reported with planned relaparotomy. Furthermore, Koperna *et al*<sup>[16]</sup> have shown that patients reoperated on after 48 h had a higher mortality rate than those operated on earlier.

Barker *et al*<sup>[4]</sup> reported their 15 years experience using

a locally designed vacuum-pack system in 258 patients (116 trauma and 142 general and vascular surgery). Primary closure was achieved in 68% and they reported a 5% fistula rate. Perez *et al*<sup>[3]</sup> reported similar results using TNP and the VAC® Abdominal Dressing System in a series of 37 patients following severe abdominal sepsis and compartment syndrome.

The use of TNP in the management of severe peritonitis was never subjected to a randomised study. Bee *et al*<sup>[17]</sup>, after damage control surgery following abdominal trauma, compared temporary abdominal closure of the open abdomen (using polyglactin mesh) with TNP and the VAC® Abdominal Dressing System or a locally designed vacuum-pack system. They failed to show a clear benefit of the latter. Furthermore, the fistula rate in the second group was 21%, but this was not statistically different from the 5% rate for the mesh group. These fistulae were related to feeding enterostomies or anastomotic dehiscences, and they all occurred with the vacuum-pack system. Adkins *et al*<sup>[18]</sup> compared the outcome of 81 patients with severe peritonitis managed with the vacuum-pack system with a historical control group. Hospital mortality was 33% and 25%, respectively. This did not reach statistical significance. A fistula rate of 14.8% was demonstrated in the open group.

TNP facilitates temporary abdominal wall closure<sup>[7]</sup>, controlled collection of exudate<sup>[2]</sup> and the small bowel " cocoons" inside the abdominal cavity, preventing interloop abscesses<sup>[19]</sup>. Furthermore the Abdominal Dressing System allows easy access for a second look<sup>[3]</sup>. While the Bogota bag<sup>[3]</sup> is a cheap alternative in managing the open abdomen; it does not control exudate and the bowel can adhere to the abdominal wall, making re-exploration difficult.

It was suggested<sup>[2]</sup> that a second look to be beneficial for patients with an APACHE II score of 10 to 25. A score greater than 26 has a high mortality rate regardless of the strategy used, and a score less than 10 has a good prognosis whatever the approach used. In our study, the operating surgeon was not aware of the APACHE II score, which was calculated independently by the intensive care staff. 14/20 had an APACHE II score of 10 to 25 and 3/20 had a score greater than 26. In addition, half of the patients had a hospital mortality probability greater than 30%. All patients in this study survived their surgical admission. Delayed abdominal wall closure was achieved in 75% of patients and intestinal continuity was restored in two patients when conditions became favourable; this is known as delayed primary anastomosis<sup>[2]</sup>.

There are very few reports of the use of TNP and the Abdominal Dressing System in peritonitis<sup>[7]</sup>. Most reports include patients with compartment syndrome<sup>[13]</sup> or trauma patients. Others include both TNP and the abdominal dressing that we used in this study, which was developed by the Wake Forest group or the vacuum-pack system that was popularized by the Chattanooga group<sup>[17]</sup>. Trevelyan and Carlson<sup>[9]</sup> suggested that the results of TNP use following sepsis should be evaluated separately from trauma cases. Its safety in the open

septic abdomen should not be assumed simply because of data gathered in trauma patients and they reported a high fistula rate<sup>[8-10]</sup>. However, it is not always clear in these reports what type of dressings were used. Over the last five years we used TNP and the Abdominal Dressing System in the open abdomen in 42 patients, of whom 20 had severe peritonitis. Two patients (2/20) developed intestinal fistulae. This is an acceptable figure in these difficult cases.

We believe patients who would benefit most from the use of this technique are: (1) Patients with anastomotic leak and iatrogenic bowel injuries; (2) Damage control for unstable patients, particularly in the presence of hypothermia, severe acidosis or coagulopathy<sup>[20]</sup>; (3) Bowel and/or abdominal wall oedema making closure difficult<sup>[19]</sup>; (4) Source of sepsis not identified<sup>[15]</sup>; (5) Sepsis not fully controlled<sup>[4]</sup>; (6) Doubtful tissue viability requiring a further look<sup>[20]</sup>; and (7) Severe faecal peritonitis, particularly if delayed primary anastomosis can be considered at a second look<sup>[2]</sup>.

Leaving an abdomen open is a decision that should not be taken lightly. It can have a negative impact on quality of life if used inappropriately.

In conclusion, the management of patients with abdominal catastrophe requires the close cooperation of surgeon, intensivist and microbiologist. In 1991 Schein<sup>[21]</sup> suggested that the open abdomen technique in the management of peritonitis generated great interest and hope. Fifteen years later, Wild *et al*<sup>[7]</sup> declared that the Abdominal Dressing System set a new standard in the management of the open abdomen following peritonitis. In our study, TNP appears to be safe and we feel its use had a positive contribution to a group of patients who were severely ill. However, used unwisely, it might lead to unnecessary morbidity. Further studies are needed to identify patients for whom this technique would be beneficial.

## COMMENTS

### Background

Surgery is the cornerstone in the management of severe peritonitis, which can be life threatening. A planned second look operation might be required. This can be achieved by leaving the abdomen open at the index operation. Over the years, different techniques have been suggested to facilitate this. Recently topical negative pressure (TNP) with VAC® Abdominal Dressing (Kinetic Concepts Inc., San Antonio, Texas, USA) were introduced. Some studies have raised concerns about its value and safety.

### Research frontiers

TNP is a wound management system that was modified to assist in the management of the open abdomen following major abdominal trauma. The research hot spot is its efficacy and safety in the management of the open abdomen following severe peritonitis.

### Innovations and breakthroughs

The management of the open abdomen is challenging. Various methods have been tried but none proved to be optimal. An ideal temporary dressing allows easy access for further surgery, controls exudate from the abdomen, reduces bowel oedema and ultimately makes abdominal closure possible when conditions are favourable. TNP with the VAC® Abdominal Dressing appears to fit these criteria.

### Applications

This study suggests that the use of TNP with the VAC® Abdominal Dressing System in patients with severe peritonitis is safe, with acceptable morbidity. Delayed closure can be achieved if conditions become favourable.

## Terminology

Peritonitis is an inflammatory process of the peritoneum caused by any irritant agent such as bacteria, fungi, virus, talc, drugs, granulomas, and foreign bodies. TNP and the VAC® Abdominal Dressing System: Encapsulated foam with a non-adherent fenestrated layer is placed between the abdominal wall and the exposed abdominal content. On top of this, a layer of perforated Granufoam® is placed; this is covered by an adhesive drape to create an airtight seal. A Pad lies on top of the foam and is connected to a fluid collection canister contained in a programmable computer controlled vacuum pump creating negative pressure at the wound surface. The dressing is changed every 48-72 h.

## Peer review

It is an interesting prospective non-comparative analysis of 20 patients with severe peritonitis and open abdomen. Fifteen patients underwent primary closure of the abdomen using VAC and TPN. In the remaining five cases, the abdomen was left open with TNP and VAC.

### Abstract

**AIM:** To investigate the liver stiffness measurement (LSM) applicability and variability with reference to three probe positions according to the region of liver biopsy.

**METHODS:** The applicability for LSM was defined as at least 10 valid measurements with a success rate greater than 60% and an interquartile range/median LSM < 30%. The LSM variability compared the inter-position concordance and the concordance with FibroTest.

**RESULTS:** Four hundred and forty two consecutive patients were included. The applicability of the anterior position (81%) was significantly higher than that of the reference (69%) and lower positions (68%), (both  $P = 0.0001$ ). There was a significant difference (0.5 kPa, 95% CI 0.13-0.89;  $P < 0.0001$ ) between mean LSM estimated at the reference position (9.3 kPa) vs the anterior position (8.8 kPa). Discordance between positions was associated with thoracic fold ( $P = 0.008$ ). The discordance rate between the reference position result and FibroTest was higher when the 7.1 kPa cutoff was used to define advanced fibrosis instead of 8.8 kPa (33.6% vs 23.5%,  $P = 0.03$ ).

**CONCLUSION:** The anterior position of the probe should be the first choice for LSM using Fibroscan, as it has a higher applicability without higher variability compared to the usual liver biopsy position.

### INTRODUCTION

A major clinical challenge is to find the best method to evaluate and to manage the increasing numbers of patients with chronic liver disease<sup>[1-4]</sup>. Liver biopsy, due to its risks and limitations, is no longer considered mandatory as the first-line indicator of liver injury, and several markers have been developed as non-invasive alternatives<sup>[1-4]</sup>.

The assessment of liver fibrosis by non-invasive techniques such as biomarkers, [FibroTest® (FT)]<sup>[5]</sup> and liver stiffness measurement (LSM) by Fibroscan®<sup>[6,7]</sup>, is now widely performed in countries where these techniques are available and approved<sup>[8,9]</sup>. It is therefore essential to identify factors associated with a variability of the results of these techniques to reduce the risk of false positives or false negatives. There are no published procedures for the most accurate position of the probe in LSM. In almost all

publications<sup>[6,7,9-10]</sup>, the described method is copied from the original description by Sandrin *et al*<sup>[13]</sup>: "Because liver biopsies are performed on the right lobe of the liver, so were the elasticity measurements. During the acquisition, patients were lying on their backs with their right arms behind their heads. The physician first proceeded to a sonographic examination to localize the best ultrasonic imaging window between the rib bones. Additionally, regions with large vessels were avoided and a minimal liver parenchyma thickness of 6 cm was sought".

Few studies have examined the variability possibly associated with different positions in the rather vaguely defined area called "the liver biopsy zone". The variability associated with position could be part of the interobserver effect. Only two published studies have estimated the interobserver effect: Sandrin *et al*<sup>[13]</sup> studied 10 patients involving 3 operators (standardized CV 3.3%) and Coco *et al*<sup>[14]</sup> compared 2 operators in 40 patients using correlation coefficients (0.92) and paired *t*-tests. Tanne *et al*<sup>[17]</sup> also observed a significant discordance (25%) between predicted fibrosis stages according to three different positions of the probe and suggested using three different positions, to reduce the "sampling error".

We previously compared 9 different positions in the right lobe in 35 healthy subjects with the same operator and observed a very significant variability<sup>[18]</sup>. Three positions were therefore selected according to their applicability: the reference position, an anterior position and a lower position.

The aims of this study were to compare the applicability of these three positions, their inter-position concordance, and their concordance alone and relative to FT, a reference biomarker of fibrosis.

## MATERIALS AND METHODS

Consecutive patients with chronic liver disease seen in the Hepatology Department of the Pitié-Salpêtrière Hospital in Paris, France were pre-included to undergo LSM and FT. Patients were not included if they did not accept the protocol, or if the quality requirements for FT were not achieved. All patients gave informed consent for the use of data and serum for research purposes in this non-interventional clinical study, which was approved by the local institutional review board. The study protocol was in accordance with the ethical guidelines of the Declaration of Helsinki.

### Biochemical markers

FibroTest, and ActiTest (Biopredictive, Paris, France) were performed according to published recommendations<sup>[5,19,20]</sup>.

### Liver stiffness measurements

LSM was performed with the non-invasive method of transient elastography (FibroScan, Echosens, Paris, France). The stiffness results were expressed in kilopascal (kPa). The technique was performed by two trained (more than 100 measurements) senior hepatologists, blinded to all other characteristics, and according to the manufacturers' recommendations. During the acquisition,

patients were lying on their backs with their right arms behind their heads. The operator firstly proceeded to a sonographic examination to localize the best ultrasonic imaging window between the rib bones in the liver biopsy area. Regions with large vessels were avoided and a minimal liver parenchyma thickness of 6 cm was sought.

The reference position was the region usually recommended for biopsy located at the intersection between the xiphoid line and the median axillary line, where the operator would have performed the biopsy. The second position (lower position) was a more posterior position 2-3 cm in the next intercostal space on the same xiphoid line as the reference position and the third position (anterior position) was an anterior position 2-3 cm ahead of the reference position in the same intercostal space.

Two of the most commonly recommended cutoffs for advanced fibrosis (F2, F3 and F4 in METAVIR staging)<sup>[21]</sup> vs non-advanced fibrosis (F0 and F1) were used: 7.1 kPa<sup>[6]</sup> and 8.8 kPa<sup>[12]</sup>.

### Applicability

The applicability for LSM was defined as: a success rate greater than 60% (SR60)<sup>[7,9,12,13]</sup>, at least 10 valid liver stiffness measurements (V10)<sup>[7,9,12,13]</sup> and an interquartile range/median LSM < 30% (IQR30)<sup>[7,9,14-19]</sup>.

The applicability for FT was defined as: a security algorithm profile excluding Gilbert's disease, hemolysis, acute inflammation profiles and extreme values of FT components, leading to a change of at least 0.30 in the FT result if the median value of each component was used<sup>[5,20]</sup>.

### Statistical analysis

The two main endpoints were the applicability rate and the discordance rate with FT, for the two new positions vs the reference position. Because of the number of statistical comparisons for these two endpoints for two positions, a *P* value lower than 0.01 has been taken for a significant difference.

The strength of concordance between each LSM, or their combinations, and FT was assessed using three methods, the kappa reliability test (K) for 2 fibrosis stages (advanced vs non-advanced fibrosis), the Spearman rank correlation coefficient (R), and the intraclass coefficient of correlation (ICC)<sup>[22]</sup>.

Applicabilities were compared using Chi square and Fisher's exact tests, quantitative variables were compared using Mann-Whitney test, Wilcoxon signed rank test for paired comparisons, and multivariate analysis using logistic regression analysis. All comparisons were performed separately with subpopulations of operator 1 and 2, as well as with the population of patients with all positions applicable and populations with at least one position applicable. Analyses were performed with NCSS software (Kaysville, Utah, USA)<sup>[23]</sup>.

## RESULTS

A total of 468 consecutive patients were pre-included

**Table 1 Characteristics of included and non-included patients n (%)**

between April and September 2007. Twenty six patients were not included and 442 patients were included (Table 1). There was no difference between included and non-included patient characteristics.

### Applicability

The applicability of LSM according to position is described in Table 2. The applicability of the anterior position (81%) was significantly higher than that of the reference (69%) and lower positions (68%), (both  $P = 0.0001$ ). These differences in applicability were mainly due to an IQR30 obtained more often with the anterior position than with the reference or lower positions for both operator 1 and operator 2 respectively: 82% vs 67%,  $P < 0.0001$ ; 82% vs 73%,  $P = 0.004$  and 91% vs 87%,  $P = 0.40$ ; 91% vs 76%;  $P = 0.004$ .

### Liver stiffness measurements between positions

Among 268 patients with both anterior and reference positions applicable, the mean LSM estimated at the reference position [9.0 kPa; (0.5)] was significantly higher in comparison to the anterior position [8.5 kPa (0.5);  $P < 0.0001$ ].

Valid10	96/113 (85)	
SR60	94/113 (83)	
IQR30	86/113 (76) <sup>b</sup>	

<sup>a</sup>Applicability of the anterior position was significantly higher than that of the reference and the lower positions (both  $P = 0.0001$ ); <sup>b</sup>IQR30 was obtained more frequently with the anterior position than with the reference and lower positions for operator 1 (82% vs 67%  $P < 0.0001$ ; 82% vs 73%  $P = 0.004$ ) and for operator 2 (91% vs 87%  $P = 0.40$ ; 91% vs 76%  $P = 0.004$ ); <sup>c</sup>Presumed fibrosis stage (METAVIR scoring system) using 7.7 kPa for F2, 8.8 kPa for F3 and 14.5 kPa for F4; <sup>d</sup>Presumed prevalence of non-advanced fibrosis was lower using the reference position than the anterior position ( $P = 0.04$ ).

There was no significant difference between LSM measured at the reference in comparison to the lower position [9.5 kPa (0.5) vs 9.3 kPa (0.5),  $n = 253$ ,  $P = 0.36$ ].

### Presumed prevalence of fibrosis

Among 268 patients with both applicable anterior and reference positions, using a 7.1 kPa cutoff, 121/268 (45%) of patients had advanced fibrosis using the reference position vs 102/268 (38%) using the anterior position ( $P = 0.10$ ). Using an 8.8 kPa cutoff, 73/268 (27%) of patients had advanced fibrosis using the reference position vs 58/268 (24%) using the anterior position ( $P = 0.40$ ).

When the prevalence of presumed fibrosis stages was compared according to the probe position of all applicable patients, prevalence of non-advanced fibrosis (7.1 kPa cutoff) was lower using the reference position (55%) than the anterior position (62%,  $P = 0.04$ ) (Table 2).

**Table 3 Strength of concordance between stiffness measurements assessed in three positions in the biopsy area**

Position (No. of patients)	Method assessing concordance	
Quantitative concordance	Spearman mean (95% CI)	Intra class coefficient mean (95% CI)
Reference vs anterior (196)	0.81 (0.75-0.85)	0.90 (0.86-0.94)
Reference vs lower (196)	0.77 (0.70-0.82)	0.86 (0.79-0.93)
Anterior vs lower (196)	0.77 (0.70-0.82)	0.87 (0.80-0.94)
Two classes concordance	Discordance rate (%)	Kappa mean (SE)
Advanced vs non advanced fibrosis		
7.1 cutoff		
Reference vs anterior (196)	35 (17.9) <sup>a</sup>	0.63 (0.07)
Reference vs lower (196)	33 (16.8) <sup>b</sup>	0.66 (0.07)
Anterior vs lower (196)	34 (17.3) <sup>c</sup>	0.64 (0.07)
8.8 cutoff		
Reference vs anterior (196)	22 (11.2)	0.71 (0.07)
Reference vs lower (196)	28 (14.3)	0.65 (0.07)
Anterior vs lower (196)	20 (10.2)	0.74 (0.07)

<sup>a</sup>P = 0.06 vs 8.8 kPa cutoff; <sup>b</sup>P = 0.50 vs 8.8 kPa cutoff; <sup>c</sup>P = 0.04 vs 7.1 kPa cutoff.

Using an 8.8 kPa cutoff, there was no difference between the prevalence of non-advanced fibrosis using the reference position (226/306, 74%) than the anterior position (275/357, 77%; P = 0.34).

### Concordance between positions

The discordance rates and strength of concordance between LSM assessed in three positions are detailed in Table 3. The discordance rate between the anterior and the lower probe positions was higher (17.3%) when the 7.1 kPa cutoff was used to define advanced fibrosis, instead of 8.8 kPa (10.2%; P = 0.04), and for the anterior vs the reference position (17.9% vs 11.3%; P = 0.06). There was no significant operator effect.

The factors significantly associated with discordance between the reference and the anterior positions were thoracic fold (P = 0.0008) thickness and non-alcoholic fatty liver disease (NAFLD) as the cause of liver disease (P = 0.008) (Table 4). BMI (P = 0.02), abdominal (P = 0.03) and waist circumference (0.047), and SteatoTest (P = 0.04) were not significantly associated when protected for multiple statistical comparisons (Table 4). In multivariate analysis, only thoracic fold was significantly associated with position discordance (regression coefficient beta= 0.07; 95% CI 0.02-0.13; P = 0.01). Same results were observed in the population with three positions applicable.

### Concordance with FT

Discordance rates and strength of concordance between LSM assessed in three positions and FT are detailed in Table 5. There were no significant differences between the discordances rates and the strength of concordance between the three probe positions at a sufficient P value protected for multiple testing.

The discordances rates between probe positions and FT were higher when the 7.1 kPa cutoff was used to define advanced fibrosis instead of 8.8 kPa for the

**Table 4 Factors associated with discordance between reference and anterior positions n (%)**

reference position (33.6% vs 23.5%, P = 0.03) in the 196 patients with all 3 positions applicable and also among the 306 patients with only the reference position applicable (34.9% vs 26.8%, P = 0.03).

The mean of the 3 positions (a total of 30 LSM), did not increase the strength of concordance with FT.

## DISCUSSION

This study provides an improved assessment of the variability of LSM due to the position of the probe in the right liver lobe. We confirmed the preliminary results we had observed in 35 healthy subjects, in whom 9 different positions had been assessed<sup>[18]</sup>.

The diagnostic value of LSM and FT has been validated in the most common chronic liver diseases and FT has shown at least a similar prognostic value as liver biopsy (which is also an imperfect gold-standard<sup>[24]</sup>) in patients with chronic hepatitis C<sup>[25]</sup> and B<sup>[26]</sup>. We demonstrated previously that the strength of concordance between LSM and FT could be used to identify LSM

variability factors<sup>[27]</sup>.

The results strongly suggest that the reference position for LSM has two weaknesses in comparison with a more anterior position: a significantly lower applicability and a possible higher variability for the diagnosis of advanced fibrosis using the 7.1 kPa cutoff. The third position analyzed at a lower level compared to the reference position had no advantage either in terms of applicability or in strength of concordance with FT.

The main significant weakness of the reference position in this population was the low applicability rate: 69% compared to 81% in the anterior position. There may be several explanations for the difference in this rate compared to the rates observed in the largest series already published.

Firstly, most Fibroscan validation studies do not apply the strict recommendations for applicability. Foucher *et al*<sup>[11]</sup> achieved in 758 patients a 93.8% applicability rate but used weak criteria: less than 5 valid measurements and a success rate lower than 30%, without taking into account the IQR/median percentage. Kettaneh *et al*<sup>[12]</sup> obtained, in 935 patients, 10 LSM in 91.6%, and did not

specify the rate of patients with a success rate lower than 60% and with an IQR/median higher than 30%. In applying only the criteria of 10 valid measurements, we also observed in the present study 95% and 100% applicability for the two operators. There is a major risk of false positive or false negative conclusions for the diagnosis of advanced fibrosis if LSM results with a low success rate or a high dispersion (IQR) are interpreted<sup>[19]</sup>.

Secondly, the design of the present study was to start at the usual position for liver biopsy and then move to a more anterior and then to a lower position. Skilled operators probably automatically make the small change of position, when they are not satisfied with the first LSM results. Our results suggest that they must probably start with the anterior position first.

The mean LSM was significantly lower (0.5 kPa) at the anterior position *vs* the reference position. This difference was also clinically significant. When using the anterior position instead of the reference position, 7% of patients changed status from advanced fibrosis to non-advanced fibrosis when a cutoff of 7.1 kPa was chosen. The difference of 0.5 kPa is particularly clinically relevant in the zone of 7 to 9 kPa for the risk of a false negative/positive diagnosis of advanced fibrosis; it is less relevant for the diagnosis of cirrhosis as LSM cutoffs are usually recommended at a 12.5 kPa or 14 kPa cutoff with a range to 75 kPa. From these data it is possible to say that the reference position using 7.7 kPa cutoff for F2 and 8.8 kPa for F3 increases the risk of false positive conclusions in comparison with 8.8 and 12.5 kPa cutoffs, respectively.

Several anthropometric factors were associated with discordance between the reference and the anterior positions but the most significant factor was the thoracic skin fold thickness. More studies must now be conducted to better understand the role of these anthropometric factors both with regard to the applicability and to the variability of LSM.

Improved knowledge of LSM variability is also important for the definition of normal values of LSM. In contrast to FT, very few studies have assessed the normal range of LSM with biopsy without fibrosis (F0 in the METAVIR scoring system). Roulot *et al*<sup>[10]</sup> proposed the 95% percentile of a healthy non-obese population as the upper normal limit; 7.8 for females and 8.0 kPa for males. If these definitions of normal range are widely validated, the usual recommended cutoffs values of 7.1 and even 8.8 kPa for stage F2 must be re-assessed, as well the performance of Fibroscan to identify the F1 stage.

Before attributing the observed variability to a specific position, the following confounding factors must be discussed: an order effect, an operator effect, and another factor associated with LSM variability such as skin fold thickness or steatosis.

The order of LSM measurements began with the reference position first, followed by the lower and finally the anterior position. There was no systematic order effect for applicability rates or strength of concordance estimates and this bias can be excluded.

Two operators participated in the present study. The study was not designed as an inter-operator study and

therefore the two operators measured LSM in different patients. There was a difference between operators for the applicability rate of the reference position due to a lower IQR30 percentage. This was not a systematic operator effect, as this lower IQR30 percentage was not observed for the anterior or the lower positions. Operator 1 had twice as many NAFLD patients [50/329 (15.2%)] as operator 2 [9/113 (8%)]  $P = 0.05$ , which could explain the greater variability of LSM and lower applicability in comparison to operator 2. As with other authors<sup>[7,12,15,16]</sup>, we previously observed that the non-applicability and the variability of LSM at the reference position were higher in patients with NAFLD vs non-NAFLD patients.

We acknowledge that the number of comparisons increased the risk of false positives. The comparison between the strength of concordance anterior position-FT and the strength of concordance reference position-FT did not reach a high statistical significance ( $P < 0.01$ ).

However, all the comparisons indicated the same direction and at least a lower concordance of the anterior position with FT in comparison with the reference position can be excluded.

In conclusion, our results suggest that the anterior position of the probe, 2-3 cm ahead of the usual position of liver biopsy, should be the first choice for LSM using FibroScan for liver fibrosis estimates. Compared with the reference position, the anterior position improved the applicability of FibroScan without decreasing its concordance with FibroTest.

## COMMENTS

### Background

Liver fibrosis describes the phenomenon of scarification of the liver tissue in chronic liver diseases. The common final path of chronic liver damage is liver cirrhosis with a high morbidity and mortality and the risk of developing liver cancer. Liver biopsy has always been the traditional gold-standard to "measure" liver fibrosis. Recently, new non-invasive methods of measurement such as serum markers (i.e. FibroTest®) or elastometry (FibroScan®) have emerged to replace liver biopsy in the clinical setting.

### Research frontiers

Liver stiffness measurement (LSM) by transient elastometry is now widely used in countries where the method is accessible and approved. However, the best location to perform the liver elastometry has not been identified and recommendations are derived from an estimated "best spot" defined in an earlier study. In this study, the authors showed that applicability rates may change in a significant way depending where the measurements are done and that results tend to vary.

### Innovations and breakthroughs

This is the first systematic research to identify applicability and variability limits of transient elastometry. The study has shown that applicability rates are higher when a more anterior position is chosen compared to the recommended position. A trend towards higher fibrosis rates measured in the recommended position compared to the anterior position has also been seen in this study. Moreover, the LSM results were compared with a well established biomarker (FibroTest®) and the anterior position was not inferior with regard to concordance rates.

### Applications

This study implies that FibroScan® examinations reach higher applicability rates when performed at a more anterior position than the hitherto recommended position.

### Terminology

Liver fibrosis is the process of collagen septa production in the hepatic tissue.

Liver biopsy gives a pathologist the possibility to examine the liver tissue but samples are potentially too small. Transient elastometry uses the change in liver stiffness due to collagen content to estimate the liver damage. Biomarkers use direct or indirect blood markers associated with liver fibrosis.

### Peer review

This study arouses interest for readers and provides an important clue to evaluate liver stiffness by using non-invasive probe techniques. Liver biopsy is day-after-day decreasing in importance when dealing with patients suffering from HCV-related chronic hepatitis mainly because all in all the therapeutic approach does not change. In this light the elastography plays a new extraordinary role and the present study contributes to its better applicability, defining rigorously the positions of the probe.

## Abstract

**AIM:** To study the association between self-reported peptic ulcer and childhood adversities.

**METHODS:** The Health and Social Support Study (HeSSup) population consisted of a stratified random sample drawn from the Finnish Population Register in four age groups: 20-24, 30-34, 40-44 and 50-54. The survey was carried out by postal questionnaire during 1998, with a response rate of 40.0%. A follow-up questionnaire was sent during 2003 to all those who responded to the first. Altogether 19626 individuals returned the follow-up questionnaire; a response rate of 75.8%. The subjects were asked whether a doctor had told them that they have or have had peptic ulcer. The analyses covered those who responded affirmatively to both the baseline and the follow-up enquiries ( $n = 718$ ). Those not reporting a peptic ulcer in either of the two questionnaires ( $n = 17677$ ) were taken as controls. The subjects were further requested (through six questions) to think about their childhood adversities.

**RESULTS:** The most common adversities mentioned were long-lasting financial difficulties in the family, serious conflicts in the family, and a family member seriously or chronically ill. All the adversities reported, except parental divorce, were more common among peptic ulcer patients than among controls ( $P$  values

## INTRODUCTION

*Helicobacter pylori* (*H pylori*), nonsteroidal anti-inflammatory drugs (NSAID) and smoking are the most important risk factors for peptic ulcer<sup>[1]</sup>. Infection with *H pylori* causes most duodenal ulcers (95%) and gastric ulcers (70%)<sup>[2]</sup>. Between 89% and 95% of peptic ulcer-related serious upper gastrointestinal events may be attributed to NSAID use, *H pylori* infection and cigarette smoking. Moreover, there is synergism for the development of peptic ulcer and ulcer bleeding between *H pylori* infection and NSAID use<sup>[3]</sup>. Alcohol intake may also play a role in the development of gastric ulcers<sup>[4]</sup>.

Between 5% and 20% of patients with gastric or duodenal ulcers lack an identifiable organic etiology<sup>[5]</sup>. Psychological stress may also have an impact on the onset and course of ulcer disease<sup>[6]</sup>. Moreover, various types of stress may play a role in the onset and modulation of acute or chronic peptic ulcer disease<sup>[7]</sup>. Persons who perceive their lives as stressful may run an increased risk of

developing peptic ulcer disease<sup>[8]</sup>. In low socioeconomic populations psychological stress and health risk behaviours contribute to an increased risk of ulcer<sup>[9]</sup>. However, familial aggregation of the disease is modest, according to a population-based twin cohort study<sup>[10]</sup>.

Childhood is an important and vulnerable period in individual development. Early life experiences are particularly important in determining how the individual responds over the life course<sup>[11]</sup>. However, very little is known as to how childhood adversities concerning financial problems, conflicts in the family, problems with alcohol, and matters of personal security are associated with peptic ulcer. We now examine this aspect in a nationwide sample in Finland, enquiring whether there has been something particular in the social circumstances of peptic ulcer patients during childhood. Do childhood adversities have a connection with the development of peptic ulcer in adulthood?

## MATERIALS AND METHODS

The Health and Social Support Study (HeSSup) is a prospective etiological follow-up study of the psychosocial health of the Finnish working-aged population. The HeSSup population is comprised of a stratified random sample drawn from the Finnish Population Register in four age groups: 20-24, 30-34, 40-44 and 50-54. The survey was carried out by postal questionnaire during 1998. Forms were returned by 25 898 individuals; a response rate of 40.0%. A follow-up was sent during 2003 to all those who responded to the first questionnaire. Altogether 19 626 individuals returned the follow-up questionnaire; a response rate of 75.8%. The Turku University Central Hospital Ethics Committee had approved the study.

The sample in 1998 was subjected to a thorough analysis of non-response<sup>[12]</sup>. The analysis was made using the official statistics of the Finnish population for the respective age groups in 1998 to assess whether the study population adequately represented the Finnish population. The major reason for refusal to participate was suspicion as to the purpose behind the request for written consent. Less educated, divorced, widowed and unemployed recipients and those on disability pension were least willing to participate. Differences in physical condition between the study participants and the general population were, however, small.

The participants were asked whether or not a doctor had told them that they have or have had a peptic ulcer. The analyses focused on those who responded affirmatively to both the baseline and the follow-up questionnaire ( $n = 718$ ). Those who did not report a peptic ulcer in either questionnaire ( $n = 17677$ ) were taken as the control group. It is noteworthy that those administered a new peptic ulcer during the five-year period were not included in the analyses.

The participants were asked to think about their childhood adversities in terms of the following questions, most of them successfully used in a nationwide interview

**Table 1 Kappa coefficients of responses between questionnaires in 1998 and 2003**

	$\kappa$ (95% CI)	
	Peptic ulcer	No peptic ulcer
Parents divorced	0.94 (0.91-0.98)	0.90 (0.89-0.91)
Long-lasting financial difficulties in the family	0.72 (0.64-0.79)	0.74 (0.73-0.76)
Serious conflicts in the family	0.71 (0.64-0.78)	0.72 (0.71-0.74)
Often afraid of some member of the family	0.64 (0.55-0.73)	0.71 (0.69-0.72)
Someone in the family seriously or chronically ill	0.55 (0.47-0.63)	0.62 (0.61-0.64)
Someone in the family had problems with alcohol	0.82 (0.76-0.87)	0.84 (0.83-0.85)

survey on living conditions<sup>[13]</sup>: (1) "Did your parents divorce?"; (2) "Did your family have long-lasting financial difficulties?"; (3) "Did serious conflicts arise in your family?"; (4) "Were you often afraid of some member of your family?"; (5) "Was someone in the family seriously or chronically ill?"; (6) "Did someone in the family have problems with alcohol?". The alternative answers were Yes, No or I do not know. Only the first two options were included in the statistical analyses. The number of childhood adversities per individual was determined. Childhood in the questionnaires, however, was not defined according to age. To confirm the reliability of the answers concerning childhood adversities, the kappa coefficient was used to assess associations between the questionnaires in 1998 and 2003. The coefficient varied between 0.55 and 0.94 among those reporting peptic ulcer and between 0.62 and 0.90 among controls (Table 1).

Participants were asked whether or not they had ever smoked. Smokers were considered those who currently smoked at least five cigarettes daily. Doses and frequency of alcohol use were also asked about and the total amount of alcohol consumed was calculated. Consumption of alcohol drinking was calculated, and at least 175 g alcohol during a week among women and at least 263 g among men was rated as heavy drinking. These limits were set because women achieve higher blood alcohol concentrations than men after drinking equivalent amounts of alcohol.

The Reeder stress inventory<sup>[14]</sup>, a 4-item questionnaire instrument previously widely used, was applied to measure the general sense of stressfulness in daily life. The inventory comprises the following four statements: (1) "In general I am usually tense or nervous"; (2) "There is a great amount of nervous strain connected with my daily activities"; (3) "At the end of the day I am completely exhausted mentally and physically"; and (4) "My daily activities are extremely trying and stressful." Participants indicate the extent to which each statement applies to them using a 5-point Likert scale (0-4). The mean value was calculated and multiplied by four, the computed value thus indicating the amount of stress. The proportion of those having a stress point higher than the upper quartile ( $\geq 12$ ) was calculated.

**Table 2** Occurrence of childhood adversities among peptic ulcer patients and controls

	Peptic ulcer (n = 604-673, %)	No peptic ulcer (n = 15 545-17 188, %)	Difference (%-units)	P value
Long-lasting financial difficulties in the family	45.2	26.8	18.4	< 0.001
Someone in the family seriously or chronically ill	42.3	26.6	15.7	< 0.001
Serious conflicts in the family	32.7	27.2	5.5	0.003
Someone in the family had problems with alcohol	30.2	25.1	5.1	0.003
Often afraid of some member of the family	19.6	13.4	6.2	< 0.001
Parents divorced	18.0	16.0	2.0	0.173

**Table 3** Age distribution and occurrence of risk factors among peptic ulcer patients and controls

	Women		P value	Men		P value
	Peptic ulcer (n = 344-362, %)	No peptic ulcer (n = 10 233-10 975, %)		Peptic ulcer (n = 326-350, %)	No peptic ulcer (n = 5 970-6 667, %)	
Age group (yr)						
25-29	8.5	28.7		4.0	22.6	
35-39	19.5	23.4		8.5	23.2	
45-49	25.3	24.3		26.8	25.2	
55-59	46.7	23.6		60.7	29.0	
Smoking						
Current smoking, ≥ 5 cigarettes daily	29.7	16.6	< 0.001	37.7	22.8	< 0.001
Heavy drinking						
> 175 g alcohol/wk	5.0	3.8	0.253	10.3	7.7	0.080
> 263 g alcohol/wk						
Stress						
Reeder points ≥ 12	32.9	20.9	< 0.001	32.8	22.8	< 0.001
Use of nonsteroidal anti-inflammatory drugs						
At least 2 mo during the last year	33.2	16.2	< 0.001	21.9	9.3	< 0.001

Regarding the matter of NSAID use, participants were asked how often they had used them during the last year. The alternative answers were "not at all", "less than 10 d", "10-59 d", "2-6 mo" and "more than 6 mo". In the analyses at least two months' consumption during the last year was taken to indicate NSAID use.

The analyses were made using the SAS System for Windows, release 9.1. Statistical significance for the occurrence of adversities was tested with  $\chi^2$ -test. The results were considered significant at  $P < 0.05$ . Age- and sex-adjusted odds ratios (OR) in the logistic regression analysis were calculated (Model 1). The same analyses were carried out with adjustment for both age and sex and smoking (Model 2), for age and sex, smoking and heavy drinking (Model 3), for age and sex, smoking, heavy drinking and stress (Model 4), and also for age and sex, smoking, heavy drinking, stress and current NSAID use (Model 5).

## RESULTS

The most common childhood adversities to emerge were long-lasting financial difficulties in the family, serious conflicts in the family and someone in the family having been seriously or chronically ill (Table 2). All adversities reported were more common among peptic ulcer patients than among controls. Alcohol problems in the family and

fear of some member of the family were also more common among peptic ulcer patients than among controls. With regard to parental divorce, there was no statistically significant difference between the two groups.

Among both genders the life-time prevalence of peptic ulcer increased with age, the tendency being, however, more apparent among men than among women. In the oldest age group the life-time prevalence was over 7% among men and nearly 5% among women. Among men, more than half, and among women, almost half, of the peptic ulcer patients belonged to the oldest age group (Table 3).

Current smoking was more common among peptic ulcer patients than among controls (Table 3). With regard to heavy drinking, there were no differences between ulcer patients and controls. The proportion of subjects scoring Reeder's stress points more than the upper quartile was greater among patients than among controls, the difference being ten percentage units among both genders. NSAID use was twice as common among patients as among controls.

The total number of childhood adversities per individual was greater among peptic ulcer patients than among controls. At least two adversities had been experienced by 46% of patients vs 33% of controls. No adversity had been experienced by 28% of patients vs 43% of controls.

**Table 4** Childhood adversities in the multivariate logistic analysis for peptic ulcer

	OR (95% CI)				
	Model 1	Model 2	Model 3	Model 4	Model 5
Long-lasting financial difficulties in the family	2.01 (1.71-2.38)	1.90 (1.60-2.26)	1.88 (1.58-2.23)	1.77 (1.48-2.11)	1.73 (1.45-2.07)
Someone in the family seriously or chronically ill	1.67 (1.42-1.96)	1.66 (1.41-1.96)	1.64 (1.39-1.94)	1.59 (1.34-1.88)	1.53 (1.29-1.82)
Serious conflicts in the family	1.47 (1.23-1.75)	1.33 (1.11-1.60)	1.33 (1.11-1.60)	1.24 (1.03-1.50)	1.22 (1.01-1.47)
Someone in the family had problems with alcohol	1.45 (1.22-1.72)	1.37 (1.14-1.63)	1.36 (1.14-1.62)	1.30 (1.09-1.56)	1.27 (1.06-1.52)
Often afraid of some member of the family	1.61 (1.32-1.97)	1.46 (1.18-1.81)	1.44 (1.16-1.78)	1.31 (1.05-1.62)	1.26 (1.01-1.57)
Parents divorced	1.60 (1.30-1.97)	1.40 (1.13-1.74)	1.40 (1.13-1.74)	1.37 (1.10-1.71)	1.37 (1.10-1.71)

Model 1: Age- and sex-adjusted; Model 2: Age- and sex-adjusted and also adjusted for smoking; Model 3: Age- and sex-adjusted and also adjusted for smoking and heavy drinking; Model 4: Age- and sex-adjusted and also adjusted for smoking, heavy drinking and stress; Model 5: Age- and sex-adjusted and also adjusted for smoking, heavy drinking, stress and NSAID use (at least 2 mo during the last year).

Age- and sex-adjusted ORs of childhood adversities for peptic ulcer were statistically significant, indicating that participants with childhood adversities had a higher proportional risk of developing peptic ulcer (Table 4). Adjusting also for smoking, heavy drinking, stress and current NSAID use had no further influence. Long-lasting financial difficulties in the family had the greatest influence.

## DISCUSSION

The principal finding in this study was that individuals reporting peptic ulcer have experienced significantly more childhood adversities than the general population. Life events include not only family problems but also financial problems and those concerning personal security. All of the childhood adversities investigated were statistically significant after adjustment for age. Adjusting for lifestyle issues such as smoking and heavy drinking had a slight influence. It is noteworthy that stress and current NSAID use had no further influence.

Findings in a previous Norwegian study did not support the concept that peptic ulcer is a psychosomatic disorder<sup>[15]</sup>. However, childhood adversities have been found in association with other diseases, for example coronary heart disease<sup>[16]</sup> and migraine<sup>[17]</sup>, and also with disability pensions<sup>[18]</sup>. According to our findings, childhood adversities are also associated with self-reported peptic ulcer. Self-reported childhood trauma has been found to be associated with an increased risk of a range of physical illnesses during adulthood, including peptic ulcer<sup>[19]</sup>. In a Danish study poor socio-economic status emerged as an important risk factor for peptic ulcer disease which exerts its effect independently of *H pylori* infection<sup>[20]</sup>. In functional dyspepsia the role of psychosocial factors continues to be the subject of debate<sup>[21]</sup>. In this respect our findings support those previous studies.

The study material may be considered representative of the Finnish working-aged population, although the response rate in 1998 was only 40%. Careful non-response analysis indicated that respondents and non-respondents were comparable with respect to the most important demographic variables<sup>[12]</sup>. Moreover, the rate of response to the follow-up questionnaire was high.

As it is a question of self-reported peptic ulcer, we

cannot be completely sure whether the subjects really have a pathological condition meeting the diagnostic criteria. Some of the subjects reporting peptic ulcer may only have non-ulcer dyspepsia. However, we regarded as peptic ulcer patients only those reporting the disease in two questionnaires carried out at 5-year intervals.

There was no way of knowing whether the ulcer reported was a duodenal or a stomach ulcer. We did not enquire whether or not the respondents had undergone gastroscopies, and have no data on the possible occurrence of complications. In Finland most uncomplicated peptic ulcers are treated in primary health care. Neither did we ask whether or not the participants had received antibiotic therapy for *H pylori* infection.

It is possible that ulcer patients reported childhood adversities more readily than did controls. Perhaps individuals with psychological stress or distress also tend to report on a peptic ulcer more easily than other people. Although retrospective studies of adverse childhood experiences have a worthwhile place in research<sup>[22]</sup>, we must concede that there are unanswered questions with regard to selective recall, and this may be considered a weakness of our study. The reports of childhood adversities are subjective, based upon memories where the time span from childhood to adulthood is not further defined. This notwithstanding, the kappa coefficients confirming the reliability of the answers may be considered quite high and also alike for the ulcer and non-ulcer groups, indicating that peptic ulcer patients had not remembered childhood adversities more readily than controls.

With regard to lifestyle issues and NSAID use there are some unknown concerns. Although we could calculate the total amount of alcohol consumed, we do not know the amount of cigarettes the respondents had smoked. Neither do we know the daily doses of NSAID use. We therefore considered it reasonable to dichotomize these variables. This may be a confounding factor. In our opinion, however, it hardly had an impact on our findings.

Peptic ulcer has been considered a valuable model for understanding the complex interactions among psychosocial, socioeconomic and infectious factors in causing organic disease<sup>[23]</sup>. Childhood adversities may be associated with lower socioeconomic level and modest living conditions, which may in part increase the risk

of infection by *H pylori*<sup>[24]</sup>. Moreover, children living in the most crowded conditions are at the greatest risk for *H pylori* acquisition<sup>[25]</sup>. Unfortunately our data did not contain details about the respondents' socioeconomic status and housing conditions.

What then are the reasons for the associations between childhood adversities and self-reported peptic ulcer? In this respect childhood adversities may predispose to *H pylori* infection. It is also possible that childhood adversities may predispose to a variety of aches and pains which are alleviated by NSAIDs. We must also admit that we do not know the possible role of genetic factors concerning e.g. the vulnerability of the gastric mucosa. Moreover, vigilant concern and anxiety might affect chronic automatized coping mechanisms and thus stress responses later in life.

Although the occurrence of peptic ulcer has declined due to widespread empirical treatment of dyspepsia, the peptic ulcer patient is still a common client in doctors' offices. Only a few decades ago peptic ulcer was considered almost exclusively a psychosomatic disease. When the association with *H pylori* was discovered in the 1980s the disease was regarded mainly as an infection, and the stress theory fell into oblivion. According to our findings there is reason to believe that stress factors during childhood still have a connection with the development of peptic ulcers. We thus venture to state that there are also social factors in the background. Childhood adversities are not necessarily true risk factors for peptic ulcer, but may play a predictive role in the development of the disease. A more comprehensive understanding of peptic ulcer patients is worth aspiring to.

## COMMENTS

### Background

*Helicobacter pylori* (*H pylori*), nonsteroidal anti-inflammatory drugs (NSAID) and smoking are the most important risk factors for peptic ulcer. However, between 5% and 20% of patients with gastric or duodenal ulcers lack an identifiable organic etiology. Psychological stress may have an impact on the onset and course of ulcer disease. Very little is known as to whether childhood adversities involving financial problems, conflicts in the family, problems with alcohol, and matters of personal security are associated with peptic ulcer.

### Research frontiers

Childhood is an important and vulnerable period in individual development. The research hotspot is whether there has been something particular in the social circumstances of peptic ulcer patients during childhood. Do childhood adversities have a connection with the development of peptic ulcer in adulthood?

### Innovations and breakthroughs

The most common childhood adversities to emerge were long-lasting financial difficulties in the family, serious conflicts in the family and someone in the family having been seriously or chronically ill. Alcohol problems in the family and fear of some member of the family were also more common among peptic ulcer patients than among controls. All of the childhood adversities investigated were statistically significant after adjustment for age. Adjusting for life style issues such as smoking and heavy drinking had only a slight influence.

### Applications

The study results suggest that stress factors during childhood have a connection with the development of peptic ulcers. Childhood adversities may play a predictive role in the development of the disease. A more comprehensive understanding of peptic ulcer patients is worth aspiring to.

### Terminology

Peptic ulcer: An ulcer on the mucous membrane of stomach (gastric ulcer) or

duodenum (duodenal ulcer) that is usually acidic and thus extremely painful. Childhood adversities: Negative life experiences during childhood such as long-lasting financial difficulties, serious conflicts in the family, fear of some family member, someone in the family being seriously or chronically ill, and someone in the family having had problems with alcohol.

### Peer review

This work is well conducted. The results from this work shows that there is a reason to believe that *H pylori* is not the only etiological factor regarding peptic ulcer but others factors like childhood adversities may play a predictive role in the development of peptic ulcer. According to this survey, it is reasonable to believe that stress factors during childhood maintain a connection with the development of peptic ulcers.

## Abstract

**AIM:** To determine cytomegalovirus (CMV) frequency in neonatal intrahepatic cholestasis by serology, histological revision (searching for cytomegalic cells), immunohistochemistry, and polymerase chain reaction (PCR), and to verify the relationships among these methods.

**METHODS:** The study comprised 101 non-consecutive infants submitted for hepatic biopsy between March

1982 and December 2005. Serological results were obtained from the patient's files and the other methods were performed on paraffin-embedded liver samples from hepatic biopsies. The following statistical measures were calculated: frequency, sensibility, specific positive predictive value, negative predictive value, and accuracy.

**RESULTS:** The frequencies of positive results were as follows: serology, 7/64 (11%); histological revision, 0/84; immunohistochemistry, 1/44 (2%), and PCR, 6/77 (8%). Only one patient had positive immunohistochemical findings and a positive PCR. The following statistical measures were calculated between PCR and serology: sensitivity, 33.3%; specificity, 88.89%; positive predictive value, 28.57%; negative predictive value, 90.91%; and accuracy, 82.35%.

**CONCLUSION:** The frequency of positive CMV varied among the tests. Serology presented the highest positive frequency. When compared to PCR, the sensitivity and positive predictive value of serology were low.

## INTRODUCTION

The frequency of cholestatic jaundice is difficult to determine, varying between 1:2500 and 1:5000

newborns<sup>[1-3]</sup>. The initial objective in the management of neonatal cholestatic jaundice is to distinguish between intrahepatic and extrahepatic causes, as the latter requires urgent surgical intervention<sup>[4]</sup>. Neonatal intrahepatic cholestasis (NIHC) represents 2/3 of the cases of neonatal cholestasis<sup>[5-9]</sup>. The most common causes of the disease are infection, including cytomegalovirus (CMV)<sup>[10-12]</sup>. Data on the prevalence of CMV in NIHC vary greatly depending on the diagnostic method used (5%-46%)<sup>[2,12-14]</sup>. Congenital CMV infection is assessed by viral isolation detected within 2-3 wk after birth<sup>[15]</sup>. If CMV is detected three weeks after birth, diagnosis of congenital infection should be supported by clinical and epidemiologic features<sup>[12,14,16]</sup>. Congenital disease might occur due to maternal primary infection (where the vertical transmission rate ranges from 40%-50%), or as a recurrence (where the vertical transmission rate ranges from 0.5%-2%). The clinical manifestations are essentially limited to neonates of mothers presenting with a primary infection during pregnancy and include: purpura, intracerebral calcifications, retinitis, ventriculitis, hepatosplenomegaly, microcephaly, intrauterine growth retardation, and jaundice<sup>[15,17-22]</sup>. The general prevalence of congenital CMV infection in Brazil is similar to that reported in studies on highly immune populations<sup>[16,23-27]</sup>. There is a higher rate of congenital infection, but fewer clinical manifestations<sup>[28,29]</sup>.

The purpose of the present study was to establish the frequency of CMV infection in patients with NIHC based on serology (IgM-ELISA), histological revision (searching for cytomegalic cells), immunohistochemistry (IHC), and polymerase chain reaction (PCR) and to verify the relationships among these methods.

## MATERIALS AND METHODS

Data from NIHC patients were evaluated at two tertiary centers between March 1982 and December 2005: the Pediatric Department of the State University of Campinas (Unicamp) Teaching Hospital and at the Children's Institute of the Medical School of the University of São Paulo (USP). A uniform diagnostic approach was followed throughout the observation period.

Cholestasis was defined by laboratory criteria as suggested by Moyer *et al*<sup>[4]</sup>. Inclusion criteria were: jaundice appearing up to three months of age and hepatic biopsy performed during the investigation.

To establish the etiology of NIHC, one author (Bellomo-Brandao) collected the following data: neonate's identification, symptoms, history, clinical findings, physical examination, and results of laboratory testing [alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (AlkPhos),  $\gamma$ -glutamyltransferase (GGT), international normalized ratio (INR), direct bilirubin (DB), albumin, liver biopsy, serum  $\alpha$ -1-antitrypsin, sweat sodium and chloride, innate metabolism errors in urine, polymerase chain reaction (PCR), CMV antigenemia, and serology of: CMV, HIV, EBV, rubella, toxoplasmosis, and syphilis].

## CMV serology

An Enzyme-linked immunosorbent assay (ELISA) was employed using commercial kits from Sorin Biomedica (Italy) and Vidas Biomerieux (France) at the Unicamp Teaching Hospital. Cobas Half Core, Roche (Germany) and MEIA, Abbott AxSYM® system (USA) kits were used at USP.

## Histological revision

Histological revision was carried out by one hepatopathologist (CAFE). When necessary, new slides were created and examined. Among the 84 liver biopsies, five were surgical and 79 were percutaneous. The presence of at least one cytomegalic cell was considered suggestive of CMV.

## IHC

Four- $\mu$ m-thick histological sections of the liver biopsies were placed on silanized slides, deparaffinized in xylene, and rehydrated. For antigen retrieval, the slides were immersed in 10 mmol/L citrate buffer (pH 6.0) in a steamer at 90°C for 30 min. A commercially available cocktail of two mouse monoclonal antibodies to CMV was applied to the sections (clones DDG9/CCH2 [prediluted]; Cell Marque, Hot Springs, AR, USA) for 1 h at 37°C and subsequently overnight (18 h) at 4°C. The reaction was amplified using the peroxidase-conjugated Novolink polymer (Novocastra, Newcastle, UK). Staining was achieved using 3,3-diaminobenzidine tetrahydrochloride (Sigma, St. Louis, MO, USA) and counterstaining with Mayer's hematoxylin. All reactions were performed with appropriate positive and negative controls. The positive control corresponded to a lung fragment from a patient who had died due to a generalized CMV infection. The negative control corresponded to the same specimen, in which a specific anti-CMV antibody was replaced by saline buffer. Positive results consisting of brown-colored nuclei were evaluated using a conventional optical microscope.

## PCR

The recommendations of Kwok and Higuchi<sup>[30]</sup> were followed to prevent sample contamination.

DNA was extracted according Saiki *et al*<sup>[31]</sup>, Shibata *et al*<sup>[32]</sup> and Demmler *et al*<sup>[33]</sup> from formalin-fixed, paraffin-embedded fragments using a commercial kit (Dneasy, Qiagen, Germany). The reaction mixture consisted of 0.5-1  $\mu$ g sample DNA in a total volume of 20  $\mu$ L, containing 50 mmol/L KCl, 10 mmol/L Tris (pH 8.4), 2.5 mmol/L MgCl<sub>2</sub>, 0.1 mmol/L of each primer, 200 mmol/L of deoxyribonucleotide triphosphates (dATP, dCTP, dGTP, and dTTP) and 2 U of *Taq* DNA polymerase. Water was used to complete the total reaction volume. The mixture was covered with a drop of mineral oil.

Amplifications were carried out in a DNA thermocycler (PTC100; MJ Research, Inc., Watertown, MA, USA) using 30-35 cycles for each sample (94°C for 45 s, 55°C for 45 s, and 72°C for 1 min). The cycles were preceded by an initial denaturation at 94°C for 5 min and

were followed by a final extension for 7 min at 72°C.

The human β-globin gene was amplified as an internal control for the reaction<sup>[32]</sup>. Primers for detection of the β-globin gene were as follows: PCO3 (5' CTCTGACAC AACTGTGTTCACTAGC 3') and PCO4 (5' TCACCAC CAACTTCATCCACGTTCAC 3').

CMV was detected by PCR and nested-PCR<sup>[32-35]</sup>. External primers were as follows: MIE4 (CCAAGCGGC CTCTGATAACCAAGGCC) and MIE5 (CAGCACCA TCCTCCTCTCCTCTGG); internal primers were as follows: IE1 (CCACCCGTGGTGCCAGCTCC) and IE2 (CCCGCTCCTCCTGAGCACCC). AD169 DNA strain was used as a positive control and water was used as a negative control.

Both β-globin and nested PCR products were visualized on ethidium bromide-stained, 2% agarose gels, after electrophoresis.

### Ethical aspects

The present research study was approved by the Medical Research Ethics Committees of both institutions. Informed consent was not needed, because serologies and liver biopsies had been done during the investigation process.

### Statistical analysis

The frequencies of CMV positive results of each test were calculated. Sensitivity, specificity, positive predictive value, negative predictive value, and accuracy were calculated between the results obtained with PCR and serology<sup>[36]</sup>.

## RESULTS

One hundred one non-consecutive patients with NIHC were included (84 patients from Unicamp and 17 patients from USP). Sixty-nine patients were males and 32 patients were females. The median age at the time of the biopsy was two months and 14 d.

The etiologies of NIHC are presented in Table 1. Most of them had an idiopathic etiology (58%). Five patients were previously diagnosed with CMV infection based on serology, PCR (plasma) and antigenemia.

This was a retrospective study and there was a paucity of liver biopsy fragments (most of the biopsies were obtained percutaneously); therefore, it was not possible to perform all four tests in all patients. In 17 patients, histological revision was not done because a shortage of paraffinized sample material did not permit making new slides. In the remaining 84 cases, the pathologist did not observe the presence of cytomegalic cells. Only one of 44 patients had positive IHC, 6/77 had positive PCR and 7/64 were IgM-ELISA positive. Table 2 shows the results of IgM-ELISA, histological revision, IHC, and PCR and the number of patients submitted to each diagnostic method.

Table 3 presents the clinical and laboratory data of PCR-positive patients. Five of six patients birth weights > 2500 g. Two of them had positive IgM-ELISA: one had a previous diagnosis of cystic fibrosis and the other had

Byler's Disease. Figure 1 shows the immunostaining of the liver in a positive case, consisting of brown colored nuclei, and Figure 2 exemplifies the PCR for CMV.

Compared to PCR, serology was highly accurate (82.35%), specific (88.89%) and had a high negative predictive value (90.01) for detecting CMV infection. However, its sensitivity was 33.3% and its positive predictive value was 28.57%. Table 4 shows the results of PCR and serology (IgM-ELISA) and the number of patients tested. Table 5 shows the results of sensitivity, specificity, positive predictive value (PV+), negative predictive value (PV-), and the accuracy between PCR and serology.

## DISCUSSION

The ubiquitous nature of CMV makes for difficulties in establishing direct evidence of the actual role of CMV in neonatal cholestasis, as stated in the editorial of Persing and Rakela<sup>[34]</sup>: "When does the detection of an infectious agent become unequivocally the etiologic agent of a specific condition?" Detection of the virus from the liver provides strong evidence that neonatal cholestasis is caused by CMV infection<sup>[15]</sup>.

Histological searching for cytomegalic cells was negative in 84 patients. Lurie *et al*<sup>[35]</sup>, after studying four fatal cases of NIHC from CMV, described the presence of cytomegalic cells in the liver from two of them. None were detected in the present study or observed in cases of extrahepatic cholestasis (EHC)<sup>[36-38]</sup>. In CMV hepatitis following orthotopic liver transplantation

(immunosuppressed patients), demonstration of cytomegalic inclusion bodies in hematoxylin and eosin sections is sufficient for a diagnosis of CMV hepatitis<sup>[39]</sup>.

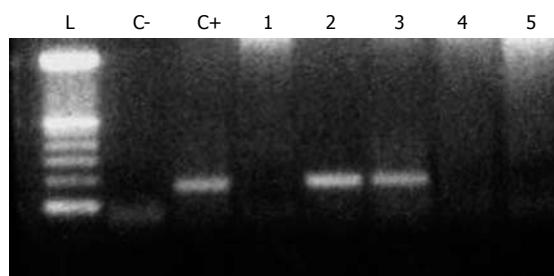

Only one patient had positive immunostaining and a positive PCR, despite encouraging data in immunosuppressed patients<sup>[40,41]</sup>. There are no reports in the medical literature in which the IHC method has been used to identify CMV in NIHC.

In the literature, the frequency of positive CMV in NIHC by PCR techniques varies between 5% and 46%<sup>[14,42,43]</sup>. Different techniques and samples make it difficult to establish a correlation between the data. In the present study, PCR was positive in 8% of the patients (6/77). Three patients had been previously diagnosed with other defined etiologies, indicating that concomitant infection by CMV and other agents is possible. This finding suggests that multiple agents must be investigated in the search for a diagnosis of NIHC. Four of these six cases presented with a negative IgM-ELISA, probably due to immaturity of the neonatal immune system<sup>[17,44]</sup>.

Few studies have been carried out comparing the different diagnostic methods of CMV infection in

neonatal cholestasis. Fischler *et al*<sup>[45]</sup> found positive serology for IgM-CMV in 32% of cases tested. In another study<sup>[6]</sup>, the same author found IgM-CMV and/or the presence of positive CMV in the urinary samples of 19/54 (35%) patients with NIHC and positive results in 4/11 carriers of  $\alpha$ -1-antitrypsin deficiency. A retrospective analysis of 39 patients (who presented with CMV in blood or urine cultures, or positive PCR in liver biopsies collected between 30 and 220 d of life) showed the presence of CMV by PCR-CMV on filter papers collected during the first three days of life in two neonates, suggesting that congenital infection was not the cause of cholestasis<sup>[42]</sup>.

Chang *et al*<sup>[14]</sup> studied 50 children diagnosed with neonatal hepatitis by PCR-CMV of liver samples. Twenty-three children had positive PCR, 13 of them had serology suggestive of an acute infection, and nine children had negative serologies; in one case serology was unknown. Twenty-one of the 27 patients with a negative PCR presented with negative serologies and six had positive serologies.

Shibata *et al*<sup>[43]</sup> evaluated 26 non-cholestatic infants

(1-24 mo old), who presented with an increase in ALT, through a quantitative PCR technique on their plasma. CMV was positive in four patients (15.4%). Three patients who presented with positive IgM-CMV did not have a positive PCR.

These studies were conducted in areas that were considered to have a low prevalence of CMV<sup>[15,46]</sup>. In Brazil, infection due to CMV is highly prevalent in the population and occurs early in the first year of life<sup>[25,26,27]</sup>. In populations where the majority of women of reproductive age have antibodies against CMV, there is a higher rate of congenital infection (as compared to populations with a low prevalence of antibodies against CMV), but without clinical disease. Although the presence of maternal antibodies does not prevent CMV transmission, it appears to confer protection or may be a marker of another factor that protects the child<sup>[28,29]</sup>.

In the present study, compared to PCR, the sensitivity and positive predictive value of IgM-ELISA serology were low, whereas specificity, negative predictive value and accuracy were high.

In conclusion, the frequencies of positive results for CMV varied from 0 (searching for cytomegalic cells) to 11% (IgM-ELISA). Disparities in serology and PCR were observed in the present study, as well as in other studies using different PCR techniques. Although our data are not encouraging, it will be necessary to conduct new studies to establish the role of IHC in the diagnosis of CMV in neonatal cholestasis. Even if there was a previous diagnosis, the involvement of CMV should be determined. All results should be interpreted considering the sum of clinical and epidemiologic features.

## ACKNOWLEDGMENTS

## COMMENTS

### Background

The ubiquitous nature of cytomegalovirus (CMV) makes for difficulties in establishing direct evidence of the actual role of CMV in neonatal cholestasis. The aim of this study was to determine the CMV frequency in neonatal cholestasis and to compare results of different diagnostic tests: serology, histology, immunohistochemistry, and polymerase chain reaction.

### Research frontiers

CMV is one of the most common causes of neonatal intrahepatic cholestasis, but the CMV best diagnostic criteria are not yet established because the positivity of different diagnostic tests varies considerably.

### Innovations and breakthroughs

In the present study, compared to polymerase chain reaction (PCR), the sensitivity and positive predictive value of IgM-ELISA serology were low, whereas specificity, negative predictive value and accuracy were high. Only one patient had positive immunostaining and a positive PCR. There are no previous reports in the medical literature on the use of immunohistochemistry to identify CMV in neonatal hepatitis.

### Applications

Even if there was a previous diagnosis, the involvement of CMV should be determined. It will be helpful to establish the role of CMV in neonatal cholestasis.

### Terminology

Serology, histology, immunohistochemistry, and polymerase chain reaction could be used in the differential diagnosis of CMV in neonatal cholestasis; however, the results should be interpreted considering the sum of clinical and epidemiologic features.

### Peer review

The study by Bellomo-Branda et al investigated the relationship between the infection with cytomegalovirus and the appearance of neonatal intrahepatic cholestasis. The aims of this study are very appealing. The study is well designed and the methods appropriate.

## Abstract

**AIM:** To study the dynamic computed tomography (CT) features of hepatic angiomyolipoma (AML) in patients with or without tuberous sclerosis complex (TSC).

**METHODS:** The clinical information, CT findings and histopathological results of hepatic AML were analyzed retrospectively in 10 patients.

**RESULTS:** Hepatic AML was prone to occur in female patients (7/10), and most of the patients (8/10) had no specific symptoms. All tumors presented as well-defined, unenveloped nodules in the liver. Six patients with sporadic hepatic AML had a solitary hepatic nodule with a definite fat component. Non-fat components of the hepatic lesions were enhanced earlier and persistently. Prominent central vessels were noted in the portal venous phase in three patients. In four patients with hepatic AML and TSC, most of the nodules were within the peripheral liver. Seven fat-deficient nodules were found with earlier contrast enhancement and rapid contrast material washout in two patients. Lymphangioleiomyomatosis was found in one patient.

**CONCLUSION:** Imaging features of hepatic AML are characteristic. Correct diagnosis preoperatively can be made in combination with clinical features.

## INTRODUCTION

Hepatic angiomyolipoma (AML) is a rare, benign mesenchymal neoplasm that consists of varying numbers of smooth muscle cells, thick-walled blood vessels, and mature adipose tissue<sup>[1]</sup>. It can occur sporadically or in conjunction with tuberous sclerosis. It is often asymptomatic and found incidentally on imaging studies for unrelated disease. The imaging features of hepatic AML are diverse as a result of the various proportions of its three components<sup>[1,2]</sup>. It should not be treated surgically because of its benign nature. However, at present, definitive preoperative diagnosis of hepatic AML is a challenge for radiologists and clinicians. We studied the imaging features of hepatic AML in patients with or without tuberous sclerosis complex (TSC).

## MATERIALS AND METHODS

### Patients and clinical data

We studied retrospectively the clinical, radiological and pathological records of 10 patients with hepatic AML, who were referred to our hospital between 2004 and 2007. There were three male and seven female patients with a mean age of 55.1 years (range, 19-78 years). Four were asymptomatic and were found incidentally upon general health examination. Two had complained of upper abdominal pain. Four had symptoms of unilateral flank pain. Previous medical history showed nephrectomy for renal AML in three patients, and recurrent pneumothorax and hydrothorax in one. Physical examination presented multiple miliary russet

papilla on the face and several periungual fibromas in four patients. Renal ultrasound demonstrated unilateral renal AML in three patients who had a previous history of nephrectomy, bilateral multiple renal AML in one, and intratumoral hemorrhage in three. Laboratory analysis showed normal liver function and serum  $\alpha$ -fetoprotein in all 10 patients.

#### **Multi-slice computed tomography (MSCT)**

MSCT was adopted for all 10 patients, using a 16-slice computed tomography (CT) scanner (Lightspeed, GE Healthcare, USA). The scan parameters included a section thickness of 5 mm, pitch of 1.375:1, reconstruction thickness of 1.25 mm, and field of view of 248 mm  $\times$  330 mm. Intravenous contrast material [60-120 mL iopamidol (Isovue 370); Bracco Diagnostics, Princeton, NJ, USA] was used in all patients. Enhanced CT was performed in the arterial phase, portal venous phase, and delayed phase with a delay time of 26, 70 and 120 s since the injection of intravenous contrast material, respectively. All imaging studies were reviewed retrospectively by the same radiologist with over 15 years experience in abdominal CT studies.

#### **Histopathological and immunohistochemical examination**

Ultrasound-guided biopsy of hepatic nodules was adopted in six patients, with an 18-gauge needle. Left hemihepatectomy was performed in two patients. Microscopical examination of the specimens was performed with routine HE staining. Immunohistochemical studies were carried out on the specimens.

## **RESULTS**

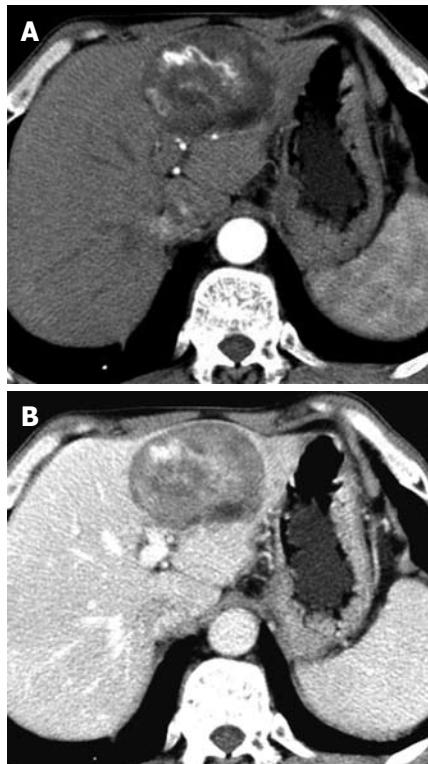

#### **Clinical information**

There were six patients with sporadic hepatic AML. The diagnosis of hepatic AML was confirmed by liver biopsy in four patients and partial liver resection in two.

Four patients with hepatic AML had associated TSC, the diagnosis of which was based on its revised criteria<sup>[3]</sup>. The diagnosis of hepatic AML was established by biopsy of the hepatic fat-deficient nodules in two patients. In another two case, the diagnosis of hepatic AML was based on the detection of fatty density in multiple hepatic nodules<sup>[4]</sup>. In one patient with hepatic AML and TSC, the diagnosis of lymphangioleiomyomatosis (LAM) was based on the typical imaging features of multiple, thin-walled lung cysts, hydrothorax and enlarged periaortic lymph nodes.

#### **MSCT findings**

Six patients with sporadic hepatic AML had solitary fat-containing masses with a mean size of 45 mm (size range, 10-80 mm) in the liver. On dynamic contrast-enhanced CT, the non-fat component of the lesions showed heterogeneous hyperdensity in the arterial phase and portal venous phase, and heterogeneous isodensity in the delayed phase, in comparison to the surrounding liver in five patients, (Figure 1A and B). Three had marked intratumoral

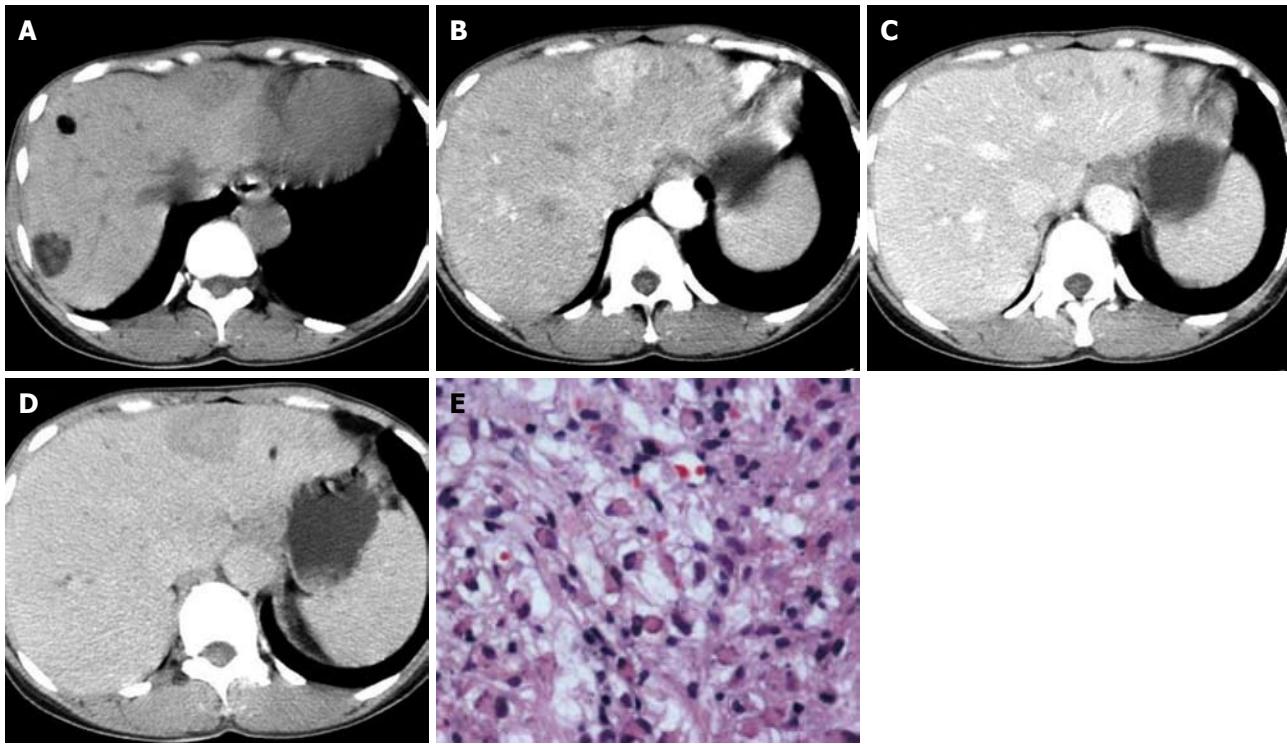

**Figure 1 Patient with sporadic hepatic angiomyolipoma.** A: Enhanced CT showed one well-defined, fat-containing nodule with prominent central vessels in the arterial phase; B: Enhanced CT showed sustained contrast enhancement of the intratumoral non-fat component in the portal venous phase.

vessels in the arterial and portal venous phases.

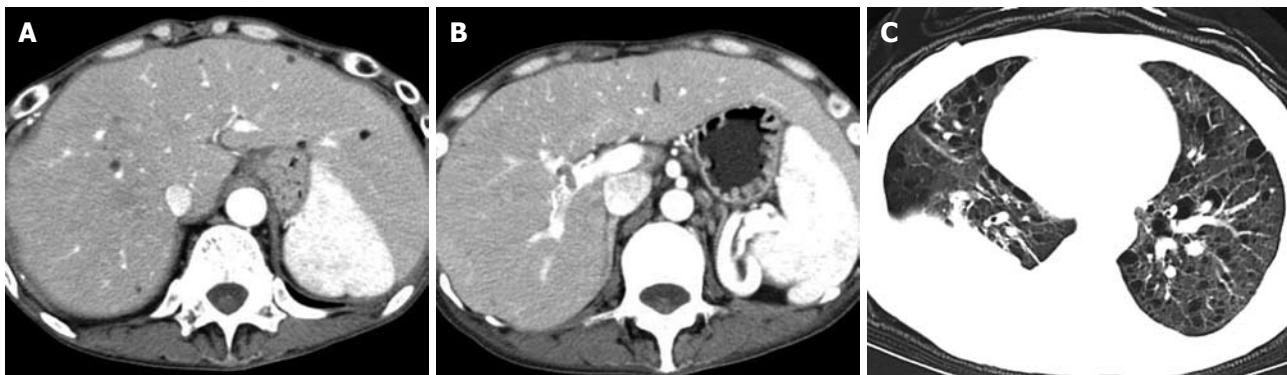

Four patients with hepatic AML and TSC had multiple, well-circumscribed hepatic nodules ranging from 2 to 40 mm (mean size, 8 mm) in the peripheral liver. Most of the nodules contained definite fatty density, and their non-fat components were enhanced mildly to markedly after administration of intravenous contrast material. Seven fat-deficient nodules were found in two patients (Figure 2A). On dynamic contrast-enhanced CT, the non-fat-containing nodules presented with heterogeneous high density in the arterial phase, mild hypodensity in the portal venous phase, and hypodensity in the delayed phase. Distorted intratumoral vessels and dilated feeding arteries were found in two of the seven nodules (Figure 2B-D). Except for multiple fat-containing nodules in the liver parenchyma, one sheet-like lesion in the right portal vein and several enlarged periaortic lymph nodes were noted in one patient (Figure 3A and B). Multiple thin-walled lung cysts and hydrothorax had been demonstrated previously by chest CT (Figure 3C).

#### **Histopathological and immunohistochemical findings**

Histopathological examination of the specimens showed various amounts of vacuolated lipocytes, blood vessels and scattered epithelioid cells with eosinophilic cytoplasm in all eight patients with liver biopsy or partial liver resection (Figure 2E). Immunohistochemistry demonstrated tumor cells with cytoplasm positive for HMB-45 in all eight patients.

**Figure 2** Patient with hepatic angiomyolipoma and TSC. A: Plain CT showed two fat-containing nodules in the right liver lobe, and one unenveloped fat-deficient nodule in the left liver lobe; B: Enhanced CT showed a fat-deficient nodule with marked hyperdensity, with intratumoral vessels in the arterial phase; C: Enhanced CT showed a fat-deficient nodule with mild hypodensity, with prominent central vessels in the portal venous phase; D: Enhanced CT showed a fat-deficient nodule with homogeneous hypodensity in the delayed phase; E: Microscopic examination demonstrated vacuolated lipocytes, blood vessels and scattered epithelioid cells with eosinophilic cytoplasm and peripherally located nuclei (HE, original magnification  $\times 40$ ).

**Figure 3** Patient with TSC and hepatic angiomyolipoma and LAM. A: Enhanced CT showed multiple fat-containing nodules in the liver; B: Enhanced CT showed an intra-portal-venous lesion and several enlarged periaortic lymph nodes; C: Chest CT showed multiple, thin-walled lung cysts and right hydrothorax.

## DISCUSSION

Hepatic AML is an unusual mesenchymal tumor that has no specific symptoms<sup>[5]</sup>. It often presents as well-demarcated hyperechoic nodules, and can be misinterpreted easily as hepatic cavernous hemangioma upon ultrasound examination<sup>[5]</sup>. It is demonstrated typically as a well-defined, unencapsulated mass with a fat component upon CT examination. However, fat-deficient hepatic AML has been reported with higher frequency than ever, and is difficult to be differentiated from hepatocellular carcinoma<sup>[6]</sup>. It is very important to recognize hepatic AML before surgery, because its natural history is benign, and it should not be removed surgically, except for patients who suffer spontaneous rupture<sup>[4,7]</sup>.

Hepatic AML can occur sporadically or in conjunction with TSC. It has been reported with a frequency of about 13% in patient with TSC<sup>[4]</sup>. Our study showed that hepatic AML often presents as a solitary mass, with a larger size in sporadic cases, but multiple smaller nodules in patient with TSC. This may be because it is asymptomatic, but growing with time. A long period before discovery may explain the relatively larger size of hepatic AML in patients without TSC. Dynamic contrast-enhanced CT showed sporadic hepatic AML as a hypervascular fat-containing mass with prominent central vessels in the arterial and portal venous phases. This was in accordance with previous studies<sup>[1,5]</sup>. In the setting of TSC, hepatic AML often presents as multiple nodules

with or without a fat component in the peripheral liver. The enhancement pattern of hepatic AML in TSC varies, and dilated intratumoral vessels are found less often than in sporadic cases. This may be related to their small size and variation in number.

Generally speaking, diagnosis of hepatic AML can be made upon detection of an unenveloped nodule with intratumoral fat, prominent central vessel and no capsule<sup>[8,9]</sup>. However, fat-deficient hepatic AML has been reported with increasing frequency in recent years<sup>[6,8]</sup>. Our study showed that fat-deficient hepatic AML has the propensity to occur in patients with TSC. Dynamic contrast-enhanced CT showed fat-deficient hepatic AML with earlier contrast enhancement and rapid contrast material washout in our two patients with TSC. The enhancement pattern was similar to that of hepatocellular carcinoma. Although it has been reported that non-fatty hepatic lesions in TSC can be regarded safely as hepatic AML<sup>[8]</sup>. However, we have reported previously a case of coexisting hepatocellular carcinoma and hepatic AML in a hepatitis B carrier with TSC<sup>[10]</sup>. This suggests that hepatocellular carcinoma should be considered upon detection of hepatic fat-deficient nodules in hepatitis B carriers with TSC.

LAM has been reported with a frequency of 1% in patients with TSC<sup>[11]</sup>. It is characterized by disorderly smooth muscle proliferation throughout the bronchioles, perivascular spaces and lymphatic system. Its diagnosis can be made on the detection of multiple, thin-walled lung cysts, pneumothorax, pleural effusion, or lymphadenopathy<sup>[12]</sup>. In our one TSC patient with hepatic AML and LAM, malignant hepatic AML could not be excluded completely because of the coexistence of intravascular lesions. This patient had an uneventful 2 years follow-up. Therefore, the intravascular lesions may be explained by invasion of LAM that originated from the perivascular space.

In summary, imaging features of hepatic AML are related closely to its clinical setting. Sporadic hepatic AML usually presents as a solitary large nodule with a varying fat component. In the setting of TSC, hepatic AML often presents as multiple small nodules, with or without a fat component, in the peripheral liver. Dynamic CT features of hepatic AML are very characteristic, and correct diagnosis can be made in combination with clinical features. When coexisting intravascular lesions and hepatic AML are found in patients with TSC, LAM should be considered.

## COMMENTS

### Background

Hepatic angiomyolipoma (AML) is a rare benign mesenchymal neoplasm. It can occur sporadically or in conjunction with tuberous sclerosis complex (TSC). Definitive preoperative diagnosis of hepatic AML is important because of its benign nature and it should not be resected. It is still a difficult condition for the radiologist and clinician.

### Research frontiers
