The correlation between hepatic AML and its clinical setting has not been reported often in the literature. The imaging features of hepatic AML vary. Fat-

deficient hepatic AML has been reported with increasing frequency in recent times. It is difficult to differentiate from hepatocellular carcinoma.

### Innovations and breakthroughs

This study emphasized that imaging features of hepatic AML are related closely to its clinical setting. Multiple hepatic AMLs, with or without a fat component, are characteristic of TSC. When coexisting intravascular lesions and hepatic AML are detected in patients with TSC, lymphangioleiomyomatosis (LAM) should be considered. Hepatocellular carcinoma must be suspected when hepatic non-fatty nodules are detected in hepatitis B carriers with TSC.

### Applications

This study serves as a reminder of the imaging features of hepatic AML in patient with or without TSC. This study is limited by its retrospective nature and small number of patients, and a large sample study should be undertaken in the future.

### Terminology

TSC is an autosomal dominant genetic disease characterized by the growth of hematomas in multiple organs. LAM is a rare disease that is characterized by disorderly smooth muscle proliferation throughout the bronchioles, perivascular spaces and lymphatic system.

### Peer review

The authors studied the dynamic computed tomography features of hepatic AML in patients with or without TSC. This study was well performed and will be of interest to readers.

### Abstract

**AIM:** To compare the outcomes of laparoscopic and open splenectomy and azygoportal devascularization for portal hypertension.

**METHODS:** From June 2006 to March 2009, laparoscopic splenectomy and azygoportal disconnection (LSD) were performed on 28 patients with cirrhosis, bleeding due to portal hypertension, and secondary hypersplenism. Success was achieved in 26 patients. Demographic, intraoperative, and postoperative variables of the patients were compared.

**RESULTS:** Success of laparoscopic splenectomy and azygoportal disconnection was achieved in all but two patients (7.14%) who required open splenectomy and azygoportal devascularization (OSD). The operation time was significantly longer in patients undergoing LSD than in those undergoing OSD ( $235 \pm 36$  min vs  $178 \pm 47$  min,  $P < 0.05$ ). The estimated intraoperative blood loss was much more in patients receiving OSD than in those receiving LSD ( $420 \pm 50$  mL vs  $200 \pm 30$  mL,  $P < 0.01$ ). The proportion of patients undergoing laparoscopic and open splenectomy and azygoportal disconnection who received transfusion of packed red blood cells during or after the operation was 23.08% and 38.46%, respectively ( $P < 0.05$ ). The time of first oral intake was faster in patients after LSD than in those after OSD ( $1.5 \pm 0.7$  d vs  $3.5 \pm 1.6$  d,  $P < 0.05$ ). The hospital stay of patients after LSD was shorter than that

### INTRODUCTION

Liver cirrhosis leads frequently to the development of ascites and formation of varicose veins in esophagus and proximal stomach. Variceal bleeding is the most severe complication of portal hypertension, which may occur in 30% of patients with cirrhosis with a 30-d mortality of 20% when the portal-systemic gradient reaches above 12 mmHg<sup>[1]</sup>. Cirrhotic patients with variceal bleeding occasionally require surgical intervention. The ideal surgical procedure is to effectively control bleeding with a little impairment of liver function and a low rate of encephalopathy<sup>[2]</sup>. The morbidity of traditional open splenectomy and azygoportal devascularization (OSD) developed first by Sugiura in the 1960s<sup>[3]</sup> is a

consequence of a large upper abdominal incision rather than removal of the spleen itself. Recent development in technical skills has extended the indications for laparoscopic removal of the spleen<sup>[4]</sup>, and significant progress in laparoscopic technology has enabled splenectomy and devascularization less invasive of the proximal stomach and distal esophagus.

Compared to open splenectomy, the advantages of laparoscopic splenectomy include decreased use of anesthetic agents, earlier initiation of oral diet, short hospital stay, and fewer complications<sup>[5-7]</sup>. However, few studies comparing the outcomes of open and laparoscopic splenectomy and azygoportal devascularization for bleeding varices are available. This study was to assess the in-hospital results of open and laparoscopic splenectomy and devascularization for portal hypertension.

## MATERIALS AND METHODS

### **Patients**

From June 2006 to March 2009, laparoscopic splenectomy and azygoportal disconnection were performed on 28 patients with cirrhosis, bleeding portal hypertension, and secondary hypersplenism and success was achieved in 26 patients (19 males, 7 females). The patients at the age 29-65 years (average  $41.5 \pm 21.8$  years) were admitted due to repeated variceal bleeding. The liver cirrhosis stage was Child-Pugh A in 17 patients, Child-Pugh B in 8 patients, and Child-Pugh C in 1 patient, respectively.

Of the 26 patients undergoing laparoscopic splenectomy and azygoportal disconnection (LSD), 23 had liver damage caused by chronic hepatitis B, 1 had alcoholic cirrhosis, and 2 had no history of hepatitis or chronic alcohol consumption and were diagnosed with cryptogenic cirrhosis. All patients had splenomegaly, and the diameter of spleen ranged 14-21 cm as shown at ultrasound, CT scan, and MRI before surgery.

The results of traditional OSD performed in January 2004 to June 2006 on the 26 patients were assessed retrospectively.

Demographic data of the patients undergoing LSD and OSD are shown in Table 1.

### **Operation procedures**

Laparoscopic splenectomy was performed with the patient placed at the right lateral semidecubitus position and the operating table slightly tilted to the reverse Trendelenburg position. The surgeon stood at the right side of operating table and 4 operative ports were used. A 10-mm trocar was placed at the right upper umbilicus for a 10-mm 30-degree telescope camera, and another 10-mm operating trocar was inserted into the left midclavicular line just below the border of spleen for passing the ultrasonic dissector or LigaSure vessel-sealing equipment. A 5-mm trocar was placed in the subxiphoid space, allowing for the use of a supplementary retractor or grasper. A 12-mm trocar was placed in the left axillary line halfway between the costal margin and iliac crest, for the application of an endoscopic linear vascular stapling

**Table 1 Characteristics of patients undergoing LSD and OSD (mean  $\pm$  SD), n (%)**

Variable	LSD	OSD	P value
Patients (n)	26	26	-
Average age (yr)	$41.5 \pm 21.8$	$44.6 \pm 19.6$	NS
Gender (M/F)	19/7	21/5	NS
Etiology			
HBV + cirrhosis	23 (88.46)	21 (80.77)	NS

device and other supplementary instruments.

The spleen was mobilized starting at the lateroposterior side by dividing the splenocolic and splenodiaphragmatic attachments. Then, the splenogastric ligament (including short gastric vessels) and the splenorenal ligament were divided with the ultrasonic dissector or LigaSure vessel-sealing equipment. Splenectomy was performed by carefully dissecting the splenic hilum to protect the pancreas and en bloc transecting the splenic artery and vein using the linear laparoscopic vascular stapler (EndoGIA).

After splenectomy, dissection was begun by approaching to the left crus with the ultrasonic dissector or LigaSure vessel-sealing equipment, then the gastrohepatic ligament was cut open to identify the right crus. The gastric coronary vein was visualized, and all branches toward the esophagus and proximal stomach were divided with the ultrasonic dissector and LigaSure vessel-sealing equipment. At least 6 cm of the distal esophagus was dissected through the hiatus with the paraesophageal venous collaterals divided.

Finally, the spleen was put into an impermeable retrieval bag and morcellated for removal.

OSD was performed either through a midline laparotomy or a left subcostal incision using traditional methods.

Operation time, estimated blood loss, intraoperative blood transfusion, time (d) of postoperative oral diet intake, pain requiring medication, postoperative complications, and hospital stay were compared.

### **Statistical analysis**

Data were compared using the *t*-test, chi-square analysis, or Fisher's exact test, where applicable, and expressed as mean  $\pm$  SD. All statistical analyses were performed using the SPSS 13.0 for Windows.  $P < 0.05$  was considered statistically significant.

## RESULTS

The demographic data included in this study are listed

**Table 2 Results and complications of LSD and OSD (mean  $\pm$  SD), n (%)**

Variable	LSD	OSD	P value
Operative time (min)	235 $\pm$ 36	178 $\pm$ 47	< 0.05
Estimated blood loss (mL)	200 $\pm$ 30	420 $\pm$ 50	< 0.01

PRBC: Packed red blood cells.

in Table 1. No difference was found in preoperative data between the two groups of patients.

The surgical results are shown in Table 2. Success of laparoscopic splenectomy and azygoportal disconnection was achieved in all but 2 patients (7.14%) who required open laparotomy because of intraoperative bleeding from the hilar vessels which was impossible to control by laparoscopic splenectomy. All the patients survived the surgery.

The operation time was significantly longer in patients undergoing LSD than in those undergoing OSD (235  $\pm$  36 min vs 178  $\pm$  47 min,  $P < 0.05$ ). The estimated intraoperative blood loss was much more in patients undergoing OSD than in those undergoing LSD (420  $\pm$  50 mL vs 200  $\pm$  30 mL,  $P < 0.01$ ). The proportion of patients undergoing LSD and OSD who received transfusion of packed red blood cells during or after the operation was 23.08% and 38.46%, respectively ( $P < 0.05$ ).

The time of first oral intake was faster in patients after LSD than in those after OSD (1.5  $\pm$  0.7 d vs 3.5  $\pm$  1.6 d,  $P < 0.05$ ). The hospital stay of patients after LSD was shorter than that of those after OSD (6.5  $\pm$  2.3 d vs 11.7  $\pm$  4.5 d,  $P < 0.05$ ). The pain requiring medication was less severe in patients after LSD in those after OSD (7.69% vs 73.08%,  $P < 0.001$ ).

As shown in Table 2, the overall complication rate was lower in patients after LSD than in those after OSD (19.23% vs 42.31%  $P < 0.05$ ). Wound seroma, pancreatic fistula, pleural effusion, and asymptomatic portal vein thrombosis were found in 1, 1, 2, and 1 patient, respectively, after LSD. Amylase elevation with effusion around the pancreatic tail was drained under ultrasound guidance. Of the patients with pleural effusion, one underwent percutaneous drainage, the other received conservative treatment. Of the patients undergoing OSD, 2 had urinary complications, 4 had wound complications, 1 had pleural effusion, 2 had pneumonia, and 1 had incisional hernia. Emergency laparotomy reintervention for bleeding was not necessary following LSD, but bleeding occurred in 1 patient after OSD. No pancreatic fistula or postoperative portal vein thrombosis was observed after OSD.

During a postoperative follow-up period of 1-34 mo for the patients after LSD, liver failure or encephalopathy or esophagus variceal rebleeding did no recur, and all the patients had an improved quality of life.

## DISCUSSION

The portal gradient exceeding 12 mmHg in patients with portal hypertension due to liver cirrhosis may result in portosystemic collaterals, in which the esophageal and proximal stomach varices present a most important connection between portal and systemic blood circulation. Unfortunately, their tendency to bleed due to rupture of esophageal and proximal varices is the most life-threatening complication in patients with portal hypertension, which can significantly increase the mortality rate of patients with liver cirrhosis. The bleeding event occurs in 10%-30% of patients with liver cirrhosis within 1 year, and reoccurs in 40% of patients within 6 wk. The mortality of bleeding varicose veins increases up to 30% depending on the liver insufficiency<sup>[8-10]</sup>. After acute treatment of bleeding, subsequent bleeding should be prevented.

Surgery for portal hypertension and variceal bleeding has evolved widely in terms of techniques and indications. Many treatment modalities available suggest that no single therapy is entirely satisfactory for all patients or for all clinical situations. Currently, shunt and devascularization surgeries are two basic surgical methods, but shunt procedures are more commonly used in Western countries and devascularization procedures are more commonly used in China<sup>[11,12]</sup>. The ideal surgical procedure for patients with bleeding portal hypertension and secondary hypersplenism should control bleeding, correct hypersplenism, avoid recurrence of bleeding, with little impairment of liver function and a low rate of encephalopathy.

The laparoscopic splenectomy has become the gold standard for removal of normal to moderately enlarged spleens. However, it is really more challenging when laparoscopic splenectomy is performed on patients with cirrhosis, portal hypertension, and splenomegaly, because portal hypertension and the severity of liver cirrhosis are the risk factors for high intraoperative blood loss during laparoscopic splenectomy<sup>[13]</sup>. In addition, it is difficult to remove the extremely enlarged spleen because of its higher conversion rate<sup>[14]</sup>.

Less invasive laparoscopic devascularization of the lower esophagus and upper stomach was performed partly through experimentation<sup>[15]</sup> or minilaparotomy<sup>[16-21]</sup>.

In this study, success of laparoscopic splenectomy and azygoportal disconnection was achieved in all but 2 patients. The patients recovered uneventfully after operation. The indications for laparoscopic splenectomy and azygoportal disconnection are similar to those for OSD. We prefer to perform laparoscopic splenectomy and azygoportal disconnection for patients with liver cirrhosis at Child-Pugh A and B. The absolute contraindications of laparoscopic splenectomy and azygoportal disconnection are patients who are not able to tolerate the general anesthesia, intractable coagulopathy, and/or unfitted to laparoscopy.

The most important intraoperative complication during laparoscopic splenectomy and azygoportal disconnection is bleeding, which is the most common

reason for conversion to open surgical procedure. Furthermore, since conversion is usually done due to lack of working space or bleeding, the operation time of converted patients is longer, leading to more blood loss than open splenectomy. However, laparoscopic splenectomy cannot effectively control massive hemorrhage from the major vessels or capsule fracture. In many cases, bleeding interferes with the dissection and does not result in any other event. Therefore, the crucial point of devascularization technique is to prevent the brisk bleeding from dilated vessels like enlarged azygoportal collaterals. Capsule or small vessel laceration may cause oozing, which contaminates the operating field and makes the surgical procedure more difficult. We recommend that complete mobilization of the spleen before operation is a safe option for adequately controlling the hilar vessels and any possible bleeding during the procedure. The splenic artery should be dissected and ligated whenever it is found superior to the pancreatic tail during the operation for splenomegaly. This maneuver can reduce the size and bleeding of spleen with a certain autotransfusion effect. Although vessels within the splenic hilum can be dissected and divided individually with vascular clips in some cases, the manipulation is quite tedious and not encouraged. In addition, if bleeding occurs in the hilum, vascular staplers should be used to control it. Use of clips should be limited since it may interfere with the use of vascular staplers.

Technical advances that have facilitated laparoscopic splenectomy and azygoportal disconnection are the availability of LigaSure vessel-sealing equipment and ultrasonic dissector, which facilitate the performance of very difficult laparoscopic procedures. LigaSure vessel-sealing equipment is safer than ultrasonic dissector in dividing the surrounding tissues of spleen, distal esophagus and proximal stomach, including paraesophageal venous collaterals, and can thus be used for mobilization of the spleen and esophagogastric devascularization. As use of clips may interfere with the use of LigaSure vessel-sealing equipment to stop the bleeding, it is wiser not to use any clips during esophagogastric devascularization.

The LigaSure vessel-sealing sealing system has been developed for the safe closure of arteries up to 7 mm<sup>[22]</sup>. Although the data about venous closure are lacking, this system can be used to close veins up to 12 mm<sup>[23]</sup>. Kwok *et al*<sup>[24]</sup> showed that the LigaSure sealing system can treat grades 3 and 4 of hemorrhoids.

In our series, intraoperative bleeding during LSD was a rare event, leading to conversion to OSD in only 2 cases (7.14%). The estimated blood loss was significantly lower in patients undergoing LSD than in those undergoing OSD.

The overall complication rate was lower in patients after LSD than in those after OSD. The main complications of LSD included pancreatic fistula and thromboembolic event, which did not occur after OSD. Meanwhile, incisional hernia was uncommon after LSD but occurred in 1 patient after OSD.

In summary, LSD can alleviate postoperative pain, earlier recovery bowel function and feeding, has

better cosmetic results, reduce the hospital stay and recovery time, and is thus advantageous over minimally invasive surgery and OSD. We believe that laparoscopic splenectomy and azygoportal disconnection is a technically feasible, safe, and preferred procedure for bleeding varices due to hypersplenism. LSD should primarily be attempted in all patients with portal hypertension, if judged technically feasible and the general condition of the patient allows laparoscopy.

## COMMENTS

### Background

Liver cirrhosis leads frequently to the development of ascites and formation of varicose veins in esophagus and proximal stomach. Variceal bleeding is the most severe complication of portal hypertension, which occurs in 30% of patients with cirrhosis. Cirrhotic patients with variceal bleeding occasionally require surgical intervention. Traditional open splenectomy and azygoportal devascularization (OSD) are performed due to large upper abdominal incision rather than removal of the spleen itself. Recent development in laparoscopic technology has enabled splenectomy and devascularization of the proximal stomach and distal esophagus less invasive.

### Research frontiers

Less invasive laparoscopic devascularization of the lower esophagus and upper stomach is performed partly through minilaparotomy. However, few studies are available on the outcomes of open and laparoscopic splenectomy and azygoportal devascularization for bleeding varices due to portal hypertension.

### Innovations and breakthroughs

Few studies are available on the outcomes of open and laparoscopic splenectomy and azygoportal devascularization (LSD) for bleeding varices due to portal hypertension. The aim of the present study, was, therefore, to assess the in-hospital results of open and laparoscopic splenectomy and azygoportal devascularization for portal hypertension. The results show that LSD can alleviate postoperative pain, earlier recovery bowel function and feeding, has better cosmetic results, reduce hospital stay and recovery time, and is thus advantageous over minimally invasive surgery and OSD.

### Applications

Laparoscopic splenectomy and azygoportal disconnection is a technically feasible, safe, and preferable procedure for bleeding varices due to portal hypersplenism. LSD should primarily be attempted in all patients with portal hypertension, if judged technically feasible and if the general condition of the patient allows laparoscopy.

### Terminology

Portal hypertension: Increased pressure in the portal vein. When the blood flow in the liver is obstructed, the blood can become backed up into the intersections of the portal venous system and the systemic venous system. The intersections of these two systems are small, fragile blood vessels known as capillaries. These vessels are not able to withstand the increased blood pressure and become engorged or dilated. Such vessels can be seen on the surface of esophagus or stomach during endoscopy. They are fragile and at a risk of bleeding. Portal hypertension can be managed through diet, medications, endoscopic therapy, surgery, or radiology. Once the bleeding episode is stabilized, treatment options should be prescribed based on the severity of symptoms and the function of liver.

### Peer review

Although laparoscopic splenectomy and azygoportal disconnection are not easy to perform, they represent a new and alternative procedure for portal hypertension and are advantageous over open splenectomy and azygoportal disconnection.

steroid pulses, and OKT3. Because of persisting signs of biopsy-proven AHR at day 26, she was treated by plasmapheresis and rituximab. Liver enzyme levels did not improve, and she died on day 41. Patient 2 experienced a biopsy-proven AHR on day 10 post-transplant. She was treated by steroid pulses, plasmapheresis, and rituximab. Liver enzymes returned to within normal range 18 d after diagnosis. Liver biopsies, at 3 and 9 mo post-transplant, showed complete resolution of AHR. We conclude that plasmapheresis should be started as soon as AHR is diagnosed, and be associated with a B-cell depleting agent. Rituximab may be considered as a first-line therapy.

## INTRODUCTION

Acute humoral rejection (AHR) is well described in ABO-incompatible orthotopic liver transplant (OLT) patients; however, its occurrence in ABO-compatible OLTs is still an uncommon phenomenon. Acute humoral or antibody-mediated rejection in ABO-identical transplants is usually related to the presence of preformed or acquired anti-human leukocyte antigen (HLA) donor-specific antibodies (DSA)<sup>[1]</sup>. The diagnosis of AHR relies on the presence

## Abstract

Acute humoral rejection (AHR) is uncommon after ABO-compatible liver transplantation. Herein, we report two cases of AHR treated with plasmapheresis and rituximab in two ABO-compatible liver-transplant patients with preformed anti-human leukocyte antigen donor-specific antibodies. Patient 1 experienced a biopsy-proven AHR at day 10 post-transplant. She was treated by

of DSA, C4d deposition, tissue pathology, and evidence of organ dysfunction<sup>[2]</sup>. Although the liver has long been regarded as resistant to antibody-mediated rejection, and despite conflicting published data, it is now thought that preformed DSA and a positive cross-match in ABO-compatible OLTs is associated with rejection and graft loss<sup>[3-6]</sup>. Recently, using a modern multiple-bead assay, i.e. Luminex, Castillo-Rama *et al*<sup>[7]</sup> have shown that Luminex-detected antibodies, as well as positive complement-dependent cytotoxicity T crossmatches, were associated with shorter graft survival within the first year post-transplant. In addition, they observed a correlation between the presence of preformed Luminex-detected class II or Luminex I and II antibodies and allograft rejection<sup>[7]</sup>. The treatment of these anti-HLA-mediated acute humoral rejections is still not well established. Herein, we report on two ABO-compatible liver-transplant patients with AHR, caused by specific anti-donor HLA antibodies (Table 1), who were treated with plasmapheresis and rituximab.

## CASE REPORT

### Case 1

A 49-year-old woman, who was ABO compatible, underwent 4 antigen mismatch orthotopic liver transplantation in July 2005 because of end-stage liver disease related to hepatitis C virus infection with hepatopulmonary syndrome. Her Child-Pugh stage was C10. Anti-viral therapy had failed to clear HCV before transplantation; and her HCV RNA concentration was 5.9 log copies/mL at transplantation. On the day of transplantation, her panel-reactive antibody rate (PRA) was 30% and she had circulating DSA directed against class II HLA antigens (anti-DR7, detected by Luminex). At the time of transplantation, crossmatches were positive for both T and B cells. The immediate postoperative period was marked by the occurrence of acute respiratory-distress syndrome, which required mechanical ventilation, and acute renal failure, which required continuous veno-venous haemodiafiltration. The initial immunosuppressive therapy was based on induction therapy of anti-thymocyte globulins (1.25 mg/kg on days 1, 3, 5 and 6; Thymoglobulin, Genzyme), plus tacrolimus monotherapy, which was introduced on day 1 at a targeted trough level of between 10 and 15 ng/mL. Liver enzyme levels improved until day 6, but then gamma glutamyl transpeptidase ( $\gamma$ GT), alkaline phosphate (AP), and total bilirubin levels increased again, while transaminases remained within the normal ranges (Figure 1). By day 10,  $\gamma$ GT, AP, total bilirubin, and direct bilirubin levels were, 251 IU/L, 808 IU/L, 258  $\mu$ mol/L, and 136  $\mu$ mol/L, respectively. Biliary tract and vascular complications were ruled out by abdominal ultrasonography and a liver CT scan. A Doppler ultrasound confirmed good blood flow in the hepatic artery, portal vein, and hepatic veins. A liver biopsy performed on day 10 revealed acute rejection with a Banff activity index of 7, mixed inflammatory cells in the portal triad, and significant cholangitis and endothelitis. Unfortunately, immunostaining for C4d

HLA: Human leukocyte antigen; CDC: Complement-dependent cytotoxicity; OLT: Orthotopic liver transplantation; DSA: Donor-specific alloantibody; AR: Acute rejection.

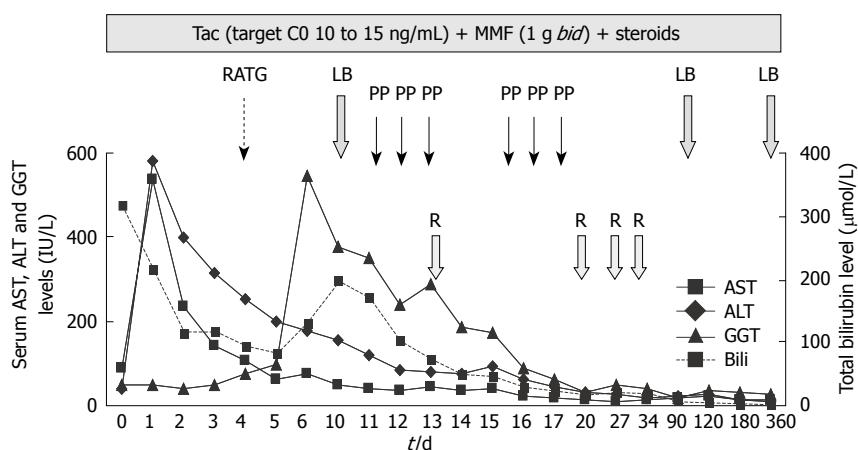

was not performed. Retrospective immunostaining of liver biopsy for the presence of T and B lymphocytes showed a high proportion of B cells, i.e. 60% of total cells. Screening for anti-HLA antibodies confirmed the presence of anti-class I (anti-A2) and anti-class II (anti-DR7) HLA antibodies directed against the donor. Because of this, the patient was treated with steroid pulses (10 mg/kg per day for 3 d, and then gradually tapered), OKT3 (10 mg/d for 10 d), plus mycophenolate mofetil was introduced at a daily dose of 2 g. In the absence of any improvement in liver enzyme levels, she underwent a second liver biopsy 16 d after the first, on day 26 post-transplant. This showed the presence of inflammatory infiltration by lymphocytes, histiocytes and plasmacytes, persistent cholangitis, venulitis, hepatocanalicular cholestasis, biliary thrombi, and hepatocyte necrosis. Retrospective immunostaining of the liver biopsy for the presence of T and B lymphocytes showed a high proportion of B cells with 30% of B cells. At that time, we decided to treat the humoral part component. She was treated with plasmapheresis (5 sessions using fresh frozen plasma or 50% fresh frozen plasma and 50% albumin) and two rituximab infusions (375 mg/m<sup>2</sup> per week for 2 wk). Unfortunately, her liver enzyme levels did not improve. She required liver support that utilized four sessions of molecular adsorbents recirculating system (MARS). Her acute respiratory distress syndrome did not improve within this postoperative period. She experienced pulmonary infections and died on day 41, i.e. 4 d after the second rituximab infusion. Before rituximab infusion, her circulating CD4-, CD8-, and CD19-positive cell counts were, respectively, 47, 49 and 85/mm<sup>3</sup>.

### Case 2

A 39-year-old woman underwent six antigen mismatch, ABO-compatible orthotopic liver transplantation in January 2008 because of end-stage liver disease related to alcohol with hepatopulmonary and hepatorenal syndromes. Her Child-Pugh stage was C10. On the day of transplantation, her PRA was 44% and she had circulating DSA directed against both class I (anti-A2, anti-A24, anti-B27) and class II (anti-DR4) HLA antigens, which were detected by Luminex. At the time of transplantation, crossmatches were positive for T and B cells. Surgery

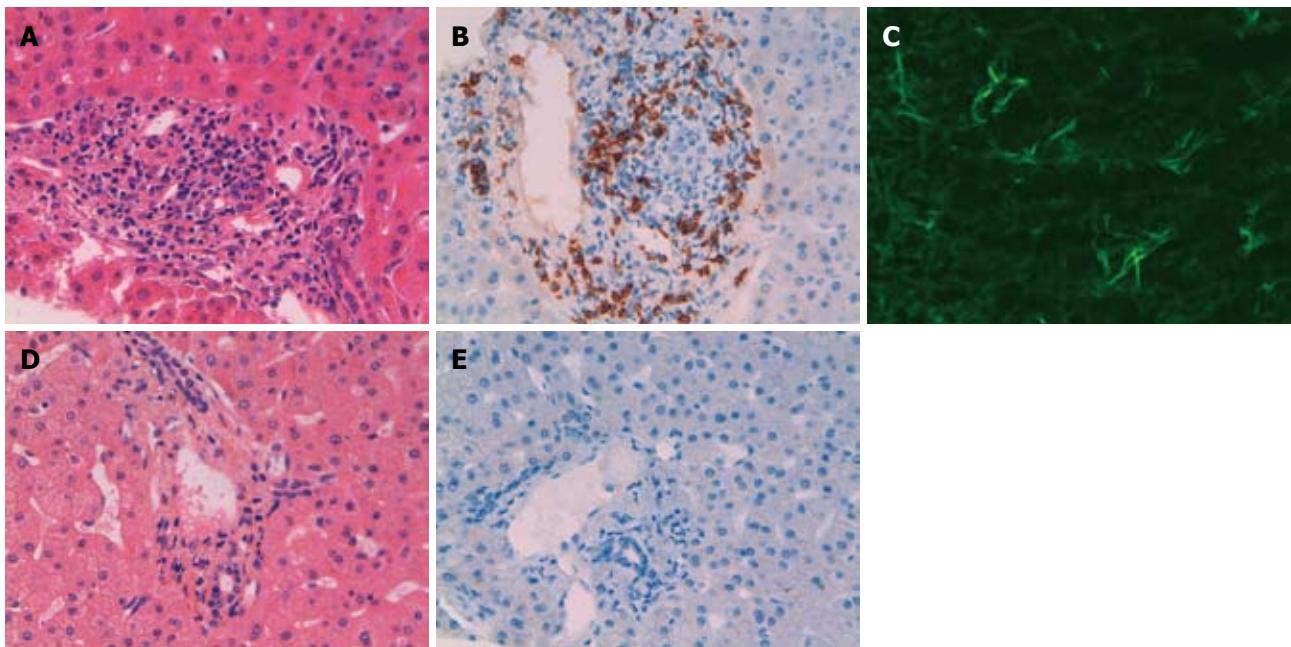

**Figure 1 Postoperative clinical course of patient 1.** Tac: Tacrolimus; MMF: Mycophenolate mofetil; RATG: Rabbit anti-thymocyte globulins; MARS: Molecular adsorbents recirculating system; LB: Liver biopsy; PP: Plasmapheresis; R: Rituximab; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: Gamma glutamyl transpeptidase.

**Figure 2 Postoperative clinical course of patient 2.**

was uneventful, and the immediate postoperative course was unremarkable with a regular decrease in liver test parameters. The initial immunosuppressive therapy was based on tacrolimus (targeting a trough level of between 10 and 15 ng/mL), mycophenolate mofetil (1 g *bid*), and steroids (10 mg/kg before transplantation, 5 mg/kg on day 1, 2.5 mg/kg on day 2, and then 1 mg/kg). By day 4, because of significant renal function impairment (serum creatinine level rose from 130 to 280 μmol/L) caused by the high tacrolimus trough level (21 ng/mL), tacrolimus was discontinued for 2 d. The patient then received one infusion of anti-thymocyte globulins (1.25 mg/kg; Thymoglobulin, Genzyme). Liver enzyme levels improved until day 5 but, on day 6, γGT, AP, and total bilirubin levels increased significantly (Figure 2). Biliary tract complications were ruled out by abdominal ultrasonography and magnetic resonance imaging. Doppler ultrasound confirmed good blood flow in the hepatic artery, portal vein, and hepatic veins. A liver biopsy performed on day 10 revealed acute rejection, with a Banff activity index of 7, diffuse cholangitis and endothelitis, periportal edema, inflammatory infiltration by lymphocytes, histiocytes and neutrophils (Figure 3A). Immunostaining for C4d was positive (Figure 3B). Immunostaining of liver biopsy for the presence of T and

B lymphocytes showed a high proportion of T cells. B cells represented 30% of total cells (Figure 3C). Consequently, she received three pulses of methylprednisolone (10 mg/kg per day), plus four infusions of rituximab (375 mg/m<sup>2</sup> per week for 4 wk). In addition, six plasmapheresis sessions using fresh frozen plasma were realized. Her liver enzyme levels improved rapidly and were within normal range 18 d after AHR diagnosis. At 3 mo post-transplant, she underwent a second liver biopsy, which showed complete resolution of the acute rejection episode (Figure 3D). Immunostaining of liver biopsy for the presence of T and B lymphocytes showed no T and B cells (Figure 3E). All previous features of acute rejection had disappeared. At 12 mo post-transplant, her liver enzyme levels were still within the normal range, DSA directed against class I HLA antigens were still detected, while the DSA directed against the class II HLA antigen was not detected anymore. A third liver biopsy was performed and was considered normal. During the 12 mo post-transplant, she did not present with any infection episodes. Her circulating CD4-, CD8-, and CD19-positive cell counts, which were 364, 165 and 45, respectively, before the first rituximab infusion, became 980, 527 and 0/mm<sup>3</sup> by month 3 and 673, 374 and 0/mm<sup>3</sup> by 12 mo post-transplant.

**Figure 3** Liver biopsies performed in patient 2. A: Liver biopsy performed on day 10. Acute rejection with mixed inflammatory cells in the portal triad, significant cholangitis and endothelitis. Banff activity index of 7 (HE,  $\times 400$ ); B: Immunostaining with L26 antibody (anti-CD20) showed moderate proportion of B cells ( $\times 400$ ); C: Liver biopsy performed on day 10: Immunostaining for C4d in liver biopsy ( $\times 400$ ); D: Liver biopsy performed at 3 mo post-transplant showed complete resolution of acute rejection (HE,  $\times 400$ ); E: Immunostaining with L26 antibody (anti-CD20) showed no B cell infiltration ( $\times 400$ ).

## DISCUSSION

Anti-HLA antibody-induced acute humoral rejection is uncommon after ABO-compatible liver transplantation. Herein, we report two cases of acute humoral rejection that occurred within the first week after an ABO-compatible liver transplantation in two patients with preformed donor-specific anti-HLA antibodies. In both cases, an acute rejection episode occurred very early after transplantation, and induced significant cholestasis, while transaminases were only moderately elevated. Liver biopsies revealed acute rejection, the presence of inflammatory infiltration and, more specifically, cholangitis, endothelitis, and periportal edema. Immunostaining for C4d was found to be positive, and immunostaining of liver biopsies for the presence of T and B lymphocytes showed a relative high proportion of B cells. To the best of our knowledge, our second case report is the first to show that early treatment of AHR with plasmapheresis and rituximab without using intravenous hyperimmune globulins (IVIg) is effective in this setting, especially in a patient with four different DSAs.

Whatever the transplanted organ may be, until recently, the treatment of AHR has been based on plasmapheresis, immunoabsorption, IVIg, and tacrolimus, mycophenolate mofetil, with or without T-cell depleting agents<sup>[8-10]</sup>. Because of B-cell involvement in humoral rejection, the use of monoclonal anti-CD20 antibodies (rituximab) has been used in this setting. For ABO-incompatible kidney and liver transplantation, as well as historical and/or current positive crossmatch pre-transplantation highly sensitized patients, and in desensitization protocols in kidney transplantation, rituximab has been successfully used in association with

splenectomy and plasmapheresis<sup>[11-15]</sup>. In kidney transplant patients, Becker *et al*<sup>[16]</sup> have shown that vascular rejection with a possible humoral component responds to a single dose of rituximab therapy when associated with plasmapheresis and steroid pulses, with or without anti-thymocyte globulins. More recently, we found that, despite a high rate of infection, the association of plasmapheresis and rituximab was efficient in treating acute humoral kidney rejection<sup>[17]</sup>. These interesting results obtained in kidney transplant patients prompted us to use the same strategy in liver transplant patients who were experiencing acute humoral rejection. Previously, Watson *et al*<sup>[6]</sup> treated a liver transplant patient with preformed anti-HLA antibodies and who experienced an early acute humoral rejection with IVIg, plasmapheresis, and one infusion of rituximab. In Watson *et al*<sup>[6]</sup> plasmapheresis and rituximab therapies were started late after AHR diagnosis, i.e. on post-transplant day 34 for rituximab, and post-transplant day 70 for plasmapheresis. This is similar to our first case report, where we treated the cellular component before the humoral component. Unfortunately, this was not effective in treating the humoral acute rejection.

In contrast, starting plasmapheresis and medications that target B cells as soon as AHR is diagnosed seems to be more effective. In our second case report, plasmapheresis and rituximab therapy were started as soon as AHR was diagnosed, i.e. on day 11 post-transplant. Similarly, Rostron *et al*<sup>[18]</sup> had previously reported a case of severe AHR in an ABO compatible liver transplant patient successfully treated with plasmapheresis, IVIg and conversion from azathioprine to mycophenolate mofetil. In the latter case, plasmapheresis was started at day 7 post-transplant. In another study on a combined kidney-liver transplant patient who experienced both cellular and humoral

rejection, early plasmapheresis associated with steroid pulses, anti-thymocyte globulins, and IVIg effectively treated both rejections<sup>[19]</sup>. Finally, Wilson *et al*<sup>[20]</sup> reported a late AHR in an ABO-compatible liver transplant patient that was successfully treated with plasmapheresis, one rituximab infusion, and anti-thymocyte globulins. However, in the latter case, we wonder whether it was a late AHR or a cellular rejection that occurred in a patient with a chronic humoral rejection. Indeed, it is unknown how many anti-HLA antibodies were present in this patient. Positive immunostaining for C4d may be related to long-term silent chronic humoral rejection. In addition, in the Wilson *et al* case report, the acute rejection that occurred very late after transplantation, which is very uncommon, may be a steroid-resistant acute cellular rejection, especially since liver enzyme levels decreased after anti-thymocyte globulin therapy.

In summary, plasmapheresis should be started as soon as AHR is diagnosed in order to remove circulating antibodies. It should be associated with either IVIg or rituximab, both of which can be effective in this setting. However, because of rituximab's capacity to deplete B-cells, and the good results obtained in ABO-incompatible liver transplant patients, rituximab could be the preferred first-line therapy. Further controlled studies to compare rituximab and IVIg are needed.

## INTRODUCTION

Goblet cell carcinoid (GCC) of the veriform appendix is an uncommon neoplasm. It is characterized by dual endocrine and glandular differentiation, a feature that has led to confusion regarding nomenclature, histogenesis, and clinical management. The origin and histogenesis of GCC are still controversial, and whether GCC represents a histological variant of appendiceal classical carcinoid or a distinct morphological subtype of appendiceal adenocarcinoma with endocrine differentiation is still a matter of debate. Rare cases of GCC combined with other benign and malignant epithelial appendiceal neoplasms have been reported; the relationship between GCC and these neoplasms is not clear. Herein, we report an unusual and rare case of combined GCC and mucinous cystadenoma (MCA) of the veriform appendix and discuss the possible related histopathogenesis.

## Abstract

Goblet cell carcinoid is an uncommon primary tumor of the veriform appendix, characterized by dual endocrine and glandular differentiation. Whether goblet cell carcinoid represents a morphological variant of appendiceal classical carcinoid or a mucin-producing adenocarcinoma is a matter of conjecture. Rare cases of goblet cell carcinoid with other concomitant appendiceal epithelial neoplasms have been documented. In this report, we describe a rare case of combined appendiceal goblet cell carcinoid and mucinous cystadenoma, and discuss the possible histopathogenesis of this combination.

## CASE REPORT

A 46-year-old woman presented with severe acute pain in the right iliac fossa and perumbilical region. Ultrasound and a computed tomography scan revealed a mucocele in the veriform appendix, with a well defined lesion located at the mid zone of the appendix. The patient underwent right hemicolectomy, and her postoperative clinical course was uneventful. Gross examination of the surgical specimen showed an enlarged appendix, which was filled with thick mucinous material. A distinct lesion which involved the appendiceal wall, and measured 1.5 cm maximally, was identified in the mid-portion of the appendix. There was no evidence of perforation, extravasation of mucin into the periappendiceal tissue, or pseudomyxoma peritonei during surgery.

Histopathological examination showed combined GCC and MCA of the veriform appendix (Figure 1A). The appendiceal lumen was dilated and lined by mucin-containing columnar epithelial cells (Figure 1B). There was no significant cytologic atypia, and no mitotic figures were identified. Focal papillary configurations of the lining epithelium, and mild epithelial pseudostratification were present. In addition, the appendiceal wall was infiltrated by glandular structures of various sizes which

**Figure 1 Histopathological examination.** A: Mucinous cystadenoma of the appendix combined with infiltrating goblet cell carcinoid (HE,  $\times 50$ ); B: The mucinous cystadenoma of the appendix showing lumen lined by mucous-containing bland epithelial cells (HE,  $\times 100$ ); C: Cells with neuroendocrine cytonuclear features in goblet cell carcinoid (HE,  $\times 200$ ); D: Mucin-filled neoplastic cells of goblet cell carcinoid (HE,  $\times 200$ ); E: The infiltrating nests of goblet cell carcinoid appear to arise from the basiglandular region of the intestinal crypts in close proximity to the mucinous cystadenoma (HE,  $\times 100$ ).

**Figure 2 Immunohistochemically.** The neoplastic cells of the goblet cell carcinoid expressed strong and diffuse positivity for cytokeratin 20 ( $\times 100$ ).

were arranged in nests and tubules. These glandular structures comprised 2 distinct types of cells: (1) small to intermediate sized monotonous neuroendocrine cells with a small amount of finely granular eosinophilic cytoplasm, and mild cytonuclear atypia (Figure 1C); (2) mucin-filled intermediate sized cells (goblet cells), with peripherally located small, crescent-like hyperchromatic nuclei, and indistinct nucleoli (Figure 1D). Scattered infiltrating single goblet neoplastic cells were focally present. As previously described<sup>[1]</sup> the tumor nests appeared to arise from the basiglandular region of the intestinal crypts in close proximity to the MCA (Figure 1E). There was no lymphovascular invasion, although perineural and intraneuronal invasion was present. The tumor infiltrated the full thickness of the appendiceal wall and extended to the mesoappendix. Ten lymph nodes were histologically identified, of which all

**Table 1 Immunohistochemical panel used in this study**

Antibody	Clone	Dilution	Source
CK7	OV-TL 12/30	1:2000	Dako corporation, carpinteria, CA
CK19	B170	1:50	Vector laboratories, burlingame CA
CK20	KS20.8	1:100	Dako
CD99	O13	1:100	Signet laboratories, dedham, MA
Ki67	MIB1	1:100	Dako
Chromogranin	DAK-A3	1:200	Dako
Synaptophysin	SY38	1:200	Dako
Serotonin	Polyclonal	1:200	Dako

were negative for malignancy.

Immunohistochemically (Table 1), the tumor cells of the GCC were positive for chromogranin, synaptophysin, and serotonin, which are neuroendocrine markers. Diffuse staining for cytokeratin (CK) 20 (Figure 2), CK19, and CD99 was also present. The Ki67 proliferating index revealed nuclear staining in approximately 15% of the tumor cells. There was no staining for CK7.

## DISCUSSION

GCC is an uncommon neoplasm of the veriform appendix with uncertain histopathogenesis and biological behaviour. It is believed that GCC represents an amphicrine tumor, which originates from a single undifferentiated pluripotent intestinal stem cell with divergent neuroendocrine and mucinous differentiation<sup>[2]</sup>, resulting in a composite biphasic neoplasm of 2 distinct populations of endoderm-derived cells. Whether this

makes GCC a variant of carcinoid tumor or a subtype of appendiceal adenocarcinoma which exhibits morphological and immunophenotypical features of neuroendocrine differentiation is still a subject of debate. Molecular studies have not elucidated the exact nature of GCC. There is a substantial overlap between GCC and classical carcinoid from a molecular standpoint<sup>[3,4]</sup>. Morphological features such as minimal cytologic atypia, presence of non-goblet cells, tubuloacinar neuroendocrine elements, continuity with the basiglandular crypt cells of the mucosal membrane, and the lack of continuity and involvement with the luminal surface mucosa, favour the GCC being related to carcinoid tumor. However, compared to classical carcinoid, the positive immunostaining for CK20<sup>[5]</sup>, the demonstration of IgA staining that is typical of intestinal crypt cells<sup>[6]</sup>, the tendency for regional lymph node and distant metastasis, and tendency for recurrence and more aggressive clinical behaviour are common features for GCC. This suggests that GCC is histologically a form of "crypt cell carcinoma" or more accurately an "amphicrine carcinoma" rather than a variant of appendiceal carcinoid.

Rare cases of GCC coexisting with conventional appendiceal mucinous tumors were reported<sup>[1,7,8]</sup>, of which 2 cases were MCA<sup>[1]</sup>. Similar to our case, both patients were women, aged 54 and 64 years, who presented with clinical features of acute appendicitis and dull ache in the right iliac fossa. Histological examination revealed combined GCC and MCA. If GCC is a true subtype of carcinoid tumor, its coexistence with an appendiceal mucinous neoplasm would support the theory that GCC is derived from a single undifferentiated pluripotent intestinal stem cell with divergent dual neuroendocrine and mucinous differentiation (unitary stem cell hypothesis). The concomitant appendiceal mucinous neoplasm may be considered a coincidental occurrence and raises the possibility of a common etiological factor for both GCC

and appendiceal epithelial neoplasms<sup>[9]</sup>. If GCC is to be considered as an adenocarcinoma of crypt cell origin rather than a carcinoid, then the occurrence of combined GCC and appendiceal mucinous neoplasms may represent an example of adenoma-carcinoma sequence<sup>[11]</sup>. The nature of GCC and its relation to other neuroendocrine and non-neuroendocrine epithelial tumors of the appendix needs further examination, and more cases of GCC with concomitant appendiceal epithelial neoplasms need to be recorded, which may help in explaining this rare association.

### INTRODUCTION

Malignant cutaneous melanoma can metastasize to virtually any organ. The most common sites of metastatic disease, apart from the regional lymph nodes, are the lungs, liver, brain and colon<sup>[1,2]</sup>. Metastases of the biliary tract are rare. Autopsy studies have shown that gallbladder metastases are found in 15% of patients with metastatic melanoma of the gastrointestinal tract, but are reported rarely during the lifetime of the patient because involvement of the gallbladder seldom produces symptoms<sup>[3]</sup>.

We report a case of metastatic melanoma of the gallbladder in a patient who developed symptomatic acute cholecystitis. The patient underwent explorative laparotomy and open cholecystectomy. Despite appropriate therapy, the diagnosis of this condition portends a poor prognosis, with very few patients surviving more than 12 mo<sup>[4,5]</sup>.

### CASE REPORT

A 58-year-old man was admitted to our clinic with abdominal pain in his right upper quadrant, and associated nausea and vomiting. On examination, he was febrile and there was tenderness upon palpation of the right upper abdominal quadrant and the epigastrium. Laboratory tests were within normal limits (white blood cell count 10 600/mm<sup>3</sup>, normal liver enzymes and normal serum amylase). An ultrasound scan demonstrated sludge in the gallbladder and thickening of the gallbladder wall, without dilatation of the intra- and extrahepatic biliary tree. The patient had undergone a Billroth II operation via median laparotomy for gastric ulcer disease 15 years previously.

A presumptive diagnosis of acute cholecystitis was made. An exploratory laparotomy and cholecystectomy was performed. Intraoperatively, the gallbladder was shown macroscopically to be acutely inflamed and

### Abstract

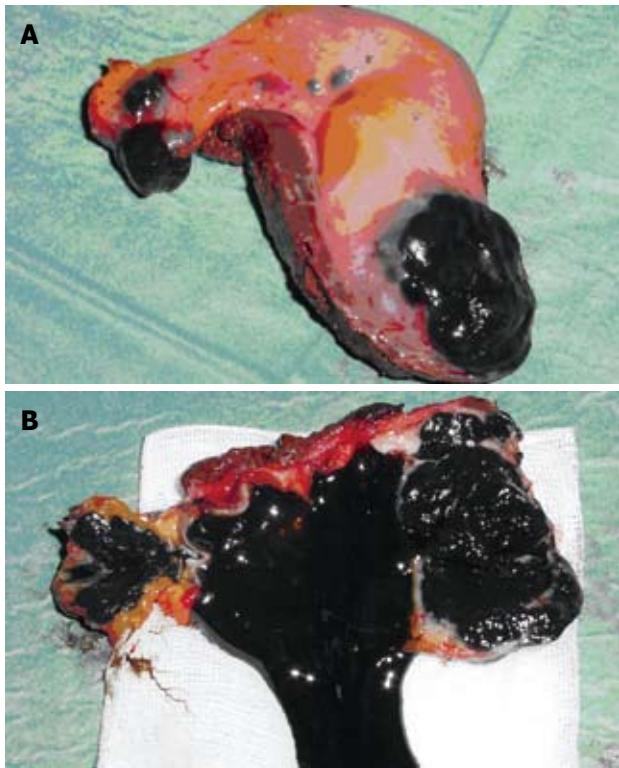

Metastatic disease from cutaneous melanoma can affect all organs of the body, and varies in its biological behavior and clinical presentation. We present the case of a 58-year-old man who arrived at our clinic with acute abdominal pain, which, after investigation, was diagnosed as acute cholecystitis. The patient underwent laparotomy and cholecystectomy. Two years ago, he underwent surgical removal of a primary cutaneous melanoma on his right upper back. Pathological examination revealed the presence of malignant melanoma with a metastatic lesion of the gallbladder.

**Figure 1** Surgical specimen. A: Ulcerated black mass in the fundus and the cystic duct of the resected gallbladder; B: Gallbladder filled with black sludge and necrotic material.

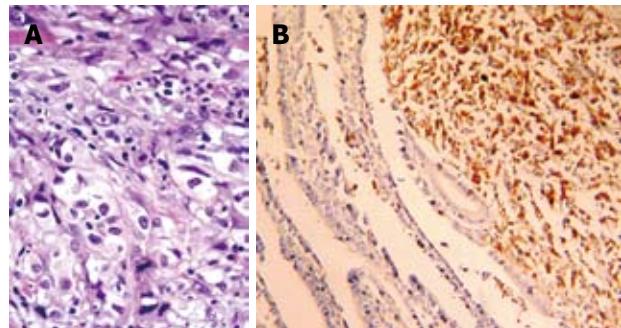

thickened. Examination of the surgical specimen showed an ulcerated black mass in the fundus and the cystic duct of the gallbladder, and the lumen was filled with black sludge and necrotic material (Figure 1).

Pathological examination revealed acute cholecystitis and the presence of a malignant tumor invading through the gallbladder wall, with extensive invasion of lymphatic vessels and fat adipose tissue around the gallbladder. Its morphologic morphological appearance and immunohistological profile<sup>[6]</sup>, corresponded to a metastatic focus of a cutaneous malignant melanoma with high cellular polymorphism and melanin production (Figure 2).

The patient had undergone surgical resection of a malignant melanoma (superficial spreading type, Clark anatomical level III, with a depth of infiltration of 3.8 mm by Breslow) 2 years ago on his right upper back. Adjuvant immunological therapy with interferon was performed at that time.

On postoperative day 7, the patient was discharged home in good condition. Four weeks later, his course was complicated by the development of increasing neurological symptoms. On computer tomography investigation, he was found to have brain metastases. The primary tumor was probably the cutaneous malignant melanoma. He received two courses of combination chemotherapy with a dacarbazine (DTIC) regimen, but the disease continued to progress. He received two cycles of chemotherapy with temozolomide, with no success.

The patient died of widespread disease 5 mo after the initial diagnosis of the metastatic disease.

**Figure 2** Pathological examination. A: Microscopic picture of metastatic melanoma in the gallbladder (HE,  $\times 20$ ); B: Neoplastic cells immunostained with anti-S-100 antibodies ( $\times 400$ ).

## DISCUSSION

Metastases of cutaneous melanoma to the gallbladder and biliary tree are uncommon and usually clinically asymptomatic. The most common sites of distant metastases are the skin, lungs, liver and brain<sup>[2,7,8]</sup>. According to autopsy results, such asymptomatic metastases to the gallbladder and bile ducts occur in 4%-20% of patients with metastatic melanoma<sup>[3,8,9]</sup>, and constitute up to 50% of the metastatic neoplasms of these organs<sup>[2,4]</sup>.

Despite these statistical data, it is rare for metastatic gallbladder melanoma to be present with symptoms during the patient's life time<sup>[4,8,9]</sup>, as demonstrated by the discrepancy in published case reports and the rate of detection at autopsy<sup>[3,4,8,10]</sup>.

The most common presentation of symptomatic metastatic disease to the gallbladder is acute cholecystitis followed by jaundice caused by obstruction of the common bile duct<sup>[4,8]</sup>. Also hematobilia and biliary fistulae may develop<sup>[4,8,11]</sup>.

The examination of choice for the assessment of gallbladder metastatic tumors is ultrasound scanning, an examination with high specificity and sensitivity<sup>[10]</sup>. In particular, the use of color Doppler ultrasound can support a preoperative differential diagnosis of malignancy, because of the presence of pathological blood flow within the lesion in patients with a past medical history of cutaneous malignant melanoma<sup>[2,4,12]</sup>.

The role of surgical treatment of metastatic melanoma of the gallbladder remains unclear because of the lack of experience<sup>[2]</sup>. Goals of therapy include palliation of symptoms, minimization of complications and improvement in overall survival. Recently, cholecystectomy has been indicated for patients with isolated, resectable gallbladder metastases, and can achieve longer survival<sup>[2,4]</sup>. As an alternative to open surgery, the laparoscopic approach has arisen as a minimally invasive option<sup>[5,8,9]</sup>.

From the literature, the prognosis of metastatic melanoma to the gallbladder is dismal, with a median survival of 6-9 mo<sup>[2,4,8]</sup> and long-term disease-free survival is achieved in only 1%-2% of patients<sup>[2]</sup>. Once involvement of the gallbladder is documented, it is probable that the metastases are widespread.

Despite the advances made in chemotherapy<sup>[13]</sup> and

immunotherapy<sup>[14,15]</sup> for metastatic melanoma, the results are still poor and disappointing<sup>[2,4,8]</sup>.

In conclusion, we report this case to make clear the necessity of meticulous investigation of lesions of the hepatobiliary system when the patient has a past history of cutaneous malignant melanoma. The best chance for achieving the longest survival is active screening and early detection. In addition, diligence and vigilance are required to ensure that patients adhere to current screening guidelines. Active follow-up is necessary to identify metachronous lesions early.

thoracoabdominal approach after transarterial embolization for giant hepatic hemangioma. *World J Gastroenterol* 2009, 15(27): 3437-3439 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3437.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3437>

## INTRODUCTION

Liver hemangiomas are the most common benign tumors occurring in the liver, and are believed to be slowly growing hamartomatous lesions or true vascular neoplasms<sup>[1]</sup>. They occur more frequently in women than in men, and are believed to be related to levels of female hormones because their size increases during pregnancy<sup>[2]</sup>. In most cases, the hemangioma is small in size and asymptomatic, and thus follow-up is considered enough, without treatment. However, a giant hemangioma, which is defined as a hemangioma over 4 cm in diameter, can cause symptoms and require intervention. Preoperative diagnosis is possible using ultrasound or helical CT, and the indications for surgical resection are the presence of symptoms, a high risk of rupture, and being indistinguishable from malignancy. Here, we report the successful removal of a giant hemangioma (over 30 cm) from the right side of the liver through a J-shaped incision, using a thoracoabdominal approach, after transarterial embolization (TAE).

## CASE REPORT

A 41-year-old female patient visited a secondary hospital for abdominal girth (which had not decreased since delivery a year ago), intermittent abdominal pain, and indigestion, as the chief complaints. Ultrasonography, performed during the visit, detected huge hyperechoic lesions, and under the diagnosis of giant hemangioma, she was recommended for surgery and transferred to the present hospital. During a physical examination upon admission, an abdominal mass was palpated from the right upper quadrant to the pelvic cavity. Preoperative serum biochemical studies revealed no abnormal findings, except for an increase of total bilirubin to 2.5 (normal < 1.20 mg/dL). Using helical CT, a non-contrast image showed a homogenous hypodense lesion

## Abstract

Hepatic hemangiomas need to be treated surgically in cases where they are accompanied with symptoms, have a risk of rupture, or are hardly distinguishable from malignancy. The present authors conducted embolization of the right hepatic artery one day before an operation for a huge hemangioma accompanied with symptoms and confirmed a decrease in its size. The authors performed a right trisegmentectomy through a J-shape incision, using a thoracoabdominal approach, and safely removed a giant hemangioma of 32.0 cm × 26.5 cm × 8.0 cm in size and 2300 g in weight. Even for inexperienced surgeons, a J-shape incision with a thoracoabdominal approach is considered a safe and useful method when right-side hepatectomy is required for a large mass in the right liver.

Seo HI, Jo HJ, Sim MS, Kim S. Right trisegmentectomy with

**Figure 1** Coronal reformatted CT scan obtained for the portal venous phase shows an ill-defined heterogeneous enhancing mass lesion in the right lobe of the liver.

**Figure 2** Angiography obtained at the delayed phase, before embolization, shows displacement of vessels and pooling of contrast medium in the right lobe of the liver.

contrasted with the surrounding liver parenchyma, the arterial image showed peripheral nodular enhancement, and the portal venous image showed progressive centripetal enhancement. These findings indicated a giant hemangioma (Figure 1). The indocyanine green clearance rate at 15 min was 13% (normal range < 15%). TAE of the right hepatic artery was conducted one day before the operation (Figure 2), and thereafter the size decreased by around 5 cm and no more.

Through a J-shaped skin incision using a thoracoabdominal approach, the incision was extended to the 10th intercostal space and the adjacent pleura and diaphragm were opened. Through the incision, the right liver was fully mobilized, and through the hanging method and Glissonian approach, a right trisegmentectomy was safely conducted. The duration of operation was 310 min and intraoperative blood loss was 250 mL. The resected tumor was 32.0 cm × 26.5 cm × 8.0 cm in size and 2300 g in weight. Upon histological examination, it was diagnosed as a cavernous-type hemangioma. The patient's postoperative course was stable. The chest tube was removed on the fifth day and the patient was discharged on the 10th day. Follow-up has been continued for eight months without any particular findings.

## DISCUSSION

Hemangiomas show specific features in imaging diagnosis, therefore most cases can be diagnosed preoperatively. As a hemangioma increases in size, it can cause congestion, bleeding, thrombosis and infarction (and consequent stomachache), Kasabach-Merritt syndrome, and spontaneous rupture. Out of the mass effect, it might show symptoms such as obstructive jaundice, biliary colic, and gastric outlet obstruction<sup>[3]</sup>. In our case, the patient complained of only non-specific symptoms such as mild abdominal pain and dyspepsia. Total bilirubin increased slightly but direct bilirubin was normal, which findings did not indicate obstructive jaundice. For the treatment of a giant hemangioma accompanied with symptoms, surgical resection is primarily recommended. Various other treatment methods have been reported but their long-term results have been poor<sup>[4]</sup>. TAE is suggested as an excellent therapy for easing the symptoms of a giant hemangioma, but recurrence is common because

of vascular recanalization. However, there is a report that TAE for a giant hemangioma, performed prior to surgical resection, facilitated the mobilization of the right liver by shrinking the hemangioma and, consequently, decreased intraoperative hemorrhage<sup>[5]</sup>. The authors also performed TAE one day before the operation, and experienced a decrease in the size of hemangioma, as in the previous report. Various complications can occur after embolization and they could postpone the operation and result in the loss of an opportunity for surgery due to vascular recanalization. Accordingly, it is desirable to perform the operation soon after embolization. Thus, the present authors performed the laparotomy within 24 h, and observed the shrinkage of hemangioma during the operation, as in the previous report. This helped minimize bleeding from the hepatic raw surface during the mobilization of the liver.

Preoperative TAE can decrease the risk of bleeding during resection of a hemangioma, but in the liver resection of a 30 cm large giant hemangioma, conventional approaches might cause difficulties. Lai *et al*<sup>[6]</sup> reported successful resection of a giant hemangioma using the anterior approach, but they recommended that it should be done by skillful and experienced surgeons because it can cause excessive bleeding from the middle hepatic vein during parenchymal resection. The thoracoabdominal approach is advantageous in that it provides a sufficiently large field of view in a partial hepatectomy or the resection of Couinaud's Segment 7 and 8, and it has been reported as a useful method for right side hepatectomy by Japanese and European researchers since the 1990s<sup>[7]</sup>. Compared to conventional approaches, the thoracoabdominal approach is just as safe as a right-sided hepatectomy, but it seems not to be used frequently because the chest has to be opened and an intra-thoracic drainage tube has to be inserted. We think that pulmonary complications are caused by thoracotomy but they are not common in the thoracoabdominal approach, and the problem of pleural effusion can be controlled by the use of an intra-thoracic drainage tube and diuretics. The present authors inserted a postoperative intra-thoracic drainage tube, and did not observe intercostal pain or neurogenic pain caused by the insertion. In addition, the intra-thoracic drainage tube was removed early; therefore it did not affect the postoperative course. The thoracoabdominal approach

is obviously a useful method for the safe resection of the right triangular ligament and mobilization of the right liver from the inferior vena cava. Accordingly, when a right-side hepatectomy is performed for a huge mass, such as a giant hemangioma in the right liver, a J-shaped incision using a thoracoabdominal approach is considered a safe and useful method. The addition of "sternotomy" to this incision might be considered of clinical value if the tumor is even larger than in this case.

## INTRODUCTION

The occurrence of two or more primary malignant tumors in a patient is regarded as uncommon. In 1889, Billroth documented several such cases as rare events. However, in recent years, several studies have noted multiple primary cancers frequently due to the prolonged survival of patients who have previously been cured of a primary cancer<sup>[1]</sup>. Multiple primary cancers are defined as either synchronous tumors or metachronous tumors, according to whether the diagnostic intervals of the lesions are shorter or longer than six months, respectively<sup>[2,3]</sup>. Synchronous multiple biliary cancers occur in 3.7%–7.4% of all surgically resected biliary tumors. Most of them develop in the gallbladder and bile duct<sup>[4-6]</sup>. On the other hand, metachronous multiple biliary cancers are rare, with only 11 cases reported in the world literature<sup>[7-17]</sup>. In Korea, one case was reported in 1997 when a 61-year-old man underwent curative resection for bile duct cancer 30 mo after a radical cholecystectomy to cure gallbladder cancer<sup>[17]</sup>.

We report the case of a 74-year-old man with metachronous gallbladder cancer and hilar bile duct cancer, who underwent curative resection twice, with an interval of nine years separating the operations. We also refer to 12 cases of metachronous biliary tract cancer published in the world literature, including the present case.

## CASE REPORT

A 74-year-old man was admitted for further evaluation

**Figure 1 Radiologic finding of hilar bile duct cancer.** A: Dynamic abdominal CT during arterial phase of axial image showed a low-density mass, 1.7 cm in diameter at the hilum of the liver, extending to the right intrahepatic bile duct (arrow) and intrahepatic bile duct dilatation in the right lobe (arrow head); B: Dynamic abdominal CT during venous phase of coronal image showed the mass extending to the second branch of the intrahepatic bile duct in right hepatic lobe (arrow); C: T2WI, axial image of MRI showed the mass located in the perihilar bile duct with the same signs of liver parenchyma (arrow), and extending to the second branch of the intrahepatic bile duct in the right hepatic lobe.

**Figure 2 Gross specimen of bile duct excision and right hepatic lobectomy.**

of elevated serum alkaline phosphatase level. Nine years previously, he had undergone a cholecystectomy and resection of his liver bed for gallbladder cancer. The pathologic specimen revealed a well-differentiated adenocarcinoma with muscular invasion, no hepatic invasion, and with negative resection margins (T2N0M0, stage I B). He did not receive adjuvant therapy and was followed up periodically without evidence of tumor recurrence. However, nine years later, blood tests showed an elevated serum alkaline phosphatase level. He had been taking antihypertensive agents and oral hypoglycemic agents for ten years. He underwent splenectomy for idiopathic thrombocytopenic purpura 15 years ago. He is a nonsmoker and a farmer.

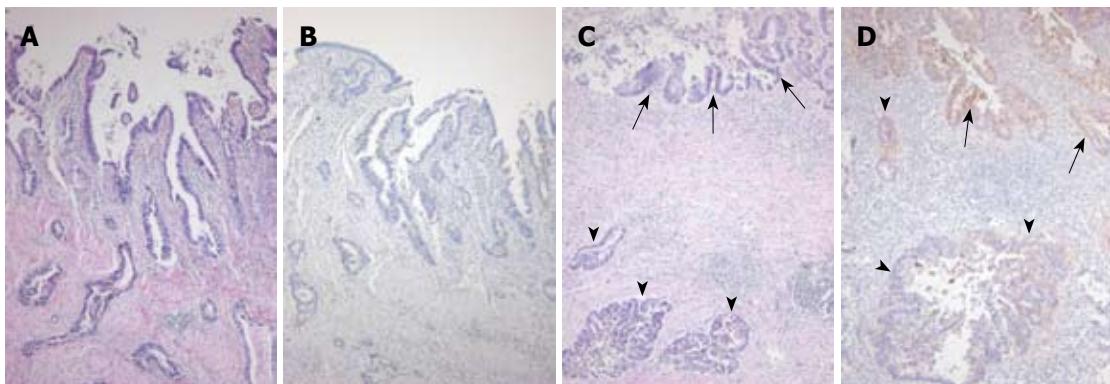

On admission, the patient complained of dyspepsia but physical examination revealed no abnormalities. Laboratory test results showed WBC  $9010/\text{mm}^3$ , hemoglobin 13.3 g/dL, hematocrit 41.3%, platelet  $312 \times 10^9/\text{L}$ , AST 44 U/L, ALT 43 U/L, total bilirubin 0.5 mg/dL, alkaline phosphatase 975 IU/L, CEA 5.2 ng/mL ( $< 5 \text{ ng/mL}$ ), and CA 19-9 77.4 ng/mL ( $< 37 \text{ ng/mL}$ ). Abdominal CT and magnetic resonance imaging (MRI) revealed an enhanced 1.7 cm mass in the hilum that extended to the second branch of the intrahepatic bile duct on the right side of the liver, as well as diffuse dilated intrahepatic bile ducts (Figure 1). These findings suggested hilar bile duct cancer, Bismuth type IIIa. There was no evidence of peritoneal metastasis or enlarged lymph nodes. The

patient underwent curative surgery comprising bile duct excision, right hepatic lobectomy and Roux-en-Y hepaticojejunostomy (Figure 2). Pathologic specimens revealed a well-differentiated adenocarcinoma invading the entire thickness of the bile duct; one of seven lymph nodes was positive for malignant cells; and there was a high degree of dysplasia around the main lesion (T1N1M0, stage II B). We used genetic alterations in CA19-9, p53 gene, and k-ras as a means of distinguishing multi-centric primary cancers from primary cancer metastases. The tissues of the gallbladder cancer and the bile duct cancer were both positive for the p53 and k-ras gene. However, CA19-9 was negative in the tissue of the gallbladder cancer, but positive in the tissue of the bile duct cancer (Figure 3). Now, 12 mo after the second operation, the patient is doing well with no evidence of recurrence. These two cancers apparently occurred independently and each surgical treatment was successful.

## DISCUSSION

Synchronous multiple primary cancers of the biliary system occur in up to 7% of resected bile duct cancers. Most are found on removing the gallbladder during a resection for bile duct cancer<sup>[4-6]</sup>. However, metachronous multiple bile duct cancer is very rare. Because biliary tract cancers are usually advanced by the time of diagnosis, and surgery involves a broad bile duct resection with curative intent, the chances of developing a metachronous double biliary cancer are slim<sup>[7-17]</sup>.

In 1932, Warren and Gates proposed the three still generally accepted criteria that had to be met in order to consider malignant tumors as multiple primary tumors rather than recurrences: first, each of the tumors must present a definite picture of malignancy; second, each tumor must have a different histological appearance; third, the possibility that one might be a metastatic lesion from a former lesion must be excluded<sup>[18]</sup>. Gertsh also stated the criteria for double primary cancer in the biliary tract: first, each tumor must be distinct; second, each tumor must be separated from normal tissue; third, there should be no evidence of invasion to the submucosal layer and lymph nodes around the bile duct<sup>[19]</sup>. Bile duct

**Figure 3 Histopathological finding of hilar bile duct cancer.** A: Histologic section of the gallbladder shows well-differentiated biliary-type adenocarcinoma infiltrating the entire thickness of the gallbladder wall (HE,  $\times 100$ ); B: None of the tumor cells expressed CA19-9 (immunoperoxidase method,  $\times 100$ ); C: Histologic section of the hepatic duct demonstrates severe epithelial dysplasia of the mucosa in the upper field (arrows) and invasive adenocarcinoma in the lower field (arrow heads) (hematoxylin and eosin,  $\times 100$ ); D: Most of the dysplastic epithelial cells in the upper field (arrows) and some of invasive tumor cells in the lower field express cytoplasmic CA19-9 (arrow heads). An invasive tumor gland is noted in the mid-left field (immunoperoxidase method,  $\times 100$ ).

cancer often exhibits metastasis to the lymph node nearest the mass, or *via* the bile duct; therefore, spreading of micro-vessels and nerve system, depth of tumors and the possibility of peri-lymph node invasion must all be considered in discriminating between metastatic cancer and double primary cancer. When multiple cancers are identified, the distinction between multi-centric primary cancers and primary cancer metastases is often clinically difficult. Recent studies reported that analysis of loss of heterozygosity, point mutations of k-ras oncogene<sup>[20]</sup>, overexpression of the tumor suppressor gene p53<sup>[20]</sup> and tumor marker CA19-9, and CEA in the cancers, may all play an important role in diagnosing the second cancer as primary or metastatic tumors<sup>[4,19]</sup>. Hori *et al*<sup>[4]</sup> diagnosed four cases of double primary cancer of gallbladder and bile duct cancer by point mutation of k-ras and overexpression of p53, CEA, and CA19-9 by immunohistochemistry. Ogawa *et al*<sup>[19]</sup> reported metastatic bile duct cancer, located in both

the upper and lower extrahepatic bile duct, which met the criteria of double primary tumors; then he revealed metastasis by analyzing the loss of heterozygosity, using microsatellite genetic markers on five arms. Therefore, it is not sufficient to diagnose double cancer only by means of pathologic examination. New diagnostic technology, such as genetic analysis, may be needed.

This case was diagnosed as metachronous double biliary cancer, which developed nine years after resection for gallbladder cancer, and was cured surgically. This case shows evidence to support a diagnosis of double primary cancers. First, both the gallbladder cancer and the bile duct cancer were malignant; however, there was no evidence of malignancy in the surgical stump, including the neck of the gallbladder, indicating there was no link between them. Second, advanced gallbladder cancers usually recur within five years of resection. The second bile duct cancer was detected nine years after the first operation, and so it would be extremely

unlikely for the second cancer to be a remnant tumor from the first operation. Third, although both tumors of the gallbladder and the bile duct showed the same histological differentiation and positive k-ras and p53 immunohistochemistry, the expressions of CA19-9 were different: CA19-9 expression was negative in the gallbladder cancer and positive in the bile duct cancer. Lastly, the bile duct cancer resembled a primary tumor from evidence of dysplastic changes near the main mass which would not be found in metastatic cancer.

The etiology of double biliary tract cancer has not been defined, but it is generally accepted that the anomalous union of the pancreaticobiliary duct (AUPBD) plays an important role in the development of multiple biliary tract cancers. Kaneko *et al*<sup>[8]</sup> and Fujii *et al*<sup>[13]</sup> reported that 50%-62.5% of cases of synchronous double biliary tract cancers were associated with AUPBD. A close relationship is known to exist between cancer of the bile duct system and AUPBD. In most patients with AUPBD, there is a long common channel between the junction of the pancreatic and common bile ducts and the sphincter of Oddi. We also know that the risk of bile duct carcinoma increases with age. Continuous reflux of the pancreatic juice into the bile duct induces chronic inflammation and metaplastic epithelial changes in the biliary tree<sup>[20]</sup>. Despite more than half of synchronous double biliary cancers having AUPBD as a risk factor, none of the twelve metachronous cases was associated with AUPBD (Table 1). Also, bile duct cancer is associated with AUPBD, almost middle and inferior regions of the bile duct and none of superior part of the bile duct cancer are associated with AUPBD<sup>[8]</sup>. This would reinforce the idea, suggested by other investigators, that upper biliary tract cancers and metachronous double biliary cancers have a strong genetic predisposition, or oncogenic susceptibility, irrespective of the presence of AUPBD. Although most metachronous double cancers have no obvious cause, several predisposing factors have been identified including: previous treatment of cancer, environmental factors, race, genetic factors, and long-term survival<sup>[1]</sup>. Although this case shows no evidence of AUPBD, double cancer of the gallbladder and bile duct is associated with expression of k-ras oncogene and the p53 tumor suppressor gene. Thus, we can guess which oncogenes were responsible for both biliary systems forming a malignant lesion simultaneously.

Table 1 illustrates all twelve cases of metachronous biliary tract cancer (including this case) previously described in the literature. There were six male and six female patients, ranging in age from 12-83 years (mean, 63 years). One patient developed metachronous biliary double cancer aged 21 years<sup>[10]</sup>. The three cases of a second cancer in the upper bile duct and six cases of a second cancer in the lower bile duct were detected at a mean age of 5.7 years after a first operation for gallbladder resection. Three second cancers developed in the remnant bile duct at 7, 4, and 2.3 years after the first operation for bile duct resection. There was no definite cause identified in the 12 cases of metachronous bile duct cancer, including this case. None of them has AUPBD as

etiology. Also, the criteria for double primary cancer are based solely on pathologic evidence: with the exception of this case, no previous cases have used gene expression as a diagnostic tool.

There is no clear evidence about follow-up intervals and diagnostic methods during postsurgical monitoring. Takai *et al*<sup>[12]</sup> reported that magnetic resonance cholangiography and gadolinium enhanced dynamic MRI were useful in the diagnosis of a bile duct cancer that developed seven years after resection for gallbladder cancer, in the anatomically rearranged structure following gallbladder resection. Merenda *et al*<sup>[16]</sup> suggested a potential role for PET-CT to detect metachronous bile duct cancer in the postsurgical monitoring of bile duct cancer when abdominal CT did not reveal any lesions. However, metachronous bile duct cancer is very rare, so it is not cost-effective to routinely provide expensive procedures, such as MRI or PET-CT, during the postoperative period. Further studies are needed to facilitate the cost-effective early detection of metachronous double cancers.

In conclusion, we present a rare case of advanced metachronous double cancer of the gallbladder and bile duct cancer, separated by a period of nine years. We enhance our report with a review of the relevant literature.

Fulminant amoebic colitis during chemotherapy for advanced gastric cancer. *World J Gastroenterol* 2009; 15(27): 3445-3447 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3445.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3445>

### INTRODUCTION

Amoebic colitis, the disease caused by the intestinal protozoan parasite *Entamoeba histolytica*, is common and sometimes fatal<sup>[1]</sup>. The manifestations of intestinal amoebiasis vary from no symptoms to severe ulceration with perforation and peritonitis. There are many reports on fulminant amoebic colitis<sup>[2,3]</sup>, but the development of fulminant amoebic colitis during chemotherapy is very rare. We describe our experience with a patient in whom fulminant amoebic colitis occurred while receiving chemotherapy for advanced gastric cancer.

### CASE REPORT

A 52-year-old man presented at our hospital suffering from epigastric pain. An upper gastrointestinal endoscopy revealed advanced gastric cancer. Abdominal ultrasonography and computed tomography showed liver metastasis and intra-abdominal lymph-node metastasis. Unresectable advanced gastric cancer was diagnosed. Chemotherapy with oral S-1 (120 mg/d), given for four weeks followed by two weeks of rest<sup>[4]</sup>, was started at the outpatient clinic. Computed tomography after seven courses of treatment showed disease progression. The chemotherapy regimen was therefore switched to second-line treatment with paclitaxel (140 mg/m<sup>2</sup>), given once every two weeks<sup>[5]</sup>. After six courses of the second-line treatment, constipation and diarrhea occurred repeatedly. During the seventh course of treatment, melena developed. Gastrointestinal bleeding caused by chemotherapy was suspected, and a gastrointestinal series was performed. An upper gastrointestinal endoscopy showed no bleeding from the primary tumor. Colonoscopic examination disclosed multiple hemorrhagic erosions throughout

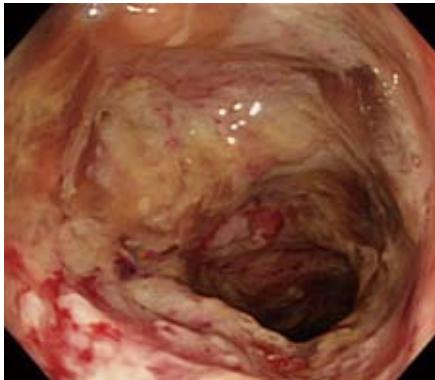

### Abstract

A 52-year-old man had bloody stools during chemotherapy for gastric cancer. A colonoscopy revealed necrotizing ulcer-like changes. A biopsy confirmed the presence of amoebic trophozoites. Subsequently, peritonitis with intestinal perforation developed, and emergency peritoneal lavage and colostomy were performed. After surgery, endotoxin adsorption therapy was performed and metronidazole was given. Symptoms of peritonitis and colitis resolved. However, the patient's general condition worsened with the progression of gastric cancer. The patient died 50 d after surgery. Fulminant amoebic colitis is very rarely associated with chemotherapy. Amoebic colitis should be considered in the differential diagnosis of patients who have bloody stools during chemotherapy.

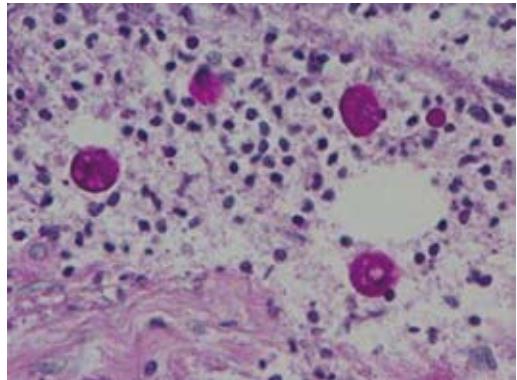

**Figure 1** Colonoscopy on admission, showing reddish, friable mucosa and necrotizing ulcers at the transverse colon.

the colon. A biopsy of the same site revealed only inflammatory-cell infiltration. Subsequently, melena became more frequent, and symptoms worsened. The patient was admitted to the hospital for further evaluation and treatment. On admission, his body temperature was 38.1°C. The palpebral conjunctivae were anemic. There was a palpable mass in the epigastric region, associated with tenderness. Edema of the lower extremities was present. On admission, laboratory examinations showed anemia, hypoalbuminemia, and elevated transaminases. A culture specimen was negative for human immunodeficiency virus.

After admission, the colonoscopy was repeated. Necrotizing ulcer-like changes covered with slough were circumferentially seen from the rectum to the transverse colon (Figure 1). A biopsy of this region showed amoebic trophozoites (Figure 2). Signs of peritoneal irritation developed two days after colonoscopic examination. Intestinal perforation was diagnosed on computed tomography, and emergency surgery was performed. The perforation point was detected in the middle of the transverse colon. Peritoneal lavage and colostomy were performed. After surgery, endotoxin adsorption therapy was performed, and metronidazole was given. The symptoms of peritonitis and colonitis resolved. However, the patient's general condition worsened due to progression of gastric cancer and the patient died 50 d after surgery.

## DISCUSSION

Dysenteric amoebiasis is caused by protozoan parasites, which can be classified into two types: pathogenic *E. histolytica* and non-pathogenic *Entamoeba dispar*<sup>[1]</sup>. The ingestion of food and drink contaminated by pathogenic *E. histolytica* causes amoebiasis. About 90% of infections are asymptomatic, and the remaining 10% of infections produce a spectrum of clinical syndromes, ranging from dysentery to abscesses of the liver or other organs. It is reported that bowel perforation occurs in nearly 1% of the patients hospitalized for amoebiasis<sup>[6]</sup>; delayed diagnosis might have resulted in high mortality even after surgical therapy. Mortality for patients who undergo colectomy with proximal ileostomy and distal colostomy is

**Figure 2** Histological findings of a biopsy specimen, showing *Entamoeba* that have ingested red blood cells, indicating that they are *E. histolytica*.

32% to 76%<sup>[2,3]</sup>. In this case, the perforation was pin hole-like lesion in the middle of transverse colon where friable mucosa and necrotizing ulcers were seen, suggesting that the reason for perforation was due to a discrete ulcer rather than due to the colonoscopic examination. However, the colectomy had not been performed and could not be reviewed pathologically, indicating limitations to diagnostic imaging studies. The possibility of iatrogenic perforation thus cannot be ruled out completely.

It is known that 4%-10% of asymptomatic individuals infected with *E. histolytica* develop disease over a year<sup>[1]</sup>. The onset is often gradual, but several studies have reported that steroids, the presence of diabetes mellitus, chronic alcoholism, and pregnancy can trigger fulminant amoebic colitis<sup>[1,7]</sup>. The classic endoscopic findings of amoebic colitis are described as discrete, round ulcerations that range in size and are covered with white or yellow exudates<sup>[8]</sup>. However, amoebic colitis can be mistaken for other causes of necrotizing colitis, such as idiopathic inflammatory bowel diseases and pseudomembranous colitis of *C. difficile*, because the appearance of amoebic ulcers is variable on endoscopic examination. Oral metronidazole is generally used to treat amoebic colitis. However, complications occur when adequate therapy and appropriate antibiotics are not initiated at an early stage, all the more so in an immunosuppressed state. It is well known that there are two high risk groups in nonendemic areas; one is homosexual men, and the other is travelers from the tropics. As for the route and time of infection, the patient had been to Southeast Asia more than 20 years before disease onset; therefore, the possibility of an acquired oral infection cannot be ruled out. In Japan, dysenteric amoebiasis is most commonly caused by *E. histolytica* infection<sup>[9]</sup>, with a particularly high incidence among homosexuals. However, it is noteworthy that our patient was not homosexual and that colitis developed during chemotherapy. In our patient, cytotoxic drugs are considered a risk factor of invasive amoebiasis, contributing to the immunosuppressed status. Cytotoxic drugs inhibit normal bacterial flora, suppress host defenses, and depress host immunity. In experimental free-living amoebic infections, some drugs suppressed host defenses with an increase in the mortality of infected mice<sup>[10]</sup>.

Amoebic colitis should therefore be included in the differential diagnosis in immunosuppressed patients with gastrointestinal signs and symptoms, such as bloody stools.

### Abstract

Esophageal carcinosarcoma is a rare malignant tumor composing of both carcinomatous and sarcomatous elements. Endoscopic therapy is less invasive and may represent an alternative to esophagectomy for superficial esophageal carcinosarcoma. Here, we report a 61-year-old male who was diagnosed as esophageal carcinosarcoma and underwent endoscopic polypectomy with well tolerance and favorable prognosis. We also present a brief review of the literature.

### INTRODUCTION

Esophageal carcinosarcoma is a rare malignant neoplasm consisting of both carcinomatous and sarcomatous

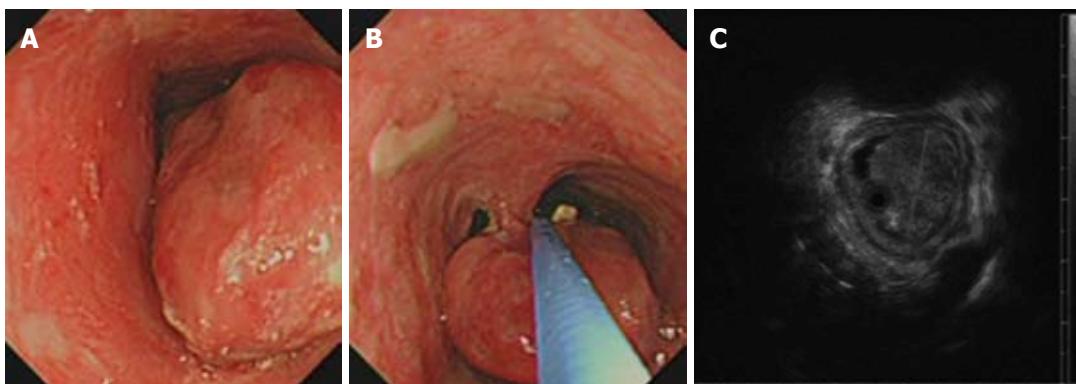

components<sup>[1]</sup>. Esophagectomy has been traditionally considered the first option for esophageal carcinosarcoma patients<sup>[1]</sup>. Endoscopic therapy is less invasive and allows the esophagus to be preserved, and may represent an alternative to esophagectomy for superficial esophageal carcinosarcoma. We here report a case of esophageal carcinosarcoma who underwent endoscopic polypectomy with well tolerance and favorable prognosis.

### CASE REPORT

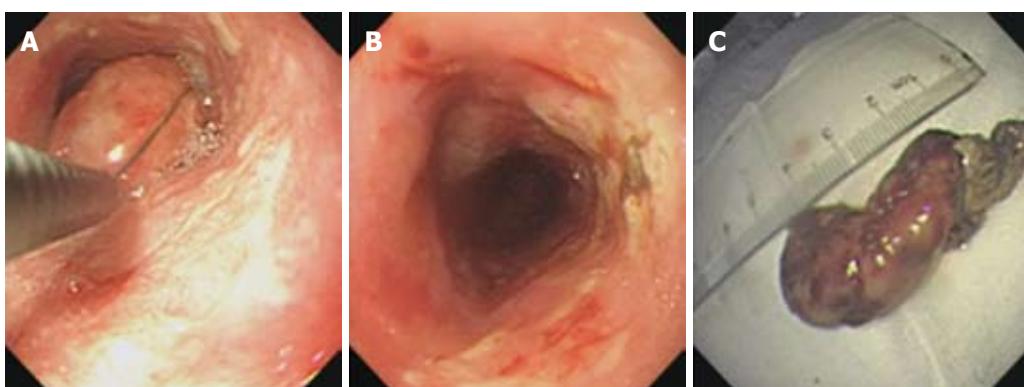

A 61-year-old male was admitted to our hospital with a 20-day history of progressive dysphagia. He was a heavy smoker and alcohol drinker, neither his medical nor family history included any relevant disease. Physical examination revealed no abnormalities. All serum tumor markers were normal. Barium meal showed a regularly-shaped circular stenosis in the upper esophagus. Endoscopy revealed a pedunculated polypoid tumor with ulcer on its surface. The tumor was located at 25-30 cm from the incisor teeth, and packed in the lumen of the esophagus (Figure 1A and B). Biopsy proved the mass to be a carcinosarcoma.

Endoscopic ultrasonography (EUS) and computed tomography (CT) scan were subsequently performed to show the stage of carcinosarcoma. EUS revealed a 5 cm × 3 cm × 3 cm hypoechoic mass with regular margins confined to the mucosal layer with no involvement of other layers or regional lymph nodes (Figure 1C). CT scan displayed an intraluminal mass but no evidence of metastases in brain, chest or abdominal organs. According to the clinical examinations, we performed an endoscopic polypectomy using a polypectomy loop to resect the bulky pedunculated tumor (Figure 2).

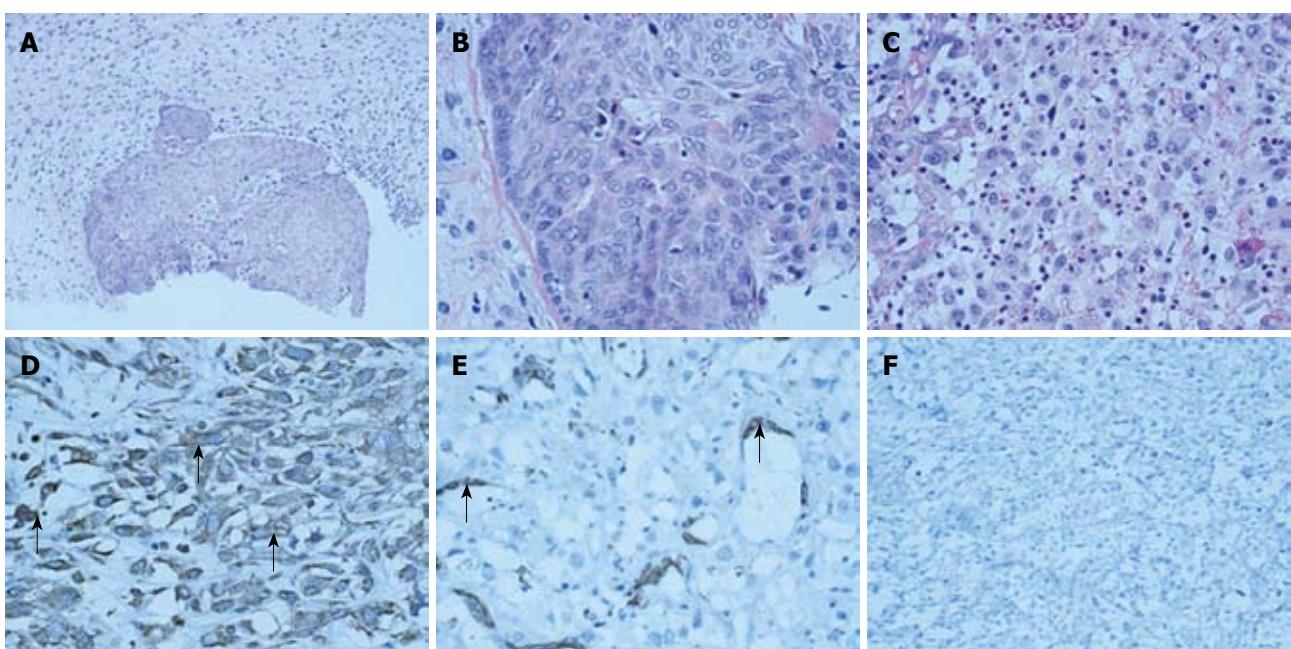

Histology confirmed both carcinomatous and sarcomatous areas in the resected mass (Figure 3A). Large nuclei of polygonal tumor cells with conspicuous nucleoli were observed in the carcinomatous area (Figure 3B) while multiform cells with abundant mitotic figures and bizarre giant cells were observed in the sarcomatous area (Figure 3C). Eosinophilic cytoplasm of tumor cells was found in both carcinomatous and sarcomatous areas with no definite keratinization and intercellular bridges between tumor cells. To further study the histogenesis of sarcoma, we used vimentin, smooth muscle antigen (SMA) and desmin (three well-established immunomarkers for mesenchymal tumor, myofibroblastoma and leiomyoma, respectively) to detect the corresponding antigen expression level in cells of the sarcomatous area. Immunohistology

**Figure 1 Endoscopic examinations.** A and B: Upper gastrointestinal endoscopy showed a pedunculated polypoid tumor of the esophagus; C: EUS found a  $5\text{ cm} \times 3\text{ cm} \times 3\text{ cm}$  hypoechoic mass with regular margins confined to mucosal layer only.

**Figure 2 Endoscopic polypectomy.** A: Pre-polypectomy; B: Post-polypectomy; C: Macroscopy of the esophageal carcinosarcoma.

**Figure 3 Histological findings.** A: Histology showing a transitional area (HE,  $\times 100$ ); B: A carcinomatous area (HE,  $\times 400$ ); C: A sarcomatous area (HE,  $\times 400$ ); D: Immunohistology showing a sarcomatous area positive for vimentin in cytoplasm (arrows, vimentin,  $\times 400$ ); E: Negative for SMA in cytoplasm and positive for internal control (arrows, SMA,  $\times 400$ ); F: Negative for desmin in cytoplasm (desmin,  $\times 400$ ).

revealed positive vimentin (Figure 3D), negative SMA or desmin (Figure 3E and F), suggesting that the sarcoma has a mesenchymal origin.

Polypectomy was performed. The patient recovered well and was discharged three days later with no relapse 17 mo after operation.

## DISCUSSION

Carcinosarcoma is a rare esophageal tumor showing polypoid configurations, with an incidence of 0.1%-1.5% of all esophageal malignancies<sup>[1]</sup>. This type of tumor is usually composed of invasive and/or *in situ* squamous carcinoma cells surrounding the base and surface of exophytic tumor and sarcomatous spindle cells forming the body of polypoid mass<sup>[2]</sup>.

The clinical presentation of esophageal carcinosarcoma is similar to that of squamous cell carcinoma with dysphagia as the most prominent and frequent symptom<sup>[1]</sup>. The mean age of patients at diagnosis in both histological groups is 70 years with a strong male predominance<sup>[1]</sup>. The anatomic distribution of both tumor types follows a similar pattern with the middle third of esophagus being the most common location<sup>[1]</sup>. The bulky nature of esophageal carcinosarcoma is due to its earlier clinical manifestations of dysphagia and obstruction<sup>[3]</sup>, which may also explain why the more favorable prognosis is associated with carcinosarcoma rather than with other esophageal tumors.

The histogenesis of sarcomatous spindle cell component of esophageal carcinosarcoma is still controversial. Some cases of esophageal carcinosarcoma with osteosarcoma, basaloid squamous carcinoma and rhabdomyosarcoma have been reported<sup>[4]</sup>. In our case, the esophageal tumor consisted of both carcinomatous and sarcomatous parts, and immunohistochemistry of sarcomatous parts revealed positive vimentin, a mesenchymal tumor immunomarker.

The treatment modality for esophageal carcinosarcoma include esophagectomy, endoscopic resection, chemo-radiotherapy, etc<sup>[5-7]</sup>. TNM staging is a critical determining factor for treatment decisions. Imaging methods such as EUS, CT and positron emission tomography (PET) play an important role in TNM staging. Compared with CT and PET, EUS is superior for T and N staging of esophageal cancer<sup>[8,9]</sup>. Esophagectomy has been traditionally considered the first option for esophageal carcinosarcoma patients<sup>[1]</sup>. With the advances in micro-invasive techniques, endoscopic procedures, including endoscopic polypectomy, endoscopic mucosal resection and endoscopic submucosal dissection, may represent an alternative to esophagectomy for superficial

esophageal carcinosarcoma<sup>[6]</sup> and are more tolerable, less invasive, less expensive, and most importantly, allow the esophagus to be preserved, compared with traditional esophagectomy.

In our case, endoscopic examination showed a pedunculated polypoid esophageal mass, biopsy indicated the diagnosis of carcinosarcoma, EUS and CT scan showed no evidence of local and distant metastases. Endoscopic polypectomy was subsequently performed. The patient tolerated well to the operation, recovered well, with no relapse during the 17-mo follow-up period, suggesting that endoscopic polypectomy is a promising therapeutic choice for esophageal carcinosarcoma.

In summary, esophageal carcinosarcoma is a rare disease entity. EUS is a useful and accurate method for T and N staging of esophageal carcinosarcoma. Endoscopic therapy is an interesting alternative to surgery for patients with large pedunculated esophageal carcinosarcoma with no involvement of lymph nodes.

**Figure 1 Abdominal CT scan.** A midline cecum (grey arrow) and dilated appendix with a thickened wall containing fecaliths consistent with acute appendicitis (white arrow).

### Abstract

Acute appendicitis is an exceptional cause of left lower quadrant abdominal pain. Computed tomography scan is the key to its diagnosis and helps to establish its early treatment. We present a case of a 35-year-old male patient who presented acute appendicitis with redundant and loosely attached cecum which was diagnosed based on his left lower quadrant abdominal pain.

### TO THE EDITOR

Acute appendicitis remains an exceptional cause of left lower quadrant abdominal pain. We report a case of an otherwise healthy 35-year-old male who presented with a 6-h increasing abdominal pain located in the left lower quadrant. The patient had a low-grade fever (38.4°C) and physical examination demonstrated that he had rebound

tenderness and guarding in the hypogastric and left paraumbilical areas. Laboratory tests revealed mild left-shifted leucocytosis ( $11.8 \times 10^9/L$ , neutrophils: 86%) and elevated C-reactive protein concentration (86.2 mg/L). According to the subtle presentation, an IV-injected and contrast-ingested computed tomography (CT) abdominal scanning showed a tubular, dilated, blind-ending and fluid-filled structure (Figure 1), strongly suggestive of acute appendicitis next to a midline-located cecum. The patient underwent appendectomy through a midline laparotomy. The appendix was acutely inflamed, while the cecum was redundant and loosely attached. Intestinal malrotation was excluded. The patient's postoperative course was uneventful.

Acute appendicitis remains an uncommon cause of left lower quadrant pain, leading to intestinal malrotation or *situs inversus*<sup>[1]</sup>. Such a clinical presentation is anecdotic in the absence of anatomic anomalies<sup>[2]</sup>. The exceptional mobility of the cecum in this case explains the left-sided symptoms. In the context of atypical acute abdominal pain, CT scan is helpful in reducing mortality and morbidity when its prompt and accurate diagnosis is established<sup>[3,4]</sup>. Actually, it is also useful in adopting the midline approach. Isolated acute appendicitis remains an exceptional cause of left lower quadrant pain which can be most accurately explored with abdominal CT scan.

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1179 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gastoesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome, liver biology/pathobiology, liver failure, growth and cancer, liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systematically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Articles: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; (13) Guidelines: To introduce Consensuses and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice in gastroenterology and hepatology.

### Published by

The WJG Press and Baishideng

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjgwjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjgnet.com](mailto:submission@wjgnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive

foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

### Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g.  $6.92 \pm 3.86$  vs  $3.61 \pm 1.67$ ,  $P < 0.001$ ; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, □, ▲, △, etc., in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

## Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub>, not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23243641.

The format for how to accurately write common units and quanta can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first

mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *argI*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindIII*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

## Editorial Office

### World Journal of Gastroenterology

Editorial Department: Room 903, Building D,  
Ocean International Center,  
No.62 Dongsihuan Zhonglu,  
Chaoyang District, Beijing 100025, China  
Telephone: +86-10-59080039  
Fax: +86-10-85381893  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>

## Language evaluation

The language of a manuscript will be graded before it is sent for revision.  
(1) Grade A: priority publishing; (2) Grade B: minor language polishing;  
(3) Grade C: a great deal of language polishing needed; (4) Grade D:  
rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

World Journal of Gastroenterology  
Volume 15 Number 28 July 28, 2009

### INTRODUCTION

*World Journal of Gastroenterology* is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

### Abstract

It has been emphasized that the assessment of residual liver function is of paramount importance to determine the following: severity of acute or chronic liver diseases independent of etiology; long-term prognosis; step-by-step disease progression; surgical risk; and efficacy of antiviral treatment. The most frequently used tools are the galactose elimination capacity to assess hepatocyte cytosol activity, plasma clearance of indocyanine green to assess excretory function, and antipyrine clearance to estimate microsomal activity. However, a widely accepted liver test (not necessarily a laboratory one) to assess quantitative functional hepatic reserve still needs to be established, although there have been various proposals. Furthermore, who are the operators that should order these tests? Advances in analytic methods are expected to allow quantitative liver function tests to be used in clinical practice.

### INTRODUCTION

Liver biopsy is the first-line method for evaluating liver injury. As a result of its limitations and risks, alternative methods have been developed. Many markers and several imaging methods have been evaluated in studies published in peer-reviewed journals. Although the methodological rigor of the design, execution and analysis of the studies proposing new tests has always been ascertained, only their regular use can establish their acceptance among physicians. Probably, nervousness-based medicine plays a role. Fear of litigation is a powerful stimulus to over-investigation, and in an atmosphere of litigation phobia, the only bad test is the test that the physician did not think of ordering<sup>[1]</sup>.

The assessment of liver function has always been considered as important for estimating such things as the severity of any acute or chronic liver disease, and its prognosis and treatment efficacy (Table 1). Generally, methods used to determine cellular damage and related consequences consist of noninvasive and rapid tests, which are easy to perform, e.g. serum enzymes, surrogate serum fibrosis markers, or transient elastography and ultrasound imaging. The first quantitative liver function tests (QLFTs) were suggested almost 50 years ago<sup>[2]</sup>. Their rationale was based on the fact that a drug or a foreign compound is metabolized primarily by the liver cytochrome P450 system, through sequential oxidative processes, and the major metabolite can be detected. The main characteristic of the proposed drug is its relatively high hepatic extraction ratio, but a QLFT depends not only on hepatic metabolic capacity, but also on hepatic blood flow. A more recent study has addressed the clinical utility of measuring galactose elimination capacity (GEC), aminopyrine breath test (ABT) and indocyanine green (ICG) retention test. The results have shown that all QLFTs are predictors of survival in cirrhosis, and that GEC adds new prognostic information to that already available using the Child-Pugh classification<sup>[3]</sup>. In spite of this, relatively few centers perform these tests. Hence, they are currently performed only in very few specialized institutions and usually within the setting of clinical research projects.

More recently, preoperative assessment of liver function and prediction of residual postoperative functional liver parenchymal mass and reserve has been ascertained to be of paramount importance to minimize surgical risk, especially in patients with hepatocellular carcinoma, the

**Table 1** Frequently used QLFTs in patients with liver cirrhosis, chronic viral hepatitis and non-alcoholic liver disease

Type	Methods/drawbacks
GEC	Intravenous administration of galactose; blood samples at 5, 25 and 45 min; urine collected for 5 h
ICG	Measurement of liver plasma flow; injection of ICG must be performed quickly; blood samples at 3, 6 and 49 min
MEGX	Blood samples at 15 and 30 min after i.v. lidocaine administration; allergy to anesthetics
ABT	Resting period of at least 30 min before the breath test that should be repeated three times at 10-min intervals
13C-C breath test	Subjects ingested 2 mg/kg of [3-methyl-13C]-caffeine sitting quietly for 15 min before and throughout the test; breath samples were collected immediately prior to, and 60 min after, caffeine ingestion
13C-M breath test	Measurement of breathed CO <sub>2</sub> by laser-based technology
SCI	Measurement of liver plasma flow. Sorbitol (500 g/L) was administered via a perfusor at 7.5 mL/h. Serum and urinary concentrations of sorbitol were determined at the beginning of the perfusion and after reaching steady-state
TOSCA	Unique sample of saliva to be collected in the morning; rare compliance to drinks containing caffeine by some patients
LURs	Volumetric information as well as functional assessment; expensive
MRI	Expensive; to be validated

QLFTs: Quantitative liver function tests; GEC: Galactose elimination capacity; ICG: Indocyanine green; MEGX: Monoethylglycinexylidide; ABT: Aminopyrine breath test; MRI: Magnetic resonance imaging; LURs: Liver uptake ratios.

majority of whom have liver cirrhosis as a complication. Incorporation of ICG into the decision tree has enabled patients conventionally classified into Child-Pugh class A to be subdivided into several groups in which various hepatectomy procedures are feasible. Applying this choice to 685 patients, during 10 years, only a single fatality was encountered<sup>[4]</sup>. Probably, this is the most important area of application of QLFTs. Indeed, new limits have been established to decrease mortality and morbidity rates after liver resection in cirrhotic and non-cirrhotic patients.

Various laboratory data and imaging techniques have been used to complement the Child-Pugh score to predict liver failure after hepatectomy and to assess functional hepatic reserve. The greatest experience has been made so far with the ABT and GEC, which are decreased among hepatic failure patients after liver resection. However, absence of these changes does not totally exclude hepatic failure. The ICG retention test is the most widely used clearance test. Nevertheless, it remains imperfect because it depends on hepatic blood flow and on the functional capacity of the liver.

Nuclear imaging plays a determinant role in assessing liver function, although it is expensive. Nuclear imaging of the asialoglycoprotein receptors with radiolabeled synthetic asialoglycoproteins provides volumetric information as well functional assessment of the liver<sup>[5]</sup>. Single photon emission computed tomography (SPECT) is superior to the planar method for determining liver uptake ratios (LURs). Evaluation of LURs is a suitable indicator of 99mTc-galactosyl serum albumin clearance from the blood pool and of binding to the asialoglycoprotein receptor, which is a simple and clinically useful indicator for the assessment of hepatic functional reserve in chronic liver diseases<sup>[6]</sup>.

Recent interest toward QLFTs comes from emergency medicine and intensive care physicians. There is no ideal real-time and bedside technique for assessing liver function in critically ill patients. Dynamic tests such as ICG plasma disappearance rate and lidocaine metabolism [monoethylglycinexylidide (MEGX) test], are superior to static tests such as prothrombin time and bilirubin measurement. Recently, the ICG plasma disappearance

rate, which nowadays can be measured reliably by a transcutaneous system in critically ill patients at the bedside and provides results within a few minutes, has been confirmed to correlate well with ICG clearance. In general, the ICG plasma disappearance rate is superior to bilirubin, and comparable or even superior to complex intensive care scoring systems in terms of outcome prediction. Furthermore, ICG plasma disappearance rate is more sensitive than serum enzyme tests for assessing liver dysfunction, and early improvement in the ICG plasma disappearance rate after onset of septic shock is associated with better outcome<sup>[7]</sup>.

## SOME APPLICATIONS OF QLFTs

### Liver cirrhosis

The aim of this report is not to review QLFTs, but to provide a critical appraisal of their extremely selective use. Widespread application of QLFTs as a prognostic tool is controversial. In a recent study, the predictive value of serial evaluations of GEC and MEGX on survival in a cohort of 35 patients was assessed, and secondarily, these tests were compared to Child-Pugh and Model for End Stage Liver Disease (MELD) scores. The end points were patient death or liver transplantation. Statistically significant differences between dead/transplanted patients and survivors were found for basal values of GEC, MEGX, Child-Pugh class and MELD score. Surprisingly, receiver operating characteristic (ROC) curves of Child-Pugh class and MELD score showed a higher prognostic accuracy than GEC and MEGX. On multivariate analysis, neither GEC nor MEGX were independent predictors of survival. Repeated-measures analysis of GEC and MEGX did not increase the prognostic accuracy of these tests, and did not add useful prognostic information on patient outcome during the following 6 mo. These data suggest that neither single nor repeated determinations of GEC and MEGX are superior to Child-Pugh class and MELD score in predicting prognosis of patients with viral cirrhosis<sup>[8]</sup>.

Blood galactose clearance after an intravenous galactose load has been used widely as a QLFT. A novel

QLFT, the galactose single point (GSP) method, has been developed to assess residual liver function in various diseases<sup>[9]</sup>. The goal of that study was to evaluate the influence of non-hepatic factors such as hyperglycemia on GSP and GEC in rats. Four groups of animal studies were carried out, i.e. normal control (NC), streptozotocin-induced diabetes mellitus (DM), CCl<sub>4</sub>-induced hepatotoxicity (CCl<sub>4</sub>), and streptozotocin-induced diabetes with CCl<sub>4</sub>-induced hepatotoxicity (DM + CCl<sub>4</sub>). The serum glucose levels in the diabetic groups (DM and DM + CCl<sub>4</sub>) were significantly increased compared with those in the NC and CCl<sub>4</sub> groups. A significant increase of aspartate aminotransferase and alanine aminotransferase was observed in the CCl<sub>4</sub>-treated groups (CCl<sub>4</sub> and DM + CCl<sub>4</sub>) compared with those in the NC and DM groups. In comparison with the NC group, the values of GSP and GEC in the diabetic groups (DM and DM + CCl<sub>4</sub>) were significantly reduced and increased, respectively. GSP had highly significant correlations with GEC. These results suggest that galactose metabolism tests should be interpreted with caution under conditions of significant hyperglycemia<sup>[9]</sup>.

### **Transplantation**

The unique ability of the liver to regenerate quickly after resection makes living donor liver transplantation (LDLT) possible. However, the quality and course of this regeneration process in humans are still unexplored. In a recent study, GEC, ICG and lidocaine half-life as markers for the quality of liver regeneration in the first 3 mo after LDLT were investigated. Twenty-two consecutive living liver donors and their corresponding recipients were analyzed at baseline and at 10 and 90 d after LDLT. Six recipients lost their grafts during the study period. We compared donors and recipients at the different time points. After LDLT, GEC decreased (-42.6%) and ICG increased (+50.6%) significantly in donors. ICG and GEC remained significantly altered over 3 mo in donors with an improvement between days 10 and 90. ICG and GEC improved significantly in recipients between days 10 and 90. The lidocaine half-life showed no significant changes. The donors had better test results and recovered faster than the recipients. In conclusion, after LDLT, the parameters for liver capacity and flow remain altered in donors and recipients despite rapid volume growth<sup>[10]</sup>.

### **Timing**

The key point of the whole problem is not how to test residual liver function but when. The <sup>13</sup>C-methacetin (13C-M) breath test enables the quantitative evaluation of cytochrome-P450-dependent liver function. 13C-M is metabolized in the liver by O-demethylation to <sup>13</sup>CO<sub>2</sub> and acetaminophen. The aim of a previous study was to evaluate the 13C-M breath test in comparison to the Child-Pugh class and other QLFTs (MEGX and ICG). 13C-M (2 mg/kg) was given orally to 31 patients with histologically proven liver cirrhosis of different etiology and severity (nine Child-Pugh class A, 13 class

B, and nine class C). The increase of exhaled <sup>13</sup>CO<sub>2</sub> was expressed as delta over baseline (DOB; delta/1000). All breath test parameters analyzed provided an excellent discrimination between cirrhotic and non-cirrhotic individuals. The DOB value at 20 min showed a superior correlation with the Child-Pugh class than did MEGX or ICG clearance results. With a cut-off value of  $\leq 25$  delta/1000 at 20 min, sensitivity and specificity to discriminate between cirrhotic and non-cirrhotic individuals was 93.5% and 95%, respectively<sup>[11]</sup>.

### **Pre-cirrhotic stage**

To find out whether this breath test is sensitive in non-cirrhotic patients who also have chronic hepatitis C in the early stages of fibrosis, the following study was carried out. Eighty-one patients with chronic hepatitis C underwent a 13C-M breath test. In all patients, a liver biopsy was performed. The liver histology was classified according to the histology activity index-Knodell score. Patients with early fibrosis did not differ in DOB values from patients at 15 min ( $23.2 \pm 7.9$  per thousand vs  $22.6 \pm 7.2$  per thousand;  $P = 0.61$ ), or cumulative recovery ( $13.6\% \pm 3.7\%$  vs  $13.2\% \pm 3.8\%$ ;  $P = 0.45$ ) from patients with more advanced fibrosis. Conclusively, the noninvasive 13C-M breath test fails to detect early stages of fibrosis in patients with chronic hepatitis C<sup>[12]</sup>.

The 13C-caffeine (13C-C) breath test is a noninvasive, QLFT that is considered to be a valid tool by many authorities. The utility of the 13C-C breath test was measured in 48 patients with chronic hepatitis B and 24 controls, along with its ability to monitor response to lamivudine. In 28 patients on lamivudine, 13C-C breath tests were performed at 1 wk and 1 year after therapy. Patients with Metavir F0-1 fibrosis had a 13C-C breath test similar to the controls. However, patients with F2-3 fibrosis and cirrhosis patients had a decreased 13C-C breath test. Fibrosis correlated best with the 13C-C breath test. The 13C-C breath test independently predicted significant ( $F \geq 2$ ) and advanced ( $F \geq 3$ ) fibrosis and yielded the greatest area under the ROC curve ( $0.91 \pm 0.04$ ) for predicting advanced fibrosis. The 13C-C breath test was unaltered by 1 wk of lamivudine but improved by 61% ( $P < 0.001$ ) in responders to long-term lamivudine, whereas in those with viremia and elevated alanine aminotransferase, values remained stable or deteriorated. The 13C-C breath test distinguishes chronic hepatitis-B-virus-related fibrosis and detects improvement in liver function in response to long-term lamivudine<sup>[13]</sup>.

### **Survival studies**

Caffeine clearance (CCl) has been suggested as a more exact method than those commonly used. The aim of the following study was to assess the usefulness of CCl in survival prediction of patients with liver cirrhosis. Thirty-four patients with cirrhosis of varying etiology were included: 19 were Child-Pugh class A or B and 15 were class C. CCl was determined from saliva samples. The mean length of follow-up was 33.8 mo. A bivariate

survival analysis was carried out following the Kaplan-Meier method, together with a multivariate analysis using the Cox proportional hazards model. Twelve patients died during follow-up. CCl values < 0.24 mL/kg per minutes, age > 60 years, and non-alcoholic cause of cirrhosis were factors predicting lower survival. CCl was the only independent predictive factor in the multivariate analysis. The authors concluded that that CCl enables hepatologists to predict survival in cirrhotic patients and, considering its harmlessness, simplicity and cost, it can be used as a routine procedure in the assessment of these patients<sup>[14]</sup>.

A simplification of this test, the so-called Total Overnight Salivary Caffeine Assessment (TOSCA), comes from another study<sup>[15]</sup> with a further application (patients divided into rapid and slow metabolizers). Furthermore, TOSCA shows near complete safety (patients drink one or two cups of coffee according their habit in the morning). One drawback of QLFTs is the possible occurrence of severe side effects that are sometimes life-threatening (e.g. anaphylaxis).

Magnetic resonance imaging (MRI) offers several advantages. Gadolinium methoxybenzyl diethylenetriamine penta-acetic acid is a newly developed MR contrast agent. Its hepatic extraction fraction is a direct, noninvasive technique for the quantitative evaluation of liver function. It may be a promising alternative, although expensive, for the determination of noninvasive hepatic function in patients with liver disease<sup>[16]</sup>.

### **Antiviral therapy**

Whether and to what extent does antiviral therapy for chronic hepatitis C influence a broad panel of QLFTs? Fifty patients with chronic hepatitis C were treated with interferon ( $n = 8$ ), interferon/ribavirin ( $n = 19$ ) or peg-interferon/ribavirin ( $n = 23$ ). Quantitative testing of liver function, including ABT, GEC, sorbitol clearance (SCI) and ICG clearance was performed before and 3 mo after initiation of antiviral therapy. After 3 mo, 36 patients showed normal transaminases and were negative for hepatitis C virus RNA, and 14 patients did not respond to therapy. ABT and GEC as parameters of microsomal and cytosolic liver function were reduced in all patients before therapy initiation and returned to normal values in the 36 therapy responders after 3 mo. Parameters of liver perfusion (SCI and ICG) were not affected by antiviral therapy. In the 14 non-responders, no changes in QLFT values were observed during the treatment period. ICG and SCI remained unaffected in patients with chronic hepatitis C, while ABT and GEC were significantly compromised. ABT and GEC normalized in responders to antiviral therapy. Early determination of ABT and GEC may differentiate responders from non-responders to antiviral treatment in hepatitis C<sup>[17]</sup>.

### **Assessing liver regeneration**

Improvement of nitrogen balance is desirable in patients with acute or chronic illness. Both growth hormone and insulin-like growth factor-I are promising anabolic agents, and their combined administration has been shown to reverse catabolism more efficiently than each

of the peptides alone. The capacity of urea-nitrogen synthesis [ $\mu\text{mol}/(\text{min} \times 100 \text{ g body weight})$ ] was evaluated in rats, unravelling a neglected QLFT, based on mitochondrial-cytosolic metabolic capacity (M-CMC) for conversion of amino-nitrogen<sup>[18]</sup>. Following this approach, the authors used GEC to assess hepatocyte cytosol activity, plasma clearance of ICG to assess excretory function, antipyrine clearance to estimate microsomal activity, and functional hepatic nitrogen clearance<sup>[19]</sup> to assess M-CMC in females with Turner syndrome<sup>[19]</sup>.

### **Non-alcoholic steatohepatitis (NASH)**

Finally,  $^{13}\text{C}$ -C, a noninvasive tool for the evaluation of the cytochrome P450 system, which is implicated in the development of NASH, has been proposed in patients with metabolic dysfunction. Up-to-date research has demonstrated that  $^{13}\text{C}$ -C can predict reliably severe hepatic fibrosis in patients with the most severe form of non-alcoholic fatty liver disease (NAFLD). Although this test does not quantify the residual functional liver mass, it is safe and easy to perform. Further large-scale studies are needed to verify its reliability<sup>[20]</sup>. A previous study that tested  $^{13}\text{C}$ -M and  $^{13}\text{C}$ -ketoisocaproate for microsomal and mitochondrial liver function has demonstrated its usefulness for better and noninvasive characterization of patients with NAFLD<sup>[21]</sup>. It is worth stressing that every breath test can be affected badly by severe restrictive lung disease, and in elderly patients with chronic heart failure<sup>[22]</sup>.

Unfortunately, MRI findings of liver steatosis and fibrosis in NASH show moderate correlations with histopathological grade of steatosis and stage of fibrosis, but MRI findings of NASH do not demonstrate any significant correlations with MELD score<sup>[23]</sup>. Liver scintigraphy (SPECT) might be a promising noninvasive tool in the follow-up of NASH patients in therapeutic trials<sup>[24]</sup>.

## **CONCLUSION**

While liver function is absolutely complex, a widely accepted test to assess quantitative functional hepatic reserve still needs to be established, although there are various tests currently available. The diagnostic and prognostic gain has been quantified as modest. A new condition in which it may be useful to test residual liver function is acute liver disease<sup>[25]</sup>. Focusing on some aspects of controversial conclusions, or those not supported by very positive results, in the context of the current doctrine is always provocative, although it provides scientists and physicians with responsible and balanced information to support experimental and clinical decisions. Future technical advances may lead to a decrease in time, cost and the number of subjects required to perform QLFTs, therefore, their use in clinical practice is expected to increase.

### Abstract

Alcoholic liver disease (ALD) and hepatitis C virus (HCV) infection represent, either alone or in combination, more than two thirds of all patients with liver disease in the Western world. This review discusses the epidemiology and combined impact of ALD and HCV on the progression of liver disease. ALD and HCV affect the progression of liver disease to liver cirrhosis and hepatocellular carcinoma (HCC) in a synergistic manner. Thus, the risk for HCC increases five times with a daily alcohol consumption of 80 g; in the presence of HCV it is increased 20-fold, and a combination of both risk factors leads to a more than 100-fold risk for HCC development. Alcohol consumption also decreases the response to interferon treatment which is probably due to a lack of compliance than a direct effect on HCV replication. Several molecular mechanisms are discussed that could explain the synergistic interaction of alcohol and HCV on disease progression. They include modulation of the immune response and apoptosis, increased oxidative stress via induction of CYP2E1 and the hepatic accumulation of iron. Thus, both HCV and alcohol independently cause hepatic iron accumulation in > 50% of patients probably due to suppression of the liver-secreted systemic iron hormone hepcidin. A better understanding of hepcidin regulation could help in developing novel therapeutic approaches to treat the chronic disease in the future. For now, it can be generally concluded that HCV-infected patients should abstain from alcohol and alcoholics

should be encouraged to participate in detoxification programs.

### INTRODUCTION

Together, alcoholic liver disease (ALD) and chronic hepatitis C virus (HCV) infection are the most frequent chronic liver diseases in the Western world. In addition, they frequently coexist in the same individual. While both diseases alone have a similar progression sequence leading to cirrhosis in circa 15% of patients within 10-20 years, their coexistence dramatically enhances disease progression in a so-called synergistic manner. This synergism affects both fibrosis progression and the development of hepatocellular carcinoma (HCC). The basic molecular mechanisms of this synergism are far from being understood but may include increased production of reactive oxygen species (ROS) and deposition of iron. In the present article, we review and discuss the epidemiology of ALD and HCV infection, the synergistic impact of combined alcohol and HCV on the progression of liver disease, viral replication and response to anti-HCV treatment. We finally analyze potentially

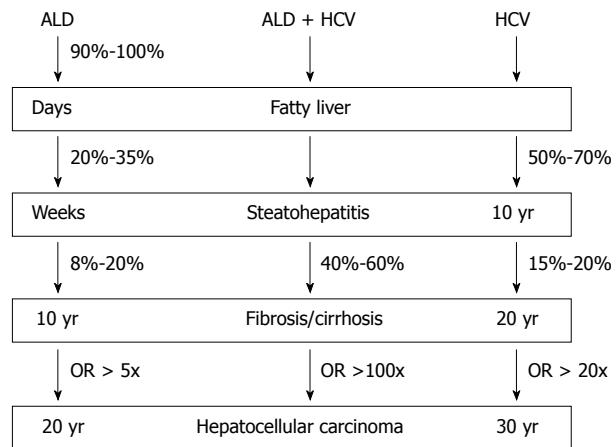

**Figure 1** HCV and ALD, either in combination or alone, represent the majority of liver diseases (data from the US Centers of Disease Control and Prevention 2007). HCV: Hepatitis C virus; ALD: Alcoholic liver disease; HBV: Hepatitis B virus.

underlying mechanisms that may explain the interaction between alcohol and HCV and offer novel molecular strategies for future therapeutic interventions.

## EPIDEMIOLOGY OF ALD AND HCV

Chronic alcohol consumption causes approximately 50% of the chronic liver disease burden in Germany and the death of more than 18000 inhabitants per year<sup>[1]</sup>. In the US alcohol is also responsible for more than 50% of liver related deaths, and ALD is a major health care cost expenditure, accounting for nearly \$3 billion annually<sup>[2]</sup>. At present, the country with the fastest increase in alcohol associated health problems is the Peoples Republic of China with an annual per capita increase in alcohol consumption of 400% and more in some geographic regions<sup>[3]</sup>. The exact number of alcohol related deaths is difficult to obtain due to inaccurate reporting of ethanol use. Since patients with compensated liver cirrhosis may often die by causes not obviously related to liver disease e.g. infectious complications, official mortality tables most likely underestimate the true prevalence of ALD. If the relationship between alcohol intake and prevalence of ALD is examined on a population basis, the risk of developing ALD starts at 20-30 g ethanol per day. Liver cirrhosis develops only in 10%-20% of people consuming more than 80 g of ethanol daily<sup>[2]</sup>. Approximately 5% of the whole population in the US meet diagnostic criteria for alcoholism<sup>[4]</sup>. In Germany, more than 17.8% of the population > 18 years drink more than 20-30 g of alcohol per day<sup>[5]</sup>, and a comparable number of 5% show high risk drinking behavior (> 80 g/d)<sup>[5]</sup>.

In contrast to ALD, the prevalence of HCV is easier to determine based on serological studies. The worldwide seroprevalence of HCV antibodies is estimated to be 3% with marked geographic variations from 1% in North America to 10% in North Africa<sup>[6]</sup>. The prevalence is higher in males than in females (2.5% vs 1.2%) and is highest in the 30-49 years old age group<sup>[7]</sup>. Taken together, there is an estimated prevalence of high risk drinking and HCV of 1%-5% in the Western world. According to re-

**Figure 2** Natural course of ALD and HCV alone or in combination. Estimated risk and time interval for disease states are indicated (for more details see text).

cent data from the Center of Disease Control and Prevention, the prevalence of HCV and ALD is relatively similar at 26% and 24%, respectively. Although there is a selection bias, these prevalence data are somehow reflected by large transplant centers. In our transplant center at the University of Heidelberg, liver cirrhosis due to HCV and ALD are leading causes for liver transplantation accounting for 32% and 24%, respectively, of all liver transplants. In summary, HCV and ALD represent either alone or in combination, more than two thirds of all patients with liver disease in the Western world<sup>[8]</sup> (Figure 1).

## NATURAL COURSE OF ALD AND HCV AND IMPORTANT PROGRESSION FACTORS

ALD is the most important organ manifestation of chronic alcohol consumption. Ninety percent to one hundred percent of heavy drinkers develop alcoholic fatty liver. Ten percent to thirty-five percent of them develop alcoholic steatohepatitis and 8%-20% develop alcoholic liver cirrhosis within 10-20 years<sup>[9]</sup>. The natural course of ALD and HCV is given in Figure 2. Due to better treatment options for complications of liver cirrhosis e.g. variceal bleeding, the prevalence of HCC is increasing with an annual risk of 1%-2%. HCC represents the most common cause of death in patients with ALD. HCV shows a similar progression pattern. In a US study, the mean interval between HCV infection, chronic hepatitis, cirrhosis and HCC was circa 10, 20 and 30 years, respectively<sup>[10]</sup>. A large cohort study with long-term follow up showed that 75% of HCV-infected patients develop persistent infection while severe progressive liver disease occurred in 15%-20%<sup>[11]</sup>.

Factors that contribute to progression of ALD and HCV are summarized in Table 1. For ALD, these include the amount of alcohol consumed over a life time<sup>[12,13]</sup>, drinking patterns, and nutritional status. Both malnutrition and obesity are associated with an increased risk for alcoholic cirrhosis<sup>[14-16]</sup>. This is especially relevant with the endemic occurrence of non-alcoholic fatty liver disease

	Amount and duration of alcohol consumption
	Continuous drinking ( <i>vs</i> sporadic drinking)
	Overweight/malnutrition
Hepatic iron deposition age > 40	Hepatic iron deposition
Immunosuppression	Vitamin A, co-medication

ALD: Alcoholic liver disease; HCV: Hepatitis C virus.

(NAFLD) in the Western World due to obesity and being overweight associated with diabetes mellitus type II and peripheral insulin resistance. Co-medication of certain drugs together with ethanol may also harm the liver by increased conversion to toxic metabolites due to induced enzyme systems. This is well known for acetaminophen<sup>[17]</sup>, methotrexate<sup>[18]</sup> and the tuberculostatic drug isoniazid<sup>[17]</sup> but also occurs with retinoids such as β-carotin and vitamin A<sup>[19]</sup>. Males and females show different courses of ALD and HCV. While females are more susceptible to alcoholic damage, they progress slower in chronic HCV infection. Other important factors that contribute to disease progression in ALD are co-morbidities such as HBV, hemochromatosis, and Wilson's disease. Factors associated with HCV progression are co-infection with HBV, HIV, schistosomiasis or conditions of immunosuppression. Finally, iron accumulation has been recognized both in ALD and HCV as an independent risk factor for the development of HCC. Pathological hepatocellular iron deposits are found in more than 50% of patients with either HCV or ALD. Underlying mechanisms and potential therapeutic options are still under investigation.

## EFFECT OF ALCOHOL ON THE PREVALENCE OF HCV INFECTION

Chronic alcoholics have an increased prevalence of HCV infection, increasing with the severity of the ALD. Takase *et al*<sup>[20]</sup> showed that HCV prevalence demonstrated by anti-HCV positivity increases with the severity of ALD, having a prevalence of approximately 5% in alcoholic fibrosis, almost 40% in alcoholic cirrhosis and almost in 80% in HCC due to alcohol. This could be due to the lifestyle of chronic alcoholics, since many of them are also intravenous drug abusers, which is a high risk for HCV infection. It could also be due to the immunosuppressive effect of alcohol decreasing the HCV-clearance rate after infection since it has been shown that alcohol suppresses the function of various immune components including natural killer cells, neutrophils, monocytes and others<sup>[21]</sup>.

## ALCOHOL CONSUMPTION, HCV REPLICATION AND RESPONSE TO HCV THERAPY

A great number of studies emphasize the fact that

alcoholics respond poorly to interferon therapy. More than ten years ago, Mochida *et al*<sup>[22]</sup> showed that almost 30% of non-alcoholics responded biochemically and virologically to interferon therapy compared to less than 10% of alcoholics. The question remained open whether this is due to a direct inhibitory effect of alcohol on interferon response or due to poor compliance of these patients. Pessione *et al*<sup>[23]</sup> studied serum HCV RNA in HCV patients with increasing alcohol intake (reported in gram per week). In this study a significant dose-dependent increase in serum HCV RNA was noted starting from 70 g alcohol per week. In line with this observation, a decrease of alcohol consumption prior treatment of hepatitis C significantly reduced viral load. In addition, Cromie *et al*<sup>[24]</sup> showed that viral load decreased highly significantly within 4 mo when patients cut down on alcohol consumption from 39-100 g/d to 0-50 g/d. More recent data, however, clearly suggest that the poor response of alcoholics towards interferon therapy is more likely due to reduced compliance. In this study, the recorded alcohol consumption during the months before HCV treatment was associated with an increased rate of therapy drop out (3% *vs* 26%,  $P = 0.002$ )<sup>[25]</sup> while the response rate was comparable (25% *vs* 23%) after correction for this confounding factor. In conclusion, poor compliance of alcoholics is probably the major cause for poor antiviral response to HCV therapy.

## COMBINED EFFECTS OF ALCOHOL AND HCV ON FIBROSIS PROGRESSION

A huge number of studies have shown that concomitant alcohol consumption in the presence of HCV increases progression of fibrosis<sup>[23,26-54]</sup>. This means that fibrosis occurs at an earlier time point and its development is accelerated. A summary of selected studies on alcohol consumption and fibrosis progression is given in Table 2. Thus, it has been shown in more than 2000 HCV patients that fibrosis progression was significant ( $P < 0.001$ ) if more than 50 g/d alcohol is consumed<sup>[26]</sup>. Similar results were obtained by Roudot-Thoraval *et al*<sup>[27]</sup> with a prevalence of cirrhosis of 35 % *vs* 18 % ( $P < 0.001$ ). Pessione showed in more than 200 HCV patients that weekly alcohol consumption correlated significantly with fibrosis score<sup>[23]</sup>. He also showed that the relative risk for decompensated cirrhosis correlated with alcohol intake. Alcohol-driven fibrogenesis in HCV patients is dose-dependent and starts at less than 30 g/d. Overweight and obese patients as well as type II diabetics are especially sensitive to fibrosis progression<sup>[55]</sup>. HCV patients with excessive alcohol abuse have a 2-3 fold increased risk of severe liver disease compared with HCV patients without a history of drinking<sup>[56]</sup>. So far it is still unclear how long a patient has to abstain from alcohol before the negative effect of alcohol is abolished<sup>[57]</sup>. Alcoholics with HCV infection seem to stop drinking more frequently compared to alcoholics without HCV infection. This is possibly due to a higher awareness in these patients that liver disease can lead to cirrhosis and death without a change in lifestyle<sup>[58]</sup>. Finally, it has been a

**Table 2 Fibrosis progression in HCV and alcohol consumption from selected studies**

No. of patients	Alcohol consumption	Results	Ref.
2235	0 g, < 50 g, > 50 g	> 50 g independent risk factor for fibrosis progression ( $P < 0.001$ )	[26]
6664	> 5/6 drinks (female/male), > 1 year	Higher risk of cirrhosis (35% vs 18%)	[27]
176	> 40/60 g (female/male), > 5 years	Faster cirrhosis progression (58% vs 10%), 2-3 fold increased risk of developing cirrhosis	[29]
168	Low < 30, medium 30-80; high > 80 g/d, > 5 J	Alcohol consumption low/medium/high significantly different between non-cirrhotics (58%/27%/16%) and cirrhotics (76%/15%/9%) ( $P < 0.05$ )	[28]
234	Lifetime alcohol consumption	Cirrhotics have greater alcohol consumption than patients with hepatitis (240 g/wk vs 146 g/wk) ( $P = 0.02$ )	[30]
233	0, 25, 50, 75, 100, > 125 g	Weekly alcohol consumption correlates with serum HCV RNA levels and fibrosis score ( $P < 0.001$ )	[23]
702	0/175 g/d	HCV increases OR for cirrhosis from 1 to 15 (0 g), 9.2 to 147.2 (175 g)	[141]
1667	Subgroup: > 260 g/wk vs < 90 g/wk	Risk for cirrhosis increases by 3.6	[31]
636	> 80	RR for cirrhosis: HCV 7.8, HCV + alcohol 31.1	[32]

continuous debate whether small amounts of alcohol (< 20-30 g/d) alter progression in HCV infection. An answer may come from a Scandinavian study by Westin *et al*<sup>[59]</sup>. These authors investigated 78 patients with hepatitis C infection who underwent two liver biopsies in a mean interval of 6.3 years. Alcohol consumption was less than 40 g/d. The authors found progressive fibrosis with (a) increased total alcohol consumption (15.4 kg vs 3.9 kg;  $P = 0.007$ ), (b) increased daily alcohol consumption (5.7 g vs 2.6 g/d;  $P = 0.03$ ) and (c) increased frequency of drinking occasions (35 vs 8 d per year;  $P = 0.006$ ). These results underscore that even small amounts of alcohol may increase fibrosis progression in HCV. Confirmation comes from another prospective study by Hezode *et al*<sup>[60]</sup> who showed an impact of mild alcohol consumption on histological activity and fibrosis starting as low as 20 g/d.

## ROLE OF ALCOHOL AND HCV ON DEVELOPMENT OF HCC

Various studies have shown that there is an increased risk of HCC in patients with HCV and alcohol abuse compared to either HCV or ALD alone<sup>[61-68]</sup>. Since these studies vary considerably in their definition of alcohol abuse, Table 3 is restricted to comparable studies that tried to identify the independent contribution of HCV and ALD to HCC development. It can be concluded from these data, that a daily uptake of > 80 g alcohol alone increases HCC risk 5-fold while the presence of HCV alone increases HCC 20-fold. A combination of both risk factors increases the risk for HCC development over 100-fold. Thus, HCV and alcohol act truly synergistic on HCC development.

## POSSIBLE MECHANISMS FOR THE SYNERGISM OF ALCOHOL AND HCV

The underlying molecular mechanisms of alcohol and HCV-mediated liver disease are complex and they are still incompletely understood despite intensive efforts over decades.

Both alcohol and HCV can reproduce the four sequential hallmarks of liver disease: steatosis, steato-

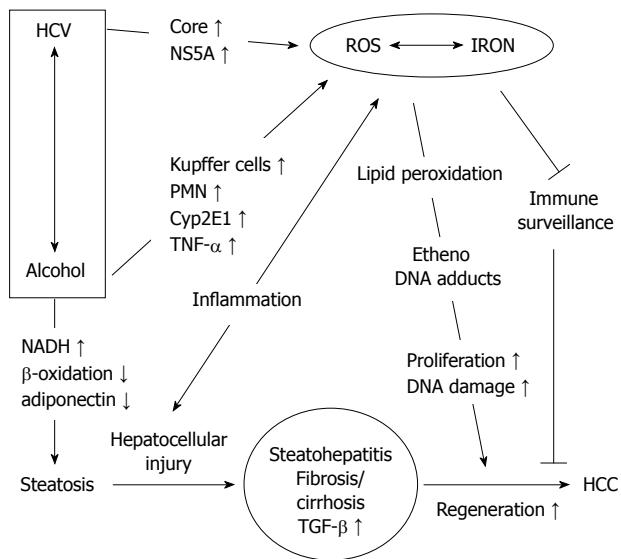

**Table 3 Odds ratio for the development of HCC as a function of HCV seroprevalence and amount of alcohol consumption**

Alcohol consumption (in grams alcohol per day)

hepatitis, fibrosis and HCC. Molecular key features of ethanol and HCV mediated liver damage include direct biochemical consequences of alcohol metabolism such as the production of acetaldehyde, generation of reactive oxygen species (ROS) and oxidative damage, epigenetic modifications such as hypomethylation of histones and modulation of the signaling machinery. Some of these events lead to similar downstream effects such as fatty liver, ROS and iron accumulation but are based on different mechanisms which could well explain the synergistic effects of alcohol and HCV on the liver. Thus, steatosis in HCV is mainly caused by impairment of mitochondria preventing mitochondrial metabolism of fatty acids, while ethanol primarily stimulates lipogenesis. On the other hand, HCV and ethanol both stimulate ROS generation via distinct mechanisms and they both lead to hepatic iron accumulation, one of the most pro-fibrogenic and protumorigenic factors in liver disease. For this reason, ROS generation and iron accumulation are discussed separately below. It should also be mentioned that alcohol may have direct molecular effects on HCV infection since it exerts stimulatory effects on HCV replication probably via signaling pathways<sup>[69]</sup>. The enhanced quasispecies complexity in the hypervariable region 1 of HCV in alcoholics may be one major cause that sensitizes for faster disease progression<sup>[70]</sup>.

### Alcohol, HCV and liver damage

Ethanol biochemically leads to a shift towards NADH which ultimately stimulates lipogenesis. In addition,

**Figure 3** Potential molecular mechanisms that explain the synergistic effect of alcohol and HCV on the progression of liver disease. Reactive oxygen species (ROS) and iron accumulation seem to be key features of both diseases.

ethanol is metabolized to the mutagenic metabolite acetaldehyde and during that reaction ROS are produced mainly as a byproduct of CYP2E1. Additional mechanisms include the release of cytokines such as TNF- $\alpha$ , which increases free fatty acid release from adipocytes in the periphery of the liver<sup>[71]</sup>, stimulates lipogenesis in hepatocytes<sup>[72]</sup>, and inhibits  $\beta$ -oxidation of fatty acids<sup>[73]</sup>. Chronic ethanol consumption also impairs transport and secretion of triglycerides as VLDL<sup>[74]</sup> which again leads to an increased hepatic fat accumulation. Activation of macrophages by lipopolysaccharides *via* the toll-like receptor 4 (TLR-4) leads to the production of a variety of inflammatory mediators, such as TNF- $\alpha$  and ROS. HCV also leads to steatosis but in contrast to ALD mainly *via* a decreased mitochondrial  $\beta$ -oxidation with ultrastructural alterations of hepatocyte mitochondria in more than half of the patients. This means that HCV and alcohol stimulate fat accumulation in the liver *via* distinct mechanisms. In addition to its role in steatosis, abnormal production of TNF- $\alpha$  is also a critical inflammatory component in the liver induced by chronic ethanol exposure<sup>[75,76]</sup>. Although direct exposure of macrophages in culture can mimic some of the effects of ethanol<sup>[77,78]</sup>, there seem to be multiple hepatic and extra-hepatic consequences of ethanol that finally render Kupffer cells more reactive to LPS, leading to generation of ROS and ROS-modulated signal transduction cascades<sup>[79,80]</sup>. The fat regulating hormone adiponectin also seems to be involved in ethanol mediated steatohepatitis<sup>[81-83]</sup>. Some data indicate that ethanol directly drives fibrosis progression: acetaldehyde is supposed to increase TGF- $\beta$ 1 secretion<sup>[84]</sup> and both ethanol and acetaldehyde induce accumulation of collagen<sup>[85]</sup>. Similar findings have been shown for HCV-replicating hepatoma cells<sup>[86]</sup>.

HCC pathogenesis by ethanol seems to require several factors<sup>[87]</sup> including the presence of cirrhosis, oxidative stress, altered methyl transfer resulting in

DNA hypomethylation, and a decrease in retinoic acid. In addition, co-morbidities such as viral hepatitis, diabetes mellitus and obesity are known to accelerate HCC development in patients with ALD. ROS play an important role in hepatocarcinogenesis<sup>[87,88]</sup>. Chronic ethanol consumption results in the generation of ROS *via* multiple pathways leading to lipid peroxidation (LPO) and LPO-byproducts such as 4-hydroxy-2-nonenal (4-HNE) and malondialdehyde (MDA). These DNA-reactive aldehydes in turn form mutagenic exocyclic DNA adducts including 1, N6-ethenodeoxyadenosine (edA) and 3, N4-ethenodeoxycytidine<sup>[89,90]</sup>.

#### Role of ROS in HCV and ALD

The generation of ROS seems to be a hallmark of both ALD and HCV<sup>[91-95]</sup> (Figure 3). While location and mechanisms of their generation differ markedly between ALD and HCV, downstream events of oxidative damage are similar due to the high but rather unspecific reactivity of species such as hydroxyl radicals or lipid peroxidation products. Hepatocyte mitochondria are structurally altered in more than 50% of HCV patients and these conditions are accompanied by a significant depletion of hepatocellular and lymphocyte glutathione (GSH), an increase of oxidized GSH (GSSG) and the lipid peroxidation marker malondialdehyde<sup>[91]</sup>. ROS are either induced directly by the virus or indirectly through activation of inflammatory cells. HCV core<sup>[96]</sup> and NS5A<sup>[96,97]</sup> have been implicated in generating ROS *via* mitochondrial damage and calcium release.

ROS also play an important role in alcohol-induced liver injury and in hepatocarcinogenesis<sup>[87-90]</sup>. Several enzyme systems are capable of producing ROS including the mitochondrial respiratory chain, the cytosolic enzymes xanthine oxidase and aldehyde oxidase, as well as the microsomal cytochrome P450-dependent mono-oxygenases<sup>[88]</sup>. One member of the latter system, cytochrome P450 2E1 (CYP2E1), is involved in the major pathway by which ethanol generates oxidative stress. Expression of CYP2E1 has been shown to correlate well with the generation of hydroxyethyl radicals and with LPO products such as 4-HNE and MDA<sup>[98]</sup>. CYP2E1 is induced by chronic alcohol consumption within a week even at a relatively low ethanol dose (40 g/d), but the degree of CYP2E1 induction shows high variations between individuals<sup>[99]</sup>. Inhibition of CYP2E1 by chlormethiazole, a specific CYP2E1 inhibitor, improved ALD as shown in the Tsukamoto-French rat model<sup>[100]</sup>. An increase of oxidative DNA adducts and of mutagenic apurinic and apyrimidinic DNA sites has been found in chronically ethanol-treated wild-type mice but not in mice that lack functional CYP2E1<sup>[101]</sup> further stressing the importance of CYP2E1 in the generation of DNA damage following ethanol ingestion. Increased levels of Cyp2E1 also potentiate pro-apoptotic effects of TGF- $\beta$  resulting in increased cell death of hepatocytes<sup>[102]</sup>. Recently, we have been able to detect etheno-DNA adducts such as edA in the livers of patients with ALD<sup>[89,103]</sup>.

Kupffer cells are also an important source of ROS

during ethanol exposure<sup>[93]</sup> and in response to LPS<sup>[104]</sup>. NADPH oxidase-dependent production of ROS is implicated in ethanol-induced liver injury since p47phox -/- mice which are deficient in this regulatory subunit of NADPH oxidase are resistant to chronic ethanol-induced injury<sup>[105]</sup>. Chronic ethanol feeding increases the LPS-stimulated production of ROS by Kupffer cells; this increase is primarily due to an increase in NADPH oxidase activation after chronic ethanol feeding<sup>[81]</sup>. Recently, Thakur and colleagues have specifically identified NADPH oxidase-derived ROS as an important contributor to increased TLR-4 mediated signal transduction and TNF- $\alpha$  expression in rat Kupffer cells, particularly after chronic ethanol exposure<sup>[81]</sup>.

### **Ethanol and HCV lead to hepatic iron accumulation**

In contrast to hepatitis B infection, iron deposits are found in more than 50% of patients with HCV infection or chronic ethanol consumption<sup>[96,106-109]</sup>. Even mild to moderate alcohol consumption has recently been shown to increase the prevalence of iron overload<sup>[110]</sup>. Iron localization has been reported in Kupffer cells<sup>[108]</sup> as well as in hepatocytes<sup>[111-113]</sup>. In our experience, iron accumulation is more common in hepatocytes than Kupffer cells in patients with ALD. Increased hepatic iron content is associated with greater mortality from alcoholic cirrhosis, suggesting a pathogenic role of iron in ALD. Genetic hemochromatosis in conjunction with excessive alcohol consumption exacerbates liver injury<sup>[100]</sup>. It should be mentioned that iron *per se* is the most profibrogenic and genotoxic factor and 50% of patients with hereditary hemochromatosis develop fibrosis and have a 200-fold increased risk for HCC<sup>[114]</sup>. On the other hand, immune surveillance can be impaired by iron overload, since it compromises anti-tumor activity of macrophages<sup>[115-117]</sup>.

The underlying mechanisms of iron accumulation observed in ALD and HCV are still poorly understood but seem to involve an inadequate upregulation of the iron hormone hepcidin. Genome wide microarray based screening for candidate genes that could cause iron overload involved several genes not yet linked to iron metabolism<sup>[118]</sup>. Preliminary data from ALD patients and ethanol-treated mice models suggest that hepatic iron uptake pathways are increased in the liver and potential mechanisms involve an increase of the transferrin receptor (TfR)1 and repression of the systemic iron hormone hepcidin that controls duodenal iron absorption and RES-mediated iron release *via* the iron exporter ferroportin<sup>[119,120]</sup>. Using novel *in vitro* and *in vivo* models<sup>[121,122]</sup>, we have recently demonstrated that H<sub>2</sub>O<sub>2</sub> alone increases TfR1 *via* posttranscriptional and translation mechanisms ultimately leading to cellular accumulation of iron<sup>[123,124]</sup>. These data show that chronic exposure of cells to non toxic levels of H<sub>2</sub>O<sub>2</sub> lead to accumulation of iron *via* distinct regulatory mechanisms promoting Fenton chemistry. We suggest that increased oxidative stress in the form of H<sub>2</sub>O<sub>2</sub> is an important regulatory factor that causes continuous iron accumulation and may support ALD progression.

Valuable information on the direct interaction of HCV with host metabolism has been gained from studies with genetically modified animals, though with some controversial results<sup>[125]</sup>. Thus mice transgenic for the total open reading frame of HCV under the murine albumin promoter developed steatosis and liver cancer<sup>[126,127]</sup>, but this association disappeared in later generations of animals, casting doubt on the earlier conclusions that HCV infection alone (in the absence of cirrhosis and iron overload) drives hepatic carcinogenesis<sup>[109,128,129]</sup>. In addition, iron overload induced in mice either through diet<sup>[130,131]</sup> or genetic deletion of the HFE locus<sup>[132]</sup> did not lead to advanced fibrosis or HCC. In HCV transgenic mice, hepcidin was found to be suppressed despite iron loading. This is unexpected, since hepcidin inhibits cellular iron efflux by inducing internalization of ferroportin<sup>[133]</sup>, an iron exporter that is expressed in macrophages, hepatocytes and intestinal cells. The mechanism by which hepcidin was downregulated in the present model remains elusive, since cytokines such as TNF- $\alpha$ , IL-1 $\beta$  and IL-6 which can upregulate hepcidin levels<sup>[134,135]</sup> were not suppressed. Other important players such as iron regulatory proteins (IRP1 and IRP2) which sense iron but also ROS at the cellular level have not been assessed<sup>[136]</sup>.

Finally, it has also been investigated whether iron directly affects HCV replication. In hepatoma cells iron loading promoted reporter expression under the control of regulatory HCV mRNA stem-loop structures by upregulating expression of the translation initiation factor 3eIF3<sup>[137]</sup>. In contrast, iron was shown to suppress HCV replication by inactivating the RNA polymerase NS5B<sup>[138]</sup>. Clinical data indicate that iron status does not significantly influence HCV replication *in vivo*, since the response to therapy of patients with  $\beta$ -thalassemia was not influenced by the degree of iron accumulation<sup>[139]</sup>, and venesection did not reduce hepatitis C viral load<sup>[140]</sup>. Taken together, iron accumulation in patients with HCV and ALD is an important progression factor. The underlying mechanisms are being intensively studied in search for novel therapeutic approaches.

### **CONCLUSION**

ALD and HCV are the most common liver diseases in the Western world either alone or in combination. Coexistence of both diseases has a true synergistic effect on fibrosis progression and HCC development. Thus, a daily consumption of more than 80 g alcohol increases the risk for HCC 5-fold, in the presence of HCV 100-fold while HCV alone increases the risk for HCC 20-fold. Alcohol abusers have an increased prevalence of HCV infection probably due to lifestyle or to immune suppression. Alcoholics also have a decreased response rate to antiviral therapy which is most probably due to poor compliance. There is obviously no safe level of drinking in patients with hepatitis C and it remains unclear how long abstinence is necessary to abolish the negative effect of alcohol on the liver. Potential mechanisms which may explain the synergistic negative effect of alcohol

and HCV infection on liver disease include generation of ROS, iron accumulation, steatosis induction, immune modulation, stimulation of HCV replication and direct DNA damage. Abstaining from drinking in HCV patients who do not respond to antiviral treatment is the sole efficient treatment option to date. A better understanding of the underlying molecular mechanisms could help to develop novel targeted treatment options.

### Abstract

Hepatitis C is recognized as a major threat to global public health. The current treatment of patients with chronic hepatitis C is the addition of ribavirin to interferon-based therapy which has limited efficacy, poor tolerability, and significant expense. New treatment options that are more potent and less toxic are much needed. Moreover, more effective treatment is an urgent priority for those who relapse or do not respond to current regimens. A major obstacle in combating hepatitis C virus (HCV) infection is that the fidelity of the viral replication machinery is notoriously low, thus enabling the virus to quickly develop mutations that resist compounds targeting viral enzymes. Therefore, an approach targeting the host cofactors, which are indispensable for the propagation of viruses, may be an ideal target for the development of antiviral agents because they have a lower rate of mutation than that of the viral genome, as long as they have no side effects to patients. Drugs targeting, for example, receptors of viral entry, host metabolism or nuclear receptors, which are factors required to complete the HCV life cycle, may be more effective in combating the viral infection. Targeting host cofactors of the HCV life cycle is an attractive concept because it imposes a higher genetic barrier for resistance than direct antiviral compounds. However the principle drawback of this strategy is the greater potential for cellular toxicity.

### INTRODUCTION

Chronic hepatitis C virus (CHC) infects approximately 170 million individuals worldwide and is a major cause of mortality and morbidity<sup>[1]</sup>.

Egypt has the highest hepatitis C virus (HCV) prevalence in the world (overall prevalence of HCV is 12% among the general population, reaches 40% in persons above 40 years of age and is more in rural areas)<sup>[2,3]</sup>.

HCV is an RNA virus that belongs to the family *Flaviviridae* with six known genotypes (numbered 1-6) and more than 50 subtypes (e.g. 1a, 1b, 2, etc)<sup>[4]</sup>. In general, the genetic make-up of the HCV genotype varies by about 30%-35% between its different genotypes<sup>[5,6]</sup>, and these differences in genotype are related to response to antiviral treatment.

Current treatment for patients with CHC is interferon-based therapies with ribavirin for 24-48 wk. Unfortunately, a sustained virological response (SVR) is achieved in only 42%-52% of treatment-naïve patients, and the rest of patients either show no response or experience a relapse when therapy is stopped<sup>[7]</sup>, with a wide profile of side effects.

The mechanisms underlying the failure of interferon therapy are not well understood, but evidence indicates that in addition to viral factors, several host factors are also involved<sup>[8]</sup>. So, CHC patients still need a novel approach for treatment of HCV infection.

A major obstacle in combating HCV infection is that the fidelity of the viral replication machinery is notoriously low, thus enabling the virus to quickly develop mutations that resist compounds targeting viral enzymes<sup>[9]</sup>. Therefore, an approach targeting the host factors that are indispensable for the propagation of viruses might be an ideal target for the development of antiviral agents because of a lower rate of mutation compared to that of the viral genome, as long as they have no serious side effects to patients.

A unique aspect of HCV that has not been observed in other viruses is that the entire viral life cycle is associated with cholesterol metabolism in host cells. Thus, drugs that target cholesterol metabolism might be useful for treating HCV infection<sup>[10]</sup>. Also, drugs targeting the host proteins required for HCV infection, nuclear receptor or anti-

receptor antibodies may be more helpful in combating the viral infection<sup>[11]</sup> (Table 1).

## INHIBITION OF VIRAL ENTRY

### Anti-receptor antibodies

HCV circulates in the bloodstream in different forms; either free or in a complex with immunoglobulin or lipoprotein. Implicated lipoproteins are very-low-density lipoprotein (VLDL), intermediate-density lipoprotein, or low-density lipoprotein (LDL)<sup>[12]</sup>. HCV RNA is always found in at least one of these fractions and represents 8% to 95% of the total plasma HCV RNA<sup>[13,14]</sup>. Entry into the host cell is the primary step in the HCV life cycle, which makes it an attractive target for antiviral therapies. Inhibition of viral entry can be accomplished at the level of cell receptor(s) or HCV pseudo-particles (HCVpp) but both approaches require an in-depth knowledge of interactions between host and virus<sup>[15]</sup>.

Attachment and cell entry of HCV is pH dependent and is a clathrin-dependent endocytic pathway<sup>[16,17]</sup>. Although the molecular details regarding how this virus enters a cell are unknown, CD81<sup>[18]</sup> and scavenger receptor class B type 1<sup>[19]</sup> seem to be the key receptor components that mediate viral entry. However, other potential receptors play a role in entry of HCV such as LDL receptor<sup>[20]</sup>, negatively charged glycosaminoglycans, and recently, Evans *et al*<sup>[21]</sup> added another molecule to the list of HCV receptors, namely, the tight junction protein claudin-1 (CLDN1).

The rationale for anti-receptor antibodies as a drug target is based on them not being prone to the problems of viral variability and high density lipoprotein (HDL) attenuation of neutralizing activity<sup>[22]</sup>.

Targeting viral receptors can be accomplished by various methods, including the design of small molecules that bind to proteins and prevent interaction(s) with HCV. The crystal structure of CD81 long extracellular loop enabled the design of small molecules that bind CD81 and prevent its association with HCV E2<sup>[23]</sup>. A recent presentation by Liu *et al*<sup>[24]</sup> identified compounds that displayed a dose-dependent inhibition of HCV infection.

**Scavenger receptor BI (SR-BI):** SR-BI is a lipoprotein receptor with the highest levels found in the liver and adrenal glands, responsible for the selective uptake of cholestryler ester from HDL<sup>[25-27]</sup>. HCV particles have been reported to be complexed with lipoproteins; it is possible that HDL interacts with HCVpp, *via* protein/protein or lipid/protein interactions<sup>[28]</sup>, suggesting an indirect interaction of virus with lipoprotein receptors<sup>[29,30]</sup>. Recent studies have demonstrated the cell culture-derived HCV association with VLDL containing apolipoprotein B (ApoB) and apolipoprotein E, supporting earlier claims of lipo-viral particles in human plasma.

Previous observations implicated SR-B1 as important for infection by different HCV subtypes and support for this hypothesis is the fact that the same SR-B1 protein element is responsible for the recognition of different HCV E2 glycoproteins despite the high level of variability between their amino acid sequences, especially in the HVR1 region previously shown to be involved in

**Table 1 Summary of the potential treatment options of CHC targeting host factors and their mechanism of action**

Drug	Mechanism of action
Nitazoxanide	Induces PKR phosphorylation
HMG-CoA reductase inhibitors	Disruption of HCV replication; depletion of geranylgeranyl lipids
Antisense RNA drugs targeting apoB	Blocks the assembly and secretion of VLDL, inhibits release of HCV particles from infected cells
Microsomal triglyceride protein (MTP) inhibitors	Blocks the assembly and secretion of VLDL, inhibits release of HCV particles from infected cells
Insulin sensitizer	
Metformin	Insulin sensitivity by acting on hepatic AMP-activated protein kinase
Thiazolidindiones (pioglitazone)	Insulin sensitivity by activating peroxisome proliferator-activated receptors (PPARs)
Debio-025	Inhibition of Cyclophilin B
NIM 811	Inhibition of Cyclophilin B
Tamoxifen, other anti-estrogen drugs	Potentially suppresses genome replication
Small molecules (e.g. receptor mimics, soluble intracellular adhesion molecule-1)	Receptor and uptake inhibition
Receptor antibodies (e.g. Anti CD81)	

interaction with SR-B1<sup>[19,31]</sup>.

HCV appears to use SR-BI during cell entry not merely as an additional site for the viral particle entry but also for exploiting its physiological activity, i.e. the capacity to mediate lipid transfer from HDL which is known to facilitate the entry of many different viruses, such as influenza virus, HIV, and HCV<sup>[32,33]</sup>. However, HCVs are many times more sensitive to HDL-mediated infection enhancement than other cholesterol-sensitive viruses. Therefore, enhancement of viral infection might be dependent on the lipid exchange activity of SR-B1<sup>[28]</sup>. Recently, a novel function of SR-Bs for viral antigen uptake and recognition has been suggested; SR-BI may represent a cell-surface receptor for the recognition of viral antigens and be implicated in trafficking exogenous viral antigens toward the MHC class I presentation pathway. The SR-BI-viral antigen interaction may represent a novel target for therapeutic or preventive strategies aiming at the induction of efficient antiviral immune responses<sup>[34]</sup>.

Moreover, HDL with SR-BI is the predominant enhancing factor in infectivity and the presence of HVR1 with HDL protects HCV from neutralizing antibodies as HDL can reduce the neutralizing effect of anti-HCV antibodies<sup>[35,36]</sup>. This phenomenon might be responsible, at least in part, for the limited ability of the humoral immune response to control HCV infection *in vivo*, which raises concerns about the efficacy of anti-HCV antibodies for active or passive immunotherapy<sup>[37]</sup>. Thus, as an alternative to the development of anti-HCV antibodies, one could consider anti-SR-B1 human MAbs or anti-CD-81 capable of interfering with HCV infection as potential therapeutic leads. Agents involved in modulating the normal hepatocellular processes of lipid transport have been reported to have pleiotropic effects on HCV infectivity. Antibodies to ApoB have been shown to have antiviral activity<sup>[13,29-31,38-43]</sup>.

Recent data show that BLT-4 and other inhibitors of SR-BI-mediated lipid transfer not only inhibit HCV entry but also fully restore the potency of neutralizing antibodies in infection assays conducted in the presence of HS/HDL, indicating an intriguing link between neutralization efficiency and stimulation of cell entry<sup>[28,35]</sup>. However, it is too early to know whether the potential for vaccines and passive immunotherapy will be realized. Cholesterol-lowering drugs may be beneficial in patients with chronic hepatitis C by exerting effects on cholesterol metabolism and lipoprotein trafficking via SR-BI (See below).

**CD81:** Recently, Meuleman *et al*<sup>[11]</sup> showed that CD81 is a critical receptor for HCV infection *in vivo*. Prophylactic injection of monoclonal anti-CD81 antibodies prevented infection of human liver-uPA-SCID mice, however once an infection occurred, no significant difference in viremia was observed between anti-CD81-treated and control animals (irrelevant antibody). These results strongly support the use of CD81 as a clinical target for HCV prevention, especially in the context of orthotopic liver transplantation<sup>[11]</sup>.

### **Modes of virus transmission**

Targeting CD81, SR-BI or CLDN1 may be complicated by receptor-independent modes of virus transmission. In general, there are two primary routes of virus transmission: cell-free and cell-to-cell. Cell-free transmission begins when virus is released from an infected cell and enters the extracellular environment. The virion can bind to surface-expressed receptors on naïve or uninfected cells, become internalized, and initiate new rounds of infection. En route from one cell to the next, the virus may encounter neutralising antibodies or other components of the immune response that may limit infection. In the second route of transmission, the virus spreads directly from one cell to another and, in doing so, may bypass receptor-mediated attachment as well as the immune response.

Direct cell-to-cell transmission has been observed with several viruses, including HIV<sup>[44]</sup>, human T-lymphotropic virus type 1<sup>[45]</sup> and vesicular stomatitis virus<sup>[46]</sup> and it was recently proposed that HCV may use this route *in vitro*<sup>[47]</sup>. Whether cell-to-cell HCV transmission occurs *in vivo* remains to be determined. If this mode of transmission exists *in vivo*, targeting cellular receptors alone may not be an effective antiviral therapy<sup>[48]</sup>.

Targeting receptors as antiviral therapy may also be complicated by their ubiquitous expression in human tissue and their essential roles in cell biology.

## **TARGETING HOST METABOLISM**

HCV seems to be not only an infectious hepatotropic virus but also a metabolic disease<sup>[49]</sup> with a wide area of metabolic disarrangement, including lipid metabolism<sup>[50]</sup>, glucose metabolism<sup>[51]</sup> and vitamin D metabolism<sup>[52,53]</sup>. Metabolism refers to all the reactions by which living things break down nutrients to produce energy, along with those reactions by which they rebuild broken-down nutrients into complex molecules (e.g. DNA). Many viruses, including influenza, HIV and hepatitis, dramatically increase cellular metabolism. The fields of metabolomics and fluxomics have emerged to

measure these patterns and to provide insight into diseases with a metabolic component, from diabetes to cancer to infectious diseases such as HCV. Many metabolic processes are essential to the survival of human cells, and so are not candidates for research efforts that would shut them down in an attempt to stop viral replication.

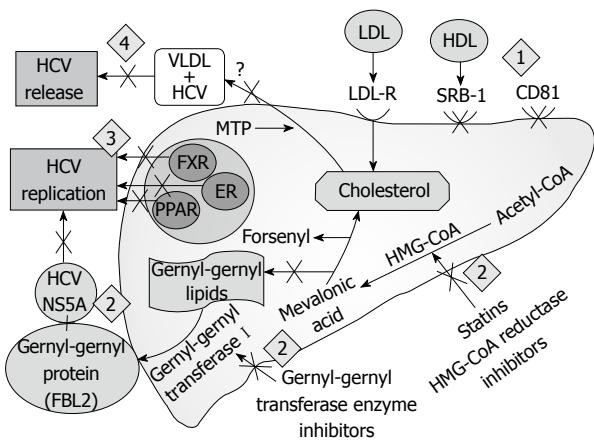

### **Host lipid biosynthesis inhibitors**

Recently, using the new fluxomic techniques, studies revealed that viral infection takes control of cellular metabolism and drives, among other things, marked increases in fatty acid synthesis. Interfering with glucose-to-fatty acid metabolism could stop viral replication, because fatty acid biosynthesis is not essential in adult humans. It does appear, however, to be essential to the ability of HCV to build their envelopes, reproduce and spread. So, targeting of host lipid metabolism by the existing anti-obesity drugs may represent a new way to block these metabolic changes and inhibit viral replication, and may therefore be a potential novel approach that could improve response rates to treatment<sup>[54]</sup>. There are at least two different molecular mechanisms representing a novel target for management of HCV through the modulation of cellular lipid and cholesterol metabolism. *In vitro* data suggest that statins, the widely used cholesterol-lowering drugs, may inhibit HCV RNA replication by depletion of geranylgeranyl lipids<sup>[55,56]</sup>. It was recently demonstrated that dose-dependent strong antiviral effects exist for all the 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, except for pravastatin, *in vitro*. Fluvastatin exhibited the strongest antiviral activity, followed by atorvastatin and simvastatin<sup>[57]</sup>.

Recently, Bader *et al*<sup>[58]</sup> reported that fluvastatin inhibits HCV RNA replication in patients with CHC; the study provided evidence that fluvastatin is well tolerated in patients with CHC and at relatively low doses.

These findings, along with other data suggesting synergism with α-interferon, support ‘proof-of-concept’ for trials combining fluvastatin with standard pegylated interferon plus ribavirin. Cautious, prospective and randomized trials are needed before we can call statin therapy an adjuvant treatment panacea<sup>[54]</sup>.

Another class of drugs designed for treating hypercholesterolemia blocks the assembly and secretion of VLDL. These drugs may also be effective in treating HCV infection because they inhibit release of HCV particles from infected cells<sup>[59]</sup>. In this regard, antisense RNA drugs targeting apoB<sup>[60]</sup> and several microsomal triglyceride protein (MTP) inhibitors<sup>[61,62]</sup> have already been tested in clinical trials because of their ability to block VLDL secretion, thereby lowering the plasma levels of VLDL triglycerides and LDL cholesterol. Long-term treatment with MTP inhibitors led to the toxic accumulation of fat in livers<sup>[61,62]</sup>, thus hampering the approval of these drugs for the treatment of hypercholesterolemia on a long-term basis. However, short-term treatment (up to several weeks) reduced the plasma level of VLDL with only minor adverse effects, which disappeared after drug discontinuation<sup>[61]</sup>. It will be interesting to examine whether short-term treatment with MTP inhibitors is beneficial in treating HCV infection (Figure 1).

**Figure 1 Possible sites targeting host factors as a novel antiviral treatment.** (1) Inhibition of HCV entry by anti-receptor antibodies; (2) Interference with the host metabolic factor involved in HCV replication; (3) Modulation of nuclear receptors involved in HCV replication; (4) Inhibition of HCV release. LDL-R: Low density lipoprotein receptor; HDL: High density lipoprotein; VLDL: Very low density lipoprotein; SRB-1: Scavenger receptor B1; FXR: Farnesoid X receptor; ER: Estrogen receptors; MTP: Microsomal triglyceride protein; HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A.

### Cyclophilin B inhibitors

Another host cell factor involved in HCV RNA replication is the human protein cyclophilin B protein which interacts with the C-terminal region of NS5B and appears to stimulate its RNA binding activity<sup>[63]</sup>. The cyclophilin B inhibitor Debio-025 potently suppresses genotype 1 HCV replication *in vivo*<sup>[64]</sup>.

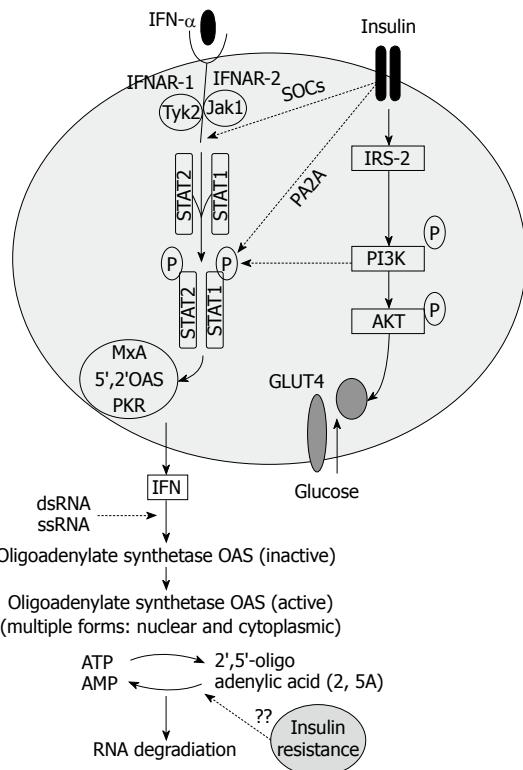

### Insulin resistance

Insulin resistance emerges as a very important host factor in patients with CHC, mainly because it has been related to steatosis development, fibrosis progression and non-response to peg-interferon plus ribavirin<sup>[65]</sup>. Insulin resistance is the main pathogenic factor in the development of steatosis in chronic hepatitis C; both viral-induced insulin resistance and metabolic insulin resistance could be implicated in the development of steatosis<sup>[66]</sup>.

Insulin resistance, calculated by the homeostasis model assessment (HOMA), has been found to be one of the most important host factors related to the impermanence of virological response to combined therapy in chronic hepatitis C patients<sup>[67]</sup>.

Recently, obesity has been identified as a modifiable host factor associated with a lower SVR. An elevated BMI is associated with reduced insulin sensitivity and HCV treatment outcome. This observation has led experts to suggest that managing insulin resistance might improve hepatitis treatment outcome and that insulin resistance seems to be a new target in the management of hepatitis C.

The rationale of increasing insulin sensitivity in patients with chronic hepatitis C is based on the premise that insulin resistant state directly or indirectly inhibits the antiviral action of interferon (IFN)- $\alpha$ - $\beta$ , or increases the viral fitness making it more resistant to therapy, or both<sup>[8,68]</sup>. Since HCV appears to directly interfere with the glucose homeostasis, several studies have tried to analyze in detail the potential interactions between viral products and insulin signaling. Experimental data suggest a direct interference of HCV

**Figure 2 Interaction between insulin and interferon-alpha signaling pathway.** SOCs: Suppressor of cytokine signaling; PA2A: Protein phosphatase 2A; PI3K: Phosphatidyl-Inositol 3-kinase; JAK: Janus kinase; STAT: Signal transduction and activator of transcription; TYK2: Tyrosine kinase 2; Dotted lines: Represent inhibition; Continuous lines: Represent activation.

with the insulin signaling cascade *via* proteasome degradation of the insulin receptor substrates-1 and -2<sup>[69,70]</sup>. HCV may also impair insulin signaling transduction indirectly, that is, through increased levels of proinflammatory cytokines such as tumor necrosis factor (TNF)- $\alpha$ <sup>[71,72]</sup>. The interference with insulin signaling seems to proceed *via* HCV genotype-specific mechanisms and insulin resistance levels vary according to the infecting HCV genotype, although all genotypes induce insulin resistance. Interestingly, intracellular factors dysregulated by HCV and responsible for the insulin resistant phenotype may play promiscuous effects as they are also involved in regulating IFN- $\alpha$  signaling (Figure 2). These factors include some members of the suppressor of cytokine signalling (SOCS) family<sup>[69,70,73]</sup> and the protein phosphatase 2A<sup>[74]</sup>. Thus, modulating the levels and/or the activity of these factors may not only reverse hepatic insulin resistance but also help in establishing the IFN- $\alpha$ -induced antiviral state at the site of HCV replication. This is one of the reasons for trying to restore insulin sensitivity in chronic hepatitis C patients, especially those who failed to respond to therapy. Although increasing insulin sensitivity may be a rational option in chronic hepatitis C patients, especially in those with metabolic syndrome, the modalities of this intervention, however, have not been established. In addition, it is unclear whether one should start the antiviral treatment together with the insulin sensitizer or only once the HOMA-IR score has been decreased to a level predicting sufficient SVR rate<sup>[67]</sup>.

However, specific inhibitors of SOCS family members and of the protein phosphatase 2A are either not suitable

for *in vivo* administration or are toxic. Alternatively, increasing insulin sensitivity may be achieved by modulating serum levels of specific cytokines, such as TNF- $\alpha$ , associated with insulin resistance<sup>[71,72]</sup>, but the administration of anti-TNF- $\alpha$  antibodies to chronic hepatitis C patients may be risky<sup>[73]</sup>. Insulin sensitizers not only increase insulin sensitivity but may also inhibit HCV replication by decreasing serum free fatty acid flow to hepatocytes; saturated and monounsaturated free fatty acids have indeed been shown to stimulate HCV replication in an *in vitro* model<sup>[57]</sup>. It is not clear whether the best approach would be using a thiazolidindione, activating peroxisome proliferator-activated receptors (PPARs) (see below), or a biguanide such as metformin, whose mechanism of action is specifically directed to the hepatic AMP-activated protein kinase.

Recently, metformin-based triple therapy has been shown to be safe, improving insulin sensitivity and increasing SVR rate by 10% in patients with hepatitis C genotype 1 and insulin resistance (HOMA > 2). This therapy was especially effective in females in whom metformin significantly raised the SVR rate<sup>[76]</sup>.

## NUCLEAR RECEPTORS

### PPAR receptor

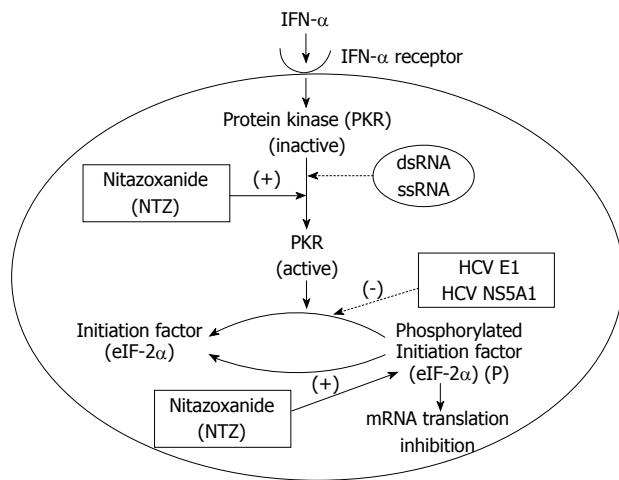

The PPARs are nuclear factors (amongst others) involved in the regulation of glucose homeostasis. In addition to the direct effects on factors involved in lipid and glucose homeostasis<sup>[77-81]</sup>, PPARs may have insulin sensitizing effects via their anti-inflammatory activity<sup>[82,83]</sup>. Thus, treatment with PPAR agonists results in improved insulin sensitivity via diverse mechanisms, both direct and indirect, and both at the level of the liver and at the level of extrahepatic tissues<sup>[77]</sup>. The relationship between HCV replication, protein expression and PPARs has been the focus of some recent studies. However, the data available so far are quite scanty and concern only the HCV genotype 3a<sup>[77]</sup>.

In a recent randomized, double-blind, placebo-controlled study, adding concurrent (PPAR- $\gamma$  agonist) pioglitazone 30 mg QD to the standard of care (i.e. without a preceding administration as monotherapy) markedly increased the on-treatment virological response, but failed to increase the SVR after the end of treatment<sup>[84]</sup>. In a related but smaller and shorter study, another research team reported that pioglitazone given as an adjuvant to pegylated interferon/ribavirin in HCV genotype one patients improved viral kinetic response during the first 4 wk of therapy<sup>[85]</sup>.

Also, in a recent study, the level of PPAR $\alpha$  mRNA was found to be profoundly suppressed in the liver of chronic hepatitis C patients (about 85% compared to control livers)<sup>[86]</sup>. The suppression of PPAR- $\alpha$  leads to the upregulation of nuclear factor (NF)- $\kappa$ B. NF- $\kappa$ B has been shown to accelerate virus replication<sup>[87]</sup>, and it has been speculated that activation of PPAR- $\alpha$  with subsequent NF- $\kappa$ B suppression leads to decreased HCV replication in hepatocytes<sup>[88]</sup>. Given the availability of potent agonists, PPARs may represent a novel pharmacological target in the treatment of liver lesions observed in chronic hepatitis C.

### Farnesoid X receptor (FXR)

The bile acid receptors were found to play a role in

**Figure 3** Antiviral mechanism of Nitazoxanide. Dotted lines: Represent inhibition; Continuous lines: Represent activation.

bile acid-mediated promotion of HCV replication<sup>[89]</sup>. Furthermore, it was discovered that bile acids compromised the anti-HCV effect of IFN in the cells. These findings suggest a mechanism for persistent infections of HCV in hepatocytes and for the failure of IFN-based treatment for certain HCV patients<sup>[89,90]</sup>. These data suggest a novel mechanism for bile acid-mediated gene regulation at virus and host levels. Importantly, these data may contribute to the finding of better regimens for the treatment of chronic HCV infections by including agents altering the bile acid-mediated FXR pathway<sup>[89]</sup>.

### Estrogen receptor (ESR)

ESR belongs to the steroid hormone receptor family of the nuclear receptor super family. There are two different forms of the estrogen receptor, usually referred to as  $\alpha$  and  $\beta$ , each encoded by a separate gene<sup>[91]</sup>. The novel role of ESR  $\alpha$  in regulation of HCV replication has been recently reported<sup>[92]</sup>. Tamoxifen and other anti-estrogens suppress genome replication, as part of ESR resides on the endoplasmic reticulum and interacts with HCV RNA polymerase NS5B, so ESR is suggested to serve as a potential novel target for anti-HCV therapies<sup>[92]</sup>.

## OTHER PRINCIPLES

### Nitazoxanide

Nitazoxanide is an oral prodrug of a thiazolidine (tizoxanide), and was approved for the treatment of protozoal infections<sup>[93]</sup>. In addition to having antiprotozoal and antibacterial activity, nitazoxanide coincidentally was discovered to inhibit HCV replication<sup>[94]</sup> through a recently identified host-mediated mechanism of action. The antiviral mechanism of action of nitazoxanide appears to be different from the mechanism of action of nitazoxanide in protozoa and anaerobic bacteria. Recent studies suggest that nitazoxanide and other thiazolidides selectively induce PKR phosphorylation, which leads to increased cell concentration of phosphorylated eIF2, a naturally occurring antiviral intracellular protein (Figure 3)<sup>[95]</sup>. This mechanism of action is only triggered when a cell is infected with HCV

while nitazoxanide has no effect in uninfected cells, which provides a possible explanation for its very low rate of toxicity.

Furthermore, nitazoxanide does not appear to induce antiviral resistance, based on an attempt to produce a resistance to nitazoxanide and tizoxanide in HCV replicon-containing cell lines<sup>[96]</sup>. With serial exposure to nitazoxanide or tizoxanide, direct HCV viral resistance did not emerge, suggesting that the genetic barrier to the development of resistance to nitazoxanide is high. The drug has been recently studied in combination with the standard of care in 96 treatment-naïve patients in Egypt infected with genotype 4 HCV infection. The combination of nitazoxanide, peginterferon α-2a, and ribavirin increased the percentage of patients with rapid and sustained virologic responses, compared with patients given peginterferon plus ribavirin, without an increase in adverse events<sup>[97]</sup>.

Nitazoxanide, a novel protein kinase inducer, has the potential not only to increase the SVR rate but also potentially to shorten the duration of therapy.

In summary, the suboptimal response to the currently available standard therapy has led to an extensive search for novel therapies with new therapeutic approaches. Targeting host cofactors of the HCV life cycle by different strategies (inhibition of viral entry, targeting host metabolism, nuclear receptors and other principles) may be a novel rational option, especially because they impose higher genetic barriers for resistance than direct antiviral compounds. However, the principle drawback of these strategies is the greater potential for cellular toxicity.

## ACKNOWLEDGMENTS

The author thanks Dr. Mohamed Eslam, from Department of Internal Medicine, El-Minia University, for assistance in the preparation of this manuscript.

greater than that in the controls ( $26.0 \pm 5.5$  and  $21.0 \pm 6.5 \mu\text{m}$ , respectively) ( $P < 0.05$ ). The mean number of ulcers per animal in the ES group in the entire esophagus was  $5.4 \pm 2.5$ , which was significantly less than that in the esophagitis group ( $9.0 \pm 3.5$ ) ( $P < 0.05$ ). The epithelial thickness in the ES group was  $97.5 \pm 32.2 \mu\text{m}$  in the lower esophagus, which was decreased compared with that in the esophagitis group ( $210.8 \pm 47.7 \mu\text{m}$ ) ( $P < 0.05$ ).

**CONCLUSION:** Mucosal inflammation extended to the upper esophagus close to the hypopharynx. Our study suggested that ES may have a useful defensive role in reflux esophagitis.

### Abstract

**AIM:** To explore the pathological findings in the entire esophagus in rats with reflux esophagitis, and the effects of ecabet sodium (ES).

**METHODS:** A rat model of chronic acid reflux esophagitis was used. In the treatment group, ES was administered after surgery ( $n = 16$ ). No drug was administered postoperatively to the esophagitis group ( $n = 9$ ). Sham-operated rats were used as a control group ( $n = 5$ ). Rats were sacrificed on day 7 after the operation. The epithelial thickness and leukocyte infiltration were examined in the upper, middle and lower areas of the esophagus. The survival rate, incidence of esophageal ulcer, and mean surface area and number of esophageal ulcers were determined in the esophagitis and ES groups. Esophageal histology was assessed in all three groups.

**RESULTS:** Leukocyte infiltration in the esophagitis group was  $26.3 \pm 22.0$  in the middle esophagus and  $8.2 \pm 4.9$  in the upper esophagus, which was significantly greater than that in the controls ( $1.3 \pm 1.1$  and  $1.4 \pm 1.0$ , respectively) ( $P < 0.05$ ). The thickness of the epithelium in the esophagitis group was  $210.8 \pm 47.7 \mu\text{m}$  in the lower esophagus and  $204.2 \pm 60.1 \mu\text{m}$  in the middle esophagus, which was significantly

### INTRODUCTION

Against the background of an aging society and changing dietary habits that now include western-style food, and despite a low rate of infection with *Helicobacter pylori* (*H pylori*), the number of patients with gastroesophageal reflux disease (GERD) has increased recently in Japan<sup>[1,2]</sup>. The symptoms of GERD decrease quality of life<sup>[3]</sup>, and long-term reflux of gastric acid is known to increase the risk of Barrett's esophagus and Barrett's adenocarcinoma. As a result of the global ground swell

of GERD, a worldwide consensus definition of GERD has been developed recently<sup>[4]</sup>. Laryngopharyngeal reflux disease (LPRD) is a common condition in the primary care setting and is one of the extraesophageal syndromes regarded as secondary to GERD<sup>[5,6]</sup>. Exactly how reflux of gastric juice influences the esophagus and/or extraesophageal structures is unknown, and the causal association between gastric-juice reflux and pathogenesis of reflux esophagitis is a controversial subject.

There are limitations associated with the investigation of the pathophysiology of GERD in humans, thus, experiments using animal models are fundamental to this investigation. Proton pump inhibitors (PPIs) and histamine-2 receptor antagonists are likely to be used for reflux esophagitis, but there have been few reports about using mucosal-protective drugs. We previously induced chronic acid-reflux esophagitis in a rat model and investigated the underlying mechanism of reflux esophagitis, with a focus on the mechanism of esophageal mucosal resistance<sup>[7,8]</sup>.

In the current study, we used a rat model of chronic acid-reflux esophagitis to explore the esophageal mucosal damage macroscopically and microscopically throughout the entire esophagus, including the upper esophagus close to the hypopharynx, and to investigate the protective effects of ecabet sodium (ES) on the esophageal mucosa.

## MATERIALS AND METHODS

### Chronic acid-reflux esophagitis model

Specific-pathogen-free male Wistar rats aged 9 wk were purchased from SLC (Tokyo, Japan). They were used after acclimatization for 1 wk in an animal room with a controlled temperature ( $23 \pm 2^\circ\text{C}$ ). The rats were fed a standard diet but fasted for 12 h prior to the surgical induction of chronic acid-reflux esophagitis, which was induced by modifying the method of Omura *et al*<sup>[9]</sup>. Anesthesia was induced by inhalation of isoflurane. After laparotomy, duodenal stenosis was accomplished by wrapping the duodenum near the pylorus with a piece of 18 Fr Nelaton catheter (length: 3.0 mm, diameter: 4.0 mm; Terumo Inc., Tokyo, Japan). To prevent dislodgement, we sutured the edge of the catheter to the serosa of the pylorus using 4-0 nylon thread. The transitional zone between the fore-stomach and the glandular portion (i.e. the limiting ridge) was ligated with 2-0 silk thread. The animals were fasted for 48 h after the operation but were allowed free access to drinking water. In those allocated to the ES treatment group ( $n = 16$ ), ES (65 mg/kg) was intragastrically administered only once immediately after surgery, and drinking water including ES ( $21.39 \pm 2.74$  mg/kg per day) was given from the day after surgery until day 7. ES was obtained from Tanabe Seiyaku Co. Ltd. (Osaka, Japan). No drug was administered after surgery to the animals in the esophagitis group ( $n = 9$ ). Sham-operated rats were used as a control group ( $n = 5$ ). The animals were sacrificed on day 7 after the operation. All

the procedures performed on laboratory animals were approved by the Institutional Animal Care and Use Committee of Juntendo University School of Medicine (Tokyo, Japan), and all the animal experiments were carried out in compliance with the guidelines for animal experimentation of Juntendo University School of Medicine.

### Measurement of gross esophageal lesions

In the chronic acid-reflux esophagitis and ES groups, the survival rate and incidence of esophageal ulcers were determined. The esophagus was resected up to the upper segment close to the hypopharynx. After taking photographs of esophageal lesions, the numbers of ulcers were measured in the upper, middle and lower segments of the esophagus. The surface areas of ulcers in these three segments of the esophagus were measured using a high-resolution computerized image analyzer (KS 400; Carl Zeiss Imaging Solutions GmbH, Hallbergmoos, Germany).

### Histological assessment

After being fixed in 10% buffered formalin, the tissues were embedded in paraffin, and 3- $\mu\text{m}$  sections were prepared and stained with HE. The epithelial thickness was assessed in the upper (approximately 5 mm below the cricopharyngeus), middle [midpoint between the cricopharyngeus and the esophagogastric (EG) junction] and lower (approximately 0.5 mm above the EG junction) segments of the esophagus, using light microscopy (high-power fields). The numbers of leukocytes that infiltrated each high-power field were counted in these three segments of the esophagus.

### Statistical analysis

All data are presented as mean  $\pm$  SD. Student's *t* test and  $\chi^2$  test were used, and  $P < 0.05$  was regarded as statistically significant.

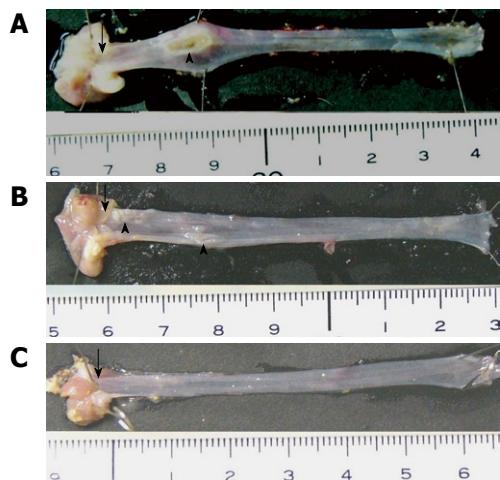

## RESULTS

### Modified chronic acid-reflux esophagitis model vs ES model

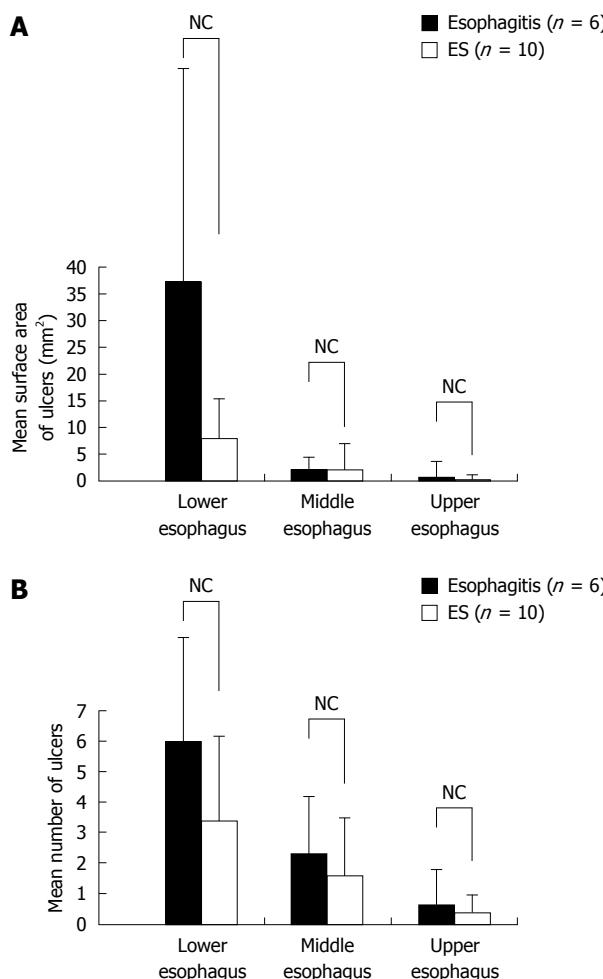

In the esophagitis group, the 7-d survival rate after the operation was 66.7% (6/9 rats), and the incidence of ulcers in the survivors was 100%. In the ES group, the 7-d survival rate after the operation was 62.5% (10/16), and the incidence of ulcers was 90.0% (9/10 rats). There were no statistically significant between-group differences in the survival rate and incidence of ulcers.

### Macroscopic assessment

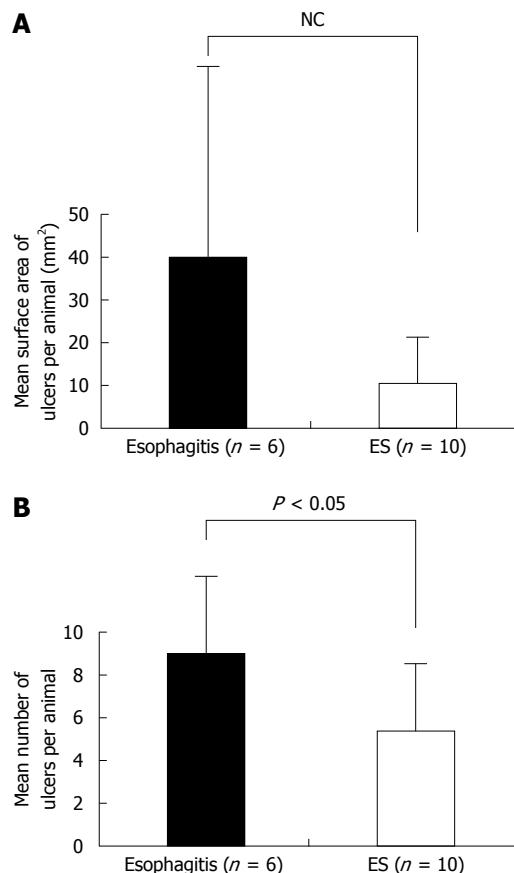

In both the esophagitis and ES groups, ulcers were noted in the mucosa, but none occurred in the control group. Also in the esophagitis and ES groups, macroscopic esophageal ulcers were found in the lower and middle parts of the esophagus in most cases (Figure 1). The mean number of ulcers per animal in the ES group in the

**Figure 1 Macroscopic findings in the three groups.** A: Esophagitis group on day 7 after operation; B: ES group on day 7 after operation; C: Control group on day 7 after operation. In the esophagitis and ES groups, ulcers were noted in the mucosa, but none occurred in the control group. The arrows indicate the EG junction. The arrowheads indicate ulcers.

**Figure 3 Mean surface area and number of ulcers in each of the three individual segments of the esophagus.** A: Mean surface area of ulcers in each part of the esophagus in the esophagitis and ES groups; B: Mean number of ulcers in each part of the esophagus in the esophagitis and ES groups. There were no significant between-group differences in terms of the number and mean area of ulcers in each of the three individual segments of the esophagus.

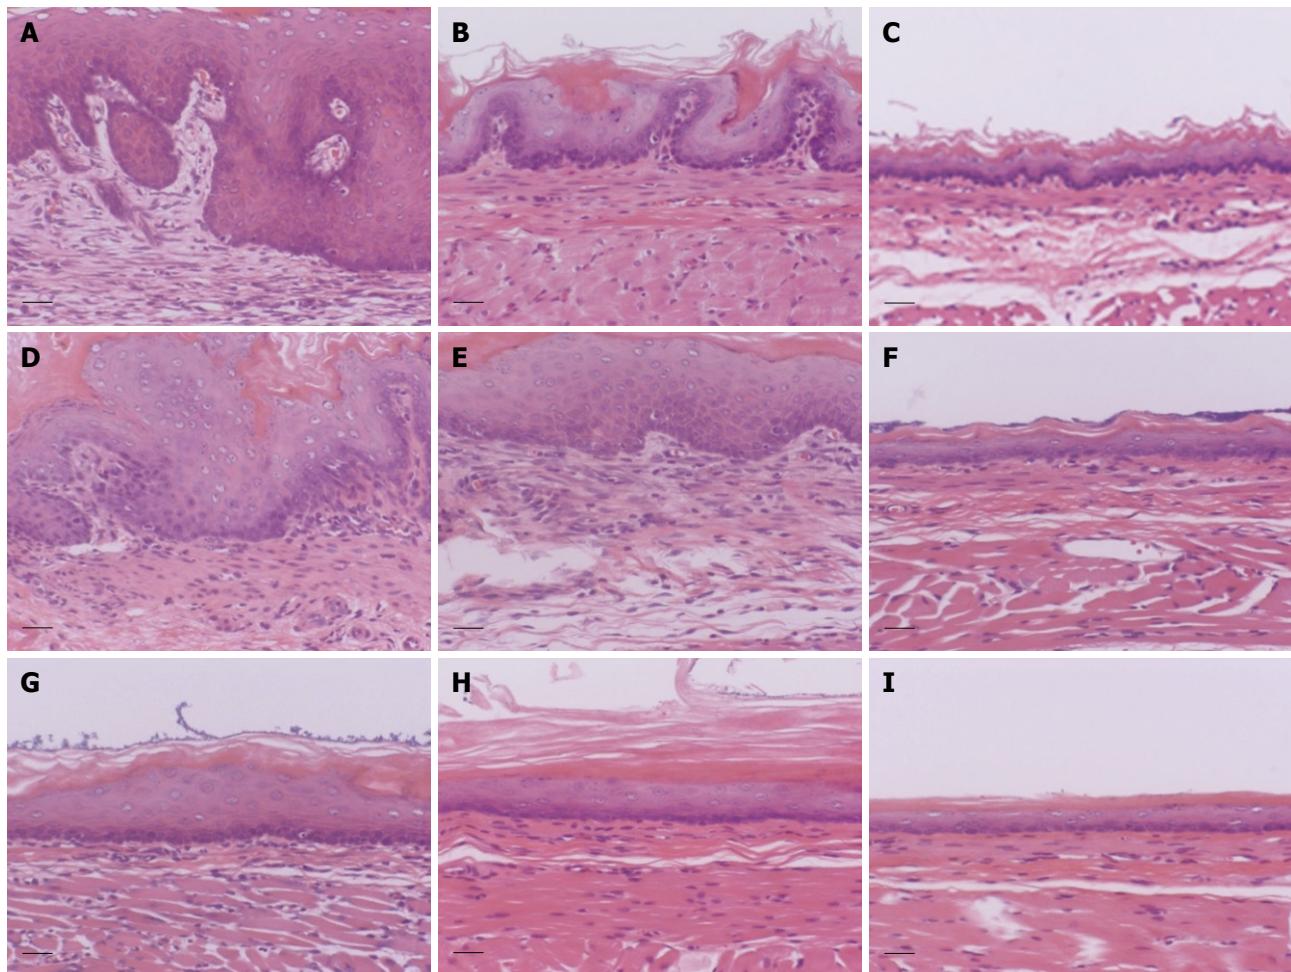

**Figure 2 Mean surface area and number of ulcers per animal.** A: Mean surface area of ulcers per animal in the esophagitis and ES groups. There were no significant differences in the mean area of ulcers between the two groups; B: Mean number of ulcers per animal in the esophagitis and ES groups. In the ES group, the number of ulcers was significantly less than in the esophagitis group ( $5.4 \pm 2.5$  vs  $9.0 \pm 3.5$ ,  $P < 0.05$ ).

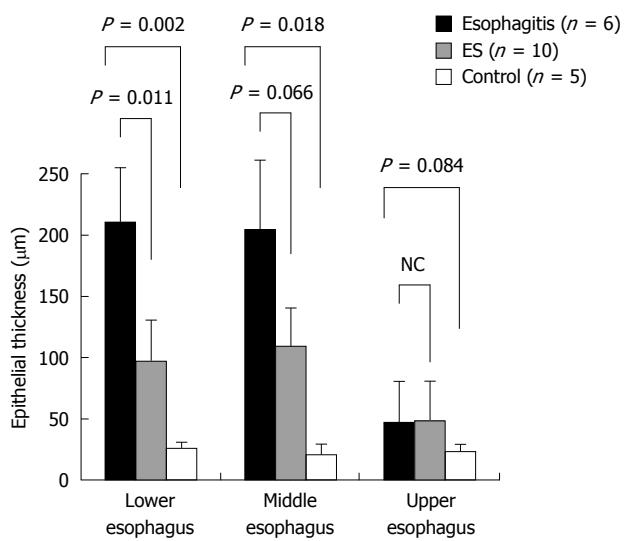

entire esophagus was  $5.4 \pm 2.5$ , which was significantly less than the number in the esophagitis group ( $9.0 \pm 3.5$ ) ( $P < 0.05$ ) (Figure 2). The mean surface area of ulcers per animal was  $40.0 \pm 56.8$  and  $10.5 \pm 8.6 \text{ mm}^2$  in the esophagitis and ES groups, respectively ( $P = 0.120$ ) (Figure 2). No significant between-group differences were found in terms of the number and mean area of ulcers in each of the three individual segments of the esophagus (Figure 3).

#### Histological assessment

Histologically, the esophagus showed a thin epithelial layer with squamous cells in the control group. In the esophagitis group, the epithelium was thickened markedly, and elongation of the lamina propria papillae into the epithelium was noted. Basal cell hyperplasia and inflammatory cell infiltration were marked in the lamina propria (Figure 4). The thickness of the epithelium in the lower esophagus was the most severely affected of the three areas. The thickness of the epithelium in the esophagitis group was  $210.8 \pm 47.7 \mu\text{m}$  in the lower esophagus and  $204.2 \pm 60.1 \mu\text{m}$  in the middle esophagus, which was significantly greater than that in the controls ( $26.0 \pm 5.5$  and  $21.0 \pm 6.5 \mu\text{m}$ , respectively) ( $P < 0.05$ )

**Figure 4** Histological findings in each part of the esophagus in the three groups (HE staining). Lower esophagus: esophagitis (A), ES (B) and control (C) groups. Middle esophagus: esophagitis (D), ES (E) and control (F) groups. Upper esophagus: esophagitis (G), ES (H) and control (I) groups. In the ES group, the thickness of the epithelium in the lower esophagus was significantly decreased compared with that in the esophagitis group. Scale bar, 30  $\mu\text{m}$ .

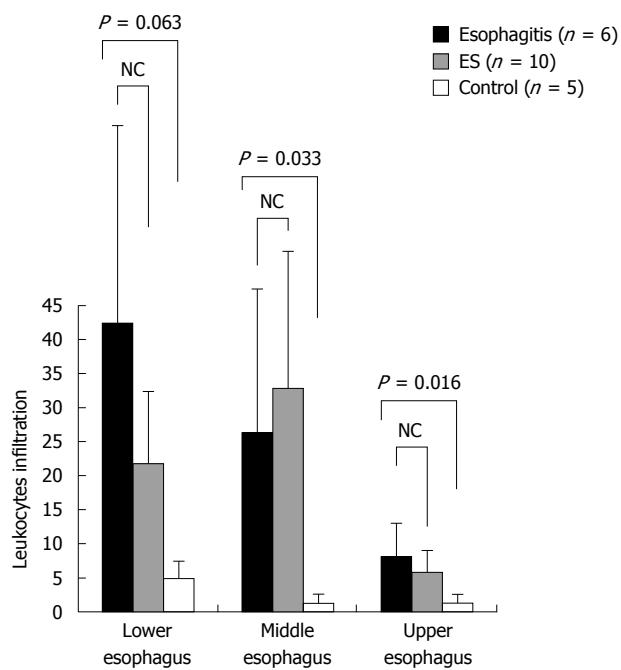

**Figure 5** Thickness of the esophageal epithelium in the three groups. In the esophagitis group, the thickness of the epithelium in the lower and middle esophagus was significantly greater than that in the controls ( $P < 0.05$ ). In the ES group, the thickness of the epithelium in the lower esophagus was significantly less than that in the esophagitis group ( $P < 0.05$ ), and the thickness of the epithelium in the middle esophagus tended to be less than that in the esophagitis group ( $P = 0.066$ ).

(Figure 5). Also, the epithelial thickness in the ES group was  $97.5 \pm 32.2 \mu\text{m}$  in the lower esophagus, which was decreased compared with that in the esophagitis group ( $210.8 \pm 47.7 \mu\text{m}$ ) ( $P < 0.05$ ), and the epithelial thickness in the ES group in the middle esophagus also tended to be less than that in the esophagitis group.

Leukocyte infiltration in the esophagitis group was  $26.3 \pm 22.0$  in the middle esophagus and  $8.2 \pm 4.9$  in the upper esophagus, which was significantly greater than that in the controls ( $1.3 \pm 1.1$  and  $1.4 \pm 1.0$ , respectively) ( $P < 0.05$ ) (Figure 6).

## DISCUSSION

We revealed that epithelial thickening occurs at the same time as inflammatory cell infiltration in the middle to lower esophagus in chronic acid-reflux esophagitis. An imbalance between offensive factors (e.g. gastric acid and pepsin) and defensive factors (e.g. mucin, saliva and the esophageal epithelial lining) results in the development of reflux esophagitis<sup>[7,10,11]</sup>. However, there have been few reports about the pathological findings in the esophageal squamous epithelium, and there are differing opinions among pathologists about the findings considered

**Figure 6 Leukocyte infiltration in the esophageal epithelium on day 7 after operation in the three groups.** In the esophagitis group, leukocyte infiltration in the middle and upper esophagus was significantly greater than that in the controls ( $P < 0.05$ ).

characteristic of chronic reflux esophagitis<sup>[12-14]</sup>. Some authors have reported the relationship between chronic inflammation and epithelial changes in other parts of the gastrointestinal tract. Yasunaga *et al*<sup>[15]</sup> have suggested that increased interleukin 1 $\beta$  and hepatocyte growth factor production caused by *H pylori* infection may contribute to fold thickening of the stomach by stimulating epithelial cell proliferation and foveolar hyperplasia in patients with enlarged fold gastritis<sup>[15]</sup>. In patients with erosive reflux disease, the thickness of the basal cell layer and length of the papillae were associated with the severity of esophagitis. After esomeprazole treatment, the basal layer thickness and length of papillae were reduced in both non-erosive and erosive reflux disease<sup>[16]</sup>. However, these studies were performed in human subjects, so detailed pathological investigation in chronic reflux esophagitis was not performed.

Recently, the mechanism by which acid may induce inflammation has been proposed by Tobey *et al*<sup>[17]</sup>. They clarified that the permeability of the esophageal epithelium to acid is increased by dilatation of the intracellular space, and PPIs may decrease inflammation of the esophageal epithelium<sup>[17,18]</sup>. These results suggest that acid may diffuse through the esophageal epithelium and induce infiltration of inflammatory cells. This increases the release of proinflammatory cytokines, which may induce thickening of the esophageal epithelium. Furthermore, we demonstrated that inflammatory cells infiltrated the epithelium of the upper esophagus close to the hypopharynx, where there was no evidence of ulcers. It has been reported previously that inflammation mainly occurs in the lower esophagus near the EG junction in cases of reflux esophagitis<sup>[8]</sup>, but how the reflux of

gastric juice influences esophageal and/or extraesophageal symptoms is unknown. Recently, GERD-related extraesophageal syndromes have attracted attention and it has been suggested that gastric-juice reflux can extend to the upper esophagus close to the hypopharynx. In a study of the pathogenesis of LPRD, which is one of the extraesophageal syndromes, Tokashiki *et al*<sup>[19]</sup> have found that patients with LPRD show a significantly longer acid reflux time in the upper esophagus than healthy volunteers do.

In our chronic acid-reflux esophagitis model, gastric juice passed through the EG junction and diffused directly into the esophagus. This model resembles the reflux esophagitis that is seen in the clinical setting. The direct acid injury to the hypopharynx appeared to be reflected in the microscopic pathological changes in the upper esophagus.

Secondarily, we demonstrated that ES inhibited the epithelial thickening of the lower esophagus, which was the most severely inflamed segment of the esophagus, and ES also tended to inhibit the epithelial thickening of the middle esophagus. ES, a dehydroabietic acid derivative from pine resin, has been used clinically in the treatment of gastritis and gastric ulcer, and is believed to exert its effects through various mechanisms<sup>[20-24]</sup>. ES binds directly to the gastric mucosa, thereby protecting the mucosa against ethanol binding, and it has been shown to inhibit pepsin activity in rat and human gastric juices.

In the present study, ES may decrease the number of ulcers in the entire esophagus by binding directly to the esophageal mucosa and inhibiting pepsin activity. ES was shown to be useful in preventing inflammation from the lower to the middle esophagus. ES may inhibit the increase in cytokines which are released as part of the inflammatory process and induce epithelial thickening. However, the relationship between the occurrence of ulcers and epithelial thickening is unknown, and further study about this relationship is necessary.

In conclusion, this study revealed that mucosal inflammation extended to the upper esophagus close to the hypopharynx, even where there was no evidence of ulcers. This finding of inflammation suggested that direct injury to the hypopharynx may occur as a result of the reflux of gastric juice. Our study also suggested that ES may play a useful defensive role in the prevention of reflux esophagitis. Further studies are necessary to explore the factors that are responsible for the protective effects of ES in reflux esophagitis.

## COMMENTS

### Background

Recently, the number of patients with gastroesophageal reflux disease (GERD) has increased in Japan. Although GERD-related extraesophageal syndromes have attracted attention, how gastric-juice reflux influences the esophagus and/or extraesophageal structures is unknown. In the present study, the authors explored the pathological findings in the entire esophagus and the effects of esacet sodium (ES).

### Innovations and breakthroughs

The authors revealed that epithelial thickening occurred at the same time as

inflammatory cell infiltration in the middle to lower esophagus in chronic acid-reflux esophagitis. Furthermore, they demonstrated that inflammatory cells infiltrated the epithelium of the upper esophagus close to the hypopharynx, where there was no evidence of ulcers. These findings suggested that the reflux of gastric juice can extend to the upper esophagus close to the hypopharynx.

### Terminology

Laryngopharyngeal reflux disease is a common condition in the primary care setting and is one of the extraesophageal syndromes regarded as secondary to GERD.

### Peer review

The authors evaluated the pathological findings in rat chronic acid-reflux esophagitis and the defensive effects of ES on esophageal mucosal injury. This an interesting, well-executed study.

### Abstract

**AIM:** To investigate the endoscopic ampullectomy practices of expert biliary endoscopists.

**METHODS:** An anonymous survey was mailed to 79 expert biliary endoscopists to assess ampullectomy practices.

**RESULTS:** Forty six (58%) biliary endoscopists returned the questionnaire. Of these, 63% were in academia and in practice for an average of 16.4 years ( $\pm$  8.6). Endoscopists performed an average of 1.1 ( $\pm$  0.8) ampullectomies per month. Prior to ampullectomy, endoscopic ultrasound was "always" utilized by 67% of respondents vs "sometimes" in 31% of respondents. Empiric biliary sphincterotomy was not utilized uniformly, only 26% "always" and 37% "sometimes" performed it prior to resection. Fifty three percent reported "never" performing empiric pancreatic sphincterotomy prior to ampullectomy. Practitioners with high endoscopic retrograde cholangiopancreatography volumes were the most likely to perform a pancreatic sphincterotomy (OR = 10.9;  $P$  = 0.09). Participants overwhelmingly favored "always" placing a prophylactic pancreatic stent, with 86% placing it after ampullectomy rather than prior to resection (23%). Argon plasma coagulation was the favored adjunct modality (83%) for removal of residual adenomatous tissue. Practitioners uniformly (100%) preferred follow-up examination to be within 6 mo post-ampullectomy.

### INTRODUCTION

Ampullary tumors account for approximately 5% of all gastrointestinal neoplasms<sup>[1]</sup>. In autopsy series, these tumors are seen in 0.04%-0.64% of the general population<sup>[2,3]</sup>. The most commonly affected patients are those with familial adenomatous polyposis with a 50%-100% lifetime incidence of peri-ampullary adenomas<sup>[4-6]</sup>. Given that the adenoma-carcinoma sequence for ampullary adenomas follows a similar progression to that of colorectal cancer, there is a need for prophylactic removal<sup>[7]</sup>. However, the associated morbidity and mortality of surgical resection for ampullary adenomas have led clinicians to seek less invasive techniques. Endoscopic ampullectomy was first described in the 1980s<sup>[8-10]</sup>. Since then, numerous case and cohort series of ampullectomies, both retrospective and prospective, have been reported<sup>[11-19]</sup>. The first prospective, randomized, controlled trial of the use of prophylactic pancreatic duct stenting for endoscopic ampullectomy was published in 2005<sup>[20]</sup>. The trial was prematurely terminated because of an elevated incidence of pancreatitis in the unsplinted group (33% vs 0%) and suggested that pancreatic stent placement confers a protective effect.

Endoscopic ampullectomy guidelines have not been established. Desilets *et al*<sup>[14]</sup> performed endoscopic ampullectomy only in tumors less than 4.0 cm in size without induration/ulceration, and with the ability to be lifted by saline solution/epinephrine injection in the absence of

extension or strictureting into the pancreatic or biliary ducts. Similarly, Cheng *et al*<sup>[18]</sup> performed endoscopic ampullectomy in lesions less than 4.5 cm without endoscopic or pathologic evidence of malignancy and a soft consistency on palpation with any device. A recent editorial by Baillie *et al*<sup>[21]</sup> suggested a tumor size greater than 3 cm requires endoscopic ultrasound (EUS) assessment prior to ampullectomy. However, a recent literature review continues to reveal diverse endoscopic practices regarding the use of biliary/pancreatic sphincterotomy, use and timing of pancreatic stenting, thermal ablation therapy and follow-up in ampullectomy<sup>[22]</sup>. The majority of the literature guiding ampullectomy practice is comprised of case reports, retrospective and prospective clinical series, except for the aforementioned randomized, controlled trial by Harewood *et al*<sup>[20]</sup>. Subsequently, a consensus for endoscopic ampullectomy practices has not been established. In this respect, it is helpful to assess opinions on endoscopic ampullectomy practices in that it may set priorities for future research. Also, this type of data could be helpful for guideline development. Therefore, we surveyed expert biliary endoscopists on their endoscopic ampullectomy techniques to determine if a consensus exists in ampullectomy practice.

## MATERIALS AND METHODS

### Sample population

Seventy-nine expert biliary endoscopists were identified by the investigators, representing 55 medical centers in 33 States and Canada. Expert biliary endoscopists were identified by selecting the primary biliary endoscopists at tertiary care centers with a medium or large gastroenterology fellowship (2 or more fellows per year) ( $n = 52$ ). Additional expert biliary endoscopists ( $n = 27$ ) from private practice were selected based on the senior investigator's (G.E.) knowledge. No surveys were distributed at the sponsoring institution (University of Michigan and the Ann Arbor Veterans Affairs hospital). By utilizing biliary endoscopists from gastroenterology fellowship training institutions our study was likely to reflect routine gastroenterology practice since trainees tend to have similar practice patterns as their teachers.

### Survey methods

An anonymous survey was sent to 79 potential respondents from May 2006 through October 2006. A self-addressed envelope was included with the survey to facilitate survey return. After 6 wk, a second survey was sent out to obtain results from endoscopists who did not respond initially with instructions to ignore the second mailing if they had already submitted the survey.

The survey instrument (Table 1) was composed of 16 questions based on an extensive literature review which identified diverse endoscopic ampullectomy practices. We performed an extensive literature search to identify endoscopic ampullectomy practices using the following search terms: ampullectomy, papillectomy, endoscopic ampullectomy/papillectomy, ampulla of Vater, major duodenal papilla and endoscopic retrograde

cholangiopancreatography (ERCP). Based upon the results of this literature search, we determined diverse approaches to the following practices: use of EUS, timing of pancreatic stent placement, pre-ampullectomy biliary sphincterotomy and pancreatic sphincterotomy, type of electrosurgical currents used, type of adjunct modality for residual tumor removal and interval for follow-up. In order

**Table 2** Respondent characteristics (mean  $\pm$  SD)

Ampullectomies per month	1.1 $\pm$ 0.8

ERCP: Endoscopic retrograde cholangiopancreatography.

to establish content validity, the results of this literature search were used to develop a draft questionnaire which was then reviewed by expert biliary endoscopists at the University of Michigan, followed by revision of the survey instrument. Since an adequate sample of expert biliary endoscopists were not available, test-retest reliability of the survey instrument could not be performed.

The study was approved by the Institutional Review Board (IRB) at the University of Michigan. In accordance to standard IRB guidelines, the need for documentation of informed consent was waived because of survey's anonymity.

### Statistical analysis

All returned surveys were included in the analysis, regardless of the completeness of the survey. Percentage calculations were performed to determine if there were variations among expert biliary endoscopists in ampullectomy practices, including the use of biliary sphincterotomy, pancreatic sphincterotomy, timing of placement of pancreatic stents, use of submucosal injection, adjunctive ablative therapies and EUS. Multivariate models were used to determine if ampullectomy practices varied by academic or private practice and by volume of ERCPs. Since our ampullectomy practice data were collected as 3-level categories of "always", "sometimes" or "never", we first used multinomial logistic regression models for the 3-level outcomes and followed with logistic regression models for 2-level outcomes after collapsing the 3 levels into appropriate 2 levels. Given that the volume of ERCPs was highly skewed to the right, we considered this in various ways: as the number of ERCPs performed per month, as the number categorized into intervals ( $\leq$  20, 20-40, 40-60,  $>$  60 per month), and as the number dichotomized to high ( $>$  10 per month) versus low volume<sup>[23]</sup>. All statistical analyses were done using STATA 9.2 (StataCorp LP, College Station).

## RESULTS

### Demographic data

Forty-six respondents completed and returned the survey (58% response rate). Two-thirds of participants were from an academic medical practice. All respondents were male. Respondents had been in practice for a mean of 16.4 years ( $\pm$  8.6 SD) at the time of the survey. There was

EUS: Endoscopic ultrasound.

a wide range in ERCP volume among respondents (ranging from 5 to 135 ERCPs per month) with an average of 36.7 ( $\pm$  26.2, median = 30) ERCPs per month. One respondent stated that he no longer performed ERCPs. Thirty-nine (85%) reported a high volume ( $>$  10) of ERCPs per month. Participants reported an average of 1.1 ( $\pm$  0.79) ampullectomies per month (Table 2).

### Practices performed prior to ampullectomy

Prior to ampullectomy, 67% of participants "always" used EUS to correctly assess tumor infiltration, 31% "sometimes" used EUS prior to ampullectomy, while only 2% "never" used EUS regularly. To maximally expose the affected ampullary epithelium, 26% of the respondents "always" performed biliary sphincterotomy and 23% "always" performed pancreatic sphincterotomy prior to resection. However, 53% of participants "never" performed pancreatic sphincterotomy and 37% "never" performed biliary sphincterotomy prior to ampullectomy. Only 12% of respondents "always" utilized submucosal injection of the ampullary adenoma to decrease the depth of thermal injury to the duodenal wall, while 49% and 39% of participants "sometimes" and "never" utilized this technique, respectively. For endoscopic ampullectomy, the most common type of electrosurgical current utilized was ERBE (67%) and blended current (17%) (Table 3).

### Pancreatic stenting

For both pre- and post-ampullectomy, 98% of respondents reported placing a prophylactic pancreatic stent. A majority of participants (86%) favored "always" placing a pancreatic stent after resection. Some overlap in practice was identified with our 2 separate questions assessing the specific timing of pancreatic stent placement. Twenty-three percent of respondents always placed a pancreatic stent prior to resection, 35% "sometimes"

**Table 4** Post-ampullectomy practices

Six months	11 (29)
One year	0 (0)

<sup>1</sup>One respondent who checked both argon plasma coagulation (APC) and multipolar/monopolar electrocoagulation probe is not included here; <sup>2</sup>Four respondents who checked 2 follow-up intervals are not included here. They each checked 1 and 6 mo, 3 mo and 1 year, 1 and 3 mo, 3 and 6 mo.

placed a pancreatic stent prior to ampullectomy whereas 42% “never” placed a pancreatic stent prior to resection.

#### Practices performed after ampullectomy

The most frequently used adjunct modality to remove residual tissue post-ampullectomy was Argon Plasma Coagulation (83%). Follow-up examination at 3 mo was the most common time frame chosen (55%) by expert biliary endoscopists. Repeat examination at 6 mo (29%) and 1 mo (16%) were less frequently used. The largest reported adenoma removed by experts was 8.0 cm (Table 4).

#### Predictors of ampullectomy practices

**Academic vs non-academic:** Multinomial logistic regression showed that for empiric biliary sphincterotomy, the relationships between factors associated with a response of “sometimes” were similar to those associated with “never”. On the other hand, for pancreatic sphincterotomy, the relationships between factors associated with “always” were similar to “sometimes”. Thus for biliary sphincterotomy, we dichotomized the practice responses to “always” vs “sometimes or never”, while for pancreatic sphincterotomy, we dichotomized the responses to “always or sometimes” vs “never”. Logistic regression analysis showed that after controlling for years in practice and high ERCP volume, an odds of “always” doing empiric biliary sphincterotomy was 0.22 (95% CI = 0.05, 1.04;  $P = 0.06$ ) for academic relative to private physicians, and an odds of “always or sometimes” doing empiric pancreatic sphincterotomy was 0.23 (95% CI = 0.05, 1.04;  $P = 0.06$ ) for academic relative to private physicians. These indicated that academic practitioners tended to be less likely to do sphincterotomy than non-academic practitioners. Regarding prophylactic stenting, academic practitioners tended to be less likely to “always” do pre-ampullectomy prophylactic pancreatic stenting ( $OR = 0.42$ ;  $P = 0.28$ ), while they tended to be more likely to “always” do post-ampullectomy prophylactic

pancreatic stenting ( $OR = 2.1$ ;  $P = 0.45$ ); however, these differences between academic *vs* private physicians were not statistically significant. Of the 18 practitioners who “never” placed a prophylactic pancreatic stent prior to ampullectomy, 17 “always” placed a prophylactic pancreatic stent after ampullectomy and only 1 “never” placed a prophylactic pancreatic stent after ampullectomy. These findings emphasize that regardless of the timing, almost all respondents utilized pancreatic stenting.

#### Volume of ERCPs

ERCP volumes were not associated with practice variation in empiric biliary sphincterotomy, but practitioners with high volumes of ERCPs (> 8 per month) tended to be more likely to “always or sometimes” do empiric pancreatic sphincterotomy ( $OR = 10.9$ ;  $P = 0.09$ ), controlling for academic status and years in practice. Practitioners with high volumes of ERCPs were also significantly less likely to “always” place prophylactic pancreatic stents prior to ampullectomy ( $OR = 0.08$ ;  $P = 0.04$ ), and more likely to “always” place prophylactic pancreatic stents after ampullectomy ( $OR = 12.8$ ;  $P = 0.06$ ).

## DISCUSSION

This research describes the most commonly used endoscopic ampullectomy techniques by expert biliary endoscopists. This survey raises some interesting findings about current practices, showing some uniformity by expert endoscopists, which is important for future guideline development. For other practices, there is more variability. Therefore, these practices should be studied in prospective trials to help refine the best practice for our patients. In this regard, our survey has helped to identify key questions for future studies.

Universal agreement among participants regarding the use of prophylactic pancreatic stenting for ampullectomy was seen. This corresponds to findings by Brackbill *et al*<sup>[24]</sup> where 100% of respondents utilized prophylactic pancreatic stenting when performing ampullectomy. Previously, in some retrospective case series, prophylactic pancreatic stenting was performed only in the setting of delayed pancreatic duct drainage<sup>[11,15,16,19]</sup>. However, recent findings by Harewood *et al*<sup>[20]</sup> showing a markedly reduced rate of pancreatitis in those receiving prophylactic pancreatic stenting. Prophylactic pancreatic stenting was most commonly performed after ampullectomy by our expert biliary endoscopists. An argument against pre-ampullectomy pancreatic stenting is that it precludes *en bloc* removal of the adenomatous tissue by practitioners who favor complete transection of the polyp with a snare, rather than piecemeal resection. Only a minority of our respondents placed pancreatic stents prior to ampullectomy. For some practitioners, the possibility of not being able to find the pancreatic duct post-resection, and the increased risk of post-ampullectomy pancreatitis without a pancreatic stent may dictate their practice of pre-ampullectomy stent placement. To alleviate this concern, endoscopists may also consider wire placement in the pancreatic duct before ampullectomy, with snare

resection over the wire as an option.

EUS is frequently utilized by biliary experts prior to resection. EUS has the benefits of assessing the depth of tumoral infiltration with 70%-90% accuracy since endoscopic biopsies are not always reliable because of sampling error<sup>[25-31]</sup>. Size and characteristics of the ampullary tumor (evidence of ulceration, friability or spontaneous bleeding) should determine the need for EUS. Baillie suggested that EUS should be performed in large lesions to determine the need for surgery<sup>[32]</sup>. If concerning findings are noted, it obviates the need for endoscopic therapy. In the literature, there has been concern about overstaging the tumor with EUS. Desilets *et al*<sup>[14]</sup> felt that the suspicion for invasive disease is more accurately predicted by the behavior of the lesion with submucosal injection and careful evaluation of the cholangiogram and pancreatogram. Adding fine needle aspiration at the time of EUS is also a consideration. Defrain *et al* found adenocarcinoma in lesions ranging in size of 1.3-3.0 cm with sensitivity, specificity, positive and negative predictive values of 82.4%, 100%, 100% and 76.9%, respectively.

Endoscopic biliary and pancreatic sphincterotomy is utilized to assess ductal involvement prior to ampullectomy. In the literature, the use of biliary sphincterotomy prior to ampullectomy is not well defined. Ideally, biliary sphincterotomy maximally exposes the affected ampullary epithelium, aiding in future surveillance and preventing biliary stenosis. In the 2 largest series reporting ampullectomy outcomes, both reported using biliary sphincterotomy at the discretion of the endoscopists, although this was not well defined<sup>[18,33]</sup>. In other series, authors always performed biliary sphincterotomy in patients undergoing ampullectomy<sup>[13-16,19,20]</sup>. However, in a recent "Expert's Corner" on endoscopic ampullectomy, biliary sphincterotomy was not mentioned<sup>[32]</sup>. Auiria *et al*<sup>[34]</sup> argued against biliary sphincterotomy since it carries the risk of bleeding, may interfere with *en bloc* resection and has the theoretical risk of seeding malignant cells present within the tumor. Unlike biliary sphincterotomy, the routine use of pancreatic sphincterotomy prior to ampullectomy has been advocated in the literature<sup>[14,19,32]</sup>. Our respondents utilized pancreatic sphincterotomy less frequently than biliary sphincterotomy prior to ampullectomy. However, Desilets *et al*<sup>[14]</sup>, Kahaleh *et al*<sup>[19]</sup>, and Baillie<sup>[32]</sup> all preferred pre-ampullectomy pancreatic sphincterotomy. The pancreatic sphincterotomy techniques that Desilets *et al*<sup>[14]</sup> described were wire-guided, involving sphincterotomies extending into normal duodenal tissue within the limits of safety. This was performed to further isolate the lesion, to remove the pancreatic orifice from the resection site and to ensure adequate drainage post-resection. Kahaleh and Baillie go on to further specify performing the pancreatic sphincterotomy solely with pure cutting current<sup>[19,32]</sup>. Our respondents with a high volume of ERCP were more likely to perform pre-resection sphincterotomy. However, Lee *et al*<sup>[35]</sup> questioned the use of pre-resection pancreatic sphincterotomy because of the higher risk of bleeding

with papillary tumors, and the distortion of the resected specimen resulting from mechanical and thermal injury, making histopathologic interpretation of the lesion difficult.

Submucosal injection prior to ampullectomy has been recommended by some authors<sup>[14,19,36]</sup>. The technique is performed to separate the tumor from the muscularis propria. As a submucosal cushion, the fluid prevents deeper coagulation into the duodenal wall and theoretically reduces the risk of perforation and pancreatitis<sup>[37,38]</sup>. Epinephrine is added to prevent bleeding. Another benefit of submucosal injection is that it can serve as an indicator of malignancy. Lack of elevation with injection suggests invasive tumor growth. However, submucosal injection may actually impede optimal snare placement. This can be seen particularly in smaller tumors since the center of these lesions are tethered by the ducts and may not lift well. The surrounding normal tissue will lift and mushroom around the adenoma, thus partially burying it<sup>[36]</sup>. However, few respondents "always" performed this technique prior to ampullectomy. Factors determining when 48% of practitioners "sometimes" utilized submucosal injection were not defined.

Our study has several potential limitations. First, because of our study population, our findings may not apply to other practice settings. Unfortunately, a strict definition for "expert biliary endoscopists" does not exist. We therefore relied on the personal knowledge of leaders in the field to choose our sample population. This was the same method utilized by Brackbill *et al*<sup>[24]</sup>; however, we expanded the field to include more community gastroenterologists. Recall bias may also be present in these data since we are relying on self-reported data. There is also the possibility that our results may reflect what the respondents think they should do versus what they actually do in everyday practice.

In endoscopic ampullectomy, experts agreed (> 50%) on the use of EUS for large lesions, prophylactic pancreatic stenting, follow-up examination and adjunct modality for residual tissue removal. Few respondents used empiric pancreatic sphincterotomy. Practitioners with high volumes were more likely to "always" perform biliary and pancreatic sphincterotomy and place pancreatic stents after ampullectomy. Among biliary experts, there was less variation in ampullectomy practices than is reflected in the literature.

## COMMENTS

### Background

Ampullary tumors account for 5% of gastrointestinal neoplasms. Because of the morbidity and mortality associated with surgery, endoscopic retrograde cholangiopancreatography (ERCP) has been utilized as a less invasive procedure to perform an ampullectomy for removal of the ampullary tumor. Specific endoscopic guidelines for ampullectomy have not been established.

### Research frontiers

Endoscopic ampullectomy has been reported widely in case reports and case series. Further study needs to be dedicated to the techniques involved in ampullectomy, in particular the use of biliary and pancreatic sphincterotomy, timing of pancreatic stenting and possible routine use of submucosal injection and endoscopic ultrasound (EUS).

## Applications

This survey demonstrated the ampullectomy practices of expert endoscopists which is important for future guideline development. Experts agree on the use of EUS for large lesions, prophylactic pancreatic stenting, follow-up examination and adjunct modality for residual tissue removal. Variability existed among experts regarding the use of biliary and pancreatic sphincterotomy prior to ampullectomy. Therefore, these practices should be studied in prospective trials to help refine the best practice for our patients.

## Terminology

The ampulla is an orifice in the second portion of the duodenum where the biliary tree and pancreas drain. Ampullectomy describes a technique to remove a tumor at the ampulla. This can be performed by surgery or using a less invasive procedure named ERCP. ERCP is an endoscopic procedure used to access the biliary tree and pancreatic duct from the second portion of the duodenum. EUS is an endoscopic procedure where an endoscope with an ultrasound probe is used to obtain images of the internal organs.

## Peer review

This article is very interesting and helpful to assess guidelines in endoscopic ampullectomy techniques for expert biliary endoscopists in North America.

*GG* genotype resulted in a higher risk of developing esophageal adenocarcinoma (OR = 3.85, 95% CI: 1.45-10.3) compared with the *-1195 AA* genotype as a reference. The *-765 G→C* genotype distribution was not different between the two groups. The *GG/GG* haplotype was present more often in esophageal adenocarcinoma patients than in controls (OR = 3.45, 95% CI: 1.24-9.58; with *AG/AG* as a reference). The same trends were observed in patients with squamous cell carcinomas, however, the results did not reach statistical significance.

**CONCLUSION:** Presence of the *COX-2 -1195 GG* genotype and of the *GG/GG* haplotype may result in a higher risk of developing esophageal carcinoma.

### Abstract

**AIM:** To determine whether *-1195 A→G* and/or *-765 G→C* polymorphisms in Cyclooxygenase-2 (*COX-2*) may have a risk modifying effect on the development of esophageal carcinoma in a Dutch Caucasian population.

**METHODS:** Two study groups were recruited, 252 patients with esophageal carcinoma and 240 healthy controls, matched for race, age, gender and recruiting area. DNA was isolated from whole blood and used for genotyping. PCR products were digested with restriction enzymes and products were analyzed by agarose gel electrophoresis. Odds ratios (OR) and 95% confidence intervals (CI) were estimated.

**RESULTS:** The distribution of the *-1195 A→G* polymorphism was significantly different in esophageal cancer patients compared to controls. The *-1195*

### INTRODUCTION

During the last few decades, the incidence of esophageal carcinoma has sharply increased in Western-lifestyle countries. Two main types of esophageal carcinoma exist, adenocarcinoma and squamous cell carcinoma. The main difference between adenocarcinoma and squamous cell carcinoma is the cell type from which the tumor originates; glandular or squamous epithelial cells, respectively.

Adenocarcinoma of the esophagus predominantly occurs in Western societies. There is a strong and probably

causal relation between gastro-esophageal reflux and the development of esophageal adenocarcinoma<sup>[1]</sup>. Gastro-esophageal reflux may cause damage to the esophageal tissue due to the high concentrations of acid and bile salts, which may induce metaplasia and cell proliferation, thereby increasing the risk of mutations. This can lead to Barrett's esophagus with high grade dysplasia and ultimately to adenocarcinoma of the esophagus<sup>[1,2]</sup>.

In contrast to adenocarcinoma, squamous cell carcinoma of the esophagus is thought to be caused predominantly by specific lifestyle or environmental factors such as heavy smoking in combination with alcohol use, chewing of tobacco or consumption of spicy foods and hot beverages<sup>[3]</sup>. In certain developing countries such as China, India or Iran, squamous cell carcinoma of the esophagus is very common, probably due to particular lifestyle habits<sup>[3]</sup>. As a result, damage to esophageal tissue may occur and tissue renewal may increase. This increased cell proliferation can lead to mutations, dysplasia and carcinoma.

Cell proliferation may play a key role in tumor genesis and cyclooxygenases (COXs) are important regulatory enzymes in this process. COXs are enzymes that catalyze the conversion of free arachidonic acid into prostaglandin H<sub>2</sub>, which is the precursor of prostaglandins, prostacyclin and thromboxanes. These regulatory compounds play a role in many biological processes such as cell proliferation, angiogenesis, immune function and inflammation, which are all crucial in the development and progression of neoplasms<sup>[4]</sup>. The human COX family consists of three members, COX-1-3<sup>[4,5]</sup>. COX-1 is found in most tissues and plays a role in homeostasis of many physiologic processes. COX-3 is an alternative splice product of COX-1 and is believed to be involved in the regulation of pain and fever. COX-2 is probably very important in the development and progression of neoplasms. COX-2 is an inducible enzyme whose expression can be induced by pro-inflammatory and mitogenic stimuli like cytokines and growth factors. COX-2 plays an important role in the development of otherwise healthy tissue into metaplastic and dysplastic tissue, as well as in the development and progression of a tumor, by taking part in the regulation of cell proliferation, cell transformation, tumor growth, metastasis and invasion. COX-2 is often found over-expressed in gastrointestinal tumors, including those of the esophagus<sup>[6-10]</sup>. Tumors which exhibit a high level of COX-2 seem to be more aggressive<sup>[6]</sup> and patients bearing those tumors showed a significantly reduced survival<sup>[10]</sup>. In addition, when COX-2 expression in laboratory animals was suppressed with medication, fewer animals developed esophageal adenocarcinoma<sup>[11]</sup>. Therefore, the role of COX-2 in the development of normal or metaplastic tissue into neoplasms seems evident.

Recently, several functional Single Nucleotide Polymorphisms in the COX-2 gene have been discovered which may contribute to the variance in inter-individual COX-2 expression. The -1195 A→G substitution in the COX-2 promotor was found to be associated with a lower expression of COX-2 in a Chinese population<sup>[12]</sup>.

Another SNP, -765 G→C was first described in a UK

population<sup>[13]</sup>. This polymorphism was shown to result in a lower promoter activity, which could subsequently lead to a lower expression of COX-2.

The purpose of this study is to determine the possible modulating effect of the COX-2 polymorphisms -1195 A→G and -765 G→C on the risk for developing esophageal cancer in a Dutch Caucasian population.

## MATERIALS AND METHODS

### **Patients and controls**

A group of 252 patients with esophageal carcinoma was recruited during the period October 2002 to January 2008, in four hospitals all localized in the South-East area of The Netherlands. These hospitals were: (1) Radboud University Nijmegen Medical Center, (2) Canisius Wilhelmina Hospital, Nijmegen, (3) Hospital Gelderse Vallei, Ede and (4) Rijnstate Hospital, Arnhem. Only patients with a diagnosis of esophageal carcinoma as confirmed by a pathologist were included in the study.

Following an advertisement in local papers, a group of 240 healthy controls was recruited from the same geographical area of The Netherlands. Controls were matched with the esophageal carcinoma patients for age, ethnicity and gender.

The study was approved in 2002 by the Medical Ethical Review Committee, region Arnhem-Nijmegen (CMO 2002/114). EDTA blood was collected from patients and controls. The whole blood samples were stored at -22°C until use. DNA was extracted from whole blood by using the Puregene DNA Isolation Kit (Gentra Systems, Minneapolis, USA) according to the manufacturer's instructions. The extracted DNA was stored at 4°C until use.

The extracted DNA was used for determination of the -1195 A→G and -765 G→C polymorphisms in the COX-2 promoter by polymerase chain reaction/restriction fragment length polymorphism (PCR/RFLP), exactly as described by Zhang *et al*<sup>[12]</sup>.

### **Statistical analysis**

The differences between characteristics of patients with esophageal carcinoma and controls were analysed with the Student's *t*-test. All genotypes of controls and patients were tested to determine whether they were distributed according to the Hardy-Weinberg equilibrium. The chi-square test was used to test for differences in distribution of genotypes between the two groups, or to estimate differences in allele frequencies. Odds ratios (OR) with 95% confidence interval (95% CI) were calculated for genotypes associated with predicted normal versus predicted altered enzyme activities (variant genotypes). COX-2 haplotypes were studied using the PL-EM software as described by Qin *et al*<sup>[14]</sup>. *P* < 0.05 was considered to be statistically significant. All data were processed using SPSS software for Windows version 16.0 (SPSS Inc, Chicago Illinois, USA).

## RESULTS

Patients with esophageal carcinoma and controls were

matched for race, age, gender and recruiting area. Table 1 shows the characteristics of the patients and controls. The COX-2 genotype distributions in patients and controls are summarized in Table 2. The polymorphisms tested here were distributed according to the Hardy-Weinberg criteria, *P*-values in patients and controls were 0.98 and 0.47 for the -765 G→C polymorphism and 0.21 and 0.24 for the -1195 A→G polymorphism, respectively.

No significant differences in the distribution of the -765 G→C polymorphism between patients with esophageal carcinoma and controls were observed (*P* = 0.80;  $\chi^2$  test). However, a significant difference in the distribution of the -1195 A→G polymorphism between patients and controls was observed (*P* = 0.02; chi square test). The -1195 G/-1195 G genotype was present more often in patients with esophageal carcinoma (whole group) as compared to the -1195 A/-1195 A genotype in controls (OR 3.57, 95% CI 1.39-9.13, *P* = 0.005). When analyzed according to the type of tumor, ORs were 3.85 (95% CI 1.45-10.3) for patients with adenocarcinoma and

3.29 (0.95-11.4) for patients with squamous cell carcinoma (Table 2). Allele frequencies in all patients with esophageal cancer (-1195 A vs -1195 G) also differed significantly from those in controls (*P* = 0.02).

When comparing the squamous cell carcinoma group (*n* = 70) with the adenocarcinoma group (*n* = 174), there were no significant differences with respect to the -1195 genotype distribution: -1195 AA, 55.7% vs 57.5%; -1195 AG, 37.1% vs 33.9% and -1195 GG, 7.2% vs 8.6% (*P* = 0.97). For the -765 genotypes no differences in distribution between the squamous cell carcinoma and adenocarcinoma groups were found: -765 GG, 69.5% vs 68.7%; -765 GC, 27.1% vs 28.2% and -765 CC, 3.4% vs 3.1% (*P* = 0.95).

Table 3 shows the results of a comparison of the distribution of the COX-2 -765 and -1195 haplotypes, according to the type of tumor. Only one significant difference was found, the GG/GG haplotype was present more often in the esophageal adenocarcinoma group than in the control group (OR = 3.45, 95% CI = 1.24-9.58). However, the number of individuals

present in these subgroups was very small ( $n = 13$  vs  $n = 6$ , respectively). The same trend was observed in the squamous cell carcinoma group, however, statistical significance was not reached.

## DISCUSSION

The -1195 GG genotype was present more often in patients with esophageal carcinoma than in controls. This is in contrast to the findings of Zhang *et al*<sup>[12]</sup> who identified the -1195 AA genotype as a risk factor for esophageal carcinoma. It is commonly reported that COX-2 expression is higher in cancerous tissue, because high COX-2 expression contributes to and sustains inflammatory and pre-cancerous processes<sup>[4,6]</sup>. Zhang *et al*<sup>[12]</sup> also concluded that COX-2 mRNA expression in -1195 AA genotypes was much higher than the mRNA expression in tissues of patients with the -1195 GG genotype. Our findings now suggest that the COX-2 -1195 polymorphism has the opposite effect on esophageal carcinoma risk in Caucasians, as compared to Chinese patients. However, two limitations must be noted: firstly, we did not measure whether the COX-2 mRNA expression in -1195 AA genotypes was highest in our group of Caucasian patients, similar to the findings of Zhang *et al*<sup>[12]</sup> in Chinese patients. Secondly, there is a difference between our study population and that of Zhang *et al*<sup>[12]</sup>; the majority of our patients had adenocarcinoma (69%) and the minority suffered from squamous cell carcinoma (28%), whereas the Chinese patients in the study by Zhang *et al*<sup>[12]</sup> all had squamous cell carcinoma. In China, esophageal squamous cell carcinoma is significantly more common than adenocarcinoma, as it is mainly caused by lifestyle factors such as drinking hot beverages and eating spicy foods, whereas adenocarcinoma is associated with acid reflux as a result of the Western lifestyle<sup>[11]</sup>. In our patient group, we found no differences in the distribution of both COX-2 polymorphisms between patients with adenocarcinoma and squamous cell carcinoma, which suggests that the differences found when compared to the results of Zhang *et al*<sup>[12]</sup> could be assigned merely to racial differences rather than to differences in the type of tumor.

Another indication that racial differences in the study populations may explain the apparent contradictory results is obtained by comparing the distribution of the COX-2 polymorphisms in the Chinese and Dutch control populations. The genotype frequencies found in our Dutch controls for the -765 G→C and -1195 A→G polymorphisms were: 66.5% GG, 30.9% GC, 2.9% CC and 64.2% AA, 33.3% GA, 2.5% GG, respectively. Zhang *et al*<sup>[12]</sup> in a Chinese population reported genotype frequencies of 95.7% GG, 4.3% GC, 0% CC and 24.1% AA, 53.4% GA and 22.5% GG, respectively. Tan *et al* in Chinese controls more recently reported approximately the same genotype frequencies as Zhang *et al*: 95.2% GG, 4.8% GC, 0% CC and 23.7% AA, 53.2% GA and 23.1% GG, respectively<sup>[15]</sup>.

On the other hand, our control group data on the COX-2 -765 genotype were in good agreement with other

European control data recently reported from Denmark, being 73.2%, 24.8% and 2.0% for -765 GG, GC and CC genotypes, respectively<sup>[16]</sup>. In addition, the COX-2 polymorphism data in our patients are very similar to the recently reported COX-2 -765 and -1195 genotype distributions in Dutch esophageal adenocarcinoma patients by Moons *et al*<sup>[17]</sup>, except for the -1195 GG genotype, which was present in 8.0% of our patients vs only 2.0% in the patients in the study by Moons *et al*<sup>[17]</sup>.

The distribution of the -765 genotypes in the control group was not found to be significantly different when compared to the esophageal carcinoma group, whereas Moons *et al*<sup>[17]</sup> reported a significantly different -765 CC genotype distribution between a Dutch esophageal carcinoma group ( $n = 140$ ) and a Barrett's esophagus ( $n = 255$ ) or reflux esophagitis ( $n = 240$ ) patient group. It should be noted, however, that the number of -765 CC genotype individuals in these patient groups was very low, being seven, four and zero individuals, respectively<sup>[17]</sup>. Two main reasons for the difference in results between the two Dutch studies are as follows: firstly, our study was performed on a larger patient population than the study by Moons *et al*<sup>[17]</sup> (252 vs 140 patients), and secondly in our study, similar to the study by Zhang *et al*<sup>[12]</sup>, a comparison between patients with esophageal cancer and healthy controls was made, in contrast to the study by Moons *et al*<sup>[17]</sup> where patients with Barrett's esophagus or reflux esophagitis, both of which are at risk for esophagus carcinoma, were used for comparison.

Analyzing the COX-2 haplotypes showed that the GG/GG haplotype was present more often in the esophageal carcinoma group, which again is not in accordance with the results of Zhang *et al*<sup>[12]</sup> and Moons *et al*<sup>[17]</sup>, who both found that the CA containing haplotypes carried the highest risk. Since the results of Zhang *et al*<sup>[12]</sup> and Moons *et al*<sup>[17]</sup> on different types of tumors (squamous cell carcinoma vs adenocarcinoma, respectively) are very similar, and more or less contradict our results, it was of interest to compare the haplotype distribution between our patients with squamous cell carcinoma vs adenocarcinoma. However, no significant differences were found.

In conclusion, the presence of the COX-2 -1195 GG genotype and of the GG/GG haplotype may result in a higher risk of developing esophageal adenocarcinoma and possibly also squamous cell carcinoma.

## COMMENTS

### Background

Cyclooxygenase-2 (COX-2) is claimed to be a key enzyme in the development and progression of neoplasms. COX-2 is often found over-expressed in gastrointestinal tumors, including those of the esophagus. The corresponding COX-2 gene is polymorphic and two single nucleotide polymorphisms; -1195 A→G and -765 G→C were demonstrated to influence the expression of COX-2. Therefore, these polymorphisms might modulate the risk for gastrointestinal cancers, including cancer of the esophagus.

### Research frontiers

In this study, the COX-2 -1195 GG genotype was found to be present more often in Caucasian patients with esophageal carcinoma than in controls. This is in contrast to earlier findings in a Chinese population, where the -1195 AA genotype was revealed as a risk factor for esophageal carcinoma.

### Innovations and breakthroughs

Presence of the COX-2 -1195 GG genotype and of the GG/GG haplotype may result in a higher risk of developing esophageal carcinoma.

### Applications

Screening for the COX-2 -1195 GG genotype in a population at risk for esophageal cancer may be valuable in the future in order to select high risk patients. Information and prevention programs can then be focused on these patients.

### Terminology

COX-2 is an enzyme that catalyzes the conversion of arachidonic acid in prostaglandin H<sub>2</sub>, the precursor of other prostaglandins, prostacyclin and thromboxanes. These regulatory compounds play a role in many biological processes such as cell proliferation, angiogenesis, immune function and inflammation, which are all crucial in the development and progression of neoplasms.

### Peer review

This study offered a controversial view of COX-2 polymorphisms in the esophageal carcinomas, compared with existing studies in Europe and China. The authors thoroughly discussed various possibilities that may lead to the different findings among studies. This manuscript is well written. Although the finding is controversial, the authors discussed this issue very well.

### Abstract

**AIM:** To assess gallbladder emptying and its association with cholecystitis and abdominal pain in patients with primary sclerosing cholangitis (PSC).

**METHODS:** Twenty patients with PSC and ten healthy subjects were investigated. Gallbladder fasting volume, ejection fraction and residual volume after ingestion of a test meal were compared in patients with PSC and healthy controls using magnetic resonance imaging. Symptoms, thickness and contrast enhancement of the gallbladder wall and the presence of cystic duct strictures were also assessed.

**RESULTS:** Median fasting gallbladder volume in patients with PSC [67 (19-348) mL] was twice that in healthy controls [32 (16-55) mL] ( $P < 0.05$ ). The median postprandial gallbladder volume in patients with PSC was significantly larger than that in healthy controls ( $P < 0.05$ ). There was no difference in ejection fraction, gallbladder emptying volume or mean thickness of the gallbladder wall between PSC patients and controls. Contrast enhancement of the gallbladder wall in PSC patients was higher than that in controls; (69%  $\pm$  32%) and (42%  $\pm$  21%) ( $P < 0.05$ ). No significant association was found between the gallbladder volumes and occurrence of abdominal pain in patients and controls.

**CONCLUSION:** Patients with PSC have increased fasting gallbladder volume. Gallbladder mucosal dysfunction secondary to chronic cholecystitis, may be a possible mechanism for increased gallbladder.

### INTRODUCTION

Primary sclerosing cholangitis (PSC) is an idiopathic chronic cholestatic inflammatory liver disease characterized by diffuse fibrosing inflammation of intra- and/or extrahepatic bile ducts, resulting in bile duct obliteration, biliary cirrhosis, and eventually hepatic failure<sup>[1,2]</sup>. Gallbladder abnormalities, including gallstones, cholecystitis and gallbladder masses are common in patients with PSC<sup>[3,4]</sup>, and seems to be part of the spectrum of the disease. Inflammation of the bile ducts in PSC is similar to that found in the gallbladder epithelium in these patients.

Functional impairment of the gallbladder in PSC is rarely studied. Van de Meeberg *et al*<sup>[5]</sup> showed enlarged fasting gallbladder volumes and increased postprandial volumes in patients with PSC compared with patients with primary biliary cirrhosis and healthy controls, although the ejection fraction of bile was normal. Other studies in patients with PSC have not found gallbladder enlargement<sup>[6,7]</sup>. Increased gallbladder volume or gallbladder retention are known to occur in conditions other than PSC such as truncal vagotomy<sup>[8,9]</sup>, chronic

pancreatitis<sup>[10]</sup>, octreotide therapy<sup>[11]</sup>, obesity<sup>[12]</sup>, diabetes mellitus<sup>[13]</sup>, pregnancy<sup>[14]</sup> and distal biliary obstruction<sup>[15]</sup>. PSC associated inflammation of the gallbladder epithelium and cholangiographic abnormalities of the cystic duct have been reported in patients with PSC<sup>[3,7,16]</sup>.

One of the most common symptoms at the time of presentation of PSC is mild to severe abdominal pain localized in the right upper quadrant<sup>[17-20]</sup>. The cause of abdominal pain is unclear, it seems, however, unrelated to the grade of bile duct strictures. In addition, cholecystectomy seldom improves abdominal pain in these patients. A possible association between enlarged fasting gallbladder volume, ejection fraction and abdominal pain has never been investigated in patients with PSC.

The primary aim of the present study, using magnetic resonance imaging (MRI), was to evaluate the fasting and postprandial gallbladder volumes and to assess whether or not gallbladder emptying is associated with abdominal pain in patients with PSC. Secondly, we studied if the presence of imaging signs of chronic cholecystitis is correlated to gallbladder volume, the emptying process or abdominal pain.

## MATERIALS AND METHODS

### Ethics

The study was approved by the Ethics committee at Karolinska University Hospital, Huddinge and written informed consent was received from all patients and controls.

### Subjects

Twenty patients, (14 men and 6 women) who ranged in age from 24 to 59 years (mean age  $39 \pm 10$  years), with well-defined PSC<sup>[21]</sup> treated at the Liver Unit, Karolinska University Hospital, Huddinge were included in the study between January 2005 and July 2006. Clinical data were obtained by review of the complete medical history collected from patient files. Patients with hepatobiliary malignancy, diabetes mellitus, chronic pancreatitis or distal biliary obstruction (dominant extrahepatic strictures) were excluded. Ten healthy subjects (5 men and 5 women), who ranged in age from 31-79 years (mean age  $47 \pm 13.5$  years), without any history of gastrointestinal disease or previous abdominal surgery served as controls. Informed consent for study participation was received from all patients and controls.

### Procedure

After overnight fasting, two intravenous cannulas were inserted into the antecubital veins: one for blood sampling and one for intravenous injection of a contrast agent for MRI. The fasting gallbladder volume was analysed by MRI, prior to injection of the contrast agent, time = 0 min. One hour later (time = 1 h) a test meal consisting of 200 g "Swedish hash" (fried diced meat, onions and potatoes served with beetroot), 250 mL milk (3% fat) and an apple, totalling 2064 kJ including 21 g fat was ingested. Postprandial gallbladder volume and

ejection fraction were obtained at 2.5 h (time = 2.5 h), that is an hour and a half after ingestion of the fat-meal at which point gallbladder contraction is supposed to be maximal<sup>[5,22-24]</sup>.

### Laboratory data

Biochemical variables including alkaline phosphatase, serum transaminases, total bilirubin, International normalized ratio (INR), serum albumin and CRP were obtained at the beginning of the procedure and analysed using standard procedures at the Karolinska University Hospital.

### Questionnaire

Every subject filled in a questionnaire for the assessment of abdominal pain localized in the right upper quadrant, abdominal discomfort and nausea, before the first MRI, just before, and one and three hours after meal ingestion. The questionnaire consisted of visual analogue scales (VAS) where the patient marked the degree of symptoms including abdominal pain, nausea and abdominal discomfort.

### Magnetic resonance imaging (MRI)

Examinations including the gallbladder and the hepatobiliary system were performed (after overnight fasting) using a 1.5 T magnetic resonance system [Magnetom Symphony ( $n = 1$  PSC), Vision ( $n = 7$  PSC) or Avanto ( $n = 12$  PSC and 10 controls]; Siemens, Erlangen, Germany]. Each patient was examined using the same unit before and after the meal combining the spine and the flexible body array coil. The use of different units was therefore not considered to influence the results. Gd-BOPTA (MultiHance® 0.5 mmol/mL, Bracco, Milan, Italy) at a dosage of 0.1 mmol/kg of was injected. Axial breath-hold 3D-T1-weighted scans (VIBE, slice thickness 1.7-2.5 mm) were performed natively and dynamically in arterial, portal-venous and delayed 5 min phase for clinical diagnosis. Postprandially, in the hepatobiliary phase, the hepatobiliary system was rescanned (VIBE).

### Gallbladder wall thickness, cystic duct and gall stones

The thickness of the gallbladder wall was measured on the axial T2 Haste slices at three different areas of the gallbladder. The mean values of the measurements were calculated for each patient. The presence of biliary stones and perivesical fluid was noted and the cystic duct was evaluated for the presence of strictures. Cystic duct abnormalities were defined as mural irregularities of the cystic duct on magnetic resonance cholangiography (MRC).

### Gallbladder wall contrast enhancement

Contrast enhancement of the gallbladder wall was analyzed in % using the formula: Contrast enhancement =  $[SI(\text{portalvenousphase}) - SI(\text{native})]/SI(\text{native}) \times 100$ .

In each patient the signal intensity (SI) of the wall was measured, in a single voxel, in three different areas, trying to avoid vessels and adjacent intestinal loops or the liver parenchyma. The same areas were measured natively

and in the portal venous phase and the enhancement was calculated for each part. The mean of the measurements was calculated for each patient.

### Gallbladder volume measurements

The 3D-T1-weighted scans were analysed using a Voxar® 3D workstation (Barco NV, Kortrijk, Belgium) using 3D segmentation and volume measurements. The volume of the gallbladder was measured fasting (delayed 5 min phase) and in the postprandial phase. In the latter hepatobiliary phase, contrast filling of the gallbladder was also noted. The analyses were made in consensus by two radiologists (NE and NA).

The ejection volume was measured in microliter using the formula: Ejection volume = volume (fasting) - volume (postprandial).

The ejection fraction or gallbladder emptying was measured in % using the formula: Ejection fraction = [volume (fasting) - volume (postprandial)]/volume (fasting) × 100.

Gallbladder fasting volume, ejection fraction and postprandial gallbladder volume of patients with PSC were compared with healthy controls. Postprandial gallbladder refilling of bile (that is, of contrast excreted to the common bile duct) was noted.

### Statistical analysis

Data were analyzed using statistical software (v 7.0, Stat Soft Inc.). Values are expressed as mean and standard deviation or as median (range). For comparison of categorical data, the Chi-square test was used, or Fisher's exact test when appropriate. Spearman's correlation test was used to determine the association between contrast enhancement and gallbladder wall thickness.  $P < 0.05$  was considered significant.

## RESULTS

The clinical characteristics of the 20 PSC patients and the healthy controls are shown in Table 1. There was no significant difference between the two groups regarding age and body mass index (BMI). The mean levels of plasma alkaline phosphatase (ALP) and plasma bilirubin were significantly higher in patients with PSC than in the healthy controls.

The median fasting gallbladder volume in patients with PSC was twice that of the healthy controls; 67 (range 19-348) mL and 32 (range 16-55) mL, respectively ( $P < 0.05$ ) (Figure 1A). The mean fasting gallbladder volume (mean ± SD) in patients with PSC was 91 ± 78 mL compared with 35 ± 11 mL in healthy controls. The median postprandial gallbladder volume in patients with PSC was significantly higher than that in healthy controls; 40 (9-345) mL and 16 (9-26) mL, respectively ( $P < 0.05$ ) (Figure 1B). Median ejection volume was 16 (1-100) mL in PSC patients and 16 (8-38) mL in healthy controls (n.s.) (Figure 1C).

There was no significant difference in ejection fraction between PSC patients and controls as shown in Figure 1D. Ninety percent (18/20) of patients had

**Table 1 Clinical characteristics of 20 patients with PSC and 10 healthy controls**

Clinical characteristic	PSC patients (n = 20)	Healthy controls (n = 10)	P value
Gender			
Male	70% (14/20)	50% (5/10)	NS

PSC: Primary sclerosing cholangitis; ALP: Alkaline phosphatase; ALT: Alanine aminotransferase; IBD: Inflammatory bowel diseases; UDCA: Ursodeoxycholic acid; UC: Ulcerative colitis; CD: Crohn's disease; NS: Not significant; BMI: Body mass index.

inflammatory bowel disease (IBD) and two of these patients had active disease. We found no significant difference in gallbladder volumes between the PSC patients with active IBD and patients who were in remission. None of the women in the PSC group were pregnant at the time of the study.

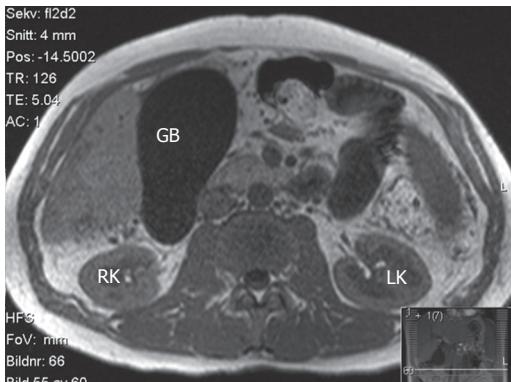

Two of the patients with PSC had liver cirrhosis. One of them, a 42-year-old man had the largest fasting gallbladder volume (348 mL) with an ejection fraction of only 1% (Figure 2). The other cirrhotic patient was a 37-year-old man with a fasting gallbladder volume of 20 mL and an ejection fraction of 55%.

Gallstones were found in the gallbladder in 20% (4/20) of the PSC patients but not in the controls. The median gallstone size was 2.5 mm (2-6 mm), these gallstones had no impact in the cystic duct in preprandial images. None of the patients had visible stones in the common bile duct. Perivesical fluid was seen in small amounts in 20% (4/20) of the PSC patients. None of the patients had a previous history of pancreatitis and we found no significant difference in gallbladder size between patients with and without abdominal pain.

The thickness of the gallbladder wall (mean ± SD) did not differ significantly between PSC patients and controls; 2.2 ± 0.5 mm and 1.9 ± 0.3 mm, respectively. However, there was a significant increase in contrast enhancement of the gallbladder wall (mean ± SD) in PSC patients compared to controls; 69% ± 32% and

**Figure 1** Fasting gallbladder volume (A), postprandial gallbladder volume (B), ejection fraction (C, ejection volume as percentage of fasting gallbladdervolume) and Ejection volume (D) measured with magnetic resonance imaging (MRI) in patients with primary sclerosing cholangitis (PSC) ( $n = 20$ ) and in healthy controls ( $n = 10$ ).

**Figure 2** MRI showing a large gallbladder volume of 348 mL in a patient with PSC.

$43\% \pm 21\%$ , respectively ( $P < 0.05$ ). There were no other signs of acute cholecystitis.

In all subjects there was a significant correlation between high contrast enhancement of the gallbladder wall and large gallbladder volume at fasting ( $P < 0.05$ ) ( $r = 0.39$ ). Postprandial gallbladder volume and ejection fraction were not significantly correlated to contrast enhancement of the gallbladder wall.

We found no correlation between patients with increased gallbladder volume, increased postprandial gallbladder volume and decreased ejection fraction and levels of P-Bilirubin, P-Cholesterol, P-Albumin, P-ALP, duration and distribution of PSC, treatment with ursodeoxycholic acid (UDCA), presence of IBD or age. In all subjects there was no significant correlation between BMI and fasting gallbladder volume or ejection fraction of the gallbladder. Seventeen of 20 patients with PSC were taking 10–15 mg/kg per day of UDCA.

The fasting gallbladder volume and ejection fraction was similar in patients who were on UDCA treatment ( $96 \pm 83$  mL and  $38\% \pm 27\%$ ) and patients who were not treated with UDCA ( $57 \pm 19$  mL and  $36\% \pm 15\%$ ) (n.s.). Seventy five percent (15/20) of the PSC patients and 100% (10/10) of the healthy controls showed contrast in the gallbladder in the hepatobiliary phase (n.s.). Abnormalities of the cystic ducts were visualized in 13 (60%) of the PSC patients and in none in the control group. No significant correlation was found between increased gallbladder fasting volume, decreased ejection fraction or lack of postprandial gallbladder refilling and presence of abnormalities in the cystic ducts.

### Symptoms

No significant association was found between gallbladder volumes or contrast enhancement and occurrence of abdominal pain, abdominal discomfort and nausea in PSC patients and controls. Before the fatty meal, 25% of PSC patients experienced abdominal pain, the visual analogue scale (VAS) ranging from 1 to 4. Twenty five percent of PSC patients experienced nausea with the VAS ranging from 1 to 2. Twenty percent of PSC patients experienced abdominal discomfort with the VAS ranging from 1 to 4. There was no significant increase in symptoms in the PSC group at one or three hours after meal ingestion. None of the healthy controls experienced symptoms pre- and postprandially.

### DISCUSSION

In the present study, we showed that patients with PSC have a significant increase in gallbladder volume both pre- and postprandially compared with healthy control

subjects. This is in agreement with a previous sonographic study by van de Meeberg *et al*<sup>[5]</sup>, who reported a fasting gallbladder volume of  $73 \pm 13.7$  mL compared with  $91 \pm 77.9$  mL in our study. The reason for the increased fasting gallbladder volume in patients with PSC is unclear. Several mechanisms may cause gallbladder enlargement, for example obstruction of the cystic duct or the common bile duct distal to the cystic duct, gallbladder dysmotility or gallbladder mucosal dysfunction may all contribute to increased fasting gallbladder volumes. In our study we excluded patients with significant extrahepatic strictures. Seventy-five percent of the PSC patients showed contrast in the gallbladder indicating the absence of a dominant stricture in the cystic duct. We also found that the gallbladder ejection fraction in PSC patients was similar to that of the healthy controls. Taken together, these findings do not suggest mechanical obstruction and/or gallbladder dysmotility as reasons for the enlarged gallbladder fasting volume in these patients.

Gallbladder abnormalities are common in PSC, and include cholecystitis which is found in 25% of all PSC patients<sup>[4]</sup>. In experimental cholecystitis the process of fluid absorption in the gallbladder epithelium changes to fluid secretion<sup>[25,26]</sup>. The secretory function of the gallbladder in PSC has been described previously in a case report of one PSC patient with concomitant cholecystitis. This patient produced between 39 mL and 52 mL of fluid daily from the gallbladder epithelium<sup>[27]</sup>. We found a similar gallbladder wall thickness in cases and controls. This finding may represent an underestimation of the wall thickness in PSC patients since the gallbladder is larger and more distended. The increased enhancement of the gallbladder wall may indicate the presence of inflammation of the gallbladder epithelium and wall in PSC patients. This sign of cholecystitis, in combination with normal ejection fraction of the gallbladder in PSC patients, support the notion that gallbladder mucosal dysfunction is a possible cause of the increased fasting gallbladder volume and residual volume in patients with PSC. The presence of inflammatory changes in the gallbladder epithelium and its effect on absorption/secretory functions is difficult to evaluate in a clinical setting. There are obvious problems in obtaining daily gallbladder volume measurements in patients, and biopsies are needed for the proper evaluation of inflammation. Measurement of bile concentration in the gallbladder could be a surrogate marker for absorption/secretory dysfunction and such measurements may be possible in the future using MR spectroscopy techniques.

The effect of UDCA treatment on gallbladder motility is unclear. Several studies have shown that UDCA treatment results in increased fasting and postprandial gallbladder volume, whereas gallbladder emptying has not been shown to be reduced or modified<sup>[28-31]</sup>. PSC patients in the study conducted by Van de Meeberg *et al*<sup>[5]</sup>, which showed similar results to ours, discontinued their UDCA medication for four weeks before commencement of the study. We decided not to discontinue therapy with UDCA based on the above studies in order to study the patients' symptoms in a true clinical setting. Eighty-five percent of

our PSC patients were treated with UDCA. We did not ascertain any significant difference in fasting gallbladder volume and gallbladder emptying between UDCA treated and untreated patients. However, this should be interpreted with caution due to the small number of patients involved.

Up to a third of all PSC patients experience pain in the upper right quadrant of the abdomen<sup>[19,20]</sup>. This abdominal pain is most often intermittent, but may occasionally be of a more continuous nature<sup>[32]</sup>. Abdominal pain has been hypothesized to result from constriction of the bile ducts. One third of patients with small duct PSC, which is characterized by the absence of strictures in the large ducts also suffer from abdominal pain<sup>[33]</sup> indicating that biliary strictures do not play a role in the development of abdominal pain. In our study, we did not find any significant difference among PSC patients regarding gallbladder dysfunction and the occurrence of abdominal pain, abdominal discomfort and nausea pre- or postprandially. Gallbladder motility dysfunction as a pathophysiological factor in the development of abdominal pain in patients with PSC is therefore unlikely.

In conclusion, patients with PSC have increased fasting and residual gallbladder volumes, whereas gallbladder emptying is normal. The reason for the increased fasting gallbladder volume is unclear. However, gallbladder mucosal dysfunction secondary to chronic inflammation of the gallbladder is a possible mechanism. Gallbladder size or emptying does not seem to be involved in the development of abdominal pain in patients with PSC.

## COMMENTS

### Background

The mechanisms responsible for the abdominal pain in primary sclerosing cholangitis (PSC) are not fully understood. The aim of the present study was to assess gallbladder emptying and its association with cholecystitis and abdominal pain in patients with PSC.

### Research frontiers

The authors compared gallbladder volumes at fasting and after ingestion of a test meal in patients with PSC and healthy controls using magnetic resonance imaging (MRI). Symptoms, thickness and contrast enhancement of the gallbladder wall and the presence of cystic duct strictures were also assessed.

### Innovations and breakthroughs

The increased enhancement of the gallbladder wall on MRI may indicate the presence of inflammation of the gallbladder epithelium and wall in PSC patients. Gallbladder size or emptying does not seem to be involved in the development of abdominal pain in patients with PSC.

### Applications

The present study provides information on the possible mechanisms of increased fasting gallbladder volume in patients with PSC.

### Peer review

This is an interesting report addressing a clinically important question: whether gallbladder emptying is associated with cholecystitis and the abdominal pain in patients with PSC. The authors analyzed 20 patients with PSC and compared with ten healthy subjects. Results indicate that patients with PSC have increased fasting and residual gallbladder volumes, probably resulting from gallbladder mucosal dysfunction secondary to chronic cholecystitis. However, gallbladder size or the emptying process does not seem to cause abdominal pain in patients with PSC.

duration of  $9.0 \pm 7.2$  years. In a logistic regression analysis corrected for disease duration, perianal disease, smoking, steroid use, early AZA or AZA/biological therapy use were independent predictors of disease behavior change. In a subsequent Kaplan-Meier survival analysis and a proportional Cox regression analysis, disease location ( $P = 0.001$ ), presence of perianal disease ( $P < 0.001$ ), prior steroid use ( $P = 0.006$ ), early AZA ( $P = 0.005$ ) or AZA/biological therapy ( $P = 0.002$ ), or smoking ( $P = 0.032$ ) were independent predictors of disease behavior change.

**CONCLUSION:** Our data suggest that perianal disease, small bowel disease, smoking, prior steroid use, early AZA or AZA/biological therapy are all predictors of disease behavior change in CD patients.

### Abstract

**AIM:** To assess the combined effect of disease phenotype, smoking and medical therapy [steroid, azathioprine (AZA), AZA/biological therapy] on the probability of disease behavior change in a Caucasian cohort of patients with Crohn's disease (CD).

**METHODS:** Three hundred and forty well-characterized, unrelated, consecutive CD patients were analyzed (M/F: 155/185, duration:  $9.4 \pm 7.5$  years) with a complete clinical follow-up. Medical records including disease phenotype according to the Montreal classification, extraintestinal manifestations, use of medications and surgical events were analyzed retrospectively. Patients were interviewed on their smoking habits at the time of diagnosis and during the regular follow-up visits.

**RESULTS:** A change in disease behavior was observed in 30.8% of patients with an initially non-stricturing, non-penetrating disease behavior after a mean disease

### INTRODUCTION

Inflammatory bowel disease (IBD) is a multifactorial disease with probable genetic heterogeneity<sup>[1]</sup>. In addition, several environmental risk factors (e.g. diet, smoking, measles or appendectomy) may contribute to its pathogenesis. During the past decades, the incidence pattern of both forms has significantly changed<sup>[2]</sup>, showing some common but also quite distinct characteristics for the two disorders.

Phenotypic classification of Crohn's disease (CD) plays an important role in determining treatment and may assist in predicting the likely clinical course of disease<sup>[3]</sup>. In 2005, the Montreal revision of the Vienna classification system was introduced<sup>[4]</sup>. Although the broad categories for CD classification remained the same, changes were made within each category. Upper gastrointestinal disease can now exist independently of, or together with, disease present at more distal locations. Finally, perianal disease, which occurs independently of small bowel fistulae, is no longer classified as penetrating disease. Instead, a perianal modifier has been introduced, which may coexist with any disease behavior.

Using the Vienna classification system, it has been shown in clinic-based cohorts that there can be a significant change in disease behavior over time, whereas disease location remains relatively stable<sup>[3,5]</sup>. An association between the presence of perianal disease and internal fistulation (OR: 2.6-4.6) was reported earlier by Sachar *et al*<sup>[6]</sup> in patients with colonic disease. Most recently, Australian authors<sup>[3]</sup> have shown that although > 70% of CD patients had inflammatory disease at diagnosis, the proportion of patients with complicated disease increased over time. Progression to complicated disease was more rapid in those with small bowel than colonic disease location ( $P < 0.001$ ), with perianal disease being also a significant predictor of change in CD behavior (HR: 1.62,  $P < 0.001$ ). Similarly, small bowel location and stricturing disease were predictors for surgery in a long-term follow-up study<sup>[7]</sup>. Finally, perianal lesions, the need for steroids to treat the first flare-up and ileocolonic location, but not an age below 40 years were confirmed as predictive markers for developing disabling disease (according to the predefined criteria) at 5 years<sup>[8]</sup>. In the same study, stricturing behavior (HR: 2.11, 95% CI: 1.39-3.20) and weight loss ( $> 5$  kg) (HR: 1.67, 95% CI: 1.14-2.45) at diagnosis were independently associated with the time to development of severe disease.

A further environmental factor which may be of importance in determining change in disease behavior is smoking. In CD, smoking was reported to be associated with disease location: most, but not all, studies report a higher prevalence of ileal disease and a lower prevalence of colonic involvement in smokers<sup>[9,10]</sup>. A recent review<sup>[10]</sup> and previous data have demonstrated that smoking, when measured up to the time-point of disease behavior classification, was more frequently associated with complicated disease and penetrating intestinal complications<sup>[9,11,12]</sup>, a greater likelihood of progression to complicated disease, as defined by the development of strictures or fistulae<sup>[10]</sup>, and a higher relapse rate<sup>[13]</sup>. In addition, the risk of surgery as well as the risk for further resections during disease course were also noted to be higher in smokers in some studies<sup>[9,14]</sup> and a recent meta-analysis<sup>[15]</sup>. The need for steroids and immunosuppressants was found to be higher in smokers compared to non-smokers<sup>[16]</sup>. Noteworthy, in one study by Cosnes *et al*<sup>[17]</sup>, immunosuppressive therapy was found to neutralize the effect of smoking on the need for surgery. In a recent paper by Aldhous *et al*<sup>[18]</sup>, using the Montreal classification, the harmful effect of smoking was only partially confirmed. Although

current smoking was associated with a lower rate of colonic disease, the smoking habits at diagnosis were not associated with time to development of stricturing disease, internal penetrating disease, perianal penetrating disease, or time until first surgery.

Finally, early postoperative use of azathioprine (AZA, at a dose of 2-2.5 mg/kg per day) appeared to delay postoperative recurrence in comparison to a historical series or placebo groups in randomized, controlled trials<sup>[19]</sup>. Furthermore, in a recent withdrawal study by the GETAID group<sup>[20]</sup>, the authors provide evidence for the benefit of long-term AZA therapy beyond 5 years in patients with prolonged clinical remission. In contrast, initial requirement for steroid use [OR: 3.1 (95% CI: 2.2-4.4)], an age below 40 years (OR: 2.1, 95% CI: 1.3-3.6), and the presence of perianal disease (OR: 1.8, 95% CI: 1.2-2.8) were associated with the development of disabling disease in the study by Beaugerie *et al*<sup>[21]</sup>. The positive predictive value of disabling disease in patients with two and three predictive factors for disabling disease was 0.91 and 0.93, respectively.

In this study, the authors aimed to assess the combined effect of disease phenotype, smoking, and medical therapy (steroid, AZA, AZA/biological) on the probability of disease behavior change in a cohort of Hungarian CD patients.

## MATERIALS AND METHODS

### Patients

Three hundred and forty well-characterized, unrelated, consecutive CD patients (age:  $38.1 \pm 13.2$  years, M/F: 155/185, duration:  $9.4 \pm 7.5$  years) with a complete clinical follow-up were included. A detailed clinical phenotypic description of these patients is presented in Table 1.

The diagnosis was based on the Lennard-Jones Criteria<sup>[22]</sup>; age, age at onset, presence of familial IBD, presence of extraintestinal manifestations; arthritis: peripheral and axial; ocular manifestations: conjunctivitis, uveitis, iridocyclitis; skin lesions: erythema nodosum, pyoderma gangrenosum; and hepatic manifestations: primary sclerosing cholangitis, frequency of flare-ups (frequent flare-up:  $> 1$  per year). The disease phenotype (age at onset, duration, location, and behavior) was determined according to the Montreal Classification<sup>[4]</sup> (non-inflammatory behavior: either stricturing or penetrating disease). Perianal disease and behavior change during follow-up were also registered. Medical therapy was registered in detail [e.g. steroid and/or immunosuppressive/biological therapy use, AZA intolerance as defined by the ECCO (European Crohn's and Colitis Organisation) Consensus Report<sup>[23]</sup>], need for surgery/reoperation (resections) in CD, and time-point of surgery/reoperation and smoking habits, were investigated by reviewing the medical charts and completing a questionnaire. Only patients with a confirmed diagnosis for more than 1 year were enrolled.

Definitions of AZA/biological therapy use and smoking: patients were regarded as AZA users if they took a dose of  $\geq 1.5$  mg/kg body weight for at least 6 mo. Early use was considered if the use of immuno-

modulatory therapy preceded the behavior change by at least 6 mo. According to the Center's policy, if AZA was started, its use was not halted even in patients with long-term clinical remission. The rate of AZA intolerance was 14.3% (including 36 additional patients), and these patients were classified as AZA-non-users. Common intolerance reactions were leukopenia, abdominal pain, and in three patients, pancreatitis. Biological therapy use was considered if the patient received at least a full, anti-tumor necrosis factor induction therapy at an appropriate dose. The definition of smoking consisted of smoking ≥ 7 cigarettes/wk for at least 6 mo<sup>[15-18]</sup> at the time of diagnosis and/or during follow-up, within 1 year of diagnosis or behavior change. Patients were interviewed on their smoking habits at the time of diagnosis and during the regular follow-up visits. Moreover, due to Hungarian health authority regulations, a follow-up visit is obligatory for IBD patients at a specialized gastroenterology centre every 6 mo. Otherwise, the conditions of the health insurance policy change and they forfeit their ongoing subsidized therapy. Consequently, the relationship between the IBD patients and their specialists is a close one. The referred patients were retrospectively interviewed about their smoking habits at the time of referral and thereafter. Smoking cessation was defined as complete abstinence of at least 1 year's duration. Only 16 (4.7%) CD patients

stopped smoking during the course of the disease, while 2 additional CD patients started smoking after the diagnosis. In patients with change in disease behavior, all CD patients stopped smoking following the change. Since macroscopic lesions on the ileal side of the anastomosis observed 1 year following surgery were not different between smokers and non-smokers and there was no significant difference reported between ex-smokers and non-smokers in reoperation rates in a recent meta-analysis<sup>[15,24]</sup>, ex-smokers at the time of diagnosis were included in the non-smoker group.

Detailed clinical phenotypes were determined by thoroughly reviewing the patients' medical charts, which had been collected in a uniform format. The central coordination of sample and database management was completed at the 1st Department of Medicine, Semmelweis University (by PLL, TS). Data capture was prospective except for referred patients in whom disease course until referral was registered at the date of the referral and prospectively thereafter. Data analysis was done retrospectively. The study was approved by the Semmelweis University Regional and Institutional Committee of Science and Research Ethics.

### Statistical analysis

Variables were tested for normality using Shapiro Wilk's W test. The *t*-test with separate variance estimates, ANOVA with *post hoc* Scheffe test,  $\chi^2$ -test, and  $\chi^2$ -test with Yates correction were used to evaluate differences within subgroups of IBD patients. Kaplan-Meier survival curves were plotted for analysis with the LogRank and Breslow tests. Additionally, forward stepwise Cox regression analysis was used to assess the association between categorical clinical variables and surgical requirements.  $P < 0.05$  was considered as significant. For the statistical analysis, SPSS 15.0 (SPSS Inc, Chicago, IL) was used with the assistance of a statistician (Dr. Peter Vargha).

## RESULTS

### Association between clinical markers and disease behavior change in CD patients

In a univariate analysis, behavior change from B1 to B2/B3 during follow-up was associated with disease duration, location, presence of perianal disease, smoking at diagnosis, frequency of relapses, steroid use, early AZA use, AZA/biological therapy use and need for resective surgery (Table 2). Although ocular manifestations were also associated with behavior change (3.6% vs 11.5%,  $P = 0.033$ ), this became non-significant after Bonferroni correction. Patients with a change in disease behavior had significantly longer disease duration ( $12.3 \pm 7.6$  years vs  $7.4 \pm 6.5$  years,  $P < 0.001$ ).

In a logistic regression model, disease duration, presence of perianal disease, smoking, steroid use, and early AZA use prior to behavior change were independent predictors for change in disease behavior (Table 3). If early AZA use was changed to early AZA and/or biological therapy use (Coefficient: -1.221,  $P = 0.002$ , OR: 0.29, 95% CI: 1.34-0.64) in the same logistic regression model, the associations remained unchanged.

**Table 2** Clinical factors associated with behavior change from inflammatory to complicated disease behavior *n* (%)

Factor	Prevalence without behavior change	Prevalence with behavior change	P-value	OR	95% CI
Disease location

Early azathioprine/biological use	83 (60.6)	25 (41)	0.01	0.45	0.24-0.84
Need for operation	19 (13.9)	37 (60.7)	< 0.001	9.6	4.72-19.4

**Table 3** Logistic regression: predictive factors for behavior change from non-stricturing, non-penetrating to complicated disease behavior in Crohn's disease

Factor	Coefficient	P-value	OR	95% CI
Disease location	-0.385	0.13	-	-
Longer disease duration ( $\leq 10$ yr vs > 10 yr)	1.476	< 0.001	4.37	2.04-9.38
Perianal disease	1.351	0.001	3.86	1.72-8.67
Frequent relapses	0.388	0.404	-	-
Smoking	1.015	0.009	2.76	1.29-5.89
Steroid use	2.089	0.01	8.07	1.64-39.7
Early azathioprine use	-1.055	0.006	0.35	0.16-0.74

The coefficient is equivalent to the natural log of the OR.

### Association between clinical markers and time to disease behavior change in CD patients

Disease location, perianal disease, early AZA or AZA/biological therapy, steroid use (LogRank  $P = 0.004$  and Breslow  $P = 0.005$ ) and smoking were significant determinants for time to behavior change surgery in a Kaplan-Meier analysis using LogRank and Breslow tests (Figure 1).

To further evaluate the effect of the above variables on the probability of behavior change, we performed a forward stepwise proportional Cox regression analysis. Each of the above variables was independently associated with the probability of disease behavior change (Table 4). The result was the same if early AZA/biological therapy use ( $P = 0.002$ , HR: 0.43, 95% CI: 0.25-0.73) was incorporated in the same analysis.

## DISCUSSION

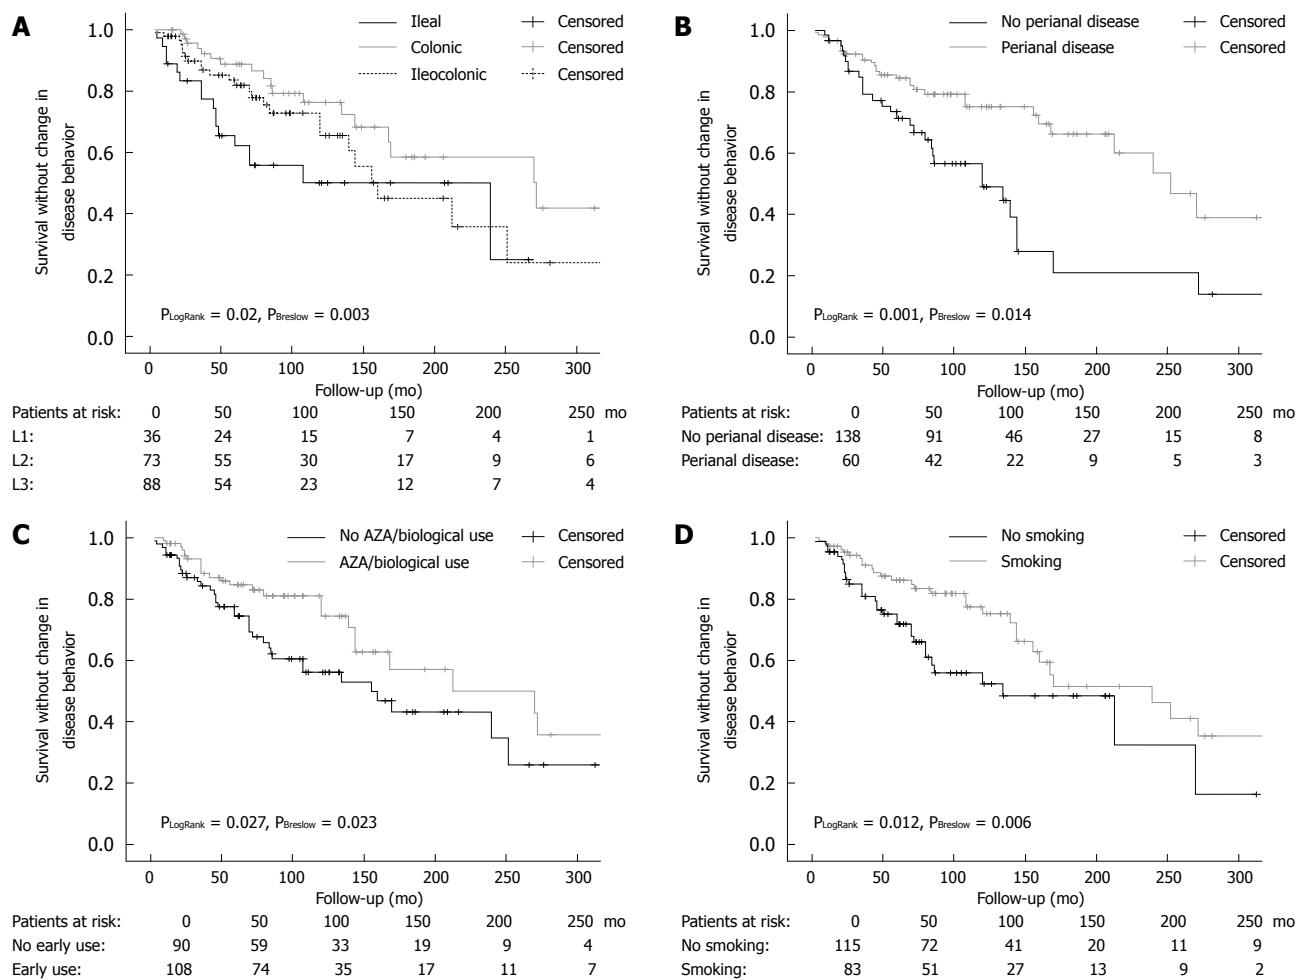

In the present study, we assessed, for the first time, the combined effect of disease phenotype and medical therapy on the probability of disease behavior change in a well-characterized CD cohort with a strict clinical follow-up. This study has shown that perianal disease, disease location, prior steroid, early AZA or AZA/biological therapy were significant independent predictors of disease behavior change during follow-up in patients with CD, in a stepwise proportional Cox regression and Kaplan-Meier analysis.

**Table 4** Summary of Cox regression model: factors affecting time to disease behavior change

	P-value	Hazard ratio	95% CI
Disease location	0.001		
L1	0.023	2.13	1.11-4.08
L2	0.05	0.54	0.27-1.001
L3		Reference	
Perianal disease			
Yes	< 0.001	3.26	1.90-5.59
No		Reference	
Steroid use			
Yes	0.006	7.48	1.79-31.2

In accordance with the findings by Tarrant *et al*<sup>[3]</sup>, the presence of perianal disease was associated with a 3-4-fold increased risk of developing complicated disease behavior in patients with non-stricturing, non-penetrating disease at the time of diagnosis. Interestingly, in both studies, approximately 50%-55% of patients with perianal disease and only 15%-20% of patients without perianal disease developed a complicated disease behavior after 10 years of follow-up. In the present study, however, only 60% of the patients presented with B1 behavior, representing the more severe disease population in referral centers. In contrast, the Australian study reports the results of a population-based cohort follow-up. Therefore, our results are not only confirmatory, but enable us to extrapolate on the finding that perianal disease is a poor prognostic factor in referral center IBD populations.

In addition, similar to the Australian study, the present study found that progression to complicated disease was more rapid in those with small bowel than colonic disease location. The HR was significantly lower (0.54,  $P = 0.05$ ) for colonic disease and significantly higher for ileal disease (2.13,  $P = 0.023$ ) compared to an ileocolonic location in the Cox regression analysis. The same conclusions were reached when data were analyzed

**Figure 1 Association between disease location (A), perianal disease (B), early azathioprine/biological therapy use (C) or smoking (D) and disease behavior change from non-stricturing, non-penetrating to complicated disease behavior in Crohn's disease.**

by the Kaplan-Meier method using the LogRank and Breslow tests for comparison. Of note, while the L1 and L3 curves ran parallel after 150 mo, the relatively small number of patients in the L1 group may have introduced a bias in the analysis. These results were only partially confirmed by Aldhous *et al*<sup>[18]</sup>. In 275 CD patients, colonic disease was negatively associated with the time required for development of stricturing complications ( $P < 0.001$ ), while any upper gastrointestinal disease (and tendentially ileocolonic disease,  $P = 0.066$ ) was the only factor significantly increasing the risk of development of fistulizing complications. Finally, small bowel involvement, stricturing disease, and a young age at diagnosis were associated with disease recurrence in another Dutch population-based study<sup>[7]</sup>.

In the present study, we could not confirm frequency of relapses as an independent prognostic factor for disease behavior change. This is somewhat in contrast with the findings by Munkholm *et al*<sup>[25]</sup>, where the relapse rate within a year of diagnosis and in the following 2 years, was positively correlated ( $P = 0.00001$ ) with the relapse rate in the following 5 years in patients with CD.

The findings were slightly different if the authors assessed the clinical factors associated with the development of irreversible structural damage. After a multivariate analysis, only stricturing behaviour at diagnosis (HR:

2.11,  $P = 0.0004$ ) and weight loss ( $> 5$  kg) at diagnosis (HR: 1.67,  $P = 0.0089$ ) were independently associated with time to the development of severe disease in the study by Loly *et al*<sup>[8]</sup>. The definition of severe, non-reversible damage was, however, much more rigorous. It was defined by the presence of at least one of the following criteria: the development of complex perianal disease, any colonic resection, two or more small-bowel resections (or a single small-bowel resection measuring more than 50 cm in length) or the construction of a definite stoma. Nonetheless, medical therapy was not included in either of the previous studies.

Similarly, although the effect of smoking was extensively investigated in IBD, most studies failed to investigate the complex associations between smoking, disease phenotype, and medical therapy. A recent review<sup>[10]</sup> and previous data have demonstrated that current smoking was more frequently associated with complicated disease, penetrating intestinal complications<sup>[9,10]</sup>, and greater likelihood to progress to complicated disease, as defined by the development of strictures or fistulae<sup>[11]</sup>. In accordance, in the present study, smoking at the time of diagnosis was independently associated with time to behavior change from a non-stricturing, non-penetrating phenotype to complicated disease behavior in CD in a Cox regression model.

However, this was not a universal finding. In a recent paper by Aldhous *et al*<sup>[18]</sup>, using the Montreal classification, the harmful effect of smoking was only partially confirmed. Although current smoking was associated with less colonic disease, the smoking habits at diagnosis were not associated with time to development of strictureting disease, internal penetrating disease, perianal penetrating disease, or time to first surgery. In contrast, disease location was associated with the need for surgery.

A more solid end-point was also deleteriously affected by smoking in the present study; the need for intestinal resection but not reoperation was also increased in smokers (HR: 3.19,  $P < 0.001$ ) not treated with immunosuppressive therapy, especially in females, in accordance with data from Cosnes *et al*<sup>[26]</sup>. Much emphasis was also placed, by some authors, on investigating the association between the amount of smoking and the above variables in both CD and ulcerative colitis. In a recent publication, the authors<sup>[18]</sup> did not find a significant association between pack-years of smoking and disease behavior or need for surgery. In addition, in a recent French publication<sup>[27]</sup>, light smokers had higher resection rates compared to non-smokers in CD, suggesting that complete smoking cessation should be advised for all smokers with CD.

The key to explaining these conflicting results lies partly in the study by Cosnes *et al*<sup>[17]</sup>, where the authors have demonstrated that immunosuppressive therapy neutralizes the effect of smoking on the need for surgery. Therefore, we aimed to analyze the effect of smoking in a more complex setting. After obtaining the results of the univariate and Kaplan-Meier analyses, we performed both a logistic regression analysis adjusted to disease duration as an independent variable and a step-wise proportional Cox regression analysis to investigate the relative weight of the risk factors. In this analysis, perianal disease, smoking, steroid use, and AZA or AZA/biological therapy use before the behavior change were independently associated with time to disease behavior change. However, a partial recall bias, especially in the referral patients, where smoking habits were analyzed in a partially retrospective manner, cannot be excluded.

Finally, the initial requirement for steroid use (OR: 3.1, 95% CI: 2.2-4.4), an age below 40 years at diagnosis (OR: 2.1, 95% CI: 1.3-3.6), and the presence of perianal disease (OR: 1.8, 95% CI: 1.2-2.8) were associated with the development of disabling disease in the study by Beaugerie *et al*<sup>[21]</sup>. The positive predictive values of disabling disease in patients with two and three predictive factors for disabling disease were 0.91 and 0.93, respectively. Nonetheless, the prevalence of disabling disease was approximately 80.5% at 5 years in the entire patient group, which makes these criteria less valuable in clinical practice. Moreover, the authors classified the need for immunosuppressive therapy as one potential disabling factor, which in light of the present study, is rather controversial. In the present study, prior steroid use was an independent predictor of time to change in disease behavior. However, again, because of the high prevalence of overall steroid use, the confidence interval is wide and, consequently, the clinical usefulness of this marker is relatively low.

In adults, early postoperative use of AZA at a dose

of 2-2.5 mg/kg per day seemed to delay postoperative recurrence in comparison to a historical series or placebo groups in randomized, controlled trials<sup>[19]</sup>. Furthermore, in a recent withdrawal study by the GETAID group<sup>[20]</sup>, the authors provided evidence for the benefit behind long-term AZA therapy beyond 5 years in patients with prolonged clinical remission. The most convincing data to support the benefit from early use of AZA, however, comes from the pediatric literature<sup>[28]</sup>, where in a randomized, controlled trial in 55 children, early 6-mercaptopurine use was associated with a significantly lower relapse rate (only 9%) compared with 47% of controls ( $P = 0.007$ ). Moreover, the duration of steroid use was shorter ( $P < 0.001$ ) and the cumulative steroid dose lower at 6, 12 and 18 mo ( $P < 0.01$ ). More recently, also in a pediatric setting, this strategy was found to be associated with a lower hospitalization rate<sup>[29]</sup>. Similarly, in the present study, early AZA or AZA/biological therapy was an independent preventive factor associated with decreased probability of developing complicated disease behavior during the course of the disease (HR: 0.46 and 0.43).

In conclusion, in the present study, we have shown that the complex analysis of disease phenotype, medication history, and smoking habits is needed, in order to study the factors associated with change in disease behavior in patients with IBD. Our data suggest that perianal disease, current smoking, prior steroid use, early AZA or AZA/biological therapy are predictors of disease behavior change in patients with CD.

## COMMENTS

### Background

Using the Vienna classification system, it has been shown in clinic-based cohorts that there can be a significant change in inflammatory bowel disease (IBD) disease behavior over time, whereas disease location remains relatively stable. Early age at diagnosis, disease location, perianal disease and, in some studies, smoking were associated with the presence of complicated disease and surgery in previous studies.

### Research frontiers

The combined effect of markers of disease phenotype (e.g. age, gender, location, perianal disease) and medical therapy (steroid use, early immunosuppression) on the probability of disease behavior change have not, however, been studied in detail thus far in the published literature.

### Innovations and breakthroughs

In the present study, the authors have shown in a well-characterized Crohn's disease (CD) cohort with strict clinical follow-up, that the complex analysis of disease phenotype, medication history, and smoking habits is needed in order to study the factors associated with change in disease behavior in patients with IBD. Their data suggest that perianal disease, current smoking, prior steroid use, early azathioprine (AZA) or AZA/biological therapy are predictors of disease behavior change in patients with CD.

### Applications

New data with easily applicable clinical information may assist clinicians in everyday, practical decision-making, when choosing a treatment strategy for their CD patients.

## Terminology

Vienna-Montreal classification: classification systems of CD disease phenotypes. The Vienna classification assesses the age at presentation, disease location and disease behavior. In the Montreal classification, the broad categories for CD classification remain the same; however, changes were made within each category. First, a new category was introduced for those aged 16 years or younger at the time of diagnosis, to separate pediatric from adult-onset IBD. Second, upper gastrointestinal disease and perianal disease became disease modifiers, which may coexist with any disease behavior or location.

## Peer review

The present article provides valuable information regarding clinical prognostic factors of phenotype changes of CD over time. The study was performed in a large cohort of patients.

was detected in eight cases (0.8%), six of them in BE patients. There was no significant difference between patients with BE and GERD regarding sex, smoking, alcohol consumption or symptoms of GERD. Patients with BE had significantly longer esophageal acid exposure time in the supine position, measured by pH monitoring.

**CONCLUSION:** The prevalence of BE in patients with GERD who were referred for endoscopy was 7.3%. BE seems to be associated with older age and more in patients with nocturnal gastroesophageal reflux.

## Abstract

**AIM:** To determine the prevalence and possible risk factors of Barrett's esophagus (BE) in patients with chronic gastroesophageal reflux disease (GERD) in El Minya and Assuit, Upper Egypt.

**METHODS:** One thousand consecutive patients with chronic GERD symptoms were included in the study over 2 years. They were subjected to history taking including a questionnaire for GERD symptoms, clinical examination and upper digestive tract endoscopy. Endoscopic signs suggestive of columnar-lined esophagus (CLE) were defined as mucosal tongues or an upward shift of the squamocolumnar junction. BE was diagnosed by pathological examination when specialized intestinal metaplasia was detected histologically in suspected CLE. pH was monitored in 40 patients.

**RESULTS:** BE was present in 7.3% of patients with chronic GERD symptoms, with a mean age of  $48.3 \pm 8.2$  years, which was significantly higher than patients with GERD without BE ( $37.4 \pm 13.6$  years). Adenocarcinoma

## INTRODUCTION

Barrett's esophagus (BE) was first identified by N.R. Barrett in 1950, who described the replacement of the normal squamous mucosa of the distal esophagus by a columnar epithelium of both gastric and intestinal types<sup>[1,2]</sup>. The definition of BE has been modified over subsequent years to include only intestinal metaplasia within the tubular esophagus.

The exact cause of BE remains unclear. A popular explanation for the occurrence of BE is that it results from mucosal damage caused by gastroesophageal reflux<sup>[3,4]</sup>. When visible upon upper gastrointestinal endoscopy, this mucosal damage is termed erosive esophagitis. However, not all patients with gastroesophageal reflux and erosive

esophagitis go on to develop BE, and not all patients with BE have a history of gastroesophageal reflux<sup>[5]</sup>. In most patients with reflux esophagitis, the epithelium heals through regeneration of the normal squamous lining<sup>[6]</sup>. Other patients, however, will develop BE with the risk of ultimately progressing to esophageal adenocarcinoma (EAC)<sup>[7]</sup>.

The prevalence of BE varies in different geographic areas worldwide. Multiple risk factors for the development of BE besides reflux have been studied, including being Caucasian and/or male, a history of smoking, and hiatus hernia<sup>[8]</sup>.

The aim of this study was to determine the prevalence and possible risk factors of BE in patients with chronic gastroesophageal reflux disease (GERD) symptoms in Upper Egypt.

## MATERIALS AND METHODS

### Ethics

This study was carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. All patients provided informed written consent.

### Location

The study was performed at two clinical centers in Upper Egypt (Southern part of Egypt): the endoscopy units of the Department of Tropical Medicine at El Minya University, and the Department of Internal Medicine at Assuit University, from January 2006 to January 2008. Both centers are referral centers for a large number of patients in Upper Egypt.

### Patients

In a prospective manner, 1000 consecutive patients with chronic GERD symptoms were recruited. All patients had a history of longstanding heartburn and or regurgitation for at least three times weekly for the last year. A questionnaire was completed by every patient, including age, sex, occupation, smoking and alcohol consumption. The symptom questionnaire also included the following criteria: primary referral symptom; frequency of GERD symptoms such as heartburn, regurgitation, and acid taste; extra esophageal symptoms; and history of systemic diseases such as scleroderma and diabetes.

### Endoscopic examination

Endoscopic examination was performed using an Olympus Evis CLV-U 200 Videoscope (Olympus, Japan). All patients were examined in our units by a well-trained endoscopist. BE was diagnosed by the presence of columnar-lined esophagus at endoscopy and the confirmed presence of intestinal metaplasia upon biopsy. In addition, information on the presence of intestinal metaplasia, evidence of dysplasia (a premalignant condition characterized by increased cell growth, cellular atypia, and altered cell differentiation) and its severity,

and the presence of coexistent EAC was obtained from histopathology records. We defined short-segment BE by the presence of less than 3 cm of columnar-lined esophagus at endoscopy. The distinction between long- and short-segment BE was made. We also recorded the presence of esophagitis or any esophageal lesions. Repeat endoscopy was done in patients with erosive esophagitis after complete healing, to confirm the presence of BE. Then the patients were classified into two groups according to presence or absence of BE.

### Histopathological examination

Fresh endoscopic biopsy samples were obtained from the operating theatre and fixed in 10% formalin within 13 h at room temperature. Tissues were subjected to a series of processing steps, which included fixation, dehydration with ethanol, clearing with xylene, and wax impregnation with paraffin, and then stained with hematoxylin and eosin (HE).

Ambulatory pH monitoring was done for 40 patients (20 patients with BE and 20 without). All patients were studied with ambulatory pH monitoring using an antimony pH electrode placed 5 cm above the proximal border of the manometrically located lower esophageal sphincter, and another electrode placed 10 cm above this point in the proximal esophagus, connected to a portable Digitrapper (Synectics, San Antonio, TX, USA) data storage unit. Intraesophageal pH was recorded continuously, with sampling obtained every 4 s. All pH tracings were analyzed for the percentage time that the distal and proximal esophageal pH was < 4, determined for the upright and recumbent time periods in each study. Average esophageal acid clearance (EAC) time was calculated for each patient by dividing the total time (in minutes) that distal esophageal pH remained < 4 by the total number of GERD episodes. This was calculated for both the upright and supine periods.

### Statistical analysis

Statistical analyses were performed using Stats Direct version 2.2.5 statistical software (Stats Direct Ltd., Sale, Cheshire, UK) and SPSS for Windows version 11.5 (SPSS, Inc., Chicago, IL, USA). All data are presented as means  $\pm$  SD.  $\chi^2$  and Fisher's tests were used to compare BE and GERD groups according to sex, smoking and alcohol consumption. Student's *t* test was used for some factors. ANOVA was used for pH measurement analysis. Significance was accepted at  $P \leq 0.05$ .

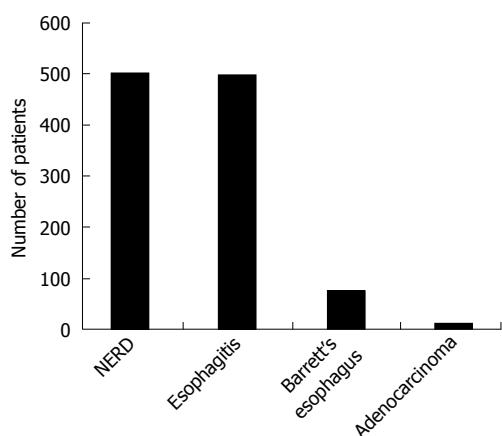

## RESULTS

This study included 1000 patients with chronic GERD symptoms (764 male and 236 female) with a mean age of  $38.81 \pm 14.52$  years. Seventy-three of these patients (7.3%) had BE suspected endoscopically and detected histopathologically. The remaining 927 patients (92.7%) were negative for BE. Accordingly, we classified the patients into two groups: group A included patients with

Hiatus hernia	29 (39.7)	389 (42.1)	0.8 (NS)
Gastritis	53 (72.7)	667 (71.6)	0.8 (NS)
Duodenitis	21 (28.7)	297 (31.8)	0.7 (NS)

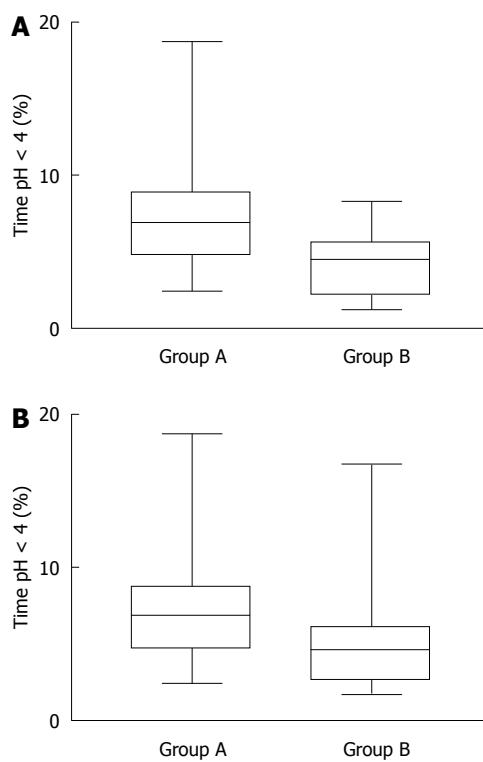

NS: Not significant;  $\chi^2$  and Student's *t* test used for statistical analysis. The patients with BE (group A) were significantly older than those with GERD (group B) ( $P < 0.05$ ).

**Figure 1** Endoscopic findings. Esophagitis was detected in 498 patients (49.8%) and NERD was seen in 502 patients. BE was present in 73 patients. EAC was detected in eight patients.

BE and group B included those with chronic GERD without BE. The mean length of BE was  $5.3 \pm 2.6$  cm. Short-segment BE was present in 61 patients (84%), while long-segment BE was present in 12 (16%). Four cases with BE were detected in endoscopy-negative patients, while the remainder was detected in patients with esophagitis. EAC was detected in eight patients (six in group A and two in group B).

Regarding age and sex, the mean age of patients in group A ( $48.3 \pm 8.2$  years) was significantly older than that in group B ( $37.6 \pm 13.4$  years) ( $P < 0.05$ ), and there was no significant difference regarding sex between the groups (Table 1). Although smoking and alcohol consumption were more frequent in the BE group, there was no significant difference from those without BE.

**Figure 2** Distal esophageal acid exposure in both groups. A: In the supine position. The median time at pH < 4 in the distal esophagus in the supine position was significantly longer in patients with BE (group A) than in those with GERD without BE (group B) ( $P < 0.03$ ); B: In the upright position. The median time at pH < 4 in the distal esophagus in the upright position did not differ significantly between patients with BE (group A) and those with GERD without BE (group B).

Also, there was no significant difference detected between the groups regarding GERD symptoms (Table 1).

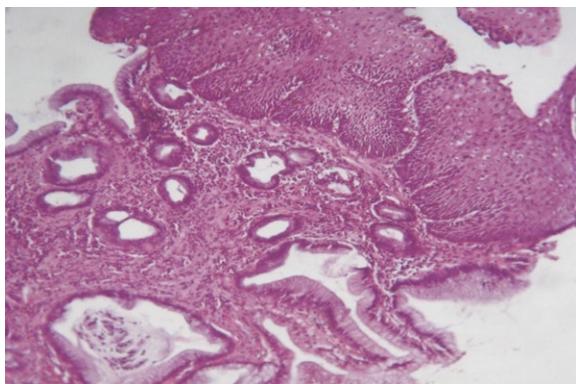

Endoscopic examination detected esophagitis in 498 patients (49.8%) and non-erosive reflux disease (NERD) was seen in 502 patients (Figure 1). Only four cases with BE were seen among patients with NERD.

The percentage of patients with abnormal esophageal acid exposure was higher in the supine position in group A (16 patients, 80%) than in group B (nine patients, 45%). The median time at pH < 4 in the distal esophagus in the supine position was significantly longer in group A than group B, while no significant difference was detected in the upright position (daytime) between the groups (Figure 2A and B).

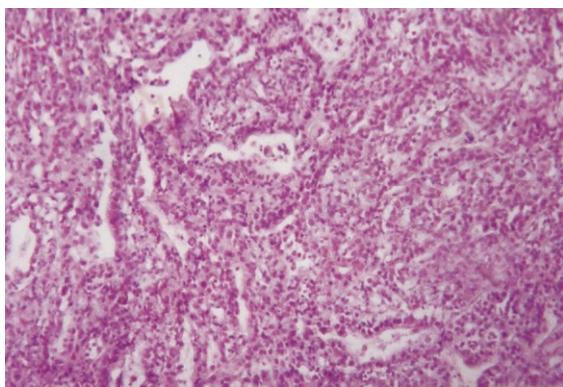

The histopathology of BE and EAC is shown in Figures 3 and 4.

## DISCUSSION

To the best of our knowledge, this is the first study reporting the prevalence of BE in patients with chronic GERD symptoms in Upper Egypt. We recruited patients with GERD symptoms. We could not perform the study on the general population as it is difficult to convince asymptomatic people to undergo endoscopic procedures. One thousand consecutive patients were referred to endoscopy units and evaluated for chronic GERD

**Figure 3** BE without dysplasia, showing true barrel-shaped goblet cells and intervening columnar cells, with incomplete brush-border, intestinal type metaplasia. The squamous epithelium of the normal esophagus was transformed into columnar epithelium (HE,  $\times 200$ ).

**Figure 4** Well-differentiated adenocarcinoma showing gland formation, and low levels of nuclear pleomorphism and atypia (HE,  $\times 200$ ).

symptoms by a well-trained endoscopist in a prospective manner.

The prevalence of BE was 7.3% in patients with GERD symptoms. Taking into considerations the type of subjects included, the prevalence could have been much lower in the general population because of the known association of BE and GERD. In Northern Egypt, Hak *et al*<sup>[9]</sup> have found a prevalence rate of 9.9% of BE in patients with GERD, which agrees with the results of our study in the Southern part of Egypt (Upper Egypt). Hak *et al*<sup>[9]</sup> recruited symptomatic patients with GERD, but with an emphasis on the effect of acid and bile reflux on the esophageal mucosa.

The prevalence of BE varies around the world and it seems to be higher in western than eastern countries. Focusing on patients who presented for their initial endoscopy in the setting of suspected GERD, Westhoff *et al*<sup>[8]</sup> studied 378 consecutive patients who had biopsies taken from areas suspicious for BE. The overall prevalence of BE was found to be 13.2%. The majority of patients diagnosed had short-segment BE, which agreed with previous data that showed the prevalence of endoscopically recognizable short-segment BE at 5%-7% vs 1%-3.4% for long-segment BE<sup>[9,10]</sup>.

Ronkainen and colleagues have used a population-based study to estimate the prevalence of BE in Sweden. Of

19 000 subjects within a target age range of 20-80 years, a random sample of 3000 was surveyed by questionnaire. A random sub-sample of 1000 subjects then underwent upper digestive system endoscopy, in which an overall BE prevalence of 1.6% was observed. However, when reflux symptoms were present, the prevalence rose to 2.3%<sup>[11]</sup>. In another study in Korea, Kim *et al*<sup>[12]</sup> have found that, in the general population, the prevalence of BE was < 1%, and remained less common in Korea than in western countries.

In our study, the prevalence of BE did not differ significantly between men and women, although the number of men recruited was much higher than women. Probably, men have more reflux symptoms or seek medical advice and endoscopic evaluation more than women do. Lin *et al*<sup>[13]</sup> have studied 543 patients with GERD symptoms, and have shown that while male and female patients demonstrated an equal severity of erosive esophagitis, only 14% of female patients had BE, compared to 23% of male patients ( $P < 0.05$ ). However, Banki *et al*<sup>[14]</sup> have shown that there was an equal prevalence of BE in men and women diagnosed with severe reflux by 24-h pH monitoring. A chart review of almost 22 000 first endoscopies identified 492 patients with BE, and suggested that there was a 20-year age shift between men and women in prevalence patterns, which resulted in a male to female OR of 4.15 (95% CI: 2.99-5.77)<sup>[15]</sup>.

In our study, the mean age in patients with BE was significantly older than in those without BE. Other studies have demonstrated that increased age is a risk factor for developing BE, as well EAC<sup>[16,17]</sup>.

We found no significant difference between the groups regarding smoking and alcohol consumption, but it seemed that the number of smokers was high in both groups. While Ronkainen *et al*<sup>[11]</sup> and Kim *et al*<sup>[12]</sup> have found that alcohol consumption and smoking are significant risk factors, others have shown no significant importance of alcohol consumption and smoking in patients with BE<sup>[18-20]</sup>.

Trying to explore the pattern of acid reflux in patients with BE, we found a significant difference between patients with BE and those with GERD for night-time acid reflux, which was more evident in patients with BE. The nocturnal gastroesophageal reflux that occurs in the recumbent position causes more injury to esophageal mucosa and may contribute to more severe chronic esophageal mucosal changes. Hak *et al*<sup>[9]</sup> have found more prolonged reflux periods in patients with BE than in those with GERD or NERD without BE. Gutschow *et al*<sup>[21]</sup> have reported that patients with BE have significantly more acid reflux events and a higher percentage of reflux time during the supine and upright phase than patients with NERD and GERD without BE. Also, Koek *et al*<sup>[22]</sup> in a multivariate analysis have found that BE is associated with male sex and exposure to both acid and duodenogastroesophageal reflux.

We conclude that BE is present in about 7.3% of patients with chronic GERD symptoms in our area.

It may be associated with older age and nocturnal gastroesophageal reflux.

## COMMENTS

### Background

Barrett's esophagus (BE) is gaining importance because of its association with esophageal adenocarcinoma (EAC). Its prevalence varies around the world. However, there are no data about its prevalence in upper Egypt.

### Innovations and breakthroughs

This is the first study to report prevalence of BE in Upper Egypt.

### Applications

This study may represent a future strategy for screening for BE and AEC in patients with chronic gastroesophageal reflux disease.

### Peer review

This was a well-conducted and interesting study that investigated the prevalence of BE in Upper Egypt.

### Abstract

**AIM:** To estimate the prevalence and identify the risk factors for metabolic bone disease in patients with cirrhosis.

**METHODS:** The study was performed on 72 Indian patients with cirrhosis (63 male, 9 female; aged < 50 years). Etiology of cirrhosis was alcoholism ( $n = 37$ ), hepatitis B ( $n = 25$ ) and hepatitis C ( $n = 10$ ). Twenty-three patients belonged to Child class A, while 39 were in class B and 10 in class C. Secondary causes for metabolic bone disease and osteoporosis were ruled out. Sunlight exposure, physical activity and dietary constituents were calculated. Complete metabolic profiles were derived, and bone mineral density (BMD) was measured using dual energy X ray absorptiometry. Low BMD was defined as a Z score below -2.

**RESULTS:** Low BMD was found in 68% of patients. Lumbar spine was the most frequently and severely

affected site. Risk factors for low BMD included low physical activity, decreased sunlight exposure, and low lean body mass. Calcium intake was adequate, with unfavorable calcium: protein ratio and calcium: phosphorus ratio. Vitamin D deficiency was highly prevalent (92%). There was a high incidence of hypogonadism (41%). Serum estradiol level was elevated significantly in patients with normal BMD. Insulin-like growth factor (IGF) 1 and IGF binding protein 3 levels were below the age-related normal range in both groups. IGF-1 was significantly lower in patients with low BMD. Serum osteocalcin level was low (68%) and urinary deoxypyridinoline to creatinine ratio was high (79%), which demonstrated low bone formation with high resorption.

**CONCLUSION:** Patients with cirrhosis have low BMD. Contributory factors are reduced physical activity, low lean body mass, vitamin D deficiency and hypogonadism and low IGF-1 level.

### INTRODUCTION

Metabolic bone disease is a common complication of long-standing liver disease, ranging from cholestatic disorders to alcoholic, autoimmune and post-viral cirrhosis<sup>[1]</sup>. Often known as hepatic osteodystrophy (HO),

it is well-recognized among individuals with chronic liver disease (CLD). Its etiology is poorly understood and is thought to vary according to the type, severity and progression of the liver disease, along with a multitude of other contributing factors including the ethnicity of the population studied. It can result in spontaneous low-trauma fractures that significantly impact on the morbidity, quality of life, and even survival, through pain, deformity and immobility. With liver transplantation steadily taking the center stage in treatment of end-stage cirrhosis of varying etiology and offering long-term survival, bone disease has snowballed into one of the major determinants of survival and quality of life in this cohort<sup>[1]</sup>.

Keeping in view the numerous therapeutic options for bone disease<sup>[2]</sup> already available and those under development, it is prudent to characterize this condition in order to give these patients a better chance of survival. The medical fraternity around the world has recognized this and has started characterizing the disorder. In various international studies, the overall incidence has varied from 11% to 48%<sup>[3]</sup>, with a fracture rate of 3%-44%<sup>[3]</sup>. This has not been studied extensively in the Indian population<sup>[4]</sup>.

## MATERIALS AND METHODS

### **Patients**

The study was performed on 72 Indian patients with cirrhosis. The group consisted of 63 men and nine women with a median age of 45 years ( $43.1 \pm 7.4$ , range 22-50 years). Twenty-five patients had hepatitis B (22 men and 3 women), 10 had hepatitis C (5 men and 5 women), and 37 had alcoholic cirrhosis (36 men and 1 woman). A diagnosis of cirrhosis was confirmed histologically or clinically if biopsy was not available. A clinical diagnosis was established in patients who demonstrated a Child-Pugh index  $> 6$  or ultrasound findings suggestive of cirrhosis (the presence of at least two of the findings of nodular irregular surface, distorted vascular pattern, or ascites). Signs of portal hypertension (endoscopically proven esophageal varices or dilated portal venous system with ultrasonography) were taken as additional corroborative evidence. The etiology of post-viral cirrhosis was proven if any of the serological markers were positive [hepatitis B surface antigen by ELISA, anti-hepatitis C virus (HCV) by third generation ELISA, or HCV RNA]. Diagnosis of alcoholic cirrhosis was made with a positive answer to more than one question in the CAGE questionnaire and a previous history of alcohol intake of  $> 80$  g/d in men and  $> 40$  g/d in women for  $> 10$  years. An aspartate aminotransferase to alanine aminotransferase (AST/ALT) ratio of  $> 1.5$  was taken as corroborative evidence. We selected only patients who had abstained from alcohol for  $> 3$  mo prior to the study.

All patients with acute exacerbation or flair of disease (suggested by a bilirubin concentration  $> 5$  mg/dL, AST  $> 2.5$  times the upper limit of normal, leukocytosis

$> 10\,000/\text{mm}^3$ , or diagnostic lesions of hepatitis on biopsy) and those with recent gastrointestinal bleeding were excluded. Patients with serum creatinine levels  $> 1.4$  mg/dL were excluded, as were those with any form of acute illness. None of the patients had a previous history of chronic disorders associated with changes in mineral metabolism (thyroid disorders, parathyroid disorders, Cushing's syndrome, diabetes, immobilization in the past, or renal failure). None had a family history of osteoporosis, nor did they receive calcium, vitamin D or any medication which may have influenced bone metabolism (corticosteroids, hormone replacement therapy, calcitonin, bisphosphonates, cytotoxics, antimetabolites, anticoagulants, anticonvulsants, thyroxine, interferon or lamivudine). Nineteen patients were receiving spironolactone and 14 were receiving spironolactone and furosemide. Patients with major sclerosis of the aorta, osteophytes, or scoliosis on X-ray, which precluded accurate measurements of lumbar bone mineral density (BMD) by dual energy X ray absorptiometry (DXA), and those who had the criteria for more than one etiology of chronic liver disease were also excluded. All patients signed informed consent and the protocol was approved by the institutional ethics committee.

### **Methods**

Demographic and disease-related data including anthropometry at the time of enrollment were captured. Each subject was interviewed to characterize sunlight exposure, physical activity and dietary intake.

Sunlight exposure was calculated in terms of length of usual weekly outdoor activity, sunscreen use, and usual outdoor attire. The "rule of nine" was adapted to estimate the fraction of body surface area (BSA) exposed to sunlight by each subject's usual outdoor attire<sup>[5]</sup>. With this, sun index was calculated as the product of hours of sun exposure per week and fraction of BSA exposed to sunlight. Mumbai is at latitude  $18^\circ 56'$  North and all of the study population were from areas below  $37^\circ$  latitude. Only sunlight exposure between 8 am to 5 pm in summer and 9 am to 3 pm in winter was measured. All our patients belonged to the same ethnicity and were of skin type 5. Physical activity was assessed using the Global Physical Activity Questionnaire (GPAQ) developed by WHO ([www.who.int/chp/steps](http://www.who.int/chp/steps)). Nutritional intake was calculated using a questionnaire with specific reference to calorie, protein, calcium (dairy and non-dairy), phosphorus and salt intake. These parameters were calculated in two different periods of life; prior to illness (5 years prior to patient perceived onset) and present state of illness.

### **Biochemical and hormonal determinations**

Blood samples were drawn in the morning after an overnight fast. In addition to standard liver function tests, serum levels of calcium, phosphate, magnesium, alkaline phosphatase, and creatinine were measured on the same day with an auto analyzer (Biosystems S.A.,

**Table 1 Demographic data of patients with normal and low BMD**

Parameter	Low BMD	Normal BMD	P value
Age (yr)	44.4 ± 6.1 (47)	42 ± 8.7 (45.5)	0.220
BMI ( $\text{kg}/\text{m}^2$ )	21.14 ± 3.55 (20.3)	23.16 ± 5.46 (22.4)	0.275
Child score	7.4 ± 1.8 (7)	7.85 ± 1.9 (8)	0.350
Lean body mass (kg)	43.3 ± 7.3 (43)	46.7 ± 8.75 (44.7)	0.290
Fat mass (kg)	11.6 ± 6.5 (11.2)	14.4 ± 7.1 (12.43)	0.150

BMD: Bone mineral density. Parameters are expressed as mean ± SD. Median value is given in parentheses.

Barcelona, Spain). The rest of the sample was centrifuged immediately and stored at -70°C for measurement of hormonal parameters, which were analyzed in a single batch. Serum was assayed using commercially available kits for 25 hydroxy vitamin D [25 (OH)D; radioimmunoassay (RIA); DiaSorin Inc., Stillwater, MN, USA], 1,25, dihydroxy vitamin D [1,25 (OH)<sub>2</sub>D; enzyme immunoassay; Immunodiagnostic Systems Inc, Fountain Hills, AZ, USA], parathyroid hormone (PTH), osteocalcin, follicle stimulating hormone (FSH), luteinizing hormone (LH), estradiol (E2), testosterone (RIA; Diagnostic Products Corp., Los Angeles, CA, USA), sex hormone binding globulin (SHBG), free T4 (FT4), thyroid stimulating hormone (TSH), insulin like growth factor 1 (IGF-1) and IGF binding protein 3 (IGFBP3). Free testosterone was calculated from total testosterone, SHBG and albumin concentration ([www.issam.ch](http://www.issam.ch)). All hormonal investigations except testosterone, 25 (OH)D and 1,25 (OH)<sub>2</sub>D were done by chemiluminescent immunometric assay with Immulite 1000 systems (Diagnostic Products Corporation). Serum testosterone, estradiol, FSH and LH were estimated from pooled sera collected three times at 20-min intervals. The morning second void urinary sample was used for urinary parameters. Urine was analyzed for calcium, creatinine and free deoxypyridinoline (UDPD). UDPD was expressed as the ratio to creatinine.

#### BMD and X-ray measurements

BMD of the lumbar spine (L1-L4) and proximal femur (femoral neck and trochanter) was measured by DXA (Delphi W 70460; Hologic Inc., USA). All scans were carried out on the same machine by the same operator and were analyzed with the same software. BMD was expressed as  $\text{g}/\text{cm}^2$  as well as Z score, compared to reference data for Caucasian populations. As there are no normative data available for the Indian population, no such comparison could be made. Low BMD was considered to be a Z score of -2 or less obtained at any site. X-ray analysis of lumbosacral spine (lateral view) and pelvis (antero-posterior view) was done to rule out any fracture. Lean body mass was also assessed by DXA.

#### Statistical analysis

Statistical analysis was done using SPSS version 14

software (Chicago, IL, USA). All results are expressed as means ± SD and median. The statistical significance between means was calculated by Student's *t* test, analysis of variance (ANOVA), or Mann-Whitney *U* test when appropriate. Differences between proportions were assessed by the  $\chi^2$  test. *P* < 0.05 was considered significant.

## RESULTS

### BMD

Among the 72 patients, 49 (68%) had low BMD. There were no significant differences in demography between the patients with normal and low BMD (Table 1). When patients were classified according to etiology of liver disease, the incidence was 56.7% alcoholic, 72% hepatitis B, and 100% hepatitis C. Incidence of low BMD was the same across all Child classes. Lumbar spine was the most frequently and severely affected site. It was involved in all patients with low BMD. Mean BMD at each site was: spine, -2.28 ± 1.1; hip, -1.27 ± 0.74; trochanter, -1.3 ± 0.8; and femoral neck, 0.75 ± 0.86. Bone mass loss in trabecular bone (lumbar spine) was more severe than that in cortical bone (femoral neck). The percentage of patients with low BMD of the hip was 14%, trochanter was 18%, and femoral neck was 7%.

### Risk factors for low BMD

Patients were evaluated further for the possible predisposing factors for low BMD. The following data pertain to the 63 men in the study. As there were only nine women, they were analyzed separately. Patients were subdivided into low BMD (Z score ≤ -2, 43 patients) and normal BMD (Z score > -2, 20 patients) groups and further analyzed.

### Relationship of BMD with physical activity, sunlight exposure and diet

Both groups showed considerable reduction in sunlight exposure and physical activity after the onset of illness (Table 2). Past and present sunlight exposure was lower in the group with low BMD, although it reached significance (*P* < 0.05) only with present exposure. Low physical activity (defined as < 600 MET·min/wk) was seen in 15 patients (23%) prior to disease onset but in 76% after developing chronic liver disease. It can be seen that the median activity level and sunlight exposure in the affected population was zero, compared to some amount of activity (120 MET·min/wk) and sunlight exposure (sun index of 0.15) in patients who were able to maintain their bone strength.

Dietary intake was comparable between the two groups. Calorie and protein intake were adequate. Calcium intake was also adequate according to the Indian Council of Medical Research guidelines (ICMR)<sup>[6]</sup>. The calcium:protein ratio (8.5-11.5) was much below the advocated range of 16-20<sup>[6]</sup>. The calcium:phosphorus ratio (0.45) was also not in the recommended range of 1:1<sup>[6]</sup>.

**Table 2** Sunlight exposure, physical activity and dietary parameters in men with normal and low BMD

Parameter		Low BMD	Normal BMD	P value
Sun index	Past	2.49 ± 3.3 (1.3)	3.54 ± 5.3 (2.5)	0.13
	Present	0.21 ± 0.41 (0)	0.83 ± 1.4 (0.15)	0.035 <sup>a</sup>
Physical activity (MET.min/wk)	Past	2188 ± 2340 (1920)	2378 ± 1855 (2450)	0.7
	Present	468 ± 1260 (0)	351 ± 659.7 (120)	0.47
Total Calorie (kcal/d)	Past	2111 ± 768 (2078)	1867 ± 524 (1878.0)	0.18
	Present	2020 ± 662 (2071)	1997 ± 422 (2078)	0.65

#### Relationship of BMD with biochemical parameters and markers of bone turnover

Biochemical parameters were comparable between both groups (Table 3). Serum calcium, magnesium, phosphorus and alkaline phosphatase levels were normal. Prevalence of vitamin D deficiency was high among patients with CLD. Among the 63 patients, vitamin D values were < 10 ng/mL in 38 patients (60%), 10-20 ng/mL in 20 patients (32%), and > 20 ng/mL in 5 patients (8%). Despite having a low vitamin D level in 92%, PTH was within the physiological range in 87% of patients.

Markers of bone turnover indicated high resorption with low formation. Serum osteocalcin was low in 43 patients (68%) and UDPD: creatinine ratio was high

in 50 patients (79%). This suggests uncoupling of bone remodeling as the cause for low BMD in CLD. The levels of bone turnover markers were comparable between the two groups.

#### Relationship of BMD to hormone parameters

There was a high incidence of hypogonadism in patients with cirrhosis. Twenty-six patients (41%) had low calculated free testosterone. This was distributed equally between the low and normal BMD groups. Among the hypogonadal patients, 18 (69%) had central hypogonadism and eight (31%) had primary testicular failure. An FSH value of > 10 IU/L with normal free testosterone was seen in an additional nine (14%) patients. Serum estradiol level was significantly elevated ( $P < 0.05$ ) in patients with normal BMD as compared to those with low BMD (Table 4). Forty-six patients (73%) had a high estradiol level, which was distributed unequally within the groups, with 90% of patients with normal BMD and 65% in the group with low BMD having values above the physiological upper range of 50 pg/mL.

IGF-1 levels were below the age-related normal range in both groups, but significantly lower ( $P < 0.05$ ) in patients with low BMD (Table 4). Forty-one patients (95%) of patients in the low BMD group and 15 (75%) in the normal BMD group had IGF-1 level below normal, which accounted for 89% of patients with CLD.

Low IGFBP3 was almost a universal finding in patients with CLD (61 of 63 patients; 97%), although it did not differ significantly between the groups ( $P = 0.071$ ).

## DISCUSSION

The purpose of the current study was to determine the prevalence of low BMD, to estimate the bone turnover and hormonal status, and to identify the factors associated with bone disease in patients with CLD. The only available Indian data on this subject are those of Sachdev *et al*<sup>[4]</sup> from 1976. The current study shows that patients with CLD have a high prevalence of decreased BMD, with the lumbar spine being the most frequently and intensely affected site. Furthermore, there was no relation between severity of hepatic dysfunction (Child class) and incidence of low BMD. These factors point to the need for early evaluation for HO in patients with CLD.

In the present cohort, low BMD was found in 68% of patients. This is comparable to the only available Indian data of Sachdev *et al*<sup>[4]</sup>, in which 64% of cirrhotic patients had low BMD. The method of evaluation and diagnosis differed greatly in that era. In the earlier study of 25 patients with cirrhosis (all aged < 40 years), diagnosis of cirrhosis was made from liver biopsy and osteoporosis from iliac crest biopsy. Scanning through western studies has indicated marked heterogeneity in BMD findings in CLD, ranging from no effect to a large BMD deficit. Leslie *et al*<sup>[7]</sup> have pooled the results from uncontrolled and controlled studies of bone mineral content in CLD. They have shown a Z score less than -2 in 21% of patients. Studies on patients with end-stage liver disease of varying etiology confirm a high but variable incidence of osteoporosis (11%-48%) and osteopenia (18%-35%)<sup>[5]</sup>. The incidence of 68% in the present study is much higher than that in any previous study. This may be because Indians have a lower BMD as compared to Caucasians<sup>[8,9]</sup>. Thus, the use of Z scores based on a Caucasian database might have resulted in overestimation of osteoporosis. However there are no published data for BMD in healthy Indian populations.

The major influences on bone metabolism are genetic, but also essential are mechanical stress (exercise and muscle activity), good nutrition, adequate calcium and vitamin D, and a normal hormonal environment. The patient with CLD could have any of these factors acting alone or in concert, which potentially predispose him/her to thin bones. Each of the above factors were assessed and compared between patients with low and normal BMD. It was found that patients with CLD had all the above and known risk factors: low sunlight exposure, reduced physical activity, low lean body mass, vitamin D deficiency and hypogonadism. The presence of risk factors in the low and normal BMD groups was probably the reason for the absence of a statistically significant difference in risk factors between the normal and low BMD groups. This indicates that all patients with cirrhosis, unless prevented, will develop

the disease. In addition, although the calcium intake was adequate by ICMR guidelines, it was well below the internationally accepted daily allowance. This added to an unfavorable calcium:protein ratio of 8.5-11.5 mg/g, and calcium:phosphorus ratio of 0.45 may have resulted in inadequate recommended daily allowance of calcium in these patients.

Vertebrae consist of 50% trabecular bone, while other bones (hip, neck and trochanter) consist mainly of cortical bone. Sites with a high proportion of trabecular bone are affected earliest in diseases that produce increased bone turnover<sup>[10]</sup>. In the present study, serum osteocalcin was low in 68% and UDPD: creatinine ratio was high in 79% of patients, which indicated a high resorptive state added to low formation. This suggests uncoupling of bone remodeling as the cause of low BMD in CLD. This can explain the predominant involvement of the spine in HO. This is also compatible with other similar studies<sup>[11,12]</sup>.

In the present study, 41% of patients were hypogonadal, although this was not correlated with the severity of bone loss. Diamond *et al*<sup>[13]</sup> and Monegal *et al*<sup>[11]</sup> have shown that hypogonadism is common in men with cirrhosis but it is not correlated with osteoporosis. A particularly interesting finding in the present study was the significantly elevated estradiol level ( $P < 0.05$ ) in patients with normal compared with low BMD. Estrogen is known to have a positive influence on the male skeleton<sup>[14]</sup>. It is also known to be increased in men with cirrhosis. Probably the anabolic and antiresorptive qualities of estrogens in bone act as protective factors in preventing bone loss in these patients with cirrhosis.

More than 90% of circulating IGF-1 is synthesized in the liver. It is a proven early marker of hepatocellular functional capacity<sup>[15,16]</sup>, and shows a marked decline in the early stages of cirrhosis (Child-Pugh class A). It starts decreasing before other liver-function parameters such as albumin, bilirubin and prothrombin become involved<sup>[15]</sup>. GH levels are increased correspondingly, which creates a state of IGF resistance<sup>[17]</sup>. IGF-1 is also a major determinant of BMD in healthy men<sup>[18]</sup>. In the present study, IGF-1 levels were below the age-related normal range in both groups, and were significantly lower ( $P < 0.05$ ) in patients with low BMD. IGF-1 values were low in 89% of patients with CLD. Previous studies have shown IGF-1 levels to correlate directly with BMD and inversely with disease severity<sup>[12,19,20]</sup>. Studies have described a role for decreased serum IGF-1, even in idiopathic osteoporosis<sup>[21]</sup>. IGF-1 expression is increased during early osteoblast recruitment, but declines as these cells undergo differentiation. It is known to stimulate osteoblast proliferation<sup>[22]</sup> and play a key role in bone remodeling and maintenance of bone mass. Simonet *et al*<sup>[23]</sup> have shown that low levels of IGF-1 may lead to increased bone resorption. Thus, the link between cirrhosis and bone loss also involves low levels of IGF-1. A significant difference in IGF-1 level between normal and low BMD patients may be a pointer to why some patients deteriorate faster, despite sharing equally all the risk factors.

IGFBP3 play a very important role in bioavailability of circulating IGF-1. It forms a stable ternary complex with an acid-labile subunit and IGF-1, and binds > 95% of circulating IGF-1. In the present cohort, low IGFBP3 was seen in 97% of patients with CLD, although this did not differ significantly between the normal and low BMD groups ( $P = 0.071$ ). This is plausible because hepatocytes are the major site of IGFBP3 synthesis. This may have further decreased the tissue bioavailability of IGF-1<sup>[24,25]</sup>.

In conclusion, the present study confirms the high incidence of low BMD in patients with CLD. Disease onset is early in the course of cirrhosis. Decreased bone formation with increased bone resorption imply that uncoupling of bone remodeling is the mechanism involved. Contributing factors are inadequate sunlight exposure, reduced physical activity, low lean body mass, vitamin D deficiency and hypogonadism. The presence of most risk factors in low and normal BMD groups indicates that all patients with cirrhosis are vulnerable, and unless prevented, will develop the disease. Our results provide evidence of the key roles played by IGF-1 and estrogen in this condition. Although risk factors are prevalent in all patients, the severity of bone loss may be accelerated in patients with low IGF-1 level. The present study also suggests a possible protective role for the high estrogen level seen in cirrhosis.

## COMMENTS

### Background

Long-standing liver disease has long been recognized to result in fragile bones with increased risk of fractures. In various international studies, the overall incidence has varied from 11% to 48%, with a fracture rate of 3%-44%. The reason for this is poorly understood. With liver transplantation becoming a viable option in liver disease and offering complete cure and long-term survival, bone disease is becoming the major determinant of survival and quality of life in these patients. The present study tried to characterize the problem and identify contributing risk factors.

### Research frontiers

Much work has been done and is still going on in the field of hepatic osteodystrophy (HO). It is a hot topic of research, as liver transplantation is improving survival of patients with end-stage liver disease, and bone disease and fracture are limiting the survival and quality of life of these patients. The medical fraternity has recognized that bone health has to be taken care of to fully translate the benefits of modern treatment into patient survival.

### Innovations and breakthroughs

Most of the data obtained in this study conform to those in the literature. Two significant findings of the study (that low levels of IGF-1 is a risk factor for decreased BMD, and increased estrogen is protective) are relatively new.

### Applications

This article provides an entirely new frontier in research, namely, to look forward to the therapeutic benefit of IGF-1 therapy in these patients. Synthetic IGF-1 is available under the name mecasermin and is used currently for the long-term treatment of growth failure in children with severe primary IGF-1 deficiency.

### Peer review

This work represents an original contribution regarding HO in patients with advanced liver disease in India. The study was well-conducted. The authors identified in cirrhotic patients that low levels of IGF-1 are a risk factor for decreased BMD, while increased estrogens protect against osteopenia.

migration occurred with a covered stent in 3 patients who underwent a subtotal gastrectomy with Billroth-II reconstruction. Two cases of partial stent migration were easily treated with a second stent or stent repositioning. The median stent patency was 56 d (range, 5-439 d). The median survival was 83 d (range, 12-439 d).

**CONCLUSION:** Endoscopic insertion of a SEMS provides safe and effective palliation of a recurrent anastomotic stricture caused by gastric cancer. A meticulous evaluation of the presence of other strictures before inserting the stent is essential for symptom improvement.

Clinical outcomes of self-expandable metal stents in palliation of malignant anastomotic strictures caused by recurrent gastric cancer. *World J Gastroenterol* 2009; 15(28): 3523-3527 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3523.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3523>

## Abstract

**AIM:** To examine the technical feasibility and clinical outcomes of the endoscopic insertion of a self-expandable metal stent (SEMS) for the palliation of a malignant anastomotic stricture caused by recurrent gastric cancer.

**METHODS:** The medical records of patients, who had obstructive symptoms caused by a malignant anastomotic stricture after gastric surgery and underwent endoscopic insertion of a SEMS from January 2001 to December 2007 at Kangnam St Mary's Hospital, were reviewed retrospectively.

**RESULTS:** Twenty patients (15 male, mean age 63 years) were included. The operations were a total gastrectomy with esophagojejunostomy ( $n = 12$ ), subtotal gastrectomy with Billroth-I reconstruction ( $n = 2$ ) and subtotal gastrectomy with Billroth-II reconstruction ( $n = 8$ ). The technical and clinical success rates were 100% and 70%, respectively. A small bowel or colon stricture was the reason for a lack of improvement in symptoms in 4 patients. Two of these patients showed improvement in symptoms after another stent was placed. Stent reobstruction caused by tumor ingrowth or overgrowth occurred in 3 patients (15%) within 1 mo after stenting. Stent

## INTRODUCTION

Local recurrence causing dysphagia occurs in approximately 20% of stomach cancer patients treated with a gastrectomy<sup>[1]</sup>. These patients are usually poor surgical candidates because of advanced malignancy, poor performance status or malnutrition. Palliative surgery carries a high risk of mortality and morbidity.

A self-expandable metal stent (SEMS) is currently the main palliative nonsurgical treatment for malignant gastric outlet obstructions<sup>[2]</sup>. Metal stents are also used to treat malignant anastomotic obstructions after esophagojejunostomy, gastrojejunostomy and gastroduodenostomy. However, there are only a few

reports on the clinical outcome of SEMS for the palliation of a recurrent anastomotic obstruction after gastric surgery<sup>[3-11]</sup>. In particular, there is one study on endoscopic insertion of a SEMS in a recurrent anastomotic stricture<sup>[11]</sup> instead of a fluoroscopically-guided method. The clinical outcomes and complications might differ according to the surgical technique because of the different anastomotic angle or different anatomical alterations during surgery.

This study evaluated the technical feasibility and clinical effectiveness of endoscopic SEMS placement in the palliation of patients with a recurrent anastomotic obstruction after gastric surgery.

## MATERIALS AND METHODS

### **Patients**

Twenty consecutive patients (M:F = 15:5, mean age 63.1 ± 10.3 years), who had a documented postoperative anastomotic stricture caused by recurrent gastric cancer and had undergone endoscopic SEMS insertion from January 2001 to December 2007, were enrolled in this study. All patients had a symptomatic obstruction characterized by nausea, vomiting, reduced oral intake and weight loss. The recurrent gastric cancer, which was the underlying cause of the obstruction, was confirmed by pathological diagnosis in all patients. None of the patients were surgical candidates based on the presence of advanced, metastatic disease or medical comorbidity.

The exclusion criteria were patients who were mildly symptomatic or patients in whom an adult endoscope could be passed through the malignant anastomotic stricture or patients showing evidence of peritonitis. An abdominal computed tomography (CT) scan or contrast media radiographic study to document multiple strictures was not performed routinely.

The surgical technique was a total gastrectomy with esophagojejunostomy in 10 patients, subtotal gastrectomy with Billroth-I reconstruction in 2 patients and subtotal gastrectomy with Billroth-II reconstruction in 8 patients. The type of reconstruction after total gastrectomy was loop esophagojejunostomy except for 2 patients with a Roux-en-Y esophagojejunostomy. Gastrojejunostomy without jeunojejunostomy was used for Billroth-II reconstruction after subtotal gastrectomy. Strictures occurring in the efferent loop were included in this study. One patient had a stricture in both afferent and efferent loops. Therefore 2 stents were inserted in both sites. Patients with recurrent cancer only in the afferent loop were excluded. Table 1 lists the patients' characteristics.

### **Methods**

NITI-S® stents (Taewoong, Seoul, Korea, n = 10), Choo stent (M.I. Tech, Seoul, Korea, n = 10) were used. These stents are commonly used commercial pyloric stents. The degree, length and site of the stenosis were evaluated using an endoscopic procedure or barium meal prior to stent insertion. Thirteen covered stents and 7 uncovered stents were inserted. The covered stent was coated with polyurethane around the body and contained the proximal flare portion. The diameter of the body and flare portions

**Table 1 Patients' characteristics**

Age ± SD (yr)	63.1 ± 10.3
Male:Female	15:5
Prior surgery (n)	
Total gastrectomy with esophagojejunostomy (10)	Covered stent (6) Uncovered stent (4)
Subtotal gastrectomy with Billroth-I reconstruction (2)	Covered stent (1) Uncovered stent (1)
Subtotal gastrectomy with Billroth-II reconstruction (8)	Covered stent (6) Uncovered stent (2)
Chemotherapy after stent insertion (number of patients)	10
Follow-up loss (n, %)	3 (15%)
30-d mortality	3/17 (18%)
Survival [median (range)]	83 (12-439) d
Stent patency duration [median (range)]	56 (5-439) d

were 18 and 26 mm, respectively. The length of these SEMS ranged from 8 to 22 cm. The outer diameter of the delivery system was 10F to 11F with an overall length of 180 cm. The stent delivery system was advanced over the guidewire. Under direct guidance of endoscopic and fluoroscopic vision, a guidewire was passed through the malignant stricture. The stent was then released and the position and location of the stent were assessed by both endoscopy and fluoroscopy. Compensatory hydrostatic dilatation of the stent was not required in any of the patients. The patients usually resumed a water or a liquid diet 24 h after stent placement. The patients started a soft or solid diet after the follow up X-ray showed full extension. There was one patient whose stent was not sufficiently expanded. He could not restart a soft diet.

After inserting the stent, a combination of 5-fluorouracil, cisplatin, and epirubicin or paclitaxel-based or docetaxel-based chemotherapy was administered when the oral intake improved and the Eastern Cooperative Oncology Group performance status was ≤ 2 (graded as follows: 0 = normal activity, 1 = symptoms but ambulatory, 2 = in bed less than 50% of time, 3 = in bed more than 50% of time, and 4 = totally bedridden). Palliative chemotherapy after stent insertion was performed in 10 patients (50%).

### **Definitions**

The outcome of the stent was evaluated using the following parameters: (1) technical success and clinical success; (2) complications; (3) stent patency.

Technical success was defined as the successful insertion of a stent in the proper position and the confirmation of patency using a combination of endoscopy and fluoroscopy with oral contrast opacification.

Clinical success was defined as an improvement in the obstructive symptoms and oral intake 1 to 3 d after placing the stent. The degree of oral intake was assessed using the Gastric Outlet Obstruction Scoring System as follows: 0 = no oral intake; 1 = exclusively liquid diet; 2 = exclusively soft solids diet; 3 = full diet possible. The improvement in oral intake was evaluated as the best degree at least 3 d after stent insertion. A primary stent dysfunction was defined as a failure to resume an oral intake after stent insertion.

**Table 2** Improvement in the oral intake status compared to before stent insertion ( $n = 20$ )

Oral intake status (by GOOSS)	Number of cases	
	Pre-stenting	Post-stenting
No oral intake (0)	15	3
Liquids only (1)	3	6
Soft solids (2)	2	8
Low-residual or full diet (3)	0	3
Mean score <sup>b</sup>	0.35 ± 0.61	1.55 ± 0.94

<sup>b</sup> $P < 0.01$  by Wilcoxon signed rank test; GOOSS: Gastric Outlet Obstruction Scoring System.

The stent patency time was defined as the duration between the initial stent placement and the recurrence of obstructive symptoms caused by a stent occlusion. It was considered to be equal to the survival time if there were no obstruction symptoms or stent occlusion.

### Follow-up

The patients were followed up to determine their clinical outcomes until they died or the stent malfunctioned, such as by migration or occlusion by tumor ingrowth or overgrowth. The data were obtained from the hospital records, radiology or endoscopic records, the patients themselves during a clinical visit and their relatives by a telephone survey. The status of oral food intake was monitored at 1 mo intervals on an outpatient basis. A follow-up barium study or endoscopy was performed only if obstructive symptoms recurred in order to evaluate stent occlusion or migration.

### Statistical analysis

The values for the patients' characteristics are expressed as the median (range). The categorical data were examined using Fisher's exact test. The degree of oral intake before and after stent insertion was compared by a Wilcoxon signed rank test. The overall survival and stent patency were estimated by Kaplan-Meier life table analysis. A  $P$ -value  $< 0.05$  was considered significant. All analyses were carried out using SPSS version 10.0 (SPSS Inc, USA).

## RESULTS

### Technical and clinical success

Endoscopic stent placement was technically successful in all patients. Clinical success was achieved in 14 out of the 20 cases (70%). The reasons for the lack of improvement in obstructive symptoms were small bowel or colon stricture ( $n = 4$ ), ileus induced by peritoneal dissemination ( $n = 1$ ) and primary stent dysfunction caused by stent expansion failure ( $n = 1$ ). The symptoms in 2 of the 4 patients with single small bowel or colon stricture improved after placing a second stent. Table 2 summarizes the improvement in the dietary status.

### Complications

There was no procedure-related mortality. In one patient who underwent a distal gastrectomy with Billroth-I

reconstruction, the uncovered stent did not expand fully and was compressed by the tumor mass until 5 d after stent placement. The symptoms were not improved. However, he refused further treatment and was lost to follow-up 7 d after stent placement.

Recurrent symptoms of an obstruction were observed in 3 patients (15%) as a result of tumor overgrowth ( $n = 2$ ) or tumor ingrowth ( $n = 1$ ) within 1 mo after stenting. The reobstruction rate (1/13 vs 2/7,  $P = 0.55$ ) of a covered stent and uncovered stent, and stent patency duration [56 d (range, 7-439) for the covered stent vs 37 d (range, 15-141) for the uncovered stent,  $P = 0.7$ ] were similar. Tumor overgrowth occurred in patients who underwent a total gastrectomy with esophagojejunostomy. Tumor ingrowth occurred in a patient who underwent a subtotal gastrectomy with Billroth-II reconstruction, in whom an uncovered stent was inserted. Two patients were treated successfully with an overlapping second covered stent. Stent migration occurred in 3 patients (15%) who underwent a subtotal gastrectomy with Billroth-II reconstruction, in whom covered stents were inserted. Complete stent migration occurred at 64 d in one patient who received palliative chemotherapy. The migrated stent was not detected until the endoscopy or radiologic study revealed no stent remaining at the previous stricture site. Therefore, the stent was believed to have migrated downward and pass out of the anus without the patient's awareness. She was asymptomatic even though there was stent migration. The reobstructive symptoms appeared 319 d after stent migration. She was treated with the placement of 3 stents at the efferent loop, the afferent loop and distal colon stricture.

Partial stent migration to the more distal side of the efferent loop occurred in a patient 2 d after stent placement. The patient was treated by overlapping a second stent into the first stent. The proximal half of one stent slipped upward to the body of the stomach in one patient, which was repositioned by grasping with the forceps. The symptoms improved. Table 3 gives a summary of the complications.

### Survival

Three patients were lost during the follow-up period and the remaining 17 patients died. The median survival period was 83 d (range, 12-439 d) and the median stent patency was 56 d (range, 5-439 d, Figure 1). There were no differences in median survival or stent patency between the patients who received palliative chemotherapy and those who did not ( $P = 0.66$ ).

## DISCUSSION

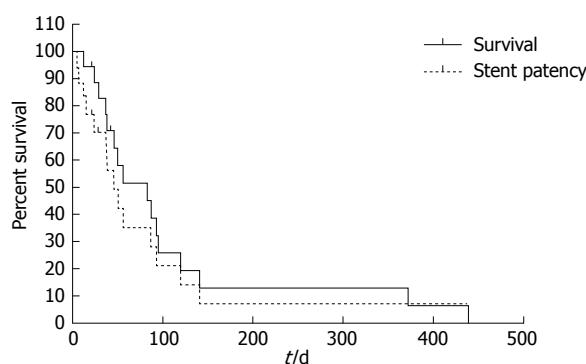

A SEMS is a simple, safe and effective palliation treatment for patients with a malignant obstruction of the gastrointestinal tract<sup>[12,13]</sup>. A SEMS has clinical advantages, compared with surgical gastrojejunostomy, such as rapid resumption of oral intake, shorter hospital stay and rapid improvement in the quality of life in malignant gastric obstruction<sup>[14,15]</sup>.

Patients with an anastomotic stricture caused

**Table 3 Complications associated with stent placement**

Patient	Complication	Type of operation	Type of stent	Days after stenting	Treatment
1	Expansion failure	Billroth- I subtotal gastrectomy	Uncovered	5	Refusal of treatment
2	Tumor overgrowth	Total gastrectomy	Covered	7	Second stent
3	Tumor overgrowth	Total gastrectomy	Uncovered	28	TPN
4	Tumor ingrowth	Billroth- II subtotal gastrectomy	Uncovered	15	Second stent
5	Stent migration (complete)	Billroth- II subtotal gastrectomy	Covered	64	Not needed
6	Stent migration (partial)	Billroth- II subtotal gastrectomy	Covered	20	Reposition
7	Stent migration (partial)	Billroth- II subtotal gastrectomy	Covered	2	Second stent

**Figure 1 Cumulative survival and stent patency of 20 patients obtained using the Kaplan-Meier method.**

by recurrent gastric cancer are likely to be severely debilitated. These patients generally have a relatively short life expectancy. Bypass or resective operations are usually impossible because of the extensive tumor invasion and metastasis<sup>[5]</sup>. Therefore, a less invasive procedure is preferred. This study evaluated the clinical effectiveness and the technical feasibility of SEMS insertion in the palliation of patients with a recurrent anastomotic stricture after various gastric surgical procedures.

The surgical techniques used were total gastrectomy with esophagojejunostomy ( $n = 10$ ), subtotal gastrectomy with Billroth- I reconstruction ( $n = 2$ ), subtotal gastrectomy with Billroth- II reconstruction ( $n = 8$ ). All procedures were performed using endoscopic guidance. The technical success rate was 100%, which is comparable to those with a primary malignant gastric outlet obstruction (83%-100%)<sup>[15]</sup>. There is one report on endoscopically-guided stent insertion in a recurrent anastomotic stricture<sup>[11]</sup>. The advantages of endoscopically-guided stent insertion are the ease of accessing the stricture site and the avoidance of looping the delivery system through the dilated gastric lumen because endoscopy offers sufficient stiffness, so that the delivery system can easily pass through the dilated gastric lumen. There was no erroneous stent placement in the incorrect loop. The efferent loop was differentiated by identifying the ampulla of Vater in the afferent loop by endoscopy, which was confirmed by fluoroscopy during stent insertion. Before stenting, knowledge of the anatomy is important because it can be altered by the surgical procedures or recurrent tumor mass occluding the efferent loop<sup>[7]</sup>.

The dietary intake improved in 14 out of the 20

patients (70%) after stent placement, which is comparable to the clinical success rate of SEMS insertion in a malignant gastric outlet obstruction (75%-85%)<sup>[13]</sup>. The improvement in symptoms after SEMS insertion in the anastomotic stricture caused by recurrent gastric cancer was reported to be 80%-90%<sup>[3-8]</sup>. The average score of the dietary status improved from  $0.35 \pm 0.61$  to  $1.55 \pm 0.94$  ( $P < 0.01$ ). Five patients whose symptoms did not improve had another single stricture at the small intestine or colon, or ileus by peritoneal dissemination. The dietary state in 2 of them improved after inserting an additional stent. This suggests that a precise study of the distal bowel loop using a CT scan or barium study before stent insertion is essential in order to exclude a concealed obstruction. A single stent may not be helpful if there are multiple strictures. Moreover, the insertion of 2 stents at one time may be necessary if the patients have another single stricture.

Stent reobstruction caused by tumor ingrowth or overgrowth occurred in 3 patients (15%) within 1 mo after stent placement. A recent study reported that early restenosis within 1 mo tended to occur more frequently in postoperative anastomosis than a gastric outlet obstruction caused by primary cancer (4/6 vs 2/6,  $P < 0.01$ )<sup>[16]</sup>. The covered stents had the merit of less frequent reobstruction by tumor ingrowth<sup>[17]</sup>. However, in this study, the reobstruction rate and stent patency duration of covered stents and uncovered stents were similar. The incidence of stent reobstruction in recurrent anastomotic stricture after gastric surgery was reported to be 0%-17%<sup>[3-8]</sup>. Most studies used covered stents. In 2 studies using uncovered stents, Lee *et al*<sup>[6]</sup> reported that one out of 4 patients had tumor ingrowths, and Song *et al*<sup>[7]</sup> reported a 50% stent reocclusion rate within 2 wk of stent placement. A recent retrospective study suggested that a double coaxial stent had a longer patency and lower migration rate than an uncovered stent in postoperative anastomotic obstructions<sup>[11]</sup>. A prospective, randomized, comparative study to determine which stent is favorable in this situation will be needed.

Three cases of stent migration (15%, 3/20) were encountered in patients who underwent a subtotal gastrectomy with Billroth-II reconstruction and had a covered stent inserted. Complete stent migration occurred in one patient who received palliative chemotherapy after approximately 64 d. Because chemotherapy might stabilize or reduce the tumor burden, it could influence stent migration. Two cases of partial stent migration were

easily treated by repositioning the stent and overlapping a second stent. The incidence of stent migration was reported to be 0%-16% in studies using a covered stent in an anastomotic stricture in various types of gastric cancer surgery<sup>[3-8]</sup>. The surgical technique can influence the rate of migration. The relatively acute angle between anastomosis and the efferent loop in gastrojejunostomy compared with the relatively obtuse angle in esophagojejunostomy or gastroduodenostomy, the radial force of the stent in the angulated loop, or the use of a covered stent may influence stent migration.

In this study, the 30-d mortality was 18%. The median survival was 83 d (range, 12-432 d). The median stent patency was 56 d (range, 5-439 d). Because the median survival in an anastomotic obstruction is comparable to that in a malignant gastric outlet obstruction, strategies to prolong stent patency and avoid the need for additional intervention are important in patients with recurrent cancer, particularly those with a relatively good performance status or who are expected to have a longer survival.

In summary, endoscopic insertion of a SEMS is a safe, technically feasible, and effective treatment for the palliation of anastomotic strictures caused by recurrent gastric cancer. A meticulous evaluation of the presence of another stricture before inserting the stent is essential for symptom improvement.

## COMMENTS

### Background

A self-expandable metal stent (SEMS) was used to treat malignant anastomotic obstruction during esophagojejunostomy, gastrojejunostomy and gastroduodenostomy. There are only a few reports on the clinical outcome of SEMS insertion for the palliation of a recurrent anastomotic obstruction after gastric surgery.

### Research frontiers

The authors aimed to evaluate the technical feasibility and clinical effectiveness of an endoscopic SEMS placement in the palliation of patients with a recurrent anastomotic obstruction after gastric surgery.

### Innovations and breakthroughs

This retrospective study has shown that the technical and clinical success of SEMS insertion for anastomotic strictures caused by recurrent gastric cancer were 100% and 70%, respectively. The main reasons for the clinical failure were small bowel or colon stricture in addition to anastomotic stricture. Stent migration (15%) was encountered in patients who underwent subtotal gastrectomy with Billroth-II reconstruction and had a covered stent inserted.

### Applications

A meticulous evaluation of the presence of other strictures is essential before inserting the stent for anastomotic strictures from recurrent gastric cancer. The possibility of stent migration is a consideration in anastomotic strictures after gastrojejunostomy.

### Peer review

This paper is a good retrospective report on the usage of a SEMS for palliation of malignant anastomotic stricture caused by recurrent gastric cancer, showing that it is a safe and effective palliation treatment.

### Abstract

**AIM:** To determine if inflammatory bowel disease (IBD) is a risk factor for osteoporosis in adult Sri Lankans.

**METHODS:** We identified eligible subjects from among consecutive patients diagnosed with IBD who attended our outpatient clinic. We included only patients aged between 20 and 70 years. Patients who were pregnant, had significant comorbidity, or were on calcium supplements or treatment for osteoporosis within the past 6 mo, were excluded. Healthy, age- and sex-matched controls were also recruited, in

a control to patient ratio of 3:1. Both groups were screened for osteoporosis using peripheral dual energy X-ray absorptiometry scanning.

**RESULTS:** The study population consisted of 111 IBD patients (male:female = 43:68; mean age 42.5 years) and 333 controls (male:female = 129:204; mean age 43.8 years). The occurrence of osteoporosis among IBD patients (13.5%) was significantly higher than among controls (4.5%) ( $P = 0.001$ ). The frequency of osteoporosis was not significantly different between ulcerative colitis (14.45%) and Crohn's disease (10.7%). However, on multivariate analysis, only age ( $P = 0.001$ ), menopause ( $P = 0.024$ ) and use of systemic steroids ( $P < 0.001$ ) were found to be associated independently with the occurrence of osteoporosis, while IBD, severity of disease, number of relapses, duration of illness or treatment other than systemic steroids were not.

**CONCLUSION:** IBD does not appear to be an independent risk factor for the occurrence of osteoporosis in this population. However, the use of systemic steroids was a risk factor.

### INTRODUCTION

The incidence of inflammatory bowel disease (IBD)

is rising in Asian populations<sup>[1]</sup>. IBD, both ulcerative colitis (UC) and Crohn's disease (CD), is a recognized risk factor for development of osteoporosis among Caucasians<sup>[2-4]</sup> but this association does not seem to have been investigated adequately in Asian populations<sup>[5]</sup>.

Osteoporosis is usually diagnosed by dual energy X-ray absorptiometry (DEXA) scanning<sup>[6]</sup>. However, peripheral DEXA (pDEXA), quantitative computed tomography (QCT), radiographic absorptiometry, and ultrasound have become useful in community screening<sup>[7-9]</sup>. In the literature, the reported prevalence of osteoporosis/osteopenia in IBD varies from 7% to 56%<sup>[10,11]</sup>. A retrospective study of a Caucasian population showed a 40% increase in the risk of fracture compared to healthy controls<sup>[12]</sup>. CD seems to be associated with a slightly higher risk than UC does for osteoporosis and subsequent fractures, although this has been disputed in some studies<sup>[13,14]</sup>. The mechanism for development of osteoporosis in IBD patients seems to be multifactorial<sup>[15]</sup>. The slightly higher incidence of osteoporosis in CD could be attributed to the presence of ileal disease or small intestinal resection causing vitamin D malabsorption, malnutrition or estrogen deficiency<sup>[16]</sup>. Some studies have shown a genetic predisposition to osteoporosis in IBD patients<sup>[17]</sup>. The identified genes involve the pro-inflammatory cytokine interleukin-6<sup>[18,19]</sup>. It is important to identify IBD patients with osteoporosis, as treatment with bisphosphonates has been found to be effective<sup>[20,21]</sup>.

There have been no large published studies regarding an association between osteoporosis and IBD in Asian populations<sup>[22]</sup>. It is important to investigate such an association because IBD among Asians seems to be genetically and phenotypically different to that in the West<sup>[23]</sup>.

## MATERIALS AND METHODS

### **Patients**

Consecutive patients with previously diagnosed IBD from a single tertiary care center in Sri Lanka were eligible for inclusion in the study. IBD was diagnosed using standard criteria<sup>[24]</sup>. Inclusion criteria were age > 20 and < 70 years and the presence of IBD. Exclusion criteria were pregnancy; uncontrolled diabetes; renal, hepatic, cardiovascular or psychiatric disease; rheumatoid arthritis; ankylosing spondylitis; primary sclerosing cholangitis; or treatment with teriparatide, calcitonin, bisphosphonates, fluoride, androgens, anabolic steroids or active metabolites of vitamin D within the past 6 mo.

### **Controls**

For each case, three age- ( $\pm$  5 years) and sex-matched healthy controls were selected from among individuals who were selected randomly from the community for a large population study that screened for non-communicable diseases. The controls were screened for diabetes and were not taking active metabolites of vitamin D or calcium supplements.

### **Steroid use**

Steroid use was defined as the continuous use of systemic steroids for > 3 mo. Others were considered steroid naïve.

### **Ethics**

The study protocol was approved by the Ethics Committee of the Faculty of Medicine, University of Kelaniya. Written informed consent was obtained from all participants.

### **Study design**

A comparative study involving IBD cases and age- and sex-matched community controls at ratio of 1:3.

### **DEXA scanning**

Both cases and controls underwent pDEXA with the accuDEXA (ADX-finger) (Schick, New York, NY, USA) using the right index finger. The bone mineral density (BMD) and *T* scores were recorded.

### **Diagnosis of osteoporosis and osteopenia**

Osteoporosis and osteopenia were diagnosed using WHO criteria<sup>[25]</sup>. Osteoporosis was defined as a *T* score of -2.5 or below, while osteopenia was diagnosed with a *T* score between -1 to -2.49.

### **Statistical analysis**

Previous studies have reported a 56% prevalence of osteoporosis among Caucasian IBD patients, and we assumed a 40% prevalence of osteoporosis among controls. We calculated that a sample size of 111 IBD patients and 333 controls was required to have 80% power to detect this difference at a significance level of 0.05. Quantitative data were compared using the *t* test, and categorical data were compared using a  $\chi^2$  test. Multiple logistic regression was used to identify independent risk factors for osteoporosis. The analysis was carried out using the statistical program SPSS version 16 (Chicago, IL, USA).

## RESULTS

One hundred and eleven IBD patients [male:female = 43:68; mean age 42.5 years; 83 (74.8%) with UC, 28 (25.2%) with CD, and 333 age- and sex-matched healthy controls (male:female = 129:204; mean age 43.8 years) were recruited (Table 1). The site of disease was mainly proctitis for UC and colonic for CD (Table 2). Osteopenia was significantly more common among IBD patients (13.51%) than the controls (4.5%) ( $P = 0.001$ ). Osteopenia ( $T < -1$ ) was also significantly more common in IBD patients than in controls (35.1% vs 22.5%,  $P = 0.008$ ). The prevalence of osteoporosis was not significantly different between patients with UC (14.45%) and CD (10.71%) ( $P = 0.616$ ). On bivariate analysis, age, female sex, menopause, presence of IBD, severity of disease and use of systemic steroids were found to be associated independently with the

Total	30	100.0

**Table 3 Summary of multiple logistic regression analyses**

<b>Variable</b>	<b>Regression coefficient</b>	<b>P value</b>	<b>OR (95% CI)</b>
Constant	-7.478		
Age	0.78	0.001	1.081 (1.032-1.133)
Sex <sup>1</sup>			
Female (pre-menopausal)	0.898	0.213	2.456 (0.597-10.108)
Female (menopausal)	1.271	0.024	3.563 (1.179-10.763)
Using steroids <sup>2</sup>	2.082	< 0.001	8.021 (2.693-23.891)

<sup>1</sup>Comparison group is males; <sup>2</sup>Comparison group is not using steroids.

occurrence of osteoporosis. In the multivariate logistic regression model, age, sex, menopausal status and use of steroids were significant predictors of osteoporosis (Table 3). IBD was not a significant predictor of osteoporosis. With each advancing year of age, there was a 1.081 times increase in the likelihood of the development of osteoporosis. Premenopausal women were 2.5 times more likely to have osteoporosis than men, and menopausal women were 3.6 times more likely to have osteoporosis than men. Steroid use increased the risk of osteoporosis by eightfold.

## DISCUSSION

The prevalence of osteoporosis and osteopenia in our IBD patients was significantly higher than in community controls. However, on multiple logistic regression analysis, only use of systemic steroids, age and menopause were found to be significant independent risk factors for osteoporosis. The presence of IBD and its severity were not, nor were the number of relapses, duration of illness, or treatment other than systemic steroids. The increased frequency of osteoporosis in our IBD patients was likely to have been caused by use of systemic steroids rather than by IBD itself. This is different to western studies, and we cannot explain this difference.

We did not find a significant difference in prevalence of osteoporosis between patients with UC and CD, although we admit that the number of CD patients in our sample was small, with mainly colonic involvement. This is in agreement with some but not all western data<sup>[26,27]</sup>. Our finding that there was no association between the occurrence of osteoporosis and severity

of IBD, number of relapses, duration of illness, and treatment other than systemic steroids, agrees with the findings of Western studies<sup>[28,29]</sup>.

We also noted a difference in the fracture risk between the two groups: 10.8% in the IBD group and 6% in the control group. However, this did not reach statistical significance, as our study was probably not adequately powered to investigate this complication. This finding is not surprising and could be attributed to steroid use as in western studies<sup>[30]</sup>.

There are several methodological weaknesses in our study. We designed this as a comparative study rather than a case-control study, as that would have been difficult to perform in an Asian country where the prevalence of IBD is much lower than in the West. We also used pDEXA scanning instead of central DEXA to diagnose osteoporosis. However, although central DEXA scanning is accepted widely as the gold standard for diagnosis of osteoporosis, there have been many studies showing that pDEXA is a good alternative, especially in the community setting<sup>[7,8]</sup>.

In conclusion, IBD does not appear to be an independent risk factor for the occurrence of osteoporosis in this population. The increased frequency of osteoporosis in our IBD patients is likely to be related to the use of systemic steroids. However, our finding that osteoporosis is more common in IBD patients, even though it may only be related to steroid use, has a direct bearing on patient management, as new guidelines advise the routine use of bisphosphonates in IBD patients with a BMD of < -1.5<sup>[31]</sup>.

## COMMENTS

### Background

Inflammatory bowel disease (IBD) is a well-recognized risk factor for osteoporosis in Caucasian patients. However, there have been very few studies on Asian patients that have investigated this problem. To the best of our knowledge, there have been no studies on this topic in Southern Asians. However, since there are obvious genetic differences between the two populations it an important area of study that has been neglected.

### Research frontiers

The genetics of IBD is a rapidly expanding field. To support this type of work, good phenotypic data from different cohorts of patients across continents are important. In studying osteoporosis, it is important to have similar data that will help in subsequent genetic studies.

### Innovations and breakthroughs

In the present study, the authors showed that IBD was not an independent risk

factor for osteoporosis, but rather the use of systemic steroids was a risk factor for the development of osteoporosis.

### Applications

It is important to know that not all Asian patients with IBD need routine bisphosphonates, as these are expensive drugs. This study will help to target whom to treat. Also, in future genetic studies, phenotypic racial differences will be important in the search for specific genes.

### Terminology

Osteoporosis is a metabolic bone disease that is characterized by reduced bone mineral density. It is usually asymptomatic until it results in fractures. It is diagnosed using dual energy X-ray absorptiometry. IBD is a chronic disease of unknown etiology that comprises Crohn's disease and ulcerative colitis.

### Peer review

This study dealt with the prevalence and risk factors of osteoporosis in adult Sri Lankan IBD patients. It is a well conceived and analyzed study.

### Abstract

**AIM:** To assess the hepatic microvascular parameters in patients with liver cirrhosis by perfusion computed tomography (CT).

**METHODS:** Perfusion CT was performed in 29 patients without liver disease (control subjects) and 39 patients with liver cirrhosis, including 22 patients with compensated cirrhosis and 17 patients with decompensated cirrhosis, proved by clinical and laboratory parameters. CT cine-scans were obtained over 50 s beginning with the injection of 50 mL of contrast agent. Hepatic microvascular parameters, mean transit time (MTT) and permeability surface area product (PS) were obtained with the Perfusion 3 software (General Electric, ADW 4.2).

**RESULTS:** The overall differences of MTT and PS between control subjects, patients with compensated cirrhosis and those with decompensated cirrhosis were statistically significant ( $P = 0.010$  and  $P = 0.002$ , respectively). MTT values were  $15.613 \pm 4.1746$  s,  $12.592 \pm 4.7518$  s, and  $11.721 \pm 4.5681$  s for the three groups, respectively, while PS were  $18.945 \pm 7.2347$  mL/min per 100 mL,  $22.767 \pm 8.3936$  mL/min per 100 mL, and  $28.735 \pm 13.0654$  mL/min per 100 mL. MTT in decompensated cirrhotic patients were significantly decreased compared to controls ( $P = 0.017$ ), whereas PS values were remarkably increased ( $P = 0.001$ ).

### INTRODUCTION

Mean transit time (MTT) and permeability surface area product (PS) of contrast material are two important parameters of perfusion computed tomography (CT). MTT is defined as the time that a contrast agent takes to go through the liver, from entry to exit and averaged over all possible paths. The PS is considered as the speed of transfer of a contrast agent from the capillary endothelium to the intercellular space (one-way). These parameters are, to a certain extent, two descriptors of parenchymal microvascular changes.

In chronic liver diseases, a capillarization of the sinusoids is observed, which is characterized by endothelial fenestration, collagen deposition in the extravascular Disse's space, formation of basal laminae<sup>[1-3]</sup>, and increased intrahepatic vascular resistance<sup>[4,5]</sup>. All these microvascular changes in cirrhosis have great influence on the development of the hepatic function<sup>[6-8]</sup>. In order to evaluate the quantitative and qualitative microvascular alterations in liver cirrhosis, these hepatic perfusion parameters (both MTT and PS) were measured in patients with liver cirrhosis by perfusion CT and the results compared to those of healthy volunteers.

## MATERIALS AND METHODS

### **Patients**

Sixty-eight adult patients were studied, including 29 controls and 39 patients with cirrhosis (22 with compensated cirrhosis and 17 with decompensated cirrhosis, divided by two experienced physicians specialized in hepatology). Four additional patients with cirrhosis were excluded because of surgically confirmed hepatocellular carcinoma. Three cirrhotic patients were excluded due to a disagreement on the assignment to the compensated or decompensated cirrhosis group. The 29 controls without liver disease (8 women, 21 men; age range: 28–78 years; average age: 49.5 years) performed perfusion CT examination of the abdomen for unrelated causes. In these 29 controls, lack of liver disease was documented by history, physical examination, laboratory screening, and Doppler sonography of the liver. Twenty-two patients (4 women, 18 men; age range: 31–78 years; average age: 58.6 years) had compensated cirrhosis. Among them, one had alcoholic cirrhosis, two had primary biliary cirrhosis, three had cryptogenic cirrhosis and 16 had posthepatitic cirrhosis. Seventeen patients (5 women, 12 men; age range: 31–78 years; average age: 55.9 years) had decompensated cirrhosis. The origin of cirrhosis in these cases was alcohol in one, hepatitis C virus in one, cryptogenic in one, primary biliary cirrhosis in one, and hepatitis B in the remaining 13 patients. All diagnoses were confirmed by appropriate clinical and laboratory examinations. No patient had portal thrombosis at ultrasonography. The study was approved by the ethics committee at our institution and was in conformity with the ethical guidelines of the 1975 Declaration of Helsinki<sup>[9]</sup>. The patients gave informed consent to participate in the study.

### **Imaging**

After an overnight fast, multiple-slices dynamic sequences were carried out. A fixed 5 mm thick slice, which was selected to include the right hepatic lobe, spleen and portal trunk, was repeatedly scanned with cine mode. Scanning was carried out using a low radiation dose (120 kV, 60 mA), cine-scan mode, standard reconstruction algorithm, 35 cm display field of view (LightSpeed RT, GE Medical Systems, Milwaukee, WI) with a 50 s of continuous scanning time set at 8 s after the injection of contrast material. A bolus infusion of 50 mL of contrast material [Omnipaque (iohexol); 350 mg I/mL; Beijing, China] was given at 5.5 mL/s via a 20 gauge intravenous catheter in the antecubital vein. Patients were advised to hold their breath as long as possible, and oxygen inhalation at 2 L/min was provided to facilitate long breathholding during scanning.

### **Data analysis**

These images were transferred to a workstation (GE Advantage workstation 4.2) for data analysis by using Perfusion 3 software. Three regions of interest (ROI) were set on the abdominal aorta, the portal vein trunk, and the right liver lobe respectively, by two radiologists

with 10 years of experience in gastrointestinal and hepatobiliary imaging. The former two ROIs were set as input function. The latter ROI of the right liver lobe was drawn on the whole visible right lobe carefully, avoiding blood vessels and margin of liver parenchyma. The value of the latter ROI was measured and averaged for the hepatic perfusion parameters.

### **Statistical analysis**

The results of the two perfusion parameters (MTT, PS) were expressed as the mean  $\pm$  SD. All data were analyzed by SPSS 11.5 software. The independent samples *t* test was used to determine differences between cirrhotics and controls. Data of the three groups (normal control subjects, patients with compensated cirrhosis, and patients with decompensated cirrhosis) were compared using one-way analysis of variance. Bonferroni's correction was applied. Statistical significance was defined as a *P* < 0.05.

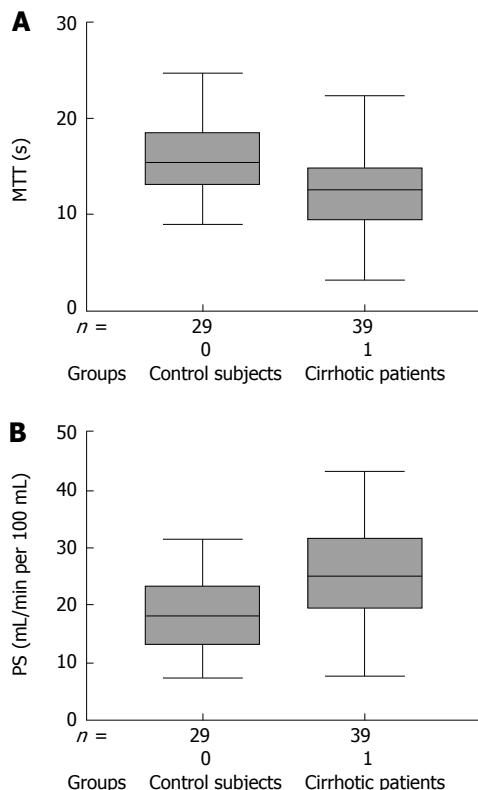

## RESULTS

### **Differences between the controls and the cirrhotics**

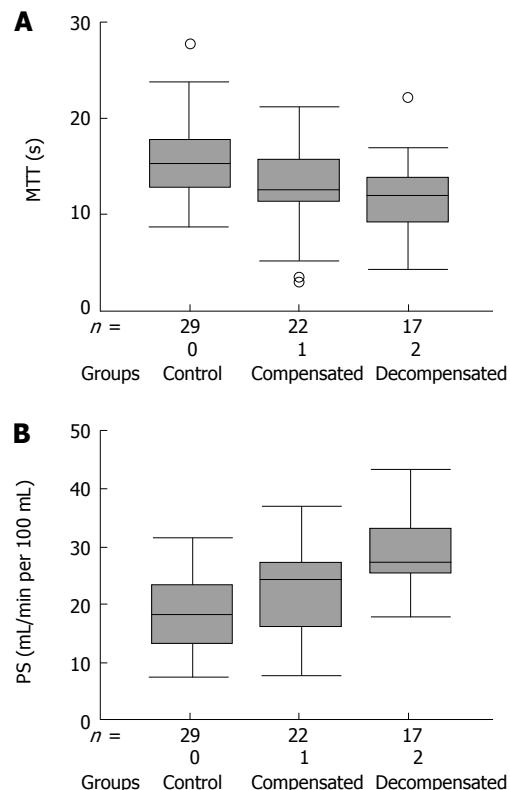

The results summarizing the MTT and PS of the controls and the cirrhotics are shown in Figure 1 and Table 1. The MTT in cirrhotic livers ( $12.212 \pm 4.632$  s) was significantly shorter than in controls subjects ( $15.613 \pm 3.942$  s), the difference being statistically significant (*P* = 0.002). PS was increased in cirrhosis compared with controls ( $24.964 \pm 8.298$  against  $18.945 \pm 7.235$  mL/min per 100 mL), and it was also significant (*P* = 0.003).

### **Differences among the three groups**

The hepatic perfusion parameters for the control subjects group, compensated cirrhosis group, and decompensated cirrhosis group are shown in Figure 2 and Table 2. Compared with the control subjects, the MTT of patients with compensated cirrhosis were decreased ( $12.592 \pm 4.7518$  s vs  $15.613 \pm 3.942$  s), and it diminished further in decompensated cirrhosis patients ( $11.721 \pm 4.568$  s) compared to compensated patients. The difference between controls and compensated cirrhotics was not significant (*P* = 0.059), nor was the difference between compensated and decompensated cirrhotics (*P* = 1.000). However, there was a markedly significantly difference between the control subjects and the decompensated cirrhotic patients (*P* = 0.017). One of the subjects, a 75 years old individual, had a MTT of 27.7 s, the highest value observed in the whole study. Another patient, with posthepatitic decompensated cirrhosis, had a rather high MTT value of 22.3 s. Other two patients in the compensated cirrhosis group showed much lower values (3.32 s and 3.79 s). The results of the PS were  $18.945 \pm 7.235$  mL/min per 100 mL,  $22.767 \pm 8.3936$  mL/min per 100 mL and  $27.806 \pm 7.4730$  mL/min per 100 mL in the three groups (controls, compensated cirrhotics and decompensated cirrhotics, respectively). The PS in compensated cirrhotic patients did not show statistically significant difference compared to control subjects (*P* = 0.25), nor was significant the

**Figure 1 Distribution of hepatic microvascular parameters in controls and cirrhotics.** Box-whisker plots are shown, in which the lower box boundary indicates the 25th percentile, the line within the box marks the median and the top box boundary indicates the 75th percentile. Error bars below and above the boxes indicate 10th and 90th percentiles. Other data are represented as individual dots. The graphs show box-whisker plots of mean transit time (MTT) (A) and permeability surface area product (PS) (B). n: Number of patients.

**Figure 2 The box-whisker plots show the distribution of hepatic microvascular parameters in controls as well as in compensated and decompensated cirrhosis patients. The values of MTT (A) and PS (B) are shown.**

**Table 2 Comparison among control subjects and compensated and decompensated cirrhosis patients on perfusion parameters (mean  $\pm$  SD)**

Group	n	MTT (s)	PS (mL/min per 100 mL)
Control	29	15.613 $\pm$ 4.175	18.945 $\pm$ 7.235
Compensated	22	12.592 $\pm$ 4.752	22.767 $\pm$ 8.394
Decompensated	17	11.721 $\pm$ 4.568	27.806 $\pm$ 7.473

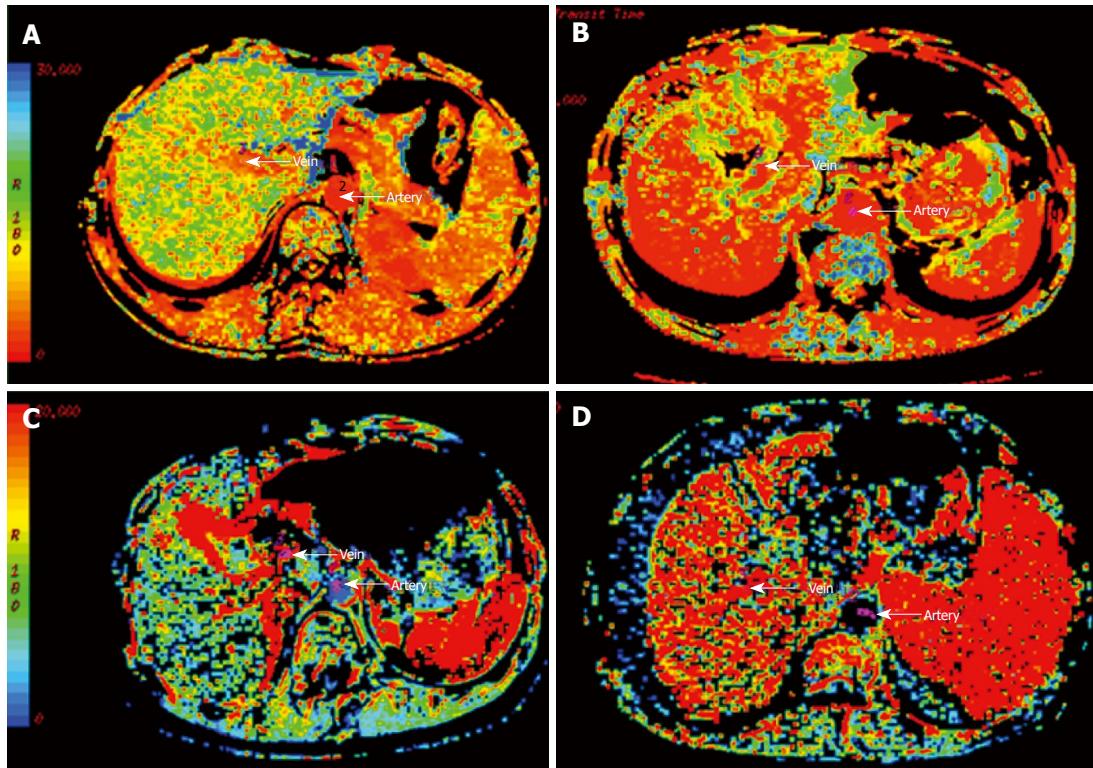

Mean transit time (MTT) in cirrhotics was shorter than in the controls ( $P = 0.002$ ). Permeability surface area product (PS) was higher in cirrhotics than in controls ( $P = 0.003$ ).

difference between compensated and decompensated cirrhotics ( $P = 0.139$ ). However, compared with controls, the PS of decompensated cirrhotic patients increased remarkably, the difference reaching statistical significance ( $P = 0.001$ ).

## DISCUSSION

A simple, noninvasive technique to separately quantify the changes of arterial and portal venous components in cirrhosis has always been a long-standing ambition of both pathologists and physicians. Most authors have reached an agreement on the notion that the increase of intrahepatic vascular resistance leads to a decrease of the portal fraction of liver perfusion<sup>[4,5]</sup>. This decreased portal perfusion is partially compensated by an increase of arterial flow, with the total liver perfusion being

reduced in cirrhotic patients<sup>[4,10,11]</sup>. More importantly, since the changes of the hepatic microcirculation in cirrhosis influence the progression of the disease, such a technique would be of greater value in hepatology. Various methods exist for the determination of hepatic microcirculation in clinical practice<sup>[12-15]</sup>. Most of them, however, are invasive or of controversial significance<sup>[12,16]</sup>. It's possible to measure both arterial and portal venous flow at the level of the main vessels using Doppler sonography, but this gives an indirect measurement of the circulation at parenchymal level. It is much harder to assess alterations in capillary blood, i.e. at the level of the microcirculation. Nuclear medicine techniques have been hindered by limited spatial and temporal resolution, and used only to estimate the arterial relative to the portal venous blood flow<sup>[17-19]</sup>, since they can hardly differentiate the overlapping fractions of hepatic artery and portal vein perfusion within the liver tissue.

**Figure 3 MTT and PS maps between controls and cirrhotic patients.** MTT in a control subject (A) was higher than in a cirrhotic patient (B). PS in a control subject (C) was lower than in a cirrhotic patient (D).

Reports have shown that the hepatic microcirculation can be estimated by the hepatic clearance of sorbitol<sup>[8,13]</sup> due to its high extraction fraction in normal subjects. The clearance of sorbitol is flow-limited and reflects hepatic microcirculation through functional sinusoids. However, sorbitol has been used as a marker of functional perfusion, which raises the issue of the decrease of the hepatocyte extraction of sorbitol in cirrhosis<sup>[20]</sup>. Moreover, the sorbitol clearance method cannot separate the measurements of arterial and portal flows. In addition, it needs to collect urine to determine the renal clearance of sorbitol after several hours, which may cause logistic problems in a busy clinical department<sup>[20]</sup>.

CT is suited for the measurement of perfusion. Because of the high spatial and temporal resolution, modern CT scanners have been used widely in clinical studies, diagnosis and treatment. The methods for quantifying tissue perfusion by dynamic CT were described previously<sup>[14,21]</sup>. Many studies have been conducted using this similar method with the use of iodinated contrast agents<sup>[5,22,23]</sup>. This technique measures the slope of the time-attenuation curve, and only the peak time-points of the aortic and portal time-attenuation curves have been applied. The procedure can quantify the arterial and portal venous blood flow at tissue level, but the use of single-slice CT hampers its limited temporal resolution and Z-axis spatial resolution<sup>[22,24,25]</sup>. Some respiratory motion artifacts are unavoidable, and they considerably influence the quantification. We used here a 16 slices spiral-CT with super high Z-axis spatial resolution and temporal

resolution, which avoided the motion artifacts in an efficient way. The perfusion parameters were measured by the deconvolution method, which uses a well-established compartmental modeling technique<sup>[26]</sup>. Several points of the time-attenuation curves were used. Arterial and portal venous perfusion was detected quantitatively. In particular, the MTT and the PS could be quantified. These parameters were important and critical to assess the function of liver, as shown by many studies in humans and animals.

The MTT mainly reflects the blood capillary's time. Some early studies almost exclusively depended on *ex vivo* evaluations using the same multiple indicator dilution technique described previously<sup>[8,13]</sup>. A study<sup>[25]</sup> on MTT had already relied upon CT, and its results were in agreement with the findings of the indicator dilution techniques. These investigators observed that the small-molecular-weight contrast agent used in their study had an increased transit time in cirrhotic patients. Some other studies<sup>[27,28]</sup> reported no difference in MTT between controls and cirrhotic patients. In the present study, however, the MTT values observed in control subjects (Figure 3A) were higher than in cirrhotic patients (Figure 3B). The MTT of contrast agent measured in the cirrhotic livers was significantly shorter than among controls ( $P = 0.002$ ) (Figure 1A). He *et al*<sup>[29]</sup> had already reported similar results, but the difference was not statistically significant. We hypothesize that there may be some differences as to etiopathogenesis, disease severity and gender distribution among the cirrhotic patients in previous studies<sup>[5,30,31]</sup>. The patients enrolled in our study (women/men: 9/30) had a cirrhosis mostly

due to hepatitis B virus (29/39) and only few had alcoholic cirrhosis (2/39), whereas no patients with hepatitis B virus infection and nine alcoholics of 18 cirrhotic patients (women/men: 6/12) were included in a previous study<sup>[25]</sup>. Histopathological examinations have shown that in the cirrhotic liver several sinusoids become capillarized and many terminal hepatic venules are distended<sup>[32,33]</sup>: the combination of these changes may lead to low-resistivity, high-speed vascular flow, with increased inflow and outflow. In addition, intrahepatic portal veins and hepatic veins cross cirrhotic areas, leading directly or indirectly into the central venous compartment. All of the above causes may have brought about the shorter MTT in cirrhotic patients.

The PS shows the permeability of blood capillaries. As shown in this study, PS may be quantified noninvasively using perfusion CT scans acquired from control subjects and patients with cirrhosis. We observed that the PS of controls (Figure 3C) was lower than in cirrhotic patients (Figure 3D): PS was in fact significantly increased in cirrhosis ( $P = 0.003$ ), (Figure 1B). This change may be explained by the results obtained with multiple indicator dilution techniques in human cirrhosis or rat cirrhotic liver. The increased microvascular resistance in the cirrhotic liver reduces capillary blood flow; the reduction in capillary blood flow is compensated by liver arterialization, increasing the capillary perfusion<sup>[4,10,11]</sup>.

In addition, we observed that MTT and PS measured by the perfusion CT tended to change significantly in patients with decompensated cirrhosis (Table 2). Compared to controls, the MTT of patients with compensated cirrhosis was decreased, while the PS was increased: however, these differences failed to reach a statistically significant level in our study. We cannot exclude that some microvascular changes might indeed occur also in cases with compensated cirrhosis (Figure 2), and that the differences between compensated cirrhotic patients and the other groups may become significant simply by increasing the size of the study population. In contrast, the microvascular perfusion parameters (both MTT and PS) were significantly altered in decompensated cirrhosis.

However, because it was difficult to control all the aspects of the study, there are several limitations associated with this study. First, the radiation dose may be one of the most important issues when using the perfusion CT, especially with cine-scan mode. Secondly, during CT imaging, patients are requested to hold their breath for long periods of time. Besides, a further limitation of our study is the small overall sample size. Perhaps, the differences between compensated cirrhosis group and the other groups would turn significant if the overall sample size increased.

Despite these limitations, our study with perfusion CT has proven that the perfusion parameters (MTT and PS) are significantly changed in patients with cirrhosis. The decreased MTT and increased PS of an iodinated contrast agent correlate with the severity of liver cirrhosis. They may be two acceptable indicators of the degree of hepatic microcirculation alteration in

patients with cirrhosis. In addition, the quantification by perfusion CT may also improve our understanding of the effects on the hepatic microcirculation of vasoactive drugs and interventional procedures for the treatment of cirrhosis<sup>[34-36]</sup>.

These findings underscore the possibility of using perfusion CT as a marker of hepatic microcirculation. Perfusion CT may be used as a noninvasive tool to quantify hepatic microvascular parameters in cirrhotic liver.

## ACKNOWLEDGMENTS

We are grateful to Zhao-Jun Li, Rui-Yi Ban and Shu-Hui Zhang for their efforts in the experimental studies. We also thank Xu-Yan Shan for his invaluable help in preparing the manuscript.

## COMMENTS

### Background

Hepatic microcirculation is of great importance in hepatology. Its changes in cirrhosis may heavily influence the progression of the disease. Various methods exist for the determination of hepatic microcirculation in clinical practice. However, most of them are invasive or controversial.

### Research frontiers

Mean transit time (MTT) and permeability surface (PS) area product of contrast material for quantifying hepatic vascular changes by dynamic computed tomography (CT) were rarely measured in previous studies. The research hotspot is whether hepatic microvascular changes can be quantified by perfusion CT and what kind of modifications can be measured.

### Innovations and breakthroughs

Previous applications of perfusion CT to the cirrhotic liver focused on hepatic haemodynamics. Most studies have reached an agreement on the fact that the increase of intrahepatic vascular resistance leads to a decrease of the portal fraction of liver perfusion. This decreased portal perfusion is partially compensated by an increase of arterial inflow, while the total liver perfusion is reduced in cirrhotic patients. However, hepatic microvascular changes were ignored. Few studies on MTT and PS have already relied upon CT. In order to explore hepatic microvascular parameters in patients with liver cirrhosis by using the perfusion CT, the authors compared hepatic microvascular parameters in patients with cirrhosis with those found in healthy volunteers. MTT and PS were significantly altered in liver cirrhosis. In order to obtain some meaningful correlations of the MTT and PS values with the severity of cirrhosis, they measured these parameters in three groups: control subjects, and patients with compensated or decompensated cirrhosis. They found that these parameters were significantly altered in patients with decompensated cirrhosis.

### Applications

Hepatic microvascular parameters may be used to quantitatively assess hepatic microcirculation: the findings correlate with the severity of liver cirrhosis. These data may improve our understanding of the hepatic microcirculation effects of vasoactive drugs and interventional procedures for the treatment of cirrhosis.

### Terminology

MTT: Mean transit time, a parameter defined as the time that a contrast agent takes to cross the liver, from entry to exit, averaged across all possible paths.

PS: Permeability surface area product, which is considered as the speed of a contrast agent from the capillary endothelium to the intercellular space (one-way).

### Peer review

The authors examined the differences in MTT and PS between normal individuals and patients with cirrhosis; they propose that perfusion CT may be utilized to quantify changes in microcirculation among stages of cirrhosis. Overall, an interesting study.

### Abstract

**AIM:** To evaluate whether urokinase perfusion of non-heart-beating cadaveric donor livers reduces the incidence of intrahepatic ischemic-type biliary lesions (IITBLs).

**METHODS:** A prospective study was conducted to investigate potential microthrombosis in biliary microcirculation when non-heart-beating cadaveric livers were under warm or cold ischemic conditions. The experimental group included 140 patients who underwent liver transplantation during the period of January 2006 to December 2007, and survived for more than 1 year. The control group included 220 patients who received liver transplantation between July 1999 and December 2005 and survived for more than 1 year. In the experimental group, the arterial system of the donor liver was perfused twice with urokinase during cold perfusion and after trimming of the donor liver. The incidence of IITBLs was compared between the two groups.

**RESULTS:** In the control group, the incidence of IITBLs was 5.9% (13/220 cases) after 3-11 mo of transplantation. In the experimental group, two recipients (1.4%) developed IITBLs at 3 and 6 mo after transplantation, respectively. The difference in the incidence between the two groups was statistically significant ( $P < 0.05$ ).

**CONCLUSION:** Double perfusion of cadaveric livers from non-heart-beating donors with urokinase may

### INTRODUCTION

Intrahepatic ischemic-type biliary lesions (IITBLs) after orthotopic liver transplantation are the most frequent cause of non-anastomotic biliary strictures in liver grafts<sup>[1-4]</sup>. They affect 2%-19% of patients after liver transplantation and have become a leading cause of liver re-transplantation in China<sup>[5,6]</sup>. Several risk factors for IITBLs have been identified, including ischemia-related injury, immunologically induced injury, and cytotoxic injury<sup>[7-9]</sup>. Although IITBLs have a multifactorial origin, ischemia-reperfusion injury and hepatic arterial thrombosis are considered to be the major causes<sup>[10-12]</sup>. In recent years, however, impaired biliary microcirculation has led to an increasing concern. Improving microcirculation can increase oxygen supply and might prevent biliary injuries. Urokinase is a proteolytic enzyme produced by the kidney, which is found in the urine. Urokinase acts on the endogenous fibrinolytic system by converting plasminogen to plasmin, which, in return, degrades fibrin clots. Since January 2006, our center has used a procedure based on the therapeutic principle of urokinase to prevent potential microthrombosis in biliary microcirculation. We have used non-heart-beating cadaveric donor grafts in which warm or cold ischemic insult was induced and which were perfused with urokinase; this procedure has produced good results.

In the present study, we evaluated prospectively 140 liver transplantation patients who received grafts with urokinase perfusion.

## MATERIALS AND METHODS

### Ethics

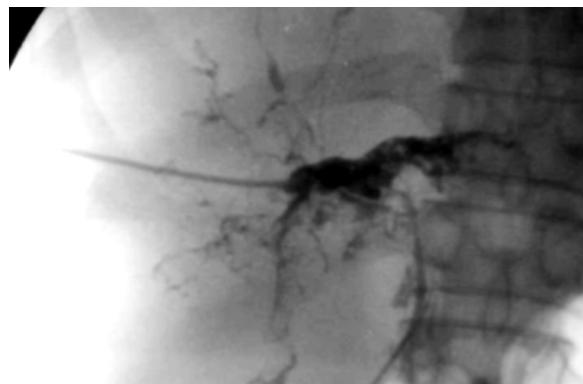

This study was approved ethically by Beijing Chaoyang Hospital. All patients provided written consent. All donors were volunteers and signed consent documents before donation.

### Clinical data

Between July 1999 and December 2005, 220 patients (176 male, 44 female; age, 14–71 years) received orthotopic liver transplantation in the Department of Hepatobiliary Surgery, Beijing Chaoyang Hospital, which is affiliated to Capital Medical University (Beijing, China). All patients survived for more than 1 year. They received ABO-compatible non-heart-beating cadaveric donor livers without urokinase perfusion. The arterial system of the donor livers was perfused with 2000 mL cold histidine-tryptophan-ketoglutarate (HTK) solution (4°C). The portal system was perfused with 2000 mL HTK solution, followed by 2000 mL University of Wisconsin (UW) solution for preservation (4°C). The biliary system was decompressed using the trocar technique. The common bile duct was perfused with normal saline at low pressure. The warm ischemia time for the donor livers was 2–8 min, and the cold preservation time was 2–13.5 h. The secondary warm ischemia for the biliary tract lasted 25–90 min. Primary diseases of the patients included posthepatitis cirrhosis in 148, primary hepatic carcinoma in 56, alcoholic cirrhosis in seven, fulminant hepatitis in four, hepatolenticular degeneration in three, and primary sclerosing cholangitis in two.

Since January 2006, all patients received donor livers with urokinase perfusion. Until December 2007, 140 patients (108 male, 32 female; age, 16–69 years) underwent liver transplantation and survived for more than 1 year. We used 2000 mL HTK solution that contained 2 MU urokinase for perfusion through the arterial system. After trimming of the donor liver, the arterial system was perfused again with 1 MU urokinase. The residual urokinase was washed out using 500 mL HTK solution before implantation. The warm ischemia time for donor livers was 2–10 min, and the cold preservation time was 2.5–15 h. The secondary warm ischemia for the biliary tract lasted 20–115 min. Primary diseases of the recipients included posthepatitis cirrhosis in 96, primary hepatic carcinoma in 34, alcoholic cirrhosis in three, fulminant hepatitis in two, hepatolenticular degeneration in two, primary sclerosing cholangitis in two, and autoimmune liver disease in one.

The immunosuppressive regimen for all the patients included cyclosporin A (CsA) (Novartis, Switzerland) or Prograf (FK506) (Astellas, Ireland), mycophenolate mofetil (CellCept; Roche, United States), and steroids. The trough CsA level was maintained at 200–300 µg/L and that of FK506 was maintained at 8–12 µg/L at 3 mo after operation. We compared the incidence of IITBLs in the patients who received grafts with or without donor urokinase perfusion.

**Figure 1** Percutaneous transhepatic cholangiography shows intrahepatic ITBL. Variant degrees of diffuse stricture and segmental dilatation of the intrahepatic bile duct in the biliary tree.

### Statistical analysis

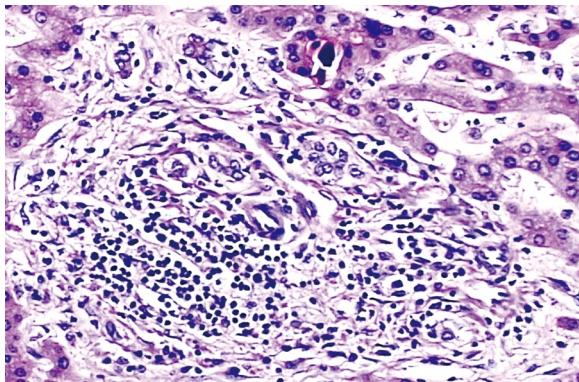

The difference between the two groups of patients was analyzed by a  $\chi^2$  test.  $P < 0.05$  was considered statistically significant. Analysis was performed using SPSS version 11.5 (Chicago, IL, USA).

## RESULTS

The incidence of IITBLs was 5.9% in patients who received grafts without urokinase perfusion (13/220 patients) 3–11 mo (mean, 5.1 mo) after transplantation, and 1.4% in the patients who received grafts with urokinase perfusion (2/140 patients) at 3 and 6 mo after transplantation. The difference in the incidence between the two groups was statistically significant ( $P < 0.05$ ). The main symptom noted in the 15 IITBL patients in both groups was progressive hyperbilirubinemia. Cholangitis was observed as a complication in three of the 15 patients. The results of a biochemical assay showed that the level of total bilirubin increased progressively. The level of direct-reacting bilirubin increased the most, followed by the level of biliary enzymes such as alkaline phosphatase and  $\gamma$ -glutamyltransferase. A slight increase in the levels of aspartate aminotransferase and alanine aminotransferase levels was detected.

Of the 13 IITBL patients who received grafts without urokinase perfusion, four were diagnosed with IITBLs by T-tube cholangiography; two by percutaneous transhepatic cholangiography; four by endoscopic retrograde cholangiography; and three by magnetic resonance cholangiography (MRCP). In the two IITBL patients who received grafts with urokinase perfusion, IITBLs were diagnosed by MRCP. The imaging of the 15 IITBL patients showed varying degrees of diffuse stricture and segmental dilatation of the intrahepatic bile duct, with withered-branch-like changes in the biliary tree (Figure 1). The stricture or embolic lesion of the hepatic artery and its major branches was excluded by Doppler ultrasonography, and acute or chronic rejections were excluded by liver biopsy.

Eight of 13 IITBL patients who received grafts without urokinase perfusion required liver re-trans-

**Figure 2 Cholestasis of hepatocytes, infiltration of inflammatory cells and proliferation of fibrous tissue in the portal area, fibrosis and luminal stenosis of bile ducts.** (HE stain,  $\times 200$ ).

plantation, and the other five patients died from liver failure while still on the waiting list. The two IITBL patients who received grafts with urokinase perfusion underwent liver re-transplantation. The injured grafts were removed from the 10 re-transplantation patients and observed pathologically. Gross findings showed patchy necrosis of the biliary endomembrane, thickened and sclerosed duct wall, and biliary sludge in the narrowed lumen. Microscopic findings showed severe cholestasis of hepatocytes, spotty or patchy necrosis, infiltration of inflammatory cells and mild to moderate proliferation of fibrous tissue in the portal area, necrosis and exfoliation of a great number of endothelial cells in small biliary lumens, formation of bile thrombus, and fibrosis and luminal stenosis of some bile ducts (Figure 2).

## DISCUSSION

IITBLs have become a leading cause of liver re-transplantation in China<sup>[13,14]</sup>. This is closely associated with the fact that non-heart-beating cadaveric livers constitute a major source of donor livers. Several studies conducted in China and other countries have suggested that cadaveric donor grafts with warm ischemic injury leads to a higher incidence of IITBLs than grafts from brain-dead donors. Abt *et al*<sup>[15]</sup> have reported that the ratio of IITBLs in biliary complications was 66.6% with non-heart-beating cadaveric livers and 19.2% with livers from brain-dead donors. Nakamura *et al*<sup>[16]</sup> have reported that the incidence of IITBLs was only 1.4% in recipients grafted with brain-dead donor livers. Zhang *et al*<sup>[17]</sup> have reported that in 235 patients transplanted with cadaveric livers and 36 transplanted with living-donor livers, the incidence of biliary complications was 19.1% and 5.6%, respectively. The incidence of IITBLs was 7.29% and 0%, respectively, and the difference was statistically significant. Researchers in China and other countries have agreed that the difference was mainly caused by warm ischemia.

What kinds of pathological or physiological changes associated with IITBLs may occur in a donor liver during warm ischemia? Generally, the initiation of intrinsic coagulation requires stoppage or slowing of blood flow, high blood viscosity, and injury of vascular

endothelial cells. After these three requirements are met, most non-heart-beating cadaveric donors are usually in a hypercoagulable state during warm ischemia. Thus, blood coagulation or microthrombi may develop rapidly in the arterioles and peribiliary capillary plexus of the donor liver within a short period. The blood clots or microthrombi are not washed out easily by subsequent cold perfusion under normal pressure, which results in inadequate perfusion of the peribiliary capillary plexus. Even after blood circulation in the donor liver returns to normal, the arterioles and peribiliary capillary plexus still lack perfusion with arterial blood. This may lead to ischemia and hypoxia of the bile duct wall; formation of biliary sludge caused by degeneration, necrosis or even exfoliation of a great number of endothelial cells; and luminal stenosis caused by gradual fibrosis of the muscular layers. By periodically sampling livers from rats dying suddenly from cardiac arrest for light microscopy, we observed blood coagulation in most arterioles in the portal area in hepatic tissue samples collected after 25 min of cardiac arrest. For the reasons described above, we adopted the strategy of double perfusion with urokinase, which aimed to achieve maximum dissolution of microthrombi, ensure better effects of cold perfusion and reperfusion, and prevent the development of IITBLs. In the present study, we found that the difference between the two groups was significant, which indicated that urokinase perfusion can effectively reduce the incidence of IITBLs.

The *in vitro* use of urokinase may not have any effect on the coagulation function of patients and is not dose-limited. Thus, urokinase usually can be administered *in vitro* at a higher concentration than when injected intravenously. For better blood circulation in arterioles and the peribiliary capillary plexus, a higher concentration of urokinase could be used to reperfuse the liver after trimming. A urokinase-free preservation solution should be used to perfuse the artery to wash out excess urokinase before completing the whole perfusion process. The activity and function of urokinase at 0–4°C have not been reported yet. In separate tests, a significant thrombolytic effect was observed when fresh blood clots in tubes at 4°C were immersed in urokinase at the above-mentioned concentrations.

The results of the present study confirm that: (1) liver transplantation from non-heart-beating cadaveric donors may lead to a higher incidence of IITBLs and a higher rate of re-transplantation; and (2) double perfusion of cadaveric livers from non-heart-beating donors with urokinase may reduce the incidence of IITBLs.

## COMMENTS

### Background

Biliary complications are a major cause of morbidity and graft failure in patients after orthotopic liver transplantation (OLT). The most troublesome is the so-called intrahepatic ischemic-type biliary lesion (IITBL), which is one of the most important reasons for liver re-transplantation. Therefore, it is clinical significance to reduce the incidence of IITBLs in order to decrease the re-transplantation rate and improve long-term life quality.

## Research frontiers

The incidence of IITBL varies between 2% and 19% after OLT. Although the exact pathophysiological mechanism of IITBL is still unknown, several risk factors of this often cumbersome complication have been identified, strongly suggesting a multi-factorial origin. Therefore, the etiology, development and prophylaxis of IITBL have been hot topics of research.

## Innovations and breakthroughs

Improving biliary microcirculation might prevent biliary injury. In this study, urokinase was perfused through the arterial system during harvesting and after trimming of donor liver in non-heart-beating cadaveric donors. This procedure has produced good results and provides the possibility of reducing IITBLs after OLT.

## Applications

This study may provide a method for clinical research into the prophylaxis of IITBLs after liver transplantation. This technique for prevention of IITBLs is easy to establish, and the results of this study confirm that urokinase perfusion may reduce the incidence of IITBLs from non-heart-beating cadaveric donors.

## Terminology

ITBL is defined as non-anastomotic destruction of the graft's biliary tree after OLT, and is characterized by bile duct destruction, subsequent stricture formation, and sequestration.

## Peer review

This is a good descriptive study in which the authors analyze the preventive effect of urokinase perfusion on IITBLs in non-heart-beating donors after OLT. The results are interesting and the conclusion is encouraging.

### Abstract

**AIM:** To investigate the role of subjective global assessment (SGA) in nutritional assessment and outcome prediction of Chinese patients with gastrointestinal cancer.

**METHODS:** A total of 751 patients diagnosed with gastrointestinal cancer between August 2004 and August 2006 were enrolled in this study. Within 72 h after admission, SGA, anthropometric parameters, and laboratory tests were used to assess the nutritional status of each patient. The outcome variables including hospital stay, complications, and in-hospital medical expenditure were also obtained.

**RESULTS:** Based on the results of SGA, 389 (51.8%), 332 (44.2%), and 30 (4.0%) patients were classified into well nourished group (SGA-A), mildly to moderately malnourished group (SGA-B), and severely malnourished group (SGA-C), respectively. The prevalence of malnutrition classified by SGA, triceps skinfold thickness (TSF), mid-upper arm muscle circumference (MAMC), albumin (ALB), prealbumin (PA), and body mass index (BMI) was 48.2%, 39.4%, 37.7%, 31.3%, 21.7%, and 9.6%, respectively. In addition, ANOVA tests revealed significant differences in body mass index (BMI), TSF, PA, and ALB of patients in different SGA groups. The more severely malnourished the patient was, the lower the levels of BMI, TSF, PA, and ALB were ( $P < 0.05$ ).  $\chi^2$  tests showed a significant difference in SGA classification between patients receiving different types of treatment (surgery vs chemotherapy/radiotherapy). As the nutritional status classified by SGA deteriorated, the patients stayed longer in hospital and their medical expenditures increased significantly. Furthermore, multiple regression analysis showed that SGA and serum ALB could help predict the medical expenditures and hospital stay of patients undergoing surgery. The occurrence of complications increased in parallel with the increasing grade of SGA, and was the highest in the SGA-C group (23.3%) and the lowest in the SGA-A group (16.8%).

**CONCLUSION:** SGA is a reliable assessment tool and helps to predict the hospital stay and medical expenditures of Chinese surgical gastrointestinal cancer patients.

## INTRODUCTION

Cancer, one of the serious global health problems today, is considered by the public as a frightening, painful, and untreatable disease that implies death. Approximately 10 million people get cancer and 5 million people face death every year throughout the world. It is estimated that the number of new cancer patients will reach 15 million in 2020<sup>[1,2]</sup>. It was reported about 20% cancer patients die of malnutrition or its relative complications rather than the malignant disease itself<sup>[3]</sup>. Many researchers have suggested that the nutritional status of cancer patients after diagnosis is associated with cancer recurrence and survival rate<sup>[4-6]</sup>, and is generally accepted as an important prognostic factor that determines patients' outcomes including treatment response, survival, and hospital stay<sup>[7-13]</sup>. Furthermore, some studies showed that good nutrition in patients with cancer can improve their quality of life<sup>[14-16]</sup>. The objective of nutritional assessment is to accurately define the nutritional status of patients, diagnose clinically relevant malnutrition, and monitor changes in nutritional status. Comprehensive and accurate information on nutritional status of patients with gastrointestinal cancer helps decide whether surgery or chemotherapy can be delayed. A number of tools have been developed for the assessment of nutritional status<sup>[17]</sup>.

Subjective global assessment (SGA) is an easy, noninvasive, and cost-effective method for the assessment of nutritional status by identifying whether the patients are malnourished or at a risk of becoming malnourished<sup>[18]</sup>. Although SGA has been originally developed to identify poor nutritional status in patients undergoing gastrointestinal surgery<sup>[19]</sup>, it can be used to quantify the prevalence of malnutrition in patients with chronic and end-stage renal failure during hemodialysis or peritoneal dialysis<sup>[20-22]</sup>. In addition, SGA is a powerful predictor of postoperative complications in general surgery<sup>[23]</sup>, liver transplantation<sup>[24]</sup>, and in patients on dialysis<sup>[25]</sup>. Although SGA has been used widely for more than two decades all over the world, few studies are available on its clinical value in Chinese cancer patients. This study was to investigate whether SGA can reliably identify malnourished patients and predict the clinical outcomes of Chinese gastrointestinal cancer patients.

## MATERIALS AND METHODS

### Ethics

This study was approved by the relevant research board and the ethics committee in Shanghai, China. All patients gave their informed consent to participate in this study.

### Patients

Adult patients diagnosed with gastrointestinal cancer (including stomach, colon, or rectal cancer) from August 2004 to August 2006 were enrolled in this study. Eligibility criteria included (a) patients diagnosed by pathology or cytology, (b) patients scheduled to undergo treatment modalities including radiotherapy

or chemotherapy or surgery, (c) patients older than 18 years, (d) patients able to read and comprehend Chinese, and (e) patients giving their informed consent. Patients with cognitive impairment, mental disorder, or communication problems were excluded from this study. The final number of recruited subjects was 751 (including 591 newly diagnosed and 160 previously diagnosed cancer patients). Of them, 384 (51.1%) were gastric cancer patients, 367 (48.9%) were colorectal cancer patients. The male/female ratio was 455/296 with a median age of 69 years (range 23-92 years). Of the 591 newly diagnosed cancer patients, 505 underwent surgery and 86 underwent chemotherapy or radiotherapy due to tumor metastasis, while the 160 previously diagnosed cancer patients received radiotherapy or chemotherapy during their hospital stay.

### Nutritional assessment

An initial assessment of nutritional status in all recruited patients was made within 72 h after admission. To avoid possible variance among observers, SGA was performed by trained researchers. Anthropometric data including body weight, height, triceps skinfold thickness (TSF), mid-upper arm circumference (MUAC), and laboratory data including albumin (ALB) and prealbumin (PA) were collected.

### Subjective global assessment

SGA of nutritional status in patients was performed based on their medical history and physical examination. Changes in weight, dietary intake, functional capacity, gastrointestinal symptoms, metabolic stress, loss of subcutaneous fat, muscle wasting, and ankle/sacral edema of the patients were recorded. After careful assessment, the changes in medical history and physical examination were classified as grade A, B, or C (Table 1). Finally, the assessment results were accumulated. If the total number of grade C was more than 5, the nutritional status of patients was classified as severely malnourished. If the total number of grade B was more than 5, the nutritional status of patients was classified as mildly to moderately malnourished. If the total number of grade C and B was less than 5, the nutritional status of patients was classified as well nourished<sup>[26]</sup>. Therefore, based on the results of SGA, patients were assigned to one of the three categories: A (well nourished), B (mildly to moderately malnourished), or C (severely malnourished).

### Anthropometric measurement

Body height and weight, and other anthropometric parameters were measured by SGA. Body mass index (BMI) was calculated based on body height and weight. BMI less than 18.5 was regarded as malnourished. MUAC and TSF were measured with intertape and adipometer. MAMC was calculated following the formula: MAMC = MUAC (mm) - 3.14 × TSF (mm). TSF ≤ 10.17 mm in males and ≤ 13.41 mm in females, or MAMC ≤ 20.52 cm in males and ≤ 18.81 cm in females was the diagnostic criterion for malnutrition. These standards of anthropometric parameters

**Table 1 Parameters and diagnostic criteria for subjective global assessment (SGA)**

Parameters	Grade A	Grade B	Grade C
Food intake	No deficiency	Definite decrease in intake or liquid diet	Severe deficiency in intake or starvation
Weight loss (during the past 6 mo)	No weight loss or weight loss > 10% during the past 6 mo but weight gain over the past month	Continuous weight loss of 5%-10%	Continuous weight loss > 10%
Gastrointestinal symptoms (nausea, vomit, diarrhea)	None	Mild or moderate GI symptoms for less than 2 wk	Continuous severe GI symptoms for more than 2 wk
Activities and function	No limitation	Not normal, but able to do fairly normal activities or do not know most things, but in bed or chair for less than half a day	Able to do little activity and spend most of the day in bed or chair; or much bedridden, rarely out of bed
Metabolic stress	No fever	Temperature > 37°C and < 39°C during the past 72 h	Continuous temperature ≥ 39°C during the past 72 h
Subcutaneous fat loss	No	Mild to moderate	Severe
Muscle wasting	No	Mild to moderate	Severe
Ankle edema/Ascites	No	Mild to moderate	Severe

Nutritional status: SGA-A (Normal); SGA-B (Mildly to moderately malnourished); SGA-C (Severely malnourished).

**Table 2 Classification standards for nutritional parameters in assessing malnutrition**

Nutritional parameter	Normal nutrition	Mildly malnourished	Moderately malnourished	Severely malnourished
TSF (mm)				
Male	> 10.17	9.04-10.17	6.78-9.03	< 6.78
Female	> 13.41	11.92-13.41	8.94-11.91	< 8.94
MAMC (cm)				
Male	> 20.52	18.24-20.52	13.68-18.23	< 13.68
Female	> 18.81	16.72-18.81	12.54-16.71	< 12.54
PA (mg/L)	≥ 200	160-199	120-159	< 120
ALB (g/L)	≥ 35	31-34	26-30	≤ 25

TSF: Triceps skinfold thickness; MAMC: Mid-upper arm muscle circumference; PA: Prealbumin; ALB: Albumin.

for classifying nutritional status were formulated in accordance with the Chinese Anthropometric Reference Data (Table 2)<sup>[27]</sup>.

### Blood measurement

Blood samples were collected at anthropometric assessment, before initiation of IV fluids. ALB and PA were measured with a standard clinical analyzer. The cut-off value for PA and ALB was set at 200mg/L (measured by immune turbidimetry) and 35 g/L (measured by biuret method), respectively. The standards for classifying nutritional status in serum proteins were also formulated in accordance with the Chinese Anthropometric Reference Data (Table 2)<sup>[27]</sup>.

### Outcome variables related to health care

Outcome variables related to health care, such as hospital stay, medical expenditures, occurrence of complications, and pathological stage of cancer were also detected. Patients were discharged according to the hospital policy. Hospital stay (d) was recorded. All patients were followed up until discharge or death. Complications, including infectious complications (septicemia, incisional, respiratory, abdominal, pelvic, and urinary tract infection) and non-infectious complications (rupture of incision, intestinal obstruction, ascites, cerebrovascular accident, bleeding, and organ failure, etc,

were monitored and recorded daily. Pathological stage of cancer was described by TNM staging according to Union International Contere Cancer (UICC) version 5.0.

### Statistical analysis

Data analyses were carried out using StatView 6.12 (SAS Institute, Cary, NC, USA). Data were expressed as mean ± SD. Differences in mean values were tested with one-way analysis of variance and Student's *t*-test.  $\chi^2$  test was used to compare differences in categorical data. Bivariate correlation analysis (Pearson's R) was performed to show the correlation between SGA grades and other nutritional parameters. Multiple regression analyses were carried out to assess the relation between SGA, other nutritional parameters, and health care outcome variables. *P* < 0.05 was considered statistically significant.

## RESULTS

### Nutritional status and cancer stage of gastrointestinal cancer patients

Based on different nutritional parameters, the number of patients with malnutrition was 362 (48.2%), 296 (39.4%), 283 (37.7%), 230 (31.3%), 145 (21.7%), and 72 (9.6%) for SGA, TSF, MAMC, ALB, PA, and BMI, respectively.

In our study, 71.1% patients were at advanced cancer stage. The number of cancer patients was 142 (18.9%), 179 (23.8%), 205 (27.3%), 225 (30.0%) at stage I, stage II, stage III, and stage IV, respectively.

### Comparison of nutritional status classified by SGA and other nutritional parameters

Based on the results of SGA, 389 (51.8%), 332 (44.2%), and 30 (4.0%) patients were classified into well nourished group (SGA-A), mildly to moderately malnourished group (SGA-B), and severely malnourished group (SGA-C), respectively. One-way analysis of variance revealed that SGA grade was closely related with other nutritional parameters (Table 3). Further analyses of Post Hoc least significant difference comparisons (LSD tests) identified that there were differences in percentage of weight loss, BMI, PA, and ALB between each two

**Table 3 Comparison of nutritional parameters in different SGA grades**

Nutritional parameters	The grade of SGA			F	P	Correlation coefficient ( <i>r</i> )	P
	SGA-A	SGA-B	SGA-C				
Weight loss (%)	2.2 ± 2.9	9.7 ± 7.0	23.2 ± 12.6	296.0	0.000	0.65	0.00
BMI	23.4 ± 3.0	21.2 ± 2.8	19.0 ± 3.3	70.8	0.000	0.40	0.00
TSF (mm)							
Male	16.0 ± 8.5	10.5 ± 6.2	9.2 ± 6.5	31.9	0.000	0.34	0.00
Female	25.0 ± 10.2	17.4 ± 8.3	14.4 ± 10.0	26.6	0.000	0.38	0.00
MAMC (cm)							
Male	21.8 ± 2.3	21.9 ± 2.1	20.6 ± 2.5	2.4	0.095	0.03	0.50
Female	18.2 ± 2.5	18.6 ± 2.4	16.8 ± 2.5	4.1	0.018	0.02	0.71
ALB (g/L)	37.7 ± 4.2	35.7 ± 5.7	30.5 ± 6.6	36.9	0.000	0.29	0.00
PA (mg/L)	246.7 ± 41.5	221.7 ± 49.2	159.6 ± 52.9	59.5	0.000	0.37	0.00

**Table 4 Comparison of SGA grades between patients before surgery and chemotherapy/radiotherapy**

Treatment	n	Grade of SGA (%)			$\chi^2$	P
		SGA-A	SGA-B	SGA-C		
Surgery	505	275 (70.7)	214 (64.5)	16 (53.3)	5.91	0.05
Chemotherapy and radiotherapy	246	114 (29.3)	118 (35.5)	14 (46.7)		
Total	751	389	332	30		

of the three SGA groups ( $P < 0.05$ ). Therefore, in general, when the patients were classified by the SGA grade as more severely malnourished, the value of the other nutritional parameters, such as levels of BMI, ALB, and PA was lower. Bivariate correlation analysis showed that SGA grade was significantly correlated with the percentage of weight loss, BMI, TSF, ALB, and PA (Table 3), even though the correlation coefficient was less than 0.3 between SGA grade and ALB level.

$\chi^2$  tests showed that SGA grade was significantly different between patients receiving surgery and chemotherapy/radiotherapy (Table 4). In addition, the percentage of weight loss ( $5.4\% \pm 6.7\% vs 8.4\% \pm 8.8\%$ ,  $P = 0.000$ ) and the serum of PA ( $235.3 \pm 46.5 vs 223.8 \pm 55.6$ ,  $P = 0.013$ ) existed obviously differences between the patients receiving surgery and chemotherapy/radiotherapy.

#### Could SGA and other nutritional parameters predict hospital stay?

One-way analysis of variance revealed that the hospital stay of 751 gastrointestinal cancer patients was not statistically different in different SGA groups ( $F = 2.46$ ,  $P = 0.086$ ). Preliminary multiple regression analysis using hospital stay as an outcome variable showed that the type of treatment was the biggest predictor for hospital stay in our study (Table 5). In general, patients receiving surgery stayed in the hospital much longer than those receiving chemotherapy/radiotherapy. Further ANOVA analysis revealed that the hospital stay was significantly longer in accordance with the increasing grade of SGA, both in patients receiving surgery and in patients receiving chemotherapy/radiotherapy (Table 6). Subgroup multiple regression analysis using hospital stay as an outcome variable, showed that SGA and serum

ALB could help explain the length of hospital stay only in surgical gastrointestinal (GI) cancer patients (Table 7), but not in patients receiving chemotherapy/radiotherapy ( $F = 1.22$ ,  $P = 0.27$ ).

#### Could SGA and other nutritional parameters predict in-hospital medical expenditures?

One-way analysis of variance revealed that the in-hospital medical expenditures of different SGA groups of patients were significantly different ( $P < 0.01$ ) (Table 6). SGA-C group had the highest expenditures, SGA-A group the lowest expenditures, and SGA-B group the medium expenditures. Multiple regression analysis using medical expenditures as an outcome variable showed that the type of treatment was the biggest predictor of medical expenditures for GI cancer patients in our study (Table 5). The multiple regression analysis revealed that SGA, serum ALB, and cancer stages (TNM) could independently influence the medical expenditures of surgical GI cancer patients (Table 7). On the contrary, no significant predictors could be found for those not undergone surgery.

#### Could SGA and other nutritional parameters predict occurrence of complications?

The occurrence of complications increased with the increasing SGA grade. SGA-C group had the highest occurrence of complications (23.3%), SGA-A group the lowest occurrence of complications (16.8%), and SGA-B group the medium occurrence of complications (19.1%) ( $\chi^2 = 1.21$ ,  $P = 0.546$ ). In addition, hospital stay of patients with complications was significantly longer than that of those without complications ( $26.1 \pm 12.1 vs 15.5 \pm 7.8$ ,  $t = -9.67$ ,  $P = 0.00$ ).

During hospital stay, 8 patients died of various

complications (5 in SGA-B group, 2 in SGA-A group, and 1 in SGA-C group). SGA grade was not related with the number of deaths in our study.

## DISCUSSION

Severe malnutrition is associated with increased

morbidity and mortality of gastrointestinal cancer, decreased treatment efficacy, and increased hospital stay<sup>[28]</sup>. Nutritional status is conventionally assessed by anthropometric measurement and laboratory assessment<sup>[29]</sup>. In this study, the prevalence of malnutrition for the same group of subjects ranged 9.6%-48.2%. The highest prevalence of malnutrition

was detected by SGA, the lowest by BMI. The purpose of nutritional assessment in cancer patients is to discover mild or moderate malnutrition before the patients become overtly wasted in order to prevent further deterioration and improve their quality of care. In clinical settings, some of the anthropometric measurements and laboratory assessments are not ideal because they are neither accurate nor convenient.

Although the British Association for Parenteral and Enteral Nutrition (BAPEN) has recommended that the measurements used for screening malnutrition should be based upon the changes in BMI and the percentage of weight loss, our study demonstrated that only a small number of patients were diagnosed with malnutrition by BMI, suggesting that BMI cannot precisely assess malnutrition in Chinese cancer patients. The established cut-off point of malnutrition for BMI largely depends on studies in younger patients<sup>[30]</sup>, and therefore, cannot be directly applied to the elderly population, which may explain why only a small number of patients were diagnosed with malnutrition by BMI in this study. It has been shown that a BMI value of 20 should alert clinicians to suspect malnutrition in the elderly<sup>[29]</sup>. It was reported that the optimal range of BMI in elderly people should be increased from 20 kg/m<sup>2</sup> to 25 kg/m<sup>2</sup> in order to identify the elderly at a risk of malnutrition<sup>[31]</sup>. On the other hand, some elderly patients spend most of their day time in bed or totally bedridden, so it is not always easy or sometimes even impossible to measure their weight or height changes.

In addition, SGA was not significantly correlated with ALB level compared to other anthropometric parameters. The ALB level alone is not a good representative marker of nutritional status of cancer patients as shown in our study. It has been shown that ALB level may be considered as an indicator of illness or as a prognostic factor for complications and mortality, but not as a major indicator of nutritional status<sup>[32]</sup>. Our study showed that ALB level was an important factor for prolong hospital stay and medical expenditures of surgical cancer patients. In patients with malignancy diseases, the ALB level can be affected by nutritional status and the malignant disease itself, or by inflammatory reactions due to any causes, such as severe liver disease, dehydration, and edema<sup>[29]</sup>. In fact, serum ALB, a negative acute phase protein<sup>[33]</sup>, is decreased in response to acute or chronic inflammation by altering the normal hepatic protein metabolism and inducing capillary leak<sup>[34-36]</sup>. Irrespective of the value of biochemical indicators, ALB level measurement is more time consuming and expensive than SGA.

SGA, one of the better available tools, can assess nutritional status, not only because it is patient centered by combining clinical history and physical examination, but also because it is associated with patient outcomes<sup>[37-39]</sup>. This is why SGA has been used widely in Western countries yielding trustworthy results. In the present study, the values of BMI, TSF, PA, and ALB were lower in more severely malnourished patients, which is consistent with previous findings<sup>[23,29]</sup>.

It has been shown that SGA grade is closely correlated with TSF, MAMC, and ALB<sup>[29]</sup>. SGA can be used as a benchmark to validate new assessment methods, such as bioelectrical impedance analysis<sup>[40]</sup> and mid-upper arm anthropometry<sup>[41]</sup>.

Although SGA is now considered a clinical method for assessing nutritional status, it was originally developed to identify patients with poorer outcomes following surgery. Baker *et al*<sup>[23]</sup> showed that patients classified as 'malnutrition' suffer more infections, use more antibiotics, and have a longer hospital stay. We hypothesized that SGA grade of patients at admission could help to predict the occurrence of complications, hospital stay, and in-hospital medical expenditures of Chinese gastrointestinal cancer patients, and found that the more severely malnourished patients had a longer hospital stay, a higher occurrence of complications, and higher in-hospitalization costs. Multiple regression analysis displayed that SGA grade could only predict hospital stay and medical expenditures of surgical cancer patients, but not those of chemotherapy/radiotherapy patients, indicating that type of treatment may influence the predictive value of SGA. Wakahara *et al*<sup>[42]</sup> reported that although SGA can be used to predict the hospital stay of patients with digestive diseases, cancer staging is a better prognostic index of cancer patients. However, the results of our study do not support the fact that advanced cancer would lead to worse nutritional status, longer hospital stay, and higher incidence of postoperative complications. In addition, patients with complications had a longer hospital stay than those with no complications. Since cancer patients are more prone to develop complications when their nutritional status deteriorates, more treatment modalities are needed to help them recover.

Although SGA could provide useful information for predicting certain outcome variables in our study, SGA was not related with death of patients. Eight patients (5 in SGA-B group, 2 in SGA-A group and 1 in SGA-C group) died of complications during hospital stay. The reason why only one patient died in the most severely malnourished SGA-C group was due to the small subgroup sample size. Whether SGA can predict the risk of in-hospital death remains unclear.

This study had some limitations. For example, the small sample size in SGA-C group resulted in a quite unbalanced distribution of nutritional status in different SGA classification groups, which may limit the power of data analysis. As an assessment tool, SGA consists of both history taking and physical examination of the patients<sup>[40,43]</sup>. Thus, reliable SGA grading depends on collection of correct history and physical examination. During our study, since some patients could not remember their exact body weight and detail dietary intake when information was collected to assess the nutritional status, the relevant information was obtained from the recall of patients and their relatives. Recently, quantification of SGA has been advocated as a way to improve the sensitivity and specificity of SGA in diagnosing malnutrition<sup>[44,45]</sup>.

In conclusion, SGA is a safe, inexpensive and reliable method for assessing nutritional status of Chinese gastrointestinal cancer patients and only can predict their hospital stay and medical expenditures in surgical GI patients. Further study is needed on the role of SGA in predicting the occurrence of in-hospital deaths.

## COMMENTS

### Background

Cancer is one of the serious health problems worldwide. A large number of cancer patients die of malnutrition or its relative complications rather than the disease itself. Malnutrition has a negative impact on the well-being of patients and evolution of the disease. A timely efficient nutritional assessment would provide a better basis for deciding whether nutritional support is given. Many nutritional assessment methods are now available. Each method has its own advantages and disadvantages. An accurate, convenient, and inexpensive method should be available for clinicians.

### Research frontiers

Subjective global assessment (SGA) has been originally developed to identify poor nutritional status in subjects undergoing gastrointestinal surgery, it can be used to quantify the prevalence of malnutrition in patients at the end-stage of renal failure, and is a powerful predictor of postoperative complications in general surgery, liver transplantation, and in patients on dialysis. In addition, a recent study revealed that although SGA can predict hospital stay of patients with benign digestive disease, its predictive power is limited in patients with malignant diseases.

### Innovations and breakthroughs

Although SGA has been used widely for more than two decades all over the world, few studies are available on SGA in Chinese gastrointestinal cancer patients. In this study, SGA was used to assess the nutritional status of Chinese patients with gastrointestinal cancer. The results show that SGA helps predict certain outcomes such as hospital stay and medical expenditures of surgical gastrointestinal (GI) cancer patients.

### Applications

As a convenient and reliable method, SGA can be used to assess the nutritional status of cancer patients since it helps predict certain outcomes of surgical GI cancer patients.

### Peer review

This manuscript is valuable and offers important data for the clinical management of GI cancer patients. The results of this study demonstrate that SGA is superior over other nutritional parameters in the assessment of nutritional status of GI cancer patients.

### Abstract

**AIM:** To evaluate the vessel grafts (VG) used to reconstruct the middle hepatic vein (MHV) tributaries with ultrasonography.

**METHODS:** Twenty-four patients undergone living donor liver transplantation were enrolled in our study. MHV tributaries larger than 5 mm in diameter were reconstructed with interposition VG. Blood flow of the graft and interposition VG was checked by Doppler ultrasonography daily in the first 2 postoperative weeks and monthly followed up after discharge. The sensitivity of VG detected by ultrasonography was assessed using surgical records as references. Student's *t* test was used to compare the velocity of VG and occluded VG in chronic patients (> 3 mo).

**RESULTS:** Thirty-one VG were used to reconstruct the MHV tributaries. Ultrasonography identified 96.7% (30/31) of large MHV tributaries and 90.3% (28/31) of VG. The diameter of VG was  $5.6 \pm 0.8$  mm and the velocity of VG was  $19.7 \pm 8.1$  cm/s. Two VG (2/31, 6.5%) were occluded on the first postoperative day in one patient who suffered from persistent ascites and had a prolonged recovery of liver function. Twenty-six VG (26/31, 83.9%) were patent 2 wk after operation. Six (6/31, 19.4%) VG were patent over 3 mo after operation. Intrahepatic venous collaterals were detected in 29.2% (7/24) patients. The velocity of VG and

occluded VG was  $30.1 \pm 5.6$  cm/s,  $16.5 \pm 5.8$  cm/s, respectively, in chronic patients. The difference between two groups was statistically significant ( $P < 0.001$ ).

**CONCLUSION:** Our results indicate that most VG are patent in the first postoperative week while only a small portion with a higher velocity remains patent after 3 mo. Intrahepatic venous collaterals can be observed in some patients after occlusion of VG.

### INTRODUCTION

Adult-to-adult living donor liver transplantation (AALDLT) is emerging as an alternative to cadaveric liver transplantation due to shortage of graft organs<sup>[1,2]</sup>. A right lobe liver graft is now commonly used in this procedure, and the middle hepatic vein (MHV) trunk is usually preserved for the donor for his or her safety<sup>[3,4]</sup>. Because hepatic venous blood of the anterior segment usually drains to the inferior vena cava through the V5 and V8 MHV tributaries, this type of grafts is inherently prone to cause congestion of the right paramedian sector (segments V and VIII), leading to tissue atrophy or necrosis<sup>[5,6]</sup>. Because establishment of optimal hepatic venous outflow is essential to a successful outcome of AALDLT, there has been emerging interest in hepatic venous congestion in the paramedian sector of the right lobe graft after AALDLT. Recently, surgical reconstruction of the major MHV tributaries using an interposition VG has been advocated to achieve optimal hepatic venous outflow

of the paramedian sector in AALDLT recipients using a modified right lobe graft. Although the indication for reconstruction of MHV is still controversial<sup>[3,7,8]</sup>, MHV tributaries in the anterior segment of the modified right lobe graft are routinely reconstructed in our institution if they are larger than 5 mm in diameter. However, compared with the recent surgical interest and investigations designed to prevent hepatic venous congestion in the right paramedian sector of the right lobe grafts after AALDLT, little attention has been given to postoperative radiological surveillance for thick MHV tributaries, VG and intrahepatic venous collaterals.

Therefore, this study was to assess the value of ultrasound in the evaluation of interposition VG and intrahepatic venous collateral formation after occlusion of the VG in AALDLT.

## MATERIALS AND METHODS

### Patients

From January 2006 to August 2007, 51 consecutive adult patients underwent AALDLT using the right lobe grafts at West China Hospital. The indications for liver transplantation included hepatitis-B virus cirrhosis in 26 patients, acute hepatic failure in 8 patients, hepatitis-B cirrhosis associated with hepatocellular carcinoma in 16 patients, retransplant for diffused ischemic intrahepatic biliary stenosis of cadaveric graft with liver failure in 1 patient. Twenty-four (47.1%) patients (21 males and 3 females) who underwent MHV reconstruction were enrolled in our study. Their median age was 38 years (range, 22–54 years). The donors (14 males and 10 females) with a median age of 36 years (range, 22–53 years) included 6 wives, 7 brothers, 2 sisters, 4 sons, 2 daughters, 2 fathers and 1 husband. All cases were approved by the ethics committee of local authority and informed consent was obtained from each patient.

### Preoperative assessment

Right liver volume was estimated by multi-slice computed tomography (CT). Candidates in whom the right liver represented more than 70% of the whole liver were excluded from prospective donors. An estimated graft volume to recipient standard liver volume ratio of 40% was the lower limit for right lobe liver transplantation. The number and diameter of thick MHV tributaries draining the right paramedian sector were evaluated by CT.

### Intraoperative evaluation

Donor hepatectomy was performed through a J-shaped incision. Intraoperative ultrasound was performed to confirm the hepatic vein anatomy and verify the transection plane. Major MHV tributaries were isolated and preserved if present and greater than 5 mm in diameter. Hepatic venous congestion in the right paramedian sector was investigated intraoperatively after parenchyma transaction by clamping test<sup>[9]</sup>. Liver surface discoloration in the right paramedian sector was observed 5 min after simultaneous clamping of MHV tributaries and the right hepatic artery. If the congested

area was dominant as determined by the clamping test or the diameter of MHV tributaries was larger than 5 mm, reconstruction of MHV tributaries was preceded. The autogenous great saphenous and cryopreserved cadaveric external iliac veins are most commonly used as interposition vessel grafts.

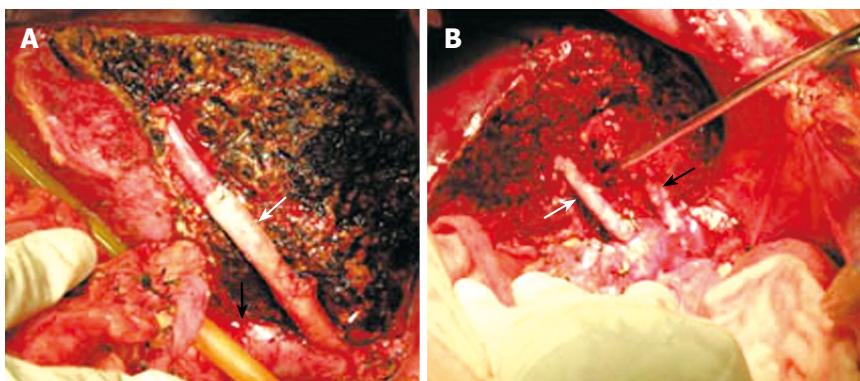

### Postoperative ultrasound examination

To prevent thrombosis of hepatic artery and vessel grafts, prophylactic anticoagulation therapy was routinely used after surgery. Blood flow in the graft or interposition vessel was checked by Doppler sonography using a HDI 5000 scanner (Philips Medical Systems, Bothell, WA) or a LOGIQ 9 scanner (GE Medical Systems, Milwaukee, Wis). Contrast enhanced ultrasound examinations were done with a Sequoia 512 ultrasound scanner (Acuson Siemens, Erlangen, Germany). The contrast agent was SonoVue (Bracco Imaging, Milan, Italy) consisting of sulphur hexafluoride microbubbles stabilized by a phospholipid shell, 2.4 mL of SonoVue per exploration was injected through a peripheral vein. A low mechanical index mode was used. Scans were performed by an ultrasound doctor with more than 5-year experience in liver transplantation ultrasound. Patients received ultrasound examination daily until postoperative day 14 and once a week thereafter until hospital discharge. Intercostal views of the right upper quadrant of abdomen were obtained to examine the full extension of the hepatic parenchyma. Thick tributaries of the MHV, identified at the left margin of the graft, were used as extrahepatic interposition VG. Fundamental gray scale, color flow images, and Doppler spectra were obtained. Angle-corrected velocities were obtained with the Doppler angle less than 60°. Contrast enhanced ultrasound study was conducted in 5 patients and late parenchymal phase (60 s after injection of SonoVue) was used to observe the patency of VG. All images were acquired when the patients did not hold their breath.

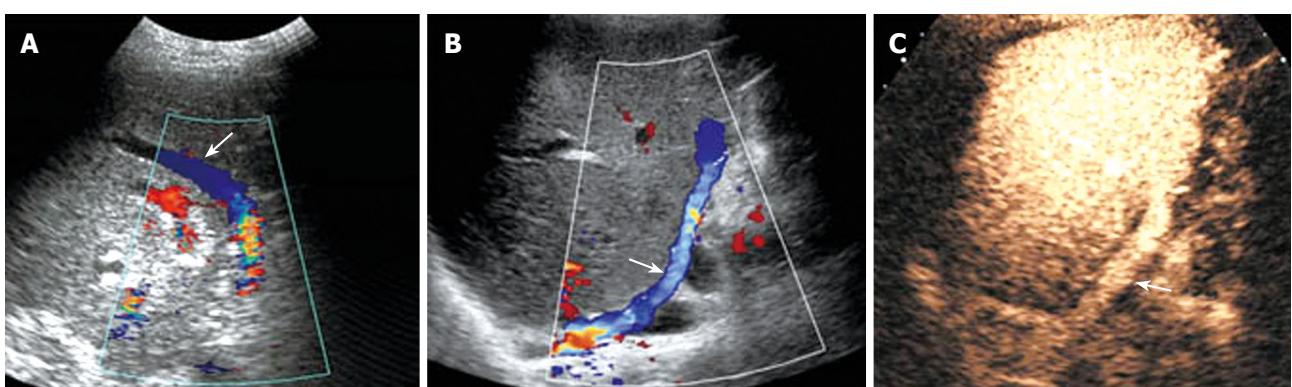

VG were divided into long term patent group and occluded group according to the vessel patency 3 mo after surgery. Student's *t* test was used to compare the velocity in two groups.

## RESULTS

Thirty-one vessel grafts were used to reconstruct the MHV tributaries, including V5 (*n* = 13), V8 (*n* = 4), both V5 and V8 (*n* = 7) (Figure 1). Ultrasonography identified 96.7% (30/31) of large MHV tributaries and 90.3% (28/31) of vessel grafts (Figure 2). The diameter of VG was  $5.6 \pm 0.8$  mm and the velocity of VG was  $19.7 \pm 8.1$  cm/s. Two VG (6.5%) were occluded on the first day after surgery in one patient (Figure 3) who had a prolonged recovery of graft function and persistent ascites for 2 mo. Twenty-six VG (83.9%) were patent 2 wk after operation. Six VG (19.4%) were patent over 3 mo after operation. Intrahepatic venous communications between the MHV tributaries and the right hepatic vein were detected in 7 (29.2%) patients (Figure 4). The velocity in long term patent VG group and occluded VG group was  $30.1 \pm 5.6$  cm/s and  $16.5 \pm 5.8$  cm/s, respectively. The

difference between two groups was statistically significant ( $P < 0.001$ ).

## DISCUSSION

The major limitation of AALDLT is the inadequacy of graft size. To guarantee the safety of the donor, many institutes perform AALDLT using a right liver graft without the MHV trunk<sup>[1,10,11]</sup>. However, this procedure might be complicated by severe congestion of the right paramedian sector, leading to tissue atrophy or necrosis. Therefore, the MHV tributaries larger than 5 mm in diameter should be preserved to achieve optimal outflow of the right paramedian sector.

Doppler sonography is generally regarded as a primary technique for vascular surveillance after LDLT and is, sometimes, the only available bedside imaging modality in the early postoperative period<sup>[12,13]</sup>. Good spatial resolution and high sensitivity to slow flow make ultrasound useful in depicting the MHV tributaries and interposition VD. In our study, Doppler sonography demonstrated 90.3% of the VG and 96.7% of the large MHV tributaries. However, ultrasound scan was interfered by bowel and lung gas, thus failing to identify the rest three VG and one MHV tributary.

Early occlusion of VG may result in an eventful recovery of liver function. One patient in whom the VG were occluded on the first postoperative day had a prolonged recovery of graft function and persistent ascites for 2 mo. Occlusion of the VG caused venous congestion of the right paramedian sector, thus delaying the recovery of liver function. Persistent ascites can be caused by an inadequate hepatic mass<sup>[14,15]</sup>. The regenerated liver cannot reach its adequate size in the early postoperative period and venous congestion of the right paramedian sector can further decrease the functional hepatic mass size.

Unlike the hepatic vein, since VG do not support the surrounding hepatic parenchyma, these VG are under a greater pressure from the neighboring structures due to liver regeneration. Moreover, because the diminished flow also attributes to the occlusion of VG, VG have a tendency to occlude with time. In our study, only 6 VG (19.4%) remained patent 3 mo after operation and had a higher velocity than the occluded VG.

Identification of intrahepatic collaterals between MHV tributaries and right hepatic vein is important, because the presence of intrahepatic collaterals indicates the outflow of the right paramedian sector is not occluded. Whether all patients have intrahepatic venous collaterals still remains controversial. De Cecchis *et al*<sup>[16]</sup> reported that intrahepatic communicating veins are sometimes observed. Kaneko *et al*<sup>[17]</sup> demonstrated that the right branch of MHV drains into the right hepatic vein via the collaterals between them. However, Cescon *et al*<sup>[18]</sup> described that the venous flow in MHV was eliminated without intrahepatic venous communication in 24 grafts of 30 living donor liver transplants when the MHV was clamped. Doppler ultrasound is sensitive to slow flow and provides information about the direction of blood flow. In our study, extensive subcapsular venous

communications were demonstrated in 7 patients (29.2%) after the occlusion of VG at follow-up ultrasound examination with no salient echogenicity change.

Contrast enhanced ultrasound is a newly emerged technique and can greatly improve the visualization of low velocity flow<sup>[19,20]</sup>. We did not routinely use it to evaluate VG due to the high price of contrast agent. In our series, 5 patients underwent contrast enhanced ultrasound study to exclude hepatic artery thrombosis and evaluate the patency of VG. The results show that it can greatly enhance the confidence of ultrasound doctors. However, further study is needed to evaluate the diagnostic value of this new technique.

In conclusion, Doppler sonography is useful in depicting thick MHV tributaries and VG. Most interposition VG are patent in the first week after surgery and trend to occlude with time with only a small portion remains patent 3 mo after operation. Intrahepatic venous collaterals can be observed after occlusion of VG.

## COMMENTS

### Background

Surgical reconstruction of major middle hepatic vein tributaries using interposition vessel grafts (VG) has been advocated to achieve optimal hepatic venous outflow of the paramedian sector in adult-to-adult living donor liver transplantation recipients using a modified right lobe graft. However, little attention has been given to postoperative radiological surveillance for thick MHV tributaries, VG and intrahepatic venous collaterals.

### Research frontiers

Doppler sonography and contrast enhanced ultrasound were used to investigate the patency and velocity of VG in study. The relation between VG velocity and long term patency was discussed. The issue of intrahepatic venous collaterals was also addressed.

### Innovations and breakthroughs

Although some studies have already discussed the issue of reconstructed vessels, our study focused on the patency of reconstructed vessels, which has received little attention.

### Applications

By displaying the relation between the velocity and patency of VG and the formation of intrahepatic venous collaterals, sonographic surveillance may represent a strategy for prediction of the VG patency and even the paramedian sector congestion of transplanted liver.

### Terminology

VG used to reconstruct middle hepatic vein (MHV) tributaries are vascular conduit between MHV tributaries and inferior vena cava. Autogenous great saphenous and cryopreserved cadaveric external iliac veins are the most frequently used VG.

### Peer review

The authors investigated the patency of vascular conduits (vessel graft) for MHV reconstruction with right liver graft in living donor liver transplantation. They used autogenous great saphenous and cryopreserved cadaveric external iliac veins as vascular conduit. Their data and experience are valuable because little evidence of the patency of reconstructed vessels is available, although similar studies are available.

have termed this rare clinical syndrome generalized  
megaviscera of lupus (GML). Although the SLE  
disease-activity parameters responded to aggressive  
immunomodulative therapy in our patient, clinical  
evidence of peristaltic dysfunction persisted in all  
involved viscera. This is a variation from the favorable  
outcomes reported previously in SLE patients with  
GML and we attribute this poor clinical outcome to  
disease severity and, most importantly, delayed clinical  
presentation. Since inflammation followed by atrophy  
and fibrosis are key aspects in the pathogenesis  
and natural history of GML, the poor response in  
our patient who presented late in the clinical course  
may be the result of 'burnt out' inflammation with  
irreversible end-stage fibrosis. Thus, early recognition  
and timely initiation of treatment may be the key to  
recover visceral peristaltic function in patients with  
GML.

## INTRODUCTION

Chronic intestinal pseudo-obstruction (CIPO) is a  
rare but important clinical syndrome as it causes 20%  
of chronic intestinal failure in adults and 15% in  
children<sup>[1]</sup>. It is characterized by ineffective intestinal  
propulsion with signs and symptoms similar to

mechanical bowel obstruction including abdominal distension, pain, nausea, vomiting, obstipation and sluggish bowel sounds, but the absence of an occluding lesion of the intestinal lumen. CIPO is idiopathic in the vast majority of cases, but secondary causes can include virtually any disease process that affects structures involved in intestinal motility, including intestinal myocytes and the extrinsic and intrinsic neural networks. The management of CIPO has been challenging, and long-term outcomes often disappointing<sup>[1]</sup>. In contrast, CIPO in systemic lupus erythematosus (SLE) patients has shown an excellent response to immunosuppressive therapy when initiated early, consistent with an autoimmune etiology<sup>[2-5]</sup>. While the pathophysiology of CIPO in SLE remains unclear, the frequent concurrence of ureterohydronephrosis (67% in one case series)<sup>[3,4,6]</sup> and histopathologic evidence of intestinal leiomyocyte damage<sup>[3-5]</sup> suggest a systemic autoimmune process targeting smooth muscle cells. Here we describe a patient with SLE who presented with refractory intestinal pseudo-obstruction, ureterohydronephrosis and megacholedochus in the setting of delayed immunosuppressive therapy. This triad of gastrointestinal, genitourinary, and hepatobiliary hollow viscera dilatation and dysmotility has been described to co-manifest in lupus only once previously<sup>[6]</sup>. We term this rare and likely under-recognized clinical syndrome Generalized Megaviscera of Lupus (GML). An understanding of the pathophysiology of these processes is needed to avoid poor outcomes resulting from either unnecessary procedures and interventions or a delay in the diagnosis and/or initiation of treatment. We review the literature and discuss the pathophysiology.

## CASE REPORT

A 46-year-old Japanese-American female presented to our hospital with a 4-mo history of worsening arthralgias, abdominal discomfort, distension and obstipation. Her past medical history was notable for SLE diagnosed in 1993, which was complicated by disseminated encephalomyelitis, malabsorption syndrome, and biopsy-confirmed membranous glomerulonephritis. In the past, she has been treated with steroids and immunomodulators; however, because of adverse reactions to several of these medications, frequent changes were made to her treatment regimen. This resulted in poor compliance and resultant breakthrough episodes of disease exacerbations affecting various organ systems. Most recently, she was being treated with mycophenolate mofetil (CellCept<sup>®</sup>) and oral prednisone which she self-discontinued 8 mo prior to admission.

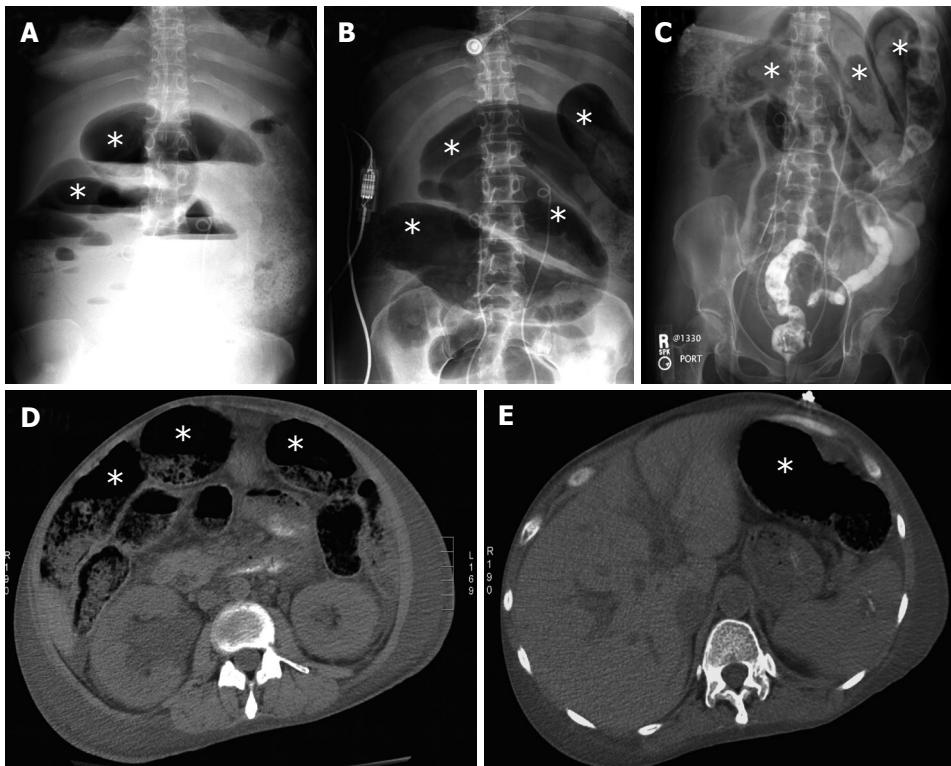

Physical examination revealed a distended tender abdomen with hypoactive bowel sounds. Laboratory tests were notable for elevated acute phase reactants, proteinuria, and acute renal insufficiency. An abdominal plain film X-ray series (Figure 1A-C) showed multiple air-fluid levels and distended loops of the large (up to

8 cm in diameter) and small (up to 3 cm in diameter) bowel without any obvious structural basis for luminal obstruction. Computed tomography (CT) of the abdomen (Figure 1D and E) confirmed the plain film findings but also showed ascites and fecalization of the luminal contents within the small bowel. Unlike lupus enteritis, the bowel wall in this case was neither thickened nor edematous<sup>[1]</sup>. Her symptoms and radiographic findings were consistent with an intestinal pseudo-obstruction. Supportive therapy was initiated with placement of a nasogastric tube in low intermittent suction, intravenous (IV) fluid, and pain medications. The patient was started on a course of tegaserod maleate (Zelnorm<sup>®</sup>) for 2 wk and 2 doses of neostigmine, with little improvement. In addition, she was also treated with enemas (glycerol, magnesium sulfate and water) and promotility agents (metoclopramide and erythromycin). A decompressive colonoscopy was attempted but the procedure was aborted at the level of the transverse colon because of poor visibility as a result of hard fecal matter and an increased risk of perforation. A gastrograffin enema was performed after the colonoscopic procedure, which demonstrated aperistaltic distal colon and contrast filling within a narrow lumen surrounded by stool that was cleared during the attempted colonoscopy (Figure 1C).

The abdominal CT scan also revealed intra- and extra-hepatic biliary tree dilatation (Figure 1E). To investigate this further, magnetic resonance cholangiopancreatography (MRCP) was performed and confirmed the presence of dilated bile ducts, without any structural basis for luminal obstruction (Figure 2). The common bile duct was dilated up to 2 cm without filling defects, calculi, or masses. The patient had no jaundice or right upper quadrant pain and her liver function tests remained within the normal limits throughout her hospital stay.

Regarding her acute renal insufficiency, she was started on IV fluid but her renal function did not improve despite adequate hydration. CT and MR images revealed bilateral hydroureters and hydronephrosis (Figure 1D, Figure 3B and C) without any structural obstruction. Obstructive uropathy resulting from lupus cystitis was entertained as a diagnosis and emergency placement of bilateral double-J ureteral stents was carried out in an attempt to decompress the genitourinary system. Despite optimal positioning of the stents, there was no improvement in the ureterohydronephrosis or her renal function. A voiding nephro-uretero-cystogram confirmed the persistence of dilated aperistaltic ureters bilaterally (Figure 3A and B). Treatment with cyclophosphamide (Cytoxan<sup>®</sup>) for presumed lupus cystitis also failed to produce any improvement. She continued to have modest urine output but nonetheless eventually required hemodialysis.

Full thickness biopsies from the genitourinary or gastrointestinal viscera were not performed in view of her poor clinical condition. She was treated with conventional immunomodulating therapies consisting of high dose IV methylprednisolone (Solu-Medrol<sup>®</sup>) and

**Figure 1** Megabowl: X-ray radiography (A-C) and computerized tomography scan (D, E) of the abdomen revealed the presence of distended loops (stars) of the small and large bowel (megabowl) in the absence of any luminal obstruction.

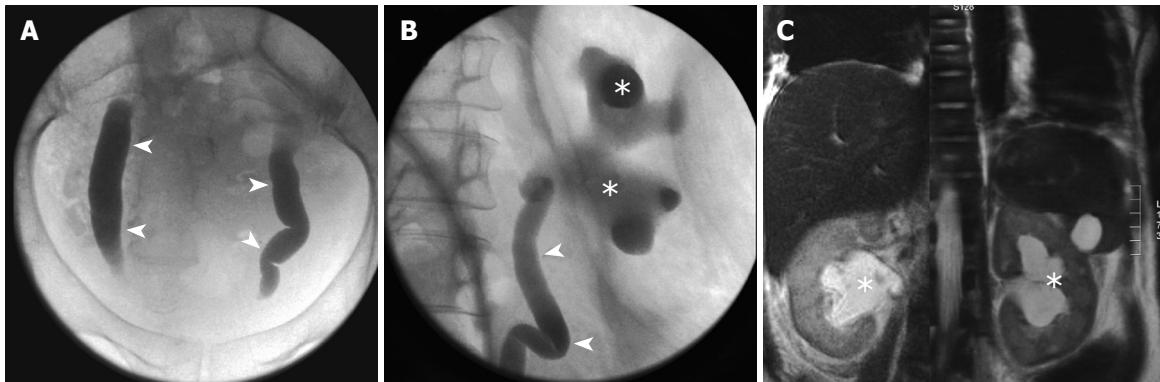

**Figure 2** Megacholedochus: magnetic resonance cholangiopancreatography revealed the presence of a distended common bile duct (megacholedochus, arrowheads) without any evidence of luminal obstruction.

mycophenolic acid (Myfortic<sup>®</sup>) along with parenteral nutrition, promotility agents, antibiotics, aggressive correction of electrolytes, and hemodialysis for presumed lupus flare with multiple organ involvement. She was discharged after improvement of her ascites, arthralgias, proteinuria and serum acute phase reactants. At 6 mo follow-up there was persistent dysfunction in all 3 organ systems without recovery of peristaltic function; however at no point during the clinical course was there any evidence of encephalopathy, cardiomyopathy, or any involvement of skeletal muscles either clinically or biochemically.

## DISCUSSION

We have described a patient with SLE who presented with abdominal distension, obstipation and renal

insufficiency with various imaging modalities revealing diffusely dilated hollow viscera in the absence of structural obstruction involving the genitourinary, hepatobiliary and gastrointestinal systems. Since these signs and symptoms are non-specific, it is important that all other possible diagnoses are entertained. The presentation as hydronephrosis in isolation deserves expert consultation and exclusion of other common causes e.g., lupus cystitis. Similarly, biliary tract dilation could occur as a result of coexisting liver diseases or as a direct consequence of an autoimmune phenomenon such as vasculitis. Hepatic artery vasculitis is known to give rise to a similar radiographic appearance but is usually accompanied by symptoms, resulting in abnormalities in liver function, and responds to systemic immunomodulation. Associated hepatobiliary diseases, e.g., autoimmune hepatitis, nodular regenerative hyperplasia, cryptococcal infection, should be considered in the differential diagnosis when isolated involvement of the biliary tract is seen. Involvement of multiple hollow visceral organs should raise suspicion of a generalized autoimmune smooth muscle injury, as in our case. Intestinal pseudo-obstruction is a very rare complication in SLE patients, but hydronephrosis are a frequent concurrent finding in these patients. The case presented here is among the first to show an additional visceral organ dilatation - megacholelithiasis. These findings suggest a truly rare, but likely under-recognized clinical syndrome we term generalized megaviscera of lupus (GML), which we define as hollow visceral dilatation and dysfunction present concurrently in more than one organ system in a patient with SLE, with intestinal pseudo-obstruction the most common manifestation.

**Figure 3** Hydronephrosis and megaureters: the presence of distended ureters (megaureters, arrowheads) was appreciated during a voiding nephro-uretero-cystogram (A, B) whereas hydronephrosis (stars) was detected by magnetic resonance imaging of the abdomen (C) as well as during the nephrogram (B).

We reviewed the anecdotal reports of patients with apparent GML in an attempt to further our understanding of the pathophysiology of this phenomenon. An overview of the pathological analysis of the gastrointestinal tract in lupus patients with CIPO revealed the following characteristics: widespread myocyte necrosis in the muscularis propria with active inflammatory cell infiltrate<sup>[5]</sup>, severe atrophy and fibrosis of the muscularis<sup>[3,5]</sup>, active serositis with serosal thickening and fibrosis<sup>[5]</sup>, little or no evidence of vasculitis or injury to bowel innervation<sup>[3-5]</sup>, and absence of thromboembolic disease<sup>[4,5]</sup>. It is notable that intestinal myonecrosis is observed without significant lupus vasculitis, often involving smooth muscle dysfunction in another organ system. These findings argue for the existence of a systemic circulating factor causing smooth muscle injury by a mechanism other than vasculitis (although the histopathologic basis for concomitant hydronephrosis and megacholedochus are yet to be determined). A good clinical response to immunosuppressive treatment has led some to hypothesize that the intestinal myopathy may be a direct result of an autoimmune phenomenon in the bowel wall<sup>[5]</sup>, and a common autoantibody against smooth muscle cells has been proposed<sup>[4]</sup>. It has been shown that autoantibodies against proliferating cell nuclear antigen (PCNA) have been detected exclusively in SLE patients and 2 cases were presented in which patients with this antibody in systemic sclerosis developed CIPO<sup>[7]</sup>; whether PCNA autoantibodies play a role in GML, however, remains unclear. Dense T-lymphocytic infiltrates with degeneration limited to the muscularis propria is considered the histopathologic hallmark of autoimmune enteric myositis causing CIPO in young children without lupus<sup>[8-10]</sup>. The location of intestinal myocyte damage is similar in SLE-associated CIPO, but dense T-cell infiltrates have not been observed; thus it is unclear whether the same disease process is involved. Autoimmune enteric neuropathy has been considered in the etiology of SLE-associated CIPO, but neuronal structures have generally been preserved on histopathology<sup>[3,5]</sup>, making this less likely. It has also been suggested that serositis can cause paralytic ileus,

and this may be a secondary cause of intestinal pseudo-obstruction in SLE<sup>[4]</sup>. Further studies will be needed to elucidate the pathogenic mechanism behind the development of GML.

In prior anecdotal reports, medical management that effectively led to improvement of GML, including remission of intestinal pseudo-obstruction and urinary symptoms, included a combination of high dose corticosteroids, immunomodulators and supportive care (parenteral nutrition, oral antibiotics, and pharmacological stimulation of small bowel motility)<sup>[2-5]</sup>. We had expected improvement and remission with similar management of our patient. Unfortunately, although there was improvement in the clinical and biochemical indicators of lupus exacerbation, e.g., ascites, arthralgias, proteinuria and serum acute phase reactants, she continued to show signs and symptoms of biliary dilatation, worsening of renal function, persistence of bowel distension and required parenteral nutrition and hemodialysis. This was concerning because of persistent generalized smooth muscle dysfunction causing aperistaltic megaviscera. While the clinical course is the best way to monitor treatment response, histopathologic reversal with immunosuppressive therapy has been documented for myositis-related intestinal pseudo-obstruction<sup>[11]</sup>. A delay in initiation of therapy has been associated with failure to regain functional peristalsis and was correlated with histopathologic progression to fibrosis and atrophy of the intestinal wall, and secondary impairment of the myenteric plexuses<sup>[12]</sup>. Progression to atrophy and fibrosis of the muscularis propria was also observed in a case of suspected non-compliance with immunosuppressive therapy in an SLE patient with CIPO<sup>[5]</sup>. Similarly, we presume that in the setting of delayed intervention and medication non-compliance, our patient developed advanced irreparable tissue destruction including myonecrosis, fibrosis and atrophy, resulting in failure of peristalsis to return despite treatment with high dose pulse steroids during her inpatient stay.

Our report emphasizes that timely diagnosis and intervention is crucial in the management of GML for the return of peristaltic activity in the various visceral organs involved. Appropriate imaging of the

gastrointestinal, genitourinary and hepatobiliary tracts should be obtained early in the investigation. It is also vital to recognize intestinal pseudo-obstruction as the cause of the symptoms and signs in order to avoid unnecessary and invasive interventions, which may confer extra risks and lead to further damage. Neostigmine was administered twice to our patient, and caused increased crampy abdominal pain and discomfort but failed to improve gut motility. Given that neostigmine acts at the myoneural junction upstream of the damaged myocyte, it is unlikely to help in this setting. Moreover, ureteral stenting has been utilized in lupus cystitis but is largely without benefit in the setting of aperistaltic ureters; this procedure caused multiple complications in our patient including ascending urinary tract infections and hematuria. The Gastroenterology service was consulted repeatedly to perform endoscopic retrograde cholangio-pancreatography (ERCP) for evaluation of her dilated biliary ducts. Biliary tree dilatation is without consequence, especially with normal liver function tests and reflects aperistalsis within the bile duct system. However, knowledge of this is essential to avoid unnecessary invasive procedures such as ERCP and/or biliary stenting. In our patient, a more conservative imaging modality, MRCP, was equally useful to rule out structural obstruction and avoided ERCP related risks. Overall, it seems that early recognition of generalized visceral organ dilatation in lupus patients, consistent with the syndrome GML, is helpful for gastroenterologists, urologists, and rheumatologists to initiate supportive care and early immunomodulation to restore peristaltic function as well as to avoid invasive procedures which may not address the basic pathophysiologic process involved.

### INTRODUCTION

The anal canal is comprised of several tissue types unique to this anatomic transition zone, ranging from colonic mucosa to keratinized epithelium with skin appendages. Anal neoplasms are a relatively uncommon occurrence in the context of all gastrointestinal tumors. Benign anal adenomas arising from the anus are particularly rare diagnoses. Furthermore, malignant neoplasms affecting the anal canal are most often of the squamous cell type and very seldom adenocarcinoma, especially in patients without known risk factors for the development of epithelial neoplasms, such as those with inflammatory bowel disease. The following describes an otherwise healthy octogenarian patient diagnosed with a well-differentiated adenocarcinoma. Although rarely reported, we concluded that this tumor may have arisen from epithelial components of the anal canal, following the sequence normal epithelium-adenoma-carcinoma (Vogelstein model) which, although has been well-described for colorectal tumors, it has only been reported twice previously.

### CASE REPORT

An 81 year-old Caucasian man presented to the emergency department with the chief complaint of continuous rectal bleeding of several months duration, which was particularly associated with bowel movements.

### Abstract

Primary neoplasms arising in the anal canal are relatively unusual. In particular, adenomas and adenocarcinomas are distinctly rare entities in this region. We describe an infiltrating, well-differentiated adenocarcinoma arising in a villous adenoma from the distal anal canal, in an otherwise healthy patient at low risk for gastrointestinal malignancy. This is the case of an octogenarian man with a several year history of hemorrhoids and intermittent rectal bleeding, more recently complaining of continuous hematochezia. Examination revealed a blood-covered pedunculated mass with a long stalk protruding from the anus. The lesion was amputated at the bedside. Microscopic evaluation revealed an infiltrating well-differentiated adenocarcinoma, arising from a villous adenoma. This was further evaluated under anesthesia and complete excision of distal anal tissue was performed. Our report is the first describing the possible malignant degeneration of a villous adenoma in the anal canal.

**Key words:** Anal adenocarcinoma; Anal canal; Villous adenoma

He reported chronic intermittently bleeding hemorrhoids for about 20 years. He denied comorbid conditions and took no medications. He also denied recent weight loss, change in appetite or bowel habits. This patient reportedly underwent a colonoscopic evaluation about four years prior to the current presentation, with negative results. His family history was unremarkable for gastrointestinal benign or malignant problems. Physical examination revealed a gentleman who appeared younger than the stated age, in no acute distress. Perianal visual and digital examination showed a blood-covered 3 cm × 4 cm pedunculated mass protruding from the anus by a stalk. Significant laboratory data demonstrated microcytic anemia (hemoglobin of 6.4 mg/dL) and normal coagulation times. He was transfused with packed red blood cells and the lesion was amputated at the bedside. Microscopic analysis revealed an infiltrating well-differentiated adenocarcinoma arising from a villous adenoma (Figure 1). Computed tomography of the chest, abdomen and pelvis demonstrated no evidence of metastatic disease. The patient was subsequently taken to the operating room for examination under anesthesia and complete excision of the anal mass. Intraoperative findings revealed very large hemorrhoids, of 0.5 cm in diameter on average occupying the entire circumference of the anus (Figure 2). Gentle dilation of the anus revealed an ulcerated area of 2 cm in length at 5 o'clock in the supine position extending from the anal orifice to about 1 cm into the anal canal. Hemorrhoidectomy was performed and the ulcerated tissue was excised. Microscopic evaluation showed evidence of the prior procedure, but did not show residual neoplasm. This tumor was staged as T<sub>1</sub>N<sub>0</sub>M<sub>0</sub>.

Detailed microscopic evaluation of the mass showed villous fronds, lined by dysplastic, intestinal-type epithelium with scattered goblet cells. Several microscopic foci of invasion into the lamina propria were identified. The neoplasm demonstrated diffuse staining for cytokeratin (CK)-20 and was negative for CK7 (Figure 3). Histologic examination of the residual anal tissue excised in the operating room clearly showed reactive (not malignant) rectal-type glands present near the surface, in between areas of squamous epithelium, as well as ulceration of superficial mucosa, consistent with the prior excision. No residual adenoma or carcinoma was identified.

This case was discussed at our local tumor board conference. No consideration for further surgical or medical therapy was deemed appropriate for his optimal care. The patient was contacted two years after his intervention, and he is doing well, without recurrence of rectal bleeding or any other problems related to the tumor herein presented.

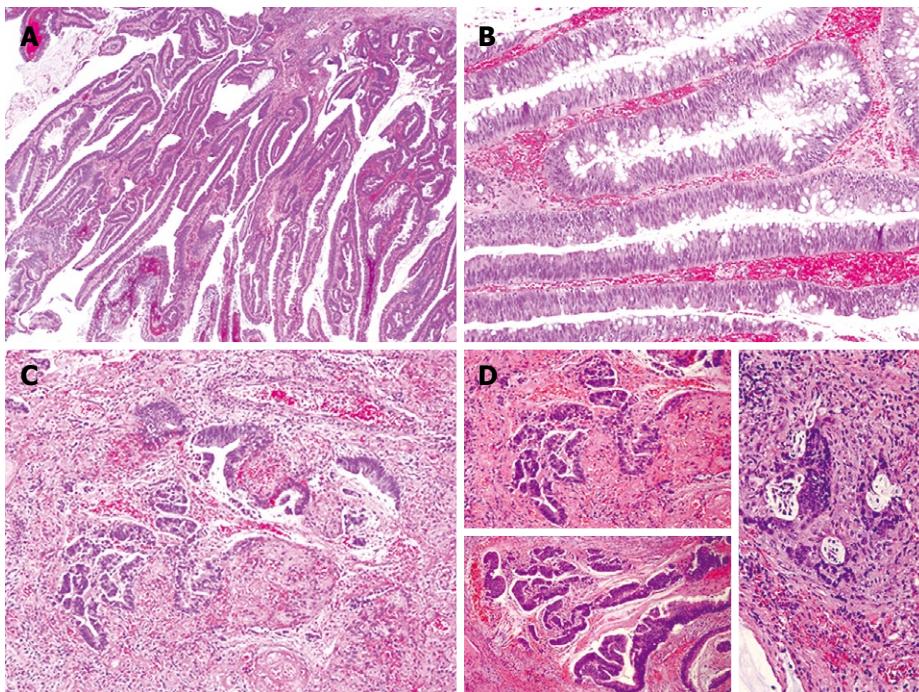

## DISCUSSION

Primary anal cancer is a rare occurrence. However, its incidence has been rising over the last 25 years. Moreover, despite the small number of patients affected by these malignancies, they remain as one of the most

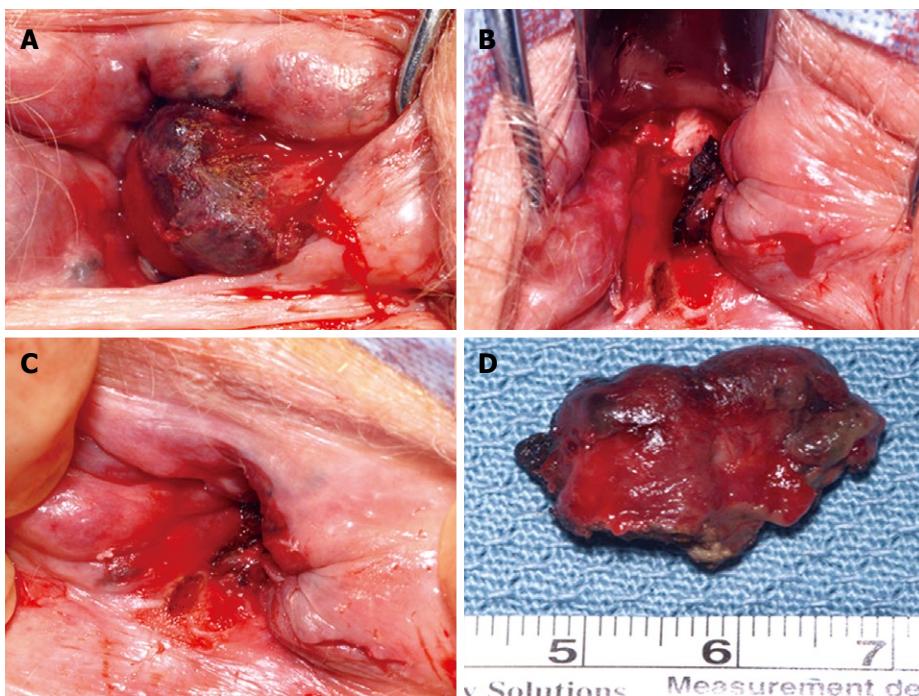

challenging cancers to treat. Once thought to be related to chronic irritation, multiple risk factors, including human papillomavirus or human immunodeficiency virus infection, anal sexual intercourse, smoking and immunosuppression, have relatively recently been identified<sup>[1]</sup>. Anal tumors represent 5% of anorectal cancers. They have been classified in tumors of the anal canal and those of the anal margin, with mainly two histological types described. Among them, squamous carcinoma comprises approximately 95% of anal tumors<sup>[2]</sup>.

Anal adenocarcinomas constitute about 5% of malignant anal neoplasms<sup>[2]</sup>. The latter tumors have been described in correlation with anal fistulae<sup>[3]</sup>, hemorrhoids<sup>[4]</sup>, after restorative proctocolectomy with a stapled ileal pouch-anal anastomosis without mucosectomy due to ulcerative colitis<sup>[5,6]</sup>, or with Crohn's disease<sup>[7]</sup>. Together, they account for 0.1% of all gastrointestinal cancers<sup>[8]</sup>.

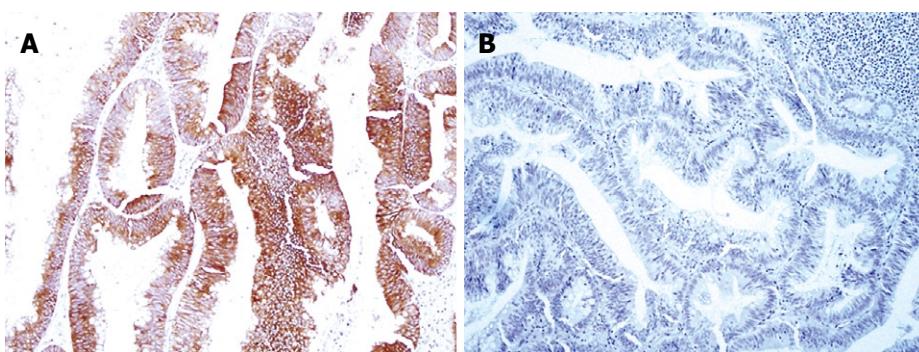

The progression of the normal colorectal epithelium to malignancy has been extensively studied in both experimental and clinical models, and a defined normal mucosa-adenoma-carcinoma sequence has been well recognized<sup>[9-11]</sup>. However, in the anal canal this information is lacking. Benign anal adenomas are extremely rare diagnoses. Multiple adenomatous polyps arising in the transitional zone of the anus in a patient with familial adenomatous polyposis (FAP) seven years after colon resection and ileo-anal anastomosis were described by Malassagne and colleagues<sup>[12]</sup>. Anand *et al*<sup>[13]</sup> reported a tubulo-villous adenoma which arose from either an anal gland or its duct that opens into the anus. These tumors are rarely encountered in patients without predisposing risk factors, such as FAP, ulcerative colitis or Crohn's disease<sup>[13]</sup>. The above-mentioned transformation from normal epithelium to malignant tumors in the anal canal has only been previously recognized twice to the best of our knowledge. MacNeill and colleagues<sup>[14]</sup> described the case of an invasive apocrine adenocarcinoma arising in a benign adenoma in the perianal region of a 45-year-old woman. Obaidat *et al*<sup>[15]</sup> reported the occurrence of anal adenocarcinoma *in situ* associated with a tubulopapillary apocrine hidradenoma. These reports suggest that adenomatous elements from the squamocolumnar junction may demonstrate hyperplastic or malignant transformation in patients without genetic predisposition. Intraoperative examination in our case made us believe that an adenomatous polypoid lesion originated from distal anal tissue in an area of chronic inflammation and ulceration consistent with the anal transition zone. Some investigators, however, have found evidence to support alternative pathways to the adenoma-carcinoma sequence<sup>[16]</sup>. Specific mutations in key onco-suppressor genes have been found to relate to the anatomical site of the tumor and therefore, a significant proportion of rectal cancers may arise *via* alternative pathways to the Vogelstein model. Polyp behavior along with malignant propensity may actually be site dependent. Rectal polyps are thought to harbor a more aggressive phenotype. In

**Figure 1 Microscopic sections.** A: The adenoma demonstrate villous architecture with long, delicate fronds (HE,  $\times 40$ ); B: The villous fronds are lined by dysplastic, intestinal-type epithelium with frequent goblet cells (HE,  $\times 100$ ); C and D: Multiple foci of invasive carcinoma are identified, with invasion confined to the lamina propria (HE,  $\times 100$ ).

**Figure 2 Intraoperative photographs.** A and D: Very large hemorrhoids up to 2 cm circumferentially located around the anal canal; B: The final appearance after complete excision of the hemorrhoids and the malignant mass; C: The area that contained the adenocarcinoma, previously excised in the emergency department, and prior to operating room excision.

**Figure 3 Immunohistochemical staining.** A: Cytokeratin 20 is diffusely positive within the epithelium ( $\times 100$ ); B: Cytokeratin 7 is negative ( $\times 100$ ).

the anal area, this remains uncertain.

CK-20 positivity with negative CK7 staining is an

immunohistochemistry profile most consistent with rectal-type mucosa and is not in keeping with the

apocrine or colloid types of adenocarcinoma that have been typically described as arising from the anal canal. In addition, the histologic appearance in this case of a well-formed villous adenoma with microscopic invasive carcinoma is different from typical anal gland carcinoma, which is characterized by small, tubular structures diffusely invading stroma. Clinical and pathologic findings in our case point to a true anal location for this pedunculated mass. Visual inspection showed this mass to arise distal to the dentate line, whereas histologic examination of the final excision specimen showed rectal-type glands present in between areas of normal squamous epithelium. The combination of these findings suggest the development of a tubulo-villous adenoma from rectal-type glands present in the anal mucosa, possibly as part of a reactive metaplastic phenomenon, similar to what was described in the case report from Anand and colleagues<sup>[13]</sup>. However, these authors did not report malignancy or immunohistochemistry findings. Therefore, whether the histologic profile of their case and ours is the same is unknown.

For anal adenocarcinoma, aggressive surgical resection remains the mainstay of therapy, with radiation therapy and chemotherapy used to aid in local disease control and for treatment of metastatic disease. A high rate of distant failure in this disease is responsible for the poor long-term prognosis<sup>[17]</sup>. Once invasive adenocarcinoma features were identified on pathologic examination of the polyp excised in the emergency department, this patient was taken to the operating room to ensure adequacy of resection. Some may argue that, to increase the chance of survival in this octogenarian, a larger extent of resection is needed. An analysis of 13 patients with primary anal adenocarcinoma who were treated over a 12-year period was performed<sup>[18]</sup>. With a median follow-up of 19 mo, the median survival was 26 mo, local failure rate was 37%, and the two-year actuarial survival was 62%. This study, although small, suggested that the combination of abdomino-perineal resection and combined modality therapy was a reasonable approach for this rare tumor<sup>[18]</sup>. However, this treatment strategy has to be individualized to both the patient and the tumor characteristics, as well as to the patients' wishes.

The need to perform lower gastrointestinal endoscopy in patients at low risk for colorectal malignancies is debatable. Patients such as the one presented herein, had rectal bleeding as the presenting symptom and without other alarming signs for colorectal cancer, such as recently altered bowel habit, weight loss and family or personal history of colorectal neoplasms, which were studied with colonoscopy by Sotoudehmanesh *et al*<sup>[19]</sup>. A number of unexpected findings were identified, such as adenomatous polyps (3%), ulcerative colitis (6%) and Crohn's disease (0.7%). Fissures were posterior in 106 cases (79.1%) and anterior in 27 cases (20.1%); one patient (0.7%) had both anterior and posterior fissures. The lower gastrointestinal endoscopy was abnormal in 10.4% of patients. No cases of adenocarcinoma were identified. Therefore, lower gastrointestinal endoscopy might be appropriate in this

selected group of patients, if these findings are confirmed by further studies<sup>[19]</sup>. Carlo *et al*<sup>[20]</sup> specifically studied patients with hematochezia but without risk factors for neoplasia, and concluded that those patients younger than 45 years of age do not need a total colonoscopy, whereas they recommended mandatory total colonoscopy in older patients even in the presence of anal pathology. In the latter group they were able to identify proximal colonic inflammatory bowel disease, neoplastic polyps and even carcinoma.

In conclusion, the transition between normal tissue-adenoma-carcinoma has been well studied in the colorectal arena but very infrequently reported in the anal canal. Our report supports the application of the same concept for the anal region, at least for patients without major risk factors for the development of gastrointestinal malignancies. The infrequent occurrence of anal adenocarcinoma and the paucity of reports in the literature documenting these tumors make conclusions about this subject difficult to reach. The literature seems to suggest further endoscopic studies of the rest of the gastrointestinal tract in elderly patients with rectal bleeding and no risk factors for colorectal cancer.

### Abstract

We report a rare case of extramedullary plasmacytoma associated with a massive deposit of amyloid in the duodenum. A 72-year-old Japanese man was admitted to our hospital presenting with a 3-mo history of epigastric pain, vomiting and weight loss. On computed tomography (CT) a wall thickening of the fourth part of the duodenum was observed. Multiple biopsies obtained from the lesion showed infiltration of plasma cells and lymphocytes, but they were not conclusive. The patient underwent resection of the lesion and, on histopathological examination, the lesion consisted of a dense and diffuse infiltrate of plasma cells and a few admixed lymphocytes with reactive follicles extending to the muscular propria. An extensive deposition of amyloid was also observed. Immunohistochemical stains revealed that a few plasmacytoid cells showed  $\lambda$  light chain staining, though most were  $\kappa$  light chain positive. These cells also were positive for CD138 and CD56 but negative for CD20 and CD79. The findings were consistent with extramedullary plasmacytoma

### INTRODUCTION

Plasma cell neoplasms account for approximately 1%-2% of human malignancies and they are classically categorized into four groups: multiple myeloma (MM), plasma cell leukemias, solitary plasmacytomas of the bone (SPB), and extramedullary plasmacytomas (EMP). EMP represents 3% of these neoplasms and it is defined as a soft-tissue plasma cell tumor occurring in the absence of systemic signs of multiple myeloma<sup>[1]</sup>. Most cases of EMP arise in the upper aerodigestive tract (UAD); other sites of involvement include the gastrointestinal tract, breast, thyroid, testis, bladder, retroperitoneum, and lymph nodes. In non-UAD regions, the gastrointestinal tract represents 40% of cases<sup>[2]</sup>. We reported an unusual case of localized

plasmacytoma associated with massive local deposition of amyloid in the duodenum.

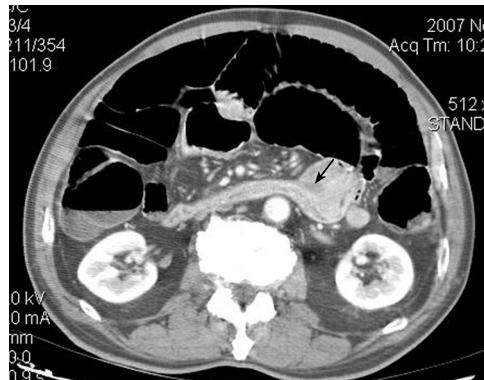

## CASE REPORT

A 72-year-old Japanese man was admitted to our hospital presenting with a 3-mo history of epigastric pain, vomiting and weight loss. No abdominal mass was palpated on physical examination. An upper endoscopy revealed a mass in the duodenum. CT showed wall thickening of the fourth part of the duodenum (Figure 1). Lymphadenopathy was not seen. Multiple biopsies obtained from the lesion showed infiltration of plasma cells and lymphocytes, but they were not conclusive. The patient underwent resection of the fourth part of the duodenum and proximal segment of jejunum. On gross examination of the surgical specimen, the involved segment measured 5 cm in length (Figure 2). On histopathological examination, the lesion consisted of a dense and diffuse infiltrate of plasma cells and a few admixed lymphocytes with reactive follicles extending to the muscular propria. An extensive deposition of hyaline amorphous eosinophilic extracellular material was also observed (Figure 3). With Congo red stain, amyloid appeared red in normal light and apple-green in polarized light. Immunohistochemical stains revealed that a few plasmacytoid cells showed  $\lambda$  light chain staining, while most were  $\kappa$  light chain positive (Figure 4A and B). These cells also were positive for CD138 and CD56 but negative for CD20 and CD79 (Figure 4C and D). The scattered lymphocytes represented a mixture of CD3-positive T cells and CD20-positive B cells. The extracellular hyaline materials also showed reactivity with anti-kappa (but not lambda) immunoglobulin light chains. The findings were consistent with a plasma cell neoplasm. A subsequent workup for MM (serum and urinary protein electrophoresis, radiographic examination of the axial skeleton and a bone marrow aspirate and biopsy) was completely negative. Anemia and hypercalcemia were not seen. The patient showed no signs of local recurrence or dissemination of the disease after 12 mo follow-up.

## DISCUSSION

The involvement of gastrointestinal tract is common in MM but a localized plasmacytoma is rare and not suspected clinically. In previous reports<sup>[3-6]</sup> of duodenal EMP, males were more affected than females and the disease was most commonly seen in patients older than 50 years of age. These patients presented with nonspecific symptoms such as dyspepsia, vomiting, epigastric pain and weight loss. As in our case, in these previous reports radiological features were not suggestive and the diagnosis was revealed only by the findings of histopathological and immunohistochemical examination of the sample biopsy or surgical specimen, mainly the light chain restriction (demonstrating the monoclonality) and positivity for CD138 (indicating plasma cell lineage).

Treatment options for EMPs include surgical resec-

**Figure 1** CT showing a mass on the fourth part of the duodenum (arrow).

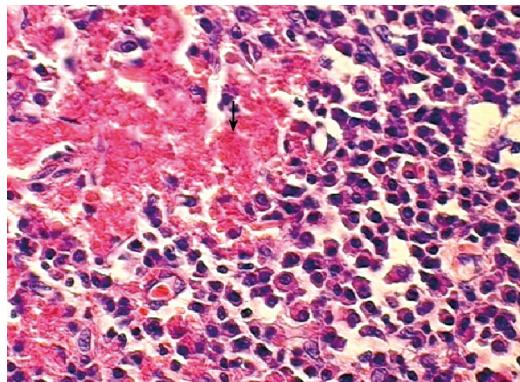

tion and radiation therapy, given the relative sensitivity of plasma cell neoplasms to radiation<sup>[2,7]</sup>. Alexiou *et al*<sup>[2]</sup> found no statistically significant difference in patient survival comparing surgery alone, surgery plus radiotherapy, or radiotherapy alone. Surgery alone, however, had the lowest recurrence rate. Our patient was not submitted to radiation after surgery. Of all of the plasma cell tumors, EMPs have the best prognosis. Progression to MM is more frequent in solitary osseous plasmacytoma than in EMP<sup>[8,9]</sup>. The prognosis of patients with EMP of the duodenum is uncertain as so few patients have been reported, but, of those cases reported in the literature, we found two that presented evolution to myeloma after surgery<sup>[10,11]</sup>.

Amyloidosis, a complication of plasmacytoma in the present case, is characterized histopathologically by the extracellular deposition of insoluble fibrillar proteins. In our case, amyloidosis was caused by the deposition of immunoglobulin light chains since both amyloid and plasma cells shared the same immunoglobulin light chain restriction (lambda-restriction). The absence of systemic amyloidosis in massive localized deposits, as in our case, may be explained by the secretion of abnormal, poorly soluble immunoglobulin molecules with a tendency toward local precipitation<sup>[12]</sup>. We did not find previous cases of amyloidosis associated with duodenal plasmacytoma, so the impact of associated amyloid accumulation on progression or response to treatment in our case cannot be determined. Amyloid deposition can be found in 15% to 40% of extramedullary plasmacytomas in the head and neck regions and, according to previous reports, without clinical significance<sup>[13]</sup>.

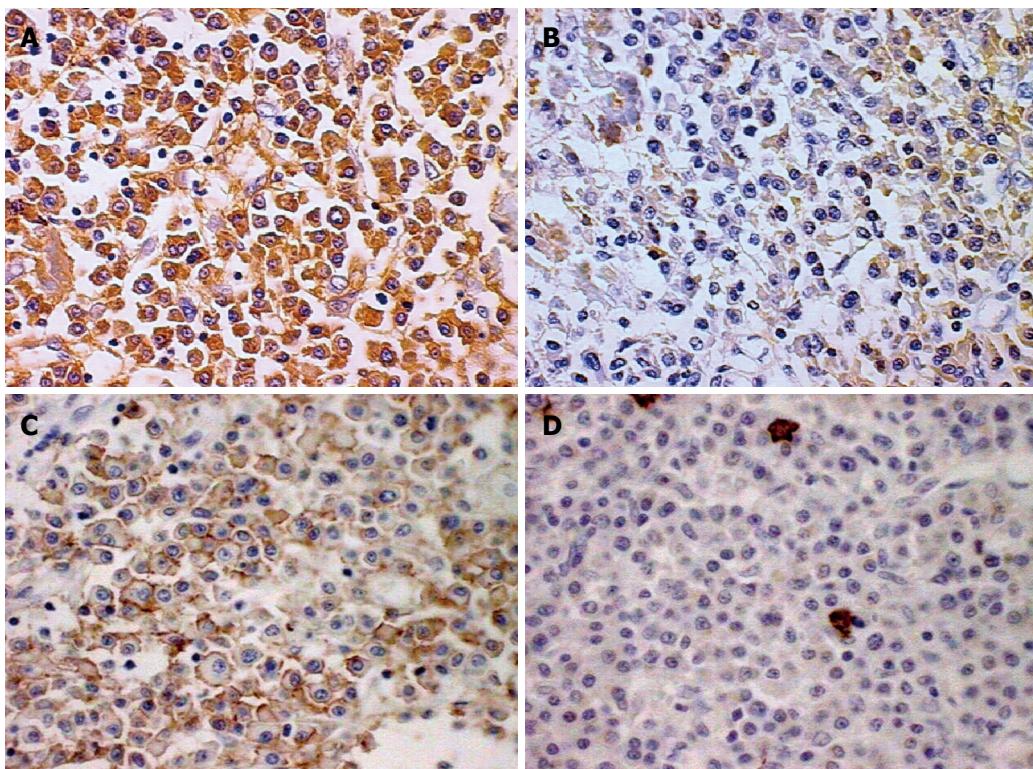

In view of their indolent biological nature and their frequent involvement of anatomic sites containing mucosal lymphoid tissues, it has been proposed that extramedullary plasmacytomas represent a low-grade lymphoma of mucosal lymphoid tissues (MALT) with extensive plasmacytic differentiation. Results from a previous study support this hypothesis<sup>[14]</sup>; morphologic features of MALT lymphoma, including centrocytic-like cells, reactive follicles, and lymphoepithelial lesions, are often found in extramedullary plasmacytomas. Besides this, amyloid deposits have also been described in lym-

**Figure 2** Gross appearance of the surgical specimen containing the tumor (arrow).

**Figure 3** Histopathological examination displaying a dense and diffuse infiltrate of plasma cells and amyloid deposit (arrow). (HE  $\times 400$ ).

**Figure 4** Immunohistochemical findings (positive cells in brown,  $\times 400$ ). A: Most plasmacytoid cells were positive for  $\kappa$  light chain; B: Few plasmacytoid cells showing  $\lambda$  light chain staining; Plasmacytoid cells were positive for CD56 (C) and negative for CD20 (D).

omas<sup>[15]</sup>. However, according to others authors, some immunohistochemical findings on plasmacytoid cells are helpful in differentiating plasmacytoma from MALT lymphoma<sup>[16,17]</sup>. These authors found that plasmacytoid cells were less likely to express CD56 in lymphoma than in myeloma. So, the positivity for CD56, in our case, suggests that it may indeed represent a true primary PC dyscrasia (plasmacytoma), with phenotypic feature similar to myeloma.

In conclusion, plasmacytoma localized in the duodenum is rare and may cause intestinal obstruction. The diagnosis is performed by histopathological examination and must be distinguished from lymphomas with extensive plasmacytic differentiation. In associations of EMP and amyloidosis, the patient must be followed up

because of the possible systemic involvement of the neoplasm and amyloidosis in future.

## Abstract

Pseudoachalasia due to pleural mesothelioma is an extremely rare condition. A 70-year-old woman presented with progressive dysphagia for solid and liquids and a mild weight loss. A barium swallow study revealed an esophageal dilatation and a smoothly narrowed esophagogastric junction. An esophageal manometry showed absence of peristalsis. Endoscopy demonstrated an extrinsic stenosis of the distal esophagus with negative biopsies. A marked thickening of the distal esophagus and a right-sided pleural effusion were evident at computed tomography (CT) scan, but cytological examination of the thoracic fluid was negative. Endoscopic ultrasound showed the disappearance of the distal esophageal wall stratification and thickening of the esophageal wall. The patient underwent an explorative laparoscopy. Biopsies of the esophageal muscle were consistent with the diagnosis of epithelioid type pleural mesothelioma. An esophageal stent was placed for palliation of dysphagia. The patient died four months after the diagnosis. This is the first reported case of pleural mesothelioma diagnosed through laparoscopy.

## INTRODUCTION

Esophageal achalasia is an uncommon disorder, with an incidence of about one case per 100 000 persons per year. The term "pseudoachalasia" generally applies to a subgroup of less than 5% of patients presenting with clinical features of achalasia in whom an occult malignant tumor is the cause of dysphagia<sup>[1]</sup>. Benign pseudoachalasia is an even more unusual condition, accounting for less than 2% of patients with achalasia-like symptoms<sup>[2]</sup>. Adenocarcinoma of the esophagogastric junction represents the most frequent diagnosis in patients with malignant pseudoachalasia, accounting for 70% of cases<sup>[3]</sup>. Other causes include lymphoma<sup>[4-6]</sup> and primary neoplasms from the lung, esophagus, liver, pancreas, colon, kidney, prostate, and breast<sup>[7-14]</sup>.

Malignant mesothelioma has been infrequently associated with dysphagia. In some reports, dysphagia was secondary to direct extension of the cancer into the esophagus and was a late, usually terminal, event<sup>[15]</sup>. The first case of pleural mesothelioma presenting as dysphagia was described by Johnson in 1983<sup>[16]</sup>. We report the case of a patient presenting with pseudoachalasia in whom the diagnosis of pleural mesothelioma was performed by laparoscopy.

## CASE REPORT

A 70-year-old woman presented in December 2007 with a two-month history of progressive dysphagia for solids and liquids, and a 5-kg weight loss. There was no prior history of gastroesophageal reflux, odynophagia, or other gastrointestinal symptoms. Social history was negative for tobacco use and alcohol intake. Physical examination was unremarkable and routine laboratory tests were within normal limits. A barium swallow study revealed a mildly dilated esophagus and a smoothly narrowed esophagogastric junction (Figure 1). An

**Figure 1** Barium swallow showing dilatation of the esophageal body and narrowed esophago-gastric junction.

esophageal manometry showed absence of peristalsis (Figure 2), but evaluation of the lower esophageal sphincter was precluded due to the inability to advance the catheter into the gastric cavity. Subsequent upper gastrointestinal endoscopy showed no evidence of gross mucosal lesions, but a mild resistance to the passage of the instrument through the cardia was noted. On retroflexed view, the esophagogastric junction appeared normal. A pneumatic dilation was performed using a 30 mm Rigiflex balloon dilator inflated at 10 PSI for one minute, and multiple esophageal biopsies were performed, which showed no evidence of malignancy.

Three weeks later, due to the persistence of dysphagia, a thoraco-abdominal CT scan was performed that demonstrated the presence of a right pleural effusion, thickening of the mediastinal and parietal pleura, and a 4-cm long concentric thickening of the distal esophageal wall (Figure 3). A thoracentesis yielded 1500 cc of yellow fluid with a protein content of 2 g/dL and a pH of 9. Bacteriological and cytological examinations of the fluid were negative. Subsequent endoscopic ultrasound examination showed the disappearance of the distal esophageal wall stratification and thickening of the wall up to 9 mm. At that point, the decision to proceed with an exploratory laparoscopy was taken in an attempt to clarify the diagnosis. Upon incision of the peritoneal reflection, the distal esophageal wall appeared markedly thickened and tightly adherent to the diaphragm. No lymphadenopathy was found in the lesser sac. Peritoneal lavage cytology was negative. Intraoperative ultrasound confirmed the thickening of the distal esophagus.

Multiple biopsies from the esophageal muscle wall and from the contiguous diaphragm were taken. Histopathological findings from the esophageal wall were consistent with the diagnosis of pleural mesothelioma (epithelioid type). Immunohistochemistry was positive for calretinin, vimentin, Ckpan and CK 7 (Figure 4). Soon after surgery the patient complained of recurrent dysphagia and onset of pain in the right side of the chest.

Two weeks later, a right thoracoscopy in the prone position with single-lumen intubation was performed to complete the staging of the disease and to provide drainage of the recurrent pleural effusion. Multiple nodularities and plaques were noted along

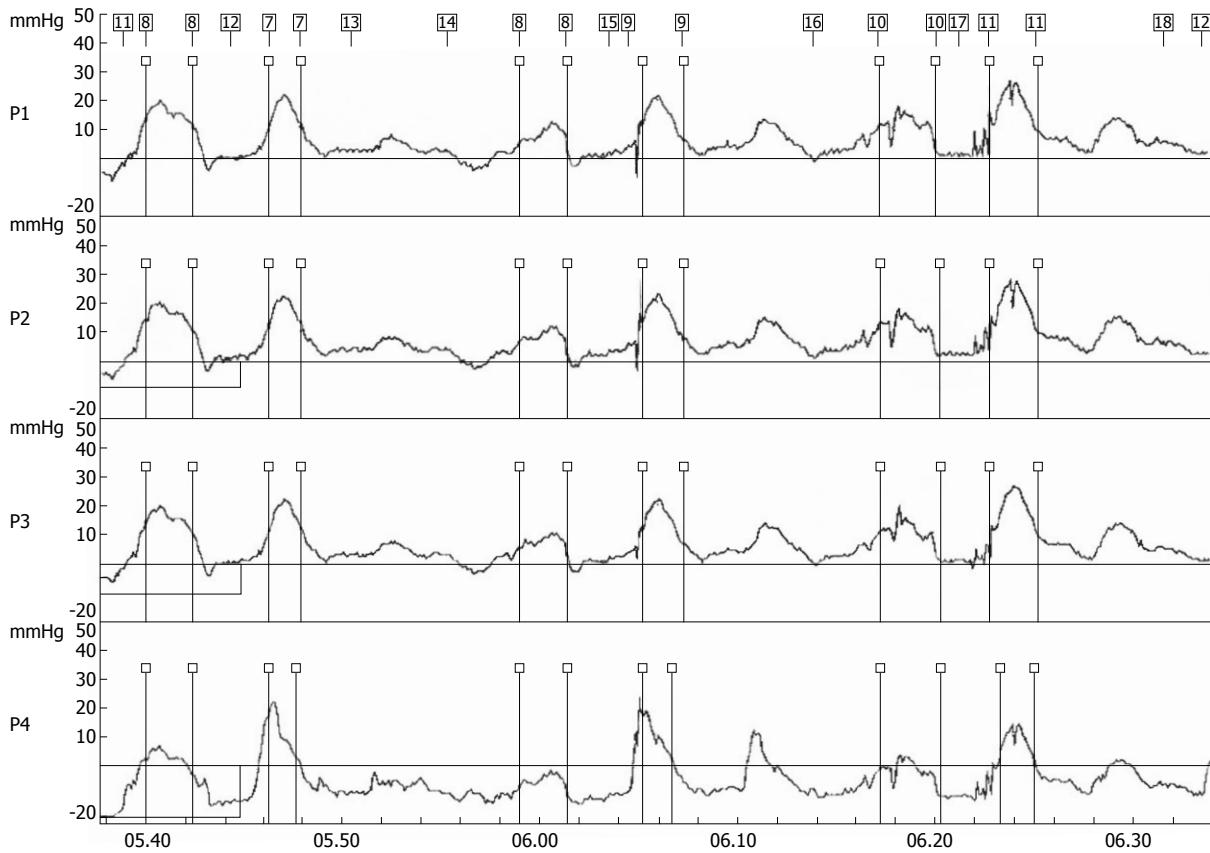

the diaphragmatic, parietal and mediastinal pleura surfaces, mostly in the lower half of the pleural cavity. Multiple biopsies were repeated, which confirmed the previous histopathological diagnosis. During the same operative session, a port-a-cath was inserted in the right subclavian vein, and a 10 cm self-expanding esophageal metal stent with antireflux valve (Hanarostent®) was deployed endoscopically. A gastrographin swallow study performed the next day showed a partial stent expansion that required a single endoscopic balloon dilation within the stent. As a result of this treatment, there was a marked improvement of dysphagia but worsening of the chest pain, requiring sustained analgesia. The patient was also started on a chemotherapy regimen. She died from septic shock four months after the diagnosis without stent related complications.

## DISCUSSION

Malignant pseudoachalasia is a term used to describe the clinical picture of gastroesophageal junction obstruction associated to an occult submucosal tumor or a non-contiguous tumor. Several mechanisms have been proposed to explain the pathogenesis of this type of secondary achalasia. First, the tumor might directly infiltrate the nerves within the myenteric plexus of the esophagus. Second, a paraneoplastic syndrome might affect the function of the distal esophagus<sup>[13]</sup>. Third, the tumor might replace the smooth muscle at the esophagogastric junction, reducing compliance of the esophageal wall to distension. In turn, the esophagus might generate high pressures to overcome this obstruction with dilatation as a compensatory response.

Patients with malignant pseudoachalasia are, as a group, older than patients with primary achalasia. In addition, there is a male predominance, in contrast to primary achalasia in which both sexes seem to be equally affected. Tucker<sup>[7]</sup> suggested that advanced age (> 50 years), short duration of symptoms (< 1 year) and marked weight loss (> 15 pounds) support the diagnosis of secondary achalasia over primary achalasia. When these criteria are met, patients should undergo additional imaging to rule out an occult malignancy. It should also be kept in mind that an occult malignancy cannot be reliably detected even during the course of a laparoscopy esophagomyotomy for presumed primary achalasia<sup>[3,17]</sup>.

Pleural mesothelioma is a rare cause of malignant pseudoachalasia, accounting for 7.5% of all diagnoses<sup>[3]</sup>. Goldschmiedt *et al*<sup>[18]</sup> reported of a 64-year-old male presenting with progressive dysphagia and radiological and manometric findings suggestive of achalasia. Thoracentesis and pleural biopsy were performed for a left pleural effusion and no malignant cells were found. The CT scan was negative. At left thoracotomy, multiple pleural plaques covered the diaphragmatic surfaces, as well as the pleura reflection over the lung. A distal esophageal myotomy was carried out and revealed an abnormal tissue consistency at the level of the esophagogastric junction. Biopsy and immunohistochemical studies showed a malignant epithelial mesothelioma.

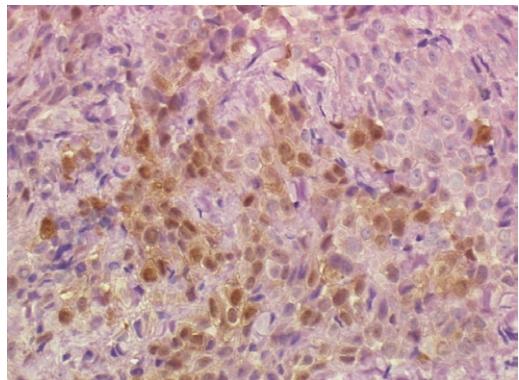

**Figure 2** Stationary esophageal manometry showing synchronous waves throughout the esophageal body indicating aperistalsis.

**Figure 3** CT scan showing right pleural effusion and concentric thickening of the esophageal wall.

The preoperative diagnosis of pseudoachalasia secondary to pleural mesothelioma is problematic. A CT scan is often inaccurate in diagnosing the extension of the disease through the diaphragm<sup>[19]</sup>. Thoracentesis is usually the initial diagnostic procedure because most patients present with a pleural effusion. However, pleural fluid cytology is positive for malignancy in less than 50% of patients. Percutaneous pleural biopsy is also unreliable because the small specimens obtained do not allow immunohistochemical studies to differentiate the disease from metastatic adenocarcinoma<sup>[20]</sup>. There is only one case report showing the efficacy of EUS-guided fine-needle aspiration to diagnose pleural malignant mesothelioma in a patient with CT and endosonographic evidence of a

**Figure 4** Biopsy of the distal esophageal wall taken at laparoscopy showing a neoplastic cell population consistent with the diagnosis of pleural mesothelioma (epithelioid type). Immunohistochemistry stains positive for calretinin (40 × HPF).

paraesophageal mass<sup>[21]</sup>. Video-assisted thoracoscopy is considered the diagnostic procedure of choice because it consistently yields a diagnosis without committing the patient to a major surgical procedure through a formal thoracotomy<sup>[22]</sup>. In our patient, laparoscopy was safe and effective in providing the correct diagnosis. To our knowledge, this is the first reported case of pleural mesothelioma diagnosed through laparoscopy.

## INTRODUCTION

Cystadenoma is a benign tumor, although prone to malignant degeneration<sup>[1]</sup>, supposedly originating in intrahepatic (and more rarely extrahepatic) embryonic tissue precursors of biliary epithelium. It is a non recurrent lesion, with only 125 cases reported in literature<sup>[2]</sup>. It may appear either as a uninodular or as a multinodular cystic lesion, and may attain large proportions.

Cystadenomas account for 4.6% of intrahepatic biliary cysts. They are more recurrent in middle-aged females (40-50 years old) with an incidence rate of 4:1 with respect to males. Cystadenomas are rarely found in extrahepatic bile ducts.

The etiology of cystadenomas remains unclear, although several theories have been suggested. Some authors consider this disease a premalignant lesion. Due to the usual absence of clinical symptoms, the most frequent diagnosis is by chance, as in the excision of a cystic lesion.

In this paper, we report a case of cystadenoma at the excision of a suspected choledochal cyst in an adult female.

## CASE REPORT

Our patient was a 60-year-old woman with a history of high blood pressure under treatment. While a laparoscopic cholecystectomy was performed for recurrent episodes of biliary colic, a dilated bile duct was evidenced intraoperatively.

Upon this finding, an informed magnetic cholangiography was requested due to dilatation of the choledochal duct. However, it did not show any proximal or distal bile duct dilatation, which was most likely a normal variant (type-1 choledochal cyst according to Todany's classification) (Figure 1). Blood tests with tumor markers were requested, and a CA19.9 of 51.8 was shown, whereas the rest of the tests were normal.

Surgery was performed as planned for the diagnosis of choledochal cyst. The patient underwent resection of the bile duct up to the pancreas joint and before the bifurcation of the hepatic duct, with terminolateral transmeso-

## Abstract

The diagnosis of cystadenoma is rare, even more so when located in the extrahepatic bile duct. Unspecific clinical signs may lead this pathology to be misdiagnosed. The need for pathological anatomy in order to distinguish cystadenomas from simple biliary cysts is crucial. The most usual treatment nowadays is resection of the bile duct, together with cholecystectomy and Roux-en-Y reconstruction.

colic Roux-en-Y hepaticojejunal anastomosis. A type-1 choledochal cyst was discovered macroscopically (Figure 2). The sample was sent to the Pathological Anatomy Service, where it was reported as a 1.4 cm extrahepatic bile duct cystadenoma, with chronic inflammation and bile duct dilatation with regenerative epithelial atypia. No evidence of malignant degeneration was found (Figure 3).

The postoperative course was eventful, with anastomotic leak noted on hepatobiliary iminodiacetic acid (HIDA) scan, central venous catheter-related septicaemia and abscess formation shown by computed tomography (CT), which were solved with percutaneous drainage. Finally, the patient was discharged from the hospital asymptotically.

## DISCUSSION

Biliary cystadenomas arise in the liver in 90% of the cases, and they are much less frequent in the extrahepatic bile ducts, as in our patient. Intra and extrahepatic concomitant cases have also been found. Despite the report of some unilocular cystadenomas, multilocular ones are by far more common. Cystadenomas are usually located in the right lobe of liver, although they may also be present in both lobes or only in the left one of liver.

Macroscopically, their surface is usually flat, and may reach great proportions. The contents are mostly liquid, tending to become mucinous texture, including biliary pigment, hemosiderine and even purulent material if overinfected. Biliary communication has been rarely reported. In some patients, the tumor projects into the bile ducts. In our case, the projection was located in the choledochal wall.

On light microscopy, the inner surface was covered with a cuboidal-to-tall epithelium and some papillary and polypous excrescences, basally oriented nuclei with prominent nucleus and thick chromatin fibers, pale acidophil cytoplasm with mucine-filled vacuoles. According

to some authors, this epithelium must be surrounded by a densely cellular mesenchymal stroma with plain muscular fibers and oval cells, which are typical of epithelia<sup>[3,4]</sup>. However, others claim that hepatic cystadenomas with such features are consistent only with females, males being different in stroma formation. That is why the latter scholars suggest the name of cystadenoma with mesenchymal stroma. Outside this cellular stroma, a dense layer of collagenous tissue separates it from the hepatic parenchyma<sup>[5]</sup>.

The etiology of cystadenomas is unclear. Cystadenomas without mesenchymal stroma have been induced experimentally with aflatoxins in an animal model. This might lead to a possible malignant transformation of simple hepatic cystic lesions<sup>[6,7]</sup>. Coincidences between cystadenoma, gallbladder embryonic tissue, and main bile ducts tissue have also been found<sup>[3]</sup>. Stimuli such as ischemia or carcinogenic elements also produce this kind of lesions.

Cystadenoma may display a wide range of symptoms, although it is mainly asymptomatic. The most typical symptoms are a slowly growing abdominal mass, upper abdomen pain, dyspepsia, anorexia, nausea and fever. Jaundice by compression, protrusion, invasion of bile ducts or by secretion of dense mucinous material has been reported<sup>[8]</sup>. Invasion of the bile ducts may result in pancreatitis episodes. In our patient, we could only reach a diagnosis by the anatomopathological study of the sample, as the patient was asymptomatic except for recurrent biliary colics due to gallbladder lithiasis.

The most widely used diagnosis methods are ecography and tomography. They allow us to observe the cyst formation walls, intracystic projections and possible multilocular arrangement. Since magnetic cholangioscopy provides precise images of the lesion, it is thus the current reference test for tumor study<sup>[8-10]</sup>.

For some scholars, ecologically-guided fine-needle aspiration puncture (FNAP) may be a good diagnostic method, but it may present drawbacks such as the danger of dissemination and its low diagnostic value<sup>[11]</sup>. CEA levels in cyst liquid help to differentiate cystadenomas from cystadenocarcinomas. Other tests, such as endoscopic retrograde cholangiopancreatography (ERCP), gammagraphy and angiography, may give indirect signs for diagnosis. In blood tests, high levels of CA 19.9 are inconsistent with relation to the lesion. In our case, the rise of this marker occurred inside a cystadenoma<sup>[12]</sup>.

Treatment must be surgical whenever possible, due to a potential malignant degeneration of these lesions. The technique chosen for bile duct sites is complete resection of the bile duct, associating cholecystectomy and recon-

struction with hepatic-jejunostomy in Roux-en-Y. When a partial resection has been done for other reasons and the sample shows evidence for a cystadenoma, complete resection of the bile duct and its reconstruction must be performed. However, this was not necessary for our case, as the bile duct was properly fully removed, and the gallbladder was previously removed.

In the hepatic lobes, enucleation must be the objective. The technique used should be personalised taking into account the placement and the patient in context<sup>[13,14]</sup>.

The patient follow-up is justified in order to avoid possible surgical complications in the bile duct, such as cholangitis, gallstones, estenosis of the anastomosis, and malignant degeneration. In hepatic cystadenomas, the high level of recurrence should be monitored in the postoperative follow-up<sup>[13,15,16]</sup>.

### Abstract

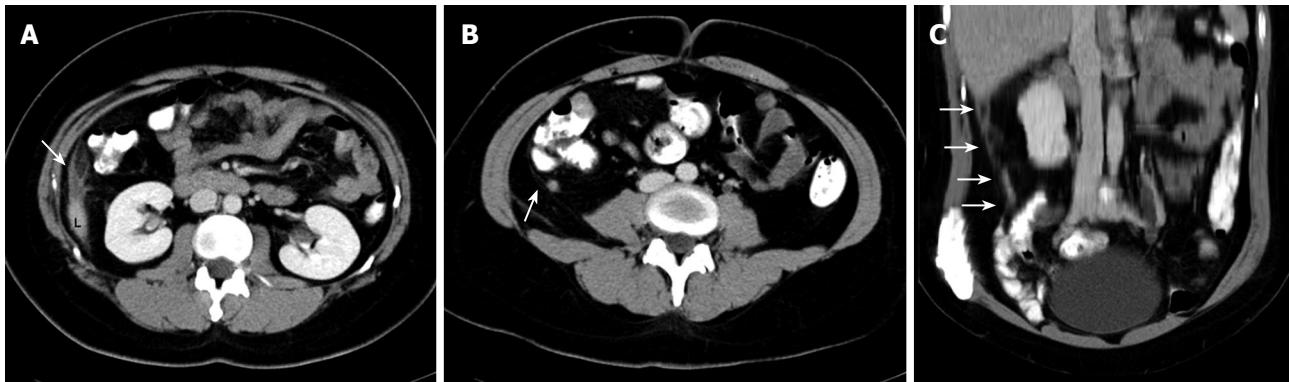

Acute appendicitis is a common surgical condition that is usually managed with early surgery, and is associated with low morbidity and mortality. However, some patients may have atypical symptoms and physical findings that may lead to a delay in diagnosis and increased complications. Atypical presentation may be related to the position of the appendix. Ascending retrocecal appendicitis presenting with right upper abdominal pain may be clinically indistinguishable from acute pathology in the gallbladder, liver, biliary tree, right kidney and right urinary tract. We report a series of four patients with retrocecal appendicitis who presented with acute right upper abdominal pain. The clinical diagnoses at presentation were acute cholecystitis in two patients, pyelonephritis in one, and ureteric colic in one. Ultrasound examination of the abdomen at presentation showed subhepatic collections in two patients and normal findings in the other two. Computed tomography (CT) identified correctly retrocecal appendicitis and inflammation in the retroperitoneum in all cases. In addition, abscesses in the retrocecal space ( $n = 2$ ) and subhepatic collections ( $n = 2$ ) were also demonstrated. Emergency appendectomy was performed in two patients, interval appendectomy in one, and hemicolectomy in another. Surgical findings confirmed the presence of appendicitis and its retroperitoneal extensions. Our case series illustrates the usefulness of CT in diagnosing ascending retrocecal appendicitis and its extension, and excluding other inflammatory conditions that mimic appendicitis.

### INTRODUCTION

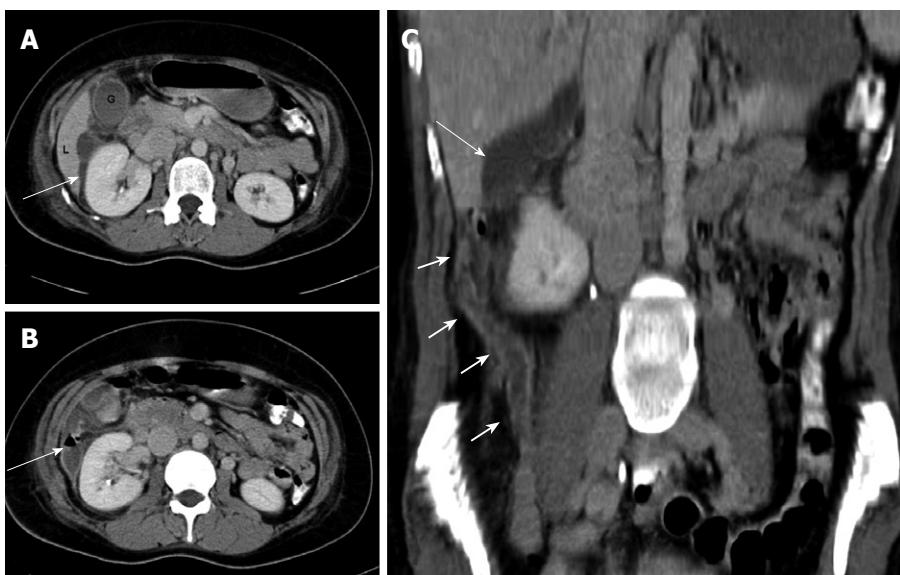

The veriform appendix may occupy several positions in relation to the cecum. The most common positions are descending intraperitoneal (31%-74%) and retrocecal (26%-65%)<sup>[1,2]</sup>. The location and spread of inflammation from acute appendicitis depends on the location of the appendix. If the appendix is located retroceally, it may give rise to an abscess in the pararenal space and spread to bare area of the liver<sup>[3]</sup>, or it may spread along the right paracolic gutter, and extend to the right posterior subhepatic and right subphrenic spaces<sup>[4]</sup>. More than half of the patients with ascending retrocecal appendicitis may have an atypical clinical presentation<sup>[5]</sup>. We present a case series of ascending retrocecal appendicitis with atypical clinical presentation, and highlight the utility of computed tomography (CT) in diagnosing the condition.

### CASE REPORT

During the period January 2003 to December 2006, a computerized search for patients with surgically confirmed retrocecal appendicitis was made. Patients with retrocecal appendicitis and preoperative CT were selected. There were four patients who had atypical clinical presentation with right upper abdominal pain, who formed the study group. The hospital records were reviewed for clinical features, laboratory investigations, surgical findings and follow-up. Preoperative ultrasound and CT were reviewed.

**Figure 1** A 30-year-old woman presenting with a clinical diagnosis of acute cholecystitis. A and B: Contrast-enhanced computed tomography (CT) sections showing inflammatory changes (arrow) adjacent to the inferior tip of the liver (L); B: Thickened appendix (arrow) with mild inflammatory changes in the retrocecal region; C: Coronal reconstruction showing the extent of inflammatory changes (arrows) from the retrocecal region to the tip of the liver.

**Figure 2** A 31-year-old woman presenting with right hypochondrial pain and a clinical diagnosis of pelvic inflammatory disease and right pyelonephritis. A: Contrast-enhanced CT scan showing fluid collection (arrow) in the subhepatic region, extending anteriorly to the gallbladder fossa with inflammatory stranding; B: Note the air fluid level in the collection adjacent to the right kidney; C: Coronal reconstruction showing the long thickened and inflamed appendix (short arrows) reaching the subhepatic region, and the subhepatic collection (arrow) is seen extending more cranially.

### Case 1

A 30-year-old woman presented with a 3-d history of right hypochondrial pain that was constant and radiated to the back. There was right hypochondrial tenderness with negative Murphy's sign and renal punch. She had leukocytosis (13 200 cells/ $\mu$ L). A clinical diagnosis of acute cholecystitis was made. Ultrasound showed a normal liver and gallbladder with no significant abnormality. She was treated initially with antibiotics. A CT scan performed 2 d after presentation showed an inflamed appendix with inflammatory changes in the retrocecal and subhepatic regions (Figure 1). Open appendectomy revealed a moderately inflamed retrocecal appendix with no perforation. Postoperative recovery was uneventful.

### Case 2

A 31-year-old woman presented with a 2-d history of right hypochondrial pain that radiated to the back and right shoulder tip, fever with chills, and vomiting. She also complained of foul-smelling urine and vaginal discharge. She had a termination of pregnancy 4 d earlier. The pain was increasing in severity and aggravated by movement and coughing. She was febrile with right hypochondrial

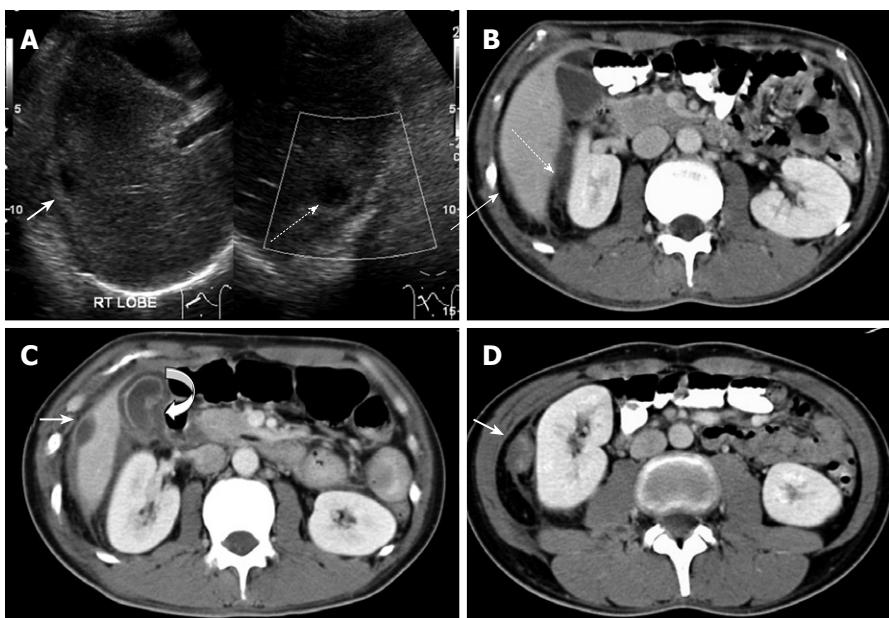

rebound tenderness and a positive right renal punch. She had leukocytosis (14 080 cells/ $\mu$ L). The clinical impression was pelvic inflammatory disease with pyelonephritis and hepatobiliary sepsis. Focused assessment with sonography for trauma (FAST) showed no fluid collection in Morrison's pouch, and pelvic ultrasound did not show any collections. CT (Figure 2) at 3 d after admission showed loculated collections adjacent to segment 6 of the liver. A long inflamed retrocecal appendix was seen with surrounding inflammation that extended to involve the hepatic flexure and anterior pararenal space. There was also consolidation of the right lung base. At surgery, there was retrocecal appendicitis with perforation that caused a subhepatic collection. The patient made a good recovery.

### Case 3

A 34-year-old man presented with right flank pain of 6 d duration. The pain was colicky and radiated to the back. There was no history of dysuria or urinary frequency, but he also had nausea and vomiting with loss of appetite for 2 d. He had leukocytosis (13 620 cells/ $\mu$ L). The abdomen was soft but the right renal punch was positive. The clinical impression was of right-sided ureteric colic and urinary

**Figure 3 A 34-year-old man with colicky right flank pain and clinical diagnosis of right ureteric colic.** A: Ultrasound showed a subhepatic fluid collection (arrows) and no other significant abnormality; B: CT scan performed 2 d later showed the collection in the subhepatic region (short arrow). Note the air-fluid level in the anterior collection (long arrow) with inflammatory changes; C: The section at the level of the cecum and appendix shows inflammatory changes in the retrocecal region (short arrow) and thickened appendix (long arrow).

**Figure 4 A 27-year-old man with recurrent right upper abdominal pain.** A: Ultrasound showed a hypoechoic area in the subphrenic (straight arrow) and subhepatic (broken arrow) region; B: Confirmation by contrast-enhanced CT; C: CT also showed a thickened gallbladder wall (curved arrow), subhepatic collection (white arrow) and inflammation in the perinephric region; D: Another caudal section shows a thickened appendix with inflammatory stranding in the perinephric region.

tract infection. Ultrasound showed no urinary calculi but there was a subhepatic collection (Figure 3) with hyperechoic areas that were suggestive of an abscess. CT (Figure 3) performed on the next day showed the appendix to be swollen and inflamed. There were collections in the subhepatic, rectovesical and paravesical regions. Surgery on the same day confirmed an inflamed and perforated retrocecal appendix with extensive retrocecal collections and abscesses, and a hemicolectomy was performed. The patient recovered uneventfully.

#### Case 4

A 27-year-old man presented with fever and right hypochondrial pain for 1 d. There was tenderness in the right hypochondrium. He was treated nonsurgically for acute cholecystitis but defaulted from treatment and follow-up. He presented again 2 mo later with fever, vomiting and right hypochondrial pain of 2 d duration. There was tenderness in the right hypochondrium with a positive right renal punch. The total white cell count was elevated at 24700 cells/ $\mu$ L but liver function tests were normal. Ultrasound showed two abscesses in the right hepatic lobe and a thickened gallbladder wall, but no gallstones were

seen. He was treated for liver abscesses with intravenous antibiotics and made an excellent recovery. Follow-up ultrasound scans showed resolution of the liver abscesses.

Four months later, he presented again with fever and right hypochondrial pain. Ultrasound showed no significant abnormality. He was treated with a further course of intravenous antibiotics and discharged. He was readmitted 5 mo later. CT showed subphrenic and subhepatic collections with a thickened inflamed appendix (Figure 4). In view of the recurrent collections, diverticulitis was suspected. Colonoscopy was normal and he was managed conservatively. Follow-up CT 3 mo later showed resolution of the collection, but the appendix was still thickened with periappendiceal inflammatory changes. Elective laparoscopic appendectomy was then performed. This showed a high retrocecal appendix with dense adhesions between the appendix and the liver. A final diagnosis of recurrent retrocecal appendicitis was made. The patient made a good recovery with no further episodes.

#### DISCUSSION

Acute appendicitis may be diagnosed easily and treated

in children and adults if there is a classical history with typical clinical signs<sup>[5]</sup>. When the appendix is in the retrocecal position, the signs and symptoms of acute appendicitis may be atypical and mimic pathology in the right flank and hypochondrium, such as acute cholecystitis, diverticulitis, acute gastroenteritis, ureter colic, acute pyelonephritis, colon cancer and irritable bowel syndrome<sup>[6]</sup>.

When the clinical impression is of gallbladder, hepatobiliary or urinary tract pathology, ultrasound is often performed. This may show liver abscesses and collections in the subhepatic and right flank regions. Although ultrasound is used frequently in the assessment of suspected acute appendicitis in young children, it requires expertise and dedicated techniques, such as graded compression. The appendix could be visualized in up to 99% of suspected cases of appendicitis in children in one series<sup>[7]</sup>. However, in adults, un-enhanced CT has been shown to be more sensitive in diagnosing acute appendicitis than ultrasound is<sup>[8]</sup>. In our series, acute appendicitis was not suspected in any of the patients, therefore, the ultrasound scan performed was not dedicated to rule out appendicitis.

CT is very sensitive for evaluating the appendix, and a thickened appendix, inflamed periappendiceal fat, collections, and presence of free gas in ruptured appendix are detected readily by CT. The inflammatory changes that result from an acutely inflamed ascending retrocecal appendix may extend to the perirenal, adrenal and subhepatic regions, and on rare occasions, inferior extension along the psoas muscle into the thigh has been reported<sup>[9,10]</sup>. The inflammatory changes are seen most commonly in the retrocolic space (88%), followed by paracolic gutter (30%), pararenal space (27%), mesentery (24%), perirenal space (18%), and less often, in the subhepatic space (3%)<sup>[6]</sup>. In a recently published series of 33 patients<sup>[6]</sup> with ascending retrocecal appendicitis who were investigated with CT, only one was found to have a subhepatic collection.

It is interesting that all four of our cases involve young adult patients rather than children. A retrocecal appendix is common and one series showed the appendix to be retrocolic and retrocecal in 58% of cases<sup>[11]</sup>. A retrocecal appendix has been described also in families and is thought to be inherited as a simple dominant unit character<sup>[11]</sup>. Studies of the fetal appendix, however, show that it is almost always subcyclic during this period<sup>[12]</sup>. It is possible therefore that the appendix continues to grow during childhood, extending further from the cecum later in life, although there have been no published studies documenting this process. Therefore, retrocecal appendicitis with symptoms remote from the right iliac fossa may occur also in an older age group.

Our case series illustrated a spectrum of uncommon

clinical and radiological manifestations of ascending retrocecal appendicitis. This emphasizes the importance of considering the possibility of ascending retrocecal appendicitis in cases in which the signs and symptoms are referred to areas along the possible location of a retrocecal appendix, especially when initial investigations like ultrasound do not support other diagnoses, such as cholecystitis, or hepatobiliary or urinary tract pathology. CT is helpful to establish rapidly the correct diagnosis, as delays in appendectomy for over 24–36 h have been shown to increase the complication rate<sup>[13,14]</sup>.

In summary, CT is useful for evaluation of patients with atypical right upper abdominal pain and nonspecific clinical findings, to rule out the possibility of retrocecal appendicitis.

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly open-access (OA) peer-reviewed journal supported by an editorial board consisting of 1179 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to rapidly report the most recent results in basic and clinical research on gastroenterology, hepatology, endoscopy and gastrointestinal surgery fields, specifically including autoimmune, cholestatic and biliary disease, esophageal, gastric and duodenal disorders, cirrhosis and its complications, celiac disease, dyspepsia, gasteroesophageal reflux disease, esophageal and stomach cancers, carcinoma of the colon and rectum, gastrointestinal bleeding, gastrointestinal infection, intestinal inflammation, intestinal microflora and immunity, irritable bowel syndrome, liver biology/pathobiology, liver failure, growth and cancer, liver failure/cirrhosis/portal hypertension, liver fibrosis; *Helicobacter pylori*, hepatitis B and C virus, hepatology elsewhere; pancreatic disorders, pancreas and biliary tract disease, pancreatic cancer; transplantation, genetics, epidemiology, microbiology and inflammatory disorders, molecular and cell biology, nutrition; geriatric gastroenterology, pediatric gastroenterology, steatohepatitis and metabolic liver disease; diagnosis and screening, endoscopy, imaging and advanced technology.

The columns in the issues of *WJG* will be adjusted in 2009, which will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systematically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Articles: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; (13) Guidelines: To introduce Consensuses and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice in gastroenterology and hepatology.

The WJG Press and Baishideng

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjgwjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjgnet.com](mailto:submission@wjgnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive

foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

### Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g.  $6.92 \pm 3.86$  vs  $3.61 \pm 1.67$ ,  $P < 0.001$ ; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, □, ▲, △, etc., in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

## Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

## Statistical expression

Express  $t$  test as  $t$  (in italics),  $F$  test as  $F$  (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as  $r$  (in italics), degree of freedom as  $v$  (in Greek), sample number as  $n$  (in italics), and probability as  $P$  (in italics).

## Units

Use SI units. For example: body mass,  $m$  (B) = 78 kg; blood pressure,  $p$  (B) = 16.2/12.3 kPa; incubation time,  $t$  (incubation) = 96 h, blood glucose concentration,  $c$  (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration,  $p$  (CEA) = 8.6 24.5  $\mu$ g/L;  $CO_2$  volume fraction, 50 mL/L  $CO_2$ , not 5%  $CO_2$ ; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23243641.

The format for how to accurately write common units and quanta can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

## Abbreviations

Standard abbreviations should be defined in the abstract and on first

mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

## Italics

Quantities:  $t$  time or temperature,  $c$  concentration,  $A$  area,  $l$  length,  $m$  mass,  $V$  volume.

Genotypes:  $gyrA$ ,  $argI$ ,  $cmyc$ ,  $c fos$ , etc.

Restriction enzymes: *Eco*RI, *Hind*II, *Bam*HI, *Kbo*I, *Kpn*I, etc.

Biology: *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

## Editorial Office

### World Journal of Gastroenterology

Editorial Department: Room 903, Building D,  
Ocean International Center,  
No.62 Dongsihuan Zhonglu,  
Chaoyang District, Beijing 100025, China  
Telephone: +86-10-59080039  
Fax: +86-10-85381893  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>

## Language evaluation

The language of a manuscript will be graded before it is sent for revision.  
(1) Grade A: priority publishing; (2) Grade B: minor language polishing;  
(3) Grade C: a great deal of language polishing needed; (4) Grade D:  
rejected. Revised articles should reach Grade A or B.

## Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

## Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

## Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

## Links to documents related to the manuscript

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

## Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

## Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

World Journal of Gastroenterology  
Volume 15 Number 29 August 7, 2009

### INTRODUCTION

*World Journal of Gastroenterology* is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

### EDITORS FOR THIS ISSUE

Responsible Assistant Editor: *Xiao-Fang Liu*  
Responsible Electronic Editor: *Xiao-Mei Zheng*  
Proofing Editorial Office Director: *Jian-Xia Cheng*  
Proofing Editor-in-Chief: *Lian-Sheng Ma*

#### NAME OF JOURNAL

*World Journal of Gastroenterology*

#### RESPONSIBLE INSTITUTION

Department of Science and Technology of Shanxi Province

#### SPONSOR

Taiyuan Research and Treatment Center for Digestive Diseases, 77 Shuangta Xijie, Taiyuan 030001, Shanxi Province, China

#### EDITING

Editorial Board of *World Journal of Gastroenterology*, Room 903, Building D, Ocean International Center, No.62 Dongsihuan Zhonglu, Chaoyang District, Beijing 100025, China  
Telephone: +86-10-59080039  
Fax: +86-10-85381893  
E-mail: wjg@wjgnet.com  
<http://www.wjgnet.com>

#### PUBLISHING

The WJG Press and Beijing Baishideng BioMed Scientific Co., Ltd. Room 903, Building D, Ocean International Center, No.62 Dongsihuan Zhonglu, Chaoyang District, Beijing 100025, China  
Telephone: +86-10-59080039  
Fax: +86-10-85381893  
E-mail: wjg@wjgnet.com

## INTRODUCTION

Hepatic portal venous gas (HPVG), an ominous radiologic sign, was first described by Wolfe and Evens in infants with necrotizing enterocolitis (NEC)<sup>[1,2]</sup>. HPVG is associated with numerous underlying abdominal diseases, ranging from benign causes to potentially lethal diseases that require prompt surgical intervention<sup>[3-6]</sup>.

The mechanism for the appearance of gas in the portal vein is not well understood. The proposed factors predisposing the portal venous system to the accumulation of gas include the following: (1) escape of gas produced by gas-forming organisms in the bowel lumen or in an abscess which then circulate into the liver or (2) the presence of gas-forming organisms in the portal venous system with passage of gas into the circulation<sup>[7]</sup>.

The diagnosis of HPVG is usually made by plain abdominal radiography, sonography, color Doppler flow imaging, or computed tomography (CT) scan. The characteristic finding on abdominal plain film is a branching radiolucency extending to within 2 cm beneath the liver capsule. This is because of the centrifugal flow of portal venous blood, which carries portal venous gas peripherally, in contrast to biliary gas, which tends to collect centrally as a result of the centripetal movement of bile. Although HPVG may be diagnosed by conventional radiography, detection is difficult and it is easily overlooked<sup>[8]</sup>. Sonography, color Doppler flow imaging, and CT scan have been reported to be superior to abdominal radiographs in identifying HPVG. Sonography coupled to Doppler is very sensitive for HPVG detection and its follow-up, and can be useful as an initial screening examination<sup>[9,10]</sup>. However, use of ultrasound is limited because of its high inter-operator variability and lack of availability at all times. The typical ultrasonographic features of HPVG are (1) highly echogenic particles, flowing within the portal vein, or (2) poorly defined, highly echogenic patches within the hepatic parenchyma, which are most apparent in the non-dependent part<sup>[11]</sup>.

## Abstract

Hepatic portal venous gas (HPVG), an ominous radiologic sign, is associated in some cases with a severe underlying abdominal disease requiring urgent operative intervention. HPVG has been reported with increasing frequency in medical literature and usually accompanies severe or lethal conditions. The diagnosis of HPVG is usually made by plain abdominal radiography, sonography, color Doppler flow imaging or computed tomography (CT) scan. Currently, the increased use of CT scan and ultrasound in the inpatient setting allows early and highly sensitive detection of such severe illnesses and also the recognition of an increasing number of benign and non-life threatening causes of HPVG. HPVG is not by itself a surgical indication and the treatment depends mainly on the underlying disease. The prognosis is related to the pathology itself and is not influenced by the presence of HPVG. Based on a review of the literature, we discuss in this paper the pathophysiology, risk factors, radiographic findings, management, and prognosis of pathologies associated with HPVG.

Color Doppler flow imaging shows hyperechogenic foci moving within the lumen of the portal vein, producing sharp bidirectional spikes superimposed on the normal monophasic portal vein wave pattern. The CT scan has a high sensitivity for detection of HPVG and can detect the underlying pathology<sup>[12,13]</sup>. On scanographic images, HPVG is characteristically associated with peripheral gas lucencies, which branch out and are noted even within the last 2 cm beneath the liver capsule. This peripheral gas distribution is related to the direction of blood flow into the liver. It is crucial to differentiate it from pneumobilia, which is centrally located because of the biliary anatomy and the direction of bile flow<sup>[14,15]</sup>. Also, a CT scan can disclose gas in the bowel wall (pneumatosis intestinalis) and in the extrahepatic portal vein or its splanchnic vasculature.

The underlying clinical events associated with HPVG might be important factors contributing to patient survival and prognosis. Liebman *et al*<sup>[7]</sup> reported that HPVG is associated most commonly with bowel necrosis (72%), followed by ulcerative colitis (8%), intra-abdominal abscess (6%), small bowel obstruction (3%) and gastric ulcer (3%). This explains the high mortality rate (56%-90%) reported in association with HPVG<sup>[16,17]</sup>. Another factor affecting the outcome of these patients is the coexistence of a long-term chronic disease, such as chronic renal failure, diabetes mellitus or hypertension<sup>[13]</sup>, which decreases immune functions and alters the intestinal microbial flora.

However, currently, the increased use of CT scan and ultrasound in the inpatient setting allows early and highly sensitive detection of such severe illnesses<sup>[16,18-20]</sup> and recognition of an increasing number of benign and non-life threatening causes of HPVG<sup>[20,21]</sup>. The prognosis is related to the pathology itself and is not influenced by the presence of HPVG<sup>[12]</sup>.

In this paper, we discuss the pathophysiology, risk factors, management, and prognosis of pathologies associated with HPVG.

## NEC

NEC is a disease of premature neonates, with 90% of cases occurring in infants born before 36 wk gestational age. In 10% of cases it occurs in full-term infants who have comorbidities predisposing them to decreased mesenteric perfusion<sup>[22]</sup>. This pathognomonic radiographic sign can be missed in extremely low birth weight (less than 1000 g) neonates, despite the gravity of the illness, because of absence of enteral feeding.

NEC is a multifactorial disease process resulting from the association of a hypoxic ischemic injury of the immature gastrointestinal tract and alterations in the microbiological intestinal flora<sup>[1]</sup>. Hypoperfusion in preterm infants has many etiologies (Table 1). It induces blood to shunt away from the bowels towards critical organs which may cause alterations in the mucosal barrier. These alterations, in combination with pathogenic microbiological intestinal flora proliferation exaggerated by

**Table 1 Pathologies associated with hypoperfusion in neonates**

**Etiologies of hypoperfusion in preterm infants**

Patent ductus arteriosus
Sepsis
Polycythemia
In utero cocaine exposure
Peri- or postnatal asphyxia
Respiratory distress syndrome
Congenital heart disease
Umbilical catheters use and exchange transfusion

feeding and antibacterial use, result in mucosal and/or transmural necrosis.

The bacterial translocation and production of hydrogen gas into the bowel wall cause pneumatosis intestinalis<sup>[1]</sup> which can be seen radiographically as linear or circular lucencies within the intestinal wall<sup>[23]</sup>. As a consequence, the gas can embolize from the bowel wall through the mesenteric veins to the portal venous system and the non-dependent parts of the liver, particularly the left lobe and anterior segment of the right lobe.

Abdominal sonography is very specific and sensitive for early detection of portal and hepatic gas thus allowing early diagnosis and efficacious treatment of NEC. The micro-bubbles of gas appear as highly echogenic particles flowing within the portal vein and highly echogenic patches within the hepatic parenchyma. At a more advanced stage, HPVG can be seen on abdominal radiographs. Furthermore, HPVG may only be a transitional sign or can persist for longer than 2 d<sup>[24]</sup>.

HPVG alone is not an indication for surgery<sup>[24]</sup>, since 47% of infants with NEC and HPVG survive without operative procedure. Surgery is indicated when infants do not improve significantly despite medical treatment for several days, as well as when radiographs show persistent fixed dilated bowel loops or pneumoperitoneum which are, respectively, signs of bowel necrosis and perforation. In infants with a birth weight > 1500 g, laparotomy and resection of the necrotic intestine is generally the preferred approach. In very low birth weight infants < 1500 g, and unstable neonates, surgery is associated with a high rate of mortality and morbidity<sup>[22]</sup>. In this case, peritoneal drainage can be indicated as a definitive procedure or as part of the resuscitation phase prior to definitive laparotomy.

HPVG has been associated, in some studies, with a poorer survival rate. In their prospective study, Sharma *et al*<sup>[24]</sup> found that infants with HPVG were 1.4 times more likely to have severe NEC, but mortality rates did not differ from those of infants without HPVG.

HPVG is associated with severe lesions of the bowel wall and intra-mural gas that leads to muscular disruption and secondary stricture formation in up to 20% of all patients with NEC<sup>[22,23]</sup>.

## BOWEL ISCHEMIA

Bowel ischemia and/or infarction is a common and

**Table 2 Etiologies of bowel ischemia**

<b>Etiologies</b>	
Thromboembolism	Atherosclerosis Arterial dissection Aortic surgery Neoplasm, inflammatory or infectious causes
Vasculitis	Producing occlusion of large, medium and small arteries
Segmental mediolytic arteriopathy	Characterized by a non inflammatory arteriopathy causing lysis of adult visceral arteries
Bowel obstruction	Distension of proximal bowel loops resulting in venous congestion Strangulation of mesenteric vessels
Abdominal trauma	Blunt abdominal trauma causing intestinal stenosis with late chronic presentation Penetrating trauma with direct injury to the major mesenteric vessels
Neoplasms	Invasion of the major mesenteric vessels by the tumor Over distension and fecal material stagnation above an obstacle
Abdominal inflammatory conditions	Mesenteric, portal and splenic vein thrombosis
Chemotherapy, drugs and corrosive injury	Vasoconstriction Hypotension Thromboembolism Liquefaction necrosis (Alkalies) Coagulative necrosis (Acids)
Radiation	Obliteration of small arterioles producing a progressive occlusive vasculitis

dangerous abdominal condition, especially in elderly patients<sup>[25,26]</sup>. It is associated with a high mortality rate that ranges from 75% to 90% of cases<sup>[15]</sup>.

Bowel ischemia is produced by insufficient blood flow to or from the intestines. It may have an acute or chronic setting depending on the underlying disorder (Table 2). The extent of bowel ischemia in the bowel wall is divided into three stages<sup>[26]</sup>: Stage I : the ischemic lesions are confined to the mucosa and are reversible (known as reversible ischemic enteritis); Stage II: characterized by necrosis of the mucosal and submucosal tissues, which may lead to fibrotic stricture development; Stage III: the entire wall is affected by ischemia. It is associated with a high mortality rate.

Intestinal ischemia results in damage to the mucosal barrier which, in association with over-distension of the bowel loops and gas-forming bacterial proliferation, leads to gas moving from the intestinal lumen to the mesenteric veins and flowing through it to the portal system and hepatic parenchyma.

Bowel ischemia is the primary etiology of HPVG (70% of cases) and when associated, they are related to transmural necrosis in 91% of cases and to a high mortality rate (85% of patients)<sup>[15]</sup>. These facts signify that HPVG is an absolute indication for surgery in the context of mesenteric ischemia.

Abdominal radiographs are not sensitive for early stage bowel ischemia detection, but they predict bowel infarction and a poor prognosis when intramural gas and HPVG are seen<sup>[23]</sup>.

Currently, the multidetector row CT angiography (MDCT) has become the first choice for HPVG detection and determination of the underlying process<sup>[20]</sup>. MDCT sensitivity has been markedly increasing over time from a low of 39% to a current high of 82%, and it has reached a similarly high sensitivity in diagnosing acute bowel ischemia as that of angiography.

HPVG is often associated with pneumatosis intestinalis, posing a grave prognosis, especially in the ischemic intestine<sup>[27-31]</sup>. The CT scan alone cannot predict which patients are experiencing true intestinal ischemia and which simply have benign pneumatosis. The presence of HPVG does not provide any information concerning the extent of bowel necrosis. In all cases, CT findings should be correlated with the clinical signs and with laboratory parameters to reach a high sensitivity and specificity level for intestinal necrosis. When HPVG associated with ischemic bowel disease is encountered, coexisting other abdominal conditions should be considered pre- and intraoperatively. Intestinal resection is performed when bowel necrosis is found on laparotomy. Nowadays, with the development of highly advanced imaging techniques, potentially severe pathologies, such as bowel ischemia, are diagnosed at much earlier stages, allowing prompt treatment and significantly reducing mortality rates.

## DIVERTICULITIS

Hepatic portal venous gas is a rare complication of diverticulitis<sup>[16,32]</sup>. However, Sellner *et al*<sup>[16]</sup> found that complicated diverticulitis is the second most frequently reported cause of HPVG, which can be due to two mechanisms: The first is a septic thrombophlebitis of the inferior mesenteric vein complicated by gas-forming pathogens. The second is a direct communication between the intestinal lumen and the portomesenteric vein system. This is caused by intramesocolic intestinal perforation, dissecting between the peritoneal leaflets of the mesocolon and creating access to mesocolic veins<sup>[33]</sup>.

Patients with mesocolic abscess have better prognosis than patients with septic pylephlebitis<sup>[16]</sup>.

Diverticulitis associated with HPVG necessitates a selective surgical approach after adequate reanimation with intravenous fluids and antibiotics<sup>[34]</sup>. However, Nobili *et al*<sup>[35]</sup> suggested that if medical conservative therapy is effective and the clinical status improves, the surgery could be delayed.

In one case, Negro *et al*<sup>[36]</sup> reported a patient with sigmoid diverticulitis who developed a massive embolism of the intra- and extra-hepatic portal systems due to an enterovascular fistula, and who was treated with fistula embolization and subsequent sigmoidectomy.

## GASTRIC PATHOLOGIES

HPVG has been reported in association with either gastric dilatation or gastric emphysema<sup>[37,38]</sup>. The treatment is conservative or surgical depending on the underlying process.

Gastroparesis is a frequent complication after a polytraumatic event, leading to gastric emphysema and subsequent HPVG<sup>[37]</sup>. In these cases, gastric decompression with a naso-gastric tube, nil by mouth and observation is sufficient treatment.

Furthermore, HPVG has been described in a patient with hypertrophic pyloric stenosis<sup>[39,40]</sup>, and in a patient with peptic ulcer<sup>[41]</sup>. A gastric volvulus in a diaphragmatic hernia, without necrosis, was also reported in one patient<sup>[42]</sup>. These observations prove that raised intra-luminal pressure results in gastric pneumatosis and HPVG in the absence of bowel ischemia and gas-forming organism proliferation.

Several cases of HPVG have been described after accidental ingestion of caustics, hydrogen peroxide and chronic toluene inhalation<sup>[30,43]</sup>, which lead to mucosal ulcerations and acute gastric distension by oxygen production. Generally, the patient will be stable and can be managed by symptomatic treatment. In cases of massive gas embolization to the portal venous system, and the presence of cardiac and neurological symptoms, hyperbaric oxygen should be used and can be a successful treatment<sup>[44]</sup>.

## INFLAMMATORY BOWEL DISEASES

Kinoshita *et al*<sup>[3]</sup> reported that in 182 cases of HPVG, 4% were associated with ulcerative colitis, and 4% with Crohn's disease.

HPVG, in patients presenting inflammatory bowel disease, can be caused by mucosal damage alone or in combination with bowel distension, sepsis, invasion by gas-producing bacteria<sup>[45,46]</sup>, or after colonoscopy, upper gastrointestinal barium examination, barium enema or blunt abdominal trauma<sup>[47]</sup>. Therefore, a finding of HPVG associated with Crohn's disease does not mandate surgical intervention especially in the absence of peritoneal signs or free intraperitoneal gas<sup>[48]</sup>.

## LIVER TRANSPLANTATION

Hepatic portal venous gas is a common finding on Doppler sonography in the early postoperative period after liver transplantation. Chezmar *et al*<sup>[3]</sup> concluded in their study that HPVG alone, in the absence of bowel necrosis, intra-abdominal abscess, small-bowel obstruction or sepsis, is a transient finding without clinical significance. Furthermore, there was no correlation between the finding of portal venous air and transplant rejection, the need for retransplantation, the cause of hepatic failure, the type of biliary anastomosis, ventilator dependence, or subsequent death.

In pediatric liver transplant recipients, Wallot *et al*<sup>[49]</sup> suggested that the detection of HPVG beyond the early postoperative period may be a sign of intra-abdominal post-transplant lymphoproliferative disease, leading to the loss of bowel wall integrity.

## CHEMOTHERAPY

Two cases of HPVG after chemotherapy have been

reported. In the first case, Kung *et al*<sup>[50]</sup> described HPVG to be secondary to pneumatosis intestinalis in a patient who received irinotecan and cisplatin. On laparotomy, the colon and the small bowel were normal, and the patient was managed supportively with success. Gastrointestinal toxicity is a common side effect of irinotecan<sup>[51]</sup> which may be exacerbated by the adjunction of cisplatin leading to mucosal ulceration, bowel distension and gas-forming anaerobic bacterial proliferation.

In the second case, Zalinski *et al*<sup>[52]</sup> reported localized HPVG in the right liver after complete colorectal cancer liver metastasis necrosis in a patient receiving a treatment of oxaliplatin and cetuximab. Infection of the necrotized metastasis was promoted by the tumor which subsequently turned into a liver abscess, and fistulized to the right portal vein.

One case of HPVG was reported after chemoradiation therapy for an advanced esophageal cancer<sup>[53]</sup>.

## OTHER CONDITIONS

HPVG has been reported in association with acute pancreatitis<sup>[54,55]</sup>, obstructive pyelonephritis after extracorporeal shock wave lithotripsy<sup>[56]</sup>, acute appendicitis<sup>[57]</sup>, cholangitis<sup>[20]</sup>, gastro-jejunal anastomotic leak after laparoscopic gastric bypass<sup>[58]</sup>, uterine gangrene<sup>[31]</sup>, and percutaneous endoscopic gastrostomy tube placement<sup>[59]</sup>. HPVG has also been seen in the presence of a jejunal feeding tube<sup>[60]</sup>, following esophageal variceal band ligation<sup>[61]</sup>, gastrointestinal perforation with amyloidosis<sup>[62]</sup>, with severe hyperglycemic shock<sup>[63]</sup>, and in superior mesenteric artery syndrome<sup>[64-66]</sup>.

These conditions may lead to bowel hypoperfusion and subsequent intestinal ischemia, or may induce an ileus and intestinal distention with mucosal damage and bacterial proliferation producing pneumatosis intestinalis and HPVG. In these cases, surgical treatment after adequate medical resuscitation is indicated depending on the underlying process.

Occasionally, in cases of abdominal blunt trauma, the increased intra-luminal pressure causes mucosal tears within the intestine, which allows gas to enter submucosal veins and flow to the hepatic portal vein<sup>[19]</sup>. However, a severe blunt abdominal trauma may lead to intestinal necrosis and eventual bowel rupture with peritonitis. Thus, when HPVG after abdominal trauma is associated with free intra-abdominal gas, pneumatosis intestinalis and signs of peritonitis, surgical intervention is mandatory.

## CONCLUSION

A radiologic finding of HPVG does not necessarily indicate a severe underlying pathology. It can be seen in relatively benign situations such as following endoscopic procedures and gastric dilatation which only necessitate conservative therapy. Traditionally, HPVG was considered as being an indicator of bad prognosis and as being associated with a particularly high mortality rate. Nowadays, with the development of highly advanced

imaging techniques, potentially severe pathologies, such as bowel ischemia, are diagnosed at much earlier stages, allowing prompt treatment and significantly reducing mortality rates. HPVG is not by itself a surgical indication and the treatment depends mainly on the underlying disease. The prognosis is related to the pathology itself and is not influenced by the presence of HPVG.

### INTRODUCTION

Irritable bowel syndrome (IBS) is a common gastrointestinal disorder characterized by abdominal discomfort and altered bowel habit with no abnormality on routine diagnostic tests<sup>[1,2]</sup>. In some patients, IBS symptoms arise *de novo* following an exposure to acute gastroenteritis (GE). This phenomenon, known as post-infectious IBS (PI-IBS), denotes the persistence of abdominal discomfort, bloating and diarrhea that continue despite clearance of the inciting pathogen<sup>[3-15]</sup>. A recent systematic review and meta-analysis demonstrated that the risk of developing IBS increases six-fold after gastrointestinal infection<sup>[16]</sup> and remains elevated for at least 2-3 years post-infection. The current conceptual framework regarding the pathophysiologic mechanism for PI-IBS suggests that PI-IBS is associated with altered motility, increased intestinal permeability, increased numbers of enterochromaffin cells and persistent intestinal inflammation, characterized by increased numbers of T-lymphocytes and mast cells, and increased expression of proinflammatory cytokines<sup>[3,12,17,18]</sup> (Figure 1). This therefore suggests that an exposure to pathogenic organisms disrupts intestinal barrier function, alters neuromuscular function and triggers chronic inflammation which sustain IBS symptoms. We provide herein a review of PI-IBS epidemiology, pathophysiology, and management.

### EPIDEMIOLOGY

A link between IBS and enteric infection was first proposed by Stewart more than five decades ago<sup>[19]</sup>. A subsequent retrospective study by Chaudhary and Truelove found that a substantial proportion of patients with IBS reported the onset of their symptoms after an acute episode of GE<sup>[20]</sup>. Since then, various prospective and retrospective studies from the United Kingdom, North America, Spain, Korea, Israel and New Zealand have reported the incidence or prevalence of PI-IBS to range from 5% to 32%<sup>[4-13,21-25]</sup>. Consistent among these studies is the suggestion that PI-IBS is a global phenomenon, and not unique to any ethnic group or

### Abstract

Post-infectious irritable bowel syndrome (PI-IBS) is a common disorder wherein symptoms of IBS begin after an episode of acute gastroenteritis. Published studies have reported incidence of PI-IBS to range between 5% and 32%. The mechanisms underlying the development of PI-IBS are not fully understood, but are believed to include persistent sub-clinical inflammation, changes in intestinal permeability and alteration of gut flora. Individual studies have suggested that risk factors for PI-IBS include patients' demographics, psychological disorders and the severity of enteric illness. However, PI-IBS remains a diagnosis of exclusion with no specific disease markers and, to date, no definitive therapy exists. The prognosis of PI-IBS appears favorable with spontaneous and gradual resolution of symptoms in most patients.

Spence <sup>[30]</sup>	Prospective	None	Confirmed <i>Campylobacter</i>	3, 6	Rome I & II	24.0	63/620 = 10.2%	New Zealand

<sup>1</sup>Thabane et al. APT 2007; 26: 535-544.**Figure 1** Conceptual model for post-infectious irritable bowel syndrome.

environment. Reported estimates of the prevalence/incidence of PI-IBS vary in part because of differences in study methodology, including the criteria used to define IBS (Table 1). In general, Rome II criteria generate lower estimates than Rome I or III.

Unlike sporadic IBS, PI-IBS has a defined moment of onset. Features of the inciting infectious illness such as diarrhea, abdominal cramps, increased stool frequency, bloody or mucous stools, positive stool culture and weight loss are potent predictors of long term outcome. The risk of PI-IBS appears to correlate with the severity of the acute enteric infection, increasing at least two-fold if diarrhea lasts more than 1 wk and over threefold if diarrhea lasts more than 3 wk<sup>[11,13]</sup>. Abdominal cramps, weight loss and bloody stools are also associated with increased risk, with abdominal cramps increasing the risk fourfold<sup>[11,12]</sup>. Various bacterial pathogens including *Campylobacter*, *Shigella*, *Salmonella* and *Escherichia coli* (*E. coli*) O157:H7<sup>[11,12,22-24,26,27]</sup> have been implicated in the development of PI-IBS but it remains unclear whether all organisms confer an equivalent risk. Viral GE appears to cause a more transient form of PI-IBS than bacterial pathogen dysentery<sup>[10]</sup>.

Other reported risk factors for PI-IBS include host factors, and psychological disorders<sup>[11-13,22,24,28]</sup>. Despite the fact that there are no reported gender differences

in the severity of initial infectious illness or immune response, the reported risk of developing PI-IBS is higher among females than males with an adjusted relative risk ranging from 1.47 to 2.86<sup>[11,13,29,30]</sup>. The female predisposition for PI-IBS may be confounded by a female preponderance of psychological distress. In a study by Gwee *et al*<sup>[22]</sup>, female gender was no longer a significant risk factor when psychological variables were controlled in a multivariate analysis. In two studies, the risk of developing PI-IBS decreased with increasing age<sup>[11]</sup> and age above 6 years was reported to have a protective effect with adjusted relative risk of 0.36<sup>[13]</sup>. Dunlop *et al*<sup>[31]</sup> demonstrated that older individuals have fewer lymphocytes and mast cells in the rectal mucosa, which may attenuate the inflammatory response to luminal antigens and yield a reduced risk of IBS.

Just as psychological disorders have been associated with development of sporadic IBS, Sykes *et al*<sup>[32]</sup> observed that people with premorbid psychiatric diagnoses, particularly anxiety disorders, are also at increased risk of PI-IBS after acute GE. In addition, depression, neuroticism, somatisation, stress and negative perception of illness have all been linked to PI-IBS<sup>[22,27,30,33]</sup>. In a recent study, patients who developed PI-IBS had significantly higher levels of perceived stress (OR 1.10, 95% CI: 1.02-1.15), anxiety (OR 1.14, 95% CI: 1.05-1.23), somatisation (OR 1.17, 95% CI: 1.02-1.35) and negative illness beliefs (OR 1.14, 95% CI: 1.03-1.27) at the time of infection than those who did not develop PI-IBS<sup>[30]</sup>. Furthermore, Gwee *et al*<sup>[22]</sup> showed that patients who developed IBS reported more life events and had higher hypochondriasis scores. These observations suggest a psychological-environmental interaction wherein exposure to GE may trigger symptoms that are sustained by psychological disturbances<sup>[30]</sup>. This paradigm provides support for cognitive-behavioral therapy as a treatment for PI-IBS.

## PATHOPHYSIOLOGY

PI-IBS patients are more likely than sporadic IBS patients to exhibit a diarrhea-predominant phenotype<sup>[11,17,34]</sup>. Spiller found that serial intestinal biopsies from patients recovering from *Campylobacter jejuni* (*C. jejuni*) showed persistent inflammation with elevated T lymphocytes and calprotectin-positive macrophages, possibly as a response to mucosal injury and inflammation<sup>[18]</sup>. Dunlop *et al*<sup>[3]</sup> noted a 25% increase in rectal enterochromaffin cells in patients with PI-IBS, compared to those with sporadic IBS or healthy controls. Significant increases in postprandial plasma serotonin levels have also been seen in PI-IBS and in sporadic constipation-predominant IBS<sup>[35]</sup>. Gwee *et al*<sup>[36]</sup> reported increased expression of IL-1 $\beta$  in rectal biopsies from patients with PI-IBS, when compared with those who suffered infectious enteritis but did not develop PI-IBS. Wang *et al*<sup>[37]</sup> also observed increased IL-1 $\beta$  in patients with PI-IBS after *Shigella* infection when compared with patients with sporadic IBS<sup>[12]</sup>.

Patients with PI-IBS also demonstrate increased small

intestinal permeability compared to non-IBS controls, suggesting a defect in epithelial integrity that might promote intestinal inflammation<sup>[18]</sup>. In one study, an increased lactulose-mannitol fractional excretion ratio was observed among patients with IBS 2 years after a waterborne outbreak of GE involving *C. jejuni* and *E. coli* 0157:H7. In this cohort, increased permeability was associated with increased stool frequency<sup>[37]</sup>. Similar elevations in gut permeability were also observed by Spiller *et al*<sup>[18]</sup>. Increased intestinal permeability can promote inflammation by facilitating exposure of the submucosa to luminal antigens with subsequent disturbance of enteric sensation and motility.

There is evidence that genetic risk factors may contribute to PI-IBS pathophysiology. A recent study by Villani *et al*<sup>[38]</sup> identified three candidate gene variants, namely *TLR9*, *CDH1* and *IL6*, which were associated with development of IBS following acute GE. These observations suggest that PI-IBS might result from abnormalities in genes encoding epithelial barrier functions and innate immune responses to enteric bacteria. This discovery is consistent with a paradigm of PI-IBS pathogenesis involving decreased mucosal barrier function, low grade inflammation, and immune activation in the colonic mucosa. Future studies are needed to confirm these potential candidate gene variant associations.

## PROGNOSIS

The prognosis of PI-IBS appears favorable with spontaneous and gradual resolution of symptoms in most patients. In the largest and longest prospective cohort study of PI-IBS, the prevalence of PI-IBS in a Canadian cohort dropped from 31% at 2 years to 23% after 4 years and 17% after 6 years<sup>[39,40]</sup>. After 6 years, the incidence of new IBS was no longer increased among those exposed to the initial infection when compared to unexposed controls. A similar decline was reported in an Asian and in a British study, where half of patients recovered 5 and 6 years respectively, after an exposure to acute GE<sup>[41,42]</sup>. In the same Asian follow up study, a 25% recovery rate was reported 3 years after infection<sup>[4]</sup>. In studies that have followed patients for only 1 year after outbreaks of bacterial dysentery, the prevalence of IBS has remained relatively stable<sup>[23,43]</sup>. Of note, in the only study to date which has followed an outbreak of viral GE, the prevalence of IBS symptoms remained elevated for only 3 mo after infection<sup>[10]</sup>. This suggests that viral GE may be associated with a more transient functional disturbance.

## THERAPY

To date there exist no therapies proven to be effective specifically for the management of PI-IBS. Because the phenomenon of PI-IBS is clinically indistinguishable from sporadic IBS, conventional approaches to the management of functional bowel disorders should be adopted. Given a limited insight into the pathogenesis of

sporadic IBS, these approaches consist largely of non-specific measures intended to relieve symptoms. However, our enhanced understanding of the pathogenesis of PI-IBS provides a compelling rationale for some specific approaches that target key mechanisms. These warrant further study in clinical trials.

Acute GE can shift colonic flora, which may in turn induce or promote many of the changes in physiology noted above. Modulation of the flora with probiotics, antibiotics or prebiotics can down-regulate inflammation, improve barrier function and reduce visceral sensitivity<sup>[44-50]</sup>. Probiotics have been proven effective in preventing or attenuating acute GE<sup>[51-53]</sup>. However, no study has yet assessed the efficacy of interventions that modulate gut flora for preventing or treating PI-IBS.

The observed increases in enterochromaffin cell numbers and post-prandial serotonin release in PI-IBS<sup>[18,53]</sup> suggest that serotonergic therapies might prove particularly effective in this population. While the therapeutic gain associated with 5-HT<sub>3</sub> antagonists<sup>[54-62]</sup> and 5-HT<sub>4</sub> agonists<sup>[63-72]</sup> in treatment of sporadic IBS has been small, patients with PI-IBS are relatively more homogeneous and might demonstrate enhanced efficacy. No study of such interventions in the management of PI-IBS has been reported.

There remains little doubt that PI-IBS is associated with persistent intestinal inflammation, and that inflammation itself can disturb gut function and generate symptoms. An underpowered randomized trial of prednisolone for treatment of established PI-IBS failed to show a significant improvement in symptoms, but did show a reduction in intestinal enterochromaffin cell and lymphocyte counts<sup>[73]</sup>. In animal models, early corticosteroid therapy has been shown to attenuate post-infectious neuromuscular dysfunction<sup>[74,75]</sup>. Hence it remains plausible that corticosteroids given to patients with GE at high risk of PI-IBS would be effective in preventing or attenuating chronic symptoms. Locally active steroids with reduced systemic toxicity, such as budesonide, are particularly attractive for this indication.

## CONCLUSION

PI-IBS is a common complication of acute enteric infection. While the epidemiology and natural history of this clinical phenomenon have been well characterized, our understanding of its pathophysiology remains limited. Future research is needed to further define this complex host-microbe interaction and provide new tools for prevention and management.

limited by irinotecan toxicity levels. To conclude, irinotecan improves the patient's quality of life and the survival rates of patients with advanced CRC. p53 and VEGF status of the patients' tumour is likely to affect the responsiveness of CRC to irinotecan. It is recommended that studies of the expression of these molecular markers in relation to chemoresponsiveness of irinotecan should be carried out for better management of patients with advanced CRC.

### Abstract

Irinotecan is the second line chemotherapy for advanced stage colorectal cancer (CRC) after failure of first line chemotherapy with oxaliplatin and 5-fluorouracil. The aim of this review is to analyse the data on irinotecan as second line chemotherapy for advanced CRC and the potential roles of the molecular markers, p53 and vascular endothelial growth factor (VEGF) in the management of advanced CRC. Thus, the English literature from 1980 to 2008 concerning irinotecan, p53, VEGF and CRC was reviewed. On review, Phase II and III clinical trials showed that irinotecan improves pain-free survival, quality of life, 1-year survival, progression-free survival and overall survival in advanced CRC. p53 and VEGF were expressed in CRC and had a predictive power of aggressive clinical behaviour in CRC. Irinotecan sensitizes p53 wild type, mutant and null cells to Fas-mediated cell apoptosis in CRC cells. Wild type p53 cells were more sensitive to irinotecan than mutated p53. Irinotecan has an anti-VEGF effect inhibiting endothelial cell proliferation, increasing apoptosis and reducing microvascular density which is only

### INTRODUCTION

Colorectal carcinoma (CRC) is one of the most common types of cancer in Western countries<sup>[1]</sup>. Five-year survival in CRC patients is related to diagnostic staging of CRC<sup>[2]</sup>. Due to the late onset of symptoms, the majority of cases are diagnosed in Duke's stages C or D. Most patients with CRC undergo surgical resection and then commence adjuvant chemotherapy, with the exception of stage A and some stage B cancers where side effects outweigh potential benefits. In patients who develop recurrent or metastatic CRC, oxaliplatin and 5-fluorouracil (5-FU) combined are the most extensively used first line treatment, with a response in approximately half of patients<sup>[3]</sup>. If the cancer progresses after this treatment, irinotecan is commenced. This review was undertaken to study the impact of irinotecan in the treatment of advanced CRC and to identify advanced CRC molecular markers that predict response to irinotecan. The aims are to influence patient selection and to recommend

evidence-based treatment options for patients with advanced CRC and to reduce patient morbidity and mortality.

## DATA COLLECTOIN

The English literature between 1980 and 2008 on the treatment of advanced CRC with irinotecan was reviewed; the effects of irinotecan on CRC, p53, vascular endothelial growth factor (VEGF) and CRC in Australia. Studies not including irinotecan as the variable were excluded, as were those without CRC. The studies were statistically significant when  $P < 0.05$ . Only original full text publications were reviewed. The selection criteria included adequate follow-up, sample numbers, second line irinotecan therapy and clinicopathological features: grading and staging of the CRCs, histological subtype, nodal and metastatic status, threshold cut off values and complete reference lists. The blinded status and number of experimental observers were noted. The review was limited by suboptimal cohort sizes as it focuses on recently emerging research. Whilst the methodology and statistical analysis varied between studies, their designs were similar.

## LITERATURE OVERVIEW

### *Irinotecan therapy*

Irinotecan is activated by hydrolysis to SN-38, an inhibitor of topoisomerase I. This is then inactivated by glucuronidation by uridine diphosphate glucuronosyltransferase 1A1<sup>[4]</sup>. The inhibition of topoisomerase I by the active metabolite SN-38 eventually leads to inhibition of both DNA replication and transcription. Unlike hepatocytes, other cells in the body have no way of detoxifying SN-38 through glucuronidation, thus contributing to its high cytotoxicity. The most frequent irinotecan toxicities are severe diarrhoea and suppression of the immune system (neutropenia). Other side effects include nausea, hyperbilirubinaemia, fatigue, emesis, fever, weight loss, alopecia, oedema, dyspnoea and thromboembolism.

A Phase II study on irinotecan therapy was performed by Cunningham and colleagues in 289 patients with advanced CRC<sup>[5]</sup>. It was shown that the survival rates were much better in 189 patients who received chemotherapy than the 90 patients who received supportive care only (36.2% vs 13.8%). In addition, both pain-free survival and quality of life were higher with irinotecan 2nd line chemotherapy. Also, irinotecan increased survival of patients without World Health Organisation (WHO) performance status deterioration and without weight loss exceeding 5%.

A Phase III study by Rougier and colleagues concluded that irinotecan produced better 1-year survival of 45% and median survival of 10.8 mo than the comparison groups treated with three different regimes of infused FU, where a survival rate of 32% and a median survival of 8.5 mo were recorded<sup>[6]</sup>. These were both well designed randomised non-blinded studies with large cohorts both in excess of 265 patients. The patients

were assessed every 3 wk with imaging and CEA levels to detect progression of disease. All the patients had metastatic CRC and had received treatment within the preceding 6 mo with 5-FU.

Clinicopathological features were a major confounding factor, however, the results of Cunningham *et al*<sup>[5]</sup> and Rougier *et al*<sup>[6]</sup> remained significant after the WHO baseline performance status of the patients was analysed with multivariate analysis. These studies support the use of second line irinotecan monotherapy to increase pain-free survival, quality of life, 1-year survival, progression-free survival and overall survival in metastatic CRC, both in comparison to best supportive care and to 5-FU.

Rothenberg and colleagues conducted a Phase II trial, involving 166 patients with metastases involving either liver, lung, lymph nodes or other soft tissue, treated with second line irinotecan monotherapy<sup>[7]</sup>. They found a significant response to irinotecan with 10.8% of patients achieving complete or partial response and 40.4% with stabilised disease. The median progression-free survival was 3.9 mo with a median survival of 9.9 mo. Unlike the above studies which examined the effect of clinicopathological variants through multivariate analysis, Rothenberg *et al*<sup>[7]</sup> directly examined the effect of symptomatic disease on overall survival. They found that asymptomatic patients had a longer overall survival than those patients with symptoms prior to irinotecan therapy. However, on further analysis the 1-year survival was 42.4%, with no significant effect from clinicopathological factors or baseline variables. There were several limitations in this study. Most importantly there was no control or comparison group. Despite the tumors being assessed every 12 wk, the assessment criteria states the tumors must decrease or remain stable for 4 wk or more to be classified as responding to therapy. Therefore the tumors needed to respond for 12 or more weeks. Such a long time lapse between monitoring affects progression-free results, leading to an underestimation of true progression-free survival. Also, the study was not blinded. However, the authors overcame this by the use of two teams assessing the imaging and CEA results, one of which involved radiologists and oncologists independent of the study.

These three major studies show statistically that clinicopathological features have no effect on overall survival, and that the presence of symptomatic disease is not an independent predictor for outcome in a multivariate analysis. Overall, irinotecan is an effective second line chemotherapeutic agent for CRC. In Phase II and III clinical trials, it has been shown to increase 1-year survival, quality of life and symptom control despite a high side effect profile.

### *Molecular targeted therapy*

Molecular targeted therapy is a “drug or therapeutic strategy with a focused mechanism specifically acting on a well-defined target or biological pathway that, when inactivated, causes the regression or destruction of cancer”. The advantages of molecular targeted therapy include (1) providing evidence-based treatment options

for patients, (2) treating patients most likely to respond to the therapy (3) sparing patients with poor response profiles from further harm in terms of side effects, (4) minimising side effects (5) streamlining healthcare resources and finally (6) to promote further research into molecular targeted therapy.

This review focused on two common genes that are commonly investigated in cancer, namely VEGF and p53. Being a second line chemotherapeutic agent, it is important to research the effects of irinotecan on such mutations as these antigens are key determinants in the survival of advanced CRCs. By researching irinotecan it is hoped that results will show different molecular targeted pathways by which irinotecan can potentially inhibit CRCs so that patients with the most responsive marker profile may be treated with a molecular targeted drug that acts on different sites rather than just one site.

### **p53 in CRC**

p53 is a tumour suppressor gene<sup>[8]</sup>. Alterations in p53 are the most common genetic changes noted in human cancer. p53 senses DNA damage in the G1 stage of the cell cycle and either prevents cell cycle progression until DNA is repaired or induces apoptosis. p53 acts as a central mediator of the cellular response to stressful stimuli. The growth-suppressive function of p53 is lost with mutation and this occurs commonly in human cancer. In addition to suppressing cancer development and progression, wild-type p53 further confers chemo-sensitivity and radio-sensitivity in tumour cells.

Our recent study, involving 188 patients, showed that p53 is over-expressed in 63% of Australian patients with CRC<sup>[9]</sup>. The survival of the CRC patients was related to staging and p53 protein nuclear expression in the tumors. In our other study, p53 was also noted to predict poorer survival in a subset of CRC patients with mucinous adenocarcinomas<sup>[10]</sup>.

Bosari *et al*<sup>[11]</sup> conducted a 5-year retrospective study on p53 immunostaining in 206 CRC specimens from patients with no neoadjuvant therapy or history of other malignancies and with clear resection margins. 65 specimens stained positive for nuclear p53 and 99 for cytoplasmic p53 accumulation. Cytoplasmic p53 accumulation correlated with reduced overall survival and reduced disease-free survival. In addition, cytoplasmic accumulation of p53 was a significant prognostic factor for poorer overall survival and disease-free survival in left sided CRC. The study could have been strengthened by the identification of the type of p53, rather than relying on past research that indicates cytoplasmic accumulation of p53 is usually WTp53. WTp53 and Mp53 respond differently in CRC and induce cell death *via* different mechanisms.

Flamini and colleagues studied 96 CRC patients, of which 47% were p53 positive<sup>[12]</sup>. The patients were studied for 3 years and treated exclusively by surgical resection of the CRC and metastases. Compared to other stages, Duke's D CRC had increased cytoplasmic p53 expression, whilst nuclear p53 was over expressed in Duke's B CRC. This study had unique findings

and is unlikely to ever be repeated due to the ethical restrictions of not treating patients with either adjuvant or neoadjuvant therapy.

Diez and colleagues studied 174 patients and concluded that p53 positivity in the primary CRC increased the risk of recurrence only after the first year of follow-up<sup>[13]</sup>. Lanza and colleagues studied 204 CRCs by IHC, of which 60.4% were p53 positive<sup>[14]</sup>. The study concluded that there was no statistical significance with regard to age, gender, tumour site, tumour stage or grade of differentiation. Of the 141 patients with TNM I - III disease who underwent curative resection, positive p53 staining was associated with poorer overall survival.

Adrover and colleagues randomly selected 111 patients with sporadic CRCs TNM stages I - IV, and quantitatively measured the cytoplasmic WTp53 and Mp53 in both the cancerous and non-neoplastic tissue of all patients using immunoassay with the p53 antibodies Ab1801 and DO1 as markers<sup>[15]</sup>. High p53 expression was defined as having  $\geq 2.7$  ng/mg cytosolic protein. TNM stage III and high p53 expression correlated with increased disease-free survival. In multivariate analysis, p53 expression is related to a survival advantage in stage III CRCs. These results significantly contradict previous studies. However, Adrover *et al*<sup>[15]</sup> were the first to identify the difference in normal p53, wild type and mutant p53. The definition of high levels of p53 is debatable as the p53 expression in adjacent non-neoplastic tissue has not been evaluated.

To conclude, p53 expression is important in the prognosis of CRC. The identification of WTp53 and Mp53 is controversial due to the half life of WTp53. Based on the larger studies, the overexpression of p53, especially cytoplasmic p53, is a crucial target for molecular targeted chemotherapy.

### **Vascular endothelial growth factor in CRC**

The VEGF family of genes are key regulators of angiogenesis<sup>[16]</sup>. VEGF expression correlated with clinical and pathological parameters in cancers<sup>[17-19]</sup>. For instance, we have shown that strong immunohistochemical VEGF expression levels tended also to have higher serum VEGF level than those with low expression levels. In addition, elevated serum VEGF levels are strongly correlated to the recurrence of thyroid cancer and the presence of lymph node metastases. VEGF expression was noted in the non-cancerous tissue adjacent to the cancer indicating that genetic changes may occur before the morphological appearance of cancer.

Colorectal mucosa contains all the subtypes of the VEGF family A-D<sup>[20]</sup>. VEGF mRNA is expressed in higher levels in human CRC cells compared to adjacent normal tissue<sup>[21]</sup>. VEGF mRNA expression rises most between CRC stages Tis to T1.

A meta-analysis involving 27 studies of VEGF expression and overall survival of CRC observed a 1.65 times poorer survival in those with higher ratios of VEGF in cancer tissue<sup>[22]</sup>. Kondo *et al*<sup>[23]</sup> found VEGF mRNA and protein only in CRCs (15 of 26 studied) compared to no expression in adenomas. They

suggested that mutant p53 induced VEGF expression, which coincides with the progression from adenoma to carcinoma in CRC.

Of the 31 human CRC cell lines examined with IHC, Kuramochi *et al*<sup>[24]</sup> concluded there was no significant difference in median VEGF mRNA levels of expression in the primary CRC in patients with or without hepatic metastases. However, the level of VEGF expression is significantly less in the hepatic metastatic tissue compared to the adjacent non-cancerous hepatic tissue. Patients with more than one site of metastasis expressed higher levels of mRNA VEGF compared to those with one metastasis site<sup>[22]</sup>.

Comparing CRC (T) to the adjacent colorectal mucosa (N), Hanrahan *et al*<sup>[25]</sup> concluded that VEGF-A and VEGF-B play a significant role in the early development of CRC from adenomas, whilst VEGF-C is expressed at higher levels in metastatic CRC. They concluded that VEGF A and C mRNA levels were correlated to tumour grade and tumour size, but not significantly related to the staging of CRC.

Ottaiano and colleagues concluded from their study of 71 patients that CXCL12 stimulates ICAM-1 and VEGF expression and clonogenic growth of CRC cells, which all lead to metastases, and that over expression of VEGF was an independent predictor of early metastases in CRC patients<sup>[26]</sup>. Ishigami *et al*<sup>[27]</sup> further concluded that over expression of VEGF mRNA also correlated with poor overall survival.

Saad and colleagues showed that VEGF expression correlated with the presence of angiolymphatic invasion, lymph node metastasis and the depth of invasion<sup>[28]</sup>. They found no significant correlation between VEGF expression and tumour grade and development of liver metastases.

### Molecular markers and irinotecan

**p53:** Yu *et al*<sup>[29]</sup> profiled the 24 genes associated with the mechanism of action of irinotecan in 52 CRC specimens from humans with no previous neoadjuvant therapy. Irinotecan is converted to SN-38 which acts on topoisomerase-1 then subsequently *via* a cascade effect on TNFSF6 to FDXR and then p53 which finally induces cell apoptosis. Through *in vitro* gene profiling and cluster analysis, Yu *et al*<sup>[29]</sup> found that the pathway leading to p53 was expressed at higher levels in tumourous tissues (T) compared to adjacent normal tissue (N), however, none as high as p53. Whilst the level of p53 RNA expression was not identical for each specimen, the general trend remained. The study showed that irinotecan is more effective in inducing apoptosis in CRC when the p53 T:N is high, despite the type of mutation in p53.

*In-vitro* studies concluded that irinotecan sensitizes p53 wild type, mutant and null cells to Fas-mediated cell apoptosis in CRC cells<sup>[30]</sup>. Irinotecan caused a significant rise in Fas mRNA in WTp53 cells<sup>[31]</sup>. However, irinotecan also caused a small increase in Fas mRNA in p53 mutant and null cells. This indicates that not only does p53 have a major role in Fas cell surface expression, but

that irinotecan also increases Fas cell surface expression independent of p53. Irinotecan induces signal transducer and activator of transcription 1 (STAT1) phosphorylation in the p53-null cell lines and increases the expression of genes involved in cell surface trafficking of Fas, despite STAT1 not being identified in the promoter of Fas. Absence of STAT1 decreases Fas expression.

McDermott and colleagues found a significant increase in STAT-1 Ser727 phosphorylation in irinotecan treated null cells<sup>[32]</sup>. The experiment was repeated with the addition of STAT1 small interfering RNA which caused a down regulation of STAT1 expression in the WTp53 and null cell lines. Subsequent treatment with irinotecan produced no change in the level of Fas mRNA, however, down regulation of STAT1 resulted in a significant decrease in Fas cell surface expression in the p53-null cell line. They proposed that STAT1 silencing was incomplete or that STAT-1 independent pathways regulate Fas ligand expression in response to irinotecan

p53 wild type cells were also more sensitive to irinotecan treatment compared to mutant p53 at low dose and high dose treatment<sup>[33]</sup>. No significant response to irinotecan treatment was recorded in the mutant p53 cell lines As irinotecan is known to have a higher response in both cytoplasmic accumulation of p53 and of WTp53, this study further suggests that WTp53 accumulates in the CRC cell cytoplasm and that WTp53 in CRC is a positive predictive factor for response to irinotecan.

Irinotecan was added to cells from a single Duke's B CRC with mutant p53 and its sub-clone transfected with wide type p53. The cells were synchronised to G0/G1 stage of the cell cycle by starvation. Following the addition of irinotecan, the wild type p53 cells were arrested in S phase whilst the mutated p53 cells continued to progress through the cell cycle, indicating a lack of functionality of p53. The functional response of irinotecan in the wide type p53 line and not the mutant p53 was observed during *in-vivo* studies of nu/nu mice with xenografted human CRC, whereby there was increased apoptosis and decreased proliferation.

Overall, irinotecan reduces progression in WTp53 CRCs, and plays a less significant role in inhibiting mutant and null p53 CRCs *via* the STAT1 pathway. Having identified p53 as the key component of the apoptotic pathway and the significance of the T:N p53 ratio in predicting a positive response to irinotecan, it is necessary that these findings are implemented in practice. Thus, further research should be conducted using *in-vivo* research methods on a large scale to confirm the clinical significance of such results.

**Vascular endothelial growth factor:** In CRCs, high levels of EGFR correlated with response to irinotecan and progression-free survival<sup>[34]</sup>. However, this did not prove that VEGF expression is correlated with response to irinotecan. The study had a small sample size, all were treated with irinotecan, 5-FU and leucovorin, and no control groups treated with single agent therapy. Whilst there was an adequate follow up period of 23 mo, there were several variables.

Koizumi and colleagues developed NK012, a SN-38 (irinotecan metabolite) releasing nanodevice and tested its efficacy in xenografted CRCs in mice<sup>[35]</sup>. A comparison of tumour size reduction with NK012 (doses 15 and 30 mg/kg per day) *vs* irinotecan (66.7 mg/kg per day) showed a significant reduction in tumour size compared to the irinotecan treatment. Compared to irinotecan, NK012 was more cytotoxic with potent anti-tumour activity, thought to be secondary to the enhanced and prolonged distribution of free SN-38 in the tumour. This showed that irinotecan and its active metabolite has an anti-VEGF effect. Thus, it can be proposed that these activities should be reflected in VEGF positive CRCs if adequate levels of SN-38 are produced, which is only limited by the irinotecan dose side effects.

Bocci and colleagues compared the effects of irinotecan metronomic monotherapy against irinotecan combined with semaxinib on xenografted CRCs in mice and in *in-vivo* CRC cell lines<sup>[36]</sup>. They analysed *in-vitro* proliferation of cells, apoptosis and thrombospondin-1 (TSP-1)/VEGF expression and concluded that in the cells treated with SN-38 monotherapy, there was inhibited endothelial cell proliferation alone, and that irinotecan worked synergistically with semaxinib to increase apoptosis and increase expression and secretion of TSP-1 and to reduce microvascular density<sup>[35]</sup>.

In *in-vitro* studies, SN-38 increased TSP-1 expression and in *in-vivo* studies, SN-38 reduced tumour and microvessel growth<sup>[37]</sup>. Higher levels of TSP-1, an anti-angiogenic factor are linked with low levels of VEGF<sup>[37]</sup>. TSP-1 inhibits angiogenesis through the inhibition of matrix metalloproteinase-9 (MMP9). TSP-1 null mice have both increased levels of MMP9, whilst over expression of TSP-1 in mammary tissue reduced the levels of active MMP9. The levels of MMP9 correlated with the level of expression of VEGF binding to VEGFR-2<sup>[38]</sup>. Gupta *et al*<sup>[39]</sup> concluded that TSP-1 inhibits VEGF mobilisation from the extracellular matrix by inhibiting active MMP9 and that TSP-1 also has a direct role in inhibiting VEGF activity.

Irinotecan increases TSP-1 expression and secretion and TSP-1 reduces VEGF expression and activity<sup>[36]</sup>. CRCs expressing high levels of VEGF respond more significantly to irinotecan as the stimulus for angiogenesis and thus subsequent growth of the tumour is reduced.

## CONCLUSION

Increased expression of p53, especially cytoplasmic WTp53 is associated with poor overall survival, decreased disease-free survival, increased relapse and metastases. However, cytoplasmic accumulation of wild type p53 is a positive predictive factor for irinotecan response. Irinotecan induces apoptosis in both mutant and null p53 CRCs to a lesser extent *via* the STAT1 pathway.

Increased expression of VEGF is correlated with multiple metastases, tissue invasion and lymph node invasion. Whilst there is evidence that irinotecan increases TSP-1 expression which in turn reduces VEGF expression and the angiogenic growth of tumors, there

is no conclusive evidence linking irinotecan with VEGF expression and response. Irinotecan has the potential for multiple effects within CRC cells which may reduce the number of prescribed drugs and side effects for patients.

As a second line therapy, irinotecan improves patient quality of life, 1-year survival and progression-free survival. It would be beneficial to all patients to determine the molecular profiles of CRC most likely to respond to irinotecan and to spare those unlikely to respond from unnecessary side effects.

A standardised criteria needs to be developed to compare marker expression in normal colorectal mucosa to that of cancerous mucosa in order to define overexpression of markers. Further research would also benefit from a standard CRC staging system so that studies can be compared directly, as well as 12 mo follow-up periods for irinotecan treatment. Areas of potential research focus include: (1) large studies on the effects of irinotecan with regard to VEGF and p53 expressions in CRC and (2) determine whether the expression of molecular markers can predict response to irinotecan.

## Abstract

**AIM:** To investigate the potential effects of chelidonine, the main alkaloid of *Chelidonium majus*, on telomerase activity and its regulation in HepG2 cells.

**METHODS:** Cytotoxicity of chelidonine for HepG2 cells was determined by neutral red assay. A modified polymerase chain reaction (PCR)-based telomerase repeat amplification protocol was used to estimate relative telomerase activity in chelidonine-treated cells in comparison with the untreated control cells. Relative expression level of the catalytic subunit of telomerase (hTERT) gene and P-glycoprotein (pgp) were estimated using semi-quantitative real-time reverse transcription-PCR (RT-PCR). Cell senescence in treated cells was demonstrated using a  $\beta$ -galactosidase test.

**RESULTS:** Cytotoxicity of chelidonine in HepG2 cells was not dose-dependent and tended to reach plateau immediately after the living cells were reduced in number to slightly higher than 50%. However, 12  $\mu$ mol/L concentration of chelidonine was considered as LD<sub>50</sub>, where the maximal attainable effects were realized. Real-time RT-PCR data showed that the expression of pgp increased three-fold in chelidonine treated HepG2 cells in comparison with the untreated controls. Morphologically, treated HepG2 cells showed apoptotic features after 24 h and a small fraction of cells appeared with single blister cell death. The relative expression

level of Bcl-2 dropped to less than 50% of control cells at a sub-apoptotic concentration of chelidonine and subsequently increased to higher than 120% at LD<sub>50</sub>. Telomerase activity was reduced considerably after administration of very low doses of chelidonine, whereas higher concentrations of chelidonine did not remarkably enhance the effect. Real-time RT-PCR experiments indicated a drastic decrease in expression level of hTERT subunit of telomerase under treatment with chelidonine. Repeated treatment of cells with very low doses of chelidonine caused a decline in growth rate by 4 wk and many of the cells appeared to be aged with large volume and dark staining in the  $\beta$ -galactosidase assay.

**CONCLUSION:** Chelidonine reduces telomerase activity through down-regulation of hTERT expression. Senescence induction might not be directly caused by reducing telomerase activity as it occurs after a few population doublings.

## INTRODUCTION

*Chelidonium majus* (*C. majus*), the greater celandine (family Papaveraceae), has a long history in phytomedicine for the treatment of many diseases or health disturbances. It contains isoquinoline alkaloids, especially protoberberine and benzophenanthridine alkaloids<sup>[1]</sup>. Extracts of this plant exhibit interesting antitumor and antiviral activities<sup>[2]</sup> in addition to hepato-protective and anti-genotoxic

effects in induced hepatocarcinogenesis in mice<sup>[3]</sup>. Ukrain, a semisynthetic derivative of *C. majus* alkaloids has been reported to be selectively toxic to malignant cells without toxic side effects to normal cells<sup>[4,5]</sup>. Ukrain has been used in the therapy of several solid tumors. It is known to induce apoptosis in glioblastoma cells<sup>[6]</sup> and in cell cultures<sup>[7]</sup>. Data from randomized clinical trials based on numerous pre-clinical and clinical investigations has established Ukrain as an anticancer drug<sup>[8]</sup>.

Chelidoneine, the tertiary hexahydro-benzophenanthridine alkaloid, is the major component of Ukrain. It primarily causes apoptosis in primary human uveal melanoma cell lines as shown by cellular morphology studies and flow cytometric analysis<sup>[9]</sup>. This alkaloid arrests mitosis by inhibition of tubulin polymerisation and activation of the stress activated protein kinase/jun kinase pathway (SAPK/JNK)<sup>[10]</sup>. A mitochondrial cell death pathway induced by chelidoneine in MT-4 cells has also been realized with an increased ratio of cytosolic to mitochondrial cytochrome c and increased percentage of cells with active caspase-3 and pro-apoptotic Bax protein<sup>[11]</sup>.

In this communication telomerase activity has been investigated in HepG2 cells after treatment with chelidoneine, using a modified telomerase repeat amplification protocol (TRAP). Telomerase, basically a reverse transcriptase, compensates telomere attrition, which occur in proliferating cells due to incomplete genome replication by DNA polymerases. This enzyme, while detectable, is diminished and shows very low activities in many adult somatic cells but is drastically overexpressed in almost 90% of different kinds of human cancer cells by up to 100-fold over the normal counterpart cells<sup>[12]</sup>, and confers a strong selective advantage for continued growth of malignant cells<sup>[13]</sup>. This enzyme is considered as a key player in cell immortality<sup>[14]</sup> as it protects chromosome ends from degradation and also plays an important role in the telomere-capping function<sup>[15]</sup>. It has been proposed that telomerase inhibitors can be utilized as complementary drugs in cancer therapy<sup>[16,17]</sup>. Critically shortened telomere(s) induce proliferative senescence, apoptosis or continued proliferation accompanied by genomic instability<sup>[18]</sup>. Many studies have indicated that inhibition of telomerase can affect the survival of cancer cells through apoptosis induction without long-term treatment of the cells<sup>[19,20]</sup>.

There is currently much interest in the inhibition of telomerase by various strategies such as antisense oligonucleotides<sup>[21]</sup>, small-molecule inhibitors<sup>[22]</sup>, ribozymes<sup>[23]</sup> and RNA interference<sup>[24]</sup>, which in turn initiate the onset of growth inhibition and antitumor activity.

This study was focused mainly on the effect of chelidoneine on telomerase activity and its regulation. The focus on drugs such as natural benzophenanthridines that may possibly inhibit telomerase may help in use of these alkaloids specifically against cancer. The expression levels of the catalytic subunit of telomerase (hTERT) gene and morphological changes were

studied as well. Expression of Bcl-2, the related gene to suppress apoptosis, P-glycoprotein (pgp) involved in drug resistance, and  $\beta$ -galactosidase assay as a biomarker to identify cell senescence were also analyzed.

## MATERIALS AND METHODS

### Cell culture

HepG2 cell line (ACC 180 from DSMZ) was maintained in 75 cm<sup>2</sup> culture flasks in RPMI-1640 culture medium (Gibco, Invitrogen), supplemented with 10% heat-inactivated fetal bovine serum (Biochrome, Berlin, Germany), 100 000 U/L penicillin, and 100 mg/L streptomycin. Cells were grown in 5% CO<sub>2</sub> and 95% air atmosphere at 37°C and 100% humidity. Media were changed every 48 h, and the cells were subcultured after 5-6 d using trypsin-EDTA. Cell viability was evaluated by staining with 0.1% trypan blue exclusion method using a hemocytometer. To estimate the cytotoxicity of chelidoneine a neutral red uptake test was employed<sup>[25]</sup>.

For long-term growth of HepG2 cells, chelidoneine-treated or untreated cells were seeded into 75 cm<sup>2</sup> tissue culture flask at 1 × 10<sup>6</sup> for 4-5 d until 70%-80% confluence, then trypsinized and counted. Each time 1 × 10<sup>6</sup> cells were replated into new culture flasks but in each passage the chelidoneine series was treated at the desired concentration for 48 h and afterward cells were fed with fresh normal medium. The rest of the cells in each passage were plated for  $\beta$ -galactosidase assay. All the treatments were done in duplicate.

### Cytotoxicity test

Exponentially growing HepG2 cells were seeded in 96 well plates with 10 000 cells per well. The medium was changed after 24 h with the fresh medium plus various concentrations of chelidoneine. After 48 h the cells were washed with PBS and incubated in fresh medium including 50 mg/L neutral red. The medium was removed after 3 h incubation and 200  $\mu$ L isopropanol containing 0.4 mol/L hydrochloric acid was added to each well and shaken for 15 min at room temperature. The absorbance of neutral red was measured at 570 nm. The test was repeated four times each in triplicate and the 50% lethal dosage, LD<sub>50</sub>, values were calculated from dose-response curves.

### Assay of telomerase activity

Subconfluent HepG2 cells were seeded in six well plates with 100 000 cells per well and incubated for 24 h at 37°C, in 5% CO<sub>2</sub> and 100% humidity. The media were then changed for fresh ones containing various concentrations of chelidoneine and followed by 48 h incubation. After trypsinizing and washing with cold PBS, lysis buffer was added to the cell pellet according to Gelmini's method with small modifications<sup>[26]</sup>. Cell lysates were incubated on ice for 30 min and then centrifuged at 16 000 g for 30 min. The protein concentration of the supernatant was measured based on the Bradford assay<sup>[27]</sup>. For each of control and/or treated cells 0.5  $\mu$ g of extracted total protein was used for TRAP assay based on Gelmini's

method<sup>[26]</sup>. Telomerase activity was determined for each concentration of chelidone in at least three repetitions, each one in duplicate. Two controls were used: a positive control using cell extract containing 0.5 µg protein of untreated HepG2 cells, and a negative control which was the same as the positive control but treated with boiling heat and/or RNase A at 37°C for 20 min.

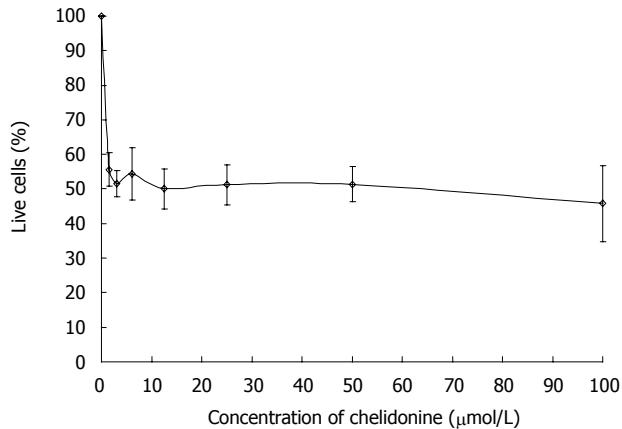

#### **RNA isolation, reverse transcription and real-time RT-PCR**

HepG2 cells were seeded in 12-well plate culture dishes with 50 000 cells per well. After 24 h incubation the medium was replaced with fresh medium including various concentrations of chelidone lower than the LD<sub>50</sub> and incubated for another 48 h. For RNA extraction, the cells were harvested and total RNA was isolated using RNeasy Mini Kit (Qiagen; Germany) according to the manufacturer's instruction and treated with DNaseI (Rnase-Free DNase Set, Qiagen; Germany) and stored at -80°C. Purity and quality of the extracted RNA were checked by gel electrophoresis, and the concentrations were measured using UV spectrophotometry.

First strand cDNA synthesis was performed according to the protocol suggested for the Reverse Transcription System (Promega Corporation; Madison, USA) using oligo(dT)<sub>16</sub> primers (Pharmacia Biotech; Uppsala, Sweden). Quantification of mRNA levels of the genes was achieved by quantitative real-time RT-PCR (Light Cycler, Roche Applied Science; Mannheim, Germany) using β2-microglobulin as the housekeeping gene. PCR amplification was carried out in 20 µL reaction volume containing 0.2 µg of cDNA, 1 × Light Cycler Fast Start DNA Master SYBR Green I (Roche Applied Science; Mannheim, Germany), 0.5 µmol/L of each primer set. MgCl<sub>2</sub> concentration was 3.25 mmol/L for β2-microglobulin gene and 3-4 mmol/L for other genes. The sequence of the primer sets used was: forward 5' GCTGCTCAGGTCTTCTTTATGTC3' and reverse 5'TCAAGTGCTGCTGATTCCAATG3' for hTERT, forward 5'AGGAAGTGAACATITCGGTGAC3' and reverse 5'GCTCAGTTCCAGGACCAGGC3' for Bcl-2. Primers used for β2-microglobulin and pgp (MDR1) were chosen as described by Albermann *et al.*<sup>[28]</sup>. Data analysis was performed using a calibrator and a standard curve for each gene and based on measurements of at least two repetitions. Each repetition includes two measurements for each of the duplicated samples for the defined concentrations of chelidone.

#### **β-galactosidase assay**

After removing medium, control and treated HepG2 cells with chelidone were washed in PBS, fixed for 3-5 min at room temperature in 2% formaldehyde/0.2% glutaraldehyde. Cells were washed twice with PBS and incubated at 37°C (no CO<sub>2</sub>) with fresh senescence-associated β-gal (SA-β-gal) stain solution containing 0.4 g/L X-gal, 40 mmol/L citric acid/sodium phosphate, pH 6.0, 5 mmol/L potassium ferrocyanide, 5 mmol/L potassium ferrocyanide, 150 mmol/L NaCl and 2 mmol/L MgCl<sub>2</sub> as described by Dimri *et al.*<sup>[29]</sup>. Staining was achieved in 2-4 h.

**Figure 1** The effect of chelidone on the growth of HepG2 cells after 48 h exposure. Viability of cells at each concentration of chelidone was evaluated by neutral red uptake test and is expressed as a percentage relative to untreated control cells. The values presented are the mean ± SD of six repeats each one in triplicate.

#### **DNA ladder formation**

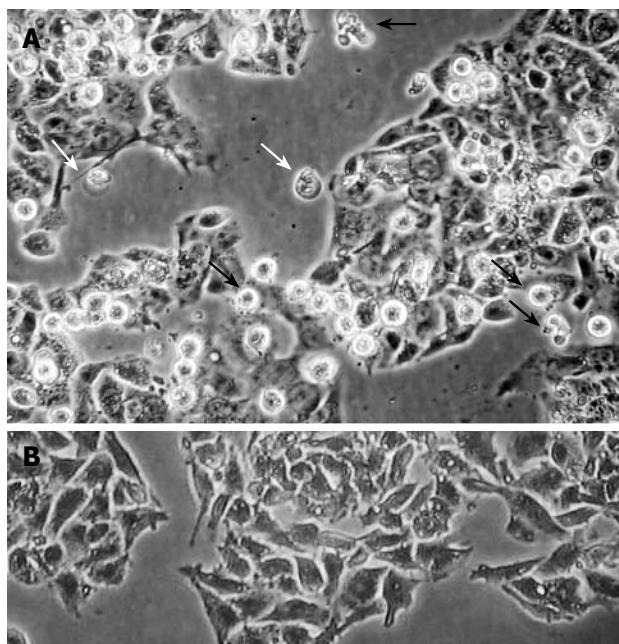

The cells were treated with chelidone at the specified concentrations for 48 h and harvested; cellular DNA was isolated and subjected to agarose gel electrophoresis followed by visualization of bands.

## **RESULTS**

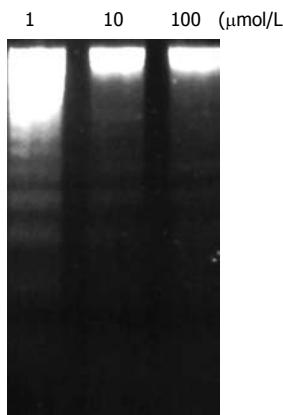

The effect of chelidone on HepG2 cell survival tested with neutral red uptake assays after 48 h treatment is shown in Figure 1. The cell viability curve of HepG2 cells under chelidone treatment had two distinct parts with quite different slopes. The first part with a sharp decline indicated its high toxicity, even at very low concentrations. The second part was a plateau. The fraction of live cells treated with 1.5-6 µmol/L chelidone was slightly more than 50% and the maximal effect of chelidone in reducing the live cells by 50% was at 12 µmol/L. By increasing the concentration of chelidone up to 100 µmol/L only a negligible increment in cytotoxicity was seen. This may suggest a potential mechanism involved in drug resistance.

Chelidone treated HepG2 cells showed apoptotic features after 24 h and a small fraction of cells appeared with single blister cell death<sup>[30]</sup>. Figure 2 shows the cells at 48 h after treatment with 12 µmol/L chelidone (LD<sub>50</sub>). DNA fragmentation due to apoptosis, as shown in Figure 3, represent the ladder formation in apoptotic HepG2 cells at different concentration after 48 h treatment.

Telomerase activity in HepG2 cells (control and cells treated with different concentration of chelidone for 48 h) is illustrated in Figure 4, which shows the resolving TRAP assay products on a native polyacrylamide gel electrophoresis. It clearly indicated decreased activity of telomerase in treated cells compared to untreated control cells. Considerable reduction of telomerase activity occurred at very low concentrations of chelidone, whereas increasing the chelidone concentration did not strengthen the effect significantly. The inhibitory ef-

**Figure 2** Morphological changes in HepG2 cells after 48 h treatment with 12  $\mu\text{mol/L}$  chelidone ( $\text{LD}_{50}$ ) visualized by phase contrast microscopy. A: Apoptotic cells (black arrows) and a few cells undergoing blister cell death (white arrows) are clearly seen; B: Untreated control HepG2 cells.

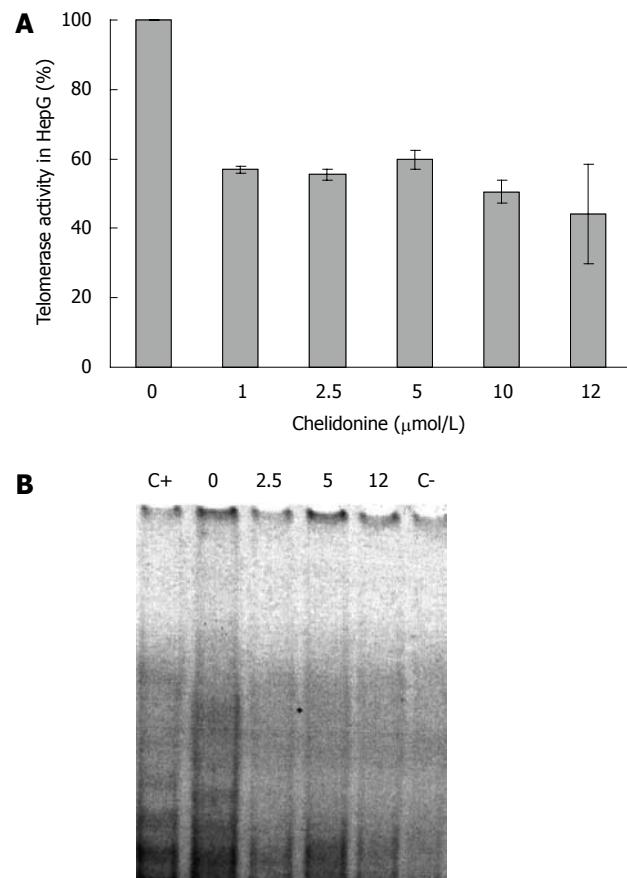

**Figure 3** Induction of DNA fragmentation in HepG2 cells after 48 h treatment with different concentrations of chelidone. The concentration of chelidone is indicated at the top of each well.

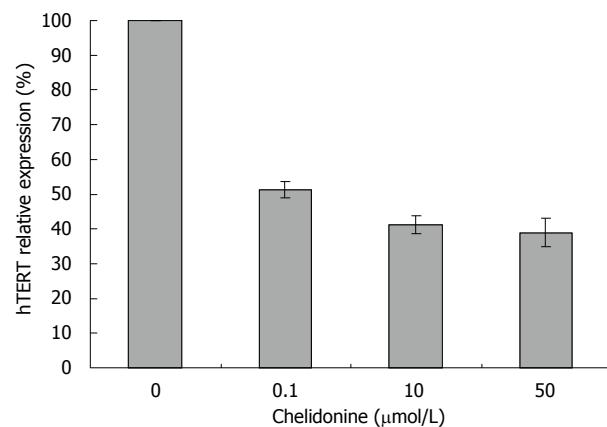

fect of chelidone on telomerase activity was not dose dependent. Moreover the 50% activity of telomerase in treated cells compared to the untreated control cells occurred almost at the same concentration ranges of chelidone as  $\text{LD}_{50}$  in cytotoxicity tests.

Real-time RT-PCR experiments showed a drastic decrease in the expression level of the hTERT subunit of telomerase by 0.1  $\mu\text{mol/L}$  chelidone. Again higher concentrations of chelidone (even up to 50  $\mu\text{mol/L}$ ) showed only slight increments of the effect (Figure 5).

Long-term treatment of HepG2 cells with 0.1  $\mu\text{mol/L}$  chelidone for 48 h in every passage showed effective growth inhibition at very low concentrations of chelidone. Figure 6 illustrates the mean number of cell population doubling in relation to different modes of treatments. The growth rate of cells that had been treated four times with 0.1  $\mu\text{mol/L}$  chelidone for 48 h per passage (re-treated 3 in Figure 6) showed a decline after 12 d and the growth rate tended to reach a plateau by 4 wk

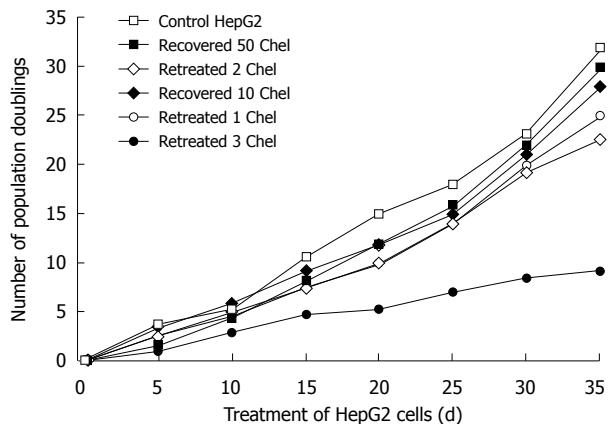

**Figure 4** Telomerase activity using TRAP assay in HepG2 control and 48 h treated cells with different concentration of chelidone up to  $\text{LD}_{50}$ . A: The relative activity of treated cells against untreated control cells are indicated as mean  $\pm$  SD; B: TRAP products resolved on non-denaturing PAGE and stained with SYBR Green. The concentration of chelidone is indicated on top of each well in  $\mu\text{mol/L}$ . C+: Positive control; C-: Negative control.

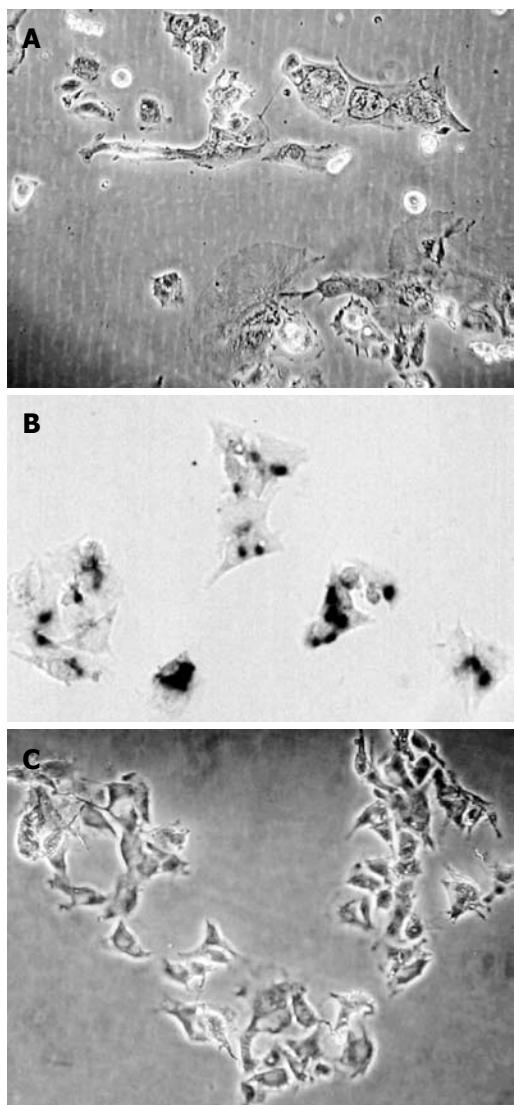

**Figure 5** HepG2 cells were treated for 48 h with medium supplemented with solvent (ethanol, not exceeding 0.1%) or 0.1, 10 and 50  $\mu\text{mol/L}$  chelidone. Relative hTERT gene expression as measured by real-time RT-PCR which was calibrated with the constitutive expression of  $\beta 2$ -microglobulin gene. hTERT level in control samples was considered as 100%. The values indicated as mean  $\pm$  SD ( $n \geq 6$ ).

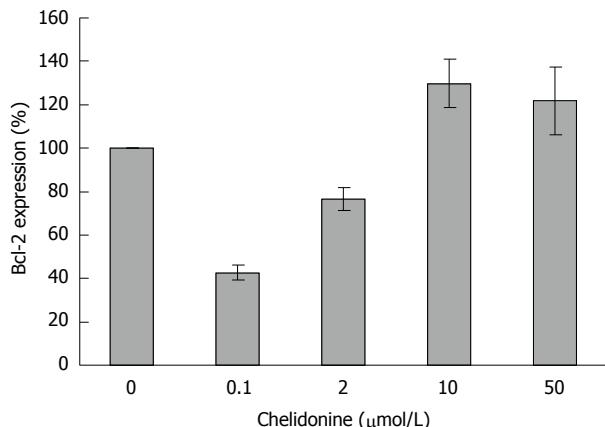

in comparison with untreated controls. Morphologically, after 28 d many of the cells appeared to be aged with a large cell volume and high cytoplasmic to nuclear ratio, which could be stained in  $\beta$ -galactosidase assay (Figure 7).

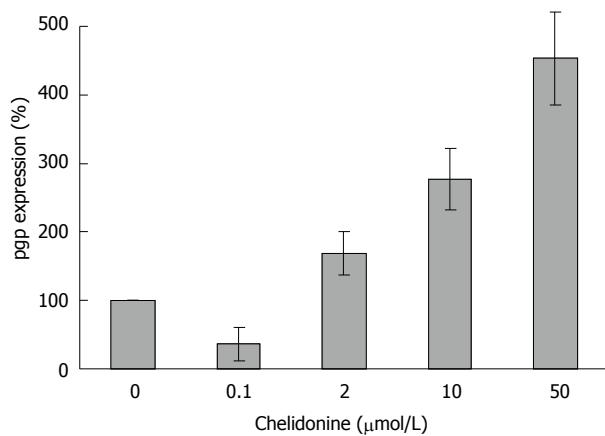

**Figure 6** Number of population doublings after long-term treatment with a sub-apoptotic dose of chelidone (0.1  $\mu\text{mol/L}$ ) or recovered cells after 48 h exposure to LD<sub>50</sub> concentration of chelidone in comparison with control HepG2 cells. In re-treatment experiments (long-term treatment) HepG2 cells were exposed to 0.1  $\mu\text{mol/L}$  only 48 h in each passage and followed by recovery with normal medium devoid of chelidone. Each point indicates the mean value of a duplicated experiment.

**Figure 7** The morphological changes and induction of senescence in HepG2 cells in a long-term treatment experiment. A: HepG2 cells after treatment five times with 0.1  $\mu\text{mol/L}$  chelidone; B: Cells retreated five times stained for  $\beta$ -galactosidase activity; C: Stained control cells.

**Figure 8** Relative expression of *Bcl-2* gene in HepG2 cells after 48 h treatment with different concentrations of chelidone in relation to untreated control cells assessed by real-time RT-PCR and calibrated with  $\beta$ -microglobulin gene expression. The expression level of *Bcl-2* in control cells was considered as 100%. mean  $\pm$  SD are indicated ( $n = 3$ ).

**Figure 9** Relative expression level of P-glycoprotein in HepG2 cells 48 h after treatment with different concentrations of chelidone. Each bar indicates the mean  $\pm$  SD ( $n = 3$ ).

The long-term treated cells showed distinctive morphological features associated with senescence of aged human cells. In contrast to control cells, the treated cells became enlarged and vacuolated in the cytoplasm.

The relative expression level of *Bcl-2* in HepG2 treated cells as compared to controls dropped to less than 50% at 0.1  $\mu\text{mol/L}$  and subsequently increased to higher than 120% in LD<sub>50</sub> values of chelidone concentration (Figure 8).

Furthermore real-time RT-PCR data showed (Figure 9) that the expression of pgp which is involved in general drug resistance increased 3-fold in chelidone treated HepG2 cells in comparison with untreated control cells. However it is interesting that at 0.1  $\mu\text{mol/L}$  chelidone expression of pgp was reduced by 40%.

## DISCUSSION

Several potent natural products, mainly secondary plant metabolites, have so far been reported as anticancer agents. Among alkaloids, derivatives of Ukrainian are used in chemotherapy<sup>[31]</sup>. An inhibition of telomerase by

berberine, an alkaloid related to chelidone, has already been reported<sup>[32]</sup>. Here for chelidone, the main compound of *Ukrain*, the mechanism of action in growth inhibition and its potential effect on telomerase inhibition and senescence induction has been analysed. Cytotoxicity of chelidone in HepG2 cells is not dose-dependent within the range examined and tends to reach a plateau immediately after reduction of live cells to a point slightly higher than 50%. Therefore several cytotoxicity methods were tested to gain the best curve. The best results were attained from the neutral red uptake assay. Even with six repeats each in triplicate, it is hard to accept 12 μmol/L chelidone as the LD<sub>50</sub> in this cell line as cell viability does not change considerably above this concentration. However, this dose was considered to be LD<sub>50</sub>, where the maximal attainable effects of chelidone were realized. The negligible increment of cytotoxicity of chelidone at higher doses could be due to stimulation of a drug resistance mechanism in this cell line. Therefore pgp as a protein involved in the general mechanism of drug resistance was analyzed. Up-regulation of the gene tested using quantitative real-time RT-PCR in comparison with the β2-microglobulin gene was seen at 2, 10 and 50 μmol/L after 48 h treatment. Enhancement of the expression of pgp looks to be dose-dependent at concentrations above 2 μmol/L. This cell response could be important in dose adjustment of the alkaloid in cancer therapy to avoid chemoresistance as well as side effects.

Chelidone showed a very strong inhibitory effect on telomerase activity in HepG2 cells after 48 h incubation. Several mechanisms need to be discussed. Some of them could include alteration of transcription, interaction with the telomerase subunits and probably interaction with telomere structure or telomere binding proteins. The DNA binding capacity (intercalation) of chelidone was already shown to be negligible<sup>[33]</sup>. Here, we focused on the expression of hTERT as the most effective component of telomerase in activity and gene regulation. As changed patterns in expression level of hTERT are very similar to TRAP assay results, it seems that chelidone modulates telomerase activity, at least partially, by down-regulation of the transcription of its catalytic subunit gene. Surprisingly expression of P-glycoprotein in 0.1 μmol/L chelidone treated cells was reduced by 40%, indicating that it may sensitize cells to chelidone toxicity, while higher concentrations close to LD<sub>50</sub> boost the drug resistance response. This could be a possible explanation of the plateau shape of the cell viability curve attained in cytotoxicity tests as well. A very sharp reduction of the survived cell number in very low concentration of chelidone is accompanied with a lower level of pgp whereas increased concentrations of chelidone probably enforce drug resistance through up regulation of pgp and reduce cell death via apoptosis.

Obvious morphological changes toward cell death appeared after 24 h treatment with chelidone by at least two different modalities of cell death; apoptosis and blister cell death. In this cell line the classical morphology of apoptosis manifests at 1 μmol/L chelidone

while single blister formation or blister cell death is also visible in a smaller number of cells. These data are in good concordance with several reports concerning the involvement of programmed cell death *via* the mitochondrial pathway induced by *C. majus* and its alkaloids in cancer cells<sup>[34]</sup>.

It seems that primary down regulation of the anti-apoptotic gene Bcl-2 in the cells treated by a lower concentration of chelidone (almost 40% in comparison with untreated controls) support apoptosis, while its return to normal expression level and even higher (about 120% in comparison with control) in LD<sub>50</sub> concentration restrains apoptosis. This could in part explain the stronger toxicity of chelidone at relatively lower concentrations.

Our data demonstrate apoptotic cell death in very low concentrations of chelidone (1 μmol/L) and down-regulation of the hTERT subunit of telomerase in sub-apoptotic concentrations (0.1 μmol/L). Both of these effects seem to be in much lower concentrations of mitotic arrest of chelidone through inhibition of tubulin polymerization, which has a LD<sub>50</sub> of 24 μmol/L in different cells including HeLa<sup>[9]</sup>. It is also noteworthy that the antimitotic effect of low doses of alkaloids of *C. majus* is reversible but the effect at higher doses is not<sup>[35]</sup>.

On the other hand long-term treatment of HepG2 cells with sub-apoptotic concentrations of chelidone is also accompanied by induction of senescence which was confirmed by β-galactosidase activity, a commonly used biomarker in such studies. The cells treated repeatedly with 0.1 μmol/L showed a cell growth plateau, which appeared at day 28 in comparison with control untreated cells that corresponded to the failure of replating the treated cells. At this time, growth of treated cells shows an almost 60% decline in population doubling without affecting cell viability, suggesting an increase in cell cycle duration. Few apoptotic cells are visible in long-term treatments with 0.1 μmol/L chelidone, whereas aged cells according to the β-galactosidase test are remarkably increased. In long-term treatment there are signs of differentiation visible in viable cells as well; some features of cell shape similar to fibroblasts, including long extensions attached to the substratum and a flat relatively large cytoplasm.

In conclusion, chelidone shows a promising effect on proliferation inhibition of cancer cells, compatible with a recent suggestion of the *Chelidonium majus* extract as an anti-tumor and hepatoprotective agent against induced hepatocarcinoma in mice<sup>[3]</sup>. Our data showed that chelidone inhibits telomerase in tumor cells strongly and may provide a basis for the development of more specific anticancer agents. Although possible selectivity effects of chelidone on cancer cells needs further investigation, in a recent study on primary mouse spleen cells and mouse lymphocytic leukemia cells, L1210, chelidone completely arrested L1210 cells with minimal cytotoxicity<sup>[36]</sup>.

## ACKNOWLEDGMENTS

We would like to thank all the people who assisted us in this research; Dr. Maren Möller and Dr. Holger Schäfer. Also

special gratitude to Dr. Meike Hoemme for kind help in designing some of the primers for real-time RT-PCR.

## COMMENTS

### Background

Telomerase, the key enzyme in most cancer cells for overcoming the proliferation limitation, is a promising target for chemotherapy. Among other strategies including PNA, antisense, ribozymes and RNA interference, chemotherapy using natural bio-products could be helpful in inhibition/down-regulation of telomerase. Several other plant secondary metabolites and their derivatives have been introduced in this proposal. *Chelidonium majus* (*C. majus*), which has been used as anti-tumor agent, in traditional medicine has been considered here and the main alkaloid of this plant was investigated for telomerase inhibitory potencies.

### Research frontiers

*C. majus* and its derivative Ukrain have been used for cancer therapy, but little is known about the mechanism of action. Whether it has telomerase inhibitory effects is the main subject of this research. This is the first published data concerned with alteration of telomerase activity in cancer cells after treatment with chelidoneine. Senescence induction is another aspect of chelidoneine effects on the cancer cell culture model.

### Innovations and breakthroughs

The molecular mechanism of chelidoneine's anti-proliferative effect on cancer cells was investigated by measuring telomerase activity and the transcription level of the catalytic subunit of the enzyme. Meanwhile population doubling and senescence induction was under consideration. All the data and viewpoints are original and never been published elsewhere.

### Applications

Chelidoneine shows strong inhibitory effects on telomerase activity and induces senescence in a cell culture model, so that it could be a promising agent in development of effective anticancer agents with higher specificities.

### Terminology

Telomerase: A special kind of reverse transcriptase which extends telomeres in chromosomes using its own RNA components as the template. It is almost completely switched off in most normal somatic cells, while it is up-regulated in more than 90% of different cancers. Chelidoneine: A benzophenanthridine alkaloid of *Chelidonium majus* - a well known plant with anti-tumor effects in traditional medicine.

### Peer review

This article shows the effect of chelidoneine on telomerase, which has therapeutic potential against cancer. The research topic is interesting and identifies the molecular target of chelidoneine.

during liver regeneration were examined by flow cytometry, *in situ* hybridization and immunohistochemistry.

**RESULTS:** ISH analysis demonstrated human Alu-positive cells in hepatic parenchyma and stroma of recipient liver. Functional human hepatocytes generated in this model potentially constituted human hepatic functional units with the presence of donor-derived human endothelial and biliary duct cells in host liver. Alpha fetoprotein (AFP)<sup>+</sup>, CD34<sup>+</sup> and CD45<sup>+</sup> cells were observed in the chimeric liver on day 10 after PHx-induced liver regeneration and then disappeared in PHx group, but not in non-PHx group, suggesting that dynamic phenotypic changes of human cells expressing AFP, CD34 and CD45 cells may occur during the chimeric liver regeneration. Additionally, immunostaining for human proliferating cell nuclear antigen (PCNA) showed that the number of PCNA-positive cells in the chimeric liver of PHx group was markedly increased, as compared to that of control group, indicating that donor-derived human cells are actively proliferated during PHx-induced regeneration of HRC liver.

**CONCLUSION:** HRC liver provides a tool for investigating human liver regeneration in a humanized animal model.

Phenotypic changes of human cells in human-rat liver during partial hepatectomy-induced regeneration. *World J Gastroenterol* 2009; 15(29): 3611-3620 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3611.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3611>

## Abstract

**AIM:** To examine the human hepatic parenchymal and stromal components in rat liver and the phenotypic changes of human cells in liver of human-rat chimera (HRC) generated by *in utero* transplantation of human cells during partial hepatectomy (PHx)-induced liver regeneration.

**METHODS:** Human hepatic parenchymal and stromal components and phenotypic changes of human cells

## INTRODUCTION

The complexity of a biologic network can only be

reproduced using an *in vivo* system, and complex biological and pathological processes often require an *in vivo* analysis. However, biomedical researches in humans are largely performed in *in vitro* models lacking of the components and complexity of a living organism because of scientific, technical and ethical considerations. Since there is a certain level of similarity between animals and humans, various laboratory animals including small (e.g. mice and rats) and large animals (e.g. pigs, dogs and non-human primates) are instrumental in increasing the understanding of human biology and disease. However, laboratory animals cannot fully replicate human physiology and disease because animal models are enormously limited by the practical considerations, physiological and genetic diversity, *etc.*

Since these findings derived from mice and *in vitro* human models cannot always be extrapolated to precisely reflect the true situations in humans, a preclinically and/or clinically relevant human-animal chimera (HAC) carrying various humanized organs, such as liver, brain, heart, kidney, *etc.*, constituted by a wide variety of transplanted donor-derived human cells with different cell phenotypes engrafted into the recipient organs, has been developed by performing *in utero* transplantation or blastocyst transplantation of various human stem cells (hSCs) during the preimmune development stage, which can imitate the *in vivo* situations in humans, thus greatly facilitating related researches based on HAC harboring humanized organs within the xenogeneic competitive settings<sup>[1-24]</sup>.

*In utero* transplantation of hSCs, such as human hematopoietic stem cells and mesenchymal stem cells, into fetal sheep<sup>[2,6]</sup>, goats<sup>[24]</sup>, rats<sup>[19,20]</sup>, and mice<sup>[18,22]</sup> or blastocyst transplantation of hSCs into mice<sup>[22]</sup>, has led to the establishment of non-injury human-animal xenograft models carrying humanized liver, in which a significant number of functional donor-derived human mature hepatocyte-like cells (HLCs) stained positively for human albumin (Alb), alpha fetoprotein (AFP) and hepatocyte nuclear factor-4 can be found. Moreover, such a "HAC liver" can also produce and secrete human Alb, alanine aminotransferase (ALT), aspartic acid aminotransferase (AST) and alkaline phosphatase (ALP) in the circulation of host mice<sup>[18]</sup> and sheep<sup>[2,6]</sup> that have undergone transplantation.

Compared with the general laboratory animals including mice, rats, pigs, dogs, non-human primates, and immune-deficient mice (*in vivo* injury model) carrying humanized liver reconstructed with human hepatocytes<sup>[5,25-28]</sup> or hSCs<sup>[29,30]</sup>, such a HAC harboring humanized liver with a relatively large number of donor-derived human liver cells clustered to form functional human liver units in host animal liver is an *in vivo* non-injury human-animal xenograft animal model with normal physiological conditions, and will become an ideal *in vivo* system for studies of the mechanisms underlying human liver development, repair and regeneration; the pathogenesis of human liver-related diseases including viral hepatitis, liver cirrhosis, hepatocellular carcinoma (HCC), *etc.*; and drug discovery and preclinical assessment of ADME-Tox<sup>[17,19,20,25,31]</sup>.

From a scientific perspective, human-rat chimera (HRC) and human-mouse chimera (HMC) carrying humanized organs are the suitable models for mechanistic research. Thus, attention has been paid to the new generation of non-injury models, such as HRC and HMC (data not shown) carrying humanized liver, and their potential applications<sup>[19,20]</sup>.

Our previous data demonstrate that donor-derived human liver cells with different cellular phenotypes are formed in chimeric liver of some animals after *in utero* transplantation of hSCs, including human liver cells stained positively for CD34 (markers for hematopoietic stem/progenitor cells and oval cells), CD45 (markers for oval cells and nucleated cells of hematopoietic lineage), AFP (embryonic hepatocyte marker), CK8 and CK18 (hepatocyte markers), CK19 (markers for cholangiocyte and bile duct cells), and Alb (hepatocyte marker), suggesting that donor-derived human hepatocyte and cholangiocyte lineages exist in host liver<sup>[19,20]</sup>. Moreover, human hepatic cell differentiation in rat liver appears to partially follow the process of hepatic ontogeny<sup>[20]</sup>.

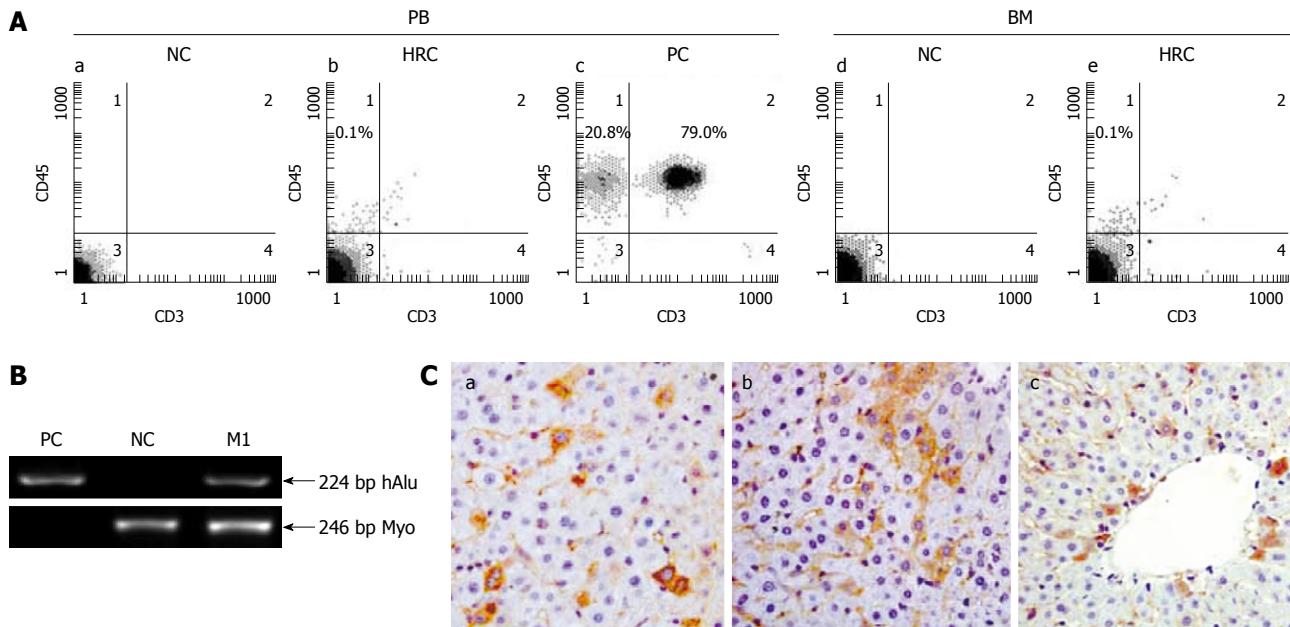

Furthermore, donor-derived functional human mature HLCs in parenchyma of human-sheep chimeric liver constitute the "humanized hepatic functional units" with the presence of donor-derived human hepatic stromal cells (endothelial and biliary duct cells) integrated into the chimeric liver stroma<sup>[2]</sup>, which remains to be confirmed in HRC liver<sup>[19,20]</sup>.

Based on the HRC carrying newly developed humanized liver after *in utero* transplantation of hSCs<sup>[19,20]</sup>, this study was to further identify the donor-derived human stromal components of HRC liver by *in situ* hybridization (ISH) for detecting donor-derived human cells in HRC liver, and to examine the changes in cellular phenotypes of donor-derived human cells during partial hepatectomy (PHx)-induced liver regeneration in the xenogeneic competitive environment, which helps to establish a solid foundation for the further research and potential applications based on such a "humanized liver".

## MATERIALS AND METHODS

### HRC generation

Human-rat hybrid animals were produced by *in utero* transplanting low-density mononuclear cells (MNCs) from human umbilical cord blood (hUCB) into fetal rats at the gestation of 9-11 d. The engraftment and long-term survival of donor-derived human cells in the HRC liver were determined by human gene-specific PCR (Figure 1B) for human Alu repetitive sequence (hAlu) on genomic DNA prepared from the liver of MNC-transplanted rats (MTRs) which were positive for human CD45 cells in peripheral blood (PB). PCR-positive organs were subjected to ISH for human Alu sequences and immunohistochemistry (IHC) using antibodies specific for human β2-microglobulin (β2-M), CK18 and CK19. Chimerism was accepted if the liver samples were positive for β2-M, CK18, CK19 and ISH. Protocols for producing and identifying HRC have been described elsewhere<sup>[19]</sup>.

**Figure 1** Screening for human-rat chimera (HRC) derived from *in utero* transplantation of hUCB-MNCs. Human-rat hybrid animals were produced by *in utero* transplantation of low-density mononuclear cells (MNCs) from human umbilical cord blood (hUCB) into fetal rats at the gestation of 9–11 d. A: Representative flow cytometric analysis of human CD45-positive cell engraftment in PB and BM of HRC. After birth, peripheral blood (PB) was collected at the indicated time points. The collected blood cells were stained with anti-human CD45 and CD3 antibodies and analyzed by flow cytometry. MNC-transplanted rat (MTR) was killed at end of each experiment, with bone marrow (BM) obtained and assessed for human CD45<sup>+</sup> cell engraftment by 2-color flow cytometry. Human PB from healthy volunteers was used as a positive control (PC) and normal rat PB was used as a negative control (NC); B: Identification of human genes in liver of MTR by human gene-specific PCR. To determine the human donor contribution in the liver of MTR, PCR was carried out on genomic DNA with primers specific for hAlu gene<sup>[19]</sup>. The PCR products were analyzed by agarose gel electrophoresis from positive-control human blood genomic DNA (lane PC), normal/non-transplanted rat genomic DNA (lane NC) and genomic DNA prepared from liver of one MTR was shown. Rat myogenin (Myo)-specific PCR was carried out for quality and quantity controls of genomic DNA with primers specific for rat Myo gene<sup>[19]</sup>. Data are representative of three independent PCRs yielding similar results. Arrow indicates the position of PCR products amplified by the primers for hAlu<sup>[19]</sup>. M1: Molecular weight DNA marker (DL2000, TaKaRa); C: Immunohistochemical analysis of various human antigens in liver of MTR. In the receipt liver, donor-derived human cells with different cellular phenotypes were detected by IHC for different human markers, such as β2-microglobulin [β2-M (a), CK18 (b) and CK19 (c)]. Brown staining shows positive human cells in various tissues from MTR and human samples (data not shown), whereas no positive human cells were found in normal control (NC) rats (data not shown).

All time points referred to the time length after birth. Animal care and experiment were performed according to the Ethical Guidelines for Animal Care, Handling and Termination established by the Subcommittee of Sun Yat-Sen University. The study was approved by the Ethics Review Committee of Sun Yat-Sen University. hUCB samples were obtained from normal full-term deliveries and informed consent was given by the participants.

#### ISH for detecting donor-derived human cells in HRC liver

After evaluation of the donor-derived human cell distribution in HRC liver by human gene-specific PCR on genomic DNA, human donor contribution in the formalin-fixed, paraffin-embedded liver tissues (from HRC) proved by PCR for hAlu gene prior to immunohistochemical assessment<sup>[19]</sup>, was further determined by ISH for human DNA Alu sequences. Digoxigenin (DIG)-labeled Alu probes (DNA probes) were obtained from PanPath B.V. (Amsterdam, Netherlands). Hybridization was performed according to the manufacturer's instructions. DIG-labeled hybrids were detected with an anti-DIG-alkaline phosphatase conjugate and a BCIP/NBT substrate giving a light-blue precipitate, and counterstained (pink) with nuclear fast red.

#### Experimental design

Seventy percent of PHx rat liver model provides an effective medium for study of the transition and regulation of hepatocytes from quiescent to proliferating phase. Ten selected rats, at the age of 2 mo, with CK18-positive and/or CK19-positive hHLC engraftment in the HRC liver were randomly divided into 70% PHx group (PHx group) and control group (non-PHx group) ( $n = 5$ ). Before (day 0) and after 10 and 20 d of PHx, minimal liver tissues were dissected from each rat of PHx group and control group, and used to detect donor-derived human cells stained positively for CK18, CK19, CD34, CD45 and AFP with IHC.

#### Immunohistochemical detection of donor-derived human cells

The minimal chimeric liver samples were immediately harvested from HRC containing donor-derived human cells in rat liver at the indicated time points after birth, fixed in 10% formalin, and paraffin embedded. The sections (4-μm) were heated in a 10 mmol/L Na-citrate buffer (pH 6.0) at 95°C for 20 min and cooled at room temperature for antigen detection. An envision system was used for immunohistochemical analysis. Human cells with different cell phenotypes in chimeric liver were detected

with antibodies to CD45, CD34, CK18, CK19 and AFP (DAKO), respectively. The complex was visualized with diaminobenzidinetetrahydrochloride (DAB) and counterstained with hematoxylin. Anti-human CD45, CK18 and AFP antibodies used as primary antibodies could specifically react with human CD45, CK18 and AFP antigens, respectively. Data from the Antibody Company indicate that anti-human CD34 and CK19 antibodies could cross-react very mildly with rat CD34 and CK19 antigens, respectively. However, our previous study strongly indicated that CD34 and CK19 antibodies do not cross-react with their corresponding antigens, CD34 and CK19, in IHC<sup>[20]</sup>. Since anti-human CD45, CK18, AFP, CD34 and CK19 antibodies have been confirmed to specifically react with human CD45, CK18, AFP, CD34 and CK19 antigens, but not with rat CD45, CK18, AFP, CD34 and CK19 antigens, thus MNC-derived human CD45<sup>+</sup>, CK18<sup>+</sup>, AFP<sup>+</sup>, CD34<sup>+</sup> and CK19<sup>+</sup> cells engrafted into rat liver can be easily distinguished from rat CD45<sup>+</sup>, CK18<sup>+</sup>, AFP<sup>+</sup>, CD34<sup>+</sup> and CK19<sup>+</sup> cells, respectively, by IHC performed on chimeric liver sections of HRC. For each staining, tissue sections were prepared from a normal rat as a negative control (NC). To identify donor-derived human cells in rat liver sections, we performed IHC on six different sections from each rat that underwent transplantation. The variability in percentage of donor-derived human cells was not significant between sections, but significant between animals which is consistent with the reported findings<sup>[19,20]</sup>.

#### IHC for proliferating cell nuclear antigen (PCNA)

To perform immunostaining for PCNA, liver tissue sections were autoclaved in a 10 mmol/L citrate buffer at 121°C for 5 min and cooled to room temperature. After washed in PBS with 0.05% Tween 20 (PBS-T), the sections were primarily incubated with anti-PCNA antibody (Sigma, St. Louis, MO, USA) overnight at 4°C. After washed three times in PBS-T, the sections were incubated with secondary HRP-conjugated anti-mouse antibody (Chemicon, Temecula, CA) for 1 h at room temperature following its manufacturer's instructions. The complex was visualized with DAB and counterstained with hematoxylin.

## RESULTS

#### **Human donor contributions in MTR liver analyzed by ISH for human Alu sequences**

Human donor contribution in recipient liver was determined by human Alu gene-specific PCR. The presence of donor-derived human cells in PCR-positive rat liver was confirmed by IHC using antibodies specific for human β2-M which is present in almost all cells of the body except for red blood cells<sup>[19]</sup> (Figure 1B and C). Moreover, 0.1%-10.7% of β2-M-positive human cells in the liver sections analyzed at the indicated time points were of human origin which is consistent with the reported data<sup>[20]</sup>.

Since human Alu (hAlu) repetitive sequence constitutes 10% of human genomes, the results of this study, obtained by PCR and IHC for β2-M, were further confirmed by ISH with a human Alu-specific probe

to detect donor-derived human cells containing Alu sequences in chimeric liver. ISH analysis indicated that a large number of human Alu-positive cells with black/dark brown nuclei were found in the hepatic parenchyma and stroma of recipients (Figure 2B-D), but not in normal control rats (NCR) (data not shown). Moreover, all human cells in human liver samples demonstrated black/dark brown nuclei (Figure 2A). These findings illustrate that there are donor-derived cells of human origin in the liver of host rats.

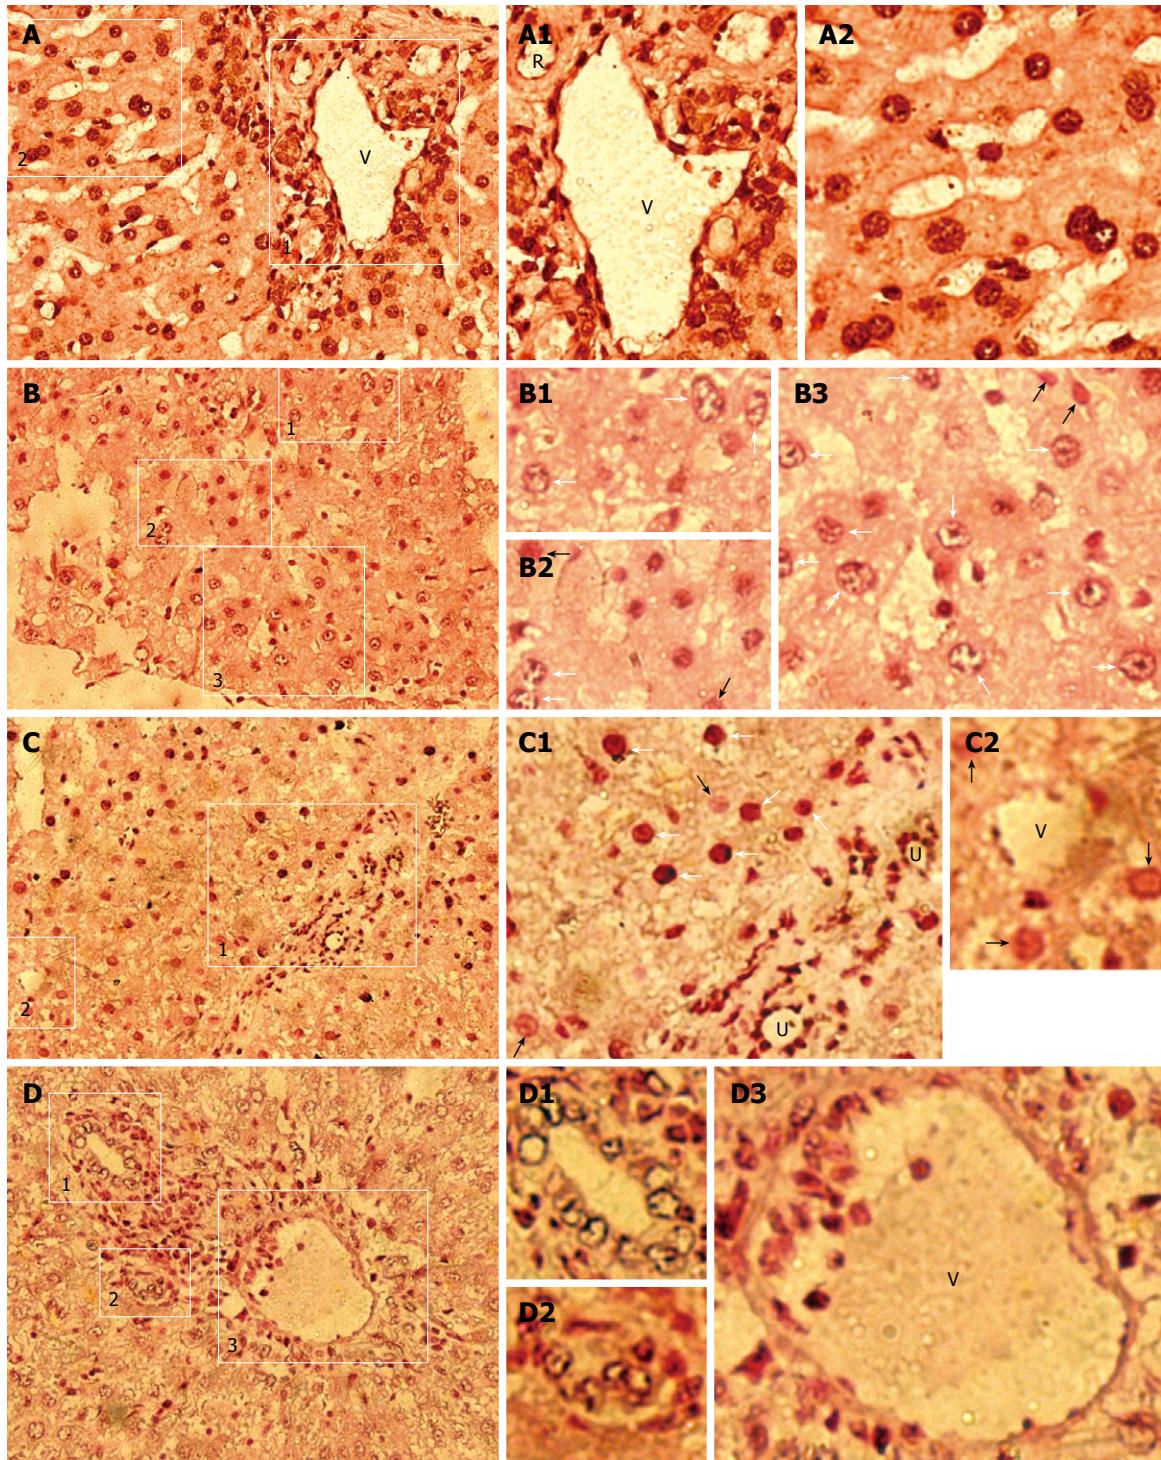

#### **Formation of humanized liver with donor-derived human hepatic parenchymal and stromal components in HRC**

Mammalian liver is composed of hepatic parenchymal components, such as stem/progenitor cells including oval cells, and cells expressing AFP, CK18, CK8, Alb, etc, in hepatocyte lineage, and hepatic stromal components including endothelial and biliary duct cells, etc<sup>[31]</sup>. Our previous data fully demonstrate that donor-derived human cells positive for CD34, CD45, AFP, CK8, CK18, CK19 and Alb are formed in the chimeric liver of HRC, suggesting that donor-derived human hepatic parenchymal components are formed in rat liver<sup>[19,20]</sup>.

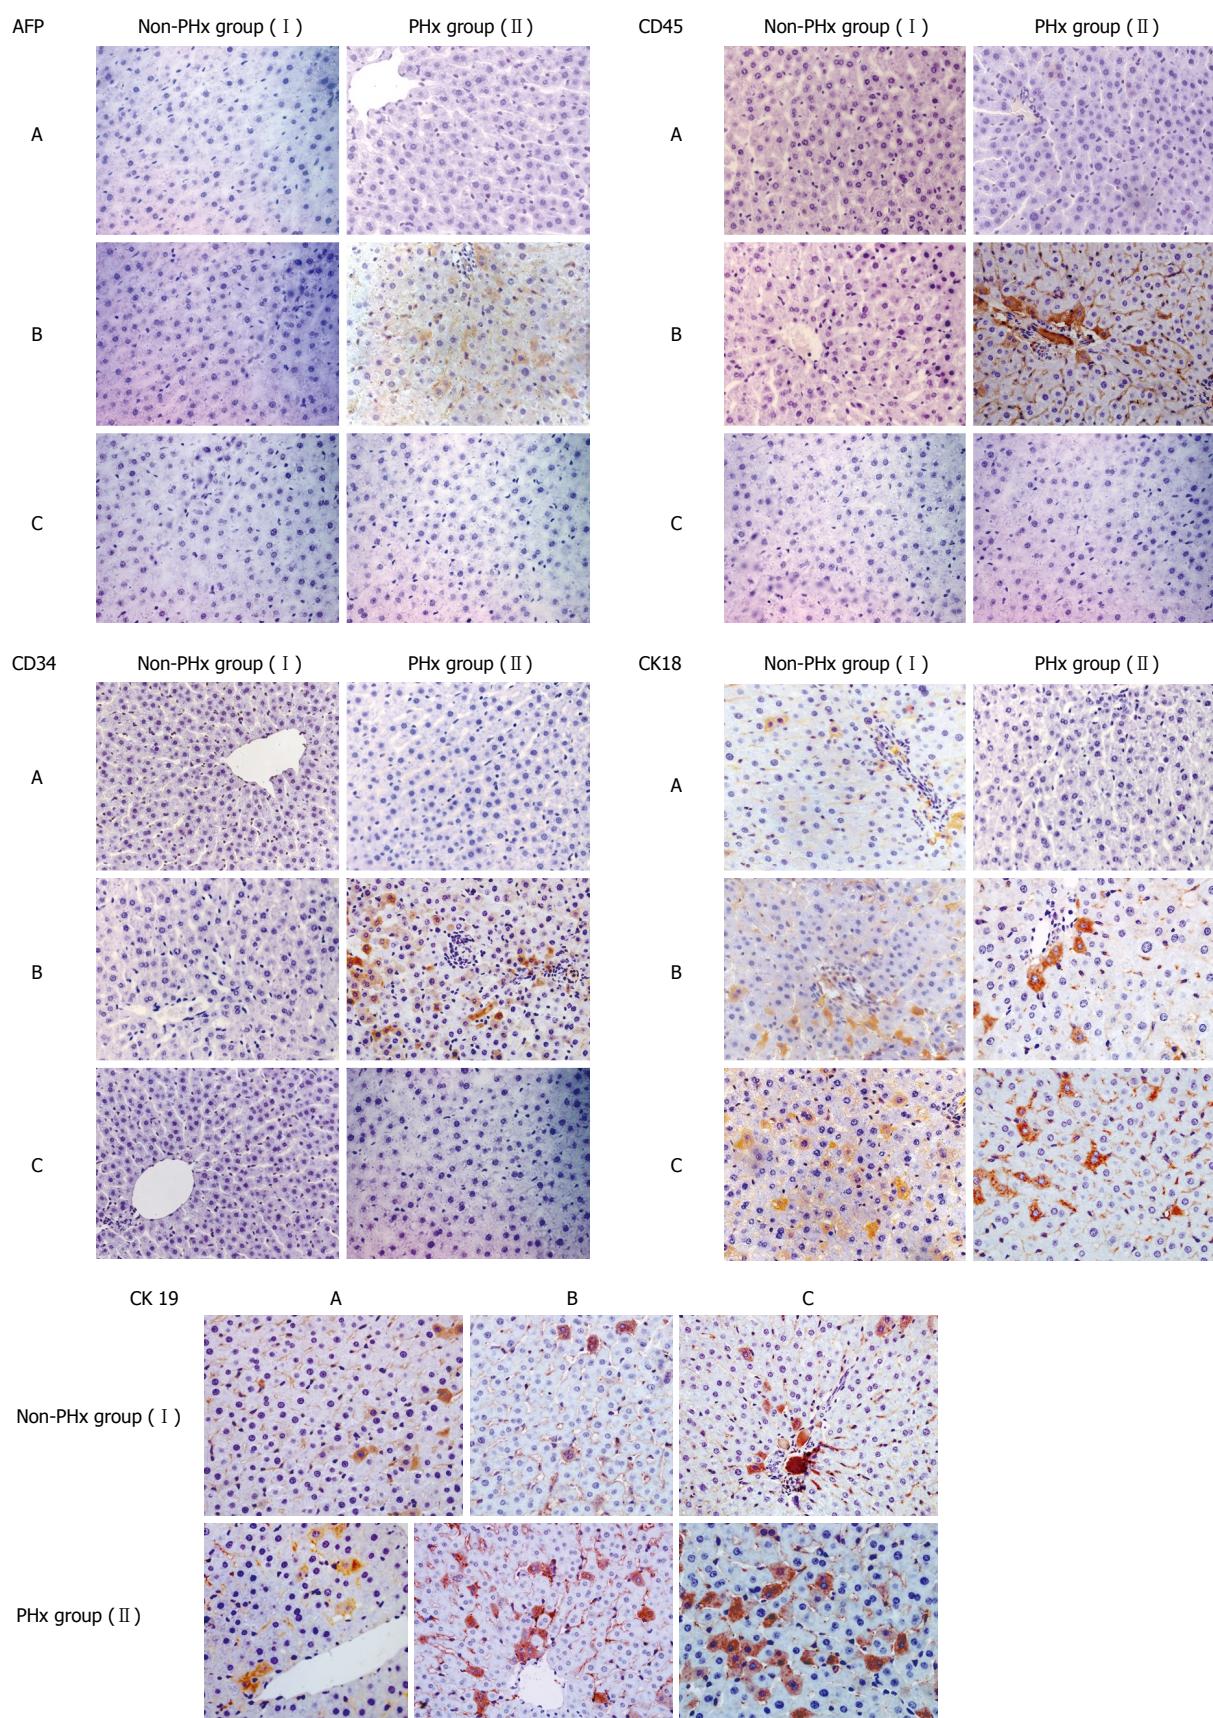

To further evaluate the *in vivo* differentiation potential of transplanted human cells into hepatic stromal cells, including endothelial and biliary duct cells, etc, in host liver, we performed ISH on liver sections from rats that underwent transplantation using a probe specific for the human Alu sequence. hAlu-positive vein (V) containing hAlu-positive human endothelial cell-like cells (hECLs), hAlu-positive artery (R) containing hAlu-positive human cells, hAlu-positive human hepatocytes, and other human cells, were found in the same liver section of human liver samples (Figure 2A). Moreover, no hAlu-positive human cells with black/dark brown nuclei were observed in the sections from control group (data not shown). ISH showed that a large number of cell nuclei in vein walls containing hAlu-positive hECLs (Figure 2C, C2 and D3) and biliary ducts containing hAlu-positive human bile duct epithelial cells (Figure 2C, C1, D1 and D2) were of human origin, indicating that donor-derived human hepatic stromal components (i.e. donor-derived human endothelial and biliary duct cells) are formed in rat liver. Furthermore, hAlu-positive vein (V) and bile duct (U) were observed in hepatic stroma and hAlu-positive human cells in hepatic parenchyma of host rats (Figure 2C and D), suggesting that humanized liver with donor-derived human hepatic parenchymal and stromal components is formed in xenogeneic competitive settings.

#### **Changes in cellular phenotypes of donor-derived human cells during PHx-induced liver regeneration in HRC**

The well-characterized PHx model of rat liver regeneration was used to explore the evolution rules in cellular phenotypes of donor-derived human cells participating in PHx-induced chimeric liver regeneration, and IHC was used to detect the expression of cell markers, such as AFP, CD34, CD45, CK18 and CK19. IHC analysis showed phenotypic changes of donor-derived

**Figure 2 Human donor contributions in HRC liver analyzed by *in situ* hybridization (ISH) for human Alu sequences.** Black/dark brown Alu-positive human cells in nuclei (white arrow) were identified in receipt liver using a probe specific for human DNA Alu sequences, and counterstained (pink) with nuclear fast red. Black/dark brown hybridization signals (white arrow) shows Alu-positive human cells in liver of MTR and human samples, whereas no Alu-positive human cells were found in normal control (NC) rats (data not shown). White arrow and black arrow indicate the partially demonstrated Alu-positive and negative human cells in B1-B3, C1 and C2, respectively. A: Human liver (positive control); B-D: Detection of donor-derived human cells in the chimeric liver of HRC. R: Artery; U: Bile duct; V: Vein. A: Low-power magnification of hAlu-positive human cells; A1: High-power magnification of the region (1) in the right rectangle of (A) demonstrating hAlu-positive vein (V) containing hAlu-positive human endothelial cell-like cells (hECLs), hAlu-positive artery (R) containing hAlu-positive human cells, and hAlu-positive human hepatocytes and other human cells in human liver; A2: High-power magnification of the region (2) in the left rectangle of (A), hAlu-positive human hepatocytes and other human cells in human liver; B: Low-power magnification of hAlu-positive human cells; B1: High-power magnification of hAlu-positive human cells (white arrow) of the rectangle region (1) in (B); B2: High-power magnification of hAlu-positive human cells (white arrow) and hAlu-negative cells (white arrowhead) of the rectangle region (2) in (B); B3: High-power magnification of hAlu-positive human cells (white arrow) and hAlu-negative cells (white arrowhead) of the rectangle region (3) in (B); C: Low-power magnification of hAlu-positive human cells; C1: High-power magnification of the rectangle region (1) in (C) showing hAlu-positive human hepatocyte-like cells (hHLCs) (white arrow), hAlu-positive bile duct (U) epithelial cells and other human cells (white arrow) in chimeric liver; C2: High-power magnification of the rectangle region (2) in (C) showing hAlu-positive hECLs in vein (V) of chimeric liver; D: Low-power magnification of hAlu-positive small bile ducts (U) and hAlu-positive vein (V) in chimeric liver; D1, D2: High-power magnification of hAlu-positive small bile ducts (U) in (1, 2) of (D), respectively; D3: High-power magnification of vein (V) containing hAlu-positive hECLs in (3) of (D).

**Figure 3 Representative immunohistochemistry analysis of phenotypic changes of donor-derived human cells in HRC liver during PHx-induced liver regeneration.** Seventy percent partial hepatectomy (PHx), a procedure that removes 70% of the liver, is regarded as the preferred *in vivo* method to study liver growth due to its synchronized growth response. In the representative chimeric livers of animals 5 and 6 (Table 1), donor-derived human cells with different cellular phenotypes were detected by IHC for different human markers (AFP, CD34, CD45, CK18 and CK19). Minimal liver tissues used for IHC were collected before PHx, and after 10 and 20 d of PHx. Additionally, the untransplanted control group was also set up when we performed this experiment (data not shown). The results demonstrate that CD45<sup>+</sup>, CK18<sup>+</sup>, AFP<sup>+</sup>, CD34<sup>+</sup> and CK19<sup>+</sup> cells could not be detected in liver sections from untransplanted control rats by human-specific IHC, suggesting that human-specific IHC can show human specificity of staining (data not shown). PHx: 70% partial hepatectomy; I : Non-PHx group; II : PHx group. A: before PHx; B: 10 d after PHx; C: 20 d after PHx.

**Table 1** Phenotypic changes of donor-derived human cells in HRC liver during PHx-induced liver regeneration

Animal No. (age)	Cell markers									
	AFP		CK19		CK18		CD34		CD45	
	I	II	I	II	I	II	I	II	I	II
1 and 2 (2 mo)	A	-	-	+	-	-	+	-	-	-
	B	-	+	+	-	-	+	-	+	-
	C	-	-	+	-	-	+	-	-	-
3 and 4 (2 mo)	A	-	-	+	+	+	-	+	-	-
	B	-	-	+	+	+	-	+	+	-
	C	-	-	+	+	+	+	-	-	+
5 and 6 (2 mo)	A	-	-	+	+	+	-	-	-	-
	B	-	+	+	+	+	+	-	+	-
	C	-	-	+	+	+	+	-	-	-
7 and 8 (2 mo)	A	-	-	-	+	+	+	-	-	-
	B	-	-	-	+	+	+	-	-	-
	C	-	-	-	+	+	+	-	-	-
9 and 10 (2 mo)	A	-	-	-	-	+	+	-	-	-
	B	-	-	-	-	+	+	-	-	+
	C	-	-	-	+	+	+	-	-	-

Animals 1-10 at the age of 2 mo with the engraftment of donor-derived hHLCs in the liver of HRC were screened by human gene-specific PCR for hAlu as previously described<sup>[19,20]</sup> and ISH for human Alu sequences confirmed by detecting human  $\beta$ 2-M expression using IHC. Animals 2, 4, 6, 8 and 10 at the age of 2 mo underwent 70% PHx. Age-matched animals 1, 3, 5, 7 and 9 (not undergone PHx), were used as negative controls. In the human-rat chimeric liver, donor-derived human cells with different cellular phenotypes were detected by IHC for different markers (AFP, CD34, CD45, CK18 and CK19). Minimal liver tissues from PHx (II) and non-PHx (I) groups used for IHC were dissected and collected before PHx (A), and after 10 d (B) and 20 d (C) of PHx.

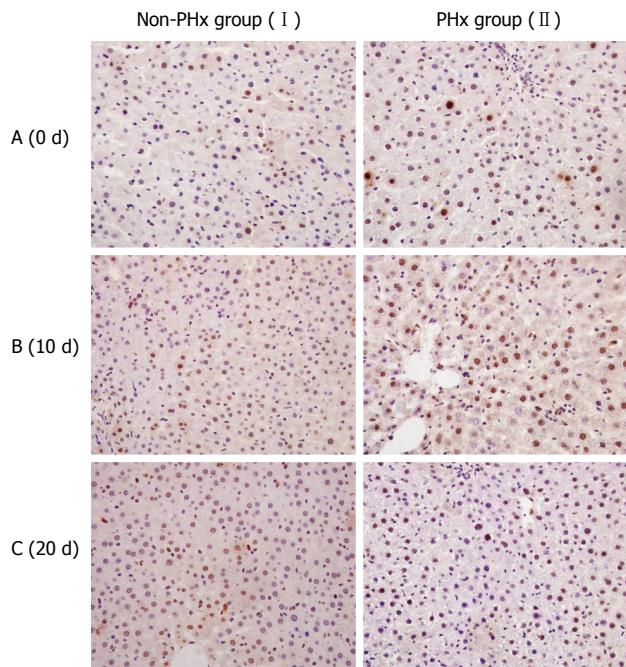

human cells during PHx-induced liver regeneration in HRC (Figure 3). The changes in the cellular phenotypes of donor-derived human cells during PHx-induced liver regeneration in five HRCs after PHx are summarized in Table 1. Donor-derived AFP<sup>+</sup>, CD34<sup>+</sup> and CD45<sup>+</sup> human cells in the portal area were found in the chimeric liver of HRC after 10 d of PHx in PHx group but not in control group (Figure 3 and Table 1), suggesting that dynamic changes of donor-derived human cells expressing AFP, CD34 and CD45 may occur during liver regeneration.

#### Proliferative activity of hHLCs during PHx-induced liver regeneration in HRC

Since PCNA is present specifically in nuclei of proliferating cells, it was employed to indicate the active proliferation of donor-derived human cells during human-rat chimeric liver regeneration in this study. Immunostaining for human PCNA showed that the number of PCNA-positive cells in chimeric liver was significantly higher in PHx group than in control group after 10 d of PHx (Figure 4), indicating that donor-derived hHLCs are actively proliferated during PHx-induced HRC liver regeneration.

## DISCUSSION

Adult mammalian liver contains different cell types, such as stem/progenitor cells including oval cells, hepatocytes, bile duct epithelial cells, vascular endothelial cells, stellate

**Figure 4** Proliferative activities of hHLCs during PHx-induced liver regeneration in HRC. Immunostaining for PCNA, a marker for cell proliferation, was performed to evaluate the proliferation of hHLCs. An antibody against PCNA antigen was used to evaluate the percentage of hepatocytes in the regenerative process after 70% hepatectomy. Ten days after PHx, PCNA staining demonstrated the active proliferation of hHLCs in the PHx group (II) compared with the control group (I).

cells, Kupffer cells (K), fibroblasts and leukocytes, etc, which constitute the functional units of liver<sup>[31]</sup>. Hepatocytes are responsible for most liver functions and account for 90% of liver weight.

Since *in vivo* study of human biology is severely limited by scientific, technical and ethical constraints, livers of small and large laboratory animals are routinely used to establish human liver biology and disease models, which, however, cannot fully replicate the complex biological and pathological processes of human liver. It is, therefore, necessary to develop a preclinically and/or clinically relevant HAC harboring a “humanized liver” with a relatively large number of different human liver and bile duct epithelial cells that cluster to form functional human liver units in host animals, which can imitate the *in vivo* situations in humans. Such a HAC harboring a “humanized liver” can be used in study of human liver development, repair and regeneration, the pathogenesis of human hepatitis virus infection, and human liver-specific metabolic responses to drugs, etc.

Transplantation of human hepatocytes into immuno-deficient mice can generate humanized mice carrying a humanized liver, and nearly 80%-90% of which can be replaced by transplanted human hepatocytes<sup>[25,27,32,33]</sup>. Furthermore, functional donor-derived human mature hepatocytes are positive for Alb, CK18 and CK8 in such a “humanized liver”. The presence of donor-derived human hepatic progenitor cells in liver parenchyma and donor-derived functional human bile canaliculi connected to mouse canaliculari can form donor-derived human

hepatic functional units in animal livers, while the plasma in humanized mice carrying a humanized liver contains human Alb and additional 21 human proteins<sup>[25,26,32,33]</sup>. However, the following significant drawbacks greatly limit the widespread use of such humanized mice derived from immunodeficient mice in study of human liver development, repair and regeneration, and pathogenesis of human hepatitis virus infection. On the one hand, transplanted foreign cells migrating into host liver from host spleen may not develop into all cell types in human liver required for normal liver function. On the other hand, immunodeficient mouse recipients have no normal immune system. In other words, after birth, this model is lack of a completely normal physiological environment, but the body immune system is involved in the pathogenesis of human hepatitis, and in control of human liver development, repair and regeneration.

Naturally occurring migration patterns of stem cells, availability of extending homing and engraftment sites, tissue- and organ-specific signals from niche in early embryo of animals greatly facilitate the widespread distribution of human donor cells in the recipient body, and promote them to home and engraft into various tissues and organs, in which human donor cells are actively influenced by the signals from niches to undergo reprogram, proliferation and differentiation in specific tissues and organs of recipients<sup>[19,20,34]</sup>. *In utero* or blastocyst transplantation of hSCs from multiple sources can form all possible donor-derived human cell types in the recipient liver, which in turn constitute human hepatic parenchymal and stromal components<sup>[2,6,18-20,22,24]</sup>. In contrast to the immunodeficient mice harboring a humanized liver, HAC in liver humanization possess and potential human immune system can be reconstituted with donor-derived human differentiated cells (data not shown). Besides the functional donor-derived human mature HLCs positive for human Alb, AFP, HNF-4, etc, throughout the host liver parenchyma, an “ideal human-animal chimeric liver” can also synthesize and secrete human Alb, ALT, AST and ALP into the circulation of host animals<sup>[2,6,18-20,22,24]</sup>. Our findings demonstrate that donor-derived human mature hepatocytes, endothelial and biliary duct cells in human-rat chimeric liver, constitute the “humanized hepatic functional units” in animal liver<sup>[2,19,20]</sup>. In addition, other donor-derived human cell types, such as liver stem/progenitor cells, stellate and Kupffer cells (K), fibroblasts and leukocytes in human liver, remain to be further identified in HRC liver.

It has been reported that after *in utero* transplantation of hMNCs, the transplanted human stem/progenitor cells can engraft into the recipient liver, and are actively influenced by niche signals to participate in organogenesis of recipients in the xenogeneic competitive settings<sup>[19,20]</sup>, indicating that HAC carrying humanized liver cells derived from *in utero* or blastocyst transplantation of hSCs is more superior to that in immunodeficient mice harboring humanized liver.

Since most of our present knowledge on liver regeneration is derived from laboratory mice and rats,

but not from human beings due to the lack of an ideal *in vivo* model<sup>[35]</sup>, HAC harboring a humanized liver will become an ideal *in vivo* system for investigating human liver regeneration and its mechanism.

Mature hepatocytes, liver stem cells or bone marrow (BM)-derived stem cells will be mobilized to participate in liver regeneration and repair, while various liver injury models, such as PHx, AAF/PHx, and AAF models, can induce different cell proliferative responses in liver<sup>[31]</sup>. In this study, the well-established 70% PHx model was used to induce acute chimeric liver injury and liver regeneration was induced with PHx. Donor-derived AFP<sup>+</sup>, CD34<sup>+</sup> and CD45<sup>+</sup> human cells were found in the chimeric liver on day 10 in PHx group but not in control group, suggesting that the donor-derived hSCs, engrafted into the BM of HAC, can be mobilized to migrate into the chimeric liver from the chimeric BM of HRC, thus participating in the regeneration and repair of injured chimeric liver during the acute liver damage. Additionally, the donor-derived human cells were engrafted in rat BM (Figure 1A). During chimeric liver regeneration, the donor-derived CD34<sup>+</sup> and CD45<sup>+</sup> human cells were detected in the portal area of chimeric liver, indicating that BM-derived hSCs participate in the regeneration of injured chimeric liver, which needs to be confirmed by further experiments. Generally, liver stem cells are not significantly proliferated after mild liver damage and BM-derived stem cells can directly enter liver from outside and subsequently develop into mature hepatic cells, but do not migrate into the portal area<sup>[31]</sup>. In this study, the markers of various donor-derived human cells in chimeric liver varied with time, demonstrating the changing process of surface markers of BM-derived hSCs, mature hepatocytes or liver stem cells during the regeneration of damaged chimeric liver. During liver regeneration after acute liver damage, the actively mobilized BM-derived hSCs in chimeric BM migrate into the chimeric liver, and further differentiate into hepatocytes to support the regeneration of injured chimeric liver, while donor-derived human mature hepatocytes and liver stem cells in chimeric liver participate in the regeneration and repair of injured chimeric liver<sup>[36]</sup>.

Anyway, HAC liver will become a powerful *in vivo* system for examining human-specific biological processes of damaged liver regeneration and repair.

Remaining constraints of such a “HAC” containing humanized liver cells include non-consistent engraftment of human cells in the same organ of different individuals, and inadequate human cells engrafted in HAC liver. For example, the percentage of donor-derived human cells in the chimeric liver of HRC is 0.1%-10.7%<sup>[20]</sup>.

The countermeasures for the elimination of the above constraints include definite cell components of human stem/progenitor cells used for transplantation, standard manipulation of transplantation, the need for genetic modifications to further humanize the host strain<sup>[37]</sup>, and loss of host hepatocytes, etc.

In summary, humanized liver can show insights into

*in vivo* human liver biology, and provide an *in vivo* powerful system for more precisely replicating the complex biological and pathological processes of human liver, and further allow us to investigate human liver-specific biological processes and diseases. However, efforts should be made to develop the optimal and pragmatic humanized animal models meeting the growing needs for animal models to carry out *in vivo* studies of human cells, tissues and organs.

## ACKNOWLEDGMENTS

The authors thank Professor Lu TC (Shihezi University, Xinjiang, China) for his unstinting advice and technical guidance, Qiu GG, Huang WG, Chen FY, Guo FF, Yang GZ and Zheng WW (Center of Experimental Animals, Sun Yat-sen University) for their technical assistance, Yang XH, Li Y and Zhang W (Zhongshan School of Medicine, Sun Yat-sen University) for kindly providing reagents.

## COMMENTS

### Background

Data demonstrate that donor-derived human hepatocyte-like cells with different cellular phenotypes and of functional human hepatocytes are formed in chimeric liver of human-rat chimera (HRC) after *in utero* transplantation of human cells. Formation of human hepatic parenchymal and stromal components in rat liver was further examined, and humanized liver harboring HRC was used to investigate the phenotypic changes of donor-derived human cells engrafted into rat liver during 70% partial hepatectomy (PHx)-induced liver regeneration.

### Research frontiers

HRC carrying humanized liver generated by *in utero* transplantation of human cells has been developed by the authors. HRC harboring human-rat chimeric liver was used to study the human liver-specific biological processes and human liver-specific diseases.

### Innovations and breakthroughs

Humanized liver was employed to investigate the process of human hepatic ontogeny and to examine the phenotypic changes of donor-derived human cells engrafted into rat liver during PHx-induced liver regeneration in this study.

### Applications

Compared with the general laboratory animals including mice, rats, pigs, dogs and non-human primates, and immune-deficient mice (*in vivo* injury model) carrying humanized liver reconstructed with human hepatocytes or stem cells, HRC carrying growing humanized liver with a relatively large number of donor-derived human liver cells clustering to form functional human liver units in host liver, is the *in vivo* non-injury human-animal xenograft animal model with normal physiological conditions, and will become an ideal and suitable *in vivo* system for studies of the mechanisms underlying human liver development, repair and regeneration, the pathogenesis of human liver-related diseases including viral hepatitis, liver cirrhosis, hepatocellular carcinoma, and drug discovery and drug preclinical assessment of ADME-Tox.

### Terminology

Humanized animals generated by *in utero* transplantation or blastocyst transplantation of various human stem cells were defined in this study as normal animals engrafted with human cells, tissues or organs with normal physiological conditions.

### Peer review

The manuscript describes the successful development of HRC carrying humanized liver generated by *in utero* transplantation of human cells. The findings of this study indicate that donor-derived functional human hepatocytes generated in this model constitute human hepatic functional units with donor-derived human endothelial and biliary duct cells in host liver. More importantly, HRC harboring human-rat chimeric liver was used to preliminarily examine the phenotypic changes of donor-derived human cells engrafted into rat liver during PHx-induced liver regeneration.

## Abstract

**AIM:** To investigate the correlation between the expression levels of interleukin (IL)-6 and proteins in tight junctions (TJs) in the esophageal mucosa of rats modeling different types of reflux esophagitis (RE), and the ability of aluminum phosphate to protect against RE-induced mucosal damage *via* these proteins.

**METHODS:** Male SPF Wistar rats aged 56 d were divided randomly into acid RE, alkaline RE, mixed RE, and control groups. Various surgical procedures were performed to establish rat models of acid RE. At 14 d after the procedure, some of the rats started aluminum phosphate treatment. Transmission electron microscopy (TEM) was used to observe the morphological features of TJs and desmosomes in the esophageal epithelium. Immunohistochemical methods and Western blotting were used to measure expression of claudin 1, occludin, ZO-1, JAM-1, DSG-1 and IL-6; reverse transcription polymerase chain reaction (RT-PCR) was used to measure expression of mRNA of claudin 1, occludin, ZO-1, JAM-1, DSG-1 and IL-6.

**RESULTS:** At day 14 after the procedures, an RE model was established in all subsequently sacrificed rats of

groups A, B and C. By both gross and microscopic observation, the mucosa was damaged and thickened as the disease progressed. With TEM observation, a widened intercellular space was noticed, with significantly fewer desmosomes. Immunohistochemistry showed significantly higher levels of all proteins in all RE models compared to control rats at 3 d after operation ( $65.5\% \pm 25.6\%$  vs  $20.5\% \pm 2.1\%$ ,  $P < 0.05$ , respectively). At 14 d after operation, along with continuing hyperplasia in the basal layer, the expression of TJ proteins in individual cells gradually decreased ( $12.4\% \pm 2.1\%$  vs  $20.5\% \pm 2.1\%$ ,  $P < 0.05$ , respectively). Western blottings and RT-PCR showed a directly proportional increase in IL-6 levels in relation to TJ proteins, as compared to controls ( $0.878 \pm 0.024$  vs  $0.205 \pm 0.021$  and  $0.898 \pm 0.022$  vs  $0.205 \pm 0.021$ ,  $P < 0.05$ , respectively). Upon treatment with aluminum phosphate, however, these protein levels were restored to normal gradually over 30-60 d in rats with acid RE ( $30.4\% \pm 2.1\%$  vs  $20.5\% \pm 2.1\%$ ,  $P > 0.05$ , treated vs untreated, respectively). These levels increased in the rat with alkaline RE, and this increase was accompanied by continued hyperplasia in comparison with controls ( $85.5\% \pm 25.6\%$  vs  $20.5\% \pm 2.1\%$ ,  $P < 0.05$ , respectively). Furthermore, the expression of TJ proteins was not correlated significantly with that of IL-6 in this group.

**CONCLUSION:** These findings indicate that TJ proteins are highly expressed as an early molecular event involved in RE development, and that IL-6 is an inflammatory factor in this process.

## INTRODUCTION

Gastro-esophageal reflux disease (GERD) is a common condition that has an impact on many millions of people worldwide, and is gaining more clinical recognition as a significant gastrointestinal disease. Lifestyle factors, such as obesity, high-fat diet, and physical inactivity, boost the incidence of GERD. GERD occurs when stomach and duodenal contents reflux into the esophagus. Reflux-induced damage and inflammation in the esophageal mucosa are referred to as reflux esophagitis (RE).

The pathogenic process of RE is highly complex. However, the current consensus among scientists is that RE mainly results from damage induced by reflux of the defending esophageal mucosa system. An imbalance between offensive and defensive factors in the esophagus leads to the development of RE. The epithelial defense system consists of three parts: pre-epithelial defense, epithelial defense and post-epithelial defense. In 2002, the German cellular biologist Langbein *et al*<sup>[1]</sup> reported that, in addition to desmosomes, tight junctions (TJs) could be found in the esophageal epithelium; and both were involved in maintaining the cellular barrier. Since then, TJs and desmosomes are considered to be important contributors to the epithelial defense of the esophageal mucosa. Other contributors include intercellular lipids, mucin and the epithelial transportation system (such as  $\text{Na}^+ \text{-H}^+$  exchanger and  $\text{Na}^+$ -dependent  $\text{Cl}^- \text{-HCO}_3^-$  exchanger). Recent studies showed that TJs created a circular substance-blocking barrier between adjacent cells. TJs also function in cell adhesion, cell polarity and permeability, and in signal transduction resulting in cell proliferation and differentiation. Intercellular TJs consist mainly of claudins, occludins, JAM and ZOs. In 2003, Calabrese *et al*<sup>[2]</sup> discovered in their studies that the intercellular space of the lower esophageal epithelium in patients with GERD was three times as wide as that in normal controls, and suggested 0.74  $\mu\text{m}$  as the threshold between normal and abnormal intercellular space. In 2004-2005, Asaoka *et al*<sup>[3]</sup> reported for the first time that expression of TJ proteins was altered during esophagitis; the expression level of claudin-3 decreased while that of claudin-1 increased<sup>[4]</sup>. Such changes have a determinant effect on the permeability of the esophageal epithelium. Therefore, further investigation is warranted using experiments testing the hypothesis that altered expression of TJ proteins and desmosome proteins results in failure of TJs and desmosomes, and thus leads to widened intercellular space and contributes to RE. In the investigation into RE, the use of human samples has methodological limitations. Hence, we created animal models of RE in rats, and sought to analyze the changes in intercellular space, changes in the distribution and expression of TJ proteins and desmosome proteins, and their correlation with the expression level of interleukin (IL)-6 in the pathogenic process of RE. Moreover, some rats were treated with aluminum phosphate to determine its efficacy in treating RE.

To explore the role of TJ and desmosome proteins in the pathogenesis of RE, we established three animal models of RE on the Wistar rat background. We performed three types of surgical procedures on these rats, and measured the distribution and expression profiles of claudin 1, occludin, ZO-1, JAM-1, DSG-1 and IL-6 in the esophageal mucosa of the various RE rats, untreated and treated with aluminum phosphate.

## MATERIALS AND METHODS

### Establishment of animal models

Two-hundred and twenty male SPF Wistar rats aged 56 d were purchased as laboratory animals at Shengjing Hospital of China Medical University, acclimatized and fed with standard chow and water *ad libitum* for 14 d in an animal room with controlled room temperature (24  $\pm$  2°C). Following the surgical procedures, the rats were fasted for 24 h and were given water *ad libitum*. Before surgery, the rats were divided into four experimental groups. The control group was comprised of 10 rats, while the experimental groups A, B and C, respectively modeling acid RE, alkaline RE and mixed RE, were comprised of 70 rats each. Prior to surgery, the rats were anesthetized with chloral hydrate (Qingdao Yulong Algae Co., Ltd, Shangdong, China) 0.3% mL/100 mg *via* abdominal injection. The control rats underwent laparotomy, modified from the methods described by Yu *et al*<sup>[5]</sup>, without any further surgical procedures<sup>[3]</sup>. After laparotomy, a pyloric stenosis was created by wrapping and ligating the pylorus with 1-0 silk thread around a metal tube (diameter: 2 mm) which was retrieved slowly after ligation. To enhance gastric reflux, a 0.5 cm longitudinal incision was made by cardiomyotomy in the esophageal-gastric junction. The incision was deep enough to expose the mucosa.

Group A rats underwent partial pyloric ligation (which is also known as incomplete pyloric ligation) and cardiomyotomy, while those in group B were treated with total gastrostomy plus end-to-side esophago-duodenal anastomosis. In the group B rats, the gastric artery and vein were separated and ligated, and then the cardia and pylorus were ligated and incised. The stomach was removed, and the cardia was then connected to the pylorus by end-to-side anastomosis<sup>[6]</sup>. The group C rats underwent cardiomyotomy and cardia ligation plus end-to-side esophago-duodenal anastomosis. To initiate surgery, the group C rats were placed in a supine position and an incision was made in the medium of upper abdomen. The lower esophagus was separated and incised and the vagus nerve was preserved. The cardia end of the stomach was disclosed with purse-string sutures, and the stomach was excluded. A 0.4-0.5 cm longitudinal incision was made on the duodenal wall at 1.0 cm from the pyloric end. The lower esophagus was connected to the duodenum with end-to-side anastomosis<sup>[7]</sup>.

On post-procedure days 3, 6, 9 and 14, subgroups of the rats were sacrificed and the middle-low esophagi

were dissected for evaluating the experimental success rates. The severity of the damage in esophagi was examined according to the diagnostic criteria of RE as determined by the Chinese Medical Association Digestive Endoscopy Society (1999).

One week following the procedure, 35 rats in group A, seven rats in group B and 21 rats in group C died. Five rats from groups A, B and C were sacrificed at post-procedure days 3, 6 and 9, respectively. At day 14, five rats in group A, five rats in the control group, 21 rats in group B and 13 rats in group C were sacrificed, and the middle-lower esophagus was obtained for calculating the success rate of the model.

**Aluminum phosphate treatment:** The remaining rats were fed 0.5 g aluminum phosphate (Boryung Pharmaceutical Co., Ltd. Fusan, Korea) in water, twice daily for 15 successive days. Five rats in group A, five rats in control group, nine rats in group B and seven rats in group C were sacrificed at post-treatment days 30 or 60. The survival, incidence of esophagitis, and average change in body mass in these model groups and in the control group were calculated.

#### **Gross and microscopic observations for evaluating the damage severity in the esophagus**

At post-procedure days 3, 6, 9 and 14, the lower esophagi were dissected for mucosal damage evaluation based on the Chinese Medical Association Digestive of Erosive Esophagitis (1999), and epithelial thickness was measured and evaluated as an indication of damage. Esophageal tissues were then fixed in 10% buffered-formalin, shaped into 4 mm tissue masses, dehydrated with gradient ethanol, clarified with xylene, embedded in paraffin and sectioned into 4  $\mu\text{m}$  slices, which were then stained with HE solution. The stained slices were then observed under the optical microscope, and a diagnosis was made based on the pathological features according to diagnostic criteria of RE by the Chinese Medical Association Digestive Endoscopic Society (1999), revealing the incidence of RE in these animal models<sup>[8]</sup>.

#### **Transmission electron microscopy (TEM) examination**

At days 30 or 60 following aluminum phosphate treatment initiation, the rats were sacrificed and a TEM (TEM; 2600 J EME2000X, Hitachi) was used to observe the morphological features of TJs and desmosomes in the esophageal epithelium. Samples were obtained from the lower esophagus at 5 cm from the lower end, fixed in glutaraldehyde solution at 4°C, and then clarified, dehydrated, embedded and sectioned into ultra-thin slices. Ten slices, prepared with samples obtained from different sites of the same esophagus, were selected for each esophagus and then observed under TEM. The LEICA image analyzing system was used to measure the intercellular space and calculate the number of desmosomes. Ten pictures were taken for each sample. In each picture, an intact cell was selected

and an intercellular space was calculated by detecting the vertical distance between the selected cell and its adjacent cells in 10 randomly selected directions, with each direction at least 1.0  $\mu\text{m}$  apart. 100 intercellular spaces were measured in 10 pictures and average width of intercellular space was calculated. We counted the number of desmosomes in the intercellular spaces of the 10 selected cells, and totaled and averaged these values<sup>[9]</sup>.

#### **Immunohistochemical assay**

Immunohistochemical methods were used to measure the expression levels of claudin 1, occludin, ZO-1, JAM-1, DSG-1 and IL-6. For these assays, the middle-lower esophagus was obtained and fixed in 10% buffered-formalin, shaped into 4.0 mm tissue masses, dehydrated with gradient ethanol, clarified with xylene, embedded in paraffin and sectioned into 4.0  $\mu\text{m}$  slices, which were then dewaxed with xylene, debenzolized with anhydrous ethanol and dehydrated with gradient ethanol, and then treated with 3.0% hydrogen peroxide and rinsed with water. After being restored at high pressure and high temperature, blocking agent (10% normal goat serum) was added to dissolve the slices at room temperature. Thirty minutes later, rabbit anti-IL-6, claudin 1, ZO-1, JAM-1 and DSG-1 antibodies were added at a dilution of 1:80, and goat anti-occludin antibody added at a 1:100 dilution at 4°C. The slices were then incubated overnight and washed with phosphate-buffered saline (PBS) 3  $\times$ , 10 min each, the next day. At room temperature, general secondary antibody was added, and the slices were incubated at 37°C for 30 min. The slices were washed with PBS 3  $\times$ , for 10 min each time. Streptavidin-peroxidase was added at 37°C. Thirty minutes later, the slices were washed again with 3  $\times$  PBS for 10 min each time. The slices were then stained with 3,3-Diaminobenzidine for 5 min, rinsed with water, and then stained with hematoxylin for another 5 min and rinsed with water again. The slices were then treated with acidic ethanol, and washed with running water for 30 min, dehydrated in gradient ethanol, and clarified with xylene, and sealed with gum. These slices of mucosa of RE were observed under the microscope for the measurement of expression of IL-6, claudin 1, occludin, ZO-1, JAM-1 and DSG-1.

#### **Western blotting**

Western blotting was used to measure the expression levels of claudin 1, occludin, ZO-1, JAM-1, DSG-1 and IL-6 (all from Santa Cruz Biotechnology, Santa Cruz, CA). For these assays, the esophageal tissue (100 mg) was obtained and added to 1.0 ml of cell lysis buffer [Tris/HCl (100 mmol/L, pH 7.5), NaCl (100 mmol/L), 0.5% sodium deoxycholate, ethylene diamine tetra-acetate (EDTA, 1 mmol/L), 1% NP40, 0.1% sodium dodecyl sulfate (SDS) and protease inhibitor]. Total protein was extracted, and the concentration was measured by the Lowry method. The extracted protein (50  $\mu\text{g}$ ) was added to 15% SDS-polyacrylamide gel for electrophoresis

**Table 1** Primer sequences for RT-PCR

Primers	Upstream primers	Downstream primers	Amplification
JAM-1	5'-ACTGCCGTCCAGGTT-3'	5'-TTCGCCACTATCAAAGG-3'	524 bp
Claudin-1	5'-GGATGCCCTGCCTTC-3'	5'-CACAGCCAAGACCCCTC-3'	674 bp
Occludin	5'-CCACTATGAAACCGACTA-3'	5'-CCAGCAACCAGCATC-3'	399 bp
Zo1	5'-CTCGGGCATTATTCTG-3'	5'-GCTTCCTGGCACTTT-3'	205bp

IL-6	5'-CTCCATCTGCCCTCA-3'	5'-CCAGGATAGAGCCACCAAT-3'	586bp
β-actin	5'-GGTCCTTAGCCACTCC-3'	5'-CCAGGATAGAGCCACCAAT-3'	701bp

(100 V for 1.5 h). When the bromophenol blue reached the bottom of the gel, the protein was blotted onto a nitrocellulose membrane. The blots were immersed in 5.0% milk (prepared with milk powder) for 2 h. Then at 4°C, rabbit anti-IL-6, claudin 1, ZO-1, JAM-1 and DSG-1 antibodies at dilutions of 1:80, and goat anti-octoccludin antibody at dilutions of 1:100 were added to the blots, which were then incubated overnight. The next day, the membrane was washed, and the corresponding alkaline phosphate-labeled secondary antibodies were added at room temperature. The membrane was then stained with O-Dianisidine Tetrazotized and β-Naphthyl acid phosphate, and analyzed with an electrophoresis gel imaging system.

Using the grey scale measurement of the electrophoresis gel imaging system, the expression levels of IL-6, claudin 1, occludin, ZO-1, JAM-1 and DSG-1 were calculated and expressed as percentages relative to the β-actin control (absorbance of these proteins/absorbance of β-actin).

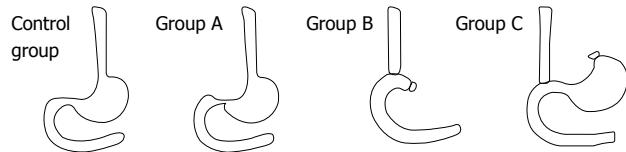

#### Reverse transcription polymerase chain reaction (RT-PCR)

RT-PCR was employed for cognate mRNA detection and quantitation. Total RNA was extracted with a Trizol Kit, (Invitrogen, Carlsbad, CA), measured, and verified with an ultra-violet spectrophotometer. Primers were designed by Primer Premier 5.0 (Premier Biosoft International, Palo Alto, CA) according to mRNA sequences (by GenBank) of IL-6, claudin 1, occludin, ZO-1, JAM-1, DSG-1 and β-actin (as control). The primer sequences are shown in Table 1. RT-PCR was performed using the Takara RNA LA PCR kit (Takara, Kyoto, Japan) according to the manufacturers' instructions. RT-PCR was catalyzed under the following temperatures: 5 min at 94°C; 35 cycles of 30 s at 94°C, 30 s at 59°C and 1 min at 72°C; finally 5 min at 72°C. 5 μg of the PCR product was added to 2 μL loading buffer, and electrophoresed in a 1.5% agarose gel at 100 V for 1.5 h. Analysis was carried out using a gel imaging system (Glyko, Novato, CA, USA).

#### Statistical analysis

Data were processed with a statistical package SPSS version 10.0 (SPSS Inc, USA).

The means between two groups were compared for differences using the student's *t*-test; comparison of the ratio between two samples was tested with the chi-square test. The data were reported as mean ± SD. A 95% confidence interval for the average weight of rats

**Figure 1** Procedure for the establishment of animal models in each group. Control: Without treatment; A: Acid RE; B: Alkaline RE; C: Mixed RE.

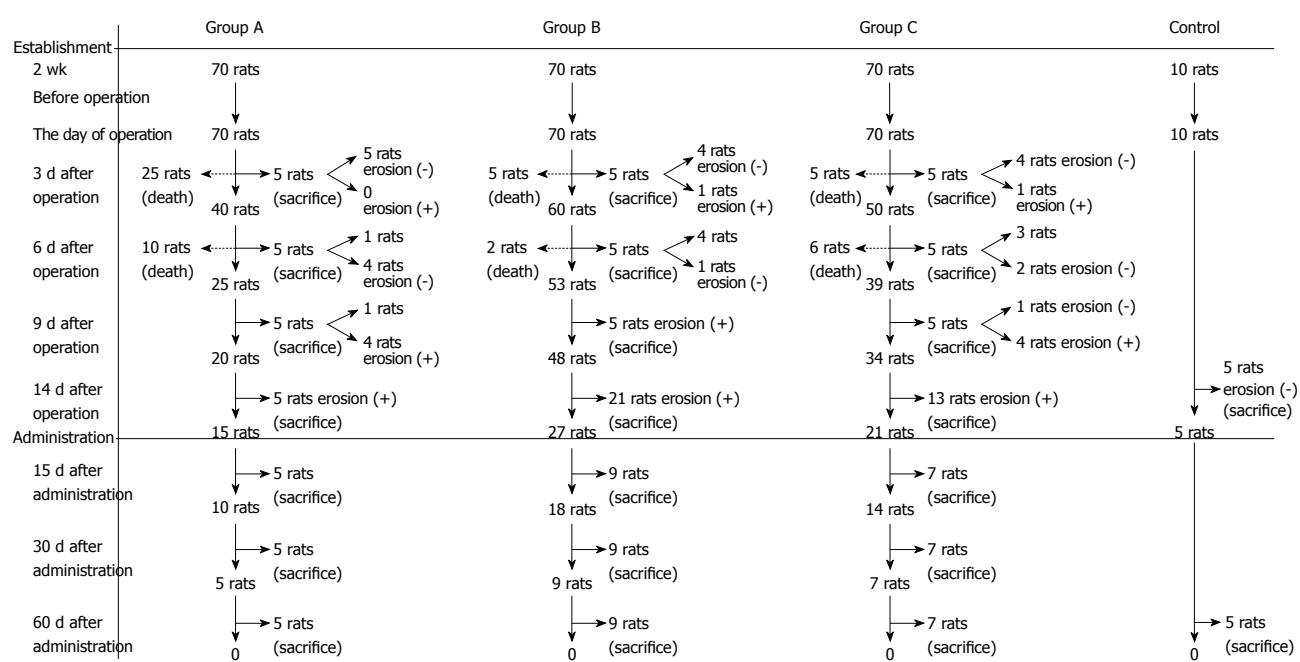

was calculated. In the analysis of correlation between expression of proteins, differences were considered significant at the  $P < 0.05$  level.

## RESULTS

At post-procedure day 14, the RE model was established in all group A-, B- and C-sacrificed rats. By gross and microscopic observation, we ascertained that the mucosa was damaged and thickened as the disease progressed. Figure 1 helps illustrate the establishment of the animal models with the three modified procedures. In the modified RE models, the survival of group A was 50% at day 14 after procedures ( $n = 35/70$ ); 90% ( $n = 63/70$ ) for group B, and 70% ( $n = 49/70$ ) for group C. At 14 d after the procedures, the RE models were established in all the rats ( $n = 39/39$ ). Survival and incidence of RE are shown in Figure 2. At days 3, 6 and 9 after the procedures, the average weight of rats in the model groups continuously decreased as compared to the control group. In aluminum phosphate-treated rats, the average weight improved as treatment progressed and was comparable to the control group at 1 mo afterward.

#### Gross observation and histological assessment

In RE models, erosions of various sizes could be seen in the mucosa, while no erosion was detected in the control group. In most cases, esophagitis occurred in the middle-low part of esophagus. Histologically, the normal esophagus revealed a thin epithelial layer with squamous cells (Figure 3A). In experimental RE models, the epithelium was markedly thickened and the lamina propria papillae were elongated into the epithelium. Basal cell hyperplasia and inflammatory cell infiltration were prominent in the lamina propria and the thickness of the esophageal epithelium increased with time in RE models (Figure 3B-E). In the control group, no expression of IL-6 was detected; claudin-1, occludin, ZO-1 and JAM-1 could be seen on the cellular

**Figure 2** Survival and incidence of RE. The modeling details are described. RE incidence rate was 100% 2 wk after treatment and rat survival rate was 50% ( $n = 35/70$ ) in group A, 90% ( $n = 63/70$ ) in group B and 70% ( $n = 49/70$ ) in group C.

membrane of the esophageal epithelial cells, mostly in the spinous and granular layers, while DSA-1 and JAM-1 could be seen on the cellular membrane of all mucosal layers. Amongst these proteins, DSG-1 had the highest expression level. In RE model rats, expression of IL-6 was only seen in inflammatory cells; the expression levels of claudin-1, occludin, ZO-1, JAM-1 and DSG-1 increased in both the cellular membrane and cytoplasm of spinous and granular layers in the mucosa around erosions, and these proteins were seen in cytoplasm as well as in membrane. However, as hyperplasia continued in the basal cells, expression of claudin-1, occludin, ZO-1, JAM-1 and DSG-1 decreased in individual cells of the spinous and granular layers (Figure 4A-C). One month after treatment started, the histological changes of RE disappeared in acid RE rats, with comparable expression levels of the proteins to the control group. Treatment was not effective for alkaline RE rats, in which hyperplasia and elevated expression of IL-6 continued and vesicles could be seen. But expression of these proteins was significantly lower in individual cells as compared to control group (Figure 5).

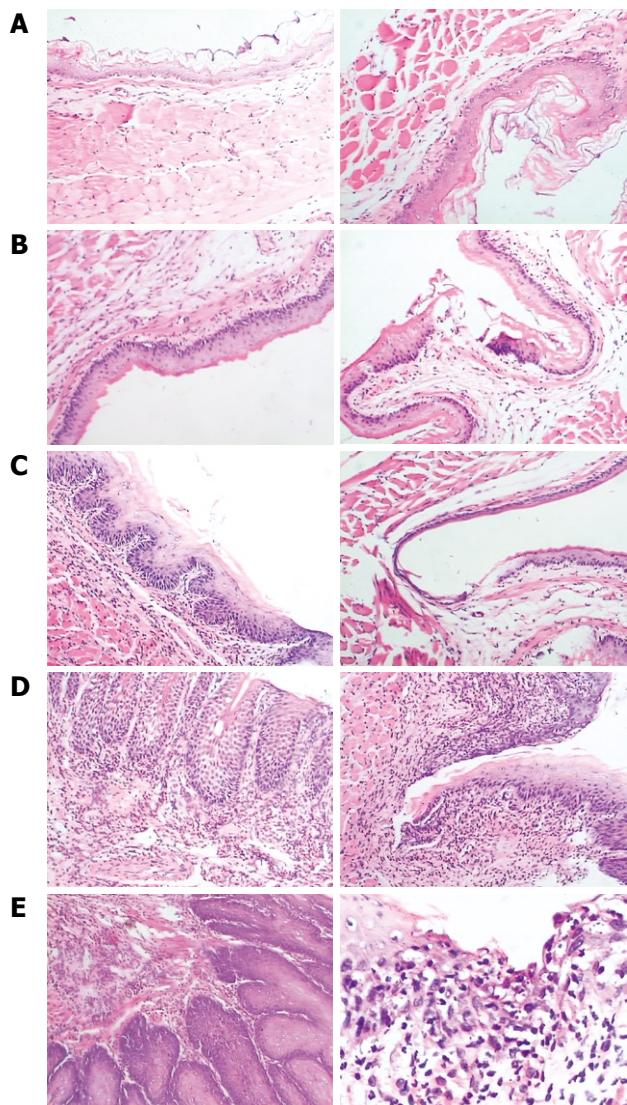

#### Changes in ultra-micro structures under TEM

As shown with TEM, the nucleus and cellular membrane were generally intact. However, a swollen cellular membrane within the intercellular space was noted; intercellular space was significantly wider in some cells, with fewer or even no desmosomes in these widened spaces. The number of desmosomes per unit area decreased as well. In RE rats, the width of the intercellular space was  $2.39 \pm 0.42 \mu\text{m}$ . As for the control rats, the width was  $0.63 \pm 0.21 \mu\text{m}$ , which was significantly smaller as compared to that in the RE rats ( $P < 0.05$ ). The average number of desmosomes was  $0.124$

$\pm 0.044/\mu\text{m}^2$ , which was also significantly smaller than that observed in the control group ( $0.221 \pm 0.031/\mu\text{m}^2$ ,  $P < 0.05$ ) (Figure 6).

#### Western blotting and RT-PCR

Compared to the control group, the Western blottings revealed that the expression levels of IL-6, claudin-1, occludin, ZO-1, JAM-1 and DSG-1 increased with time in the RE groups. In the aluminum phosphate-treated acid RE rats, the expression levels of claudin-1, occludin, ZO-1, JAM-1 and DSG-1 gradually decreased as treatment progressed and reverted to normal levels 30 d after treatment initiation. As for the mixed RE rats, the expression levels of IL-6, claudin-1, occludin, ZO-1, JAM-1 and DSG-1 returned to normal within 60 d after treatment initiation, while the expression levels of these proteins in the alkaline RE rats were markedly high at all time points during the study (Figures 7 and 8). The results of the Western blotting and RT-PCRs suggested that as the expression level of IL-6 increased, those of claudin-1, occludin, ZO-1, JAM-1 and DSG-1 increased as well and became more prominent as the disease progressed. Within 30 d after initiation of the aluminum phosphate treatment, the Western blotting and RT-PCR results indicated that the expression levels of IL-6, claudin-1, occludin, ZO-1, JAM-1 and DSG-1 in the acid RE rats (group A) decreased gradually and became comparable to that of the normal control group. Hyperplasia and widening of the intercellular spaces were restored as observed by microscopy. At day 60, the Western blotting and RT-PCR results suggested that the expression levels of these proteins decreased gradually in the mixed RE rats (group C), but increased dramatically in the alkaline reflux group (group B).

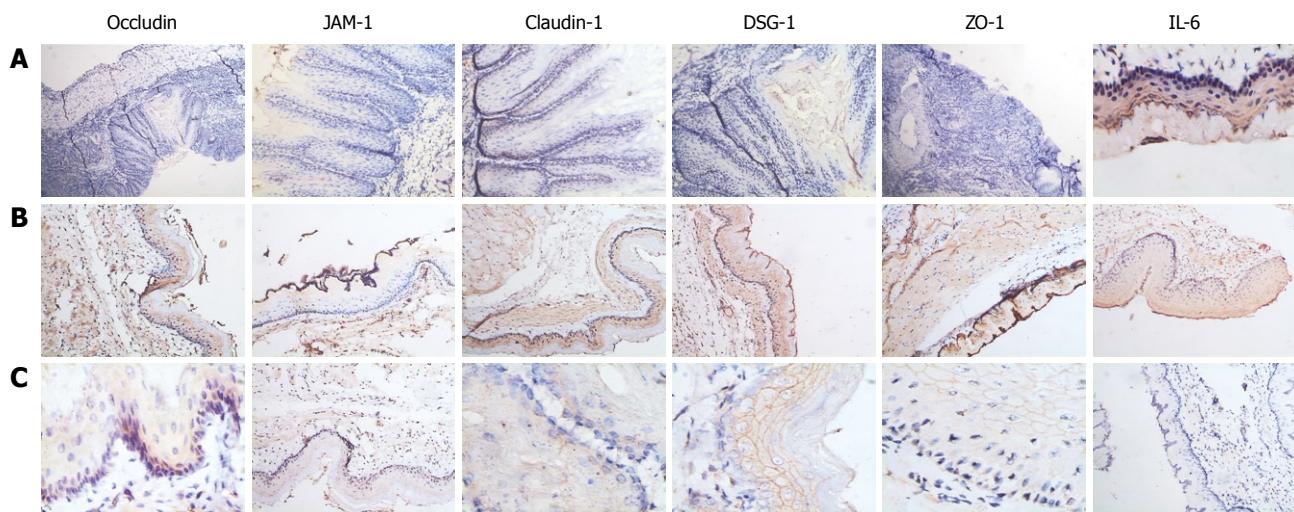

**Figure 3** Histological findings of control esophagus and chronic reflux esophagitis ( $\times 100$ ). A: Normal mucosa; B: At day 3 after operation; C: At day 6 after operation; D: At day 9 after operation; E: at day 14 after operation. B-E (left): Basal cell hyperplasia became severe along with the reflux time; B-E (right): Epithelial mucosa ulcer became severe along with the reflux time.

## DISCUSSION

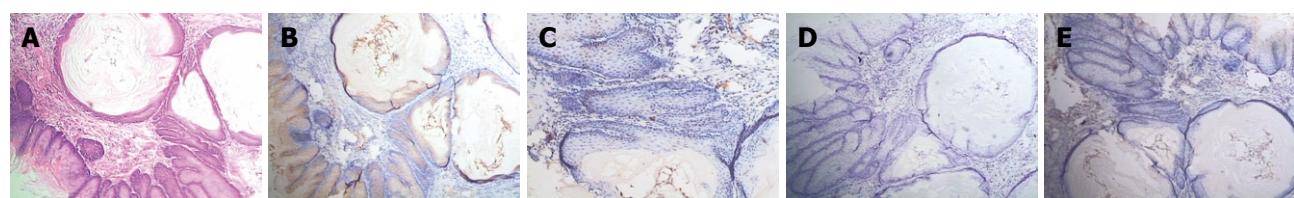

Numerous studies have described the establishment of animal models of RE. The success rate was about 10% when the rat model was created by using the method described by Yu *et al*<sup>[5]</sup>. Most rats died of reflux-related complications, such as asphyxia, pulmonary edema and pulmonary hemorrhage. Therefore, we modified their method by using a 2.0 mm metal tube in the partial pyloric ligation instead of a 1.5 mm tube. Furthermore, in our study, the tube was not inserted into the stomach as it was in Qiang Yu's method, which helped avoid artificial gastric perforation. These modifications increased the success rate to 50% ( $n = 35/70$ ). Two weeks after the procedures, the success rate was 100% ( $n = 5/5$ ) as confirmed by histological examination. RE models created with the other procedures were even more stable, with higher survival levels of 70% and

90%. Prominent hyperplasia and erosion appeared at post-procedure day 6. At post-procedure day 14, the RE model was established in all examined rats<sup>[8]</sup>.

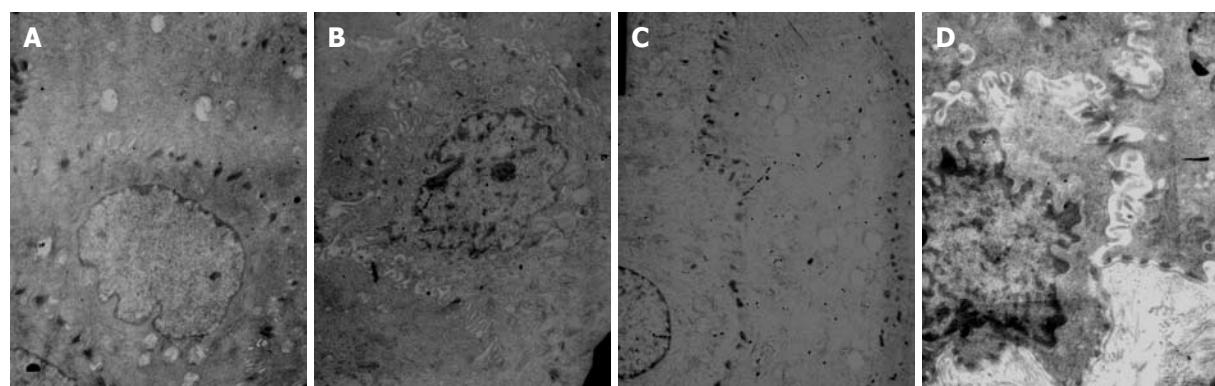

Histological assessment of the esophagitis models showed that the epithelium was significantly thickened; the lamina propria mucosa was markedly elongated into the epithelium. Inflammatory cell infiltration was noted in lamina propria. Such histological findings were extremely similar to those seen in examples of human RE. Thus, these models can help us deduce the development of the process of erosion. In our study, no prominent erosions were noticed within 6 d after the procedure. However, microscopic observation revealed that the thickness of the esophageal mucosa had already increased at this time point, and continued to increase with time. This finding suggested that irritants such as inflammation had promoted cellular proliferation and epithelial hyperplasia before the erosions occurred<sup>[10,11]</sup>. Moreover, we found that expression levels of claudin-1, occludin, ZO-1, JAM-1 and DSG-1 in the model rats were significantly higher than that of the control group; however, as hyperplasia of basal cells occurred, expression of these proteins in the individual cells decreased. These findings suggested elevated expression of these proteins was an early molecular event in the pathogenesis of RE, which occurred significantly earlier than hyperplasia. In the immunohistochemical staining, we noted that DSG-1 could be found on the membrane in all layers of the mucosa and had the highest expression level among these proteins, which suggests that the desmosome is the main cell junction in the esophageal epithelium. With TEM, we found that as RE progressed, the swollen cellular membrane within the intercellular space was noted in model rats in comparison with control rats; the intercellular space was significantly widened in some cells, with fewer or even no desmosomes in these spaces, which was consistent with the findings of Calabrese *et al*<sup>[2]</sup> and Tobey *et al*<sup>[12]</sup> in 2003. Western blottings and RT-PCR revealed that, as the expression of the inflammatory factor IL-6 increased in the model rats, the expression levels of claudin-1, occludin, ZO-1, JAM-1 and DSG-1 in esophageal mucosa increased as well. With the information from immunohistochemical assays, we found that the expression level of these TJ proteins in the model rats was significantly higher than that in control rats as early as 3 d after the procedures, but the Western blotting and RT-PCR suggested that the total amount of these proteins remained the same at this time point. When elevated expression levels of these proteins were detected by these assays, we could see hyperplasia in the basal cells under the microscope, while expression of these proteins decreased in the individual cells. These findings suggest that hyperplastic cell populations require more cell junctions and more cell junction proteins, but production of these proteins has started to decrease in individual cells, which leads to failure of cell junctions in these cells. A possible explanation is: when reflux occurs and TJs and desmosomes in

**Figure 4** Immunostaining for occludin, JAM-1, claudin-1, DSG-1, ZO-1, IL-6 in controls and reflux esophagitis model ( $\times 400$ ). A: Protein expression on day 14 in chronic RE model; B: Protein expression on day 3 in chronic RE model; C: Protein expression on day 14 in control esophagus.

**Figure 5** HE and immunostaining ( $\times 40$ ). A: HE; B: DSG-1; C: Claudin-1; D: ZO-1; E: JAM-1. Hyperplasia and vesicles could be seen, but expression of these proteins was significantly lower in individual cells as compared to control group.

the intercellular space are damaged, the cells begin to express more TJ and desmosome proteins in response in an effort to repair the damaged TJs and desmosomes; if damage persists and reflux starts to provoke hyperplasia, even more proteins are needed in the formation of cell junctions in these new cells. At this point, the production of TJ proteins and desmosome proteins falls short of the need, which leads to the failure of this protein compensating mechanism. Subsequent decreased expression of these proteins in individual cells leads to failure of cell junctions and further widening of the intercellular space and elevated permeability in the esophageal epithelium, resulting in damaged epithelial

defense and the pathological changes of RE, such as swollen mucosa, erosion and ulcer. These findings also suggest that elevated expression of claudin-1, occludin, ZO-1, JAM-1 and DSG-1 is a part of the pathogenesis of RE and an early molecular event in the development and progression of RE, and also one protective mechanism against the damage in RE.

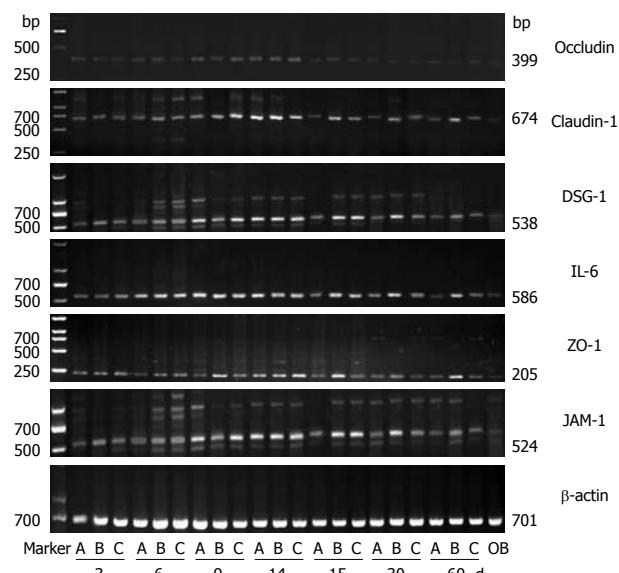

In 2005, Calabrese *et al*<sup>[2]</sup> found that widening of the intercellular spaces in squamous cells of the lower esophagus in patients with GERD could be restored after being treated with omeprazole for 3-6 mo. In our study, we treated RE rats with aluminum phosphate and it emerged that the three groups of rats responded

**Figure 7 Western blotting.** A: Model GER (acid reflux esophagitis); B: Model DER (alkaline reflux esophagitis); C: Model DG-ER (mixed reflux esophagitis). 1: Samples from control rats ( $n = 5$ ); 2-8: Samples from rats with 3, 6, 9, 14, 15, 30 and 60 d after operation ( $n = 5$ ).

differently to the treatment, with the most significant efficacy noticed in acid RE rats. Western blotting and RT-PCR assays suggested the expression of claudin-1, occludin, ZO-1, JAM-1 and DSG-1 decreased in these rats accordingly and gradually. At 1 mo after treatment started, expression of these proteins reverted to normal levels. Microscopic observation revealed that swelling and hyperplasia of the basal cells were restored, and the intercellular space was comparable to the normal controls. Within 60 d after treatment started, expression of these proteins gradually decreased in mixed RE rats, with milder hyperplasia under the microscope as compared to alkaline RE rats; swollen mucosa, erosion and ulcer disappeared as well. However, no significant treatment benefit was seen in alkaline RE rats. Western blotting and RT-PCR assays revealed that with persistent elevated expression of IL-6, claudin-1, occludin, ZO-1, JAM-1 and DSG-1, hyperplasia continued and vesicles developed. Microscopically, we found that expression of cell junction proteins was significantly lower in individual cells compared to those of control group. Aluminum phosphate is a weak acidic insoluble gel with a high level of absorbance. It creates a colloid membrane that lasts for 1.5 h on the surface of the esophageal and gastric mucosa. It can also repair damaged digestive mucosa by preventing erosions caused by esophageal reflux and gastric acid, and by preventing self-digestion induced by digestive juice. Therefore, it is more effective in treating acid RE.

Result of the four TJ proteins and one desmosome protein in our study revealed positive correlation between two of these proteins, which suggests that positive regulation and synergism might occur in the pathogenesis of esophagitis and that these proteins function as a group. Furuse *et al*<sup>[13]</sup> found TJs in occludin gene-deleted rats, indicating that these four TJ proteins work in synergism in maintaining cell junctions. Claudins, the main components of TJs, are potent adhesive proteins that create a cell junction and seal the intercellular space<sup>[14]</sup>. They also play an important role in specific functions of TJs, such as fence and barrier functions. Altered expression of claudins might lead to malformation of TJs. Occludins are mainly seen in TJ fibrils and are involved in signal transduction in the formation of TJs<sup>[15-17]</sup>. ZO-1

**Figure 8 RT-PCR.** Samples from rats with 3, 6, 9, 14, 15, 30 and 60 d after operation. A: GER model; B: DER model; C: DG-ER model; OB: Samples from control rats ( $n = 5$ ).

is a bridge that connects the TJs to intracellular structures<sup>[18-20]</sup>, while JAM has a role in regulating permeability of TJs<sup>[21,22]</sup>. Desmosomes, a kind of cell junction that specifically localizes in epithelium and mainly consists of DSG, is a structure that facilitates connection and signal transduction between cells. Inspired by the pathogenesis of inflammatory bowel disease<sup>[23-25]</sup> as described by Gassler *et al*<sup>[26]</sup>, we deduce that from the outset, esophageal reflux might destroy the structure of claudin-1 and occludin, and then ZO-1 fails to connect claudin-1 to the cellular membrane resulting in the re-distribution of ZO-1 and damage to the TJs and a subsequent increase in the permeability of esophageal epithelium; in response, expression of JAM and DSG increases, leading to more damage to the desmosomes, and eventually RE. These findings have certain implications in explaining the molecular mechanism of RE.

Statistical analysis was done to investigate the correlation between IL-6 and TJ proteins, and desmosome proteins. The results revealed no correlation. IL-6, an inflammatory factor in the development and progression of RE, is a pleiotropic cytokine produced by monocytes/macrophages. Jia *et al*<sup>[27]</sup> indicated that the IL-6 level in patients with active ulcerative colitis (UC) was markedly higher than that in patients with inactive disease and normal controls, but was not related to site and scale of the lesion. Martinez de Haro *et al*<sup>[11]</sup> found that the IL-6 level in normal mucosa of patients was higher than in normal controls but levels were not significantly different between normal mucosa and affected mucosa obtained from the same patient. These data suggest that the IL-6 level might reflect the activity of UC and RE to a certain extent.

Hamaguchi *et al*<sup>[28]</sup> found that in chronic esophagitis rats, expression of cytokines and adhesive molecules increased. Although currently, we don't see any connection between cytokines and TJ proteins, we might assume

that inflammatory cytokines and subsequent damage to the tissue might have regulated the permeability of esophageal epithelium in esophagitis. Cytokines might damage the barrier function and increase the permeability of the epithelium.

In summary, in molecular cell biology and microscopic technology which accelerate research in this field<sup>[29,30]</sup>, we now have an increasingly profound understanding of the function and structure of TJ, TJ proteins' regulation of the TJ formation and structure, as well as the roles of epithelial permeability and TJs in epithelial defense. Simonovic *et al*<sup>[31]</sup> and Jin *et al*<sup>[32]</sup> proposed that phosphorylation of occludins was the determinant factor in the distribution of these proteins, but its regulating mechanism, as well as the biological mechanism underlying the feedback regulation of these proteins, are still unclear and need to be further explored in more studies.

## COMMENTS

### Background

Tight junction (TJ) and desmosome proteins in esophageal epithelium create a circular substance-blocking barrier between adjacent cells. These proteins function in cell adhesion, contribute to cell polarity and permeability and facilitate signal transduction in cell proliferation and differentiation. We investigated the correlation between the expression levels of IL-6 and the proteins in TJs, including claudin 1, occludin, ZO-1, JAM-1 and DSG-1, in the esophageal mucosa of rats modeling different types of reflux esophagitis (RE), and the ability of aluminum phosphate to protect against RE-induced mucosal damage via these proteins.

### Innovations and breakthroughs

Further investigations are warranted using experiments testing the hypothesis that altered expression of TJ proteins (claudin 1, occludin, ZO-1, JAM-1) and desmosome proteins (DSG-1) results in failure of TJs and desmosomes, which thus leads to widened intercellular space and contributes to RE. Moreover, some rats were treated with aluminum phosphate to determine its efficacy in treating RE.

### Applications

These findings indicate that increased expression of TJ proteins, as an early molecular event, is involved in RE development and that IL-6 is an inflammatory factor in this process. Aluminum phosphate significantly protects esophageal mucosa by enhancing its defense against damage. However, efficacy of the drug is related to pH value of the reflux: it is effective in treating acid RE rather than alkaline RE.

### Terminology

GERD occurs when stomach and duodenal contents reflux into the esophagus. Reflux-induced damage to, and inflammation in, the esophageal mucosa are referred to as RE. TJs create a circular substance-blocking barrier between adjacent cells. TJs also function in cell adhesion, cell polarity and permeability, and in signal transduction resulting in cell proliferation and differentiation. Intercellular TJs consist mainly of claudins, occludins, JAM and ZOs.

### Peer review

This interesting study was to determine the changes of IL-6 and various TJ proteins in the esophageal mucosa induced by RE. Authors conducted these studies in rats and nicely correlated between the expression pattern of claudin, occludin, ZO-1 and JAM-1 proteins in different types of RE and the ability of aluminum phosphate to protect against RE. Results presented in this manuscript showed that there is a significant difference between RE induced and sham-control groups.

### Abstract

**AIM:** To evaluate the accuracy of spot urinary Na/K and Na/creatinine (Cr) ratios as an alternative to 24-h urinary sodium in monitoring dietary compliance in patients with liver cirrhosis and ascites treated with diuretics.

**METHODS:** The study was carried on 40 patients with liver cirrhosis and ascites treated with diuretic therapy. Patients were divided into two groups according to 24-h urinary sodium. We measured spot urine Na/K ratio, Na/Cr ratio and 24-h urinary sodium. Student's *t* test was used to compare the interval variables and  $\chi^2$  test to compare the nominal variables between the two groups. Receiver operator characteristic curve was used to identify the best cutoff point for Na/K and Na/Cr ratio.

**RESULTS:** The best cutoff point for Na/K ratio was 2.5 ( $P < 0.001$ ) and area under the curve (AUC) was 0.9, and for Na/Cr ratio, the best cutoff point was 35 ( $P < 0.001$ ) and AUC was 0.885. Na/K ratio showed higher sensitivity and accuracy compared to Na/Cr ratio (87.5% and 87% for Na/K ratio; 81% and 85% for Na/Cr ratio, respectively).

**CONCLUSION:** Spot urine Na/K ratio has adequate accuracy for assessment of dietary sodium restriction

compared with 24-h urinary sodium in patients with liver cirrhosis and ascites.

### INTRODUCTION

Ascites is considered to be the most common of the three major complications of cirrhosis; other complications are hepatic encephalopathy and variceal bleeding. It is estimated that about 50% of patients with compensated cirrhosis will develop ascites within 10 years of observation<sup>[1]</sup>. The development of ascites in patients with liver cirrhosis is associated with poor prognosis and an increased risk of mortality, as approximately 50% of patients with ascites are expected to succumb within 2 years<sup>[2]</sup>.

The development of ascites is secondary to renal retention of sodium and water because of underlying activation of neurohormonal mechanisms<sup>[3]</sup>. Therefore, patients who accumulate ascites have urinary excretion of sodium that is significantly lower than their dietary salt intake. This means that, in order to achieve successful ascites mobilization, patients should have a negative sodium balance. This can be achieved through education regarding dietary sodium restriction (2 g/d) in addition to oral diuretic therapy<sup>[4]</sup>. The usual diuretic regimen starts with single morning doses of oral spironolactone (100 mg) and furosemide (40 mg). Efficacy of therapy is monitored through the goal of average weight loss of 300-500 g/d in patients without peripheral edema and 800-1000 g/d in those with peripheral edema. Doses can be increased gradually in patients who show inadequate response,

to reach a maximum of 400 mg/d spironolactone and 160 mg/d furosemide<sup>[5]</sup>.

This approach is effective in approximately 90% of patients and 10% are considered diuretic-resistant and second-line therapy is indicated for ascites mobilization<sup>[6]</sup>. However, patients who are not compliant with diet may also show inadequate response to maximum diuretic doses. Assessment of dietary compliance is important in order to avoid mislabeling patients with refractory ascites, while their problem is inadequate dietary salt restriction<sup>[7]</sup>. Several methods have been suggested for assessment of dietary compliance: (1) The usual method is measuring 24-h urinary sodium excretion. Patients who gain weight despite excreting more than 78 mEq Na/d are not compliant with the diet<sup>[8]</sup>. However, the main problem here is that it may be difficult for the patient to accurately collect 24 h urine. At the same time, using spot urinary sodium is easier for the patient but it is not accurate because of the lack of uniform excretion of sodium throughout the day. (2) Furosemide-induced natriuresis can be used. A single intravenous 80-mg dose of furosemide is given and urinary sodium is measured in the next 8 h. Patients with diuretic resistance have sodium excretion < 50 mEq/8 h<sup>[9,10]</sup>. (3) There is some evidence that spot urinary Na/K ratio may be as helpful as 24-h urinary sodium collection, with adequate accuracy, when the ratio more than a given cut value (one in some studies) is equivalent to 24 h sodium more than 78 mmol Na/d<sup>[11,12]</sup>.

The aim of this study was to assess the accuracy of spot urinary Na/K and Na/creatinine (Cr) ratio for assessment of dietary sodium restriction in patients with liver cirrhosis and ascites treated with diuretic therapy.

## MATERIALS AND METHODS

The study was conducted on 40 patients (28 male and 12 female; mean age 50 ± 4.5 years) with liver cirrhosis and ascites treated with diuretics, who were admitted to the Department of Internal Medicine in Ain Shams University Hospitals. The study was performed according to the ethical standards for human experimentation and was approved by the scientific committee of Ain Shams University. Informed consent was obtained from the selected patients after explaining the aim of the study and the nature of the investigations required. Liver cirrhosis was documented by clinical assessment, laboratory findings and evidence of liver cirrhosis upon abdominal ultrasound. Ascitic fluid analysis was done to exclude malignancy and spontaneous bacterial peritonitis. Patients with evidence of portosystemic encephalopathy or intrinsic renal disease were excluded from the study. All patients had normal kidneys upon ultrasound and no proteinuria or active urinary sediment upon urine analysis. Daily monitoring of patient weight and lack of response to diuretics was defined according to the consensus conference of the International Ascites Club, which is mean weight loss of < 0.8 kg over 4 d<sup>[5]</sup>.

Collection of 24-h urine sample for calculation of sodium was done in sterile plastic containers by recording the volume in 24 h, starting at 08:00. Verbal instructions

were given to assure completeness of collection. Samples were centrifuged and sodium concentration was measured in mEq/L using a Beckman Synchron CX5 ISE (NJ, USA) chemistry analyzer. All samples were processed on the day of collection. In order to obtain the whole 24-h urinary sodium, we multiplied sodium concentration by the volume in liters. Spot urine samples were collected for measurement of sodium, potassium and creatinine. Samples were handled as previously described for 24-h samples, except that volume was not recorded, as it has no significance in this setting. Patients were divided into two groups according to 24-h urinary sodium.

## Statistical analysis

Data were collected, revised, verified and edited on a PC. Data were then analyzed statistically using SPSS statistical package version 25 (SPSS, Chicago, IL, USA). Patients were divided according to 24-h urinary sodium excretion into diuretic-resistant (16 patients with 24-h urinary sodium < 78 mEq) and diuretic-sensitive (24 patients with 24-h urinary sodium ≥ 78 mEq). Data were reported in the form of mean ± SD. Student's *t* test was used to compare the interval variables and the  $\chi^2$  test was used to compare the nominal variables between the two groups. Correlation between 24-h urinary sodium and other variables was done using Pearson correlation. In order to identify the best cutoff point for Na/K ratio and Na/Cr ratio, a receiver operator characteristic (ROC) curve was used.  $P < 0.05$  was considered statistically significant.

## RESULTS

According to the type of diuretic used, 28 patients were taking furosemide and spironolactone in combination; four, furosemide alone; three, spironolactone alone; and five, spironolactone in combination with bumetanide. There was no significant difference between the two groups with regard to type of diuretics used.

As shown in Table 1, there was no significant difference between the groups as regards age, sex, serum creatinine, serum potassium, liver enzymes, serum bilirubin, total proteins, international normalized ratio or partial thromboplastin time. The following parameters were significantly lower in the diuretic-resistant group: serum sodium, serum albumin, white blood cell (WBC) count and platelet count. However, the diuretic-resistant patients had higher blood urea nitrogen (BUN) and higher Child score. Table 2 shows that 24-h urinary sodium, spot urine Na/K ratio and spot urine Na/Cr ratio were significantly lower in the diuretic-resistant patients.

Significant correlation was noted between 24-h urinary sodium and Na/K ratio ( $r = 0.76, P = 0.001$ ), Na/Cr ratio ( $r = 0.56, P = 0.001$ ), serum sodium ( $r = 0.59, P = 0.001$ ), serum BUN ( $r = -0.31, P = 0.046$ ) and Child score ( $r = -0.31, P = 0.05$ ).

## Determination of best cutoff point for Na/K ratio

Figure 1A represents the ROC curve for the best cutoff point to differentiate between diuretic sensitivity and resistance using spot urine Na/K ratio. Area under

**Table 1** Patients characteristics (mean  $\pm$  SD)

	Diuretic-resistant group (n = 24)	Diuretic-sensitive group (n = 16)	P
Age (yr)	50 $\pm$ 4	49 $\pm$ 4	NS
Sex ratio (Male/female)	17/7	11/5	NS
Weight loss (yes/no)	0/24	9/7	0.001
Serum creatinine (mg/dL)	1.1 $\pm$ 0.2	0.9 $\pm$ 0.2	NS
BUN (mg/dL)	23.5 $\pm$ 8.3	18.5 $\pm$ 8.3	0.033
Serum sodium (mEq/L)	128 $\pm$ 5	136 $\pm$ 5	0.001
Serum potassium (mEq/L)	4.3 $\pm$ 0.6	4.3 $\pm$ 0.5	NS
AST (U/L)	68 $\pm$ 34	69 $\pm$ 40	NS

**Table 3** Sensitivity and specificity of different Na/K and Na/Cr ratios in determination of diuretic resistance or sensitivity

Ratio	Sens (%)	Spec (%)	PPV (%)	NPV (%)	Acc (%)
Na/K ratio	1	93.8	58.3	76.7	90.0
	2.5	87.5	87.5	91.3	82.4
	3.5	50	95.8	92.3	55.6
Na/Cr ratio	20	93.8	66.7	82.1	91.7
	35	81	87.5	91	77.8
	45	62.5	87.5	88.2	60.9

PPV: Positive predictive value; NPV: Negative predictive value; Sens: Sensitivity; Spec: Specificity; Acc: Accuracy.

the curve (AUC) was 0.9 and  $P < 0.001$ . According to the curve, the best cutoff point was 2.5, with 87.5% sensitivity and specificity and 85% accuracy. Using higher or lower cutoff points shows lower accuracy although sensitivity or specificity may be higher (Table 3).

#### Determination of best cutoff point for Na/Cr ratio

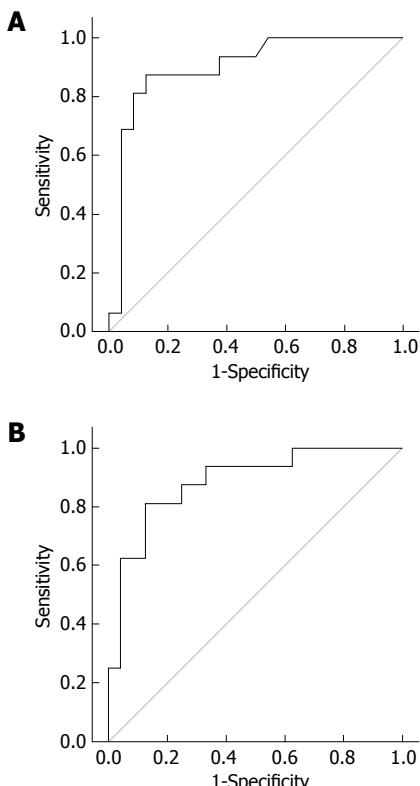

For Na/Cr ratio, AUC was 0.885 and  $P$  was  $< 0.001$ . The best cutoff point according to the curve (Figure 1B) was 35, with 81.3% sensitivity, 87.5% specificity and 87% accuracy. Other cutoff values showed lower accuracy (Table 3).

## DISCUSSION

During treatment of ascites in patients with liver cirrhosis, excess sodium intake can be misinterpreted as diuretic unresponsiveness, as in the present study, seven patients showed no weight loss in response to diuretics, while their 24-h sodium excretion was  $> 78$  mEq. Appropriate identification of such patients is also important to avoid complications of unnecessary increase in diuretic dosage

**Table 2** Difference between groups as regards 24-h urinary sodium and spot urine ratios (mean  $\pm$  SD)

	Diuretic-resistant group (n = 24)	Diuretic-sensitive group (n = 16)	P
24 h urinary sodium (mEq)	33 $\pm$ 19	126 $\pm$ 46	0.001
Spot urine Na/K ratio	1.3 $\pm$ 1.3	3.7 $\pm$ 1.6	0.001
Spot urine Na/Cr ratio	21 $\pm$ 18	100 $\pm$ 87	0.001

**Figure 1** ROC curve for the best cutoff point to differentiate between diuretic sensitivity and resistance using spot urine Na/K ratio (A) and Na/Cr ratio (B).

(mainly encephalopathy and electrolyte disturbance) and complications of unnecessary large volume paracentesis (mainly mechanical trauma, post-paracentesis circulatory dysfunction and possible increased incidence of spontaneous bacterial peritonitis caused by ascitic fluid protein depletion)<sup>[13]</sup>.

Measuring 24-h urinary sodium is used currently to identify such patients; however, it may be difficult for patients to collect urine appropriately and lack of appropriate collection can lead to false low results, and again, false-labeling of the patient as unresponsive to diuretics. Using 24-h urinary creatinine has been proposed as a method to ensure adequate collection of urine<sup>[14]</sup>, but even this may not be accurate, because patients with advanced liver cirrhosis can have muscle wasting, and therefore, lower creatinine excretion in urine, even with complete collection<sup>[15]</sup>.

The present study shows that spot urine Na/K ratio can be used as an easier alternative to 24-h urinary sodium excretion, with adequate accuracy. At the best cutoff point, Na/K ratio was shown to be more accurate than

Na/Cr ratio, with better sensitivity and specificity. Similar observations as regards spot urine Na/K ratio have been made by others<sup>[11,12]</sup>. However, according to these other studies, the best cutoff point is 1, while in the present study, the best sensitivity, specificity and accuracy was noted at a cutoff point of 2.5. This difference may have been caused by a difference in types of diuretics used, which may affect urinary sodium and potassium excretion. Further studies are needed with classification of patients into groups according to types of diuretics used in order to document any significant effect on Na/K ratio.

Another test used is furosemide-induced natriuresis, which can identify diuretic unresponsiveness with adequate accuracy<sup>[9,10]</sup>. However, it still needs urine collection for 8 h after furosemide administration. At the same time, it can identify patients with refractory ascites (those who do not respond to maximum doses of diuretics), even before reaching the maximum dose, which is an advantage over spot urine Na/K ratio. Probably we should use Na/K ratio for routine assessment of sodium restriction during diuretic therapy, and keep the furosemide-induced natriuresis test for patients that we suspect are completely resistant to medical treatment, therefore, we can make early referral for liver transplantation or procedures like transjugular intrahepatic portosystemic shunt.

Patients with more advanced liver disease have more deterioration in liver function and marked degrees of circulatory dysfunction and neurohumoral activation [including antidiuretic hormone (ADH)], which results in enhanced sodium renal tubular reabsorption, and therefore, more diuretic resistance<sup>[16]</sup>. It has been shown also by another study that lower urinary sodium in cirrhotic patients with ascites is associated with reduced survival<sup>[17]</sup>. This was noted in the present study, as patients with lower urinary sodium had more advanced liver disease in the form of lower serum albumin and higher Child-Pugh score. Also, lower serum sodium in the resistant group represents more impairment of free water excretion because of a high level of ADH that leads to dilutional hyponatremia in patients with more resistant ascites<sup>[7,18]</sup>.

According to the main theory of ascites formation, the initial step in pathogenesis is the development of portal hypertension<sup>[16]</sup>. Platelet and WBC counts are already suggested as noninvasive tests for prediction of esophageal varices<sup>[19,20]</sup>, another complication of portal hypertension. The lower platelet and WBC counts associated with diuretic resistance in the present study may also represent more advanced liver disease and more severe portal hypertension in the unresponsive patients.

One of the results of neurohormonal activation in advanced liver disease is renal vasoconstriction, which may reduce the glomerular filtration rate (GFR) and present later as hepatorenal syndrome<sup>[6,21]</sup>. The reduction in GFR in these patients may be masked by serum creatinine concentration that appears to be within the normal range, with a GFR as low as 20 mL/min<sup>[15,22]</sup>. In the present study, patients in the resistant group had higher BUN, which was similar to that in a previous study<sup>[12]</sup>. This may represent impairment in renal function masked by normal serum creatinine.

In conclusion, dietary sodium restriction is essential in mobilization of ascites caused by liver cirrhosis in addition to diuretics. Monitoring of dietary compliance is essential and exclusion of excess sodium intake is important in patients who appear unresponsive to diuretics. However, this is often missed, perhaps because of the difficulty of 24-h urine collection. Using spot urine Na/K ratio may be as accurate as 24-h urinary sodium measurement, with the advantage of being more applicable for the patient. However, further studies are still needed before accepting this test in practice, mainly testing the effect of the type of diuretic used on the best cutoff value. Another point we recommend testing is whether there is diurnal variation for this ratio, and if there is a preference for a first morning voiding sample.

## ACKNOWLEDGMENTS

The authors thank Dr. Yahya Makkeyah for his helpful assistance in statistical analysis and interpretation of the data.

## COMMENTS

### Background

Monitoring dietary compliance is an important aspect in treatment of ascites caused by liver cirrhosis. The standard test used is 24-h urinary sodium, however, its use is limited by difficulty of urine collection over 24 h. Few studies have evaluated spot urine Na/K ratio as an alternative.

### Research frontiers

In the present study, the standard 24-h urine test was compared to spot urine Na/K and Na/creatinine (Cr) ratio in patients with ascites caused by cirrhosis, treated with diuretics.

### Innovations and breakthroughs

The present study showed adequate accuracy for spot urine tests when compared to 24-h urinary sodium assessment. The accuracy, sensitivity and specificity of Na/K ratio are higher than those for Na/Cr ratio. Also, the study showed greater deterioration in liver function in patients who had lower urinary sodium excretion.

### Applications

Na/K ratio may be used in clinical practice to monitor dietary sodium compliance in patients with ascites and liver cirrhosis. It should be more convenient for the patient compared to the 24-h urinary sodium test.

### Peer review

Spot urinary Na/K ratio was previously proposed a few years ago as a substitute for 24-h urinary sodium. Nevertheless the first communications were only published as abstracts. As far as we know, this is the first full publication regarding this issue. The statistical procedures are adequate and the methods of the research are good. The only criticism is the low sample size. This paper should be useful for readers of the journal.

### Abstract

**AIM:** To study the efficacy of low-dose imipramine in relieving symptoms associated with the irritable bowel syndrome (IBS).

**METHODS:** A randomized, double-blind trial of 25 mg imipramine vs matched placebo for 12 wk was performed. Doubling the dose was allowed once at week 2 in case of an unsatisfactory early response. Primary efficacy variables were subjective global symptom relief and quality of life (QoL) using SF-36 at week 12.

**RESULTS:** One hundred and seven patients were enrolled by advertisement or referral by general practitioners and 56 (31 imipramine: 25 placebo) completed the 16-wk study. Baseline characteristics were comparable. A high overall dropout rate was noted in the imipramine and placebo arms (47.5% vs 47.9%,  $P > 0.05$ ), a mean of 25.0 and 37.4 d from enrollment, respectively ( $P < 0.05$ ). At the end of 12 wk, there was a significant difference in global symptom relief with imipramine over placebo (per-protocol: 80.6% vs

48.0%,  $P = 0.01$ ) and a trend on intent-to-treat (ITT) analysis (42.4% vs 25.0%,  $P = 0.06$ ). This improvement was evident early and persisted to week 16 ( $P = 0.024$  and 0.053 by per-protocol and ITT analyses, respectively). Mean cumulative and component-specific SF-36 scores improved in the imipramine group only (per-protocol,  $P < 0.01$ ). Drug-related adverse events leading to patient dropout were more common in the imipramine group (25.4% vs 12.5%,  $P > 0.05$ ).

**CONCLUSION:** Imipramine may be effective in the treatment of IBS patients and is associated with improved QoL. Careful patient selection, initiation of a low dose with gradual escalation and monitoring for side effects may result in an improved therapeutic response.

A randomized controlled trial of imipramine in patients with irritable bowel syndrome. *World J Gastroenterol* 2009; 15(29): 3636-3642 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3636.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3636>

### INTRODUCTION

Irritable bowel syndrome (IBS) is a common disorder of the gastrointestinal (GI) tract characterized by abdominal pain or discomfort and altered bowel habits. The exact pathophysiology of IBS remains unclear but is thought to involve altered intestinal motility and increased visceral sensitivity as a result of a dysregulated bidirectional communication between the enteric nervous system and the brain, the so-called brain-gut axis. The role of tricyclic antidepressants (TCAs) in the

treatment of IBS has been systematically reviewed by the American Gastroenterology Association and the American College of Gastroenterology<sup>[1,2]</sup>. TCAs have been found to improve abdominal pain in IBS patients; however there was inadequate evidence to support an effect on improvement of global IBS symptoms. Notably, most randomized, controlled trials of TCAs in IBS were completed before the publication of the ROME II committee recommendations for the study design of treatment trials for IBS and suffered from suboptimal study design, small sample size, and short treatment duration<sup>[3,4]</sup>.

The exact mechanism of action of TCAs is not known, but may be mediated *via* potentiation of adrenergic synapses by blocking uptake of the neurotransmitters, norepinephrine and serotonin, at nerve endings<sup>[5,6]</sup>. Their reported benefit in IBS appears, however, to be unrelated to an antidepressant effect given that a response is commonly noted early and with doses generally well below the effective antidepressant doses. Potential beneficial mechanisms of TCAs in IBS include a reduction in visceral pain sensitivity and, to a lesser extent, their anticholinergic effects.

The aim of this study was to evaluate the efficacy and safety of imipramine hydrochloride, a tertiary amine TCA, in patients with IBS who have failed to respond satisfactorily to antispasmodics. The primary study endpoint was global symptom relief as assessed by the patient at the end of the 12-wk treatment. Secondary endpoints were symptom relief at week 16 and changes in quality of life (QoL) as measured using the short form SF-36 questionnaire.

## MATERIALS AND METHODS

Figure 1 shows the general design of the study. Study subjects were recruited by either advertisements posted in clinics and pharmacies or by referral from primary care or specialty clinics at the American University of Beirut Medical Center (AUBMC). A preliminary telephone interview was conducted for patients who answered to posted advertisements. Those who satisfied inclusion criteria were asked to present for interview and examination by a general practitioner to confirm adherence to study inclusion criteria: (1) fulfillment of the Rome II criteria for the diagnosis of IBS and (2) history of an unsatisfactory response to one or more prescription antispasmodics available on the Lebanese market (trimebutine, mebeverine hydrochloride, otilonium bromide, or alverine citrate). Exclusion criteria were age below 18 years, allergy to imipramine, history of hematochezia or melena, constitutive symptoms (such as fever and weight loss), severe constipation (less than one bowel movement per 3 d), pregnancy, history of cardiac arrhythmias, use of any drug that could influence bowel function within 1 mo of entering the study (such as tegaserod, laxatives, antibiotics, or probiotics), known lactose intolerance, use of antidepressants or presence of signs and symptoms suggestive of clinical depression, or any evidence of advanced organic or psychiatric

disease that may impact compliance or adherence to the study protocol. Similarly, patients who were referred from primary care or specialty clinics were screened for inclusion and exclusion criteria and records of previous medical investigations relating to the patient's complaint were carefully reviewed to exclude organic disease.

After initial evaluation and assessment, written informed consent was obtained, and patients were asked to complete a pre-treatment QoL questionnaire, the SF-36, a reliable and valid measure of QoL<sup>[7-9]</sup>. A word-for-word Arabic language translation of the SF-36 was available for non-English speaking patients; however the translated version was not subjected to validation studies.

### Assignment

All subjects were randomized by an independent investigator using a computer-generated random numbers table with a 1.2 to 1 stratification in favor of imipramine. The randomization key was kept under lock until the completion of the study.

### Masking

Study drugs were provided in opaque envelopes as imipramine (Tofranil, Novartis Pharma AG, Basle, Switzerland) 25 mg tablets, one tablet daily before bedtime for 84 d (12 wk) or matching placebo tablets.

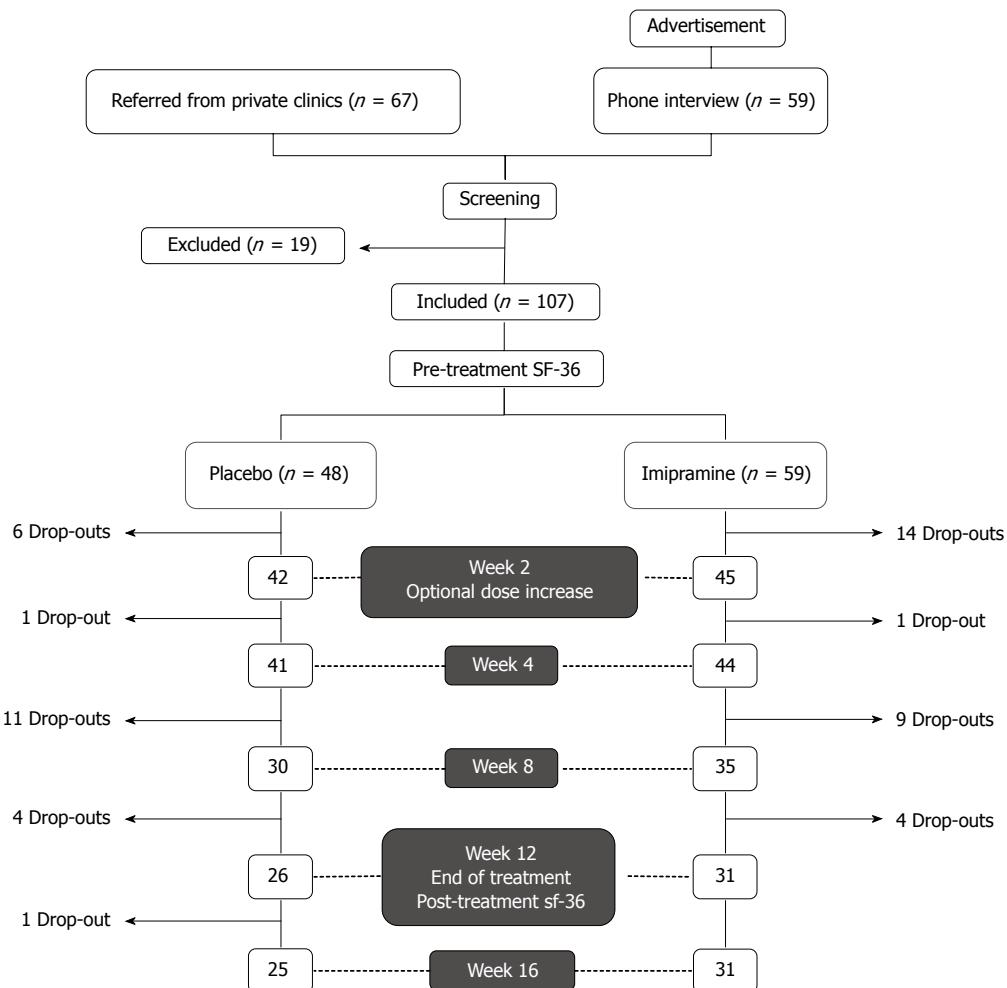

### Protocol and patient follow-up

Patients were contacted by phone at day 7 and day 14 of treatment to report any side effects. At day 14, patients who reported unsatisfactory global improvement of symptoms were given the choice of either continuing the treatment as before or doubling the daily dose (one tablet twice daily). The decision was left to the patients based on their level of tolerance to side effects, if any (the change, however, had to be effected once and on, or starting at, day 14).

The study's main variable was the subjective feeling of global symptom relief as reported by the subjects in response to the following question: "Have your symptoms improved satisfactorily since starting the study drug?" Patients were contacted on weeks 4, 8 and 12 of treatment to answer this question. At week 12, patients were requested to complete a post-treatment SF-36 questionnaire. An off-treatment follow-up was done at week 16 to answer the same global relief question mentioned above. Compliance was checked by pill count. The trial was approved by the Institutional Research Board of the AUBMC.

### Statistical analysis

Sample size calculation was estimated based on the assumption of a 60% response to imipramine *vs* a 30% response to placebo. The estimated sample size was 56 patients per arm. Projecting a 20%-30% dropout rate, the sample size was calculated at 70 patients per arm. The data were entered and analyzed using SPSS version 11.5. Frequency tables and cross-tabulations were derived in order to depict any associations between the different variables. Analysis of the primary end-point (global symptom relief) was done according to an intent-

**Figure 1** Study design.

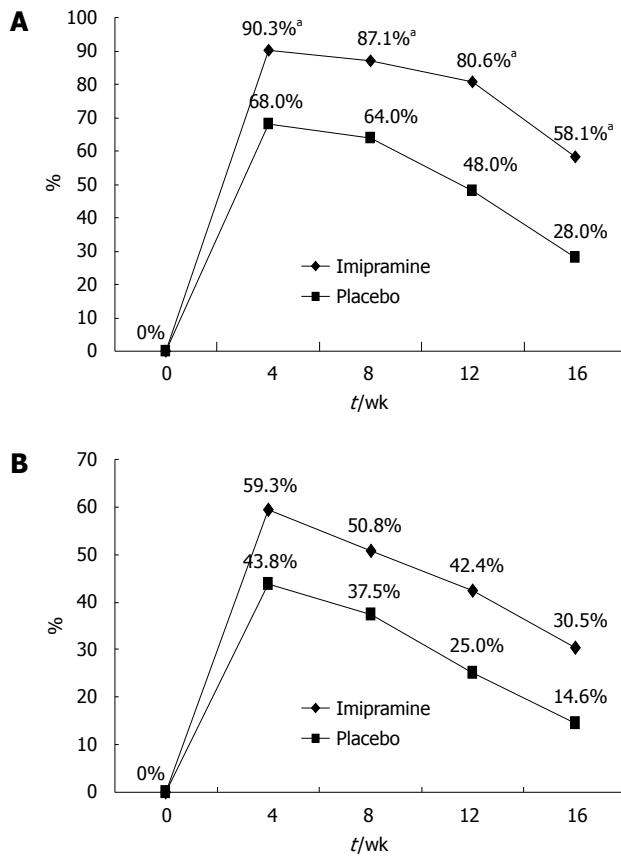

to-treat (ITT) basis. The paired samples *t*-test and the independent-samples *t*-test were used to compare the QoL scores before and after treatment. The change in SF-36 scores between week 12 (end of treatment) and baseline was calculated only in patients who completed the study and had paired SF-36 scores (PP analysis). A *P*-value at or below 0.05 was considered as the cut-off point for statistical significance.

## RESULTS

From December 2004 to May 2006, 67 patients were referred from private clinics and 59 patients answered to posted advertisements. Because of significant thinning of patient recruitment late in the study period as well as extenuating political circumstances in Lebanon, the study was closed in June 2006 before the preset sample size could be reached. Of the 136 screened subjects, 107 met the criteria for enrollment; 59 were randomized to imipramine and 48 to placebo. Since enrollment was stopped prematurely, the power calculation was performed *ad hoc*. Assuming a 60% response rate to imipramine *vs* a 30% response rate to placebo, with  $\alpha = 0.05$  (two-tailed), the above sample size allowed us to detect a significant difference between the two groups with a calculated power of 88.4%.

Both groups were comparable with regard to age, sex, and symptoms (Table 1). The mean age in the imipramine arm was  $42.6 \pm 12.4$  years *vs*  $45.3 \pm 13.8$  years for the placebo arm, with a slight male predominance. Fifty-seven individuals of the total patient sample (52.5% *vs* 54.2%) had undergone endoscopic procedures with no abnormal findings. The remaining patients had undergone other diagnostic testing based on their primary physician's recommendations (blood count, inflammatory markers, stool studies, and imaging) which were non-revealing.

All patients fulfilled the Rome II criteria for IBS and had a history of at least one previous treatment using off-the-counter or prescribed antispasmodic medications with unsatisfactory results. The patients' global relief of symptoms during the different intervals of the trial is shown in Figure 2. The ITT population included all 107 patients while the per-protocol analysis was based on results from the 56 patients (31 on imipramine and 25 on placebo) who completed the 12-wk active treatment period and the 4-wk off-treatment follow-up. The imipramine group reported relief of baseline symptoms in 80.6% of patients at the end of the 12-wk treatment period as compared to 48.0% in the placebo arm (*P* = 0.01). The highest rate of relief was achieved at week 4 in both groups: 90.3% for imipramine and 68.0% for

**Figure 2** Rate of global symptom relief (A) per-protocol and (B) per intent-to-treat analysis (<sup>a</sup> $P < 0.05$ ).

placebo ( $P = 0.037$ ). Per-protocol analysis revealed a significantly greater improvement of baseline symptoms in the imipramine arm *vs* placebo group at all checkpoints of the 12-wk trial including 4 wk after stopping treatment ( $P = 0.024$ ). ITT analysis of all 107 patients who received at least one tablet of the assigned treatment showed higher rates of global symptom relief in favor of imipramine at all study points; however, the difference was not statistically significant (42.4% *vs* 25% at week 12,  $P = 0.06$ , Figure 2).

The dropout rate was similar in both study groups: 28/59 (47.5%) for imipramine and 23/48 (47.9%) for placebo. Subjects receiving imipramine dropped out of the trial earlier than in the placebo arm with a mean dropout time of  $25.0 \pm 17.9$  d *vs*  $37.4 \pm 20.8$  d, respectively ( $P = 0.026$ ). The reasons for dropout were loss to follow-up, premature withdrawal of treatment without side effects (at or before 2 wk of treatment), protocol violation, and side effects (Table 2). Premature withdrawal accounted for 60.9% of dropouts in the placebo group. Fourteen of the 28 dropouts (50%) on imipramine reported that side effects were the main reason for withdrawal with a predominance of anticholinergic side effects (Table 3). Of those 14 patients, only two had doubled the dose of medication (to 50 mg imipramine) after a sub-optimal response at 2 wk. In general, the rate of side effects was higher in the imipramine group (64.4% *vs* 39.6%, respectively,  $P = 0.01$ ). However, when comparing the rates of side effects which led to subject

**Table 1** Baseline patient characteristics *n* (%)

	Imipramine ( <i>n</i> = 59)	Placebo ( <i>n</i> = 48)
Mean age (yr)	$42.6 \pm 12.4$	$45.3 \pm 13.8$

Flushing & sweating	1
Constipation	1

dropout, the difference was not statistically significant (25.4% *vs* 12.5%,  $P = 0.094$ ).

Sixteen patients (27.1%) from the imipramine group compared to 19 (39.6%) patients from the placebo arm opted for doubling of the dose at day 14 of treatment ( $P = 0.188$ ). There was no association between increasing the dose in the imipramine group and global symptomatic improvement, development of side effects, or adverse events leading to dropout; however, it was observed that 8/16 (50%) of patients whose treatment dose was doubled dropped out of the trial as compared to 15/38 (39.5%) patients maintained on the original dosage ( $P = 0.038$ ). Furthermore, 41.8% (28/67) of patients recruited from clinics dropped out compared to 57.5% (23/40) of self-referred patients ( $P = 0.12$ ), independent of assigned treatment ( $P = 0.10$  for imipramine;  $P = 0.60$  for placebo).

The change in QoL was assessed by asking patients to complete the SF-36 questionnaire upon onset of treatment and at completion of therapy (week 12). Only patients with paired completed SF-36 questionnaires

**Figure 3** Percent mean SF-36 before and after treatment ( $^aP < 0.05$ ).

were included in this analysis (PP group,  $n = 56$ ). Before beginning treatment, the mean SF-36 scores were similar for imipramine and placebo groups ( $96.1 \pm 25.0$  vs  $102.2 \pm 17.0$ ,  $P = 0.307$ ). After treatment, the mean SF-36 scores for the imipramine and placebo groups increased to  $113.7 \pm 19.4$  and  $108.6 \pm 15.9$ , respectively ( $P = 0.3$ ). The mean percent difference in SF-36 scores before and after treatment for imipramine was  $11.8\% \pm 13.2\%$  compared to  $4.3\% \pm 9.0\%$  for placebo ( $P = 0.02$ ). Further analysis of SF-36 results showed a trend for greater improvement in all components of the questionnaire in the imipramine arm compared to placebo (Figure 3).

## DISCUSSION

The current ROME II committee recommendations for conducting randomized, controlled trials in IBS have stressed the use of the Rome criteria to identify patients with IBS, and a randomized, parallel-trial, double-blinded design with no placebo run-in, with minimum treatment duration of 8–12 wk, follow-up of symptoms after treatment is stopped, and assessment of compliance with therapy. Moreover, trials should include baseline assessment of symptoms, account for patient disposition (discontinuations, withdrawals, etc), provide sample size calculation and enroll an adequate number of patients, with the primary outcome being improvement of global IBS symptoms based on patient assessment and/or use of a validated scale to assess IBS symptoms<sup>[3]</sup>. To date, 10 randomized, controlled trials and two crossover studies have evaluated the effectiveness of TCAs in the treatment of IBS<sup>[10–18]</sup>. The largest and best study to date on TCAs was done by Drossman *et al*<sup>[19]</sup>, investigating the role of desipramine in patients with functional disorders. However, the study involved patients with functional abdominal disorders (IBS, functional abdominal pain, painful constipation, and unspecified functional bowel disorders) and was therefore not restricted to IBS. Although the findings of that study supported a role of TCAs in functional bowel disorders, it is difficult to draw a firm conclusion regarding IBS

given the inhomogeneous study population. On the other hand, few of the other trials used the Rome criteria to identify patients with IBS, measured compliance, or presented sample size calculations. Most had small sample sizes, and only one trial was more than 8 wk in duration. A most recent study by Rajagopalan *et al*<sup>[11]</sup> met most recommendations for optimal study design but again suffered from a small sample size (20 patients per arm of whom nine dropped out from each group), and the lack of patient follow-up after the treatment was stopped. Our study meets almost all of the above requirements and is the largest randomized trial to date investigating the role of TCAs in patients with IBS. The study findings provide support for the efficacy of TCAs in the treatment of IBS, particularly after failure of antispasmodics, commonly used as first-line agents in IBS.

The fact that antidepressants are more consistent in improving global measures than specific GI symptoms has raised concerns about their true effect in functional GI disorders including IBS<sup>[20]</sup> where changes in symptoms are weak predictors of changes in well-being following treatment with TCAs<sup>[21]</sup>. Although controversial<sup>[22]</sup>, the use of global symptom improvement as the primary end point may arguably be more important because of the wide and varied symptomatology of IBS and functional abdominal symptoms, and the varying importance that patients place on particular symptoms. This helps overcome inherent disadvantages of symptom score systems, which measure physiologic epiphénoména such as stool characteristics and subtypes of IBS<sup>[23]</sup>, but do not address the impact of this on global well-being.

The mechanism of action of TCAs in IBS remains unclear but appears to primarily involve a modulation of the brain-gut neurologic axis. Using functional magnetic resonance imaging, Morgan *et al*<sup>[24]</sup> have shown that rectal pain following balloon distension induced significant activation of the perigenual anterior cingulate cortex, right insula and right prefrontal cortex, and that amitriptyline use was associated with reduced pain-related cerebral activation in some centers, but only during stress. This effect was thought to occur in the central nervous system, rather than peripherally, to blunt pain and other symptoms exacerbated by stress in IBS. Another putative mechanism of action of TCAs is by modulation of gut motility *via* action on peripheral muscarinic receptors and/or on ATP-sensitive K<sup>+</sup> channels in interstitial cells of Cajal<sup>[25,26]</sup>. Identifying an anxiety or affective disorder is not necessary for initiating TCAs since they appear to have an analgesic advantage on somatic pain independent of psychiatric effects. Response to TCAs may in fact be attenuated in the presence of active psychiatric illness<sup>[27,28]</sup>. Because of their side effects, particular effort must be taken to initiate treatment with TCAs. In our study, major side effects leading to premature dropout were more common in the imipramine group and were primarily anticholinergic side effects. The incidence of adverse events was similar to previously published trials of TCAs in patients with functional GI disorders or neuropathic pain<sup>[29]</sup>. This emphasizes the need to warn

patients about potential side effects of TCAs and weigh these against any expected or perceived benefit.

Health-related QoL is affected significantly in patients with IBS compared to the general population. The health-related QoL is associated with perceived IBS severity defined by the overall disease limitations rather than symptoms and appears to improve in treatment responders and correlates with symptom improvement<sup>[30,31]</sup>. For that reason, the SF-36 model, a general health status instrument, was used in our study to assess QoL. We found that the post-treatment SF-36 mean total score was significantly higher than the pre-treatment score in the imipramine group only with a notable improvement in all components of the health-related QoL instrument used.

The limitations of this study include the single center nature of the study, the lack of formal assessment of baseline co-morbid psychiatric distress and the possibility of unblinding given the untoward, primarily anticholinergic adverse events of TCA in some patients. This potential unblinding is unlikely, however, to have biased the measured patient-specific endpoints of global symptom relief or the SF-36 components. Other limitations include the fact that dose escalation was allowed at week 2 and the high dropout rate noted in both the imipramine and placebo arms (47.5% vs 47.9%, respectively) as well as the inability to meet the preset sample size for the study. The restriction of dose escalation to a single early time point (at 2 wk) was felt to best reflect the real-life clinical situation where dose adjustments are often made in the dose of TCAs according to patient response and possible drug-related adverse events. The high dropout rate in our trial can be explained by several factors. First, the IBS patient population is hard to study because of an existing high degree of psychosomatization. Second, and perhaps more importantly, these patients have an often unrealistic expectation of rapid symptomatic relief or even cure, and a 12-wk period may therefore constitute an unduly long period of time to "experiment" with a placebo or a drug that they may perceive as investigational and possibly ineffective. It is for this reason that most large studies on functional GI disorders have included a 2-4 wk run-in phase wherein patients who are more likely to continue the trial period are consequently selected. However, and despite these run-in or screening periods, dropout rates in these large trials remain in the order of 20%-25%<sup>[32,34]</sup>. Lastly, and perhaps most importantly, adherence may have been further reduced in our patient population for cultural reasons such as the unfamiliar concept of a "placebo" control arm and the fact that the use of the active drug in this particular study (a medication approved for the use of depression) may suggest or connote a "psychiatric" label to the patients' condition. These factors, as well as the single center nature of the study, may have contributed to our inability to reach the preset sample size and to the premature closure of the study. The above notwithstanding, this study remains the largest placebo-controlled trial of TCAs in patients with IBS as defined by strict clinical criteria.

In conclusion, this randomized, double-blind, place-

bo-controlled trial provides evidence in support of the efficacy of imipramine in reducing symptoms of IBS and providing global relief. Symptom improvement is associated with improved QoL. Careful patient selection and education about the role of TCAs, the rationale for their use, and the recognition of potential side effects are important considerations. Gradual dose escalation, perhaps in small increments of 10 mg, and close monitoring are likely to result in a better therapeutic response.

## ACKNOWLEDGMENTS

This article was selected for oral presentation at the ACG 71st Annual Scientific Meeting (October 20-25, 2006, Las Vegas, NV, USA) and awarded the ACG/Novartis Motility Abstract Award.

## COMMENTS

### Background

Tricyclic antidepressants (TCAs) were found to improve abdominal pain in irritable bowel syndrome (IBS) patients. This trial aimed to study the effect of imipramine, a TCA, on global symptom relief in patients with IBS.

### Research frontiers

TCAs have been shown in a few trials to improve abdominal pain in patients with IBS; however there was inadequate evidence to support an effect on improvement of global IBS symptoms. Notably, most randomized, controlled trials of TCAs in IBS were completed before the publication of the ROME II committee recommendations for the study design of treatment trials for IBS and suffered from suboptimal study design, small sample size, and short treatment duration.

### Innovations and breakthroughs

This trial did not include a run-in-phase in order to simulate the real-life scenario in the clinic, and to obtain a valid assessment of the utility and compliance with TCAs. It was rigorously designed and included a formal assessment of quality of life (QoL) indicators and followed all the recommendations of the Rome committee on the optimal design of IBS trials. Only a few published trials on TCAs have done so and all included less than 20 patients per arm, making this trial the largest ever conducted on the use of TCAs in patients with IBS.

### Applications

IBS remains a common intestinal disorder causing significant discomfort and poor QoL to patients who have the diagnosis. TCAs have been shown to improve abdominal pain in patients with IBS; however, there is insufficient evidence of global symptom relief. The search for an optimal treatment to improve symptoms and QoL in IBS remains ongoing.

### Terminology

IBS is a common disorder of the gastrointestinal tract characterized by abdominal pain or discomfort and altered bowel habits. The exact pathophysiology of IBS remains unclear; however, it is thought to involve altered intestinal motility as a result of dysregulated communication between the brain and enteric nervous system. The mechanism by which TCAs affect this neural communication is yet unknown.

### Peer review

Few trials have adequately studied the effect of TCAs on global relief of symptoms in patients with IBS. The aim of this study was to evaluate the efficacy and safety of imipramine in patients with IBS who have failed to respond satisfactorily to antispasmodics.

### Abstract

**AIM:** To detect a possible association between the polymorphism of the (-670 A/G) Fas/Apo1 gene promoter and susceptibility to Crohn's disease (CD) and ulcerative colitis (UC) in the Tunisian population.

**METHODS:** The (-670 A/G) Fas polymorphism was analyzed in 105 patients with CD, 59 patients with UC, and 100 controls using the polymerase chain reaction restriction fragment length polymorphism method.

**RESULTS:** Significantly lower frequencies of the Fas -670 A allele and A/A homozygous individuals were observed in CD and UC patients when compared with controls. Analysis of (-670 A/G) Fas polymorphism with respect to sex in CD and UC showed a significant difference in A/A genotypes between female patients and controls ( $P$  corrected = 0.004 in CD patients and  $P$  corrected = 0.02 in UC patients, respectively). Analysis also showed a statistically significant association between genotype AA of the (-670 A/G) polymorphism and the ileum localization of the lesions ( $P$  corrected = 0.048) and between genotype GG and the colon localization ( $P$

corrected = 0.009). The analysis of inflammatory bowel disease patients according to clinical behavior revealed no difference.

**CONCLUSION:** Fas-670 polymorphism was associated with the development of CD and UC in the Tunisian population.

### INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic disorder of the gastrointestinal tract characterized by immune dysregulation and leukocyte recruitment<sup>[1]</sup>. IBD may manifest as either Crohn's disease (CD) or ulcerative colitis (UC), which are two distinct forms of IBD with some common clinical, epidemiological, and immunological features, but they can be distinguished by anatomical and histological features as well as by serologic markers<sup>[2,3]</sup>.

The etiology of IBD is unknown, but the condition seems to be the result of a combination of environmental, genetic, and immunologic factors in which an uncontrolled immune response within the intestinal lumen leads to inflammation in genetically predisposed individuals<sup>[4]</sup>.

Genetic factors are known to play an important role in determining an individual's susceptibility to IBD. Significant linkages in chromosomes 1, 3, 6, 7, 12, 14, 16 and 19 have been reported<sup>[5-8]</sup>. However, IBD-1, a susceptibility locus in chromosome 16, was the first gene to be clearly associated with CD<sup>[9,10]</sup>.

Although the underlying genetic and environmental causes remain to be elucidated, CD4+ T helper 1 (Th1) lymphocytes play a pivotal role in the pathogenesis of these diseases. A Th1-like phenotype, with its signature cytokines interferon (IFN)- $\gamma$  and tumor necrosis factor (TNF)- $\alpha$ , is shared among many colitis models and is found in patients with active CD<sup>[1,11,12]</sup>. Moreover, IFN- $\gamma$  not only cooperates with TNF- $\alpha$  to cause colonic cell death, it also modulates epithelial Fas expression and sensitizes colonic epithelial cells to Fas-induced apoptosis<sup>[1]</sup>.

Programmed cell death, or apoptosis, is regulated by tightly controlled intracellular signaling events in response to pathological cytotoxic stimuli including TNF- $\alpha$ , TNF-related apoptosis-inducing ligand (TRAIL), and Fas<sup>[13-15]</sup>. Fas, a member of the tumor necrosis factor superfamily, is constitutively expressed by the basolateral membrane of normal colon and small intestinal epithelium<sup>[11,12,16-19]</sup>. Fas ligation induces apoptosis in colonic epithelial cells and is implicated in the epithelial damage seen in ulcerative colitis<sup>[11,12,16-19]</sup>. The ligand for Fas (FasL) is expressed by intraepithelial and lamina propria lymphocytes, and its expression is increased in the lamina propria of UC patients, suggesting that Fas-FasL-induced apoptosis participates in the mucosal damage of UC<sup>[11,12]</sup>. Inhibition of cytokine-regulated apoptosis may therefore be useful in preventing or treating intestinal lesions in patients with IBD.

The Fas/Apo-1 gene has been mapped to the chromosome 10q24.1 region<sup>[20]</sup>. The gene consists of nine exons and eight introns. Two polymorphisms located in the promoter region of the Fas gene have been reported<sup>[21]</sup>. One of these polymorphisms is a single nucleotide substitution (A/G) at the -670 position. Several studies have shown an association between this A/G single nucleotide polymorphism (SNP) and autoimmune diseases such as type 1 diabetes<sup>[22]</sup>, multiple sclerosis<sup>[6]</sup>, Sjögren's syndrome<sup>[23]</sup>, rheumatoid arthritis<sup>[24]</sup>, and systemic lupus erythematosus<sup>[6,24]</sup>.

In this study, we have analyzed the Fas/Apo1 gene promoter (-670 A/G) polymorphism in unrelated Tunisian patients with CD and UC to evaluate the contribution of the Fas/Apo1 (CD95) gene to genetic susceptibility to IBD.

## MATERIALS AND METHODS

### Patients

Blood samples were obtained from 164 subjects with IBD, composed of 13 cases of familial forms and 151 cases of sporadic forms. These patients were classified into 105 patients with CD (50 men, 55 women) with a mean age of 36.07 years (range, 23-60 years), and 59 patients with UC (17 men, 42 women) with a mean age of 37.89 years (range, 25-74 years). A total of 100 healthy individuals (52 men and 48 women) matched for age, sex and ethnicity were included as controls. None of the healthy controls had any evidence of autoimmune diseases such as inflammatory bowel disease, diabetes, or

other autoimmune diseases. All subjects were unrelated Tunisians treated at the Department of Gastroenterology of Charles Nicolle and La Rabta Hospitals in Tunis. The diagnoses of CD and UC were determined according to conventional endoscopic, radiological, and histological criteria<sup>[25]</sup>. Data obtained from each patient included age at diagnosis, disease location, disease characteristics, and extraintestinal location, which were used to group the patients according to the Vienna classification<sup>[26]</sup>. All patients and controls gave informed consent to participate in this study which was approved by the Ethics Committee of Charles Nicolle Hospital in Tunis.

### Methods

Transition A/G, in position -670 of the promoter of the Apo1/Fas gene, was analyzed by the polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP) method. The Apo1/Fas marker frames an area of 232 Pb in the area of the promoter and was able to contain a site of cut for the enzyme Bst I (Promega). The digestion of the amplified fragment gave rise to two types of allele: the allele G marked by the presence of two fragments 188 Pb and 232 Pb and the allele A characterized by the absence of cut (A), therefore a fragment of 232 Pb. The PCR was carried out in a final volume of 20  $\mu$ L containing 5  $\mu$ L of genomic DNA at 40 ng/ $\mu$ L, 1 U of *Taq* polymerase, 1.5 mmol/L of MgCl<sub>2</sub>, 0.2 mmol/L of dNTP and 10 pmol of each primer.

The primers used were: Fas (1); 5'-CTACCTAAGA GCTATCTACCGITTC-3' and Fas (2); 5'-GGCTGTCC ATGTTGTGGCTGC-3'. The amplification of product was carried out on 2% agarose gel and visualized under UV. Ten microliter of the amplified fragments were then digested by 5 U of Bst I in a final volume of 20  $\mu$ L and the mixture was left 2.5 h at 60°C. The separation of the products of digestion was performed on 3% agarose gel and visualized under UV.

### Statistical analysis

Frequencies of the genotypes, alleles, and phenotypes were analyzed by using the  $\chi^2$  test. The odds ratio (OR) and 95% confidence interval were calculated to measure the strength of the association observed. Hardy Weinberg equilibrium was tested by calculating the  $\chi^2$  for reliability of fit. Calculations were made by using Internet programs from [www.myatt.demon.co.uk/epicalc.htm](http://www.myatt.demon.co.uk/epicalc.htm). Statistical significance was defined as  $P < 0.05$ .  $P$  values were corrected by Bonferroni correction for multiple comparisons, taking into account the number of alleles studied.

## RESULTS

As shown in Table 1, Crohn's disease (64%) was more frequent than ulcerative colitis (36%) in the study. The peak of the disease is between 20 and 40 years. The familial forms represent 8.57% of the CD cases and 6.77% of the UC cases. The principal clinical manifestations observed during evolutionary flares of

the disease depended on the site: Ileum (25.71%), Colon (22.85%) and Ileocolon (51.42%) for CD patients and Pancolitis (20.33%), Distal (35.59%) and Left-sided colitis (44.06%) for UC patients. Results for the genotyping of the Fas/Apo1 gene promoter (-670 A/G) SNP in 105 patients with CD, 59 subjects with UC, and 100 healthy controls are summarized in Table 2. The allele frequencies were in Hardy-Weinberg equilibrium both in the patients and in controls. We have compared the A/A genotype frequencies found in various subgroups of IBD patients with those in the entire control population.

When comparing CD patients with the control group, the frequency of the -670 A allele was found to be significantly lower in CD than in controls. Also, the distribution of the -670 A/A genotype was significantly lesser in CD patients than in controls. When comparing UC patients with the control group, the frequencies of the -670 A allele and the homozygous -670 A/A genotype were lower in UC patients than in controls and these differences were statistically significant. When we analyzed the Fas/Apo1 gene promoter (-670 A/G) polymorphism with respect to gender (Table 3), we found that Fas/Apo1 genotype frequencies were similar in controls of both sexes (48 females and 52 males). However, the frequency of CD female patients carrying the -670 A/A genotype was significantly less when compared with the control group. The same result was obtained in women with UC when compared with those in the control group. Thus, the homozygosity for the A allele could be a protective factor for development of IBD in female patients. An analogous analysis has been done on male patients with CD and UC. The results did not show a statistically significant association for either CD or UC patients compared with the control group. Subsequently, we sought to investigate whether this polymorphism could be linked to a particular clinical phenotype. When stratifying CD patients according to the Vienna classification, as shown in Table 4, we found a statistically significant association ( $\chi^2 = 3.89$ , two degrees of freedom, *P* corrected = 0.048) odds ratio of 2.48 (0.90 < OR < 6.87, CI = 95%) between genotype AA of the Fas/Apo1 gene promoter (-670 A/G) polymorphism and the ileum localization of the lesions. In addition, we found a statistically significant association ( $\chi^2 = 6.74$ , two degrees of freedom, *P* corrected = 0.009) odds ratio of 3.38 (1.19 < OR < 9.67, CI = 95%) between genotype GG of the polymorphism and the colon localization of the lesions. Analysis of IBD patients according to clinical behavior revealed no difference between those carrying

**Table 3** Incidence of (-670 A/G) Apo1/Fas gene polymorphism analyzed with respect to sex in IBD patients *n* (%)

Fas genotypes were similar in controls of both sexes: 52 males and 48 females;  $\chi^2 = 0.06$ ,  $P = 0.8$ , two degrees of freedom; <sup>a</sup> $\chi^2$  test of heterogeneity between CD females and controls ( $\chi^2 = 8.15$ , two degrees of freedom,  $P$  corrected = 0.004) odds ratio for AA genotype is 0.36 (0.16 < OR < 0.77, CI = 95%); <sup>b</sup> $\chi^2$  test of heterogeneity between UC females and controls ( $\chi^2 = 5.04$ , two degrees of freedom,  $P$  corrected = 0.02) odds ratio for AA genotype is 0.42 (0.18 < OR < 0.96, CI = 95%); <sup>c</sup> $\chi^2$  test of heterogeneity between UC females and controls ( $\chi^2 = 6.46$ , two degrees of freedom,  $P$  corrected = 0.01) odds ratio for AG genotype is 2.57 (1.15 < OR < 5.76, CI = 95%).

or not carrying the (-670 A/G) allele (data not shown). We did not find an association between (-670 A/G) polymorphism and the severity of disease in any of the IBD patients, as defined by the need for surgery (data not shown).

## DISCUSSION

There are several candidate genes potentially involved in the pathogenesis of IBD because of chromosomal location or function within inflammatory processes or both<sup>[27]</sup>. Much investigation has surrounded the FasL system, a major pathway responsible for inducing apoptosis of T cells and enterocytes in the colonic mucosa<sup>[28]</sup>. Fas is a type I transmembrane protein and a member of the TNF receptor superfamily that may be expressed constitutively by gut lamina propria T (LPT) cells<sup>[29]</sup>. FasL is a type II transmembrane protein that is expressed on cytotoxic T cells and that induces apoptosis of cells expressing Fas<sup>[30]</sup>. Defective apoptosis of LPT cells may be a factor in mucosal immune dysregulation and tissue inflammation. Rioux *et al*<sup>[31]</sup> found that 15% of LPT cells underwent apoptosis in normal individuals. There was a marked reduction in apoptosis of LPT cells in patients with UC and CD and those with specific colitis. In the present study, we genotyped Fas-670 polymorphisms in Tunisian patients with IBD and healthy controls, and found that the frequencies of the A allele and the AA genotype were significantly lower in patients with IBD compared with those in the control group, and in UC patients compared to CD patients, but here the difference was not significant. Thus, we have demonstrated an association between a promoter polymorphism of the (-670 A/G) Fas/Apo1 gene and IBD in this study. The significance of this association may differ according to the population studied and the type of inflammatory bowel disease. In fact, no association of (-670 A/G)

**Table 4** Association between (-670 A/G) Apo1/Fas gene polymorphism and location of lesion

Apol/Fas	UC (n = 59)			CD (n = 105)			
	G/G	G/A	A/A	G/G	G/A	A/A	
Distal	4	9	8	Ileum	5	10	12 <sup>a</sup>
Left-sided colitis	5	15	6	Colon	13 <sup>b</sup>	8	3
Pancolitis	3	8	1	Ileocolon	16	22	16

<sup>a</sup> $\chi^2$  test between AA genotype and ileum location of lesion in CD patients ( $\chi^2 = 3.89$ , two degrees of freedom,  $P$  corrected = 0.048) odds ratio is 2.48 (0.90 < OR < 6.87, CI = 95%); <sup>b</sup> $\chi^2$  test between GG genotype and colon location of lesion in CD patients ( $\chi^2 = 6.74$ , two degrees of freedom,  $P$  corrected = 0.009) odds ratio is 3.38 (1.19 < OR < 9.67, CI = 95%).

Fas/Apo1 SNP with IBD in Chinese, Dutch, Australian and Korean patients exists<sup>[32-35]</sup>. Confusingly, in some studies the A variant was found as a susceptibility factor for rheumatoid and multiple sclerosis disease. Stratification analyses revealed that the association was stronger in males than in females. Sex effects in IBD have already been reported by Huang *et al*<sup>[36]</sup> who have identified several putative regions of sex-specific linkage. Regions on chromosomes 6, 11, 14 and 18 showed strong evidence of linkage in male-affected families but not in female-affected families. Moreover, oral contraceptives have been shown to be associated with increased risk for CD<sup>[37]</sup>. It has been proposed that epigenetic factors play an important role in the pathogenesis of IBD<sup>[38]</sup>, and that sex effects are mediated by sexual hormones, which have an effect on gene expression and consequently could lead to differential expression of disease susceptibility genes in males and females. According to our findings, it appears that Fas/Apo1 gene polymorphisms decrease susceptibility to CD and UC in females in the Tunisian population. However, because there was no evidence of linkage of the Fas/Apo1 gene with the X chromosome, it is possible that this difference could be a random variation. On the other hand, it appears that CTLA-4 +49 gene polymorphisms increase susceptibility to CD in females in the Tunisian population and in the same patients as have Fas/Apo1 polymorphisms. No explanations have been presented for the discrepancy between positive findings, like ours, and the negative findings of others. The most plausible is the known genetic diversity of the different populations at the haplotype level. Our present results and the lack of previous studies on the sex distribution of Fas/Apo1 polymorphisms in patients with IBD warrant further investigation. The reason for this divergence is not clear but might reflect an ethnic difference in the contribution of genetic factor(s).

Fas-670 polymorphism within the promoter region is situated at a transcriptional binding site (the  $\gamma$  interferon activation site) and may potentially have a functional effect on gene regulation of factors such as STATs as well as on expression of proapoptotic proteins (Fas, FasL). In fact, in patients with UC, concentration of a systemic soluble form of Fas was found to be significantly lower in active UC than in controls<sup>[35]</sup>. Garcia Rodriguez *et al*<sup>[39]</sup> have studied Fas/FasL expression on activated colonic T

cells of UC patients, as well as the susceptibility of such T cells to activation-induced cell death, and have reported that CD4+ and CD8+ T cells in UC mucosa expressing FasL were significantly enhanced, suggesting that T cells in UC are less sensitive to apoptotic signals mediated by Fas. A few studies reported the association between the Fas/Apo1 gene promoter (-670 A/G) polymorphism and the localization of the lesions in IBD. Xia *et al*<sup>[40]</sup> have not found a difference between left-sided and total colitis ( $P = 0.8242$ ). Moreover, in our study we found an association between ileum and colon localization of the lesions in CD patients and (-670 A/G) polymorphism.

Regarding the Fas-670 polymorphism, it has been hypothesized that either increased apoptosis of intestinal epithelium or decreased apoptosis of lamina propria lymphocytes may induce inflammation of the gut and, although expression and functional effects of the Fas antigen have been found to be associated with IBD, the relationship between Fas-670 polymorphism and IBD has not been reported yet. However, in this study, a Fas-670 polymorphism was associated with the development of CD and UC, providing strong support for an IBD susceptibility gene in the region surrounding Apo1/Fas. It remains to be determined precisely how the Fas alleles influence the pathogenesis of IBD. Finally, it is possible that haplotypes exist in our population which we may have missed. We conclude that our results must await confirmation by other investigators.

## COMMENTS

### Background

In recent years, a few studies have been published addressing the question of where and under what conditions ligand for Fas (FasL) is produced in the gut in the normal and neoplastic situation. Some of these studies have considerably influenced our view of the role of the CD95/CD95L system. That is why it is necessary to analyze the Fas/Apo1 polymorphism in unrelated Tunisian patients with Crohn's disease (CD) and ulcerative colitis (UC) to evaluate the contribution of the CD95 gene to genetic susceptibility to inflammatory bowel disease (IBD).

### Research frontiers

Inhibition of cytokine-regulated apoptosis may be useful in preventing or treating intestinal lesions in patients with IBD.

### Innovations and breakthroughs

The relationship between Fas-670 polymorphism and IBD has not been reported yet. This is probably the first report on the association of Fas-670 polymorphisms in Tunisian IBD patients. However, this polymorphism was associated with the development of CD and UC, providing strong support for an IBD susceptibility gene in the region surrounding Apo1/Fas.

### Applications

By understanding how the Fas-670 polymorphism is associated with the development of CD and UC, this study may indicate a future strategy for therapeutic intervention in patients with IBD.

### Peer review

The manuscript by Ben Aleya *et al* reports on the association of a Fas/Apo1 promoter polymorphism with IBD in Tunisian patients. The experiments are performed well and the results are interesting.

## Abstract

**AIM:** To present our experience with pregnant patients who underwent endoscopic retrograde cholangiopancreatography (ERCP) without using radiation, and to evaluate the acceptability of this alternative therapeutic pathway for ERCP during pregnancy.

**METHODS:** Between 2000 and 2008, six pregnant women underwent seven ERCP procedures. ERCP was performed under mild sedoanalgesia induced with pethidine HCl and midazolam. The bile duct was cannulated with a guidewire through the papilla. A catheter was slid over the guidewire and bile aspiration and/or visualization of the bile oozing around the guidewire was used to confirm correct cannulation. Following sphincterotomy, the bile duct was cleared by balloon sweeping. When indicated, stents were placed. Confirmation of successful biliary cannulation and stone extraction was made by laboratory, radiological and clinical improvement. Neither fluoroscopy nor spot radiography was used during the procedure.

**RESULTS:** The mean age of the patients was 28 years (range, 21-33 years). The mean gestational age for the fetus was 23 wk (range, 14-34 wk). Five patients underwent ERCP because of choledocholithiasis and/or

choledocholithiasis-induced acute cholangitis. In one case, a stone was extracted after precut papillotomy with a needle-knife, since the stone was impacted. One patient had ERCP because of persistent biliary fistula after hepatic hydatid disease surgery. Following sphincterotomy, scoleces were removed from the common bile duct. Two weeks later, because of the absence of fistula closure, repeat ERCP was performed and a stent was placed. The fistula was closed after stent placement. Neither post-ERCP complications nor premature birth or abortion was seen.

**CONCLUSION:** Non-radiation ERCP in experienced hands can be performed during pregnancy. Stent placement should be considered in cases for which complete common bile duct clearance is dubious because of a lack of visualization of the biliary tree.

## INTRODUCTION

Hormonal changes during pregnancy increase the lithogenicity of bile and impair gallbladder emptying, which create a favorable environment for gallstone formation. The prevalence of gallstones in pregnancy has been reported as 3.3%-12.2%<sup>[1-3]</sup>. Acute cholecystitis is the second most common non-obstetric emergency in pregnant women. Choledocholithiasis and consequent

complications such as pancreatitis and cholangitis are potentially lethal diseases for the mother and fetus. Acute pancreatitis in pregnancy has been shown to be closely related to gallstone disease<sup>[4]</sup>. Biliary pancreatitis has been found to be associated with 15% and 60% of maternal and fetal mortality rates, respectively<sup>[5]</sup>.

During pregnancy, the treatment is usually conservative since surgery is associated with an increased rate of complications such as preterm labor and spontaneous abortion. In choledocholithiasis, endoscopic retrograde cholangiopancreatography (ERCP) is the first-line treatment of choice. One should try to avoid the use of fluoroscopy during pregnancy, especially in the first trimester. ERCP with 3.2 min mean fluoroscopy time and 310 mrad estimated mean fetal radiation exposure has been found to be safe for the mother and fetus during pregnancy<sup>[6]</sup>. However, a clear-cut safe radiation dose for ERCP in pregnancy is still unknown. Here, we present our experience with pregnant women who underwent ERCP without using radiation.

## MATERIALS AND METHODS

Seven hundred and fifty ERCP procedures for choledocholithiasis and/or choledocholithiasis-induced acute cholangitis were performed on 597 patients in our Endoscopy Unit at Vakif Gureba Research and Training Hospital from 2000 to 2008. Six out of 598 ERCP patients were pregnant. One patient with biliary fistula caused by surgery for hepatic hydatid disease was also included in the study. The data regarding laboratory, ultrasonographic and endoscopic findings, and clinical course of the patients were analyzed. Magnetic resonance cholangiopancreatography (MRCP) was used for diagnosis of fistula after hydatid surgery, and for control of fistula closure after the first ERCP procedure in the patient with hepatic hydatid disease. MRCP was also used for diagnosis of choledocholithiasis in the patient with elevated bilirubin levels and a dilated common bile duct shown by ultrasonography. Patients with fever, jaundice, abdominal pain and radiological findings were diagnosed with choledocholithiasis-induced acute cholangitis.

All patients included in the study signed an informed consent for the procedures, after receiving an explanation on the risks, benefits and alternatives of ERCP and associated therapeutic procedures.

The patients were counseled by the Gynecology and Obstetrics Department before the procedure. Pre-procedural complete blood count, bilirubin, transaminase and  $\gamma$ -glutamyl transferase levels were noted. The fetal heart sounds were controlled before the ERCP procedure. Pethidine HCl ( $\leq 100$  mg) and midazolam ( $\leq 3$  mg) were used for analgesia and sedation. The patients were positioned in the left lateral position to avoid vena caval or aortic compression. After introducing the duodenoscope into the duodenum, the bile duct was cannulated with a guidewire through the papilla, and bile aspiration and/or visualization of the bile oozing around the guidewire was used to confirm correct cannulation. Following sphincterotomy, the stones were extracted by balloon sweeping. When indicated, stents were placed.

Confirmation of successful therapeutic ERCP was made by laboratory and clinical improvement of the patients. After all ERCP procedures, one experienced and the same radiologist performed ultrasonographic evaluation of the biliary system in order to eliminate inter-observer variations. Neither fluoroscopy nor spot radiography were used during the procedure. After the ERCP procedure, laboratory findings and clinical progression of the patients were recorded and followed until discharge.

## RESULTS

The mean age of the patients was 28 years (range, 21-33 years). The mean gestational age of the fetus was 23 wk (range, 14-34 wk). The demographic and laboratory data of the patients are shown in Table 1. The treatment results and obstetric findings of the patients are summarized in Table 2. There were no complications related to sedoanalgesia in the mother and fetus after the procedure.

In one case, stone extraction after precut papillotomy with a needle-knife was performed since the stone was impacted. One patient had ERCP because of persistent biliary fistula after hepatic hydatid disease surgery. Following sphincterotomy performed by bipolar current, scoleces were extracted from the common bile duct. Two weeks later, since the fistula persisted, repeat ERCP was performed and a polyethylene stent was placed. The fistula was closed after the procedure. The laboratory abnormalities of the other patients with choledocholithiasis and/or choledocholithiasis-

**Table 2** Treatment results and obstetric findings

Patient number	Diagnosis	Procedure	CBD content	Gestational time (wk)	Delivery time (wk)

<sup>1</sup>After hydatid disease surgery; <sup>2</sup>Same patient with repeat ERCP.

induced acute cholangitis were normalized after ERCP. Ultrasonographic confirmation of stone extraction was made in all patients. Post-ERCP complications, premature birth, abortion or intrauterine growth retardation were not observed. The clinical follow-up of the patients until discharge was uneventful.

## DISCUSSION

Cholangitis in pregnancy is a serious condition for the mother and fetus, and results in high mortality and morbidity. ERCP is the first-line treatment of choice for cholangitis and pancreatitis caused by choledocholithiasis. However, the use of ERCP in pregnancy is limited because of the use of radiation. In previously described ERCP procedures performed during pregnancy, abdominal shielding was used to minimize radiation exposure<sup>[7]</sup>. Fetal damage by radiation is related to the time of pregnancy and the radiation dose. Several studies have demonstrated that ERCP can be successfully and safely performed during pregnancy<sup>[2,6,8-10]</sup>. The role of ERCP during pregnancy for complicated biliary tract diseases is well established. However, there remains the primary concern of fetal safety in relation to exposure to ionizing radiation. The putative risks may include fetal death, intrauterine growth retardation, malformations, and childhood cancer. It has been recommended that imaging modalities without ionizing radiation be used during pregnancy<sup>[9]</sup>. Therefore, attempts for complete exclusion of radiation are of paramount importance in ERCP. The literature has shown that ERCP can be performed safely without necessitating fluoroscopic use<sup>[11,12]</sup>.

Therapeutic ERCP is used routinely in pregnancy, with strict indications in clinical practice. Although the literature related to radiation exposure in ERCP has shown that ERCP is safe and effective in the early period after the procedure, the long-term negative effects of radiation exposure of children are unknown. Late adverse effects, such as cancer, may take years to develop after delivery, therefore, it is very difficult to determine the safe dose of radiation in pregnancy for ERCP. In order to overcome this problem, ERCP without radiation in pregnancy should be the first-choice treatment modality for therapeutic ERCP procedures.

In our study group, we cannulated the bile duct with the assistance of a guidewire. Cannulation was

confirmed by bile aspiration and/or visualization of the bile oozing around the guidewire after cannulation. Afterwards, bipolar biliary sphincterotomy with balloon sweeping of the biliary duct was performed. At least three times, the stone extraction balloon catheter had to be passed inside the bile duct and pulled out to achieve complete ductal clearance in patients with multiple stones. Improvements in laboratory, clinical and ultrasonographic findings were used as simple and accessible reference points for tracking the patients after ERCP. Maintenance of normal findings during follow-up of the patients after ERCP was thought to be related closely to the success of the procedure with regard to stone extraction. As wire-guided cannulation in non-radiation ERCP has the limitations of incorrect placement of the wire in the cystic duct and retained proximal stones after the procedure, choledochoscopy, real-time percutaneous ultrasonography, linear echoendoscopy, and intraductal ultrasonography are recommended for improving the performance of non-radiation ERCP<sup>[12]</sup>. Linear echoendoscopy, intraductal ultrasonography, and choledochoscopy may necessitate additional sedoanalgesia, which has a potentially jeopardizing effect on the fetus. As a result of this concern, we recommend simple monitoring of the patient with ultrasonography and biochemical and clinical parameters after the procedure. In our study, no complication was observed using these monitoring procedures.

Here, we presented six pregnant women with different etiologies, who underwent successful ERCP without the use of fluoroscopy. One case that makes our series interesting is the patient with biliary fistula after hepatic hydatid surgery. The patient was operated on because of liver hydatid disease that imitated acute abdominal findings. As a result of persistent biliary fistula after the operation, she underwent ERCP and sphincterotomy. Since the fistula lasted for an additional 2 wk after the procedure, which was documented by continuous drainage of the bile from the catheter and by MRCP, repeat ERCP with stenting was performed. In the following period, the clinical course was uneventful with closure of the fistula, and delivery occurred without any complication. The stent was removed after delivery.

In conclusion, there have been only a few studies of non-radiation ERCP during pregnancy. Therapeutic non-radiation ERCP with wire-guided cannulation, in

pregnant women with strong indications for ERCP, may be an effective treatment strategy in experienced centers. Laboratory and ultrasonographic follow-up of the patients after the procedure may be a safe, simple and cost-effective strategy for monitoring the effectiveness of the procedure. Stent placement should be considered in cases in which clearance of the common bile duct has failed. Larger studies are needed to draw strong conclusions about non-radiation ERCP.

## COMMENTS

### Background

Acute cholecystitis is the second most common non-obstetric emergency in pregnant women. Choledocholithiasis and consequent complications such as pancreatitis and cholangitis are potentially fatal diseases for the mother and fetus. During pregnancy, treatment is usually conservative since surgery is associated with an increased rate of complications such as preterm labor and spontaneous abortion. In choledocholithiasis and/or choledocholithiasis-induced acute cholangitis, endoscopic retrograde cholangiopancreatography (ERCP) is the first-line treatment of choice. Already, it has been reported that non-radiation ERCP might be an option for pregnant women with choledocholithiasis and/or choledocholithiasis-induced acute cholangitis.

### Research frontiers

Non-radiation ERCP has been used in some studies for the treatment of choledocholithiasis in pregnant women and strict guidelines have not been established.

### Innovations and breakthroughs

The authors reported that therapeutic non-radiation ERCP with wire-guided cannulation in pregnant women with strong indications for ERCP may be an effective treatment strategy in experienced centers. Laboratory and ultrasonographic follow-up of the patients after the procedure may be a safe, simple and cost-effective strategy for monitoring the effectiveness of the procedure.

### Applications

This study may be useful for showing the safety and effectiveness of non-radiation ERCP in pregnant women with choledocholithiasis and/or choledocholithiasis-induced acute cholangitis or biliary fistula.

### Peer review

This study examined the acceptability of ERCP without radiation during pregnancy. The authors showed their experience with six pregnant women who underwent ERCP without using radiation. The results are interesting and may form a reference for the treatment of pregnant women with strong indications for ERCP.

[adjusted odds ratio (aOR), 1.66; 95% CI: 1.21-2.26], middle/high school (aOR, 1.38; 95% CI: 1.01-1.89), and university or higher (aOR, 1.64; 95% CI: 1.13-2.37) were more likely to undergo gastric cancer screening than those who received no formal education at all. The population with the highest income tertile had more attendance at gastric screening compared to those with the lowest income tertile (aOR, 1.36; 95% CI: 1.06-1.73). Gastric screening was also negatively associated with excessive alcohol consumption (aOR, 0.71; 95% CI: 0.53-0.96). A positive attitude to preventive medical evaluation was significantly associated with better participation in gastric cancer screening programs (aOR, 5.26; 95% CI: 4.35-6.35).

**CONCLUSION:** Targeted interventions for vulnerable populations and public campaigns about preventive medical evaluation are needed to increase gastric cancer screening participation and reduce gastric cancer mortality.

### Abstract

**AIM:** To identify the factors associated with participation in gastric cancer screening programs.

**METHODS:** Using data from the Korea National Health and Nutrition Examination Survey 2005 (KNHANES III), a nationwide health-related survey in Korea, a cross-sectional study was performed to investigate the multiple factors associated with gastric cancer screening attendance among persons aged at least 40 years. The study population included 4593 individuals who completed a gastric cancer screening questionnaire and had no previous cancer history. Four groups of individual-level or environmental level covariates were considered as potential associated factors.

**RESULTS:** Using KNHANES III data, an estimated 31.71% of Korean individuals aged at least 40 years adhered to gastric cancer screening recommendations. Subjects who graduated from elementary school

### INTRODUCTION

Gastric cancer is a major public health burden. Although the worldwide incidence of gastric cancer and associated mortality is decreasing, gastric cancer is still the fourth most common cancer and the second leading cause of cancer-related death, causing 700 000 deaths annually<sup>[1]</sup>. In contrast to the worldwide trend, in Korea the incidence of gastric cancer has been reported to be stable or increasing, and is still one of the most common forms

of cancer and one of the leading causes of death from cancer among both sexes<sup>[2,3]</sup>. According to the Korea Central Cancer Registry Data, gastric cancers comprised 18% of all new cancers and caused 15.3% of cancer deaths in 2005.

Despite the increasing incidence of gastric cancer in Korea, mortality due to gastric cancer is decreasing. This is due to advances in surgical techniques, chemotherapy and radiological therapy, and to early detection by gastric cancer screening programs<sup>[4]</sup>. Because patients with early-stage gastric cancer often show no clinical symptoms, a significant proportion of patients are diagnosed when the disease is at an advanced stage, which is associated with poor prognosis. If screening for gastric cancer were universal, beginning at the age of 40 years, and combined with timely treatment of surgical or endoscopic mucosal removal of early cancers, the gastric cancer mortality rate could be markedly reduced<sup>[5,6]</sup>. A recent study in Korea also showed that repeated endoscopic screening within 2 years decreased the incidence of gastric cancer and endoscopic resection could be applied to more patients who underwent EGD screening within 2 years<sup>[7]</sup>.

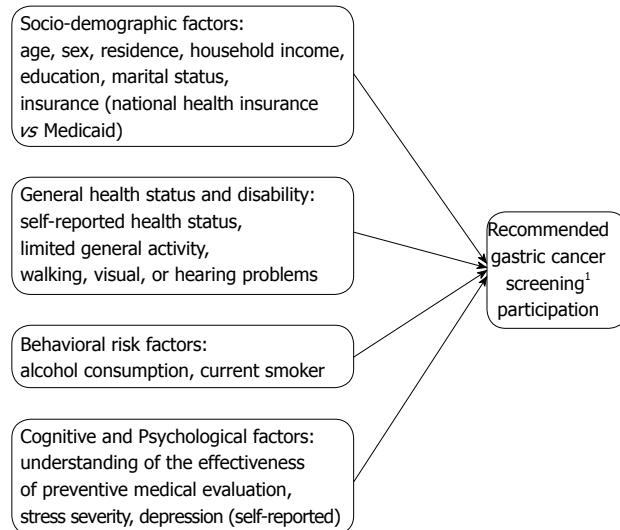

In the past decade, the Korean Ministry of Health and Welfare (MOHW) agency has established multiple cancer control programs. In 1996, the Korean government initiated a comprehensive “10-year plan for cancer control”. As part of this program, the Korean Government initiated the National Cancer Screening Program (NCSP) in 1999. Since then, the NCSP has provided free cancer screening for common cancers to low-income individuals receiving medical aid<sup>[8]</sup>. However, the rate of participation in gastric cancer screening programs is not optimal<sup>[9,10]</sup>. Therefore, to increase the participation rate and improve the survival rate of gastric cancer patients, identification and removal of potential barriers to cancer screening participation might be of great importance. However, few studies have investigated the individual and environmental predictors of gastric cancer screening participation in the Korean population.

In the present study, we analyzed the relationship among four dimensions of individual-level factors, including socio-demographic characteristics, general health status, gastric cancer risk factors and cognitive factors, and gastric cancer screening participation (Figure 1), among individuals included in the Third Korea National Health and Nutrition Examination Survey 2005 (KNHANES III).

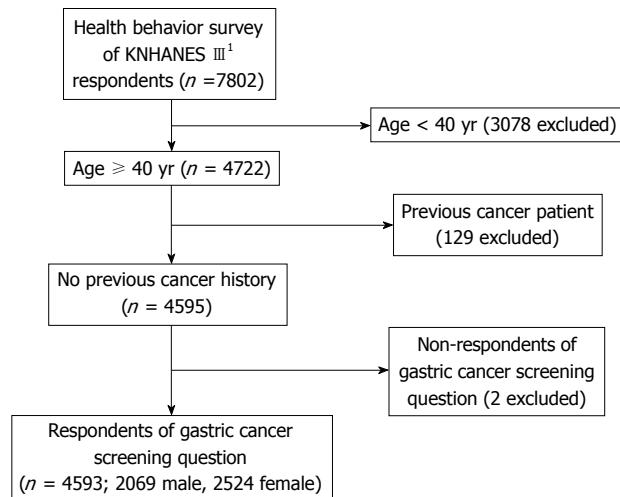

## MATERIALS AND METHODS

### **Study population**

This study was based on data obtained from the KNHANES III. The KNHANES is a national household survey that provides comprehensive information on health status, health care utilization, and socio-demographics of a nationally representative sample of 34145 individuals from 13800 households. The KNHANES III is composed of four parts: health interview survey, health behavior survey, health examination survey and nutrition survey.

**Figure 1** Framework of study investigating factors associated with gastric cancer screening participation. <sup>1</sup>Endoscope or upper gastrointestinal series; every 2 years, starting at the age of 40 years.

**Figure 2** The study population framework. <sup>1</sup>2005 Korean National Health and Nutrition Examination Survey.

We performed a cross-sectional analysis of data from the 7802 individuals who completed the health behavior survey. We then selected individuals aged at least 40 years who answered the gastric cancer screening behavior question, yielding 4722 individuals. After excluding 129 individuals who had previously been diagnosed with cancer, 4593 people (2069 men and 2524 women) were eligible for our analyses (Figure 2).

### **Gastric cancer screening behavior outcome**

According to the KNCSP guidelines, persons aged at least 40 years should undergo gastroscopy or upper gastrointestinal series (UGIS) examinations every 2 years. Subjects were asked the question “when was the last time you had a gastric cancer screening examination (endoscope or UGIS)?” The possible responses were “never”, “less than 1 year”, “1-2 years”, “more than 2 years”.

In the present study, the outcome variable is whether

the individuals adhere to KNCSP guidelines or not. We recognized that individuals who reported never taking a gastric cancer screening examination or having undergone examinations more than 2 years prior to completing the questionnaire would be classified as not adhering to KNCSP guidelines.

### **Independent variables**

Data about variables were also obtained from the KNHANES III and their associations with gastric cancer screening were investigated. We considered 17 variables as potential factors that could be associated with gastric cancer screening (Figure 1); these 17 variables were classified into one of four groups: (1) socio-demographic factors [age, gender, residential area (metropolitan area or not), household income, education level, marital status, insurance (national health insurance or Medicaid)]; (2) general health status and disability (self-reported health status, limitation of general activity, walking problem, visual problem, hearing problem; (3) gastric cancer risk factors (alcohol consumption, current smoker); (4) cognitive and psychological factors (attitude to routine health checks, stress severity, depression).

Patients were stratified by age; age 40-49, 50-59, 60-69 and  $\geq 70$  years. Residential area was classed as metropolitan or non-metropolitan area. Income was calculated by dividing the household monthly income by the square root of the household size (equivalized income), and was categorized into three groups<sup>[11,12]</sup>. Education level was categorized as uneducated, elementary school graduate, high school graduate, and college or higher education graduate. Marital status was recorded as married, unmarried, widowed, or divorced, and was dichotomized as living with or without spouse. South Korea has a universal health insurance system; hence we compared individuals with national health insurance (NHI) and those receiving Medicaid (the Korean government program for low-income or medically needy individuals).

Alcohol consumption was assessed using the question "how often do you binge drink?" (binge drinking was defined as seven or more drinks for men and five or more drinks for women), and was categorized into three groups: (1) non-binge drinker, nondrinker or social drinker who reported binge drinking no more than once per month; (2) binge drinker, reported binge drinking 1-4 times per month; and (3) frequent binge drinker, reported binge drinking more than twice per week<sup>[13]</sup>. Individuals were asked "Do you now smoke cigarettes?" and, based on responses, were categorized by smoking status into three groups: (1) never smoker, have never smoked; (2) ex-smoker, have quit smoking; and (3) current smoker, smoke daily or intermittently smoke.

For cognitive and psychological factors, we considered attitudes to preventive medical evaluation, stress severity and self-reported depression.

### **Statistical analysis**

The dependent variable of interest was whether the

patient had undergone gastric cancer screening within the previous 2 years; independent variables were the 17 factors described above.

Descriptive statistical methods were used to describe the basic characteristics of the study population; numbers and percentages are reported for each variable. First, to identify the factors associated with undergoing gastric cancer screening, we used univariate logistic regression analysis. Odds ratios and confidence intervals for the associations between gastric cancer screening attendance and each factor were calculated. A *P*-value less than 0.05 was considered significant. Next, the factors identified as significantly associated with gastric cancer screening by univariate analysis (*P* < 0.05) were analyzed by multivariate logistic regression analysis. All statistical tests were performed using STATA, version 10.0.

## **RESULTS**

### **General characteristics of the study population**

Characteristics of the study population are summarized in Table 1. In the study population, 1457 individuals (31.71%) had undergone a gastric cancer screening examination within the previous 2 years. The mean age of our study population was 55.12 years; 54.95% were women. Three-quarters of the population were living with a spouse and most were enrolled in the national health insurance program. Of the study population, 8.69% were frequent binge drinkers, consuming large quantities of alcohol almost daily. A total of 6.30% of women were current smokers, compared with 48.77% of men; this result is similar to that reported for adult men in Korea in 2006 (44.7%)<sup>[8]</sup>.

### **Factors associated with gastric cancer screening attendance**

Table 2 shows the univariate analysis results; crude odds ratios (ORs) and 95% confidence intervals (95% CIs) were reported. The factors associated with gastric cancer screening participation were age (more than 70 years), income, education level, marital status, limited general activity, visual problems, smoking status, attitude to preventive medical health assessments, stress and alcohol consumption.

By multivariate logistic regression analysis, only four of these factors were significantly and independently associated with gastric cancer screening (Table 3): household monthly income, education level, alcohol consumption and attitude to preventive medical evaluation.

Of the socio-demographic factors considered, higher household income was found to be associated with a higher OR. Compared with the lowest income tertile, the adjusted OR (aOR) of the highest income tertile was 1.36 (95% CI: 1.06-1.73). There was also a clear trend to increased rates of gastric cancer screening with greater education level (elementary school graduate: aOR, 1.66; 95% CI: 1.21-2.26; middle or high school graduate: aOR, 1.38; 95% CI: 1.01-1.89; university or higher education graduate: aOR, 1.64; 95% CI: 1.13-2.37).

## DISCUSSION

In this national representative household survey, we found that the participation rate of gastric cancer screening in Korea amongst individuals aged 40 years or more, is only 31.71%, even though gastric cancer is largely treatable when detected at an early stage. Our study also found that low household income, low education level, frequent binge drinking and a negative attitude to preventive medical evaluation were significantly associated with poor participation in gastric cancer screening programs. Our study is the first to use multivariate analysis to identify the factors associated with gastric cancer screening in clinical practice, including demographic factors, general health status, behavioral risk factors and psychological factors.

Factors associated with unhealthy behavior, such as alcohol consumption and smoking, are considered

gastric cancer risk factors<sup>[14-17]</sup>, and high levels of tobacco smoking and alcohol consumption have been shown to substantially increase the relative risk of this cancer<sup>[15]</sup>. Therefore, preventive measures, such as gastroscopy or UGIS, are likely to be of particular benefit in frequent binge drinkers and smokers. However, in this study, we found that frequent binge drinkers were less likely to undergo gastric cancer screening tests compared with others. Current smokers also showed a low participation rate in screening programs, although the difference compared with non-smokers was not significant. These findings indicate that more interventions are needed for individuals with unhealthy behavioral risk factors, and suggest that successful preventive measures could markedly reduce the number of gastric cancer deaths.

Our study also showed that a positive attitude to the effectiveness of preventive medical evaluation is strongly associated with gastric cancer screening participation. Previously, several studies have demonstrated that cognitive elements can directly affect the decision to undergo gastric cancer screening, and personal background and other socio-demographic factors might have indirect effects through their effects on cognitive variables<sup>[9,18]</sup>. These findings indicate that improved public education about the benefits of preventive cancer screening and routine health checks could have important influences on individual patient decisions to undergo gastric cancer screening.

Household income and education level were shown to be significant predictors of participation in gastric cancer screening in the present study. Previous studies have reported inconsistencies in the relative strength and significance of the correlations between cancer screening and socio-demographic factors<sup>[1,9,18-21]</sup>. There are several possible reasons for this inconsistency. One possibility is that physiologic medical accessibility may vary with health care policy and location; for example, developed *vs* non-developed countries or urban *vs* rural area. Therefore, the study location and health policy status should be considered when different studies are compared. Another possible reason is the differences in study design. Several recent reports in Korea have highlighted the factors associated with cancer screening participation, but showed no associations between gastric cancer screening and socio-economic factors<sup>[9,18]</sup>. This can be explained by the differences in study design, such as variable categories and outcome variable. In the present study, we used equivalized household income which was calculated by dividing the household monthly income by the square root of the household size, while other previous studies usually did not consider the household size and simply used the crude household income<sup>[9]</sup>. In addition, a major focus of one study was the intention to receive gastric cancer screening, not receipt of gastric cancer screening, which could lead to different results from our study<sup>[18]</sup>.

The Korean Government initiated the National Cancer Screening Program (NCSP) in 1999, and it has since expanded its target population. Currently, NCSP provides Medical Aid recipients and NHI beneficiaries within the lower 50% income bracket with free gastric cancer screening services<sup>[8]</sup>.

In addition, the costs of gastric cancer screening in Korea are low compared with other countries, which could improve the accessibility of these services to low-income individuals<sup>[22]</sup>. However, our results indicate that socio-economic inequalities in gastric cancer screening participation have not yet been sufficiently overcome. To increase gastric cancer screening participation, improved intervention programs for individuals with low income and education level are needed.

No general health status or disability-related factor was significantly associated with gastric cancer screening participation, which is in contrast to our original hypothesis that there might be disability-related barriers to participation in screening programs. A recent cross-sectional study reported that individuals with a disability showed reduced levels of participation in mass screening programs compared with those without a disability<sup>[23]</sup>. However, few studies have assessed the association between physical disability and gastric cancer screening participation. Further research about gastric cancer screening patterns among individuals with a disability is required to determine these associations.

Our study has several limitations. First, as the findings were based on patient self-reported health status data, respondents may under-report, over-report, or choose not to respond, leading to possible inaccuracy. Second, information about gastric cancer screening was obtained from the responses to a single question, and any symptoms at the time of the examination were not reported. Cancer screening prevention programs are designed for individuals with no associated symptoms; therefore, there could be some misclassification of gastric cancer screening participation by including individuals with symptoms indicative of gastric cancer. However, previous studies have also not considered accompanying symptoms, and used a similar definition of cancer screening participation<sup>[21,24,25]</sup>.

In conclusion, we found that more than two-thirds of the Korean population did not comply with the gastric cancer screening recommendations. These findings indicate that there is scope for further improvement. In particular, targeted interventions are needed for vulnerable populations such as those with low income, low education level and unhealthy behaviors. In addition, public campaigns to improve attitudes to preventive medical evaluation could be powerful methods to increase gastric cancer screening participation.

## COMMENTS

### Background

The mortality of gastric cancer is decreasing despite the increasing incidence in Korea. This can be explained by surgical technique development and early detection by endoscopic screening or upper gastrointestinal study.

### Research frontiers

Despite the development in national cancer control programs, the rate of participation in gastric cancer screening programs is still not optimal. However, few studies have investigated the individual and environmental predictors of gastric cancer screening participation in the Korean population. In this study, the authors identified the factors associated with participation in gastric cancer screening programs.

### Innovations and breakthroughs

Recent reports in Korea have highlighted the factors associated with cancer screening participation, but reported inconsistencies in the results. It can mainly be explained by the differences in study design, that is, different variable categories and outcome variables. Our study shows predictors associated with gastric cancer screening in multiple dimensions, both at the individual level and at the environmental level.

### Applications

The authors' findings indicate that targeted interventions and public campaigns for vulnerable populations could be powerful methods to increase gastric cancer screening participation.

### Peer review

In the present study, authors have performed a cross-sectional study investigating the factors associated with participation in a gastric cancer screening program in Korea, and multivariate analyses have revealed independent predictive factors to be household income, education, alcohol consumption and attitude to health check-up. The manuscript is relatively well written, and the results are moderately interesting.

## INTRODUCTION

Intrahepatic stones is a common disease in Eastern Asia. Hepatectomy that can remove stones, strictured bile duct and atrophic liver tissue seems to be the optimal treatment for intrahepatic stones in selected patients. It has been accepted increasingly as the definitive treatment for intrahepatic stones in Eastern Asian<sup>[1-5]</sup> and some European countries<sup>[6,7]</sup>. Most of the previous studies have demonstrated that liver resection for intrahepatic stones has been confined to unilateral resection. The outcomes of bilateral liver resection for bilateral intrahepatic stones have not been clarified.

The aims of this study were to evaluate the short- and long-term outcomes of bilateral liver resection for bilateral intrahepatic stones.

## Abstract

**AIM:** To evaluate the short- and long-term outcomes of bilateral liver resection for bilateral intrahepatic stones.

**METHODS:** We reviewed retrospectively 101 consecutive patients with bilateral intrahepatic stones who underwent bilateral liver resection in the past 10 years. The short- and long-term outcomes of the patients were analyzed. The Cox proportional hazards model was used to identify the risk factors related to stone recurrence.

**RESULTS:** There was no surgical mortality in this group of patients. The surgical morbidity was 28.7%. Stone clearance rate after hepatectomy was 84.2% and final clearance rate was 95.0% following postoperative choledochoscopic lithotripsy. The stone recurrence rate was 7.9% and the occurrence of postoperative cholangitis was 6.5% in a median follow-up period of 54 mo. The Cox proportional hazards model indicated that liver resection range, less than the range of stone distribution ( $P = 0.015$ , OR = 2.152) was an independent risk factor linked to stone recurrence.

**CONCLUSION:** Bilateral liver resection is safe and its short- and long-term outcomes are satisfactory for bilateral intrahepatic stones.

## MATERIALS AND METHODS

### Patients

The study included 101 consecutive patients with bilateral intrahepatic stones who underwent elected bilateral liver resection between January 1997 and December 2007. There were 45 men and 56 women with an average age of 47.2 years (range, 20-72 years). Forty-nine (48.6%) patients had undergone previous biliary surgery. Fifty-two (51.5%) patients also had extrahepatic stones. Twenty (19.8%) patients also had common bile duct cysts, and nine (8.9%) had hilar stricture.

### Indications of hepatectomy for intrahepatic stone

The indications of hepatectomy for bilateral intrahepatic stones were: (1) bilateral segmental liver parenchymal atrophy caused by stones; (2) stricture of stone-bearing bile ducts; (3) estimated liver remnant is sufficient after hepatectomy; and (4) the general condition of patient

was good and liver function was Child-Pugh A class, and he/she could tolerate the hepatectomy.

### Preoperative preparation

Preoperative preparation included liver biochemistry, coagulation profile, ultrasound and computed tomography (CT). If the liver resection range was larger than four liver segments, volumetric CT was done to estimate the volume of the liver remnant. Percutaneous transhepatic cholangiography or endoscopic retrograde cholangiopancreatography was performed selectively for patients with intrahepatic bile duct dilatation, which aimed at delineating the site of the bile duct stricture. For patients with acute cholangitis, percutaneous transhepatic cholangiodrainage (PTCD) guided by ultrasound or endoscopic nasobiliary drainage (ENBD) was performed preoperatively, and definitive hepatectomy was performed 1-3 mo later<sup>[8]</sup>. There were 17 patients with acute cholangitis who received PTCD and ENBD before definitive hepatectomy.

### Definitions

Bile leakage, defined as bile fluid draining from the peritoneal cavity or oozing from the wound, was demonstrated by cholangiography through a T tube or transanastomotic tube<sup>[8]</sup>. Postoperative liver failure was defined as serum total bilirubin > 85 μmol/L and coagulopathy (international normalized ratio > 1.5) that lasted for > 2 wk after hepatectomy. Patients presented with ascites and/or encephalopathy. Surgical mortality was defined as death within 30 d after hepatectomy. Major hepatectomy was defined as resection of more than three liver segments.

### Follow-up

Patients after surgery were followed up twice a year. Liver biochemistry and ultrasound were performed routinely. If stone recurrence was highly suspected, CT was performed. Stone recurrence was defined as stone recurrence intra- or extrahepatically after complete initial clearance. Patients who presented with right upper quadrant pain, chill and fever, with or without jaundice, were considered to have an acute attack of cholangitis.

At the end of the study (December 2008), 92 of 101 patients completed a median follow-up period of 54 mo (12-120 mo).

### Statistical analysis

Patient data were analyzed by SPSS version 13.0 software (Chicago, IL, USA). The Cox proportional hazards model was used to identify the risk factors associated with stone recurrence.  $P < 0.05$  was considered statistically significant.

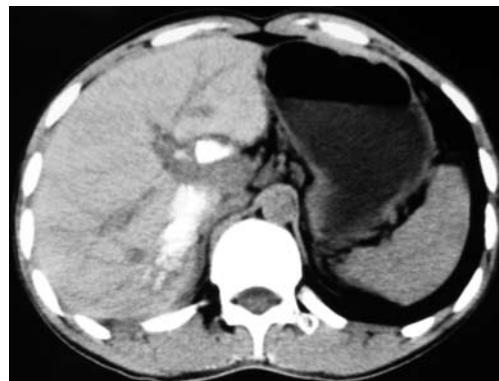

## RESULTS

### Procedures of bilateral liver resection

The detailed procedures of bilateral liver resection of the 101 patients are listed in Table 1. The most common

**Table 1 Liver resection procedures of 101 patients**

Procedures	n (%)
Left lateral sectionectomy plus right posterior sectionectomy	38 (37.6)
Left lateral sectionectomy plus segmentectomy of segments 5-7	18 (17.8)
Hemihepatectomy plus ipsilateral segmentectomy	21 (20.8)
Left hepatectomy plus right posterior sectionectomy	11 (10.9)
Left hepatectomy plus left caudate sectionectomy	9 (9.0)
Left trisegmentectomy	2 (2.0)
Left and right hepatectomy (leaving hypertrophic caudate lobe)	1 (1.0)
Segmentectomy of segments 2-5, 7, 8 (leaving hypertrophic segment 6)	1 (1.0)

**Figure 1** A patient with left lateral section and right posterior section stones underwent left lateral sectionectomy and right posterior sectionectomy.

procedure performed in this group of patients was left lateral sectionectomy plus right posterior sectionectomy (Figure 1), which accounted for 37.6% of patients. Four patients underwent more aggressive liver resection, which included two left trisegmentectomies; one left and right hepatectomy that left only the hypertrophic caudate lobe (970 g estimated by volumetric CT); and one segmentectomy of segments 2, 3, 4, 5, 7 and 8, which left only the hypertrophic segment 6 (670 g estimated by volumetric CT).

Twenty-nine of 101 (28.7%) patients had concomitant hepaticojejunostomy following resection of common bile duct cysts and bile duct strictureplasty.

The consistency between liver resection range and the range of stone distribution was classified into two categories: liver resection range equal to stone distribution, and liver resection range less than stone distribution. Fifty-eight of 101 (57.4%) patients had a liver resection range that was equal to the range of stone distribution, and the others had a resection range that was less than the range of stone distribution.

### Surgical mortality and morbidity

There was no surgical mortality in our group of patients. Twenty-nine (28.7%) patients developed one kind of complication (Table 2). One patient suffered from postoperative hemobilia at postoperative day 5, and he underwent emergency surgical exploration. Bleeding

**Table 2 Surgical complications**

Complications	n (%)
Wound infection	18 (17.8)
Bile leak	8 (8.0)
Peritoneal infection	7 (7.0)
Pleural effusion	10 (10.0)
Liver failure	2 (2.0)
Pulmonary infection	2 (2.0)
Hemobilia	1 (2.0)
Sepsis	1 (1.0)

of the anastomotic mouth was found and hemostasis was achieved by fine suturing the bleeding vessel at operation. He recovered well. The other complications were cured by conservative treatment.

### Stone clearance

Residual stone was confirmed by postoperative cholangiography through a T tube and transanastomotic tube, or ultrasound findings. Sixteen patients had residual stones after hepatectomy. The stone clearance rate was 84.2% (85/101). The final stone clearance rate was 95.0% (95/101) following 1-5 sessions of postoperative choledochoscopic lithotripsy through the T-tube or transanastomotic tube route. Residual stones could not be completely removed in five patients. This was because of tiny stones located at the peripheral bile duct or segregated bile duct that could not be reached by choledochoscopy ( $n = 3$ ), or because the sharp angle formation of the jejunal loop of hepaticojjunostomy hindered entry of the choledochoscope ( $n = 2$ ).

### Stone recurrence

At the end of this study, 92 patients had completed the follow-up, including 89 whose stones were completely removed at initial operation and three patients with residual stones. In a median follow-up period of 54 mo, seven (7.9%) patients developed stone recurrence. Six patients suffered from at least one attack of acute cholangitis. Four of six patients had stone recurrence and the other two had residual stones. The occurrence of acute cholangitis was 6.5% (6/92). Stone recurrence and residual stones were the major causes of postoperative acute cholangitis.

To identify the risk factors related to stone recurrence, six clinical factors including age ( $\geq 50$ ,  $< 50$  years), sex, previous history of biliary surgery, complicated with extrahepatic stones, concomitant hepaticojjunostomy, and consistency between liver resection range and the range of stone distribution were analyzed by the Cox proportional hazards model. It indicated that liver resection range less than the range of stone distribution ( $P = 0.015$ , OR = 2.152, 95% CI: 1.624-4.721) was the only independent risk factor associated with stone recurrence.

## DISCUSSION

The treatment principle of intrahepatic stones consists

of complete removal of the stones, strictured bile duct and atrophic liver parenchyma, and establishment of satisfactory biliary drainage. Bilateral intrahepatic stones is a complex condition, and treatment of this disease remains a challenge. Hepatectomy that can remove stones and resect strictured bile ducts seems to be the optimal treatment for intrahepatic stones. Whether bilateral liver resection is feasible for bilateral intrahepatic stones and its outcome have not been evaluated.

Our results demonstrated that stone clearance rate after hepatectomy was 84.2%, and the final clearance rate was 95% following choledochoscopic lithotripsy. There was no surgical mortality. The stone recurrence rate was 7.9% and the occurrence of acute cholangitis episodes was 6.5%, after a median follow-up period of 54 mo. This indicated that bilateral liver resection for bilateral intrahepatic stones was safe, and its short- and long-term outcomes were satisfactory.

The locations of intrahepatic stones are strictly within segments. Most commonly, the involved segments are destroyed and atrophic, and the stone-bearing bile ducts show fibrotic thickening or stricture because of repeated attacks of acute cholangitis, whereas, the non-involved segments are hypertrophic (especially in patients with bilateral stones). Therefore, anatomical hepatectomy for the affected segments is feasible, with the prerequisite of there being sufficient remnant liver. The Cox proportional hazards model indicated that a liver resection range less than the range of stone distribution was the only independent risk factor associated with stone recurrence in this study. A liver resection range less than the range of stone distribution may leave bile duct stricture, which is a key predisposing factor for stone recurrence<sup>[9-11]</sup>.

There is reluctance among some surgeons to perform bilateral liver resection for bilobar stones because of the associated surgical risks. It has been reported that hepatectomy for the more severely affected side, combined with hepaticojjunostomy for removal of stones on the other side, is an effective approach<sup>[2]</sup>. We do not advocate that the liver resection range should be consistent with the range of stone distribution for every patient with bilateral intrahepatic stones. However, we suggest strongly that the strictured stone-bearing bile ducts and atrophic liver tissue should be resected, with the prerequisite of leaving sufficient remnant liver. This is because the strictured inflammatory bile ducts and atrophic tissue are predisposing risk factors for stone recurrence<sup>[9,10]</sup> and the occurrence of cholangiocarcinoma<sup>[12-14]</sup>. If the estimated future liver remnant was not sufficient, hepatectomy was performed for the severely affected side and the ipsilateral stones were removed as cleanly as possible via intraoperative choledochoscopic lithotripsy. Whenever possible, we do not perform hepaticojjunostomy for intrahepatic stones, but attempt to preserve the normal anatomy of the common bile duct because hepaticojjunostomy cannot drain residual stones effectively<sup>[15]</sup>, and it has a high incidence of cholangitis after hepaticojjunostomy<sup>[16,17]</sup>. Twenty-nine patients in our group had concomitant

hepaticojejunotomy following resection of common bile duct cysts and bile duct strictureplasty.

All liver resections in our 101 patients were major hepatectomies (resection of more than three segments). There was no surgical mortality and the postoperative morbidity was 28.7%. We concluded that the zero surgical mortality and acceptable morbidity of this study were the result of deliberate preoperative preparations. Preoperative volumetric CT estimation is of critical importance for patients who undergo resection of more than four liver segments. Sufficient future remnant liver is mandatory for preventing postoperative liver failure. For patients with acute cholangitis, preoperative PTCD or ENBD is indicated for relieving biliary sepsis. Definitive hepatectomy is performed 1 mo later after sepsis subsides<sup>[8]</sup>. This management may decrease the surgical morbidity.

In conclusion, this study demonstrated that bilateral liver resection is safe and its short- and long-term outcomes are satisfactory. A liver resection range less than the range of stone distribution is an independent risk factor associated with stone recurrence. Complete resection of strictured stone-bearing bile ducts and atrophic liver tissue, with the prerequisite of sufficient future remnant liver may decrease stone recurrence.

## COMMENTS

### Background

Intrahepatic stones is a common disease in Eastern Asia. Hepatectomy that can remove stones, strictured bile duct and atrophic liver tissue seems to be the optimal treatment for intrahepatic stones, and has been accepted increasingly as the definitive treatment. Most of the previous studies have demonstrated that liver resection for intrahepatic stones is confined to unilateral resection. The outcomes of bilateral liver resection for bilateral intrahepatic stones have not been clarified. Therefore, this study was conducted to evaluate the short- and long-term outcomes of bilateral liver resection for bilateral intrahepatic stones.

### Research frontiers

This study evaluated the feasibility and outcomes of bilateral liver resection for bilateral intrahepatic stones.

### Innovations and breakthroughs

There have been an increasing number of studies on hepatectomy for intrahepatic stones in recent years. For the subgroup of patients with bilateral intrahepatic stones, the feasibility and outcome of bilateral liver resection have not been clarified. This study is believed to be the first to demonstrate that bilateral liver resection for bilateral intrahepatic stones is safe and its long-term outcome is satisfactory, with a stone recurrence rate of 7.9% and an acute cholangitis rate of 6.5%.

### Applications

The most important clinical application of this study is that bilateral liver resection is indicated in a subgroup of patients with bilateral intrahepatic stones. The results of this study expand the surgical indications of hepatectomy for intrahepatic stones.

### Terminology

Bilateral liver resection is defined as bilateral resection of stone-bearing segments, with the prerequisite of leaving a sufficient liver remnant, for example, left lateral sectionectomy plus right posterior sectionectomy.

### Peer review

This paper is very interesting and well written. The study is provocative and the findings might be helpful for understanding the indications for bilateral liver resection of bilateral intrahepatic stones.

at the ablated area was 17% for all patients, 11% and 23% for patients in sequential group and cryo-alone groups, respectively ( $P = 0.001$ ). The overall 1-, 2-, 3-, 4- and 5-year survival rate was 72%, 57%, 47%, 39% and 31%, respectively. The 1- and 2-year survival rates (71% and 61%) in sequential group were similar to those (73% and 54%) in cryo-alone group ( $P = 0.69$  and 0.147), while the 4- and 5-year survival rates were 49% and 39% in sequential group, higher than those (29% and 23%) in cryo-alone group ( $P = 0.001$ ). Eighteen patients with large HCC (> 5 cm in diameter) survived for more than 5 years after sequential TACE while no patient with large HCC (> 5 cm in diameter) survived more than 5 years after cryosurgery. The overall complication rate was 24%, and the complication rates were 21% and 26% for the sequential and cryo-alone groups, respectively ( $P = 0.06$ ). The incidence of hepatic bleeding was higher in cryo-alone group than in sequential group ( $P = 0.02$ ). Liver crack only occurred in two patients of the cryo-alone group.

**CONCLUSION:** Pre-cryosurgical TACE can increase the cryoablation efficacy and decrease its adverse effects, especially bleeding. Sequential TACE and cryosurgery may be the better procedure for unresectable HCC, especially for large HCC.

Sequential use of transarterial chemoembolization and percutaneous cryosurgery for hepatocellular carcinoma. *World J Gastroenterol* 2009; 15(29): 3664-3669 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3664.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3664>

## INTRODUCTION

Cryosurgery has been used for two decades in treatment of many benign, malignant, and metastatic tumors<sup>[1-3]</sup>.

**RESULTS:** During a mean follow-up period of 42 ± 17 mo (range, 24-70 mo), the local recurrence rate

Furthermore, hepatocellular carcinoma (HCC) has been successfully treated either with cryosurgery alone or in combination with resection<sup>[4-6]</sup>.

Transarterial chemoembolization (TACE) itself is not associated with improved survival for patients with HCC<sup>[7]</sup>. However, it can shrink the HCC mass. It has been shown that sequential use of TACE and hepatectomy improves the outcome of patients with large HCC<sup>[8]</sup>. Cryosurgery is similar to the surgical resection of HCC in terms of total destruction of the tumor tissue. Therefore, TACE in combination with cryosurgery is expected to yield a better therapeutic effect on HCC, especially on large HCC.

From March 2001 to December 2006, 510 patients with HCC underwent percutaneous cryosurgery with or without TACE. In this study, we retrospectively investigated the results of 420 patients with HCC. Of them, 290 were treated with sequential use of TACE and percutaneous cryosurgery, and 130 received percutaneous cryosurgery alone.

## MATERIALS AND METHODS

### **Patients**

A total of 420 patients (310 males and 110 females) at a median age of 43 years (range, 21-81 years) were enrolled in this study. The diagnosis of HCC was made by abdominal computed tomography (CT), liver ultrasonography, and/or whole positron emission tomography-CT (PET-CT). Two hundred and ninety-five patients had an elevated serum  $\alpha$ -fetoprotein (AFP) level. HCC was proven by biopsy in 286 patients. All the patients were considered to have unresectable tumors due to their location or size or comorbidity. Patients with Child-Pugh C tumors and cirrhotic ascites were excluded from this study. The patients were divided into sequential TACE-cryosurgery (sequential) group ( $n = 290$ ) and cryosurgery alone (cryo-alone) group ( $n = 130$ ) (Table 1). There were no differences in age, sex and Child-Pugh classification of the patients between the two groups. However, patients in the sequential group tended to have larger tumors and a greater number of tumors compared to those in the cryo-alone group ( $P < 0.05$ ). Tumors larger than 10 cm in diameter were only found in the sequential group. All patients gave their informed consent. The study was approved by the Ethical Committee of Fuda Cancer Hospital (Guangzhou, China).

### **Methods**

TACE was performed after cross-sectional images were reviewed as previously described<sup>[9]</sup>. A French vascular sheath was placed into the femoral artery, and a 0.035 inch diameter Mickaelson catheter was advanced into the celiac and superior mesenteric arteries. Contrast was injected into the arteries during rapid-sequence radiographic imaging. Arterial branches supplying the tumors were then located. The venous phase was carefully examined for patency of the portal veins. A 0.018 inch diameter Tracker catheter was advanced through the Mickaelson catheter to the arterial branches supplying the tumors. The mixture of

doxorubicin (50 mg), mitomycin (10 mg), and lipiodol (4-15 mL) was injected into the arterial branches until hemostasis was achieved. If the tumors had no shrinkage 2 wk after the procedure, a second TACE was performed.

Percutaneous cryosurgery was performed under the guidance of ultrasound. Right lateral intercostal access was used to place cryoprobes in most patients. The size of cryoprobes used depended upon the tumor size and number. Small lesions were ablated with one or two 2-mm cryoprobes. Larger caliber cryoprobes (5-mm) or multiple probes were used according to the size of lesions. The cryoprobes were placed in the centre of tumor using a modified Seldinger technique under real-time ultrasound guidance. Multiple cryoprobes were placed 1.5-2 cm apart in the tumor periphery. Once the cryoprobe was positioned, freezing was initiated using an argon/helium-based cryosurgery system (EndoCare, Inc., Irvine, Calif. USA). Two freeze cycles (15 min each) were applied for 10-15 min of helium thaw following each freeze. The size of the ice ball formed by the cryoprobes was evaluated by ultrasound and made at least 1 cm larger than the apparent ultrasonic size of the tumor. Generally, separate lesions were frozen sequentially rather than simultaneously. The probe was removed after the second freeze/thaw cycle and the tract was filled with Gelfoam strips soaked in thrombin to facilitate hemostasis<sup>[10,11]</sup>.

### **Follow-up**

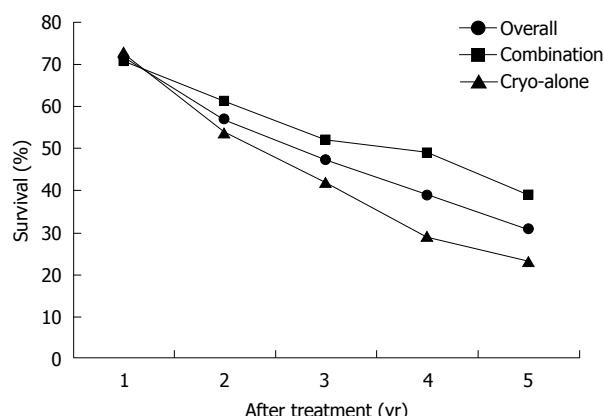

Follow-up consisted of ultrasonography and/or helical CT of the liver and serial check of AFP levels 1 mo after surgery and then every 2-3 mo for 1-2 years. Eighty-two patients underwent PET-CT during the follow-up and were subsequently reassessed every 6 mo with PET-CT. Successful tumor ablation (disease-free) was ideally defined by disappearance or no expansion of the ablated lesion on CT follow-up or no metabolic activity on PET-CT. Tumor recurrence or persistence was also defined using CT. Percutaneous biopsy was used in 79 patients to verify the eradication or recurrence of tumors.

### **Statistical analysis**

Survival rate of the patients was calculated from the

**Table 2 Survival rate of patients after sequential TACE-cryoablation or cryo-alone groups (%)**

	Patients (n = 420)	Sequential group (n = 290)	Cryo-alone group (n = 130)	P

time of cryosurgery to the time of death or last follow-up with Kaplan-Meier method (*J Am Stat Assoc* 1958; 53: 457-481). Values were expressed as mean  $\pm$  SD. Variables were compared using Fisher's exact test (two-sided) or rank-sum test when appropriate.  $P < 0.05$  was considered statistically significant. SPSS 9.0 (SPSS, Chicago, Illinois) was used for data analysis.

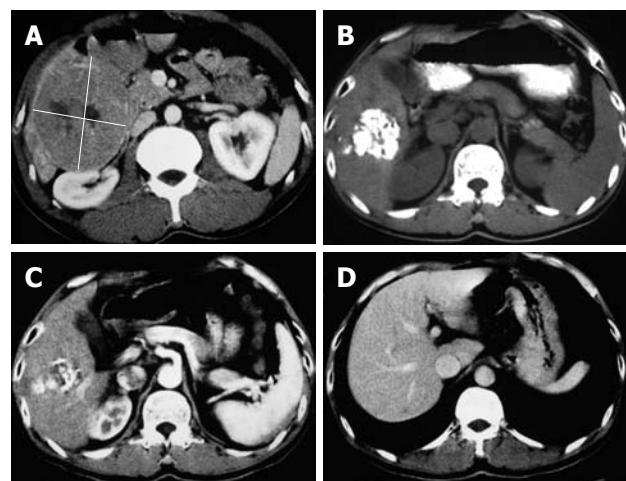

## RESULTS

### Survival

The patients were followed up for  $42 \pm 17$  mo (range, 24-70 mo) (Table 2). The local recurrence rate at the ablated area was 17% for all patients, and 11% and 23% for sequential and cryo-alone groups, respectively ( $P = 0.001$ ). The overall 1-, 2-, 3-, 4- and 5-year survival rate was 72%, 57%, 47%, 39% and 31%, respectively. The 1- and 2-year survival rates (71% and 61%) for sequential group were similar to those (73% and 54%) for cryo-alone group ( $P = 0.69$  and 0.147, respectively), while the 4- and 5-year survival rates were 49% and 39% for sequential group, higher than those (29% and 23%) for cryo-alone group ( $P = 0.001$ , Figure 1).

Eighteen patients with large HCC (> 5 cm in diameter) survived more than 5 years after sequential TACE-cryosurgery while no patient with large HCC survived more than 5 years after cryosurgery alone.

The CT of liver for selected patients is illustrated in Figures 2-4.

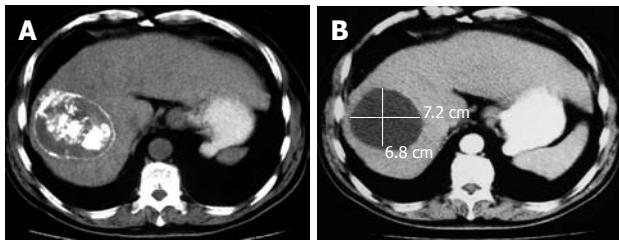

**Figure 2 Biopsy showing a HCC mass (11 cm x 9 cm) in the right liver lobe. The sequential changes (A-D) of the mass were disappeared after sequential therapy.**

### Complications

The main complications were hepatic bleeding, liver crack and failure, thrombocytopenia and/or clotting dysfunction, acute renal failure with myoglobinuria and pneumonia (Table 3). The overall complication rate was 24%, and the complication rate was 21% and 26%, respectively, for the sequential and cryo-alone groups ( $P = 0.184$ ). The incidence of hepatic bleeding was higher in cryo-alone group than in sequential group ( $P = 0.001$ ). Liver crack only occurred in the cryo-alone group. The incidence of thrombocytopenia and/or clotting dysfunction, liver failure and pneumonia was similar in the two groups ( $P = 0.599$ ). Acute renal failure with myoglobinuria was observed in two patients of the sequential group and in one patient of the cryo-alone group. Agranulocytosis occurred in only four patients of the sequential group. Two patients in the cryo-alone group died of liver crack and massive hepatic bleeding during pericyrosurgery.

## DISCUSSION

Surgical resection (hepatectomy) can achieve a long-term

**Figure 3 Histology showing the HCC mass at 3 mo (A) and 28 mo (B) after sequential therapy.** The cryoablated mass had cavitation formation. No cancer cells were identified by needle aspiration.

survival time in up to 30% of patients with HCC. Unfortunately, because of the limitations of surgical techniques and patient condition, only 25% or less of patients are estimated to be candidates for resection of HCC<sup>[12]</sup>. Since cryosurgery is a focal treatment, sparing more normal liver tissues than resection, it can be used for unresectable multiple lesions affecting both liver lobes and large tumors abutting major vessels<sup>[13,14]</sup>. It has been shown that mini-invasively percutaneous hepatic cryosurgery under guidance of real time ultrasound can achieve a long-term survival of patients with both primary and metastatic hepatic malignancies<sup>[15,16]</sup>.

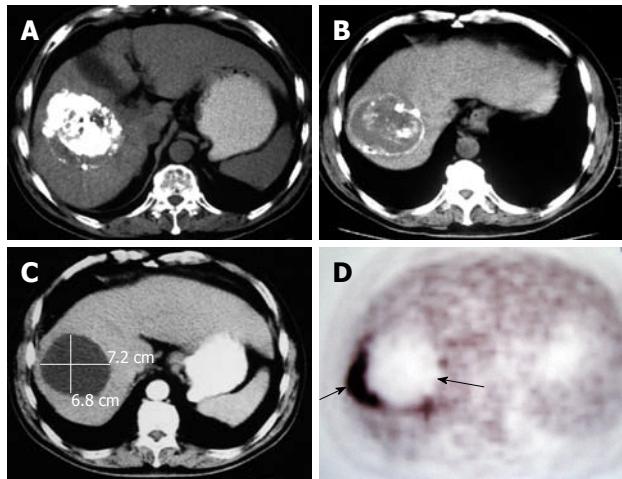

Cryoablation is effective for tumor mass, but post-cryosurgical recurrence is often observed due to insufficient freezing during cryosurgery<sup>[17]</sup>. Overcoming this problem is the key to the improvement of overall survival rate of patients.

TACE is used either as an adjuvant therapy or as a palliative procedure for patients with unresectable HCC<sup>[18,19]</sup>. It has been shown that TACE prior to surgical resection can not only prevent recurrence of HCC by controlling intrahepatic spread via the portal system, but also facilitate surgery by reducing tumor bulk<sup>[20]</sup>. Cryosurgery, in which tumors are frozen and then left *in situ* to be reabsorbed, is equivalent to the surgical resection of HCC in terms of total destruction of the tumor tissue, indicating that it is reasonable to perform TACE for tumors prior to cryosurgery.

In our study, the 1-, 2-, 3, 4- and 5-year survival rate was 71%, 61%, 52%, 49% and 39%, respectively, for the 290 patients after sequential TACE-cryosurgery, and 73%, 54%, 42%, 29% and 23%, respectively, for the 130 patients after cryo-alone. The 4- and 5-year survival rates were higher for the patients of sequential group than for those of cryo-alone group, suggesting that cryosurgery in combination with TACE can achieve a better long-term outcome, which is consistent with the reported findings<sup>[21]</sup>.

The relatively good outcome obtained in our study was due to the complementary effect of sequential TACE and cryosurgery.

Several factors can influence cryo-induced tumor cell destruction. Among these factors, temperature is a critical factor since a temperature lower than -40°C is assumed necessary to ensure tumor ablation. An ice-ball larger than the target lesion is thus necessary for complete tumor ablation, because the temperature at the

**Figure 4 A biopsy-proved HCC a female.** A: A space-occupying lesion in right lobe of the liver after TACE and prior to the cryosurgery; B: The cryoablated lesion at 3 mo and 3 years, respectively, after cryosurgery; C: Needle aspiration showing liquefaction of the cryoablated lesion and no cancer cells; D: PET-CT showing no metabolic activity in the cryoablated mass 5 years after therapy.

edge (a few millimeters in thickness) of an ice-ball is non-lethal<sup>[22]</sup>. An ice-ball encompassing the entire tumor mass 1 cm beyond the tumor border should be considered adequate for ablation. According to the MRI-estimated three-dimensional temperature distribution in liver cryolesions<sup>[23]</sup>, the mean value of distances calculated between the -40°C isotherm and cryolesion edge is a median of 4.1 mm and the largest distance defined for each cryo-lesion is a median of 8.1 mm. However, the distance is related to the volume of the cryo-treated tumor. The largest distance defined between the the -40°C isotherm and the edge of cryo-lesion may be close to 1 cm for a cryo-lesion volume less than 25 cm<sup>3</sup>, while a cryo-lesion larger than 25 cm<sup>3</sup>, the 1-cm ice-ball extension cannot ensure the temperature adequate for ablation in the entire volume enclosed by the rim zone. It has been shown that tumor size influences the tumor ablation rate, and lesions larger than 3 cm are more likely associated with a higher recurrence rate than smaller tumors<sup>[24]</sup>.

Therefore, the smaller the tumor is, the more effective the cryoablation is and the lower the recurrence rate is. Since TACE can shrink HCC mass, it can be expected to increase the efficacy of cryoablation for HCC, and to decrease its local recurrence if performed prior to cryoablation. In our study, the recurrence rate of HCC was 11% for the sequential group and 23% for the cryo-alone group, respectively, that is of special significance for large tumors close to large vessels, because the temperature cannot reach the edge zone of cryo-lesions due to its blood warming effect<sup>[25,26]</sup>. This opinion is supported by our study in which 18 patients with large HCC (> 5 cm in diameter) survived more than 5 years after sequential TACE while no patient with large HCC survived more than 5 years after cryosurgery alone.

The major complications of cryosurgery are hemorrhage and liver crack<sup>[27,28]</sup>. In our study, post-cryosurgery hepatic bleeding occurred in 16 patients.

Of them, 11 (8.5%) received cryo-alone and 5 (1.7%) underwent sequential TACE. The most dangerous liver crack was observed in only two patients of the cryo-alone group. Clavien *et al*<sup>[21]</sup> treated 15 HCC patients with cryosurgery and found that only one patient who did not undergo pre-cryosurgery TACE had hepatic bleeding, suggesting that TACE can reduce post-cryosurgery complications, such as bleeding and liver crack.

Pre-surgical TACE may be contraindicated in patients with resectable HCC and cirrhosis, because it causes progressive deterioration of liver function<sup>[29]</sup>. However, Kaibori *et al*<sup>[20]</sup> reported that TACE prior to HCC resection improves the prognosis of HCC patients with severe liver dysfunction, because decreasing resection of non-tumorous liver tissue avoids postoperative hepatic failure in patients with cirrhosis. In our study, liver failure occurred in 16 patients (3.8%), including 12 patients in the sequential group and four patients in the cryo-alone group, with no increased risk of liver failure caused by TACE. Other adverse effects of cryosurgery, such as thrombocytopenia and/or clotting dysfunction, acute renal failure with myoglobinuria, were observed in both groups of patients. In our study, four patients in the sequential group developed agranulocytosis due to a higher dose of chemotherapeutic agents used in TACE. The complication became less when the dose of chemotherapeutic agents was reduced.

In conclusion, TACE prior to cryosurgery can increase cryoablation efficacy and decrease its adverse effects, especially bleeding. Sequential use of TACE and cryosurgery may be a better procedure for improving the outcome of patients with unresectable HCC, especially large HCC. Further prospective study is required to fully evaluate its value.

## COMMENTS

### Background

Hepatocellular carcinoma (HCC) is one of the most common cancers in the world. Its treatment modalities, including surgical resection or liver transplantation, benefit only a small proportion of such patients. Cryosurgery, one of the proposed therapies for HCC, can improve the survival time of such patients.

### Research frontiers

Although cryosurgery is considered an effective treatment modality for unresectable HCC, it has been performed only for smaller tumors. Selected patients with stage III/IV HCC can be down staged with transarterial chemoembolization (TACE). Importantly, patients who are successfully down staged have a higher overall survival rate after resection of HCC. TACE prior to cryosurgery should be a good choice for HCC.

### Innovations and breakthroughs

Few reports are available on combined TACE and percutaneous cryosurgery. This study showed that pre-cryosurgical TACE could increase the cryoablation efficacy and decrease its adverse effects, especially bleeding, and improve the outcome of patients with unresectable HCC, especially large HCC.

### Applications

To the best of our knowledge, this is the first study comparing sequential TACE and cryosurgery for HCC patients. The results of this study show that sequential TACE and cryosurgery are a rather good treatment modality for HCC.

### Terminology

Cryosurgery, also known as cryotherapy or cryoablation, has gone through a long process of development. From the end of the 20th century, the development of imaging techniques and new freezing equipments has led to the emergence of modern cryosurgery. Liquid nitrogen operation system and

argon-helium surgical system are representative of two important stages of modern cryosurgery. Apart from liver cancer, cryosurgery has been successfully performed for a variety of tumors.

### Peer review

The study seems to be very interesting. The results, based on clinical observation and follow-up, suggest that sequential TACE and percutaneous cryosurgery are a better choice for unresectable HCC, especially large HCC.

### Abstract

**AIM:** To investigate contrast-enhanced ultrasound (CEUS) for early diagnosis of postoperative vascular complications after right-lobe living donor liver transplantation (RLDLT).

**METHODS:** The ultrasonography results of 172 patients who underwent RLDLT in West China Hospital, Sichuan University from January 2005 to June 2008 were analyzed retrospectively. Among these 172 patients, 16 patients' hepatic artery flow and two patients' portal vein flow was not observed by Doppler ultrasound, and 10 patients' bridging vein flow was not shown by Doppler ultrasound and there was a regional inhomogeneous echo in the liver parenchyma upon 2D ultrasound. Thus, CEUS examination was performed in these 28 patients.

**RESULTS:** Among the 16 patients without hepatic artery flow at Doppler ultrasound, CEUS showed nine cases of slender hepatic artery, six of hepatic arterial thrombosis that was confirmed by digital subtraction angiography and/or surgery, and one of hepatic arterial occlusion with formation of lateral branches. Among the two patients without portal vein flow at Doppler ultrasound, CEUS showed one case of hematoma compression and one of portal vein thrombosis,

and both were confirmed by surgery. Among the 10 patients without bridging vein flow and with liver parenchyma inhomogeneous echo, CEUS showed regionally poor perfusion in the inhomogeneous area, two of which were confirmed by enhanced computed tomography (CT), but no more additional information about bridging vein flow was provided by enhanced CT.

**CONCLUSION:** CEUS may be a new approach for early diagnosis of postoperative vascular complications after RLDLT, and it can be performed at the bedside.

Luo Y, Fan YT, Lu Q, Li B, Wen TF, Zhang ZW. CEUS: A new imaging approach for postoperative vascular complications after right-lobe LDLT. *World J Gastroenterol* 2009; 15(29): 3670-3675 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3670.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3670>

### INTRODUCTION

A right-lobe living donor liver transplantation (RLDLT), with or without the middle hepatic vein (MHV), is now used generally for adult-to adult liver transplantation<sup>[1]</sup>. A right liver graft only involves part of the liver lobes from healthy donors, whose vessels are very slender and the reconstruction of one or more tributaries of the MHV (bridging vein) is sometimes involved. RLDLT can be complicated by a high incidence of postoperative vascular complications, which may cause graft dysfunction and liver failure. Therefore, early diagnosis of postoperative vascular complications is very important after RLDLT. As noninvasive examinations, 2D and Doppler ultrasound play important roles in

screening for postoperative complications, but vascular visualization is not always satisfactory<sup>[2-4]</sup>. Contrast-enhanced ultrasound (CEUS) has been applied gradually in recent years and has provided a great improvement for this defect, because of its fine vascular tracing and perfusion visualization<sup>[5-8]</sup>.

The present study analyzed retrospectively CEUS in patients who underwent RLDLT in West China Hospital, Sichuan University from January 2005 to June 2008, to investigate the diagnostic value of CEUS in postoperative vascular complications.

## MATERIALS AND METHODS

### Clinical data

The study was conducted under the approval of the Ethics Committee of West China Hospital, and written informed consent was obtained from all patients who received CEUS examination. We analyzed retrospectively the ultrasound results of 172 consecutive patients (137 men and 35 women, aged 18-63 years, mean 39.1 years), who underwent RLDLT from January 2005 to June 2008 in West China Hospital. Bypass of MHV tributaries was performed in 83 cases. The primary diseases included 98 with cirrhosis, 58 with malignant liver tumors, 12 with acute liver failure, one with hepatic echinococcosis, one with Budd-Chiari syndrome, and two cases liver re-transplantation.

### Instrument and methods

Phillips HDI5000 and HD 11 (Phillips Medical Systems, Bothell, WA, USA) with 2-5-MHz probes were used in our study as conventional ultrasound equipment. CEUS examinations were performed with Acuson Sequoia 512 with contrast pulse sequencing (Siemens Medical Solutions, Mountain View, CA, USA) or Phillips IU 22 (Phillips Medical Systems) with the pulse inversion technique. Gray-scale ultrasound was used to observe liver graft parenchyma, and portal and hepatic veins, and Doppler ultrasound was used to measure blood flow and its velocity in the hepatic artery, portal and hepatic veins, and bridging vein. CEUS was performed in patients without hepatic artery and/or portal vein flow and/or patients without bridging vein flow accompanied by liver regional inhomogenous echo. The aim of CEUS was to observe blood flow in the above vessels, as well as perfusion of the liver. Conventional Doppler ultrasound and CEUS were performed by two experienced ultrasound physicians with more than 5 years experience in liver transplantation. Ultrasonography was performed everyday within the first week after operation in the intensive care unit (ICU), and afterwards, the time and interval of ultrasound examination depended on laboratory results and clinical conditions. The contrast agent was SonoVue (Bracco Imaging, Milan, Italy), which consists of an inert gas, sulfur hexafluoride and phospholipid peplos with high flexibility. CEUS was performed using 1.2-2.4 mL SonoVue suspension by rapid bolus injection through the left ulnar vein,

followed by 10 mL saline flush and an ultrasonic inner time counter started simultaneously. Dynamic and static images were recorded to observe patency of the hepatic artery, portal and hepatic veins, and bridging vein, as well as perfusion of the liver parenchyma.

## RESULTS

Among these 172 patients, 16 patients' hepatic artery flow and two patients' portal vein flow was not observed by Doppler ultrasound, and 10 patients' bridging vein flow was not shown by Doppler ultrasound and there was a regional inhomogeneous echo in the liver parenchyma upon 2D ultrasound. Thus, CEUS examination was performed in these 28 patients.

Among the 16 patients without hepatic artery flow at Doppler ultrasound, CEUS showed a slender right hepatic artery in nine (Figure 1), hepatic artery thrombosis (HAT) in six (Figure 2), all confirmed by digital subtraction angiography and/or surgery, hepatic artery occlusion accompanied by lateral branches in one (Figure 3).

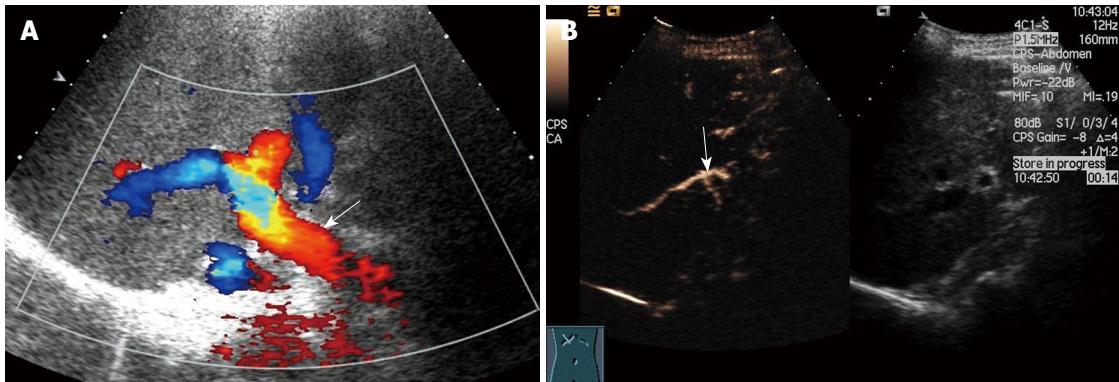

Among the two patients without portal vein flow at Doppler ultrasound, CEUS showed one with hematoma compression and one with portal vein thrombosis, both of which were confirmed by surgery.

The 10 patients without bridging vein flow and with regional liver inhomogenous echo at Doppler ultrasound were demonstrated by CEUS to have corresponding poor liver graft perfusion. The diagnosis was confirmed by enhanced CT in two cases. However, CT scan did not yield any additional information on bridging vein visualization (Figure 4).

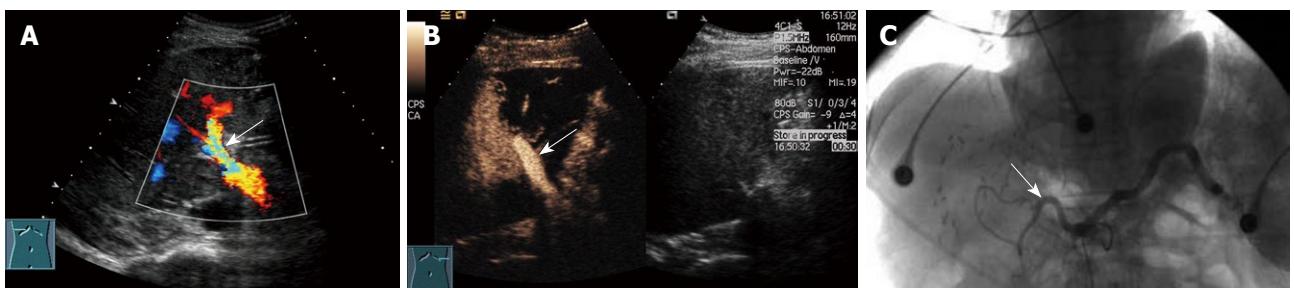

## DISCUSSION

### Hepatic artery complications after RLDLT

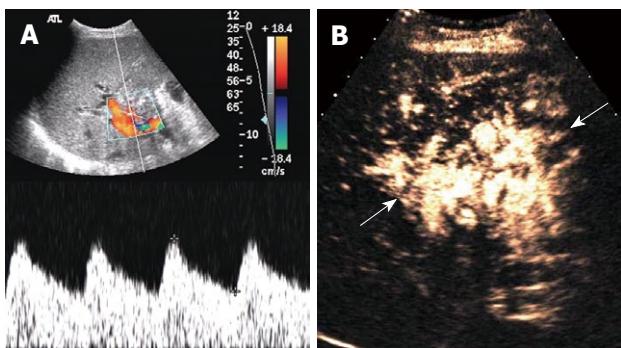

Hepatic artery complications, including HAT, hepatic artery stenosis (HAS) and pseudoaneurysm, are some of the most severe complications after liver transplantation, with an incidence of 5%-15%. HAT often occurs early after surgery, especially within 6 wk. Mortality from HAT is as high as 20%-60% and re-transplantation is usually required<sup>[2]</sup>. Therefore, early examination and diagnosis after surgery are crucial for graft survival and good prognosis. Ultrasound manifestations of HAT include the disappearance of blood flow at the porta hepatis, disappearance of or abnormal intrahepatic blood flow, such as the tardus-parvus spectrum wave form, possibly followed by secondary changes including biliary complications, hepatic infarction and abscess. HAT is highly suspected if no blood flow signal is present in the hepatic artery at Doppler ultrasound. However, false-positive results must be excluded, and the main reasons include instrumental insensitivity to blood flow, improper adjustment of parameters, incorrect detection approach, early transient artery spasm, and slender graft arteries. HAT sensitivity of Doppler ultrasound has been reported

**Figure 1 Slender hepatic artery in 54-year-old woman who received right-lobe living donor liver transplantation (RLDLT).** A: Longitudinal oblique Doppler Ultrasound (US) scan 2 mo after RLDLT did not reveal the right hepatic artery beyond the level of the right portal vein (arrow); B: Longitudinal oblique contrast-enhanced ultrasound (CEUS) scan obtained followed the Doppler scan. The right hepatic artery (arrow) was seen clearly 14 s after contrast material injection, but it was small.

**Figure 2 HAT in a 35-year-old man who underwent RLDLT.** A: Longitudinal oblique Doppler US scan 1 d after RLDLT did not reveal the right hepatic artery beyond the level of the right portal vein (arrow); B: Longitudinal oblique CEUS scan obtained following the Doppler scan. The right hepatic artery was still not seen after contrast material injection, but the right portal vein was demonstrated clearly (arrow). A complete unenhanced area indicates a lack of perfusion of the liver parenchyma in the anterior right lobe; C: Selective angiogram obtained after celiac artery injection confirmed complete thrombosis of the right artery at the level of the anastomosis (arrow).

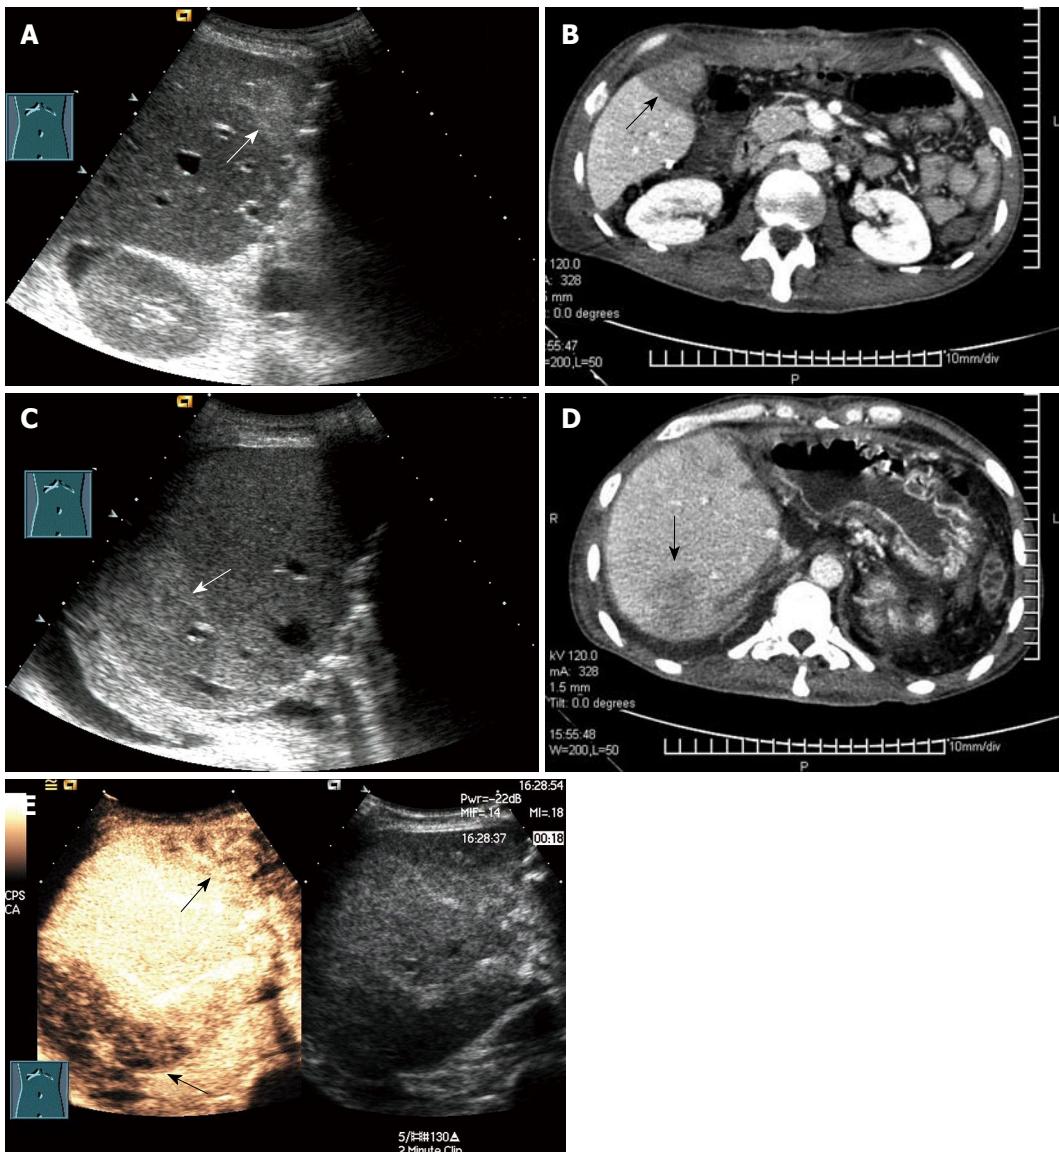

**Figure 3 Hepatic artery obstruction with collateral circulation in a 36-year-old man who underwent RLDLT.** A: Longitudinal oblique Doppler US scan 6 mo after RLDLT revealed a tardus-parvus spectrum at the porta hepatis; B: Longitudinal oblique CEUS scan obtained following the Doppler scan. A reticulate vessel instead of the right hepatic artery trunk was seen (arrows) at the porta hepatis after ultrasound agent injection.

to be 60%-90%<sup>[2-4,9-17]</sup>. Color Doppler technology has improved considerably during the past 10 years, and the possibility of non-flow visualization in the hepatic artery has decreased. In the present study, hepatic flow was not demonstrated in 1.3% (16/1231) of scans, similar to the study of Hom *et al*<sup>[5]</sup>. Visualization of the hepatic artery is improved significantly by CEUS. The accuracy of CEUS in diagnosing HAT was 100% in our study, similar to previous studies<sup>[5-8,18]</sup>.

The incidence of HAS is 5%-10%, which occurs mostly at the anastomotic stoma. Severe stenosis may result in similar outcomes to HAT, such as biliary ischemia, graft dysfunction and liver failure. Tardus-parvus changes ( $RI < 0.5$  and accelerating time  $> 0.08$  s) detected at Doppler ultrasound suggest HAS, and it is also suspected when regional blood flow velocity is  $> 200$  m/s at the anastomotic stoma. However, it is difficult to observe directly the stenosis site by ultrasound for intestinal gas or liver artery curvature. The value of CEUS in diagnosing HAS remains controversial. Some studies have revealed that CEUS may be more capable than conventional ultrasound of visualizing the trunk of the hepatic artery, possible sites of stenosis, and peripheral branch circulation<sup>[2-4,7,10-12,18]</sup>.

#### Portal vein complications

Portal vein complications include portal vein thrombus (PVT), stenosis and phlebolithoma. The incidence of PVT and stenosis is about 1%-2%. Monitoring of the portal vein after surgery is also important, because the blood supply from portal vein is essential for graft survival after liver transplantation. Once PVT or severe stenosis in the portal vein of liver grafts occurs after surgery, patients may suffer from primary graft dysfunction, visceral bleeding, bile leakage, ascites, splenectomy, and re-transplantation, re-operation or

**Figure 4** Regional congestion in a 35-year-old man who underwent RLDLT. A: Longitudinal oblique 2D US scan 1 d after RLDLT revealed regional echogenicity in segment V; B: Contrast-enhanced CT showed poor perfusion (arrow) in segment V 2 d after ultrasound examination; C: Longitudinal oblique 2D US scan revealed regional echogenicity in segment VII; D: Contrast-enhanced CT showed poor perfusion (arrow) in segment VII; E: Longitudinal oblique CEUS scan obtained following the Doppler scan. At CEUS, the poor perfusion area (arrows) was seen as an inhomogenous echo that corresponded to segment V and segment VII. This patient remained asymptomatic and formed collaterals between the tributary of the middle hepatic vein and the right hepatic vein at Doppler ultrasound follow-up.

interventional therapy are required. PVT is not difficult to diagnose using 2D and Doppler ultrasound. CEUS is helpful when the trunk or branches of the portal vein are not well visualized as a result of surgery or other causes<sup>[2-4,5,7,8,19-21]</sup>.

Caliber mismatch between the portal vein of the donor and recipient is very common, and is manifested as a hyperechoic ring at the anastomotic stoma and regional blood flow disorder by Doppler ultrasound. Currently, the diagnostic criteria for portal vein stenosis include: regional stenosis with a diameter of 2.5 mm, blood flow aliasing and acceleration at the stenosis site, blood flow velocity  $> 150$  cm/s at the stenosis site, or a prestenotic:stenotic blood flow velocity ratio of  $> 4:1$ , accompanied by symptoms of portal hypertension, including splenomegaly, ascites and branched circulation formation. CEUS is useful for diagnosis of portal vein

complications, because it can determine clearly the diameter of the portal vein and clarify the severity and range of portal vein stenosis<sup>[2-4,5,7,8,19-21]</sup>.

#### Outflow tract complications

Outflow tract in RLDLT includes the hepatic vein and bridging vein. Hepatic vein complications after surgery include thrombosis (HVT) and stenosis (HVS), with an incidence of about 1%. HVT is not difficult to diagnose by conventional ultrasound, but the diagnosis of HVS by Doppler ultrasound remains controversial. It has been reported that obvious stenosis can be observed by 2D ultrasound, when the ratio of prestenotic/stenotic blood flow velocity is higher than 3-4:1, the distal blood flow spectrum is straight and blood flow is decelerated or reversed, and the negative predictive value of phase loss in HVS is reported to be 98.4%. However, other

studies have concluded that ultrasound is inaccurate for the diagnosis of HAS, which should be combined with a pressure gradient for the hepatic vein and inferior vena cava, or depend on clinical manifestations<sup>[2-4,22-25]</sup>.

As RLDLT without the MHV has been performed increasingly in recent years, reconstruction and bypass of MHV tributaries have received more attention from clinicians, because "small-for-size syndrome" may be caused by early occlusion of bridging veins. However, these vessels are so tiny and deep that postoperative monitoring is difficult. CEUS improve the visualization of these bridging vessels and the perfusion of their drainage area<sup>[25-27]</sup>. However, there were only 10 patients who underwent bridging vessel monitoring by CEUS in our study, and thorough investigations with a larger sample size are required to clarify its diagnostic value.

Conventional 2D and Doppler ultrasound play important roles in screening and early diagnosis of vascular complications after RLDLT, but their inability to depict flow in some patients remains a substantial problem. Our initial experience shows that CEUS improves visualization of hepatic artery, portal and hepatic vein and bridging vein blood flow, as well as evaluation of perfusion of the liver graft parenchyma. Furthermore, CEUS can be performed at the bedside, and it has no iodine allergy or X-ray exposure. Therefore, CEUS provides a new approach in monitoring postoperative vascular complications after RLDLT, and more studies are needed for further evaluation.

## COMMENTS

### Background

Right-lobe living donor liver transplantation (RLDLT) is considered to be complicated liver surgery, with a high incidence of postoperative vascular complications that may cause graft dysfunction and liver failure. Noninvasive 2D and Doppler ultrasound play important roles in screening for postoperative complications, but vascular visualization is not always satisfactory. Contrast-enhanced ultrasound (CEUS) provides a great improvement for this defect because of its fine vascular tracing and perfusion visualization. Therefore, the authors investigated if CEUS improved the diagnosis of postoperative vascular complications after RLDLT.

### Research frontiers

CEUS has been applied gradually in recent years and focuses mainly on characterization of focal liver lesion and ablation monitoring. CEUS has the ability to show macro- as well as microvasculature, but there have been more studies based microvasculature.

### Innovations and breakthroughs

CEUS can improve flow visualization of the hepatic artery, portal and hepatic veins and bridging vein, as well as evaluation of perfusion of liver graft parenchyma after RLDLT.

### Applications

RLDLT is now generally used for adult-to adult liver transplantation worldwide. CEUS provides a new approach in monitoring postoperative vascular complications after RLDLT.

### Peer review

This is a good descriptive study in which the authors analyzed the value of CEUS in vascular complications after ALDLT. The results suggest that CEUS can be performed at the bedside; it has no iodine allergy, no X-ray exposure, and can be repeated with little interference to the vessels. Thus, CEUS will be a new advanced and noninvasive technique for vascular complications in RLDLT.

## **Abstract**

**AIM:** To explore the effect of *Astragalus mongholicus* polysaccharide (APS) on gene expression and mitogen-activated protein kinase (MAPK) transcriptional activity in intestinal epithelial cells (IEC).

**METHODS:** IEC were divided into control group, lipopolysaccharide (LPS) group, LPS+ 50  $\mu$ g/mL APS group, LPS+ 100  $\mu$ g/mL APS group, LPS+ 200  $\mu$ g/mL APS group, and LPS+ 500  $\mu$ g/mL APS group. Levels of mRNAs in LPS-induced inflammatory factors, tumor necrosis factor (TNF)- $\alpha$  and interleukin (IL)-8, were measured by reverse transcription-polymerase chain reaction. MAPK protein level was measured by Western blotting.

**RESULTS:** The levels of TNF- $\alpha$  and IL-8 mRNAs were significantly higher in IEC with LPS-induced damage than in control cells. APS significantly abrogated the LPS-induced expression of the *TNF- $\alpha$*  and *IL-8* genes. APS did not block the activation of extracellular signal-regulated kinase or c Jun amino-terminal kinase, but inhibited the activation of p38, suggesting that APS inhibits LPS-induced production of TNF- $\alpha$  and IL-8 mRNAs, possibly by suppressing the p38 signaling pathway.

**CONCLUSION:** APS-modulated bacterial product-mediated p38 signaling represents an attractive strategy for prevention and treatment of intestinal inflammation.

## **INTRODUCTION**

Intestinal epithelia cells (IEC) are the first line of defense against noxious intraluminal agents, including microorganisms and toxic antigens<sup>[1]</sup>. Although IEC are less responsive to polysaccharide than monocytes/macrophages, it has been shown that endotoxin triggers a proinflammatory gene transcriptional program in some IEC<sup>[2]</sup>, including the rat small intestinal cell line IEC-6<sup>[1,3,4]</sup>. Luminal endotoxin may participate in various intestinal inflammatory disorders. Modulation of bacteria- and bacterial product-induced gene expression in the intestine may have a significant impact on intestinal inflammatory disorders<sup>[5]</sup>.

*Astragali Radix*, root of *Astragalus membranaceus* Bunge, is a popular herb that has been used for thousands of years in treatment of a variety of diseases in oriental medicine. *Astragalus mongholicus* polysaccharide (APS) is the main ingredient of *Astragali Radix*. Studies have

revealed the anti-inflammatory, antioxidant, and immune regulatory roles of APS<sup>[6]</sup>. However, knowledge of how APS exerts its anti-inflammatory effects is still limited. Lee *et al*<sup>[7]</sup> reported that *Astragali Radix* appears to exert immune modulating effects by regulating the expression of cytokines, such as interleukin (IL)-1, IL-6 and inducible nitric oxide synthase (iNOS), as well as the production of nitric oxide (NO). In this study, the effect of APS on LPS-induced mitogen-activated protein kinase (MAPK) signaling and pro-inflammatory gene expression in IEC-6 cells was investigated, showing that APS prevents the activation of p38MAPK signaling in IEC-6 cells *in vitro*.

## MATERIALS AND METHODS

### Materials

APS was isolated from a 6-year-old *Astragalus membranaceus* sample purchased from the Chinese Medicinal Herbs Company (Beijing, China), with a purity of 98.5%. IEC-6 cells were purchased from the Chinese Academy of Medical Sciences, Center for Biological Detection (Beijing, China). Lipopolysaccharide (LPS, *Escherichia coli* O55:B5) and insulin (I5500) were purchased from Sigma (USA). Phospho-specific rabbit polyclonal antibodies against Thr180 and Tyr182 dual-phosphorylated p38, Thr183 and Tyr185 dual-phosphorylated c Jun amino-terminal kinase (JNK), Thr202 and Tyr204 dual-phosphorylated extracellular signal-regulated kinase (ERK)/2 and total p38, ERK1/2, JNK were purchased from Cell Signaling Technology (USA). A rabbit polyclonal antibody against actin and a peroxidase (HRP)-labeled anti-rabbit IgG antibody were purchased from Sigma (USA).

### Culture and treatment of IEC

The rat small intestinal cell line IEC-6 was grown in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum and 0.01 mg/mL insulin. IEC-6 cells were grown in 6-well plates at a density of  $5 \times 10^5$  cells per well and cultured in DMEM at 37°C in a humidified atmosphere containing 50 mL CO<sub>2</sub> for 24 h. After incubation, non adherent cells were removed and adherent cells were pretreated for 1 h with APS at different concentrations (50, 100, 200 and 500 µg/mL). The cells were then stimulated with LPS (10 µg/mL) and harvested at the indicated time points.

### RNA isolation and reverse transcription-polymerase chain reaction (RT-PCR) analysis

IEC-6 cells were cultured in DMEM containing LPS with or without various concentrations of APS, for 1 h to allow detection of tumor necrosis factor (TNF)-α mRNA, and for 2 h to allow detection of IL-8 mRNA. Cells were washed in PBS and used for RNA isolation. Total RNA was isolated using Trizol reagent according to its manufacturer's instructions. RT-PCR was carried out using 1 µg of total RNA from IEC-6 cells and an oligo(dT)<sub>12-18</sub> primer.

The sequences of primers for amplification of cDNAs of rat TNF-α-U, TNF-α-L, IL-8-L, GAPDH-U and GAPDH-L are 5'-TTCGGGGTGATCGGTCCAA-3', 5'-AGCATCTCGTGTGTTCTGA-3', 5'-CCTGAAGA CCCTACCAAG-3', AGGCTCCATAAATGAAAGA-3', 5'-ATCACTGCCACTCAGAAGAC-3', 5'-TGAGGG AGATGCTCAGTGTT-3', respectively. GAPDH was used as an invariant housekeeping internal control gene. Twenty-five cycles of amplification were performed for all reactions. The length of PCR products of TNF-α, IL-8 and GAPDH was 750, 494 and 580 bp, respectively.

### Western blotting analysis

IEC-6 cells were stimulated with LPS (10 µg/mL) for various periods of time (0-1 h). The cells were cultured in a medium containing LPS with or without various concentrations of APS for 1 h to detect phosphorylated-p38, ERK1/2, JNK, and total p38, ERK, and JNK, and lysed with a SDS sample buffer. The supernatants were analyzed by 10% SDS-PAGE. Proteins were transferred to nitrocellulose membranes, which were blocked with 10% nonfat dry milk in TBST containing 20 mmol/L Tris (pH 8.0), 137 mmol/L NaCl and 10% Tween-20, and blotted with the relevant primary antibody, then with a horseradish peroxidase-conjugated secondary antibody. Bound proteins were detected by enhanced chemiluminescence according to its manufacturer's instructions.

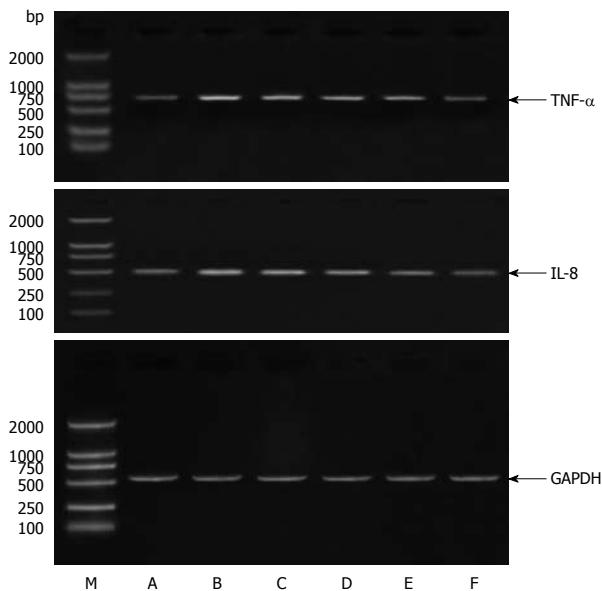

### Statistical analysis

Statistical analysis was performed using SPSS 11.5. All data were expressed as mean ± SE. Statistical significance of differences among values was determined by ANOVA and LSD was used for inter-group comparison. *P* < 0.05 was considered statistically significant.

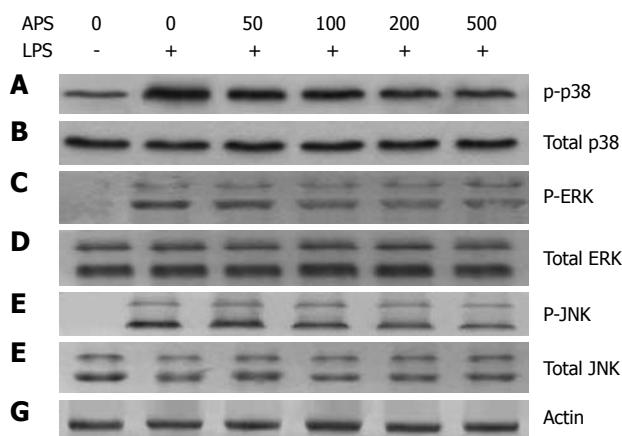

## RESULTS

### APS abrogated LPS-induced TNF-α and IL-8 gene expression in IEC-6 cells

The effects of APS on LPS-induced TNF-α and IL-8 gene expression in the intestinal cell line IEC-6 were evaluated. Stimulation of IEC-6 cells by LPS markedly increased the production of TNF-α and IL-8. The effect of APS on the levels of TNF-α and IL-8 mRNAs in IEC-6 cells was detected after LPS stimulation. IEC-6 cells were pretreated with APS at different concentrations (50, 100, 200 and 500 µg/mL) for 24 h, stimulated with LPS (10 µg/mL) for 1 h. TNF-α and IL-8 gene expressions were detected by RT-PCR. As shown in Figure 1, RT-PCR analysis revealed that TNF-α and IL-8 mRNAs were induced readily in IEC-6 cells by LPS. However, this induction was inhibited by APS in a concentration-dependent manner, namely 50 and 500 µg/mL APS partially and significantly suppressed the production of TNF-α and IL-8 mRNAs in the presence of LPS-activated IEC-6 cells compared with LPS stimulation in the absence of APS (*P* < 0.01).

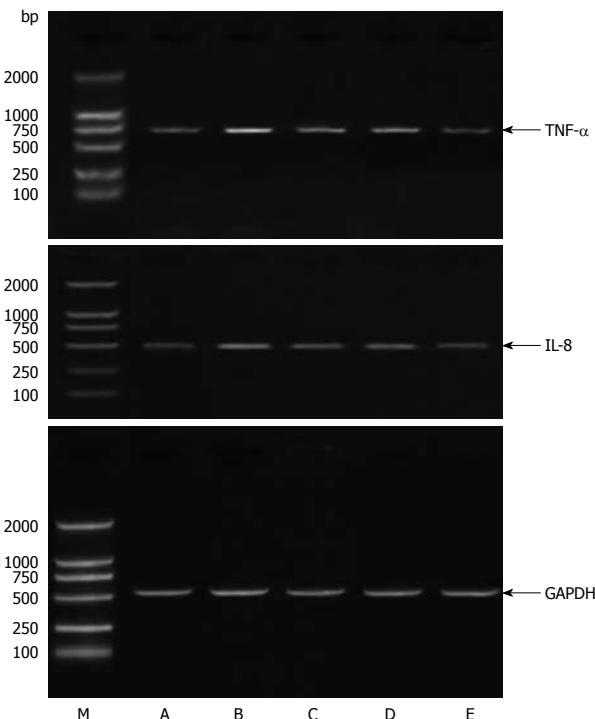

**Figure 1** *Astragalus mongholicus* polysaccharide inhibits TNF- $\alpha$  and IL-8 production in LPS-stimulated rat small intestinal cells. Intestinal epithelial cells (IEC) were treated with APS for 1 h, and cultured in a medium containing 10  $\mu$ g/mL LPS with APS at different concentrations for 1 h to detect TNF- $\alpha$  and IL-8 mRNAs in the cells by RT-PCR. M: Marker. A: Control group; B: LPS+ 0  $\mu$ g/mL APS group; C: LPS+ 50  $\mu$ g/mL APS group; D: LPS+ 100  $\mu$ g/mL APS group; E: LPS+ 200  $\mu$ g/mL APS group; F: LPS+ 500  $\mu$ g/mL APS group.

**Figure 3** *Astragalus mongholicus* polysaccharide inhibits p38 phosphorylation but not ERK1/2 or JNK activation in LPS-stimulated rat small intestinal cells. IEC were treated as described in Figure 1. After incubation in a medium containing 10  $\mu$ g/mL LPS with APS at different concentrations for 1 h, Western blotting analysis was performed to detect phosphorylated p38 (A), total p38 (B), phosphorylated ERK (C), total ERK (D), phosphorylated JNK (E), total JNK (F) and actin (G).

#### APS inhibited both TNF- $\alpha$ and IL-8 production by LPS-activated IEC-6 cells in a time-dependent manner

IEC-6 cells were pretreated with APS (500  $\mu$ g/mL) for 24 h, stimulated with LPS (10  $\mu$ g/mL) for 1-4 h. The expression of the TNF- $\alpha$  and IL-8 genes was detected by RT-PCR. As shown in Figure 2, LPS-induced TNF- $\alpha$  mRNA expression was inhibited 10.3% and 25.5% by APS treatment at 1 and 4 h post-stimulation, respectively. LPS-induced IL-8 mRNA expression was also inhibited 15.3% and 18.8% by APS treatment at 1 and 4 h post-stimulation, respectively.

**Figure 2** *Astragalus mongholicus* polysaccharide inhibits TNF- $\alpha$  and IL-8 production in LPS-stimulated rat small intestinal cells. IEC were treated with APS (500  $\mu$ g/mL) for 1 h, and cultured in a medium containing 10  $\mu$ g/mL LPS for up to 4 h to detect TNF- $\alpha$  and IL-8 mRNAs in the cells by RT-PCR. M: Marker. A: Control group; B: LPS+ 0  $\mu$ g/mL APS group; C: LPS+ 50  $\mu$ g/mL APS group; D: LPS+ 100  $\mu$ g/mL APS group; E: LPS+ 200  $\mu$ g/mL APS group; F: LPS+ 500  $\mu$ g/mL APS group.

#### APS inhibited p38 phosphorylation but not ERK1/2 or JNK activation in LPS-activated IEC-6 cells

Activation of MAPK p38 can mediate the production of pro-inflammatory cytokines when IEC-6 cells are activated. To further understand the mechanisms underlying the APS-mediated anti-inflammation in IEC-6 cells, we examined whether APS inhibits LPS-triggered activation of MAPK signaling, including phosphorylation of p38, ERK1/2 and JNK. The levels of phosphorylated (activated) p38, ERK1/2 and JNK were analyzed in LPS-stimulated IEC-6 cells following treatment with or without APS. p38, ERK1/2 and JNK were strongly activated in IEC-6 cells stimulated with LPS. However, APS treatment decreased LPS-induced p38 phosphorylation. Moreover, p38 phosphorylation was inhibited by LPS in a concentration-dependent manner. Fifty micrograms per millilitre APS partially blocked LPS-induced p38 phosphorylation and 500  $\mu$ g/mL APS significantly inhibited p38 phosphorylation in LPS-stimulated IEC-6 cells (Figure 3) while the total protein level of p38, ERK1/2 or JNK remained unchanged, indicating that APS inhibits the activation of p38 but not ERK1/2 and JNK in IEC-6 cells after LPS stimulation.

## DISCUSSION

The search for active compounds in natural products used in traditional medicine has attracted great interest,

because traditional herbal drugs have many benefits, few side effects and low cytotoxicity<sup>[8-11]</sup>. Isolation, identification and characterization of these compounds, and evaluation of their potential benefits to humans, have become an important field in pharmaceutical research<sup>[12]</sup>.

It has been reported that APS has a variety of pharmacological properties. Traditionally, APS is used to treat weakness, wound, anemia, fever, multiple allergies, chronic fatigue, and loss of appetite<sup>[13]</sup>. APS is used as a diuretic and tonic herbal medicine in Asian countries, to enhance physical strength and endurance, strengthen the immune system, decrease blood pressure, and promote excretion and circulation<sup>[6,14,15]</sup>. Clinically, APS is used to treat chronic phlegmatic disorders and general gastrointestinal disturbances including stomach ulcer and diarrhea<sup>[16,17]</sup>. The mechanism by which APS mediates the above-mentioned effects is unclear. Studies on the use of APS in treatment of various human diseases showed that this herb may act as an immune regulator that can enhance strength, immunity and circulation<sup>[18-21]</sup>. It has been reported that APS also appears to exert an immune modulating effect by regulating the expression of cytokines such as IL-1, IL-6 and iNOS, as well as the production of NO<sup>[6]</sup>. In this study, APS inhibited the production of both TNF- $\alpha$  and IL-8 in LPS-stimulated IEC-6 cells in a concentration-dependent manner (Figure 1). Since excessive production of TNF- $\alpha$  and IL-8 induces tissue injury, septic shock and inflammatory intestinal disease, APS can be developed into a drug for intestinal injury.

MAPKs (ERK, p38, JNK)<sup>[11,22-24]</sup> and NF- $\kappa$ B<sup>[25-27]</sup> positively control TNF- $\alpha$  and IL-8 expression in LPS-activated IEC-6 cells, via a unique signaling pathway. Inhibition of any of the three MAPK pathways is sufficient to block the TNF- $\alpha$  and IL-8 induced by LPS in IEC-6 cells<sup>[28-30]</sup>. In this study, whether APS exerts its effects on TNF- $\alpha$  and IL-8 by interfering with the activation of ERK, p38 and JNK was tested, showing that APS cannot block the activation of ERK or JNK. Therefore, these two pathways do not mediate any inhibitory effect of APS on TNF- $\alpha$  and IL-8 production by LPS-stimulated IEC-6 cells. In our study, APS inhibited the activation of p38 and the expression of the TNF- $\alpha$  and IL-8 genes, suggesting that inhibition of the activation of p38 but not ERK and JNK may inhibit the production of TNF- $\alpha$  and IL-8.

In summary, APS inhibits the production of both TNF- $\alpha$  and IL-8 in LPS-stimulated IEC-6 cells by suppressing p38 signaling.

## COMMENTS

### Background

*Astragalus mongholicus* polysaccharide (APS) with a variety of pharmacological properties is a component isolated from *Astragali Radix*, a traditional Chinese herbal medicine. Studies have revealed its anti-inflammatory, antioxidant, and immune regulatory effects. However, knowledge about how APS exerts its anti-inflammatory effects is still limited.

### Research frontiers

*Astragali Radix* appears to exert its immune modulating effects by regulating the

expression of cytokines, such as interleukin (IL)-1, IL-6 and inducible nitric oxide synthase, as well as the production of nitric oxide. Thus, whether APS affects the production of tumor necrosis factor (TNF)- $\alpha$  and IL-8 in lipopolysaccharide (LPS)-activated intestinal epithelial cells (IEC)-6 cells by interfering with mitogen-activated protein kinase (MAPK) signaling was investigated in this study.

### Innovations and breakthroughs

This is the first study to investigate the effect of APS on LPS-induced MAPK signaling and pro-inflammatory gene expression in IEC-6 cells. APS was found to inhibit the production of both TNF- $\alpha$  and IL-8 in LPS-induced IEC-6 cells in a concentration-dependent manner, and excessive production of TNF- $\alpha$  and IL-8 was observed to induce tissue injury, septic shock and inflammatory intestinal disease.

### Applications

APS can be developed into a drug for intestinal injury.

### Terminology

MAPK phosphorylates serine and threonine residues of proteins in cells. MAPK is also an important signal regulator linking cell surface receptors to changes in gene expression. In mammalian cells, at least three members of the MAPK family including extracellular signal-regulated kinase (ERK), c Jun amino-terminal kinase (JNK), and p38 have been cloned.

### Peer review

In this study, the authors detected the protective effects of a purified herbal product on LPS-induced intestinal inflammatory mucosal injury and conducted their study in IEC-6 cells and measured the levels of TNF- $\alpha$  and IL-8 mRNAs as well as proteins in the p38 signaling pathway. The results presented in this paper show that purified herbal polysaccharide can inhibit LPS-induced production of TNF- $\alpha$  and IL-8 by suppressing p38, P-ERK and P-JNK. In general, the experiments in this study were carefully designed and carried out. Data description is clear and the results are adequately discussed.

Bilhemia after trans-jugular intra-hepatic porto-systemic shunt and its management with biliary decompression. *World J Gastroenterol* 2009; 15(29): 3681-3683 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3681.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3681>

## INTRODUCTION

Transjugular intrahepatic portosystemic shunt (TIPS) is a frequently performed procedure to achieve decompression of the portal venous system in the treatment of (1) uncontrolled acute variceal bleeding, (2) prevention of recurrent variceal bleeding, (3) refractory ascites, and (4) hepatic hydrothorax<sup>[1]</sup>. Early complications (within 24-48 h) include intraperitoneal bleeding, shunt occlusion, vascular fistulae, and hepatic infarction. We report a case of bilhemia (bile mixing with blood) after TIPS which was successfully managed with endoscopic decompression of the biliary system.

## CASE REPORT

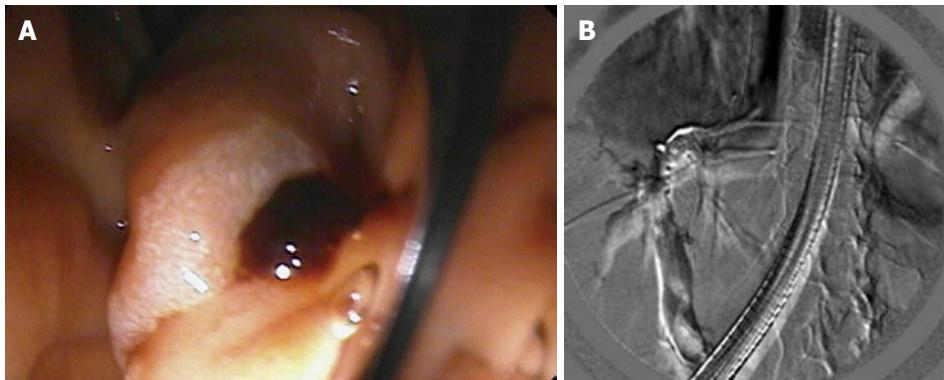

A 73 year-old Caucasian female with sarcoidosis-associated cirrhosis underwent TIPS for the treatment of refractory hepatic hydrothorax. The diagnosis of cirrhosis was made in 2002 based on liver biopsy findings. The patient had a history of cholecystectomy in the remote past. Evaluation of liver function tests in 2002-2003 showed total bilirubin (TB) 1.8 mg/dL, alkaline phosphatase (ALP) 560 IU/L, aspartate aminotransferase (AST) 87 IU/L, alanine aminotransferase (ALT) 63 IU/L, total proteins (TP) 7.1 g/dL and albumin 3.4 g/dL. Ascites was managed with diuretics and salt restriction until December 2008 when she developed shortness of breath. Due to closure of our institution during Hurricane Ike, she was referred to another hospital. On work-up she was found to have pleural effusion on the right side. The pleural fluid was transudate with a serum-fluid albumin gradient > 1.1, consistent with hepatic hydrothorax. As she required repeated thoracocentesis, pleurodesis was tried using talc, however, this was unsuccessful. In mid January, an

## Abstract

Bilhemia or bile mixing with blood is a rare clinical problem. The clinical presentation is usually transient self-resolving hyperbilirubinemia, progressive and rapidly rising conjugated hyperbilirubinemia, or recurrent cholangitis. Endoscopic retrograde cholangio-pancreatography (ERCP) plays an important role in diagnosis and management. Biliary decompression with endoscopic sphincterotomy is useful in treating these patients. If not recognized and treated in time, the condition can be fatal in a significant proportion of patients. This usually occurs after blunt or penetrating hepatic trauma due to a fistulous connection between the biliary radicle and portal or hepatic venous radical. Cases have been described due to iatrogenic trauma such as liver biopsy and percutaneous biliary drainage. However, the occurrence after trans-jugular intra-hepatic porto-systemic shunt (TIPS) is very rare. We report a case of bilhemia presenting as rapidly rising bilirubin after TIPS. The patient was managed successfully with ERCP and removal of a blood clot from the common bile duct.

**Key words:** Bilhemia; Biliary-venous fistula; Portal vein-biliary fistula; Trans-jugular intrahepatic shunt

**Figure 1** Endoscopic retrograde cholangiogram with the endoscopic view showing a blood clot at the ampulla (A), and a fluoroscopic image showing the blood clot within the common bile duct (B).

indwelling pleural catheter was placed in her right pleural cavity. In early February 2009, she came back to us for follow up after our institution reopened. The catheter was draining about 500-1000 cc every day. The patient did not show any clinical evidence of infection. Placement of an indwelling catheter or a chest tube is not recommended for the management of hepatic hydrothorax<sup>[2]</sup>. Therefore, it was decided to control her hydrothorax with TIPS to be followed by the removal of the chest catheter at a later date.

Laboratory parameters prior to TIPS were: TB 0.4 mg/dL, albumin: 2.8 g/dL, ALP 259 IU/L, ALT-33 IU/L, AST52 IU/L, international normalized ratio (INR) 1.1, hemoglobin 11.7 g/dL and serum creatinine 0.7 mg/dL. During the procedure while attempting to cannulate the hepatic vein, the interventional radiologist noticed the presence of bile in the catheter. However, the shunt was placed between the right hepatic vein and the right main branch of the portal vein using a 1 cm × 7 cm polytetrafluoroethylene covered stent (Gore Viatorr, USA). The procedure was successful in achieving decompression of the portal venous system with a reduction of the portosystemic gradient from 16 before TIPS to 0 after the procedure. Post-procedure the patient remained in hospital to determine the amount of drainage from the pleural catheter in order to decide on its removal. The patient was doing well until the second day after the procedure, when she was noted to be diffusely yellow. Laboratory evaluation at this time showed hemoglobin to be 11.7 g/dL, white blood cell count 11.9/cubic mL, INR 1.2, creatinine 0.7 mg/dL, TB 15.9 mg/dL, conjugated bilirubin 15.2 g/dL, AST 183 IU/L, ALT 71 IU/L, and ALP 409 IU/L. She denied any abdominal pain or fever and there was no change in her mental status. The next day her bilirubin increased to 22.4 mg/dL. A CT scan of the abdomen showed dilatation of the common bile duct (CBD) and intra-hepatic biliary radicles along with a filling defect in the CBD suggestive of sludge or a blood clot. An emergency endoscopic retrograde cholangio-pancreaticogram (ERCP) was performed at this stage. The endoscopic examination showed clotted blood at the ampulla. Cannulation and contrast injection of the CBD showed a dilated CBD (to 12 mm) with a luminal filling defect due to a blood clot (Figure 1). The blood clot was removed using a balloon. An adequate sphincterotomy was successfully performed for further decompression of the biliary system. On follow up, the TB rapidly decreased to 18.1 mg/dL the next day and to 3 mg/dL within 48 h. She was discharged from hospital in good condition.

The pleural catheter drained about 500 cc on day 1 and had to be flushed with TPA for adequate drainage. As the catheter was still draining approximately 500 cc/d, she was discharged home with this catheter in place.

On follow up, one week after discharge, the patient was doing well. As the diuretics were not reinstated after the TIPS, the patient developed significant leg edema. She denied any respiratory or cardiac symptoms. As the chest catheter did not drain any fluid for 2-3 d it was removed by the interventional radiologist. On the clinic visit her bilirubin had normalized to 0.1 mg/dL. After restarting her diuretics (furosemide 40 mg/d and spironolactone 100 mg/d), the leg edema improved and she lost 16 lbs of bodyweight (137 to 121 lbs) over a 2-wk period.

## DISCUSSION

Conjugated hyperbilirubinemia can result due to hepatocellular or biliary disease. Diversion of portal venous blood (about 70% of total hepatic blood supply) to the systemic circulation after TIPS can potentially result in liver dysfunction. This is the basis of hepatic encephalopathy, a common complication after TIPS<sup>[1]</sup>. However, this is unlikely in our patient for the following reasons: (1) occurrence of liver dysfunction after TIPS is related to pre-TIPS liver function<sup>[2]</sup>. Our patient with a pre-TIPS model of end-stage liver disease score of 7 was not at risk for post-TIPS liver dysfunction despite reducing the porto-systemic gradient from 16 to 0 mmHg, (2) patients with ischemic hepatocellular liver damage usually have transaminases > 1000 IU/L and our patient had very minimal elevations in liver enzymes, (3) there was no change in mental status which would have been a significant feature in the patient's presentation if this level of bilirubin was due to hepatocellular dysfunction, and (4) ability to handle and conjugate the increased load of bilirubin by a well compensated liver.

The presence of a blood clot in the CBD on ERCP examination makes biliary disease the likely cause of hyperbilirubinemia. However, bleeding into the bile duct or hemobilia does not explain the clinical picture in the absence of biliary colic and/or gastrointestinal bleeding. Moreover, the hemoglobin remained stable. In addition, a rapid rise in bilirubin (1-18 mg/dL within 48 h and to 22.4 mg/dL within 72 h of the procedure) does not occur with obstruction of the bile ducts

including hemobilia. However, this has been described in cases of bilhemia secondary to the development of biliary-venous fistula<sup>[3]</sup>. It is likely that hyperbilirubinemia in our patient was the result of biliary-venous fistula resulting in bilhemia. Aspiration of bile by the interventional radiologist while trying to puncture the right hepatic vein raises this suspicion further. After the development of a fistula, the direction of flow depends upon the pressures on either side. Normal pressure in the hepatic vein is 0-5 mmHg and in the CBD is 10-12 mmHg, and in the portal system in this case the pressure was 16 mmHg<sup>[3]</sup>. Therefore, if the pressure in the venous side is higher than in the CBD, this will result in hemobilia and bilhemia will be a major manifestation if the pressure is higher in the CBD. Lack of visualization of the fistula despite an occlusive cholangiogram could either be due to its presence in the small peripheral biliary radicle or to spontaneous closure by the time cholangiogram was performed.

How do we explain the presence of a blood clot in the CBD? We propose that the following sequence of events occurred: Initially the bile duct radicle was inadvertently punctured creating a fistula with one of the small portal venous radicles. This initiated bleeding into the bile duct due to a higher portal pressure initiating hemobilia. However, successful placement of the TIPS decompressed the portal venous system. This favored leakage of bile into the blood causing bilhemia. In fact, the blood clot resulting from the clinically insignificant bleeding exaggerated the biliary pressure, further favoring leakage of bile into the blood.

Although, the term bilhemia was introduced in 1975, the first case was described in 1952<sup>[4]</sup>. Most cases of bilhemia are reported after hepatic trauma and its occurrence after TIPS is a rare event<sup>[5-7]</sup>. The patient can be asymptomatic or present with transient hyperbilirubinemia with spontaneous improvement due to closure of the fistula. If the shunt is infected, recurrent cholangitis and bacteremia could dominate the clinical picture<sup>[5-7]</sup>. To our knowledge, this is the first report of portal vein-biliary fistula causing bilhemia and presenting with rapidly rising bilirubin within 48 h of the TIPS procedure. This condition can be lethal in about 50% of cases, mostly due to fat embolism from a sudden gush of un-dissolved bile into the bloodstream<sup>[4,8]</sup>. ERCP is the most useful tool to diagnose this condition as it follows the direction of flow across the fistula<sup>[8]</sup>. Scintigraphy may be used if endoscopic expertise is unavailable<sup>[8]</sup>.

Treatment of patients with bilhemia should aim to achieve decompression of the biliary system and to

reduce the pressure within the CBD. This will allow drainage of bile towards the gut and prevent leakage into the blood. This is best achieved by endoscopic biliary sphincterotomy. In a series of 20 patients with biliary leaks (four with bilhemia), endoscopic sphincterotomy successfully managed all patients but one who died of bile thromboembolism<sup>[9]</sup>. In the event of a higher location or lack of available technical expertise for ERCP, percutaneous drainage of the biliary system is an alternative<sup>[8]</sup>. Unfortunately, if the shunt is infected, liver transplantation is the only option to salvage these patients as when the TIPS is placed it can not be removed<sup>[5,7]</sup>. In our patient, the presence of a blood clot added to the severity of the problem and its removal and the performance of endoscopic sphincterotomy achieved successful biliary decompression resulting in a positive patient outcome.

In summary, the occurrence of jaundice after TIPS raises the suspicion of a biliary-venous fistula. A high index of suspicion is required for successful management and the prevention of mortality. ERCP with endoscopic sphincterotomy is an effective modality for managing this potentially lethal complication.

## INTRODUCTION

Splenosis is a condition in which splenic tissue is present in a non-anatomical position due to its auto-transplantation after splenic trauma or surgery causing injury to the splenic capsule. It can be found as a single mass or multiple intraperitoneal or pelvic masses that may or may not be associated with pain. In some cases, it can manifest as an acute abdominal pain secondary to the torsion of the splenic pedicle. These splenic implants can mimic neoplasms and only specific examinations can confirm the diagnosis. Although ultrasonography, computed tomography (CT) and magnetic resonance imaging (MRI) can help in localizing and establishing the size and structure of these implants and in determining their relationship with adjacent organs, they are non-specific examinations. Only by using specific agents that are selectively sequestered by the reticulo-endothelial system [such as <sup>99m</sup>Technetium-labelled heat-denatured autologous red blood cells or <sup>111</sup>Indium-labeled platelets, single photon emission computed tomography scans and recently ferumoxide-enhanced MRI (small iron oxide particles SPIO)] allow a specific diagnosis of intra-abdominal splenosis. However, these examinations cannot be performed in an emergency situation.

Several authors report the role of these advanced imaging techniques in the diagnosis of splenosis, however, there exist no studies in the literature reporting the use of imaging techniques in emergency situations.

Here we describe the role of contrast-enhanced CT in the diagnosis of splenosis in an emergency situation.

## CASE REPORT

A 23-year-old male patient was admitted to the emergency

© 2009 The WJG Press and Baishideng. All rights reserved.

**Key words:** Splenosis; Ectopic splenic tissue; Computed tomography scan; Splenectomy; Emergency

**Figure 1** Post-contrast CT scans (after intravenous injection of 130 mL of contrast media, Ultravist, 3 mL/s flow rate). Lesions are homogeneously hyperdense (92 HU) in the arterial phase (no typical striped enhancement pattern).

**Figure 2** Isodensity in the early portal venous phase.

**Figure 3** Intraoperative picture revealing a large red mass adherent to the bladder and prostate gland and a small red mass implanted on the rectum.

department of our hospital with acute abdominal pain. He presented with fever, periumbilical colic-like pain, nausea and vomiting with absolute constipation. Clinical examination revealed a distended abdomen that was tender but not peritonitic and feverous. At auscultation, peristalsis was very slow. Digital rectal examination revealed a large lobulated mass imprinting the anterior wall of the rectum, while testicular palpation did not reveal abnormal findings. Laboratory results revealed the presence of leukocytosis. The patient had a history of childhood splenectomy for a blunt abdominal trauma caused by a horse's kick. No other significant medical data were reported.

An abdomino-pelvic CT scan revealed a small bowel obstruction and two well-demarcated rounded solid masses (10 and 3.5 cm) located in the rectovesical pouch posterior to the prostate gland and the seminal vesicles. These lesions did not show any macroscopic contiguity with the surrounding organs (i.e. the prostate gland, the bladder, the seminal vesicles and the rectal ampulla). No lymphadenopathy (iliac or obturator group) or signs of invasion of the adipose tissue of the rectovesical pouch were found. These features excluded malignant behaviour of the lesions.

Pre-contrast CT images showed these masses were isodense to liver. In particular, a quantitative analysis of the density value was made by the positioning of multiple regions of interest (ROIs) into the lesions, demonstrating Hounsfield Unit (HU) values ranging between 55 and 60. In the post-contrast CT scans (after intravenous in-

jection of 130 mL of contrast media, Ultravist, 3 mL/s flow rate), these lesions became homogeneously hyperdense (92 HU) in the arterial phase (no typical striped enhancement pattern) (Figure 1) and isodense in the early portal venous phase (Figure 2). Quantitative analyses of the different density values in the arterial and early portal venous phases demonstrated that these lesions were highly vascularised (92 and 97 HU, respectively). The enhancement pattern was similar to that of parenchymatous organs, such as the liver. The origin of the masses as being from the prostate or seminal vesicles was thereby ruled out because of the early and homogeneous enhancement. On the basis of both the CT findings and clinical data, the splenic origin of these lesions was hypothesized.

The patient underwent surgery to resolve the intestinal occlusion. An adhesiolysis for small bowel obstruction secondary to adhesive intestinal syndrome was conducted. A mass was found in the rectovesical pouch attached to the bladder and to the prostate gland and was macroscopically compatible with splenic tissue. Another similar smaller mass was found adherent to the rectum (Figure 3). This mass was successfully removed. Histopathologic examination demonstrated the benign nature of the lesion, which consisted of splenic tissue. The larger mass was not removed as it was not associated with any clinical symptom.

## DISCUSSION

Although splenic implants are generally asymptomatic, they can lead to recurrent episodes of abdomino-pelvic pain or small bowel obstruction secondary to adhesive bands to the splenic implants. Splenosis can be confused with other intra-abdominal masses. Differential diagnoses of splenosis include endometriosis, peritoneal mesothelioma, renal neoplasms, abdominal lymphomas and peritoneal metastatic implants<sup>[1]</sup>. Splenosis should be suspected in patients with a history of splenic trauma. Non-invasive diagnosis of splenosis needs integration of radiological and scintigraphic methods<sup>[2]</sup>.

In patients with bowel obstruction, a history of splenic trauma and an occasional finding of an abdominal mass, contrast-enhanced CT scan is an efficient tool for the diagnosis of splenosis. In pre-contrast enhanced CT scans, normal splenic tissue appears homogenous

with a density ranging between 56 and 65 HU, which is similar or slightly lower than that of normal liver tissue. After high flow-rate (3-4 mL/s) administration of contrast media, early post-contrast scans show an inhomogeneous impregnation with a cord-like pattern. This is probably related to the existence of a double blood-circulation inside the red pulp where areas of early enhancement represent fast circulation with direct connections between arterioles and venules, and areas of late enhancement represent a slower circulation with connections between the arterioles and the venules through the Billroth-channels<sup>[3,4]</sup>. The splenic parenchyma reaches a homogeneous enhancement approximately 1 min after contrast agent administration with density values ranging between 75 and 97 HU<sup>[5]</sup>.

Although differential diagnosis includes a variety of other conditions presenting with a pelvic mass, the relation with the surrounding tissues and the contrast-enhancement characteristics can help in the diagnosis of splenosis. In particular, in the case we present, the absence of infiltration of the prostate gland, seminal vesicles and rectum ruled out the malignant nature of the masses. Furthermore, the enhancement pattern made a malignancy less probable, such as a sarcoma that would have presented as an inhomogeneous enhancement on

both pre- and post-contrast images. The hypothesis of an ectopic splenic mass was made after an accurate evaluation of the CT images and correlation with clinical history.

In the case, we present demonstrates the importance of contrast-enhanced CT imaging with ROI analysis in the differential diagnosis of splenosis from other pelvic masses in emergency conditions.

### Abstract

Fibroepithelial polyps or hypertrophied anal papillae are essentially skin tags that project up from the dentate line and the junction between the skin and the epithelial lining of the anus. They are usually small in size, but sometimes they become enlarged, causing unexpected medical conditions. An extremely rare case of a giant hypertrophied anal papilla complicated by obstructive ileus is reported. Fibroepithelial anal polyp, despite its size, should be included in the differential diagnosis of a smooth mass located near the anal verge, especially in a patient with a history of chronic anal irritation or infection.

### INTRODUCTION

Fibroepithelial polyps of the anus, also referred to as hypertrophied anal papillae, are structures formed by hyperplasia of connective tissue in the vicinity of the anal columns. They are usually relatively small in size and asymptomatic. Enlargement of anal papillae is thought to be due to a hyperplastic response of the modified ectoderm to chronic irritation, injury or infection. Following repeated inflammatory episodes they can hypertrophy into the rectum and be confused with adenomatous polyps. Fibroepithelial polyps of the anus should be included in the differential diagnosis of a smooth mass located near the anal verge, especially in a patient with a history of chronic anal irritation or infection. To our knowledge, this is the first case of a giant fibroepithelial polyp of the anus complicated by obstructive ileus: there is only one similar case study in the medical literature regarding a giant hypertrophied anal papilla complicated by massive anal bleeding and prolapse<sup>[1,2]</sup>.

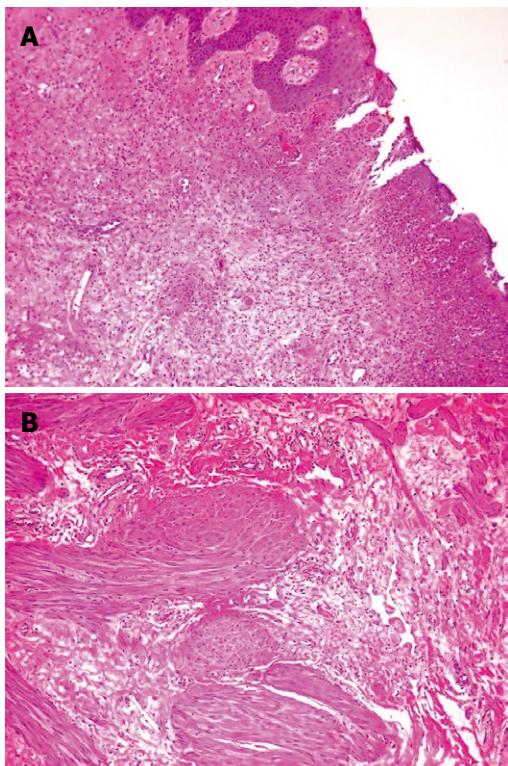

### CASE REPORT

A 67-year-old woman was admitted to the emergency room with a diffuse, cramping abdominal pain of progressive onset, tendency to vomit and constipation for 5 d. She had experienced similar episodes of intermittent abdominal pain, anal bleeding and persistent perianal pain due to long-standing hemorrhoidal disease over the last 7 years. Despite having been aware of the presence of chronic constipation, she had not sought timely medical treatment. Her family history was unremarkable, as was her medical history, except for clonazepam intake due to epileptic episodes during her childhood.

On physical examination, she had reduced bowel sounds, while the upper abdomen was distended with mild tenderness on palpation. Digital examination was negative for the presence of blood in the rectum, but revealed a giant elastic mass with convoluted grooves on a smooth surface in the distal rectum. This lesion was located 2 cm above the dentate line, obstructing the intestinal lumen. Preoperative examinations, consisting of a full blood count, serum kidney and liver functions, as well as cancer markers (CEA, CA 19-9), were within

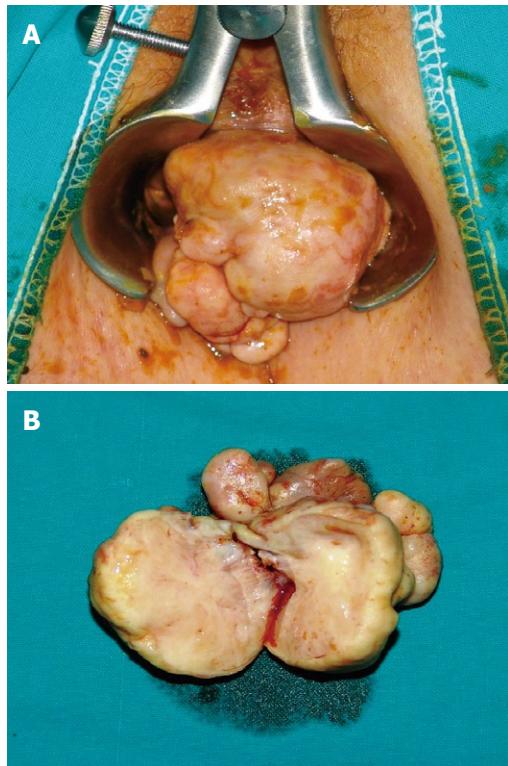

**Figure 1** Computed tomography of the pelvis showing the mass in the rectum.

**Figure 3** Histological features of the fibroepithelial polyp. A: Photomicrograph of resected polyp showing fibrous tissue covered by squamous epithelium, small vessels and the ulceration of fibrous stroma (HE,  $\times 100$ ); B: Deeper layer of the polyp showing scattered smooth muscle fibers within the fibrous stroma (HE,  $\times 100$ ).

normal limits. Plain abdominal X-rays revealed the presence of dilated small intestine with air-fluid levels. A computed tomography of the abdomen and pelvis demonstrated the presence of a mass in the rectum (Figure 1). Anal examination under anesthesia was carried out. A giant (measuring 15 cm  $\times$  12 cm) smooth mass attached to a wide pedicle extending over the entire posterior wall of the anal canal, above the dentate line, was easily observed (Figure 2). During the proctoscopy, biopsy specimens and frozen section analysis confirmed the benign nature of the lesion.

The huge mass was uneventfully removed by local excision with the aid of an electrothermal bipolar

**Figure 2** Clinical appearance of the giant fibroepithelial anal polyp. A: The clinical aspect of the mass during surgery; B: The gross macroscopic specimen.

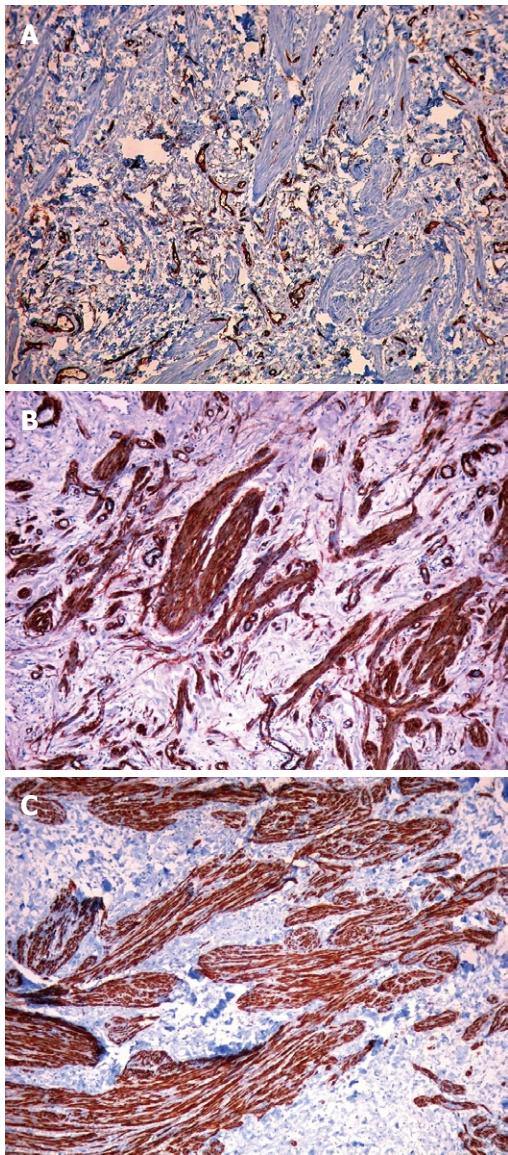

vessel sealer (LigaSure Precise<sup>®</sup>). The histological assay of the resected specimen showed fibrous tissue covered by multilayered squamous epithelium, many small dilated vessels filled with red blood cells, scattered smooth muscle fibers and a superficial ulceration of the fibrous stroma (Figure 3). In all immunohistochemical sections from the giant fibroepithelial polyp, spindle and stellate mononucleated stromal cells were positive for CD34, SMA (Smooth Muscle Actin) and desmin (Figure 4).

The histological and immunohistochemical findings therefore established the diagnosis of fibroepithelial polyp of the anus. The patient presented no postoperative complications and was discharged after 3 d of hospitalization.

## DISCUSSION

Fibroepithelial polyps of the anus, also known as hypertrophied anal papillae, are common lesions that have attracted little attention in the medical literature. They are enlarged, benign, polypoid projections of the anal squamous epithelium and the subepithelial connective tissue. These lesions are present in 45% of patients who undergo proctoscopic examination and are considered to be acquired triangular protrusions that arise from the base of the rectal columns of Morgagni at the dentate line<sup>[2]</sup>. As regards our patient, this is a report of a unique case of a very oversized fibroepithelial polyp of the anus which finally led to intestinal obstruction.

Clinically, these polyps may have the appearance of hemorrhoids, but they do not display thick-walled veins or any evidence of hemorrhage and organizing thrombi.

**Figure 4** Immunohistochemical analysis of the polyp. A: Stromal cells strongly express SMA; B: Stromal cells strongly express desmin; C: Stromal cells strongly express CD34.

In persons with poor anal hygiene, local disease or bowel dysfunction, these structures may become inflamed and edematous. They are usually small in size, asymptomatic and can be regarded as normal anatomic variations. Most anal papillae are 2-5 mm at their greatest dimension, although rarely they may exceed 2 cm. Enlargement of a fibroepithelial polyp to more than 3 cm in diameter is rare, and it is therefore necessary to differentiate such lesions from malignant tumors including leiomyosarcoma, anorectal carcinoma and malignant lymphoma.

Hypertrophied anal papillae are liable to trauma during the passage of stools and may become inflamed. Furthermore, they produce symptoms by projecting at the anal orifice during defecation and sometimes require digital repositioning, strongly simulating a rectal prolapse. Pruritus, foreign body sensation, mucus discharge, sense of incomplete evacuation and discomfort while sitting are the prevailing symptoms associated with this medical condition. The location of a smooth mass just

inside the anal verge should suggest the possibility of a fibroepithelial polyp, especially in a patient with a history of chronic anal irritation or locoregional infection<sup>[2,3]</sup>.

Endoscopically, a fibroepithelial polyp can be easily distinguished from an adenomatous polyp by several distinctive characteristics: (1) its mucosa is whitish compared with the reddish appearance of an adenomatous polyp, (2) the “stalk” of a hypertrophied anal papilla originates from the squamous side of the dentate line, (3) closure of the biopsy forceps on a fibroepithelial polyp results in pain, and (4) biopsy of these structures always demonstrates squamous epithelium. On the other hand, radiographic demonstration (on barium enema examination or computed tomography) of a fibroepithelial polyp is uncommon and occurs only when it becomes large enough to prolapse into the rectum. The differential diagnosis should always include internal hemorrhoids, rectal polyp, anal carcinoma and submucosal anorectal tumor<sup>[4,5]</sup>.

Groisman *et al*<sup>[6]</sup> studied the histological, immunohistochemical and ultrastructural features of a series of 40 fibroepithelial polyps of the anus. The authors concluded that fibroepithelial polyps of the anus are benign lesions characterized by the presence of mononucleated and multinucleated, sometimes atypical, CD34+ stromal cells showing fibroblastic and myofibroblastic differentiation. They also suggested that polyps harboring atypical cells are those of large size. The morphologic resemblance between these lesions and normal anal mucosa supports the hypothesis that fibroepithelial polyps may represent a reactive hyperplasia of the subepithelial connective tissue of the anal mucosa. Mast cell infiltration, by means of their fibrogenic, fibrolytic and angiogenic activities, may play an important role in the pathogenesis of these structures.

The presence of smooth muscle bundles and hyalinized vascular changes at the base of anal fibroepithelial polyps has also been reported. The rectal muscularis mucosa may be found in the upper part of the anal transitional zone. An increase in smooth muscle bundles could be the result of the hyperplastic response which caused anal fibroepithelial polyps to form a central core, and to become enlarged<sup>[7]</sup>. In our case study, the presence of abundant smooth muscle fibers in the stroma merely emphasizes the extreme enlargement of the polyp.

Another prominent histological feature of fibroepithelial polyps of the anus, but of uncertain significance, is the eosinophilic epithelial vacuolation. This is characterized by the accumulation of PAS-positive homogeneous eosinophilic material in superficial keratinocytes. This change may be a non-specific reaction to mechanical trauma, particularly given its propensity to afflict the apex of polyps. Pathologists should be very careful to avoid a misdiagnosis of extramammary Paget disease or oral white sponge nevus, which may sometimes affect anal epithelium<sup>[8]</sup>.

A fibroepithelial polyp that starts projecting into the anal canal requires attention and proper therapeutic strategy. Complete removal by crushing of the base and excision after using an electrothermal bipolar vessel

sealing system (EBVS-LigaSure), electrocauterization or ultrasonic energy (Harmonic Scalpel) has been suggested by many authors. Some other surgeons have found that the use of radio frequency devices is a quick, easy and significantly complication-free procedure for these pathological entities. This type of device can ablate the papillae instantly, while the fibrous polyps can be excised after coagulation of the bases and thereafter the pedicles<sup>[9]</sup>.

Although in our case we had no other option but to remove this giant polyp due to the intestinal obstruction it caused, in general, complete removal of these structures, regardless of the method used, offers definite therapeutic benefits and results in improved patient satisfaction.

## INTRODUCTION

Patients with abnormal thickening of the gallbladder wall caused by benign lesions such as chronic cholecystitis and adenomyomatosis are often encountered in daily clinical practice. Sometimes, it is difficult to differentiate these from gallbladder carcinoma by the conventional imaging techniques of ultrasonography, computed tomography (CT) and magnetic resonance imaging (MRI). Recently, several reports have demonstrated that fluorine-18 fluorodeoxyglucose positron emission tomography (FDG-PET) is useful in differentiating between benign and malignant lesions in the gallbladder<sup>[1-5]</sup>. However, 18F-FDG is not specific for malignant lesions, and can accumulate in inflammatory lesions with increased glucose metabolism. We present a patient with irregular thickening of the gallbladder wall which was diagnosed as a gallbladder carcinoma by ultrasonography and CT. FDG-PET showed increased activity. However, postoperative pathological examination revealed a xanthogranulomatous cholecystitis (XGC) with no evidence of malignancy. In this case, FDG-PET, ultrasonography and CT resulted in a misdiagnosis of gallbladder carcinoma.

## Abstract

Recently, several reports have demonstrated that fluorine-18 fluorodeoxyglucose positron emission tomography (FDG-PET) is useful in differentiating between benign and malignant lesions in the gallbladder. However, there is a limitation in the ability of FDG-PET to differentiate between inflammatory and malignant lesions. We herein present a case of xanthogranulomatous cholecystitis misdiagnosed as gallbladder carcinoma by ultrasonography and computed tomography. FDG-PET also showed increased activity. In this case, FDG-PET findings resulted in a false-positive for the diagnosis of gallbladder carcinoma.

## CASE REPORT

A 76-year-old man receiving treatment for rheumatoid arthritis with prednisolone 7.5 mg/d underwent blood examination in a routine checkup. An increased serum level of  $\gamma$ -glutamyltranspeptidase was found. He received abdominal ultrasonography for further examination. It showed an irregular thickening of the gallbladder wall on the hepatic side (Figure 1). No gallstones were detected. A CT scan also revealed an irregular thickening of the wall of the gallbladder body on the hepatic side. The border between the thickened gallbladder wall and liver parenchyma was indistinct (Figure 2A and B). There was no dilatation of the intrahepatic and extrahepatic bile duct. No lymphadenopathy was detected. FDG-PET/CT scan showed increased activity

**Figure 1** Abdominal ultrasonography showed an irregular thickening of the gallbladder wall on the hepatic side. No gallstones were detected.

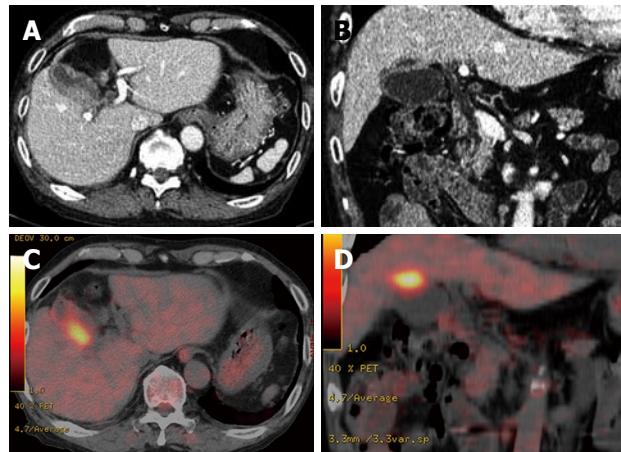

**Figure 3** Cut surface of the specimen. A yellowish tumor about 2 cm in diameter was observed between the mucosa of the body of the gallbladder and the liver parenchyma in the cut specimen.

in the thickened wall of the gallbladder. The increased uptake area appeared to extend into the liver parenchyma (Figure 2C and D). Endoscopic retrograde cholangiopancreatography showed no abnormality of the biliary tract including the cystic duct. An anomalous pancreaticobiliary ductal junction was not found. The result of laboratory examination showed no significant abnormality except for an increased serum level of  $\gamma$ -glutamyltranspeptidase (207 IU/L). C-reactive protein (CRP) was within the normal range (0.09 mg/dL). Tumor markers [carcinoembryonic antigen, carbohydrate antigen (CA19-9), and DUPAN2] were not elevated. We diagnosed the lesion preoperatively as a gallbladder carcinoma with direct invasion to the liver bed. We performed subsegmentectomy of the liver S4a + S5 and lymph node dissection of the hepatoduodenal ligament without extrahepatic bile duct resection. Gross examination of the specimen demonstrated no obvious tumor on the mucosa of the gallbladder. There were no gallstones and only a small amount of biliary sludge in the gallbladder. A yellowish tumor about 2 cm in diameter was observed between the mucosa of the body of the gallbladder and the liver parenchyma in the cut specimen (Figure 3). Pathological examination revealed a XGC with no evidence of malignancy. The postoperative course was uneventful. He is now in good health 8 mo after surgery.

## DISCUSSION

XGC is an unusual inflammatory disease of the

**Figure 2** Abdominal computed tomography (CT) and fluorine-18 fluorodeoxyglucose positron emission tomography (FDG-PET). A, B: Abdominal CT scan revealed an irregular thickening of the wall of the gallbladder body on the hepatic side. The border between the thickened gallbladder wall and liver parenchyma was indistinct; C, D: FDG-PET/CT scan showed increased activity in the thickened wall of the gallbladder. The increased uptake area appeared to extend into the liver parenchyma.

gallbladder manifested by abnormal thickening of the wall. It was first reported and named by McCoy<sup>[6]</sup> in 1976 and described as a distinct pathological condition by Goodman and Ishak<sup>[7]</sup> in 1981. It is a variant of cholecystitis characterized by intense acute or chronic inflammation, severe proliferative fibrosis with formation of multiple yellow-brown intramural nodules and foamy histiocytes. It is speculated that XGC may result from extravasation of bile into the gallbladder wall with involvement of Rokitansky-Aschoff sinuses or through a small ulceration in the mucosa. The inflammatory process often extends into neighboring organs, such as the liver, omentum, duodenum, and colon<sup>[6-12]</sup>. The clinical importance of XGC lies in the fact that it can be confused radiologically with a gallbladder carcinoma. Several reports demonstrated the radiological features of XGC. However, as some are nonspecific, it is often difficult to distinguish XGC from gallbladder carcinoma by the conventional imaging techniques of ultrasonography, CT and MRI<sup>[13-18]</sup>. Moreover, the fact that XGC can infrequently be associated with gallbladder carcinoma<sup>[19-20]</sup> makes the differentiation more difficult. Consequently, patients with XGC have sometimes undergone excessive surgical resection with preoperative diagnosis of advanced gallbladder carcinoma<sup>[21-22]</sup>.

Recently, several reports have demonstrated that FDG-PET is useful in differentiating between benign and malignant lesions in the gallbladder. They reported the sensitivity and specificity of FDG-PET for the diagnosis of gallbladder carcinoma as 75%-100% and 75%-89%, respectively<sup>[1-5]</sup>. However, 18F-FDG is not specific for malignant lesions and can accumulate in inflammatory lesions with increased glucose metabolism. Indeed, false-positive results in benign lesions, including chronic cholecystitis, tuberculosis, and adenomyomatosis of the gallbladder have been reported<sup>[4,23,24]</sup>. Nishiyama *et al*<sup>[25]</sup> evaluated the correlation between CRP and

18F-FDG uptake in gallbladder lesions. They reported that the specificity of FDG-PET for the diagnosis of gallbladder carcinoma was 80% in the group with normal CRP levels; on the other hand, it decreased to 0% in the group with elevated CRP levels. They recommended FDG-PET for patients with normal CRP levels to differentiate between malignant and benign lesions. In our case, although the patient had no obvious symptoms, such as fever and abdominal pain, and the laboratory data showed no significant inflammatory reaction, such as increased white blood cell counts and elevated CRP level throughout his clinical course, FDG-PET examination resulted in a false-positive diagnosis. It was speculated that the inflammatory reaction in the gallbladder might have been concealed by the effect of the steroid he had daily taken for the treatment of rheumatoid arthritis. From now on, FDG-PET may be applied for the diagnosis of gallbladder carcinoma more frequently. We should consider the possibilities of false-positive results as a result of inflammatory lesions, because of the frequent occurrence of inflammatory diseases in the gallbladder.

### INTRODUCTION

Neuropsychiatric side effects of long-term recombinant interferon- $\alpha$  (IFN- $\alpha$ ) therapy consist of a large spectrum of symptoms. Organic personality syndrome, organic affective syndrome, psychotic manifestations, and seizures are more common side effects of IFN- $\alpha$ , whereas cranial neuropathy and movement disorders are less common<sup>[1]</sup>.

We present a patient with chronic hepatitis C who showed an increase in choreiform movements associated with Huntington's disease (HD), and also developed Bell's palsy during treatment with pegylated interferon (peginterferon) and ribavirin.

### CASE REPORT

A 54-year-old woman presented with anti-hepatitis C virus (HCV) positivity and elevated alanine aminotransferase (ALT) levels in February 2007. After documentation of PCR-based HCV viremia, she underwent liver biopsy. As pathological examination revealed stage III fibrosis, it was planned to give her antiviral therapy that consisted of peginterferon- $\alpha$  and ribavirin. However, she had a history of minor choreiform limb movements for the past few years, but no cognitive impairment was observed. Her mother and sister had similar movements, and her mother had dementia consistent with HD. She also had been taken L-thyroxine for hypothyroidism for a few years. Although genetic analysis for exclusion of HD was proposed before starting antiviral therapy, the patient preferred to start therapy without genetic analysis for HD. She commenced peginterferon- $\alpha$ 2b 100  $\mu$ g once weekly and ribavirin 1000 mg/d in May 2007. In the third month of therapy, she had a 2 log decrease in HCV viral load.

After the fourteenth dose of peginterferon, she suffered pain behind her right ear, followed by dropping of the right side of the face. She attended the emergency

### Abstract

Neuropsychiatric side effects of long-term recombinant interferon- $\alpha$  therapy consist of a large spectrum of symptoms. In the literature, cranial neuropathy, especially Bell's palsy, and movement disorders, have been reported much less often than other neurotoxic effects. We report a case of Bell's palsy in a patient with chronic hepatitis C during peginterferon- $\alpha$  and ribavirin therapy. The patient subsequently developed clinically inapparent facial nerve involvement on the contralateral side and showed an increase in choreic movements related to Huntington's disease during treatment.

service of a local hospital, and she was started on anti-inflammatory therapy, but not on steroid therapy, because of the possibility of increasing HCV viral load. She then attended an outpatient clinic of the neurology department in our hospital. Neurological examination revealed right-sided Bell's palsy of House-Brackmann grade V<sup>[2]</sup>. The right facial nerve had 90% degeneration on electroneurography (ENG). No motor unit potentials were identified by needle electromyography (EMG). Contrast-enhanced magnetic resonance imaging (MRI) of the inner ear showed abnormal enhancement of the intracanalicular portion of the right facial nerve. Serological examination of some viral diseases revealed that herpes simplex virus (HSV) type I IgG and anti-cytomegalovirus IgG were positive, whereas IgM tests for these viruses were negative. IgG and IgM tests for HSV type II were also negative. She stopped antiviral therapy and was given anti-inflammatory therapy. An operation for facial nerve palsy was advised by the consultant in otorhinolaryngology, but hypothyroidism, most likely caused by inappropriate usage of oral thyroid hormone therapy, was found on preoperative screening tests. Two months after the facial symptoms began, she was euthyroid, and she underwent surgery for facial nerve decompression. She promptly experienced a virological and biochemical relapse after cessation of antiviral therapy. Three and a half months after facial paralysis, she chose to continue antiviral therapy, but this time peginterferon- $\alpha$ 2a 180  $\mu$ g was reinstated along with ribavirin. Two and a half months after the operation, facial movements were shown to be improved and graded as House-Brackman 3 on the right side. The right facial nerve had 48% degeneration upon ENG. We also observed reinnervation potentials on needle EMG. MRI of facial nerves performed after 5 mo of the second round of antiviral therapy revealed contrast enhancement of bilateral facial nerves, even though she had no clinical findings on the left side of her face. At the same time, the patient reported a noticeable increase in her choreiform movements, which were not found to be related to L-thyroxin overdose, after performing thyroid function tests. Upon neurological examination, clear choreiform movements of her upper and lower limbs were observed. There was no cognitive deterioration. Genetic analysis revealed increased CAG repeat length (23/43) consistent with HD. Her movement disorder did not deteriorate further and she did not experience facial palsy on the other side despite continuing therapy, but she was treated with systemic steroids during the last 2 wk of therapy to prevent overt facial palsy. She completed the 48-wk course of antiviral therapy. Although her choreic movements decreased upon completion of antiviral therapy, a prominent improvement in her movement disorder was observed with tetrabenazine (50 mg/d), which was started 3 mo after completion of antiviral therapy.

## DISCUSSION

Bell's palsy is often idiopathic, but has been linked to

some viral infections, particularly with herpes viruses<sup>[3,4]</sup>. Other infections, such as human immunodeficiency virus infection and Lyme disease, may also lead to idiopathic facial paralysis. Neither acute nor chronic HCV infection has been implicated previously in Bell's palsy, but IFN- $\alpha$  may have a role<sup>[5]</sup>.

IFN- $\alpha$ , or peginterferon, together with ribavirin are the current treatment regimen for chronic hepatitis C. Large studies have shown that whereas flu-like symptoms and reversible hematological cytopenia are common side effects of this treatment regimen, more serious side effects are rare. In a large retrospective study from Italy, with a total of 11 241 patients who received IFN- $\alpha$ , new neurological problems including seizures and neuropathy occurred in less than 10 patients<sup>[6]</sup>. In a study of 677 Japanese patients treated with high-dose IFN, only one suffered a neurological complication, and developed sudden hearing loss<sup>[7]</sup>. However, psychiatric symptoms such as depression or anxiety have been seen commonly during IFN treatment. The reported frequency of neurotoxicity, including psychiatric side effects during IFN treatment ranges from 25% to 33%<sup>[8]</sup>. In another study from Italy, 108 out of 441 patients treated with IFN plus ribavirin for hepatitis C failed to finish combination therapy because of adverse effects. Ten patients suffered from neuropsychiatric problems: six presented with depression or anxiety, one with erectile dysfunction, one with seizures, one with vertigo and one with peripheral neuropathy<sup>[9]</sup>. There are also reports of IFN therapy leading to ischemic optic neuropathy, retinopathy, peripheral neuropathy, oculomotor neuropathy and trigeminal sensory neuropathy<sup>[10]</sup>.

We found only six cases of Bell's palsy associated with IFN, in our literature search<sup>[5,10-12]</sup>. However, one case was associated with peginterferon- $\alpha$ <sup>[10]</sup>. Ogundipe *et al*<sup>[11]</sup> firstly documented two cases of Bell's palsy that developed during IFN- $\alpha$  and ribavirin therapy for chronic HCV. In both cases, facial palsy developed a number of months after commencing therapy and resolved, one with and one without cessation of therapy. The authors have suggested that a neuropathic effect of IFN- $\alpha$ 2b on the facial nerve may result in facial paralysis. In another report including two patients with chronic HCV infection, Bell's palsy occurred during treatment with IFN- $\alpha$ 2b and ribavirin at week 7 in one patient and week 12 in another<sup>[12]</sup>. Facial paralysis resolved in both cases after withdrawal of antiviral therapy. However, one of these patients experienced Bell's palsy shortly after an outbreak of HSV oral stomatitis. Thus, it is difficult to implicate exclusively combination therapy as the etiology for this case of Bell's palsy.

Hoare *et al*<sup>[5]</sup> have reported that three patients with chronic HCV infection also developed Bell's palsy during combination therapy, with spontaneous resolution after withdrawal of treatment. Two of the patients had immune-mediated baseline disease, ulcerative colitis and focal segmental glomerulonephropathy, which may have increased their risk of complications such as Bell's palsy.

The present case is, to the best of our knowledge, the second case of Bell's palsy associated with peginterferon

therapy reported in the literature. Bilateral facial nerve involvement is another interesting feature of our case. Hypothyroidism may be another cause for the primary right-sided palsy. However, subclinical involvement of the other facial nerve, which was found to be contrast-enhanced by MRI, during the second round of antiviral therapy, supported the suggestion of IFN-induced neurotoxicity.

Some adverse effects of IFN are thought to be caused by immune dysregulation, and a good example is autoimmune thyroiditis<sup>[13]</sup>. Previous studies on Bell's palsy have shown that it may be the result of an attack on cranial nerve VII by lymphocytes that sensitized to the Schwann cell membrane of the nerve itself<sup>[14]</sup>. Thus cell-mediated immunity, augmented by peginterferon and ribavirin, may target Schwann cells of cranial nerve VII and consequently lead to facial paralysis. Another possible mechanism might involve microvascular lesions that result from vasculitis or vasospasm, because there is evidence of IFN- $\alpha$ -induced retinal abnormalities, including ischemic lesions, cotton wool exudate, capillary occlusion or retinal hemorrhage<sup>[15,16]</sup>.

To the best of our knowledge, four cases of chorea, associated with IFN- $\alpha$  were have been reported in the literature so far<sup>[17-20]</sup>. These were not associated with HD. Choreaform movements may increase during IFN- $\alpha$  therapy, since it affects dopaminergic pathways. Long-term IFN- $\alpha$  therapy acts as a dopamine antagonist by altering dopaminergic pathways through an opioid-receptor-associated action, and may cause choreic movements by dysfunction of basal ganglia-thalamocortical loops<sup>[17]</sup>.

Bell's palsy and movement disorders are rare complications of IFN therapy. We suggest that the underlying mechanisms involve autoimmunity or neurotoxic effects of IFN on the neuroendocrine system and neurotransmitters, thus physicians should be aware of these rare neurotoxic side effects of IFN- $\alpha$ .

### INTRODUCTION

Giant fibrovascular polyps of the esophagus are rare. Even though they are benign, they may be lethal due to either bleeding or asphyxiation if regurgitated. Recurrence of these giant polyps are rare and treatment is often difficult, specialized and may require combination of a few treatment approaches and modalities including endoscopy and open surgical techniques. We illustrate this problem with a case report and review the literature.

### Abstract

Giant fibrovascular polyps of the esophagus and hypopharynx are rare benign esophageal tumors. They arise most commonly in the upper esophagus and may, rarely, originate in the hypopharynx. They can vary significantly in size. Even though they are benign, they may be lethal due to either bleeding or, rarely, asphyxiation if a large polyp is regurgitated. Patients commonly present with dysphagia or hematemesis. The polyps may not be well visualized on endoscopy and imaging plays a vital role in aiding diagnosis as well as providing important information for pre-operative planning, such as the location of the pedicle, the vascularity of the polyp and the tissue elements of the mass. They can also be recurrent in rare cases, especially if the resection margins of the base are involved. We review the recent literature and report a case of a 61-year-old man with a recurrent giant esophageal fibrovascular polyp with illustrative contrast barium swallow, CT and intra-operative images, who required several surgeries *via* a combination of endoscopic, trans-oral, trans-cervical, trans-thoracic and trans-abdominal approaches.

### CASE REPORT

A 61-year-old man with a medical history of hypertension and hyperlipidemia presented with melena and symptomatic anemia. His initial hemoglobin was 6.2 g/dL. He was transfused appropriately and underwent an emergent esophago-gastro-duodenoscopy (OGD). The endoscopy revealed a large polyp, arising from the upper esophagus settling in the upper stomach (Figure 1). The endoscopic biopsy revealed benign squamous mucosa and granulation tissue. He was offered surgical excision of the polyp in view of the bleeding episodes from the ulcerated polyp but he declined surgery. He was initially able to regurgitate polyps out into the mouth, but he gradually progressed to mild intermittent dysphagia and agreed to surgical intervention 6 mo after initial presentation.

Under general anesthesia, laryngoscopic and esophagoscopic evaluation revealed two polyps with broad long stalks arising from the upper third of the oesophagus. The decision was made to proceed with a left cervical esophagotomy. There was difficulty in retracting the polyps cranially *via* the left cervical approach. A decision was then made to perform a gastrotomy *via* a laparotomy in an attempt to retract and pull the polyps into the stomach. The large polyps were noted at the cardio-esophageal junction but it was not possible to pull the polyps with their long stalks into the stomach for adequate resection. In view of these difficulties, we proceeded with esophagotomy *via* a left thoracotomy approach to deliver and excise the polyps.

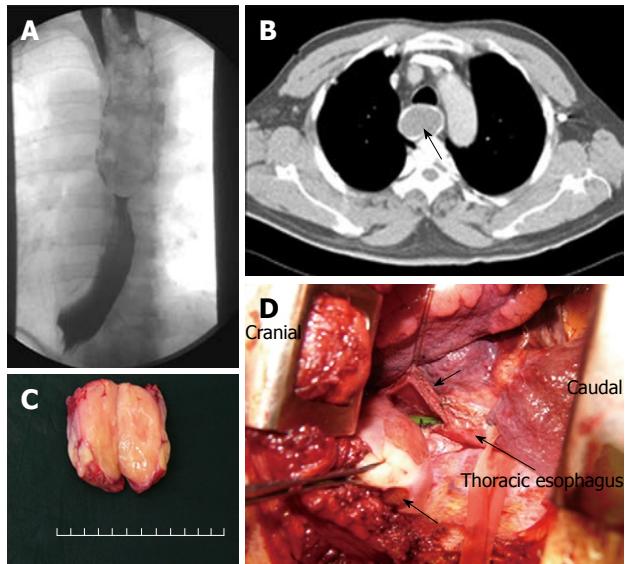

**Figure 1** Endoscopy showing the long broad pedicle and broad base.

Final histology revealed two fibrovascular polyps with ulceration measuring  $4\text{ cm} \times 4\text{ cm}$  and  $6\text{ cm} \times 6\text{ cm}$ , respectively. There was no evidence of malignancy. He was discharged in good health and followed up in the outpatient clinic at 3-6 mo intervals. He developed gradual intermittent dysphagia again 2 years later. A flexible OGD was performed and it revealed a recurrent fibrovascular polyp. In this admission, peroral excision of the recurrent polyp was performed with the aid of an ENDO GIA™ 30 stapler (Ethicon, Cincinnati, OH). The esophageal lumen was then inspected endoscopically and found to be free from bleeding, mucosal tears, or perforation prior the end of the procedure.

Histology was consistent with a previous report of a giant fibrovascular polyp, measuring  $5\text{ cm} \times 6\text{ cm}$ . There was no evidence of malignancy, however, the resection margin was noted to be involved. He was discharged in good health and followed up in the outpatient clinic at 3-6 mo intervals.

He re-presented approximately 2 years later, again for similar symptoms of intermittent dysphagia. An examination under anesthesia with a direct laryngoscopy and a rigid esophagoscopy revealed another polyp with a long stalk arising from the upper esophagus. In view of the recurrent nature and the previous surgeries, a barium swallow and CT of the neck and thorax were performed to aid surgical planning (Figure 2).

In this second recurrent episode, intra-operative findings revealed a  $6\text{ cm} \times 7\text{ cm}$  polyp with a long stalk measuring about 5 cm and a broad base of 1 cm width originating from the upper third of the esophagus. A trans-cervical esophagotomy was performed initially but due to the size of the polyp, it was not possible to deliver the polyp and an upper esophagotomy *via* a right thoracostomy approach was performed to deliver and resect the polyp. Excision of the polyp *via* the thoracic esophagotomy and excision of fibro-vascular stalk *via* the cervical esophagotomy was performed (Figure 2). Histology was consistent with that of a giant

**Figure 2** Recurrent Giant Esophageal polyp in 61-year-old man. A: Barium swallow study; B: CT Thorax, showing the homogenous nature of the polyp (arrow); C: Bi-valved bulk of the polyp without its pedicle, showing the fatty nature of the polyp; D: Intra-operative trans-thoracic view showing the polyp's head and an ulcer (bottom arrow), esophagotomy (top arrow) with the nasogastric tube *in-situ* (middle arrow).

fibrovascular polyp with no evidence of malignancy. He was discharged and is well to date.

## DISCUSSION

Fibrovascular polyps of the esophagus are rare benign tumors, comprising about 1% of all benign esophageal tumors, however, they are the most common intraluminal benign tumors of the esophagus<sup>[1]</sup>. Giant fibrovascular polyps are defined as polyps larger than 5 cm in maximum diameter. To date, there are just over 100 reported cases in the literature and the largest single series consists of 16 patients<sup>[2,3]</sup>. They are slow growing, pedunculated tumor masses that often arise from the upper esophagus, near the level of the cricopharyngeus at the pharyngo-esophageal junction, and this area has also been termed as the Laimer-Haeckermann triangle (also known as the Laimer's triangle)<sup>[4]</sup>. The pathogenesis of these polyps is thought to originate from the loose and redundant submucosal tissue near the Laimer's triangle. This relatively mobile tissue due to lack of muscular support, through years of esophageal peristalsis traction and swallowing, is dragged along, elongated and enlarged intraluminally.

The histology of the fibrovascular polyp consists of a mixture of lipomatous tissue among dense or loose fibrous elements, accompanied by an abundant network of vessels and covered by a normal squamous epithelium. The squamous epithelium may ulcerate and bleed especially in the larger tumors. Particularly in giant polyps, different histological components may vary and one may predominate leading to different terminology of these lesions as fibroepithelial polyps, fibrolipomas, fibromyxomas, lipomas, fibromas. These are all now collectively classified by World Health Organisation as

fibrovascular polyps. The more common differential diagnosis includes leiomyomas, leiomyosarcomas, squamous papillomas, lymphomas, spindle cell carcinomas and hemangiomas amongst others.

Malignant transformation is rare but has been reported in esophageal polyps. The lipomatous components can undergo sarcomatous changes, the squamous mucosa can develop into squamous carcinomas and small polyps have developed into adenocarcinoma<sup>[1]</sup>.

Due to the indolent nature of these polyps and the potential space the esophagus provides, these fibrovascular polyps can grow up to considerable sizes without causing many symptoms till late, measuring as big as 26 cm in largest diameter<sup>[5]</sup>. The majority of fibrovascular polyps occur in elderly men aged between 60 and 70 years old, but they have been reported in a 5-month-old infant<sup>[5,6]</sup>.

Though biologically benign, these giant fibrovascular polyps can have dramatic and even life-threatening presentations. Due to their size and mobility, they can be regurgitated and can cause asphyxiation or require emergent airway management<sup>[1,7]</sup>. In the literature, dysphagia was the most common complaint (present in 87%), followed by respiratory symptoms (25%) and regurgitation of the polyp into the pharynx or mouth (12%). The other reported non-specific symptoms included epigastric pain, odynophagia, non-exertional substernal chest pain, loss of weight, persistent cough and in our case, gastrointestinal bleeding<sup>[1,8]</sup>.

In the absence of an obvious regurgitation of the polyp during examination, diagnosis can be a challenge<sup>[8]</sup>. During endoscopy, the lesion may be missed especially if the origin of the stalk is not visualized, as the polyp may occupy the esophageal lumen and the surface of the polyp can resemble normal esophageal mucosa<sup>[5]</sup>. Diagnosis can be made by a combination of clinical history and various investigations such as endoscopy and imaging studies like barium swallow studies, endoscopic ultrasonography (EUS), CT and magnetic resonance imaging (MRI). Barium studies are commonly used and can show up the characteristic appearance of a smooth intra-luminal sausage-shaped mass with bulbous tips, with varying degrees of lobulation (Figure 1)<sup>[9]</sup>. It must be noted that, on occasion, these polyps may be opposed against the esophageal wall and give a false impression of a normal barium swallow. EUS can be a useful adjunct as it provides information on the size, origin of the stalk and vascularity of the polyp. In addition, EUS-fine needle aspiration may provide a more diagnostic histological sample than a superficial biopsy from an endoscopic approach. CT has been recommended by some; in addition to providing information on the components of the tumor, at an early arterial phase, especially in large polyps, feeding vessels can be visualized which can aid in surgical planning. In such cases, where a large feeding vessel is demonstrated, open surgery is advocated instead of endoscopic techniques e.g. snare polypectomy<sup>[10]</sup>. MRI is also a useful adjunct in diagnosis and surgical planning as it provides multiple planes of section and high soft tissue differentiation resolution<sup>[11]</sup>.

The mainstay of treatment once diagnosis is achieved is surgical excision in view of the potential risk of respiratory compromise, bleeding (as in this patient) and the debilitating symptoms. Surgery also serves to exclude cancer and avoid the small risk of malignant degeneration. Depending on the size, the location of the stalk's base and its mobility, different approaches have been practiced. The different methods include simple endoscopic excision techniques using electrocautery or even Nd:YAG laser ablation in a case, cervical esophagotomy, trans-thoracic esophagotomy and esophagectomy<sup>[4]</sup>. Smaller polyps, less than 2 cm in diameter with a thin pedicle, can be removed endoscopically without many complications but this is not recommended in larger tumors (length > 8 cm). Due to the thick vascularized pedicle, hemostasis is most safely achieved by open surgical techniques<sup>[5]</sup>. As the origin of the pedicle of the polyp in the majority of the cases lies in the upper third of the esophagus, cervical esophagotomy seems like the approach of choice. However, it is important to take note, at this point, the value and accuracy of pre-operative assessment of the base of the pedicle and the bulk of the tumor mass. Occasionally, a thoracotomy should be considered as it may be required for difficult, large lesions or lesions with a low origin. On occasion, a trans-abdominal approach via laparotomy may be a useful option as well, to aid in the delivery of the bulky polyp head through a gastrotomy<sup>[5]</sup>.

We advocate an individualized surgical strategy according to the characteristics of each polyp and recommend that in difficult cases [recurrent cases, patients with more than one polyp or patients with a large polyp (> 5 cm) with a long stalk (> 5 cm)] esophagotomy via thoracotomy should be considered for good control of hemostasis as well as for providing adequate exposure for resection of the pedicle's origin and any redundant mucosa around the pedicle. Recurrence of giant fibrovascular polyps is rare but has been described<sup>[2,12,13]</sup>. We believe that residual tissue around the pedicle's base may cause recurrent polyp formation which we hypothesize is the reason for the recurrent nature of polyp formation in our patient.

We therefore suggest appropriate pre-operative counseling and investigations such as obtaining additional informed consent for thoracotomy and laparotomy procedures. We also recommend patients who smoke or have significant respiratory morbidity should have a pre-operative lung function assessment. Peri-operatively it is also essential to inform the anesthetist and operating theatre staff and prepare the patient in anticipation for a thoracotomy or a laparotomy should the situation arise.

In summary, giant fibrovascular polyps are rare esophageal tumors and recurrences are even more uncommon. Although most are benign, surgical excision is recommended in view of potential deadly complications e.g. asphyxiation, bleeding, malignancy. Adequate pre-operative investigations should aim to identify the pedicle's origin and the bulk of the polyp to aid the planning of the surgical approach

to ensure adequate hemostasis and clear resection of the base to prevent recurrences. The surgical options include endoscopic resection, open surgery *via* trans-cervical, trans-thoracic or trans-abdominal approaches. This should be tailored on a case-to-case basis and a combination of the approaches should be considered in difficult cases.

### INTRODUCTION

Heterotopic pancreas is defined as pancreatic tissue found outside the usual anatomical location of the pancreas. It is usually found in the upper gastrointestinal tract. The incidence of heterotopic pancreas is low. Preoperative diagnosis is difficult. Although echogastriccopy is helpful for diagnosis<sup>[1]</sup>, it is difficult to distinguish from gastrointestinal stromal tumor (GIST). Frozen sections may help in deciding the extent of resection intraoperatively. We report two cases of heterotopic pancreatic lesions in the duodenum and gastric antrum.

### CASE REPORT

#### Case 1

A 60-year-old man presented to the gastroenterology outpatient clinic complaining of joint pain all over the body of 2 years duration, and abdominal distension for 1.5 years. He had a history of dermatomyositis. Physical examination revealed some symptoms of carcinoid syndrome including face rubeosis, abdominal bulge, and abdominal distension after walking for several minutes. Laboratory findings were that routine blood examination was normal, blood clotting and erythrocyte sedimentation rate were normal, postprandial blood sugar was 11.10 mmol/L, anti-dsDNA antibody, anti-O antibody and antinuclear antibody were normal, serum rheumatoid factor was 34.00 IU/mL, total cholesterol was 6.1 mmol/L, triglyceride was 2.85 mmol/L, 24-h urinary protein was normal, tumor markers were normal except that CA72-4 was a little high. Epigastric CT revealed a duodenal bulb submucosal lump that showed exophytic growth, which was possibly a benign GIST. Gastroscopy revealed chronic atrophic gastritis. Echogastriccopy revealed a mass in the duodenal submucosa, which might have been GIST. The patient underwent exploratory laparotomy after general anesthesia. During the operation, surgeons discovered that there was a tenacious mass in the duodenal bulb subserosa, with a diameter of 1.5 cm, and it did not encroach on mucosal

### Abstract

Heterotopic pancreas is defined as pancreatic tissue found outside the usual anatomical location of the pancreas. It is often an incidental finding and can be found at different sites in the gastrointestinal tract. It may become clinically evident when complicated by pathological changes such as inflammation, bleeding, obstruction, and malignant transformation. In this report, a 60-year-old man with carcinoid syndrome caused by heterotopic pancreatic tissue in the duodenum is described, along with a 62-year-old man with abdominal pain caused by heterotopic pancreatic tissue in the gastric antrum. The difficulty of making an accurate diagnosis is highlighted. The patients remain healthy and symptom-free after follow-up of 1 year. Frozen sections may help in deciding the extent of resection intraoperatively. Although heterotopic pancreas is rare, it should be considered in the differential diagnosis of gastrointestinal stromal tumor.

membrane. Local excision was carried out, and frozen sections showed heterotopic pancreas in the duodenal bulb. After surgery, paraffin sections showed that heterotopic pancreas in the duodenal bulb with papillary hyperplasia of the pancreatic duct epithelium. He was discharged 10 d after surgery without face rubeosis or abdominal distention after walking. He remained in good health during follow-up.

## Case 2

A 62-year-old man complained of repeated, vague right upper quadrant pain for 2 years. Physical examination and laboratory findings were unremarkable. Endoscopy showed a solid tumor mass in the gastric antrum (Figure 1). Epigastric zone CT also showed a mass in the gastric antrum (Figure 2). Echogastroscope showed that there was a solid tumor mass under the mucosal membrane in the gastric antrum (Figure 3), which was suggestive of GIST (a low-echogenicity mass under the gastric wall submucosal muscularis propria, with a clear boundary and uneven internal echo, and measuring 24.6 mm × 16.5 mm). Tumor markers were normal. During the operation, surgeons discovered that there was a tenacious mass with a diameter of 2 cm in the gastric antrum, which was considered to be GIST. Partial gastrectomy was performed because endoscopy could not rule out the possibility of malignancy. Frozen and paraffin sections showed heterotopic pancreas in the gastric antrum

**Figure 2** CT reconstruction showing a mass with a diameter of 2 cm in the gastric antrum.

**Figure 4** Lobules of pancreatic tissue with ducts located within the smooth muscle of the pylorus (HE,  $\times 100$ ).

(Figure 4). He was discharged 14 d after surgery without abdominal pain or complications. He remained in good health during follow-up.

## DISCUSSION

Jean-Schultz was the first to report that heterotopic pancreas is pancreatic tissue found outside the usual anatomical location of the pancreas<sup>[2]</sup>. It is a congenital abnormality. Its precise incidence rate has not been reported either in China or abroad, but it is very low. The incidence rate is 0.11%-0.21% at autopsy, with a male to female ratio of 3:1<sup>[3]</sup>. Heterotopic pancreas can exist at any position in the abdominal cavity. It is usually found in the upper gastrointestinal tract, with > 90% of the cases involving the stomach, duodenum or jejunum. Unusual locations are the colon, spleen or liver<sup>[4,5]</sup>. Heterotopic pancreas is usually buried in the submucosa, which makes it difficult to distinguish from GIST<sup>[4,6-8]</sup>. The diameter of heterotopic pancreatic tissue is generally about 1-2 cm, and in our cases, the diameter was 1.5-2 cm.

Patients with heterotopic pancreas can be normal, or present with abdominal pain and distension. In addition, it can manifest clinically in some rare diseases of the pancreas including pancreatitis, islet cell tumor, pancreatic carcinoma, and pancreatic cyst<sup>[9]</sup>. In our study, one of the patients revealed some symptoms of carcinoid syndrome, which is rare, including face rubeosis, abdominal

bulging, and abdominal distention after walking for several minutes. There is no specific examination and diagnostic method at present, and it is difficult to diagnose this disease definitely before laparotomy<sup>[2,10,11]</sup>. Echogastroscope, CT and gastroscopy can be helpful in diagnosis. The literature shows that the rate of diagnosis of this disease is high with echogastroscope<sup>[1]</sup>. In our two patients, echogastroscope and epigastric CT before laparotomy did not reveal heterotopic pancreas, and diagnosis was dependent on frozen or paraffin sections postoperatively. Heterotopic pancreas should be considered in the differential diagnosis of GIST. Medical treatment is not effective for heterotopic pancreas, and surgical excision is the first and best choice<sup>[12-14]</sup>. It is often impossible to distinguish gastric heterotopic pancreas from primary or metastatic cancer because endoscopic biopsies are often unremarkable. Therefore, frozen sections should be taken rapidly and routinely so as to confirm the diagnosis and avoid unwanted radical surgery such as Whipple's procedure or subtotal gastrectomy. Heterotopic pancreas may manifest some symptoms of carcinoid syndrome, and surgical treatment may eliminate such symptoms. Asymptomatic heterotopic pancreas is hard to diagnose. The treatment of asymptomatic histologically verified gastric heterotopic pancreas is debatable<sup>[15]</sup>.

In summary, the incidence of heterotopic pancreas is low and preoperative diagnosis is difficult. Although echogastroscope is helpful for diagnosis<sup>[1]</sup>, it is difficult to distinguish from GIST. Frozen sections should be taken so as to distinguish heterotopic pancreas from malignant tumor.

## INTRODUCTION

Gastrointestinal stromal tumor (GIST) is an uncommon tumor and can be seen mostly in gastrointestinal tract origin<sup>[1]</sup>. Sporadic primary GISTs unrelated to the tubular gastrointestinal tract, such as the omentum, mesentery or retroperitoneum, gallbladder, uterus and liver<sup>[1-4]</sup>, have been reported suggesting that these tumors are more widespread than commonly appreciated. Herein, we report a case of primary GIST of the liver evaluated by contrast-enhanced ultrasound (CEUS) and enhanced spiral computed tomography (CT) with histological and immunohistochemical diagnosis.

## CASE REPORT

A 17-year-old man, who was a HBV carrier without symptoms, was found to have a mass in the anterior segment of the right liver lobe by B-mode ultrasound examination at a local hospital and was then transferred to our hospital. Abdominal physical examination found no palpable mass. Laboratory studies showed positive HBsAg, HBe-Ab as well as HBc-Ab, and negative HBs-Ab, HBeAg, HCV, CEA, AFP, CA 19-9, CA 12-5, and CA 15-3. Blood chemistry was normal except for an alanine aminotransferase level of 60 U/L which was slightly increased. The fecal occult blood test was negative. Chest X-ray was also negative.

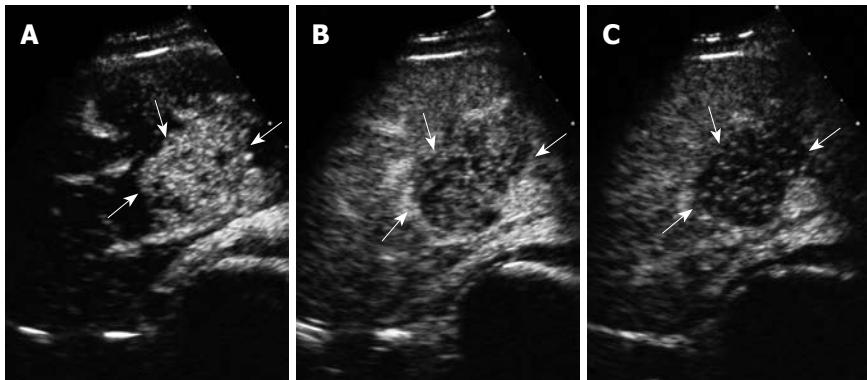

On CEUS examination using a 3.5 MHz convex transducer and a harmonic tissue program (Sequoia 512, Acuson Corporation, USA), a solid, oval-shaped, hyperechogenic 5.1 cm × 3.8 cm × 4.6 cm mass in the anterior segment of the right lobe next to the liver hilum was detected, showing vascularization on color Doppler imaging. Contrast-enhanced sonography with pulse inversion sequence imaging was performed which

## Abstract

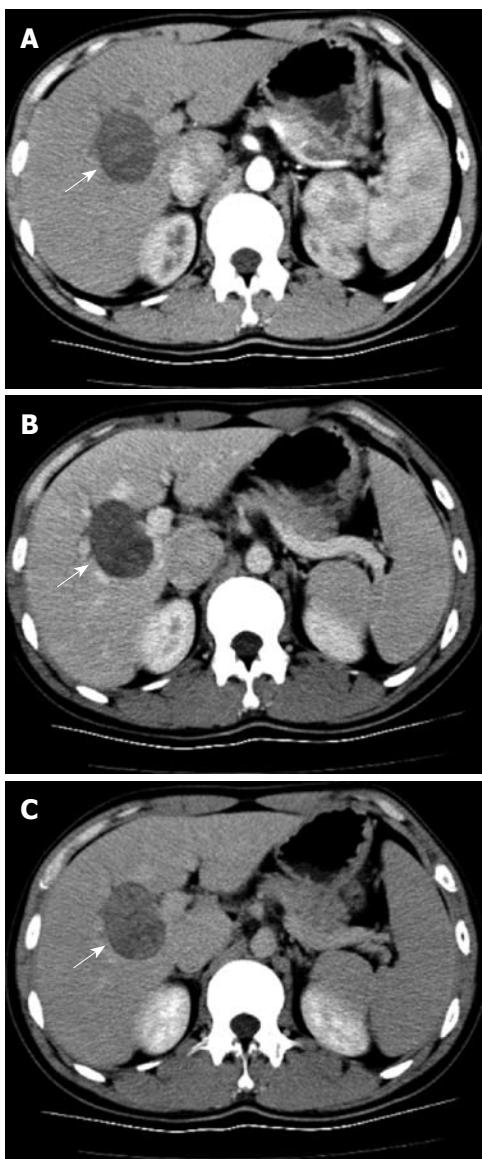

We report a case of primary gastrointestinal stromal tumor (GIST) of the liver. A 17-year-old man with a solid mass in the anterior segment of the right liver was asymptomatic with negative laboratory examinations with the exception of positive HBV. Contrast-enhanced ultrasound (CEUS) revealed a hypervascular lesion in the arterial phase and hypoechoic features during the portal and late phases. However, enhanced spiral computed tomography (CT) showed hypoattenuation in all three phases. Following biopsy, immunohistochemical evaluation demonstrated positive CD117. Different imaging features of primary GISTs of the liver are due to pathological properties and different working systems between CEUS and enhanced spiral CT.

**Key words:** Contrast-enhanced ultrasound; Enhanced spiral computed tomography; Gastrointestinal stromal tumor; Liver

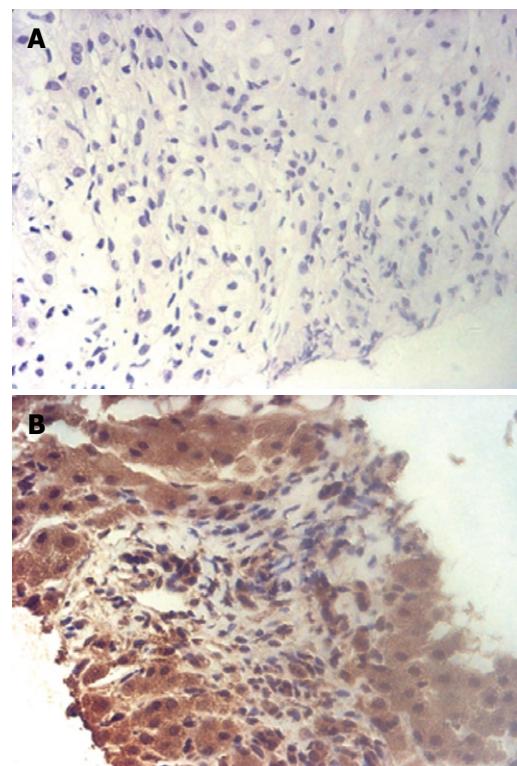

**Figure 1** Real-time CEUS showing a solid, oval-shaped, hyperechogenic  $5.1 \text{ cm} \times 3.8 \text{ cm} \times 4.6 \text{ cm}$  mass in the anterior segment of the right liver lobe. A: Hypervascularity in the arterial phase; B: Partial wash-out in the portal venous phase; C: Hypoechoic feature in the late phase.

**Figure 2** Transverse sequential triple-phase enhanced spiral CT showing a hypovascular mass in the anterior segment of the right liver lobe. A: The arterial-dominant phase; B: The portal-dominant phase; C: The late phase.

Showed contrast enhancement in the lesion appeared 14 s after a bolus injection of 2.4 mL SonoVue® (Bracco Diagnosis, Italy) and peaked at 27 s. Contrast enhancement subsequently decayed 30 s after injection to the end of the delay phase and the lesion was hypoechoic compared with that of the adjacent liver parenchyma (Figure 1).

**Figure 3** Histologic and immunohistochemical examinations of the tumor biopsy specimen. A: Neoplastic spindle cells in an irregular pattern, with normal hepatic parenchyma in peripheral areas (HE, original magnification,  $\times 200$ ); B: Diffuse and strong positivity for CD117 (original magnification,  $\times 200$ ).

Enhanced spiral CT (Aquilion, 16-slice, Toshiba, Japan) was performed 2 wk after CEUS and sequential triple-phase scanning began 20 s after 80 mL Iopromide (Ultravist, Schering, Berlin, Germany), an iodinated contrast, was injected at a flow rate of 3 mL/s. A hypodensity mass was demonstrated in the right liver lobe with slight enhancement in the arterial phase, which gradually increased in the portal phase and reached a maximum in the late phase (Figure 2).

Thereafter, biopsy was performed under the guidance of ultrasound. Histologic examination of the biopsy specimen showed that the tumor consisted of irregular neoplastic spindle cells and no mitoses were found (Figure 3A). Immunohistological staining showed positive reactivity for CD117 (Figure 3B), vimentin and CD34, and staining for keratin, HHF35, a-SMA, desmin, NF and S-100 was negative. With no other

findings in the abdominal and pelvic cavity on CEUS and enhanced spiral CT studies, the final diagnosis of a GIST originating from the liver was made. The patient was subsequently treated with radiofrequency ablation therapy. CEUS examination 3 mo later demonstrated no vascularity in the tumor.

## DISCUSSION

GIST is one of the soft tissue sarcomas arising from a pacemaker cell known as the interstitial cell of Cajal<sup>[5]</sup>, and can be seen mostly in gastrointestinal tract origin but predominantly occurs in the stomach (60% to 70%) and small intestine (25% to 35%), with rare occurrences in the colon and rectum (5%), esophagus (< 2%) and appendix<sup>[1]</sup>. GISTs originating from outside the gastrointestinal tract are extremely unusual. Regardless of where they occur, almost all GISTs have the same biologic behavior with the expression of the c-kit (CD117) protein, which is a growth factor transmembrane receptor with tyrosine kinase activity and differentiates these tumors from other mesenchymal tumors<sup>[1-4]</sup>.

The diagnosis of GIST mainly depends on histologic and immunohistochemical appearance, usually after surgery. GIST is mainly composed of spindle cells, which are randomly arranged in a variety of patterns. Immunohistochemical profiles show positivity for CD117, CD34, and vimentin; however, they are usually negative for keratin, S-100 protein, and smooth muscle actin. Tumor size and mitotic counts are used as prognostic factors, and mitotic counts exceeding 5 per 50 high power fields or size larger than 5 cm can predict future recurrence or metastasis to other areas with a predilection for the liver or the peritoneal cavity<sup>[1,6]</sup>. In our case, the histologic and immunohistochemical findings strongly supported the diagnosis of GIST. Owing to the fact that almost all GISTs in the liver are malignant, and metastatic lesions usually arise from the gastrointestinal tract, we carefully scanned the abdominal and pelvic cavities and showed no other positive findings. In addition, no mitoses were noted on pathological evaluation. The final diagnosis was primary GIST of the liver which was hypothesized to originate from progenitors of mesenchymal cells capable of differentiation toward a pacemaker cell phenotype<sup>[3,4]</sup>. The tumor was graded as low-grade malignant GIST due to its size.

Imaging modalities play an important role in detecting tumor localization, staging tumor status, assessing response to treatment and in monitoring tumor recurrence following treatment. Imaging features have revealed that the majority of GISTs manifest themselves as having an exophytic and cavitary nature with heterogeneous enhancement of contrast agents<sup>[6,7]</sup>. In Vanel's<sup>[6]</sup> report, 13 cases of hepatic metastases from GISTs were heterogeneous hypodense lesions with progressive, concentric enhancement. In our case, hypoattenuation with a gradual contrast enhancement pattern on enhanced spiral CT was coincident with those of metastatic GISTs of the liver. However, hypervascularity with quick wash-in

and wash-out on CEUS resembled malignant tumors of the liver, and because the patient was a HBV carrier, the initial diagnosis was highly suspicious for hepatocellular carcinoma. An analogous case appeared in Nicolau's report<sup>[8]</sup>, where the CEUS pattern in one benign solitary fibrous tumor (SFT) presented as arterial enhancement with quick wash-out in the portal and late phases which led to the misdiagnosis of a malignant tumor. It is worth noting that SFT is also one of the soft tissue sarcomas which are thought to have many clinical and pathologic features in common and the tumors are generally rich in vasculature even in benign stages<sup>[9,10]</sup>.

Although imaging findings did not seem to be a determinant factor in the diagnosis of this case, when the medical records were reviewed some clues were revealed. In this patient, a solitary parenchymatous tumor was found in the liver, with negative tumor markers on laboratory testing and no other findings on medical examination except positivity for HBV. This implied that it would be necessary to make a differential diagnosis from a relatively large spectrum of tumors. It should be borne in mind that some soft tissue sarcomas, such as GISTs, have prominent vascular features and the pharmacokinetics and pharmacodynamics of the contrast agent entering these types of tumors may be similar to those in malignant tumors.

Discrepancies between CEUS and enhanced spiral CT may be due to the distinct vascular architecture of GISTs and different working systems existing in the two imaging modalities. Contrast enhancement in CT or MR imaging can not be performed in real-time. Single frames are obtained during each of the phases of the liver. The time window of contrast-enhanced CT to image the liver lesion during the hepatic arterial-dominant phase is so short (approximately 20-30 s) that it results in the possibility of missing the early arterial enhancement. Since CEUS performed in real-time has the ability to continuously evaluate the entire arterial, portal, and late phases, if a lesion shows rapid changing enhancement, it is possible that this change in enhancement may be better visualized in CEUS than in contrast enhanced CT or MR imaging in the early phase. In Murphy-Lavallee's<sup>[11]</sup> studies, most hepatic metastases, including those thought to be hypovascular, showed transient arterial hypervascularity followed by rapid and complete wash-out within the conventional arterial phase on CEUS. The time to peak arterial enhancement of these tumors ranged from 8 to 27 s, and the beginning of wash-out ranged from 13 to 50 s.

Conclusively, primary GIST of the liver is extremely rare. Despite some discordance between CEUS and enhanced spiral CT in our case, their imaging features still seem to mimic those of the malignant tumors of the liver, irrespective of whether they are primary or metastatic lesions. To date, there are only two cases of primary GIST of the liver reported in the English literature, and to our knowledge, the case presented here is the first report of both CEUS and enhanced spiral CT evaluations before the final diagnosis. The present case may be taken as a warning for future clinical practice.

## Meetings

### Events Calendar 2009

January 12-15, 2009  
Hyatt Regency San Francisco, San Francisco, CA  
Mouse Models of Cancer

January 21-24, 2009  
Westin San Diego Hotel, San Diego, CA  
Advances in Prostate Cancer Research

February 3-6, 2009  
Carefree Resort and Villas, Carefree, AZ (Greater Phoenix Area)  
Second AACR Conference  
The Science of Cancer Health Disparities in Racial/Ethnic Minorities and the Medically Underserved

February 7-10, 2009  
Hyatt Regency Boston, Boston, MA  
Translation of the Cancer Genome

February 8-11, 2009  
Westin New Orleans Canal Place, New Orleans, LA  
Chemistry in Cancer Research: A Vital Partnership in Cancer Drug Discovery and Development

February 13-16, 2009  
Hong Kong Convention and Exhibition Centre, Hong Kong, China  
19th Conference of the APASL  
<http://www.apasl2009hongkong.org/en/home.aspx>

February 27-28, 2009  
Orlando, Florida  
AGAI/AASLD/ASGE/ACG Training Directors' Workshop

February 27-Mar 1, 2009  
Vienna, Austria  
EASL/AASLD Monothematic: Nuclear Receptors and Liver Disease  
[www.easl.ch/vienna2009](http://www.easl.ch/vienna2009)

March 13-14, 2009  
Phoenix, Arizona  
AGAI/AASLD Academic Skills Workshop

March 20-24, 2009  
Marriott Wardman Park Hotel  
Washington, DC  
13th International Symposium on Viral Hepatitis and Liver Disease

March 23-26, 2009  
Glasgow, Scotland  
British Society of Gastroenterology (BSC) Annual Meeting  
Email: bsg@mailbox.ulcc.ac.uk

April 8-9, 2009  
Silver Spring, Maryland  
2009 Hepatotoxicity Special Interest Group Meeting

April 18-22, 2009  
Colorado Convention Center, Denver, CO  
AACR 100th Annual Meeting 2009

April 22-26, 2009  
Copenhagen, Denmark  
the 44th Annual Meeting of the European Association for the Study of the Liver (EASL)  
<http://www.easl.ch/>

May 17-20, 2009  
Denver, Colorado, USA  
Digestive Disease Week 2009

May 29-June 2, 2009  
Orange County Convention Center Orlando, Florida  
45th ASCO Annual Meeting

### Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol*) ISSN 1007-9327, DOI: 10.3748 is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1126 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastrolesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in *WJG* will include the following. (1) Editorial: to introduce and comment on major advances in rapidly developing areas and their importance. (2) Frontier: to review recent developments and comment on current research status in important fields, and propose directions for future research. (3) Topic Highlight: this column consists of three formats, including: (a) 10 invited review articles on a hot topic; (b) a commentary on common issues associated with this hot topic; and (c) a commentary on the 10 individual articles. (4) Observation: to update the development of old and new questions, highlight unsolved problems, and provide strategies for their resolution. (5) Guidelines for Basic Research: as suggested by the title. (6) Guidelines for Clinical Practice: to provide guidelines for clinical diagnosis and treatment. (7) Review: to review systematically the most representative progress and unsolved problems, comment on current research status, and make suggestions for future work. (8) Original Article: to report original and innovative findings. (9) Brief Articles: to report briefly on novel and innovative findings. (10) Case Report: To report a rare or typical case. (11) Letters to the Editor: to discuss and reply to contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest. (12) Book Reviews: to introduce and comment on quality monographs. (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities on basic research and clinical practice.

The WJG Press and Baishideng

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments,

References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [submission@wjgnet.com](mailto:submission@wjgnet.com), or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

### Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g.  $6.92 \pm 3.86$  vs  $3.61 \pm 1.67$ ,  $P < 0.001$ ; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, □, ▲, △, etc., in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[12,21]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc, assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

**Statistical data**

Write as mean  $\pm$  SD or mean  $\pm$  SE.

**Statistical expression**

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

**Units**

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) =  $8.6 \pm 24.5$   $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub>, not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23243641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

**Abbreviations**

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

**Italics**

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *argI*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindIII*, *BamHI*, *KboI*, *KpnI*, etc.

Biology: *H pylori*, *E coli*, etc.

## SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

**Editorial Office**

**World Journal of Gastroenterology**

Editorial Department: Room 903, Building D, Ocean International Center,

No.62 Dongsihuan Zhonglu, Chaoyang District, Beijing 100025, China

Telephone: +86-10-59080039

Fax: +86-10-85381893

E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)

<http://www.wjgnet.com>

**Language evaluation**

The language of a manuscript will be graded before it is sent for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

**Copyright assignment form**

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

**Responses to reviewers**

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

**Proof of financial support**

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

**Links to documents related to the manuscript**

*WJG* will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

**Science news releases**

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

**Publication fee**

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

World Journal of Gastroenterology  
Volume 15 Number 30 August 14, 2009

### INTRODUCTION

*World Journal of Gastroenterology* is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Singal AK, Anand BS. Management of hepatitis C virus infection in HIV/HCV co-infected patients: Clinical review. *World J Gastroenterol* 2009; 15(30): 3713-3724 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3713.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3713>

### Abstract

Nearly one fourth of individuals with human immunodeficiency virus (HIV) infection have hepatitis C virus (HCV) infection in the US and Western Europe. With the availability of highly active antiretroviral therapy and the consequent reduction in opportunistic infections, resulting in the prolongation of the life span of HIV-infected patients, HCV co-infection has emerged as a significant factor influencing the survival of HIV patients. Patients with HIV/HCV co-infection have a faster rate of fibrosis progression resulting in more frequent occurrences of cirrhosis, end-stage liver disease, and hepatocellular carcinoma. However, the mechanism of interaction between the two viruses is not completely understood. The treatment for HCV in co-infected patients is similar to that of HCV mono-infection; i.e., a combination of pegylated interferon and ribavirin. The presence of any barriers to anti-HCV therapy should be identified and eliminated in order to recruit all eligible patients. The response to treatment in co-infected patients is inferior compared to the response in patients with HCV mono-infection. The sustained virologic response rate is only 38% for genotype-1 and 75% for genotype-2 and -3 infections. Liver transplantation is no longer considered a contraindication for end-stage liver disease in co-infected patients. However, the 5 year survival rate is lower in co-infected patients compared to patients with HCV mono-infection (33% vs 72%, P = 0.07). A better

### INTRODUCTION

Co-infection with hepatitis C virus (HCV) and human immunodeficiency virus (HIV) is common as both viruses share similar modes of transmission. The management of HCV infection in the HIV infected population poses a serious challenge for physicians. Approximately two thirds of co-infected patients do not receive anti-HCV treatment for reasons such as poor compliance with highly active anti-retroviral therapy (HAART), decompensated liver disease, co-morbidities, active substance use, ongoing alcohol use, and advanced HIV disease<sup>[1,2]</sup>. Thus, only a minority of such patients receive anti-HCV treatment<sup>[2-4]</sup>. In order to improve the outcome in co-infected patients, it is important to have a good understanding and knowledge of HAART and its interaction with drugs used for HCV treatment.

### EPIDEMIOLOGY AND PREVALENCE OF HCV IN HIV INFECTED INDIVIDUALS

In the US, about 25% to 35% of patients with HIV are infected with HCV, with a higher prevalence (40%) in US military veterans<sup>[5,6]</sup>. This translates to nearly 300 000 people in the US who are co-infected with HIV and HCV. The co-infection rate is higher when transmission occurs through the parenteral route

compared to when the infection is acquired by sexual contact. The prevalence of HCV in HIV patients who acquire infection through intravenous drug abuse (IVDA) or multiple blood transfusions is 75%-90%<sup>[3,7]</sup>. Although sexual contact is a common route of HCV transmission<sup>[8,9]</sup>, it is difficult to determine its true significance because other variables are frequently also involved. Bollepalli *et al*<sup>[10]</sup> reported that IVDA, snorting drugs, sharing toothbrushes/razors, being in prison, and tattooing are significant non-sexual risk factors, while sex for money or drugs, sex with IVDA users, and men who have sex with men (MSM) are significant sexual risk factors for co-infection. However, on multivariate analysis, only IVDA emerged as a risk factor for co-infection ( $P = 0.001$ )<sup>[10]</sup>.

## SIGNIFICANCE OF HCV AND HIV CO-INFECTION

With the availability of HAART, the outcome of patients infected with HIV has improved remarkably in the last decade<sup>[11,12]</sup>. Since HIV patients are now surviving longer, liver disease due to HCV co-infection has emerged as a significant problem. The presence of HIV alters the natural history of HCV infection. After acquiring HCV, the infection has a tendency to chronicity in over 90% amongst HIV patients due to the lack of critical CD4 T cell responses against HCV<sup>[13,14]</sup>. Once chronic HCV infection is established, fibrosis progression is much faster, resulting in a higher frequency of cirrhosis and its complications compared to HCV mono-infection<sup>[15,16]</sup>. A meta-analysis of 8 studies involving 1871 HCV positive patients (601 co-infected with HIV) showed a relative risk of 2.92 (95% CI 1.70-5.01) for more severe disease, 2.07 (95% CI 1.40-3.07) for histological cirrhosis and 6.14 (95% CI 2.86-13.20) for decompensated liver disease<sup>[15]</sup>. Similarly, there is a higher incidence of hepatocellular carcinoma (HCC) in co-infected patients<sup>[17,18]</sup>. Co-infected patients with HCC are younger ( $42 \pm 10$  year *vs*  $69 \pm 9$  year,  $P < 0.001$ ) and have a shorter duration of HCV infection ( $18 \pm 3$  year *vs*  $28 \pm 11$  year,  $P < 0.05$ ) compared to patients with HCC in HCV mono-infection. Tumors at presentation in co-infected patients have an infiltrative pattern, are at an advanced stage, and have more frequent extra-nodal metastasis<sup>[18]</sup>.

The mechanism of interaction between the two viruses and their impact on liver injury is not completely understood. HCV is not directly cytopathic and the pathogenesis of liver injury is believed to be immune mediated<sup>[19]</sup>. It can be argued that HIV patients should develop less severe liver injury because of immune-suppression, while the use of HAART with resultant immune restoration should lead to increased liver damage. However, such a scenario is not observed in clinical practice. Puoti *et al*<sup>[20]</sup> showed that a CD4 count of  $< 500$  was an independent predictor ( $P = 0.04$ ) for stage 3-4 disease in a study on 204 patients with chronic HCV infection (84 with HIV co-infection).

A reduction in fibrosis progression, as well as liver disease, has been observed with successful control of the HIV infection<sup>[21,22]</sup>. In a retrospective analysis of 381 patients, Verma *et al*<sup>[21]</sup> showed that the fibrosis progression rate and cirrhosis in co-infected patients was significantly reduced in patients who received HAART as the initial therapy compared to those who received NRTIs followed by HAART (50% *vs* 68%,  $P < 0.006$ ). It has been shown that co-infected patients are more susceptible to liver toxicity and steatosis from HAART, and more so with the use of NRTIs<sup>[23]</sup>. Despite immune suppression, HCV-specific CD8 and CD4 cell responses have been observed in the livers of patients with HIV and HCV co-infection<sup>[24]</sup>. Moreover, the HCV viral load is higher in co-infected patients compared to HCV mono-infection<sup>[25,26]</sup>. Whether high HCV load is associated with more severe liver injury is not known. The lack of an animal model prevents development of a better understanding of the pathogenesis of liver disease in co-infected patients.

## MANAGEMENT OF HIV/HCV CO-INFECTION

### Timing of treatment

With improved survival of HIV patients in the HAART era, liver disease has emerged as an important cause of morbidity and mortality in co-infected patients. In an analysis of the adverse events of anti-HIV drugs, 1246 patients out of a total of 23441 died over a 5-year follow-up period; liver failure constituted 15% of the mortality and over 50% of deaths occurred despite adequate HIV suppression<sup>[27]</sup>. Therefore, effective treatment for both viruses is essential for a favorable outcome in co-infected patients.

The treatment of HCV in HIV infected patients is a challenging undertaking. Management should ideally be provided in a center with experience in treating such patients, preferably under the care of a multidisciplinary team comprised of hepatologists, infectious disease physicians, psychiatrists, pharmacists, social workers, and a substance abuse program.

All HIV patients should be tested for HCV as soon as HIV is diagnosed. An HIV patient negative for anti-HCV, but with significant risk factors for HCV, should be tested for HCV-RNA as a minority of HIV patients may have viremia despite a negative anti-HCV test<sup>[28]</sup>. Assessment of viral load of HIV and HCV along with a CD4 count should be obtained. The current recommendation is to suppress HIV before starting anti-HCV therapy<sup>[29]</sup>.

### Selection of patients

Patients positive for HCV RNA with ALT elevation and/or stage 2 disease (or more) on liver biopsy should be considered for treatment. Patients with mild disease (stage 1 fibrosis) may also be considered if they are good treatment candidates (low viral count, genotype-2 and -3). About 25% patients with mild disease on the initial

Social support and treatment compliance

HIV: Human immunodeficiency virus; HCV: Hepatitis C virus; CTP: Child Turcotte Pugh; AFP:  $\alpha$ -feto protein; USG: Ultrasonogram; HBV: Hepatitis B virus; HBsAg: Hepatitis B surface antigen; HCC: Hepatocellular cancer; HAART: Highly active antiretroviral therapy; TSH: Thyroid stimulating hormone; HCG: Human chorionic gonadotropin.

liver biopsy develop significant fibrosis over an average period of 3 years. The occurrence of ALT elevation during the follow up period is an independent predictor of disease progression<sup>[30]</sup>. Therefore, if the treatment was deferred at the initial evaluation, regular clinical and laboratory follow-up should be pursued. A repeat liver biopsy should be performed after 3 years, especially in patients with ALT elevation on follow up.

#### Assessment of liver fibrosis before treatment

Assessment of fibrosis allows treatment to be deferred in patients with mild disease due to genotype-1 or -4 infections. As mentioned earlier, treatment may be considered for genotype-2 or -3 disease as the response to therapy in this population is very good. Liver biopsy is the gold standard for the assessment of fibrosis and cirrhosis. However, liver biopsy has certain disadvantages. Being an invasive procedure, serious complications such as bleeding can occur<sup>[31]</sup>. Sampling error due to tissue fragmentation and small sample size may provide inaccurate results. Moreover, the procedure adds to the overall cost of the treatment<sup>[32]</sup>.

Non invasive markers of fibrosis are available and may replace liver biopsy in the future. Various surrogate serum markers such as AST to platelet ratio index (APRI), Fibrotest score (comprised of serum bilirubin,  $\alpha$ -2 macroglobulin, Apolipoprotein A1, haptoglobin, and gamma glutamyl transpeptidase activity), SHASTA index (hyaluronic acid, AST, and albumin levels), Forn's

index (platelet, GGT, age, and cholesterol), and FIB-4 (age, AST, ALT, and platelets) have been tested in HIV-HCV co-infected patients with generally favorable results<sup>[33]</sup>. The measurement of liver stiffness by elastography (Fibroscan or Elastoscan) using an ultrasonic transducer is a rapid, simple, non-invasive, and reproducible technique. It is also more accurate than serum markers in the diagnosis of cirrhosis in co-infected patients<sup>[34]</sup>.

#### Pre-treatment assessment

A detailed clinical evaluation with history and physical examination is essential before starting anti-HCV therapy (Table 1). Patients with decompensated liver disease; i.e., with presence of ascites, variceal bleeding, jaundice, and encephalopathy (Child Turcotte Pugh or CTP stage B and C), do not tolerate interferon (IFN) based therapy well<sup>[35]</sup>. Patients should have a hemoglobin level > 11 g/dL in females and > 12 g/dL in males, a platelet count > 75 000/cm and an absolute neutrophil count (ANC) > 1500 before starting treatment. A baseline fundus examination is recommended as pegylated interferon (PEG-IFN) can cause retinopathy with visual disturbances<sup>[36]</sup>. Combination of Didanosine (DDI) and Zidovudine (AZT) should be avoided to prevent hepatic and mitochondrial toxicity<sup>[37,38]</sup>.

#### Therapeutic regimen for treating HCV

The introduction of interferon (INF) in 1991 has revolutionized the treatment of HCV infection. In HIV/HCV co-infected patients, results obtained with PEG-IFN + ribavirin (RBV)<sup>[39-54]</sup> were superior to those with PEG-IFN alone, standard IFN alone<sup>[48]</sup>, or standard IFN + RBV (Table 2). A meta-analyses of 6 randomized controlled studies showed superior sustained virologic response (SVR) with PEG-IFN + RBV compared with IFN + RBV and PEG-IFN monotherapy. The response was more favorable in males, patients with CD4 > 500, HCV load < 100 000, and in non drinkers<sup>[55]</sup>. Currently, PEG-IFN and RBV combination is the standard of care for the treatment of HCV in HIV patients.

#### Response rate

In an intention to treat analysis, the end of treatment response (ETR); i.e., negative HCV-RNA at the end of treatment, and SVR; i.e., negative HCV-RNA 24 wk after discontinuation of treatment with PEG-IFN + RBV, in IFN naïve HIV/HCV co-infected patients were 29%-62% and 17%-53%, respectively (Table 2). The large difference in the response rates is due to variable frequency of baseline characteristics, such as the presence of cirrhosis, frequency of genotype-1 (GT-1), baseline HIV parameters, dose of RBV, and treatment discontinuation rate. The ETR and SVR rates were superior for the GT-2/3 (44%-81% and 24%-62%, respectively) compared to GT-1/4 (19%-47% and 9%-38%, respectively)<sup>[44,46,47]</sup>. In a recent study, the treatment response rates were similar with the use of PEG-IFN 2a and 2b<sup>[56]</sup>.

The highest SVR rate of 53% was reported by Hopkins *et al*<sup>[49]</sup>, which may be related to the lower

<sup>1</sup>Responses are on intent to treat analysis. ETR: End of treatment response (HCV RNA < 50 copies/mL); SVR: Sustained virologic response (HCV RNA < 50 copies/mL 6 mo after discontinuing treatment); PEG-IFN: Pegylated interferon; RBV-ribavirin; GT: Genotype; tiw: Three times a week; ACTG: AIDS clinical trial group; APRICOT: AIDS pegasys ribavirin international coinfection trial.

proportion of GT-1 patients (33%) compared with other studies (48%-77%) (Table 2). The pooled SVR rate with the use of PEG-IFN + RBV obtained from 7 randomized controlled trials or prospective cohort studies involving 784 HIV + HCV co-infected patients was 33.3% (27.3%-44.2%)<sup>[57]</sup>. The SVR rate in HCV mono-infection with PEG-IFN + RBV was much better (52% for GT-1 and 80% for GT-3)<sup>[58]</sup>. A head-to-head

comparison of the two groups also showed superior ETR and SVR rates for GT-1 infection (46% vs 25%,  $P < 0.05$  and 37% vs 17%,  $P < 0.05$ , respectively)<sup>[50]</sup>. These inferior response rates in co-infected patients can be explained to some extent by the greater number of patients with cirrhosis (43% vs 11%,  $P = 0.0001$ ), and lower doses of RBV used ( $12.75 \pm 1.46$  vs  $14.10 \pm 1.88$ ,  $P = 0.0001$ ) in these patients.

**Figure 1** Patients who consumed > 80% of their anti-HCV medications showed a trend towards better sustained virologic response (SVR) compared to those with < 80% drug compliance (72% vs 57%,  $P = 0.06$ ). The SVR was much better in GT-1 infections (63% vs 34%,  $P = 0.008$ ) but not in GT-2 or -3 infections (94% vs 95%,  $P = 0.88$ ). Wk: Week.

**Figure 2** Results of virologic response in different studies. PRES CO study 33% and 84%, respectively, at weeks 4 and 12 for GT-1 infections; APRICOT study 13% and 34%; PISG study 31% and 71% respectively. Similar figures for GT-2 and -3 infections were 47% and 92%, 37% and 72%, 84% and 96%, respectively.

**Table 3** Barriers against anti-HCV therapy in co-infected patients

Patient-related factors	
Active substance abuse	
Concern regarding adverse effects	
Cost of treatment	
Lack of social support	
Lack of transport	
Number of pills and dosing frequency (including HAART)	
Physician-related factors	
Lack of experience	
Lack of awareness	
Lack of motivation for referral	
Fear of adverse effects	

HAART: Highly active anti-retroviral therapy.

Another important reason for the lower SVR in the co-infected population is the high treatment dropout rate (12%-51%) (Table 3). The importance of medication compliance was shown in a recent retrospective analysis on HCV mono-infected patients<sup>[59]</sup>. Patients who consumed > 80% of the medications (PEG-IFN + RBV), had a superior SVR compared to those with < 80% compliance (Figure 1). The difference in SVR was noted for GT-1 but not for GT-2/3 infection. The treatment discontinuation rates were 39% in both the APRICOT and RIBAVIC trials, and 12% in the ACTG study<sup>[44,46,47]</sup>. Discontinuation of treatment due to adverse effects was observed in 13%, 17%, and 12% of patients, respectively. These figures are similar to discontinuation rates in the HIV negative population<sup>[60]</sup>. Other reasons for treatment discontinuation were patient refusal (4%), lack of follow up (4%), and violation of the study protocol (1%) in the APRICOT study. Another reason was relapse of substance abuse in 1%-4% patients<sup>[41,48]</sup>.

The barriers to anti-HCV treatment may be patient as well as physician related (Table 3). Education and motivation of patients with intensive training and provision of better infrastructure for the treating physicians may improve the outcome. Most studies to date have excluded patients with active substance abuse (Table 3). A recent NIH consensus conference has

recommended that active substance abuse should not be considered a contraindication to anti-HCV treatment<sup>[61]</sup>. Instead, greater integration of HCV treatment in HIV clinics and detoxification programs and provision of additional social support should be encouraged<sup>[62]</sup>. In a retrospective analysis of 73 patients with HCV infection (32% with HIV) treated at a methadone maintenance treatment program, encouraging ETR and SVR rates of 55% and 45%, respectively, were obtained<sup>[63]</sup>.

### Drug doses

The recommended dose of PEG-IFN 2a is 180 µg/wk and for PEG-IFN 2b is 1.5 µg/kg per week (Table 2). Because of the wider systemic distribution of PEG-IFN 2b, it is essential to adjust the dose for body weight, as compared to PEG-IFN 2a, which is restricted to blood and interstitial fluids only. In most studies, RBV has been used at a dose of 800 mg/d or 10.6 mg/kg per day in co-infected patients (Table 2). Virologic response at weeks 4 and 12 were superior with the use of 1000-1200 mg of RBV compared to 800 mg/d of RBV (Figure 2). Improved SVR rates, similar to that seen in HCV mono-infection, were observed when RBV was used at a dose of 1000-1200 mg<sup>[49,64,65]</sup>. Based on the current data, it is recommended that weight-based RBV (1000 mg/d for < 75/kg and 1200 mg/d for 75 kg and above) should be used in co-infected patients.

### Duration of therapy

The use of PEG-IFN + RBV for 48 wk in GT-1/4 and 24 wk in GT-2/3 infections yielded ETR in 53%-82% and SVR in 42%-75% patients (Table 2). On the other hand, treatment for 48 wk for all GTs achieved an ETR in 50%-80% and SVR in 44%-73% co-infected patients<sup>[44,46,47]</sup>. In the recently completed PRES CO trial, PEG-IFN and weight-based RBV were used for 48 wk or 72 wk for GT-1/4 and 24 wk or 48 wk for GT-2/3<sup>[65]</sup>. The overall SVR was 49.6% (72.4% in GT-2/3 and 35% in GT-1/4,  $P < 0.001$ ). In patients with GT-2/3, a higher relapse rate was seen in patients treated for 24 wk compared to those receiving 48 wk of treatment (40% vs

**Table 5** Hepatotoxicity of highly active anti-retroviral therapy drugs and guidelines for their use in patients with liver disease

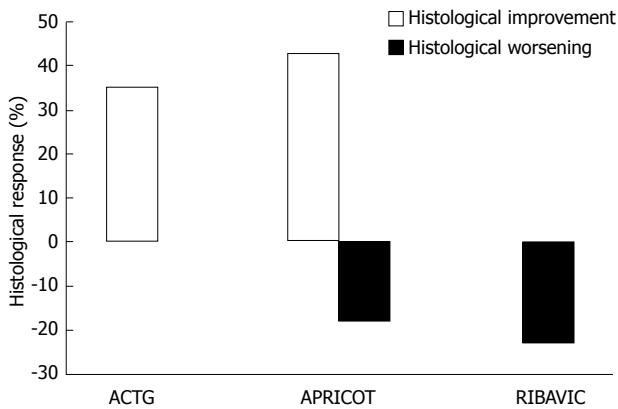

Group	Drug	Dose adjustment
NRTI	Didanosine	Use cautiously
NNRTI	Delavirdine, Efavirenz, Nevirapine	Caution with hepatic impairment
PIs	Lopinavir, Nelfinavir, Ritonavir, Saquinavir	Caution with hepatic impairment
	Atazanavir	Reduce 25% of dose in patients with CTP stage B and C
	Indinavir	Reduce dose by 25% in CTP stage B and C
	Tipranavir	Avoid in patients with CTP stage B or C
	Fosamprenavir	Avoid in patients with CTP stage C
	Darunavir	Avoid in patients with CTP stage C

10%,  $P = 0.02$ ). Patients treated for 48 wk were 5.4 times more likely to achieve SVR. If these data are confirmed in other studies, the standard of care in co-infected patients will be 48 wk of treatment with PEG-IFN and weight based RBV, irrespective of the GT.

#### Safety and tolerability of medications

Adverse effects are seen in the majority of patients (Tables 4 and 5). The most common adverse effects are influenza-like symptoms (Table 4). About one third of patients experience a drop in hematologic parameters. In most cases, the adverse effects are mild, but, treatment

discontinuation was needed in 12%-17% of patients and dose modification of PEG-IFN and RBV, due to either adverse events or a change in laboratory values (neutropenia or thrombocytopenia with PEG-IFN and anemia with RBV), was required in 25%-33% patients<sup>[35,47]</sup>. RBV-induced anemia is exacerbated with the concomitant use of AZT<sup>[38]</sup>. This was confirmed in the PRESCO study where RBV-induced anemia was observed in only 2.6% patients, despite using weight-based higher doses of RBV<sup>[65]</sup>. Every effort should be made to maintain patients on the medications, while simultaneously managing the hematologic abnormalities

**Figure 3** A beneficial histological response was seen in 35% and 43%, respectively, in patients with no sustained virologic response (SVR) in the ACTG and APRICOT trials. Worsening histology was seen in 18% patients with no SVR in the APRICOT study; similar data were not available in the ACTG study. In the RIBAVIC study, histological worsening was seen in 23% without SVR while histology remained stable in the remaining patients.

using blood products and growth factors. In a recent study, the use of Eicosapentaenoic acid prevented RBV dose reduction during first 12 wk of treatment<sup>[66]</sup>.

#### Patient monitoring during therapy

To ensure the safety of treatment, patients should have regular assessment with complete blood count and liver tests. Efficacy of treatment is assessed by quantitative HCV-RNA at weeks 4, 12, 24, 48, and 72. The goal of therapy is to achieve a SVR as this is associated with < 1% recurrence of infection at 5 years<sup>[67]</sup>. Assessment of a 2 log reduction in the HCV viral load at week 12 is crucial; lack of such a reduction has a 98%-100% probability of not achieving a SVR. Recently, data have emerged that patients who become HCV-RNA negative at wk 4 (rapid virologic response or RVR) have a SVR rate of 82%, while 99% of those who fail to achieve a 1-log reduction at week 4 are unlikely to have a SVR<sup>[68]</sup>. However, the current recommendation is to stop further treatment in patients who fail to achieve a 2-log reduction at week 12 of treatment.

#### Management of non-responders and relapsers

The role of induction therapy using a higher IFN dose was tested in the CORAL-1 study<sup>[69]</sup>. The use of PEG-IFN  $\alpha$ -2a at a dose of 270  $\mu$ g for 4 wk followed by 180  $\mu$ g for 8 wk was compared with the standard dose of 180  $\mu$ g for 12 wk. Both groups received 1000-1200 mg/d of weight-based RBV. Although the induction dose was safe and well tolerated, it failed to provide any efficacy benefit. Treatment for an extended duration was assessed in another study in which patients who failed to achieve a 2-log reduction at 12 wk were randomized to receive either 48 wk or 72 wk of PEG-IFN + RBV. This approach also lacked efficacy as only one (2.5%) patient achieved an SVR.

The lack of an animal model has hampered the development of a vaccine against HCV. Several new drugs for treating HCV are under various stages of development<sup>[70]</sup>. These include improved IFN

molecules (albumin fused with IFN- $\alpha$ ,  $\Omega$  IFN, sequential treatment with IFN- $\alpha$  and IFN- $\gamma$ ), improved RBV molecules (Viramidine with a lower potential for hemolysis, and Levovirin), immunomodulators (histamine dihydrochloride, thymosin  $\alpha$ , and isatoribine), and directly acting anti-HCV agents (HCV protease inhibitors, HCV entry inhibitors, ribozymes, and antisense nucleotides)<sup>[70]</sup>.

The anti-fibrotic effect of IFN, with the potential of reducing fibrosis and HCC, is the basis for its use as a maintenance therapy. A beneficial histological response (HR) was observed in all 3 trials with co-infected patients who did not achieve a SVR (Figure 3). In the ACTG and APRICOT studies, HR was defined as an improvement of  $\geq 2$  points in the HAI<sup>[35,44]</sup>, and an improvement of  $\geq 1$  point in the Metavir score in the RIBAVIC study<sup>[47]</sup>. Currently, other studies (SLAM-C and ENDURE) are in progress to confirm the role of maintenance therapy in HIV patients who fail anti-HCV treatment<sup>[71]</sup>.

#### General advice

Patients should be counseled on treatment compliance, and should be encouraged to consume a healthy diet. Patients should abstain from alcohol as HCV and alcohol have a synergistic effect on liver injury<sup>[72]</sup>. Patients with active substance abuse use should be enrolled in drug detoxification programs. Safe sex practices should be encouraged amongst high risk populations, such as multiple sexual partners, active sexually transmitted disease, and MSM. Patients should be instructed to report to their physician if they experience any unusual symptoms, and should avoid herbal or over the counter medications. Patients who are negative for anti-HBs and antibodies to hepatitis A virus (HAV) should be vaccinated against HAV and HBV<sup>[73]</sup>.

## MANAGEMENT OF SPECIAL GROUPS

#### *Patients with normal aminotransferase (PNAL)*

PNAL is defined as the presence of at least 3 normal ALT values, each at least 2 mo apart, over a period of 12 mo. The prevalence of PNAL in co-infected patients is 8%-30%<sup>[74-76]</sup>. Although, the prevalence of stage 3-4 disease in patients with HCV mono-infection and PNAL was lower compared to patients with elevated ALT (5% vs 20%,  $P = 0.01$ ), the prevalence was similar in co-infected patients (37% vs 32%,  $P = 0.6$ )<sup>[77]</sup>. Five year follow-up of 27 co-infected patients with PNAL showed intermittent or persistent elevation of ALT in more than one third of the patients, with the development of decompensated cirrhosis in 2 patients and death in one patient<sup>[75]</sup>.

Treatment of every co-infected patient with PNAL is a daunting task, with considerable expenditure of time and cost. Therefore, it is important to identify factors that may induce rapid FPR in these patients. Currently, it is recommended that treatment should be considered in highly motivated patients and/or those with GT-2/3 infection<sup>[29]</sup>.

### **Management of acute HCV infection**

In the US, about 30 000 cases of acute HCV infection occur annually with increasing incidence in MSM<sup>[78-80]</sup>. The diagnosis is important since unrecognized infection tends to become chronic in 90%-95% co-infected patients<sup>[79]</sup>. The criteria for diagnosis are: elevation of ALT > 10 times the upper limit of normal (ULN), a positive HCV-RNA test and exposure to HCV during the preceding 2-12 mo<sup>[78]</sup>. A high index of suspicion is required, and acute HCV should be excluded before attributing the elevated of ALT to HAART.

The current data on the treatment of acute hepatitis C in HIV patients is limited to a few case studies with SVR of 59% to 91%<sup>[81-83]</sup>. The large difference in the response rates may be due to factors such as clinical presentation (anicteric vs symptomatic) and compliance with therapy. The timing of treatment in co-infected patients is not clear. In HCV mono-infection, a 12 wk waiting period is recommended to allow spontaneous clearance of the virus. Consideration should be given to early treatment of acute HCV in HIV patients because of a higher frequency of chronic disease. However, issues such as the timing of treatment, treatment with PEG-IFN alone, and the role of extended treatment can only be determined by properly conducted controlled trials. Until then, it is recommended that acute HCV infection in HIV positive subjects should be treated with PEG-IFN and RBV for a total of 24 wk, irrespective of the GT<sup>[14]</sup>.

### **Management of HIV- HCV co-infected patients with end-stage liver disease**

With the reduction in occurrence of opportunistic infections with the use of HAART, HCV-induced end-stage liver disease (ESLD) is now one of the leading causes of death (denominator effect) in these patients<sup>[84]</sup>. Indeed, HCV is considered as an OI in HIV patients<sup>[85]</sup>. The development of HCC is an important reason for high mortality in co-infected patients, and its incidence has increased from 4.7% in 1995 to 25% in 2000<sup>[86]</sup>. Whether co-infected patients with cirrhosis and end-stage liver disease (ESLD) should be screened for HCC every 6 mo or earlier is not clear. In one study, 5 of 8 patients diagnosed with advanced HCC were tumor negative 6 mo earlier<sup>[18]</sup>. Until more data on the screening interval and the factors that influence progression to HCC becomes available, we recommend that co-infected patients should be screened for HCC every 6 mo<sup>[87]</sup>.

Previously, HIV infection was considered a contraindication for liver transplantation (LT). However, in the HAART era, the outcome after LT has improved considerably, with survival at 1 year and 3 years of 87%-91% and 64%-73% ,respectively<sup>[88]</sup>. A recent retrospective analysis of the United Network for Organ Sharing (UNOS) database showed that although the 2 year survival of HIV patients ( $n = 138$ ) was inferior to HIV -ve patients (70% vs 81%), the survival was similar in HIV -ve patients and HIV +ve patients without HCV or HBV co-infection<sup>[89]</sup>. Similar poor outcome in HIV patients with concomitant HCV infection has been

observed in other studies<sup>[88,90-95]</sup>. Survival of co-infected patients was inferior to HCV mono-infected patients at 1 year, 3 years, and 5 years (68%-80% vs 76%-87%, 56%-57% vs 72%-81%, and 33%-51% vs 72%-81%, respectively)<sup>[88,93,94]</sup>. Poor survival with co-infection has been attributed to the recurrence of HCV, which runs an aggressive course, with frequent development of fibrosing cholestatic hepatitis<sup>[93]</sup>. Moreover, the treatment of recurrent HCV is associated with inferior results (SVR of 27%-28%) compared with treatment of post-LT HCV recurrence in mono-infected patients<sup>[93,96]</sup>. Other factors affecting post-LT survival were intolerance to HAART, CD4 < 200, HIV viral load > 400 cpm, African American race, and model of end-stage liver disease (MELD) score of > 20<sup>[88,93]</sup>. Whether such patients should be treated with pre-emptive anti-HCV therapy or maintenance treatment is unclear. Moreover, the ethical consideration of performing LT in HIV/HCV patients is questionable given the short supply of organ donors in the US<sup>[97]</sup>. An NIH sponsored prospective study on OLT in co-infected patients reported 1 year and 3 year patient survival of 91% and 64%, with graft survival of 82% and 64%, respectively<sup>[98]</sup>. Based on these data, it can be concluded that OLT should be performed only on selected HIV patients in centers with adequate expertise.

The criteria for LT are the same as for HIV -ve patients, including abstinence from drugs for  $\geq 2$  years and abstinence from alcohol for  $\geq 6$  mo. HIV should be adequately controlled with VL < 400 cpm and CD4 > 100. OIs precluding LT are multifocal leucoencephalopathy and multi-drug resistant fungal infections<sup>[99]</sup>. The major issues after LT in co-infected patients are the interaction of HAART with immunosuppressive drugs and recurrence of HCV disease. Most of the immunosuppressive medications are metabolized by the cytochrome P450 system. Protease inhibitors, such as ritonavir, can reduce metabolism of calcineurin inhibitors (CIs), such as cyclosporine and tacrolimus. Therefore, the doses of CIs need to be reduced by about 50%-75% with concomitant administration of PIs. On the other hand, drugs like mycophenolate mofetil interact with nucleoside analogues with decreases in efficacy of zidovudine and stavudine and increases in activity of abacavir and didanosine<sup>[100]</sup>.

### **FUTURE DIRECTIONS**

Based on the literature, recommendations on management of HCV in HIV patients can be made (Table 6). However, there are still many gaps in knowledge and new areas for future research. To better understand the pathogenesis of co-infection, there is an urgent need for *in vitro* and *in vivo* models of dual HIV/HCV infection. The issue of non-invasive means of assessing hepatic fibrosis requires further study. Strategies for the treatment of acute hepatitis C in HIV patients are unclear and involve issues such as the timing of treatment and treatment regimens. The response rate with PEG-IFN and RBV combination for chronic

**Table 6 Recommendations for management of HCV in HIV patients**

All HIV patients should be screened for concomitant HCV infection  
Effective management of HCV is crucial to improve the survival of HIV patients  
Patients with stage 2 or more disease are candidates for therapy provided their HIV disease is controlled  
Pegylated interferon and weight based ribavirin combination is recommended  
Liver transplantation is no longer a contra-indication in the presence of HIV and should be considered in appropriate patients  
Patients with cirrhosis should be screened for esophageal varices and for hepatocellular carcinoma

HCV in HIV patients is low. The safety and efficacy of newer anti-HCV drugs needs to be determined. It should be noted that patients with PNAL have significant disease and therefore should be considered for treatment. However, whether prolonged PEG-IFN therapy or maintenance IFN therapy has any role in non-responders remains to be determined. Currently, co-infected patients with ESLD are screened for HCC every 6 mo, however, advanced HCC has been known to occur within the 6 mo interval. The cost-efficacy of more frequent screening is unknown. In order to improve the post-OLT survival of co-infected patients, strategies to prevent and treat HCV recurrence in this setting are crucial.

### Abstract

Bile duct strictures remain a major source of morbidity after orthotopic liver transplantation (OLT). Biliary strictures are classified as anastomotic or non-anastomotic strictures according to location and are defined by distinct clinical behaviors. Anastomotic strictures are localized and short. The outcome of endoscopic treatment for anastomotic strictures is excellent. Non-anastomotic strictures often result from ischemic and immunological events, occur earlier and are usually multiple and longer. They are characterized by a far less favorable response to endoscopic management, higher recurrence rates, graft loss and need for re-transplantation. Living donor OLT patients present a unique set of challenges arising from technical factors, and stricture risk for both recipients and donors. Endoscopic treatment of living donor OLT patients is less promising. Current endoscopic strategies for biliary strictures after OLT include repeated balloon dilations and placement of multiple side-by-side plastic stents. Lifelong surveillance is required in all types of strictures. Despite improvements in incidence and long term outcomes with endoscopic management, and a reduced need for surgical treatment, the impact of strictures on patients after OLT is significant. Future considerations include new endoscopic technologies and improved stents, which could potentially allow for a decreased number of interventions, increased intervals before retreatment, and decreased reliance on percutaneous and surgical modalities. This

review focuses on the role of endoscopy in biliary strictures, one of the most common biliary complications after OLT.

### INTRODUCTION

Complications of the biliary tract have been considered the technical ‘Achilles heel’ of orthotopic liver transplantation (OLT) because of their high frequency, need for long term treatment and potential detrimental effects on graft and patient survival. While in early reports, morbidity rates of up to 50% and mortality of 25%-30% were reported, with improvements in organ selection, retrieval, preservation and standardization of the methods of biliary reconstruction, the incidence of these complications have been reduced dramatically<sup>[1-9]</sup>. The biliary tract, however, still remains the most common site for postoperative complications in OLT<sup>[4,10]</sup>. Biliary complications, which most frequently include bile duct strictures and leaks, also include casts, sludge, stones, sphincter of Oddi dysfunction, mucoceles, and hemobilia in 10%-25% of cases and result in death in up to 10% of cases<sup>[1,2,6,8,9,11-17]</sup>. These high rates of post-transplant biliary complications, may point to an inherently sensitive nature of the biliary epithelium to ischemic damage in comparison to hepatocytes and vascular endothelium<sup>[18]</sup>. Beyond graft survival, biliary complications also have a major impact on the quality of life for an OLT recipient, as they entail frequent readmission, repeated imaging, invasive procedures, and occasional reoperation, all adding to the

significant monetary cost of OLT and to the emotional toll these patients suffer<sup>[5]</sup>. While surgical treatment used to be the standard of care at one time, the non-operative management of biliary complications following OLT has become standard practice with primarily endoscopic techniques as the preferred diagnostic and therapeutic modalities, obviating the need for surgery in a majority of patients<sup>[9,19,20]</sup>.

This article will review the role of endoscopy in the diagnosis, treatment options, outcome, and future therapy considerations of biliary strictures after OLT, from the perspective of the practicing gastroenterologist.

## INCIDENCE OF BILIARY STRICTURES

While there has been a decreasing trend in recent years, bile duct strictures are still frequent and account for approximately 40% of all biliary complications after LT, occurring with an incidence of 5%-15% after deceased donor OLT and 28%-32% after right-lobe live donor OLT, with higher incidences seen in reports with a longer follow-up<sup>[7,14,21-33]</sup>. Strictures can occur with either type of biliary anastomosis, although according to some series, strictures were more common with Roux-en-Y hepaticojjunostomy or choledochojejunostomy reconstructions than duct-to-duct anastomoses<sup>[1,14,21]</sup>. Although strictures can present at any time, the overwhelming majority occur within the first year after OLT<sup>[1,23]</sup>. The mean interval at the time of presentation is 5-8 mo after OLT<sup>[3,7,23,34,35]</sup>. Recent studies suggest that their prevalence continues to increase with time<sup>[36]</sup>. Strictures which occur early mostly result from technical problems, whereas later strictures mainly arise from vascular insufficiency and problems with healing and fibrosis<sup>[37,38]</sup>.

## CLASSIFICATION OF BILIARY STRICTURES

Biliary duct strictures can be classified according to their location; strictures localized at the site of the biliary anastomosis or anastomotic strictures are usually single while non-anastomotic strictures in other locations of the biliary tree are most often multiple<sup>[36,39-42]</sup>. These 2 types of biliary strictures differ in incidence, etiology, presentation, natural history and response to therapy rendering their distinction clinically relevant<sup>[25]</sup>. Biliary strictures tend to be a common problem after living donor OLT in both the donor and the recipient and are discussed separately.

### Anastomotic strictures

**Pathogenesis and risk factors:** Anastomotic strictures occur in 5%-10% of cases, are most often isolated, short in length, and are a result of fibrotic healing within the first year after transplantation<sup>[1,7,36]</sup>. Among the etiological factors for anastomotic strictures which appear early in the postoperative period, technical issues appear to be the most important: improper surgical techniques, small

caliber of the bile ducts, a mismatch in size between the donor and recipient bile ducts, inappropriate suture material, tension at the anastomosis, excessive use of electrocauterization for control of bile duct bleeding, and infection<sup>[25]</sup>. Bile leak is an independent risk factor for the development of anastomotic strictures<sup>[17]</sup>. Later onset anastomotic strictures, most likely indicate fibrotic healing arising from ischemia at the end of the donor or recipient bile duct<sup>[34,36,38,40,43-46]</sup>. Anastomotic strictures are reported to be more common after hepaticojjunostomy than after direct duct-to-duct anastomosis<sup>[1,14]</sup>. Duct-to-duct biliary anastomosis has the additional advantage of easy endoscopic access to the biliary system and preservation of the sphincter of Oddi which in theory avoids reflux of contents into the bile duct<sup>[44]</sup>. While biliary complications including bile leaks and cholangitis appear to be higher in patients with T-tubes, biliary strictures appear to be increased following duct-to-duct anastomosis in non-T-tube recipients as compared to anastomosis over a T-tube<sup>[15,47-50]</sup>. Anastomotic strictures are more frequent than non-anastomotic strictures in living donor OLT as compared to recipients of deceased donor OLT<sup>[51-53]</sup>.

**Presentation:** The majority of anastomotic strictures occur within the first 12 mo after OLT. Patients may be asymptomatic at presentation, with elevations of serum aminotransferases, bilirubin, alkaline phosphatase and/or gamma-glutamyl transferase levels. Occasionally, patients have non-specific symptoms such as fever and anorexia, right upper quadrant pain, pruritus, and/or jaundice. A high index of suspicion must be maintained, as pain may be absent in the transplant setting because of immunosuppression and hepatic denervation<sup>[41,44,54]</sup>.

**Diagnosis:** Once abnormalities in liver function chemistries raise the possibility of biliary strictures, further imaging, either noninvasive or invasive, should be performed. Biopsy may only rarely suggest the presence of pathology and thus has a limited role<sup>[55]</sup>.

Initial evaluation should include liver ultrasound (US) with Doppler evaluation of the hepatic vessels. If hepatic artery stenosis or occlusion is suspected on Doppler US, hepatic angiography is usually indicated. Unfortunately, in liver transplant patients, abdominal US may not be sufficiently sensitive (sensitivity of 38%-66%) to detect biliary obstruction<sup>[4]</sup>. The absence of biliary dilation has been found to be an unreliable indicator of adequate biliary drainage<sup>[49]</sup>. The size of the duct is also unreliable in following up these patients or in assessing the response to treatment. Indeed, US has been shown to have a high false negative rate in liver transplant recipients. Furthermore, there appears to be a significant lack of correlation between ductal dilation on US and the cholangiographic and clinical picture<sup>[23,56]</sup>. It is not clear why the donor bile ducts do not respond to distal obstruction by displaying the same degree of proportional dilation as non transplanted livers, however the presence of fibrosis leading to less pliable ducts has been suggested as a possible etiology<sup>[57]</sup>. Therefore, the absence of biliary

dilation identified on US should not preclude further evaluation with more sensitive techniques if the suspicion of biliary stricture remains strong.

Scintigraphy of the hepatobiliary tract with 99-technetium labeled iminodiacetic acid identifies strictures with 75% sensitivity and 100% specificity but a lack of therapeutic benefit limits its clinical use<sup>[58,59]</sup>. Biliary scintigraphy is therefore rarely performed when biliary stricture is suspected but still remains an excellent test to detect biliary leaks<sup>[58]</sup>.

If there is strong clinical suspicion or an US indicates a possible bile duct obstruction, a cholangiogram should be obtained and is considered the reference standard for the diagnosis of biliary tract complications<sup>[2,3,7,8,36,44,54]</sup>. While endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) remain the gold standard, particularly when there is a very high pretest probability of a biliary stricture and need for intervention, magnetic resonance cholangiopancreatography (MRCP) has gained increasing acceptance as a reliable technique in detecting biliary complications. In a study of 64 consecutive patients with suspected biliary complications, MRCP had a sensitivity of 95%, a positive predictive value of 98% and an overall accuracy of 95% compared to ERCP as the reference standard<sup>[60]</sup>. MRCP is currently considered an optimal noninvasive diagnostic tool for the assessment of biliary complications after OLT<sup>[25]</sup>. Once MRCP expertise becomes more widely available, it should have an even more prominent role in limiting the role of invasive cholangiography for therapeutic purposes. The chief disadvantage of MRCP, beyond lack of availability, is the lack of its therapeutic ability. However, it can still be used as a second step after ultrasound in patients for whom the use of ERCP or PTC carries a higher procedural risk.

Use of ERCP *vs* PTC depends on the type of biliary reconstruction, the likelihood of therapeutic intervention and the available expertise. ERCP has the advantage over PTC as it is not only more physiological but also less invasive. In most large tertiary care centers, ERCP is seen as the best diagnostic and therapeutic intervention in patients with duct-to-duct anastomosis. PTC is most often reserved for patients in whom ERCP is unsuccessful and in patients with Roux-en-Y hepaticojjunostomy or choledochojejunostomy. While an inherent limitation of ERCP is the problem of access in patients with Roux-en-Y reconstructions, in high volume centers with experienced endoscopists, newer approaches of ERCP can be successfully performed using the variable stiffness colonoscope, double balloon enteroscope, single balloon enteroscope, and spiral overtube<sup>[61-64]</sup>.

The characteristic cholangiographic appearance of an anastomotic stricture is that of a thin, short, localized, isolated narrowing in the area of the biliary anastomosis. In some patients, a transient narrowing of the anastomosis may become evident within the first 1-2 mo after OLT as a result of postoperative edema and inflammation<sup>[56]</sup>.

**Management:** Over the past 2 decades, there has been

a transition in the primary management of anastomotic strictures from predominantly surgical management to primarily endoscopic management. Percutaneous therapy, although it has a success rate of 40%-85% is still considered a second-line option because of its invasive nature and the associated complications of hemorrhage, bile leaks and significant morbidity<sup>[5]</sup>. Surgical revision is now reserved for patients who have failed the endoscopic and transhepatic measures, and retransplantation is the final option when all else fails<sup>[1,21,23,65]</sup>.

Balloon dilation alone without stent placement is only successful in approximately 40% of cases<sup>[66]</sup>. Balloon dilation with additional stent placement however, appears to be more successful with a durable outcome in 75% of patients with anastomotic strictures<sup>[32,66]</sup>. Placement of not one, but multiple side-by-side plastic stents further increases successful outcomes in 80%-90% of patients<sup>[67-69]</sup>. There is some experience in temporary placement of covered self-expanding metal stents to reduce the need for repeated stent exchanges, but the data are limited<sup>[70]</sup>. A smaller subset of patients, with transient narrowing of the anastomosis within the first 1-2 mo after OLT, presumably due to postoperative edema and inflammation, may respond with a single intervention of endoscopic balloon dilatation and plastic stent placement without need for further treatment<sup>[36]</sup>.

Most patients with anastomotic strictures require ongoing ERCP sessions every 3 mo with balloon dilation of 6-10 mm and multiple stents of 7 Fr to 10 Fr repeated for 12-24 mo<sup>[54,68,69]</sup>. Stents are exchanged at 3-monthly intervals to avoid stent occlusion and bacterial cholangitis. An increasing number of stents can be used at each session to achieve a maximum diameter. The majority of patients require several endoscopic interventions, with a mean of 3 to 5 with long term success rates in the range of 70%-100%<sup>[3,32,36,37,68,69,71-74]</sup>. A protocol of accelerated dilation every 2 wk, and a shortened stenting period of an average of 3.6 mo, showed some encouraging results with a high 87% success rate<sup>[68]</sup>. In patients with duct-to-duct anastomosis, endoscopic management is hence first line, and it appears that while repeat endoscopic treatment is needed, shorter intervals in between treatments may ultimately reduce the time needed for successful long term outcomes (Figure 1).

The major drawbacks of endoscopic dilation with placement of one or more stents as a standard of care in the management of anastomotic strictures, are the need for multiple procedures repeated over extended periods of time, and the risk of cholangitis resulting from stent occlusion.

When endoscopic access to the anastomotic stricture is unobtainable, as in Roux-en-Y reconstructions, another option to be considered is a combined approach where access to the biliary tree is obtained *via* a percutaneous transhepatic route followed by "rendezvous" endoscopy<sup>[62,75]</sup>. Management including using percutaneous transhepatic drainage achieves success rates of 50%-70%<sup>[74]</sup>. The role of surgical revision is confined to endoscopic failures, and the long term results are good with no effect on patient or graft survival<sup>[7,11,76]</sup>.

**Figure 1** Cholangiograms showing anastomotic stricture (A) dilated and stented with 3 plastic stents (B) leading to resolution of the stricture (C).

**Natural history:** Patients with anastomotic strictures require long term surveillance since strictures often recur. Anastomotic strictures identified within 6 mo after OLT usually have a good response to short term stenting (3-6 mo), with the lowest recurrence rates<sup>[36]</sup>. Anastomotic stricture recurrence, however, is particularly high among patients with an initial delayed presentation beyond 6 mo after OLT, and very tight strictures<sup>[5]</sup>. Surveillance is lifelong in all anastomotic stricture patients with a need for periodic evaluation of liver enzymes and imaging. In an illustrative study, patients who developed biliary strictures after OLT and were initially treated endoscopically with balloon dilation and plastic stents, had a recurrence rate of 18% with a mean time to recurrence of 110 d<sup>[71]</sup>. However, patients appear to respond well to repeated endoscopic treatment after recurrence<sup>[68]</sup>. Overall, when anastomotic strictures are treated appropriately, the long term results in terms of patient and graft survival are equivalent to those for matched controls without anastomotic strictures<sup>[2,3,77]</sup>.

#### Non-anastomotic strictures

**Pathogenesis and risk factors:** Non-anastomotic strictures account for 10%-25% of all stricture complications after OLT, with an incidence of 1%-19%; these are often multiple, longer and occur earlier than anastomotic strictures. Multiple factors contribute to the occurrence of non-anastomotic strictures with the main categories of risk factors including ischemia-related injury with or without hepatic artery thrombosis, immunologically-induced injury including chronic ductopenic rejection, and cytotoxic injury induced by bile salts<sup>[1,23,25,29,35,39,77]</sup>. Ischemic and immunological injuries to the biliary epithelium are the most important contributors. Ischemic injury may result from arterial insufficiency and hepatic artery thrombosis, or other forms of ischemia because of donation after cardiac death, prolonged use of vasopressors in donors, older donor age or longer cold and warm ischemia times<sup>[1,3,26,27,78-85]</sup>. Immunological injury is assumed to be a risk factor based on the relationship of non-anastomotic strictures with ABO incompatibility, polymorphism in genes encoding chemokines, and pre-existing immunologically-mediated disease seen in recipients with underlying disease such as primary sclerosing cholangitis (PSC) or autoimmune hepatitis<sup>[78]</sup>. Less important and

inconsistent are the reported associations with hepatitis C and cytomegalovirus<sup>[21,39,86]</sup>.

**Presentation:** Non-anastomotic strictures tend to occur earlier than anastomotic strictures, with a mean time to stricture development of 3-6 mo<sup>[23,39]</sup>. Buis *et al*<sup>[78]</sup> further reported that non-anastomotic strictures secondary to ischemic causes presented within 1 year of transplant, whereas the occurrence after 1 year was more often related to immunological causes as the risk factors. Patients appear to present with similar non-specific symptoms as patients with anastomotic strictures<sup>[42]</sup>.

**Diagnosis:** Diagnosis of non-anastomotic strictures is made with the same modalities as those described for anastomotic strictures. Non-anastomotic strictures can occur proximal to the anastomosis in the extra- or intra-hepatic bile ducts. These strictures tend to be multiple, and longer in length<sup>[23,29,39]</sup>. There may be multiple strictures involving the hilum and intrahepatic ducts causing a cholangiographic appearance that resembles PSC. Biliary sludge can accumulate proximal to the strictures leading to the formation of casts<sup>[42]</sup>. Biliary sludge and casts can rapidly accumulate even after the biliary tree has been cleared and adequate drainage has been achieved. This most likely arises from ongoing sloughing of the biliary epithelium as a result of the underlying ischemic or immunologic injury<sup>[5]</sup>.

**Management:** Non-anastomotic strictures are more difficult to treat than anastomotic strictures with more complications of cholangitis, and overall less favorable outcomes including increased graft loss and death. Only 50%-75% of patients have a long term response to endoscopic therapy with dilatation and stent placement compared to 70%-100% in patients with anastomotic strictures as described above<sup>[2,3,23,54,77]</sup>. Accumulation of biliary sludge and casts renders therapy particularly difficult because of rapid stent occlusion. Non-anastomotic strictures require an increased number of interventions compared to patients with anastomotic strictures<sup>[23]</sup>. Time to response with non-anastomotic strictures is more prolonged than with anastomotic strictures<sup>[23]</sup>. In an illustrative study, the median time of response was 185 d for non-anastomotic strictures *vs* 67 d for anastomotic strictures<sup>[77]</sup>. Also, treatment of non-anastomotic

strictures did not result in significant long term improvement of liver chemistry<sup>[23]</sup>. It does not appear that the poor response of non-anastomotic treatment to treatment varies with etiology<sup>[39]</sup>.

Endoscopic therapy of non-anastomotic strictures typically consists of extraction of the biliary sludge and casts which are routinely present, and balloon dilation of all accessible strictures followed by placement of plastic stents with replacement every 3 mo<sup>[39]</sup>. Balloon dilation of all strictures is frequently not feasible because of the multifocal distribution of the strictures and their predilection for the smaller intrahepatic ducts. Furthermore, rapid stent occlusion with recurrent cholangitis is an ongoing challenge when managing non-anastomotic strictures. Finally, ischemic events which are associated with diffuse intrahepatic bile duct strictures are associated with poor graft survival, and in most instances may require early retransplantation in suitable cases. Hence, endoscopic therapy is also first line in non-anastomotic strictures and may occasionally be a definite solution, but appears to play a more prominent role as a bridge to liver retransplantation<sup>[46,85]</sup>.

**Natural history:** Patients with non-anastomotic strictures require lifelong surveillance since strictures are likely to recur. Complications with cholangitis after treatment are not uncommon, with subsequent repeated need for hospitalization. Most importantly, non-anastomotic strictures may result in significantly increased graft loss; up to 30%-50% of patients undergo retransplantation or die as a consequence of this complication despite endoscopic therapy<sup>[23,39,44,54,87]</sup>.

Surgical revision may ultimately be required in patients with strictures that are refractory to endoscopic or percutaneous treatment. A Roux-en-Y hepaticojejunostomy is usually performed in patients with duct-to-duct anastomosis. In those who already have a Roux-en-Y hepaticojejunostomy anastomosis, a revision may be required by repositioning the bile duct of the graft to a better vascularized area<sup>[42]</sup>.

### **Living donor liver transplantation associated biliary strictures**

Biliary complications are more common in living donor OLT patients compared to deceased donor OLT patients, occurring in up to 32% of patients compared to 10%-15% of patients who undergo deceased donor OLT<sup>[51,88]</sup>. Studies have shown that despite the difference in incidence, the types of complications are similar with biliary strictures as the most common<sup>[54]</sup>. Living donor OLT patients present a unique problem, as not only are recipients at increased risk of biliary duct strictures, but donors too are at risk of these complications. Living donor OLT patients present with the usual factors putting them at risk of biliary strictures, but also with factors unique to surgical techniques required for living donor OLT. The presence of bile leaks has emerged as one of the most important factors in the causation of these strictures, in addition to elderly donors and small duct size (< 4 mm) in duct-to-duct anastomoses<sup>[22,42,66,87,88]</sup>. It appears

that rates of complications with bile duct strictures after Roux-en-Y reconstructions and duct-to-duct anastomoses are similar<sup>[22]</sup>. Presentation is not unlike that in deceased donor OLT patients, however a recent report highlighted the use of a serum bilirubin over 1.5 mg/dL as a better indirect marker of biliary stasis in these patients than alkaline phosphatase which may be overly sensitive<sup>[89]</sup>.

**Recipient-associated biliary strictures:** Bile duct strictures occur in an estimated 1%-9% of these patients<sup>[88,90]</sup>. Ischemic biliary injury in recipients of living donor OLT is a well recognized risk factor which has been associated with extensive dissection of the right hepatic artery and bile duct in the donor in early cases of living donor OLT. In living donor transplantation the incidence of anastomotic strictures appears to be consistently higher than non-anastomotic strictures as compared with recipients of whole liver grafts<sup>[51-53]</sup>. This is considered to be related to the blood supply of the anastomosis and often the presence of multiple and small caliber donor ducts. In terms of management, the therapeutic value of ERCP and PTC in living donor OLT is still under evaluation<sup>[5,54]</sup>. Methods of treatment and success rates of long term endoscopic intervention therapy are difficult to interpret because of the presence of multiple ductal anastomoses, smaller size, peripheral location and increase risk for devascularization<sup>[51-53]</sup>. To date, only 6 published trials have evaluated the efficacy of endoscopic therapy in anastomotic strictures after living donor OLT<sup>[24,30,35,52,84,87,91]</sup>. Endoscopic treatment success rates appear significantly less than for anastomotic strictures in deceased donor OLT at 60%-75%<sup>[52,84,87,91]</sup>. Just as in deceased donor OLT patients, the combination of balloon dilatation and stenting is more effective than either modality alone<sup>[91]</sup>. Technically, living donor OLT presents a challenge with the most common reason for failure being the inability to traverse the stricture and complex peripheral anastomosis, rendering plastic stent placement difficult<sup>[52]</sup>. A subset of patients with a sharp angulation or "crane neck" deformity of the bile duct may make strictures resistant to endoscopic treatment<sup>[53]</sup>. Percutaneous transhepatic therapy appears safe and effective when ERCP fails<sup>[53,92,93]</sup>. Non-anastomotic strictures in living donor OLT have even lower success rates ranging from 25% to 33%, significantly below the 50%-75% seen in patients with deceased donor OLT<sup>[31,52,53,92,93]</sup>. Overall, surgical revision is carried out more frequently in recipients after living donor OLT than after deceased donor OLT<sup>[87]</sup>.

**Donor associated biliary strictures:** In living donor OLT, not only recipients but also donors are at risk of biliary complications including biliary duct strictures. While the overall incidence of bile duct injury in liver donors is low, biliary strictures are increasingly recognized complications in this subset of patients and have even been reported much beyond the early postoperative period<sup>[94-97]</sup>. In a survey of 1508 donors in Asia, complications were seen more commonly with right-lobe as compared to left-lobe or left lateral segment donation<sup>[90]</sup>.

The general principles of management discussed earlier for all biliary strictures apply to living donors with biliary strictures. Similar outcomes were noted for both donors and recipients with biliary strictures with surgical revisions needed more often than for deceased donor OLT<sup>[87]</sup>.

## FUTURE DIRECTIONS

Innovations in ERCP techniques are likely to change the management of biliary duct strictures in the future. Technical reasons for failure of therapeutic ERCP indicate that the presence of a stricture that is too tight to allow access to the central duct system is the most common cause of ERCP failure in anastomotic strictures, non-anastomotic strictures and biliary strictures after living donor OLT<sup>[36,42]</sup>. Use of new intraductal endoscopy technologies such as the SpyGlass direct visualization system (Boston Scientific, Natick, Mass.), which allows visualization of the inner wall of the biliary tree and can act as the guidance system for passage of the guidewire through a tight stricture, has shown some early promise in this area<sup>[5,98-100]</sup>. A recent case report detailed the use of methylene blue-aided chromoendoscopy *via* peroral cholangioscopy to successfully optically diagnose extensive ischemic-type non-anastomotic biliary lesions after transplant<sup>[101]</sup>. Also, new types of balloons and stents will also have a significant role in improvement of management of biliary strictures. Preliminary evidence shows that peripheral cutting balloons may be more effective in biliary strictures not responsive to standard measures<sup>[102]</sup>. Plastic stents and catheters presently used carry a high risk for occlusions. Use of larger metallic open mesh or partially covered stents increases the probability of patency but carries several disadvantages including ingrowths of tissue from reactive hyperplasia, their permanency and the potential difficulty of removing them at surgery. Therefore uncovered and partially covered self-expandable metal stents cannot be recommended for therapy of biliary strictures. Newer removable fully covered metal stents could offer potential therapeutic options for patients with biliary strictures with increased duration of patency than plastic stents<sup>[25]</sup>. More distant in the future are bioabsorbable stents which could be deployed and would remain in place for several months with subsequent biodegradation. These innovations will hopefully allow treatments with single interventions rather than the current practice of repeated interventions and thus have a significant positive impact on the quality of life of the patients treated.

## CONCLUSION

Despite advances in organ procurement and surgical techniques, biliary complications remain a significant source of morbidity in patients after OLT, with biliary strictures still among the most common of these complications. In recent years, endoscopy has played a progressively greater role in the diagnosis and

management of biliary stricture complications after transplantation. Repeated endoscopic dilation with placement of one or more plastic stents is currently the standard first line management of biliary strictures avoiding the need, particularly in anastomotic strictures, for percutaneous transhepatic approaches and surgical management in most cases. Percutaneous and surgical modalities are now reserved for patients in whom endoscopic treatment fails and for those with multiple inaccessible intrahepatic strictures or Roux-en-Y anastomoses. Even in these latter cases, with the recent advances of deep small bowel enteroscopy techniques, the role of endoscopic therapy is expanding. Indeed, as technology progresses with newer endoscopic techniques including intraductal endoscopy, this will allow for enhanced access and visualization of complex strictures as well as improved stenting modalities, and offer hope that the burden to OLT patients related to biliary stricture complications will be reduced even further in the future.

### Abstract

There are differences between African-American and white patients with colorectal cancer, concerning their characteristics before and after diagnosis. Whites are more likely to adhere to screening guidelines. This is also the case among people with positive family history. Colorectal cancer is more frequent in Blacks. Studies have shown that since 1985, colon cancer rates have dipped 20% to 25% for Whites, while rates have gone up for African-American men and stayed the same for African-American women. Overall, African-Americans are 38% to 43% more likely to die from colon cancer than are Whites. Furthermore, it seems that there is an African-American predominance in right-sited tumors. African Americans tend to be diagnosed at a later stage, to suffer from better differentiated tumors, and to have worse prognosis when compared with Whites. Moreover, less black patients receive adjuvant chemotherapy for resectable colorectal cancer or radiation therapy for rectal cancer. Caucasians seem to respond better to standard chemotherapy regimens than African-Americans. Concerning toxicity, it appears that patients of African-American descent are more likely to develop 5-FU toxicity than Whites, possibly because of their different dihydropyridine dehydrogenase status. Last but not least, screening surveillance seems to be higher among white than among black long-term colorectal cancer survivors. Socioeconomic and educational status account for most of these differences whereas little evidence exists for a genetic contribution in racial disparity. Understanding the nature of racial differences in colorectal cancer allows tailoring of screening and treatment interventions.

### INTRODUCTION

Colorectal cancer is the third most common malignancy and third most frequent cause of cancer-related death in the United States, with 148 810 new cases and 49 960 deaths anticipated in 2008<sup>[1]</sup>. Screening for this type of malignancy reduces mortality through detection of cancer at an earlier, more treatable stage as well as by identification and removal of the precursor lesion, the adenomatous polyp. Today there is a range of options for colorectal cancer screening in the average-risk population, with current technology falling into 2 general categories: stool tests, which include tests for occult blood or exfoliated DNA, and structural exams, which include flexible sigmoidoscopy, colonoscopy, double-contrast barium enema, and computed tomographic colonography. Several treatment options are available after diagnosis depending on the stage including radiation for rectal cancer, surgery and systemic chemotherapy for colon and rectal cancer.

This is a review of the bibliography concerning the differences between African Americans and Caucasians before and after the diagnosis of colorectal cancer. Issues such as screening trends, biologic background, racial variation of colorectal cancer risk and sub site specific risk, prognosis, treatment and surveillance are examined. In addition, socioeconomic and educational disparity has been taken into consideration.

## RACIAL DIFFERENCES BEFORE DIAGNOSIS

### **Colorectal screening disparities between African American and White populations**

Being African American is associated with a lower screening rate for colorectal cancer<sup>[2-12]</sup>. Perceived positive beliefs or barriers about colorectal cancer screening, physician recommendation and knowledge of screening tests and colorectal cancer risk are responsible for a great deal of the difference. Socioeconomic status which is composed of education and income also account partly for the observed difference. African Americans and Caucasians seem to prefer different screening options. In addition, screening disparity exists among Blacks and Whites with positive family history. However, not all studies confirm these data.

**Knowledge about colorectal cancer and screening:** African-Americans' perceptions of sigmoidoscopy and colonoscopy differ from fecal occult blood testing (FOBT) with respect to perceived benefits *vs* barriers. Specifically, barriers are significantly and negatively associated with FOBT and sigmoidoscopy, whereas there is a significant positive association between perceived benefits and sigmoidoscopy or colonoscopy but not with FOBT<sup>[13]</sup>. Higher educational status and greater knowledge of flexible sigmoidoscopy predicted greater adherence to screening flexible sigmoidoscopy guidelines, whereas greater knowledge of FOBT and doctor recommendation predicted greater adherence to FOBT screening guidelines in an African American population in East Harlem<sup>[14]</sup>. Knowledge status about colorectal cancer is lower in African Americans than in Whites<sup>[15]</sup>. In addition, African Americans who adhered to the screening guidelines tended to be more knowledgeable about colorectal cancer and to hold more positive beliefs about the benefits of screening than those who were not up-to-date with screening. Moreover, they tended to receive more physician recommendation and to have better insurance status<sup>[16]</sup>. Low-income African Americans are optimistic and hopeful about early colorectal cancer detection and believe that thorough and accurate screening is valuable. Lack of colorectal cancer knowledge and fear are major barriers to screening for this population<sup>[17]</sup>. African American descent, communication with the health care provider<sup>[18]</sup>, knowledge about colorectal cancer<sup>[18]</sup> and physician recommendation<sup>[19]</sup> predicts adherence to the screening guidelines. Perceived absolute risk, comparative risk or colorectal cancer concerns, predict planning to get an FOBT in the next 2 years among low income African Americans<sup>[20]</sup>. It appears that doctor's recommendation, awareness of screening, older age, greater education and perceived susceptibility account for the differences in colorectal cancer screening among Blacks and Whites in a study<sup>[11]</sup>. African American women who perceive fewer barriers, more benefits, and have increased confidence

in the accuracy of screening are more likely to undergo screening<sup>[21]</sup>.

**Socioeconomic contribution to the racial screening disparity:** Having either a screening sigmoidoscopy or colonoscopy is positively associated with educational status, being married, higher household income, recent medical visit, higher age and public or private insurance among African Americans<sup>[5]</sup>. White race and higher socioeconomic status are associated with higher rate of physician recommendation of screening<sup>[6]</sup>. A study showed that screening rate varies less by race than by region<sup>[22]</sup>. This study concentrated on Southern US regions where there are high concentrations of African Americans as well as high levels of unemployment and poverty. Screening disparities between Blacks and Whites were eliminated after adjusting for socioeconomic status as this was defined by income and education<sup>[23]</sup>. Medicare coverage of colonoscopy since 2001 did reduce racial screening disparities between elderly Whites and Blacks<sup>[24]</sup>.

**Blacks and Whites undergo different screening tests:** It appears that preferred screening techniques vary according to race. African Americans tend to receive significantly less frequent screening colonoscopy than Whites. On the other hand, African Americans are more likely to receive a screening sigmoidoscopy at regular intervals<sup>[5]</sup>. Whites are more likely, in a statistically significant manner, to undergo an endoscopy as a colorectal cancer screening test than African Americans<sup>[9]</sup>. Racial/ethnic minorities are significantly less likely than Whites to prefer computed tomography colonography (CTC) over optical colonoscopy (OC) (Whites, 65.7%; Blacks, 45.1%; Hispanics, 35.8%; and other, 35.7%;  $P < 0.001$ ). Racial/ethnic minorities are less satisfied with CTC (Whites,  $8.4 \pm 1.7$ ; Blacks,  $7.8 \pm 1.7$ ; Hispanics,  $7.4 \pm 1.8$ ; and other,  $7.5 \pm 2.1$ ;  $P = 0.001$ ) and are significantly less willing to undergo CTC again in the future (Whites, 95.5%; Blacks, 80.3%; Hispanics, 84.9%; and other, 85.7%;  $P = 0.006$ )<sup>[25]</sup>. Among tests that examine the entire colon, barium enema is more commonly used among Blacks, whereas colonoscopy is more commonly among Whites<sup>[26]</sup>.

**Screening among people with positive family history:** Screening for colorectal cancer differs between Blacks and Whites with a positive family history for colorectal cancer. Among people with multiple affected first degree relatives (FDRs), or relatives diagnosed before age 50 years, African Americans were less likely than Whites to follow the screening guidelines after adjusting for age, sex, educational status, annual income, insurance status, total number of affected and unaffected FDRs, and time since last medical visit. Specifically, 27.3% of the African-Americans reported having had a colonoscopy during the last five years *vs* 43.1% of Whites [ $P < 0.001$ , odds ratio (OR) = 0.51, 95% CI 0.38-0.68]<sup>[27]</sup>. Another study confirmed this

outcome (27.9% of Whites *vs* 9.3% of Blacks with a positive family history had undergone an endoscopic screening procedure in the last 10 years,  $P = 0.03$ ). After adjusting for age, family history, gender, educational level, insurance status, and usual source of care, Whites were more likely to be current with early initiation endoscopic screening recommendations than African Americans ( $OR = 1.38$ , 95% CI 1.01-1.87)<sup>[28]</sup>. Family history did not predict screening in African Americans when the analysis was controlled for age, education, and insurance. African Americans who have a family history are less likely to screen compared with their white counterparts and compared with African Americans who are at average risk for colorectal cancer ( $P < 0.05$ )<sup>[29]</sup>. Tailored intervention increased screening *via* FOBT in a statistically significant manner in the Caucasian but not in the non-Caucasian population of first degree relatives of people affected with colorectal cancer<sup>[30]</sup>.

**Studies that do not confirm higher screening rates in the White population *vs* Blacks:** Few studies have shown either a higher screening rate in the African-American than in the white population, or no racial difference. In a Veteran medical centre, patients' files were retrospectively analyzed and it was shown that Blacks are more likely to receive either an FOBT within the last year or a flexible sigmoidoscopy/colonoscopy within the last five years than their white counterparts although physician recommendation did not vary among the racial groups<sup>[31]</sup>. No screening differences were noticed between African Americans, European Americans and Native Americans<sup>[32]</sup>. Adherence to the Medicare-covered intervals for colorectal cancer screening tests is low (56.8% for Whites, 39.1% for African Americans), and did not significantly differ by race after adjustment. African Americans were, however, significantly less likely to have ever been tested ( $OR = 0.48$ , 95% CI 0.33-0.70) and more likely to have had an endoscopic test than an FOBT in this study ( $OR = 3.06$ , 95% CI 1.70-5.51)<sup>[33]</sup>. After adjusting for age, having a regular doctor and participation in general medical exams, Blacks and Whites did not vary significantly in their current colorectal cancer screening status, with an OR of 1.1 (95% CI 0.7-1.6)<sup>[34]</sup>. No racial difference was observed in the percentage of people with a positive FOBT who underwent a colonoscopy in the following 12 mo<sup>[35]</sup>. A study among low income women showed that African-American descent predicts a lower likelihood of reporting having had screening colonoscopy within the past 10 years ( $OR = 0.46$ ,  $P < 0.001$ ) although following the screening guidelines did not vary by race<sup>[36]</sup>.

**Findings from colonoscopy screenings:** A study<sup>[37]</sup> carried out and led by David Lieberman, MD, of Portland VA Medical Center collected information from colonoscopy screenings of 5464 African-Americans and 80 061 Whites from 67 screening centers around the United States as published in the September 24, 2008 issue of *The Journal of the American Medical Association*.

The researchers found that "asymptomatic black men and women undergoing colonoscopy screening are more likely to have one or more polyps sized more than 9 mm compared with white individuals. The differences were especially striking among women. These findings emphasize the importance of encouraging all black men and women to be screened."

**The findings:** Nearly 8% of African-American patients had one or more polyps larger than 9 mm; 6% of Whites had one or more polyps larger than 9 mm; African-American women had a 62% greater risk of having such a polyp in the colon when compared with white women; African-American men had a 16% greater chance of having large polyps when compared with white men.

#### **Sub site location of colorectal cancer according to race**

It appears that colon cancer sub site varies according to race. Differences in location among African-Americans and non-Hispanic Whites implicate different screening guidelines in the two racial groups.

A study showed that the proportion of sigmoid colon cancer is 15.6%-21.3% lower in African Americans than non Hispanic Whites over three successive time periods between 1973 and 2002, whereas the diagnosis of descending colon cancer is 40.5%-45.3% higher in the African-American than the white subgroup<sup>[38]</sup>. Regression analysis in this study confirmed that tumors sited proximal to the sigmoid colon or to the splenic flexure are more common in Blacks than in Whites. African Americans are less likely to have colonic polyps ( $OR = 0.77$ , 95% CI 0.70-0.84) and more likely to have colonic tumors than Whites ( $OR = 1.78$ , 95% CI 1.14-2.77), but they are more likely to have polyps in the proximal colon ( $OR = 1.30$ , 95% CI 1.11-1.52) and colonic tumors in the proximal colon ( $OR = 4.37$ , 95% CI 1.16-16.42)<sup>[39]</sup>. Advanced proximal colon cancer is more frequent in African-Americans<sup>[40-42]</sup>. Blacks are more likely to receive a diagnosis of proximal colon cancer than distal colorectal cancer but within the same sub site, they are less likely than Whites to receive a diagnosis of localized disease<sup>[41]</sup>. African Americans tend to have more proximal tumors than Whites<sup>[43]</sup>. Another study confirmed African American predominance in proximal colorectal cancer and white predominance in distal tumors<sup>[44]</sup>. Carcinoma *in situ* has the same pattern of distribution in Blacks and Whites as invasive colorectal carcinoma (white predominance in distal disease and black predominance in proximal disease)<sup>[45]</sup>.

However, an older study, showed no racial variation in cecum or ascending colon cancer incidence, black predominance in transverse or descending colon cancer and white predominance in sigmoid and rectal cancer<sup>[46]</sup>.

#### **Racial variation of colorectal cancer risk**

African-Americans are at increased risk of developing colon cancer<sup>[47]</sup>, especially distant disease<sup>[48]</sup>, compared with Whites, but rectal cancer rate was shown to be higher among Whites when compared with Blacks<sup>[47]</sup>. Black seniors are less likely to be diagnosed with early

stage disease than their white counterparts and this association is greater in areas with high racial segregation and low income<sup>[49]</sup>. Between the years 1992-2001 a decline is observed in colorectal cancer incidence among Whites (1.2% per year in white men and 0.7% per year in white women) but not among Blacks<sup>[50]</sup>. Colorectal cancer was found to be more common in the black population than in the other racial groups and colorectal cancer screening beginning at the age of 50 is more cost-effective in the black population<sup>[51]</sup>. Colorectal cancer incidence was higher in the white than the black race until the mid 1980s whereas the opposite is true in the following years. Furthermore, the same study showed that proximal and transverse colon cancers are more common in Blacks than in Whites and distal colon and rectal cancer are more common in Whites than in Blacks. Colorectal cancer is of lower grade and of greater stage in Blacks than in Whites. In both racial groups, there is a decline in the incidence of distant disease, more in Whites than in Blacks. In the former, the incidence of localized and regional disease was found to be increasing, whereas in the latter this incidence is decreasing<sup>[42]</sup>. Colorectal cancer risk in people younger than 50 years old is higher in African Americans than in Whites<sup>[52]</sup>. In addition, the high incidence and younger age at presentation of colorectal cancer in African Americans warrants initiation of colorectal cancer screening at the age 45 year rather than 50 year<sup>[53]</sup>.

**Nutritional habits and colorectal cancer risk:** African-Americans were found to consume less micronutrients than Whites. High intake of beta carotene, vitamin C and calcium are associated with a lower risk of colorectal cancer in the white population whereas high intake of vitamin C and E are inversely associated with colorectal cancer risk in the African-American population<sup>[54]</sup>. Usage of non-steroidal anti-inflammatory drugs is associated with a reduced risk of colorectal cancer and this association did not vary among African Americans and Whites<sup>[55]</sup>. Fiber consumption is significantly associated with 50%-60% reduced risk of colorectal cancer in African Americans and non-significantly with 30% reduced risk of colorectal cancer in Whites<sup>[56]</sup>. Hydrogen response to 10 g of oral lactulose is significantly higher in the African-American than in the Caucasian American population implicating a difference in colonic bacterial metabolism between the two groups<sup>[57]</sup>. African Americans in all age groups seem to consume fewer mean daily servings of total dairy, milk, cheese, and yogurt than non-African Americans, and have lower mean intakes of calcium, magnesium, and phosphorus<sup>[58]</sup>.

**Racial polymorphism variation:** Cigarette smoking was found to be positively associated with colorectal cancer risk in the white but not in the black population<sup>[59]</sup>. This study also examined the possible association between GSTM1 and GSTT1 polymorphisms with colon cancer. There is a trend towards increased risk of colon cancer for individuals with GSTM1 null (African Americans, OR = 1.43, 95% CI 0.98-2.09; Whites, OR = 1.19, 95%

CI 0.90-1.58) and a decreased risk of colon cancer for individuals with GSTT1 null (African Americans, OR = 0.59, 95% CI 0.40-0.86; Whites, OR = 0.72, 95% CI 0.53-1.00). There are weak interactions between GSTT1 null and cigarette smoking in Whites, and GSTM1 null genotype and cigarette smoking in African Americans. African Americans are more likely to have the BLFA haplotype of the vitamin D receptor (6.5% in the white population vs 41.2% in the African American population) which was found to be associated with increased risk of colorectal cancer (OR = 2.4, 95% CI 1.38-4.38)<sup>[60]</sup>. Adjusted ORs for the combined effects of codon 677 CC and codon 1298 AA genotypes (these codons being part of the 5-10 methylenetetrahydrofolate reductase gene) and folate intake < 400 µg/d are 1.9 (95% CI 1.1-3.4) in African Americans and 2.5 (95% CI 1.2-5.2) in Whites<sup>[61]</sup>. Arachidonate lipoxygenase (ALOX) and cyclooxygenase (COX) are considered important in the development of colon cancer. ALOX5 Glu254Lys, COX2 C-645T and Val511Ala allele frequencies vary among Caucasians and African-American controls ( $P < 0.001$ ). The ALOX5-1752 and -1699 polymorphisms are in linkage disequilibrium ( $P < 0.001$ ) and lower colon cancer risk in Caucasians in ALOX5 haplotype analyses ( $P = 0.03$ ). Furthermore, an inverse association is observed between A alleles at positions -1752 and -1699 of ALOX5 and colon cancer risk in Caucasians, but not in African-Americans. Caucasians with A alleles at ALOX5-1752 have a reduced odds of colon cancer vs those with G alleles [OR (GA vs GG) = 0.63, 95% CI 0.39-1.01; OR (AA vs GG) = 0.33, 95% CI 0.07-1.65,  $P$  (trend) = 0.02]. The same is observed for ALOX5 G-1699A [OR (GA vs GG) = 0.59, 95% CI 0.37-0.94; OR (AA vs GG) = 0.27, 95% CI 0.06-1.32,  $P$  (trend) = 0.01]<sup>[62]</sup>. Serum 25-(OH)D levels are higher in non-Hispanic Caucasians than in subjects of other ethnicities ( $P < 0.001$ ) in both people with and without colorectal adenomas. Serum 25-(OH)D is inversely associated with colorectal adenomas showing a 26% decrease in the rate of colorectal adenoma with each 10 ng/mL increase in serum 25-(OH)D<sup>[63]</sup>. N acetyltransferase 2 rapid/intermediate genotype is associated with increased colon cancer risk in Whites (OR = 1.4, 95% CI 1.0-1.8), when compared with the slow genotype, which is not true for Blacks<sup>[64]</sup>. N-myc downstream-regulated gene 1 (NDRG1) expression is correlated to histopathological type, Dukes' stage and HIF-1 alpha expression in US-Caucasian patients but not in US-African American patients. Interestingly, Kaplan-Meier survival analysis demonstrated that NDRG1 expression correlated significantly with poorer survival in US-African American patients but not in other patient groups<sup>[65]</sup>.

## POSTDIAGNOSIS DISPARITIES BETWEEN WHITES AND AFRICAN AMERICANS

### **Racial prognosis difference due to socioeconomic status, stage and other tumour characteristics**

Colorectal cancer mortality declined in Whites but

increased in Blacks from 1950 to 1992<sup>[66]</sup>. However, mortality has declined in both Blacks and Whites from 1990 to 1998, although the rate for Blacks has remained high<sup>[67]</sup>. Disparity in survival between Blacks and Whites is confirmed by another study<sup>[68]</sup>. There is no difference in survival between Blacks and Whites with colorectal cancer among patients with the same stage receiving the same treatment<sup>[69]</sup>. Recurrence-free survival is modestly lower in African-Americans than in Whites with operable rectal cancer [hazard ratio (HR) 1.25, 95% CI 0.94-1.66] whereas racial disparity in mortality rate is larger (HR 1.45, 95% CI 1.09-1.93)<sup>[70]</sup>. Furthermore, after adjusting for socioeconomic status, mortality in stage II and III colon cancer patients was only marginally higher in African Americans than in Whites<sup>[71]</sup>. An older study showed that among patients with colon cancer, black to white mortality was 1.5 (95% CI 1.2-1.9) and 1.2 after adjustment for stage (95% CI 1.0-1.5)<sup>[72]</sup>. In the same study, differences in mortality was observed in stages II and III (HR 1.8, 95% CI 1.0-3.1 and HR 1.5, 95% CI 1.2-2.3, respectively) but not in stage IV. Furthermore, another study confirmed that Blacks are more likely to die from colorectal cancer than Whites (relative risk = 1.34, 95% CI 1.26-1.42)<sup>[73]</sup>. In this study, socioeconomic status and stage accounted for half of the disparity for all stages and socioeconomic status accounted for all the disparity in stage III of colon and stage II and III of rectal cancer. In addition, comorbidity did not contribute to the disparity, but treatment (surgery, radiation, chemotherapy) explained a very small proportion of the black-white difference. The fully-adjusted relative mortality rate comparing Blacks to Whites was 1.14 (1.09-1.20) for all-cause mortality and 1.21 (1.14-1.29) for colorectal cancer specific mortality. A large meta-analysis (including articles in English from 1966 to August 2007) showed that racial disparities in survival for colon cancer between African-Americans and Caucasians are only marginally significant after adjusting for socioeconomic factors and treatment (HR 1.13, 95% CI 1.01-1.28)<sup>[74]</sup>. On the other hand, another study showed that there is higher stage-specific mortality in Blacks compared with Whites and socioeconomic status accounts for some but not all of this disparity<sup>[75]</sup>. Increased mortality rate in Blacks compared with Whites is the outcome of another study<sup>[76]</sup>. After adjustment for age, sex, histology, site within the colon, and stage, African Americans are more likely to die compared with Caucasian patients with colorectal cancer (colon: HR 1.19, 95% CI 1.14-1.25; rectum: HR 1.27, 95% CI 1.17-1.38). However, after further adjustment for socioeconomic status and treatment, the risk of death for African-Americans compared with Caucasians is substantially diminished (colon: HR 1.08, 95% CI 1.03-1.13; rectum: HR 1.11, 95% CI 1.02-1.20)<sup>[77]</sup>. Survival in patients suffering from colorectal cancer with more than 16 years of education increased from 1993 to 2001 [2.4% ( $P < 0.001$ ), 4.8% ( $P = 0.011$ ), 3.0% ( $P < 0.001$ ), and 2.6% ( $P = 0.030$ ) annually among white men, black men, white women, and black women, respectively]. Among patients with less than 16 years of

education, an increase in mortality was observed only in black men (2.7% per year;  $P < 0.001$ ) whereas the death rate remained stable in the other groups<sup>[78]</sup>. Blacks with colonic adenocarcinoma were found to have a reduced 5- (OR = 1.67, 95% CI 1.21-2.33) and 10- (OR = 1.52, 95% CI 1.12-2.07) year survival than Whites after surgery<sup>[79]</sup>. The strongest and statistically significant association was observed only among patients with stage II. No racial differences in overall survival were observed among patients with rectal cancer. In this study no neo-adjuvant or adjuvant treatment was given to the patients. Among patients who underwent an operation for primary colorectal carcinoma and did not receive pre-surgical or post-surgical chemotherapy, 54% of African Americans and 21% of Caucasians with high grade tumors died within the first year after surgery ( $P = 0.007$ ). African Americans with high-grade tumors were 3 times (HR 3.05, 95% CI 1.32-7.05) more likely to die of colon carcinoma within 5 years post-surgery, compared with Caucasians with high-grade tumors. There were no survival differences by race among patients with low-grade tumors<sup>[80]</sup>.

Another study showed no association between socioeconomic status and survival in patients with colorectal cancer treated in city and university hospitals<sup>[81]</sup>. However, Blacks are more likely to be treated in city than in university hospitals (53% vs 20.6%,  $P < 0.001$ ). Patients treated in city hospitals had a worse prognosis than those treated in university hospitals and Blacks had a worse prognosis in both city and university hospitals in this study.

### Racial variation in treatment

In adjusted comparisons with white patients with colorectal carcinoma, African American patients reported more problems with coordination of care ( $P < 0.001$ ), psychosocial care ( $P = 0.03$ ), access to care ( $P = 0.03$ ), and health information ( $P < 0.001$ )<sup>[82]</sup>.

**Surgical treatment of colorectal cancer in African-Americans and Whites:** Among patients who underwent surgery for rectal cancer, the rate of sphincter-ablating procedure was 37% for Whites and 43% for Blacks [adjusted odds ratio (AOR) 1.42, 95% CI 1.23-1.65]<sup>[83]</sup>. Blacks had a higher risk of dying from colorectal cancer (HR 1.17, 95% CI 1.06-1.30) in a study and adjustment for tumour stage reduced the hazard ratio to 1.11 and surgical treatment further reduced hazard ratio to 1.06<sup>[84]</sup>. Black patients were more likely than Whites not to receive surgical treatment in stage I (OR = 2.08, 95% CI 1.41-3.03 among males; OR = 2.38, 95% CI 1.69-3.45 among females) and IV (OR = 1.25, 95% CI 1.01-1.56 among males; OR = 1.41, 95% CI 1.14-1.72 among females) colon cancer and most stages of rectal cancer, and they were more likely to refuse recommended treatment<sup>[85]</sup>. Black patients were less likely to undergo surgery than Whites (86% vs 91%,  $P = 0.02$ ) but the same study showed no racial differences in overall survival<sup>[86]</sup>. However, long term survival after rectal cancer surgery was shorter for Blacks

than for Whites [five-year survival rates were 41% and 50%, respectively ( $P < 0.0001$ )]. In this study, African Americans were more likely to be treated by low volume surgeons and not to receive adjuvant chemotherapy<sup>[87]</sup>.

**Chemotherapy and radiation therapy in white and black patients with colorectal cancer:** African Americans were treated less frequently with chemotherapy and radiation therapy compared with their Caucasian counterparts, in a retrospective analysis of data coming from a single institution<sup>[88]</sup>. African Americans with stage III colon cancer are less likely to receive adjuvant chemotherapy after surgery and they gain less benefit from adjuvant chemotherapy than Whites<sup>[89]</sup>. There is no statistically significant difference between black and white patients with stage II and III rectal carcinoma in the frequency of consultation with a medical oncologist (73.1% for Blacks *vs* 74.9% for Whites, difference = 1.8%, 95% CI 5.9%-9.5%,  $P = 0.64$ ) or radiation oncologist (56.7% *vs* 64.8%, difference = 8.1%, 95% CI 0.5%-16.7%,  $P = 0.06$ ), but Blacks are less likely than Whites to consult with both a medical oncologist and a radiation oncologist (49.2% *vs* 58.8%, difference = 9.6%, 95% CI 0.9%-18.2%,  $P = 0.03$ ). Among patients who visited an oncologist, black patients are less likely than white patients to receive chemotherapy (54.1% *vs* 70.2%, difference = 16.1%, 95% CI 6.0%-26.2%,  $P = 0.006$ ), radiation therapy (73.7% *vs* 83.4%, difference = 9.7%, 95% CI 0.4%-19.8%,  $P = 0.06$ ), or both (60.6% *vs* 76.9%, difference = 16.3%, 95% CI 4.3%-28.3%,  $P = 0.008$ ). Patient and provider characteristics have minimal influence on the racial disparity in the use of adjuvant therapy<sup>[90]</sup>. The same was shown for stage III colon cancer in elderly patients: consultation with a medical oncologist was equal among black and white patients, but the former were less likely to receive chemotherapy (59.3% *vs* 70.4%, difference = 10.9%, 95% CI 5.1%-16.4%,  $P < 0.001$ ). Disparity was higher among patients aged 66-70 (black patients 65.7%, white patients 86.3%, difference = 20.6%, 95% CI 10.7%-30.4%,  $P < 0.001$ ) which was confirmed by regression analysis and decreased in older patients. Disparity in this age group was partially due to patient, physician, hospital and environmental factors (accounted for 50%), surgical length of stay, neighbourhood socioeconomic factors (27%) and health system factors (12%)<sup>[91]</sup>. Furthermore, 53% of Whites and 56% of Blacks received no radiation therapy for stage II to III rectal cancer (AOR, 1.30; 95% CI, 1.15-1.47) in a study<sup>[83]</sup>. White patients received standard adjuvant therapy more frequently than African-Americans (OR = 1.75; 95% CI 1.09-2.83)<sup>[92]</sup>.

On the other hand, race was not associated with receipt of adjuvant chemotherapy in patients with stage III colon cancer<sup>[93]</sup>. This is confirmed by another study in which after adjustment for socioeconomic status, race was not associated with receiving adjuvant treatment or radiation in stage III colon and stage II, III rectal cancer<sup>[94]</sup>.

#### Racial variation in response to chemotherapy:

**Table 1 Differences in toxicity of the standard treatments for colorectal cancer between whites and AAs**

Regimens	Toxicity
Irinotecan and oxaliplatin	FOLFIRI, FOLFOX and IROX are less toxic to AAs than Whites
Fluoropyrimidines	5-FU is less toxic to AAs than Whites
Cetuximab	Whites are more prone to hypersensitivity reactions

AAs: African Americans.

In at least one study<sup>[95]</sup>, it was shown that Caucasian patients with metastatic colorectal cancer respond better to standard chemotherapy combinations (IFL, FOLFOX or IROX) than African-Americans (response rate for African Americans 30%, for Caucasians 41%,  $P = 0.015$ ). This was shown in multivariate analysis as well (29% response rate for African Americans *vs* 41% for Caucasians,  $P = 0.012$ ). The difference was noted in each treatment arm. However, no association was noted between race and time to progression or overall survival. The same study showed racial variation in pharmacogenomic parameters. Specifically, UGT1A1 6/7 and 7/7 polymorphisms were more common in African Americans, whereas UGT1A1 6/6 was more common in Caucasians ( $P = 0.0081$ ). In addition, ercc2-d A/A and A/B was more common in Caucasians and ercc2-d B/B more common in African Americans ( $P = 0.0002$ ). GSTM1-0 was more frequently absent in Caucasians and more frequently present in African Americans ( $P = 0.001$ ). Finally xrcc1-r399q C/C was more frequent in African Americans than in Caucasians, whereas in the other genotypes the opposite was true ( $P = 0.0006$ ). Moreover, a study showed that there is a higher risk of neutropenia in UGT1A1 7/7 patients especially in patients treated with IROX<sup>[96]</sup>. No association was found between this genotype and overall survival, time to progression, response rate or diarrhoea. Among previously treated patients with metastatic colorectal cancer who received bevacizumab or FOLFOX4 or the combination of these regimens, African Americans differed significantly from Whites in response rate and overall survival, whereas there was no significant difference in progression-free survival (RR: 10.2% *vs* 11.8%,  $P = 0.03$ ; OS: 10.2 mo *vs* 11.2 mo,  $P = 0.03$ ; PFS 4.2 mo *vs* 5.0 mo)<sup>[97]</sup>.

**Disparities in treatment related toxicity between the two ethnic groups:** The data concerning toxicity difference between Caucasians and African Americans are summarized in Tables 1 and 2.

#### Stage and grade at diagnosis

Two studies showed that black patients with colorectal carcinoma are diagnosed at a more advanced stage than their white counterparts<sup>[76,77]</sup>. Blacks are more likely to be diagnosed at a younger age and at a more advanced stage than white patients with rectal cancer<sup>[83]</sup>.

Apart from socioeconomic status, black-white

**Table 2 Differences in toxicity of the standard treatments for colorectal cancer between Whites and African Americans**

Regimens	Toxicity	Difference	Reference
Irinotecan and oxaliplatin	FOLFIRI, FOLFOX and IROX are less toxic to AAs than Whites	34% vs 48%, $P = 0.004$ , for severe toxicity	[95]
Fluoropyrimidines	5-FU regimens in the adjuvant setting differed between AA and Whites, with AA experiencing statistically significantly lower rates	5% vs 17%, $P = 0.004$ for diarrhea Diarrhea ( $P < 0.001$ ) Nausea ( $P < 0.001$ ) Vomiting ( $P = 0.01$ ) Stomatitis ( $P < 0.001$ ) Overall toxicity ( $P = 0.005$ )	[98]
DPD deficiency	AA, particularly AA women, have significantly reduced DPD enzyme activity compared with Whites, which may predispose this population to less 5-FU toxicity	-	[99]
Cetuximab	In a retrospective analysis, it was shown race was strongly associated with HSR to cetuximab among patients with CRC and head and neck cancer, with Whites experiencing HSR more frequently than AA	(Fisher exact) $P = 0.017$	[100]

HSR: Hypersensitivity reactions; AA: African American.

differences in tumour grade among patients with colon cancer were found. Specifically, Blacks appeared less likely to suffer from poorly differentiated tumors-grade 3 (OR = 0.44; 95% CI 0.22-0.88) with lymphoid reaction (OR = 0.49; 95% CI 0.26-0.90) when compared with Whites. This outcome remained statistically significant after adjusting for age, sex, metropolitan area, socioeconomic status, body mass index, and health care access and utilization. A trend without statistical significance was shown towards less high-grade (grade 3) nuclear atypia, mitotic activity, and tubule formation in Blacks compared with Whites. These findings were confirmed in patients with advanced but not with early disease. In addition, no differences were found in blood and lymphatic vessel invasion, mucinous histology, necrosis or fibrosis.

Blacks were more likely to suffer from better differentiated tumors in the proximal, but not in the distal colon. These outcomes suggest that factors other than tumour differentiation contribute to the different survival between Blacks and Whites along with socioeconomic status disparity<sup>[101]</sup>. Another study confirmed that African Americans are more likely to be diagnosed with more advanced and better differentiated tumors than Whites<sup>[43]</sup>.

African-Americans were more likely to present with life-threatening symptoms at the time they were diagnosed with colorectal cancer than Whites. This association was found to be independent of socioeconomic status. In addition, African Americans were more likely to die during their hospitalization when compared to Whites in both overall and high socioeconomic status<sup>[102]</sup>.

#### Quality of life in long term colon cancer survivors

African Americans are more likely to report better quality of life and psychological well being (marginally statistically significant,  $P = 0.07$ ) as long-term colon cancer survivors<sup>[103]</sup>. Among colon cancer survivors, African Americans presented with higher fruit/vegetable consumption than Whites<sup>[104]</sup>. White colorectal cancer survivors are more likely to undergo colon examination surveillance than African Americans 1, 2

and 5 years after diagnosis<sup>[105]</sup>. After adjusting for socio-demographic, hospital and clinical characteristics, Blacks are 25% less likely than Whites to receive surveillance<sup>[106]</sup>. This finding was not statistically significant in another study (relative risk 0.70,  $P = 0.14$ )<sup>[107]</sup>.

## CONCLUSION

African Americans are at increased risk of developing advanced colorectal cancer and are less likely to be up to date with colorectal cancer screening guidelines when compared with Whites. They also tend to be diagnosed with more proximal, more advanced and better differentiated tumors than Whites. In addition, they seem to have a worse prognosis and to receive appropriate treatment to a lesser extent. Socioeconomic factors, educational status, different beliefs and physician recommendation account for most of the disparity. However, little evidence exists concerning genetic differences which would explain the variety in colorectal cancer predisposition, sensitivity to carcinogens, response and toxicity of treatment between Blacks and Whites. In our opinion further research on these issues should be performed. Therefore, continued research efforts are necessary to disentangle the clinical, social, biological, and environmental factors that constitute this racial disparity. In addition, results across data sources should be considered when evaluating racial differences in cancer outcomes.

### INTRODUCTION

The relapsing and remitting nature of inflammatory bowel disease (IBD) with its high morbidity makes transition of children with IBD into adult care a mandatory step in their care<sup>[1]</sup>. As young people move to maturity, their medical and psychological needs change and it is crucial for them to receive age-appropriate medical care<sup>[2]</sup>. This highlights the importance of what is called health-care transition. Preparing older children and young adults for this process is very important as they need to develop a sense of independence and maturity<sup>[3]</sup>.

There have been several definitions of the process of transition of medical care but the most quoted one is that by Blum *et al*<sup>[3]</sup> “the purposeful planned movement of adolescents and young adults with chronic physical and medical conditions from child-centered to adult-oriented health care systems”.

The aim of the transition program is to achieve for each chronically ill patient a continuum of care that includes normalization of social and emotional development and acquisition of independent living skills<sup>[5]</sup>.

Several hurdles may interfere with this process. As the patients and their families are used to dealing with certain faces, they may be reluctant to move to an adult health care system. A strong sense of bonding usually develops over years of care under pediatric service. On the other hand, pediatric caregivers may also find it difficult to give up their patients after years of care and strong ties. They may feel that the adult caregivers are unable to provide the same quality of, not only medical, but also psychological care during this critical period<sup>[6]</sup>.

In addition, the adult caregivers may feel that patients and their families with pediatric-onset disease may be too demanding. The adult caregivers may assume that patients should take a large part of responsibility for the details of their care. Adult care normally lacks the multidisciplinary team approach that pediatric service usually offers<sup>[7,8]</sup>.

### WHAT IS THE BEST STRATEGY OF TRANSITIONING CHILDREN WITH IBD?

Most of the available pediatric IBD transition literature is

### Abstract

Children with chronic long-term disorders need to move to the adult practice at some point in their life. Establishing a smooth and efficient transition process is a complicated task. Transition of medical care to adult practice is defined as the purposeful planned movement of adolescents and young adults with chronic physical and medical conditions from child-centered to adult-oriented health care systems. This step is of the utmost importance for several reasons. There is an obvious deficiency of research in this area especially when it comes to pediatric inflammatory bowel disease (IBD). There is a considerable difference in individual practice among different centers. Also, age of transition varies among different countries and sometimes, even within the same country, transition age may vary among different provinces and districts! Interestingly, local politics and many factors other than children's welfare often play a role in deciding the age that older children move to adult practice at. This review discusses transition of children with IBD in view of the available evidence.

**Table 1** Checklist of tasks for the patients and the medical team based on chronological age as suggested by Hait *et al*<sup>[8]</sup>

Age	Patient	Medical team
11-13	Able to articulate his or her GI condition Able to name medications, doses, side effects Knows strategies to take his or her medications Able to use and read a thermometer Articulates impact of IBD on school and daily life	Introduces idea of future independent visits Asks parents to remain in waiting room for a portion of the visit Anticipatory guidance about fitness, sexuality, and substance abuse
14-16	Able to identify medical team Knows names and purposes of procedures and tests done on him or her Knows his or her medical history Knows names of IBD social support groups and community organizations Understands the medical risk of no adherence Understands the impact of drugs and alcohol on the illness	Directs all questions and explanations to patient Patient ask for input first Explores family's apprehensions about patient taking in primary role Clarifies to patient what must legally be disclosed to parents
17-19	Knows how to gather information about IBD Demonstrates consistent ability to book own appointments, fill prescriptions, contact medical team Able to name his or her insurance coverage and plans for next 2 years of coverage Carries insurance information in wallet/purse/backpack	Initiates conversation about potential barriers to transition Identifies potential adult GI providers Encourages patient to meet and interview providers Reminds patient and family that at age 18 the patient has the right to make his or her own health choices
20-23	Has had a telephone conversation with potential adult GI providers Initial visit with adult GI is scheduled while IBD stable	Provides patient with medical summary and checklist (see Table 2) Transfers medical records to adult provider

IBD: Inflammatory bowel disease; GI: Gastrointestinal.

in the form of some guidelines based on personal experience. The North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) indicates its recommendations for this process as<sup>[6]</sup>: (1) The pediatric gastroenterologist should start seeing adolescent patients without their parents in order to build some sort of relationship that promotes independence, so the patient will have this well-established before going to adult practice. Nevertheless, it is not clear at what age pediatric gastroenterologists should start implementing this recommendation. (2) Introduction of the patients subject to transition, and their families, to a gastroenterologist who is trained in internal medicine. Emphasis placed on benefits of transition to the patients and their families, including exposure to a physician experienced in aspects that pediatricians are not exposed to such as pregnancy, fertility and cancer surveillance. (3) Selection of an adult gastroenterologist who cares for young adults and identifies what this sector of patients may need that differs from newly diagnosed young adults. (4) The transition process should include a detailed letter from the pediatric to the adult gastroenterologist with a copy to the family. (5) The timing of the transition should be flexible according to patients' individual needs, e.g. the pediatric gastroenterologist should continue to follow those patients with delayed puberty who still have some potential to grow.

In a recent report, Hait *et al*<sup>[8]</sup> recommended some tasks and knowledge that pediatric patients at different age groups should be able to accomplish and be familiar with through the help of the medical team (Table 1).

This work has not been validated.

In a similar report, Pinzon *et al*<sup>[7]</sup> also recommended a certain amount of information pediatric patients should know in certain age groups (Table 2).

Dabadie *et al*<sup>[9]</sup> have recently conducted a survey on a small sample of young adults with IBD. Their mean age of transition was  $17.9 \pm 0.9$  years. Eighty five percent of patients and 74% of their parents felt they were ready to move to adult practice. The transition model they were using involved having one joint pediatric-adult care visit before moving completely to adult care. The majority of patients felt comfortable with this model<sup>[9]</sup>.

Many other centers are using the same model. In fact some hospitals may have more than one visit per patient to the joint clinics before transitioning children to adult practice. Most of these clinics take place in hospitals where both adult and pediatric gastroenterology departments exist. The problem with this system is the diversity of patients' location especially in large countries. As the number of adult gastroenterology centers exceeds that of pediatric centers, some patients may choose to move to an adult gastroenterologist near where they live, in which case they would not see the same gastroenterologist from the transition clinic. Available health resources may interfere with arranging transition clinics where patients reside.

Another survey by Hait *et al*<sup>[10]</sup> was done among 1132 adult gastroenterologists in the Netherlands. The response rate was only 34% but the majority of these gastroenterologists reported a lack of medical knowledge among young adults with IBD. They also reported receiving inadequate

**Table 2 Clinical transition framework<sup>[9]</sup>**

	<b>Early (10 to 12 years of age )</b>	<b>Middle (13 to 15 years of age)</b>	<b>Late (16 to 18 years of age )</b>
Self-advocacy	Describe GI condition	Name and describe the role of those involved in care	Review successful changes achieved in life
Independent behaviors	Learn about transition process Name medications and doses Choose method to remember to take medication	Learn about rights and responsibilities Describe tests and reasons for them Plan and prepare for appointments Discuss differences in pediatric and adult care Encourage self-reporting	Review GI conditions and ways to stay informed Demonstrate knowledge in dealing with own care needs (e.g. booking appointments, refilling prescriptions)
Sexual health	Discuss puberty and changes related to GI condition and medication side effects	Discuss safer relationships and dating Name places for reliable sexual health information	Aware of sexual capability and ability to have children Understands sexual behaviors and its risks
Social supports	Describe role of family in transition process	Discuss family medical history Discuss ways to benefit from peer support	Enrolls in GI support associations Identifies contacts in case of need of emotional support
Educational/vocational planning	Discuss school attendance, goals and strengths	Review restrictions for education or work Discuss volunteering opportunities at school or community	Aware of work opportunities Discuss further plans for insurance coverage
Health and lifestyles	Review healthy active living Tobacco use or other substances	Review ways of coping with stress Learn of risks associated with driving and GI condition	Describes exercise/activity routines Discuss importance of planning ahead for trips and being away from home

Adapted from the ON-TRAC abo model at the British Columbia Children's and women' Health Center.

medical history from their pediatric colleagues.

We recently started conducting a survey looking at the level of disease-related knowledge among older children and young adults with IBD. We asked patients and their parents to complete the same questionnaire forms independently. The preliminary results showed a significant lack of knowledge among those children and a significant knowledge deficit between children and their parents. This was the case despite the presence of a meticulous program for educating newly diagnosed children with IBD. The problem is that patients in this age group are often highly dependant on their parents on selecting and filtering all the information they need. Consequently we started seeing older patients with IBD on their own without their parents early before transitioning them to our adult colleagues. We are also evaluating a new strategy for patients' education to see if the outcome can be improved.

## LESSONS FROM OTHER SUBSPECIALTIES

Taking in consideration the huge advances in patient care and management, children with chronic disease are expected to live longer. Consequently, the area of transition has been explored in most other pediatric subspecialties.

In a recent multicentre audit from the UK, Robertson *et al*<sup>[11]</sup> reported some improvements in their transition program after highlighting the aspects of care provisions in transition through a national UK service framework of children. Improvements took place in the documentation of transition issues and in some educational needs of patients and their parents that were related to their disease. The concept of independent clinic visits was introduced at an earlier age (mean of 15.8 years vs 16.8 years before provision).

A service model for adults with congenital heart disease was recently published stressing the importance of close communication between local district general hospitals, tertiary specialist centers and primary care clinics. The authors suggested that transition clinics should start at the age of 12 years<sup>[12]</sup>.

McDonagh and Kelly summarized determinants of the timing of transition as follows<sup>[13]</sup>: (1) Chronologic age; (2) Maturity; (3) Current medical status; (4) Adherence to therapy; (5) Independence in health care; (6) Self-advocacy skills; (7) Preparation; (8) Readiness of the young person and (9) Availability of an appropriate adult specialist.

Clearly it is not an easy task for pediatric gastroenterologists to determine the exact maturity status for each child with IBD. Moreover, even when we feel that some children are not mature enough to move to adult service at the age of 16-17 years; it is not easy to convince health authorities to keep seeing these children in pediatric services. In fact, the differences between transition services in different health care systems were proven to inhibit a smooth and successful transition process in a recent study by Reiss *et al*<sup>[14]</sup>.

There have been some attempts to create a self-efficacy/independence scale to facilitate assessing older children with chronic disease for maturity. Schlosser and Havermans created and validated a self-efficacy scale for children with bronchial asthma between 10-18 years of age<sup>[15]</sup>. The scale consisted of 38 items partly taken from a self-efficacy scale by Grossman *et al*<sup>[16]</sup> for diabetics. Older children scored higher on the total scale. One major flaw in this study was the lack of adjustment for obvious confounders like social class or IQ. These points were partially taken into consideration in another independence-scale that was designed for children with cystic fibrosis (SCIS). The scale consisted of 44 items. An initial interview was done to screen for children with an average or high cog-

nitive function<sup>[17]</sup>. The study was conducted among CF patients aged from 14-17 years. Based on age, two different intellectual screening tools were used. There was a positive correlation between SCIS scores, patient's age and the number of years since diagnosis<sup>[17]</sup>. A similar study with a larger sample size was conducted among patients with diabetes not only for children but also for parents assessing independence of their children<sup>[18]</sup>. Approximately 25% of parents of children 6 years-old, 50% of parents of children 8 years-old and 75% of parents of 14 year-old children reported that their children had mastered their disease-related skills<sup>[18]</sup>.

Another tool was developed by the Boston Children's Hospital, USA to allow older children to evaluate their readiness for transition. This tool consisted of 15 questions<sup>[19]</sup>. Validation of this tool remains questionable.

Two case studies were recently published demonstrating the concept of "a medical home"<sup>[20]</sup>. This concept was highlighted in a statement by the American Academy of Pediatrics. It was stated that all children and youth with special health care needs should have a medical home where health care services are accessible, family centered, continuous, comprehensive, coordinated and compassionate<sup>[21]</sup>. The authors tried to set a model for transitioning older children with chronic, disabling medical problems using the above concept.

Currently there is a residency program in the United States (combined Medicine-Pediatrics Residency Program) that helps in qualifying physicians to look after children with chronic disorders during this critical period<sup>[22]</sup>. Training includes pediatric and adult subspecialty experience. Spreading this program to other countries may help in smoothing the transition process.

## CONCLUSION

Transitioning adolescents with IBD to adult gastroenterologists requires an understanding of the specific issues and challenges involved in the management of pediatric IBD<sup>[23]</sup>. Currently there is no consistency in transition practice among different centers.

The best strategy for health education or patients' transition is yet to be determined. Assessing children with IBD for maturity could be a challenge in view of the lack of validated scales. Current guidelines and suggestions are based on personal opinions. More research addressing best strategy for education, transition and building bridges with adult gastroenterologists are needed.

one focal liver lesion detected in baseline ultrasound (US) were examined with conventional US, contrast-enhanced US ( $n = 134$ ), contrast-enhanced CT ( $n = 115$ ) and/or dynamic contrast-enhanced MRI ( $n = 70$ ). The lesions were classified as malignant, benign or indeterminate and the type of lesion was determined. The final diagnosis based on the combined information of all imaging examinations, clinical information and histology ( $n = 32$ ) was used. Comparisons were made to see whether the addition of contrast-enhanced US led to the improvement of the characterization of doubtful focal liver lesions.

**RESULTS:** In comparison with unenhanced US, SonoVue® markedly improves sensitivity and specificity for the characterization (malignant/benign) of focal liver lesions. In comparison with CT and/or dynamic MRI, SonoVue®-enhanced sonography applied for characterization of focal liver lesions was 30.2% more sensitive in the recognition of malignancy and 16.1% more specific in the exclusion of malignancy and overall 22.9% more accurate. In the subgroup with confirmative histology available ( $n = 30$ ), sensitivity was 95.5% (CEUS), 72.2% (CT) and 81.8% (MRI), and specificity was 75.0% (CEUS), 37.5% (CT) and 42.9% (MRI). The sensitivity and specificity of CEUS for the identification of focal nodular hyperplasia (FNH) and hemangiomas was 100% and 87%, resulting in an accuracy of 94.5%.

**CONCLUSION:** SonoVue®-enhanced sonography emerges as the most sensitive, most specific and thus most accurate imaging modality for the characterization of focal liver lesions.

## Abstract

**AIM:** To evaluate in a multicenter study whether the sonographic characterization of focal liver lesions can be improved using SonoVue®-enhancement; and to compare this method with computed tomography (CT) and magnetic resonance imaging (MRI).

**METHODS:** One hundred and thirty four patients with

of focal liver lesions with SonoVue®-enhanced sonography: International multicenter-study in comparison to CT and MRI. *World J Gastroenterol* 2009; 15(30): 3748-3756 Available from: URL: <http://www.wjgnet.com/1007-9327/15/3748.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.3748>

## INTRODUCTION

Whereas un-enhanced ultrasound and color Doppler ultrasonographic examination are widely used to screen for liver lesions, these techniques have limited performance in the characterization of solid focal tumors<sup>[1-3]</sup>. Thus contrast enhanced computed tomography (CT) or magnetic resonance imaging (MRI) is required to assess the malignancy of the tumors as basis for therapy decisions. The characterization of lesions with contrast enhanced CT or MRI is based on the vascularity and enhancement pattern within the lesion<sup>[4-7]</sup>. SonoVue® is a microbubble contrast agent of the 2nd generation, allowing the assessment of vascularity and enhancement pattern of focal lesions with ultrasound in real-time, using low mechanical index scanning technology<sup>[8-24]</sup>. Low-mechanical index (MI) real-time ultrasound in combination with SonoVue® allows the continuous assessment of tumor vascularity and enhancement during the different vascular phases (arterial, portal and late phase) with better temporal resolution than with CT or MRI<sup>[18-19]</sup>. Safety and effectiveness of this agent have been proved in numerous clinical studies. In this clinical study, we compared the diagnostic performance of this technique in a multicenter study using different systems with conventional unenhanced ultrasound as well as with contrast-enhanced CT and MRI, being the current state-of-the-art methods for characterization of focal liver lesions. Contrast specific US scanning modes, equipments, manufacturers, transducers and range of low mechanical index are extremely varied in clinical practice and validation of SonoVue®-enhanced sonography in a multicenter and multi-equipments study is an essential requirement before introducing this method in routine clinical practice.

Our purpose was to evaluate in a controlled multicenter study whether the characterization of focal liver lesions can be improved by using SonoVue®-enhanced sonography, as compared with unenhanced sonography, contrast-enhanced CT and contrast-enhanced MRI.

## MATERIALS AND METHODS

### Study population

The study population consisted of 179 patients [85 men and 94 women, mean age 55.3 years (range 19-93)] with one single focal liver lesion, detected with unenhanced sonography (screening). The lesion had to be clearly identifiable in the different modalities (US, CT, MRI) for matching of results. Exclusion criteria were age < 18 years, pregnant or lactating women, acoustic window insufficient for adequate sonographic examination of the liver, a contra-indication to SonoVue® or any of the

diagnostic examinations, and/or inability to give informed consent.

This study was a phase IIIb, multicenter, multinational, open label within patient comparison in 9 centers (5 in France, 2 in Czech Republic, 1 in Belgium and 1 in Poland), performed between December 2003 and February 2005. The study was performed according to Good Clinical Practice (GCP) and the ethical principles of the declaration of Helsinki, in particular approval by the responsible Ethical Committees was obtained and all patients gave written informed consent. Due to the fact that a new imaging modality (dynamic low-MI real time sonography) was used, a technical run-in phase was performed to allow establishment of adequate machine settings with 45 patients (5 in each center). The following 134 patients were part of the main phase and constituted the intent-to-treat population. Of these 134 patients 7 patients were excluded due to the following reasons: missing reference examination (CT and MRI) in 3 patients, reference examination outside of acceptable time window ( $\pm$  3 mo) in 2 patients, ultrasound examination not possible due to technical reasons in 1 patient and final reference diagnosis not supported by valid reference examinations in 1 patient. Therefore, the protocol-correct population used for efficacy analysis consisted of 127 patients [54 men and 73 women, mean age  $54.8 \pm 19.9$  years (range 19-93), mean height  $168.7 \pm 8.5$  cm (range 154-190), mean weight  $69.7 \pm 13.7$  kg (range 43-106)].

### Imaging procedures

All imaging examinations were performed by experienced radiologists. For the contrast-enhanced ultrasound examinations a technical training was performed, including an educational lecture, local setup of contrast-specific software and standard settings in cooperation with contrast ultrasound application specialists and examination of 5 run-in patients under technical supervision. Different US systems were used (Table 1). The sequence of the different imaging procedures (i.e. US, CT and MRI) was not fixed by the study protocol and could be arranged to the organizational situations in the different study center. All examinations should have been performed within 14 d, however in individual cases a time range of up to 3 mo was accepted if there was no treatment or indication of significant changes in between, to avoid repeated radiation exposure.

### Baseline ultrasound

First, an unenhanced sonography was performed to verify the presence of one single focal liver lesion with grey-scale imaging (B-mode). Each focal lesion was measured, localized (Couinaud segments) and the characteristic features (border, shape, echogenicity) were described. The vascularisation was assessed by color Doppler ultrasound. Representative sequences of the examination were stored digitally.

### Contrast-enhanced ultrasound (CEUS)

Each patient received at least 2 bolus injections of

**Table 1** US equipment and contrast-specific modes

Equipment manufacturer	Scanning mode	No. of patients scanned	Transducer	Mechanical index
Elegra, Siemens	Ensemble contrast imaging (ECI)	25	Convex array 3.5C40H	0.10-0.30

SonoVue®, a first one for characterization of the detected focal lesion and another one for detection of additional lesions. Contrast-enhanced sequences were obtained using dedicated low-MI contrast-imaging software (MI < 0.2). Standard pre-settings were used, with the possibility to adjust settings to the individual patient. SonoVue® was injected intravenously as a bolus of 2.4 mL, using a 20 gauge cannula placed in the antecubital vein, followed by a flush of 5 mL normal saline solution. Digital cine clips representing the dynamic contrast enhancement within the lesion and the surrounding liver tissue were recorded continuously, starting 5 s before the SonoVue® injection and covering the arterial (i.e. 10-45 s inject.), portal (i.e. 60-90 s inject.) and late (i.e. 120-150 s inject.) phase. In case of a suspected hemangioma, additional 15 s scans were performed after 240 s and 300 s. The injection could be repeated in case of technically insufficient quality, using the same dose (2.4 mL) or double dose (4.8 mL), up to a total dose of 9.6 mL SonoVue®. All sequences were recorded and stored digitally. Intratumoral vascular geometry and enhancement pattern of the lesions were described.

#### Analysis of malignancy and lesion type

The lesion was classified separately for unenhanced and SonoVue®-enhanced sonography as benign, indeterminate or malignant. In addition, the particular type of lesion was determined according to pre-defined criteria (Table 2).

With unenhanced sonography the classification was based on echogenicity, morphological criteria, and color Doppler signals reflecting abnormal vascularity, using the following criteria: lesion size, lesion depth, border definition (clear or blurred), shape (round, oval or irregular) and echogenicity (hypoechoic, isoechoic or hyperechoic).

With contrast-enhanced sonography, the classification was based on the dynamic enhancement pattern reflecting vascularity and perfusion pattern of the lesion, using the following criteria: vascularity (no intratumoral vessel, straight feeding vessels, irregular feeding vessels, radial intratumoral vessels/spoke and wheel sign or basket-like

vessels around the lesion), enhancement pattern in arterial and portal-venous phase (hypoenhancing, isoenhancing or hyperenhancing) and homogeneity of enhancement (homogeneous or non-homogeneous). The characteristic enhancement pattern used for classification were in accordance with pattern described earlier for CT, MRI and contrast-enhanced US<sup>[17]</sup>.

#### CT and MRI examination

All patients received at least one triple phase contrast-enhanced reference examination with CT or MRI. Single-slice CT was available in 37/127 patients, multi-slice CT in 78/127 patients and dynamic MRI in 70/127 patients. In all (except one) patients having just a single-slice CT, an additional dynamic MRI examination was performed to be sure to have a proper representation of the different enhancement phases in the reference examination. In the one patient with just a single slice CT without additional MRI, all imaging examinations resulted in the same diagnosis (HCC), which was confirmed by histology, so that the reference examination was considered to be acceptable. In patients having a CT and MRI examination available, a combined tomographic diagnosis (consensus) was made.

#### Histology

In 32 patients, a histological examination of the lesion was available. Samples for histology could be obtained by biopsy or surgical resection, according to the clinical situation and requirements. Due to ethical reasons, no tissue samples were taken for study reasons only without clinical indication<sup>[25]</sup>. From 32 histology specimen 2 were classified as indeterminate, so that in 30 patients a histological diagnosis could be obtained.

#### Final reference-standard diagnosis

After all examinations were completed, a final diagnostic assessment was performed, taking into consideration all-available imaging examinations and clinical information (i.e. US, CT, MRI, clinical data, biochemical markers and histology, if available) of the respective patient. This was considered to reflect the true-disease-state of the

**Table 2 Classification and diagnostic criteria for the assessment of focal liver lesions**

<b>Lesion type</b>	<b>Arterial phase</b>	<b>Portal venous phase</b>	<b>Sinusoidal phase</b>
Malignant lesions			
Hepatocellular carcinoma (HCC)	Hyperenhanced, often with prominent delineation of feeding vessels around and inside of the lesion, however in well differentiated tumors sometimes only weak arterial enhancement	Iso- or hypoenhanced, usually rapid contrast wash-out	Mostly hypoenhanced, however in well differentiated tumors some portal venous enhancement may be present
Cholangiocarcinoma (CCC)	Moderately hyperenhanced	Iso- or hypoenhanced	Mostly hypoenhanced
Hypervascular metastases (MET)	Hyperenhanced, often restricted to the margin of the lesion	Iso- or hypoenhanced	Always hypoenhanced (black spots)
Hypo-vascular metastases (MET)	Not enhanced or only few isolated spots inside of the lesion	Hypoenhanced	Always hypoenhanced (black spots)
Other malignant			
Benign lesions			
Hemangioma (typical)	Peripheral nodular enhancement, sharp margin in high-flow hemangiomas: complete filling of the lesion during arterial phase	Slow centripetal progression of the enhancement ('iris diaphragm sign'), leading to an iso- or hyperenhanced appearance; fill-in can be very slowly (lasting minutes) or rather fast (lasting less than a minute)	More or less complete enhancement, prolonged compared to surrounding liver tissue and therefore hyperenhanced at later time points; enhancement may be incomplete in case of (partial) thrombosis
Hemangioma (atypical)	Peripheral nodular enhancement, sharp margin or no enhancement (complete thrombosis) or complete enhancement (high flow hemangioma)	Slow centripetal progression of the enhancement ('iris diaphragm sign'), leading to an iso- or hyperenhanced appearance; fill-in can be very slowly (lasting minutes) or rather fast (lasting less than a minute)	More or less complete enhancement, prolonged compared to surrounding liver tissue and therefore hyperenhanced at later time points; enhancement may be incomplete in case of (partial) thrombosis
Focal nodular hyperplasia (FNH)	Hyperenhanced, with fast centrifugal filling of the lesion; usually a central vessel and radial vascular branches can be delineated, especially in larger lesions ('spoke and wheel sign')	Iso- or hyperenhanced	Iso- or hyperenhanced, central scar may become visible
Hepatic adenoma	Hyperenhanced, frequently with fast centrifugal filling and rapid contrast wash-out; no radial vascular structures visible	Iso- or hyperenhanced; hypoenhanced areas in case of central bleeding or scar	Iso- or hyperenhanced; hypoenhanced areas in case of central bleeding or scar; no central scar or radial intralesional structures
Large regenerating or dysplastic nodules	Isoenhanced	Isoenhanced	Isoenhanced
Focal fatty accumulation	Isoenhanced	Isoenhanced	Isoenhanced
Focal fatty sparing	Isoenhanced	Isoenhanced	Isoenhanced
Cyst	No enhancement	No enhancement	No enhancement
Other benign			

patient and used as gold standard. For the final reference diagnosis, malignancy and lesion type was determined using the same classification as described above.

### Statistical analysis

All continuous variables were presented with its summary statistics (*n*, mean, standard deviation and range). Categorical data were given by frequency distribution tables.

Sensitivity, specificity and accuracy for the assessment of malignancy were calculated for unenhanced ultrasound, SonoVue®-enhanced ultrasound and combined CT/MRI, using the final reference diagnosis as gold standard. Indeterminate classifications were rated as incorrect classifications. Patients for whom the final reference diagnosis was indeterminate (*n* = 4) were excluded from these analyses. Differences between unenhanced ultrasound, SonoVue®-enhanced ultrasound and combined CT/MRI were analysed by using McNemar test two-sided test. *P* < 0.05 was considered as statistically significant.

## RESULTS

Complete data for unenhanced and SonoVue®-enhanced ultrasound were obtained in 127 patients. Four patients were excluded because no decisive final reference diagnosis could be obtained (indeterminate character of the lesion), so that in 123 patients the accuracy of the ultrasound examinations *versus* the final reference diagnosis could be calculated.

According to the final reference diagnosis, 68 focal liver lesions were benign and 55 were malignant. The detailed lesion characters of target lesions are presented in Table 3. The number of correctly classified lesions was significantly higher with SonoVue®-enhanced ultrasound compared to unenhanced ultrasound (benign lesions: 60/68 vs 25/68, malignant lesions: 54/55 vs 22/55). This results in a sensitivity, specificity and accuracy of 98.2%, 88.2% and 92.7% for CEUS compared to 40.0%, 36.8% and 38.2% for unenhanced ultrasound, respectively. In comparison unenhanced US

**Table 3** Lesion character of target lesion: SonoVue®-enhanced sonography vs other imaging modalities and final reference diagnosis n (%)

	Unenhanced sonography	SonoVue®-enhanced sonography	CT and/or MRI	Histology	Final reference diagnosis
n	127	127	115	31	127
Benign	25 (19.7)	61 (48.0)	41 (35.7)	8 (25.8)	68 (53.5)

CT: Computed tomography; MRI: Magnetic resonance imaging.

was significantly ( $P < 0.0001$ ) less sensitive, specific and accurate than SonoVue®-enhanced ultrasound.

In 2 patients, no CT/MRI evaluation of the target lesion could be obtained. Therefore, a comparison of the accuracy of SonoVue®-enhanced ultrasound and combined CT/MRI examination could be performed in 121 patients.

Correct classifications of benign lesions could be obtained with CEUS in 59/67 lesions and with CT/MRI in 50/67 lesions. Correct classifications of malignant lesions could be obtained with CEUS in 53/54 lesions and with CT/MRI 37/54 lesions. This results in a sensitivity, specificity and accuracy of 98.2%, 88.1% and 92.6% for CEUS compared to 68.5%, 74.6% and 71.9% for CT/MRI. In comparison CT/MRI was significantly less sensitive ( $P < 0.0001$ ), less specific ( $P < 0.029$ ) and less accurate ( $P < 0.0001$ ) than SonoVue®-enhanced ultrasound. In the subgroup of patients with histological diagnosis as part of the final reference standard ( $n = 30$ ) the excellent performance of SonoVue®-enhanced ultrasound could be confirmed. Sensitivity, specificity and accuracy of the 3 modalities were 95.5%, 75.0% and 90.0% for CEUS, 72.7%, 37.5% and 63.3% for CT and 81.8%, 42.9% and 66.6% for MRI, respectively.

Looking on the false positive classifications (malignant or indeterminate instead of benign) of the different methods CEUS was indeterminate in 5 patients and wrongly classified two FNH (as HCC and hypervascular metastasis) and one adenoma (as hypovascular metastasis). CT was indeterminate in 17 patients and missed the lesion in 2 patients. MRI was indeterminate in 11 patients. With regard to false negative findings (benign or indeterminate instead of malignant), CEUS was indeterminate in 1 patient with an HCC. CT was indeterminate in 17 patients and misdiagnosed 1 hypovascular metastasis as hemangioma. MRI was indeterminate in 9 patients, missed one hypervascular metastasis and misdiagnosed one

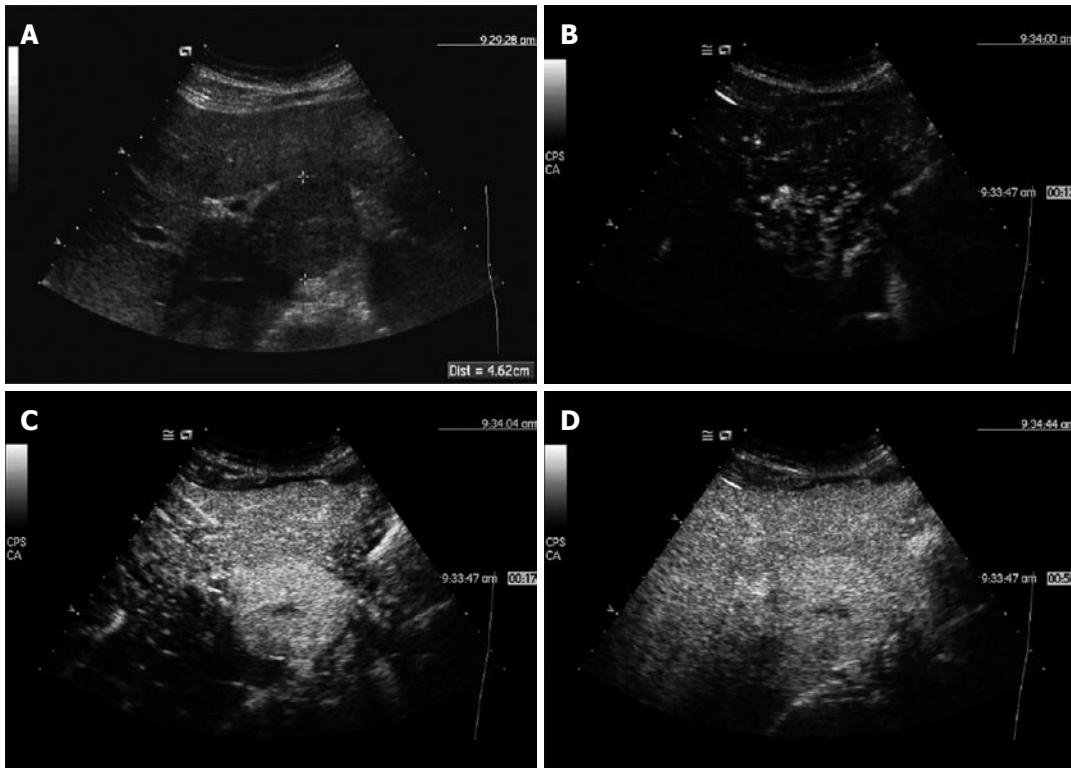

hypovascular metastasis as hemangioma.

Safety assessment was performed in all patients receiving SonoVue® ( $n = 179$ ). Four adverse events were reported, 3 with mild and 1 with moderate intensity. Three of these adverse events were local reactions at the injection site (2 pain and 1 pruritic rash), from which 2 (1 pain and 1 rash; 1.1% of the patients population) were considered to be possibly related to the contrast agent. One adverse event was systemic (nausea), but this was considered related to a recent cholecystectomy and not to the study agent. The related adverse events were of mild intensity and both patients recovered spontaneously without sequelae.

## DISCUSSION

Characterization of a focal liver lesion requires the assessment of morphological characteristics as well as vascularity and enhancement patterns within the lesion. Therefore, the administration of a contrast agent, demonstrating the intratumoral vascularity and blood flow, gives essential information for the characterization of focal liver lesions. In CT and MRI, the acquisition of contrast-enhanced images in different phases is a well-established standard procedure<sup>[4-6]</sup>. In ultrasound, the standard approach for focal lesion characterization includes only the use of color-coded Doppler imaging, which is not able to demonstrate microvascular flow and dynamic enhancement patterns<sup>[1-3]</sup>. With the introduction of second generation ultrasound contrast agents like SonoVue®, in combination with appropriate scanner technology (low-MI real-time contrast imaging), the assessment of intratumoral vascularity and dynamic enhancement pattern became possible, comparable to the information obtained by CT and dynamic MRI<sup>[17,26-28]</sup>.

Contrast-enhanced imaging with ultrasound has two major advantages: (1) the microbubble contrast agents

**Figure 1 45-year-old female patient.** A: 4.6 cm isoechoic lesion in segment 1 found in B-Mode sonography; B: Contrast-enhanced sonography with SonoVue® showed an early arterial enhancement with radial intratumoral vessels seen 13 s after injection; C: Strong enhancement of the whole lesion after 17 s, with a central scar becoming visible; D: In the portal phase, the lesion becomes isoenhancing with the surrounding normal liver tissue. The enhancement pattern is typical for a focal nodular hyperplasia (FNH).

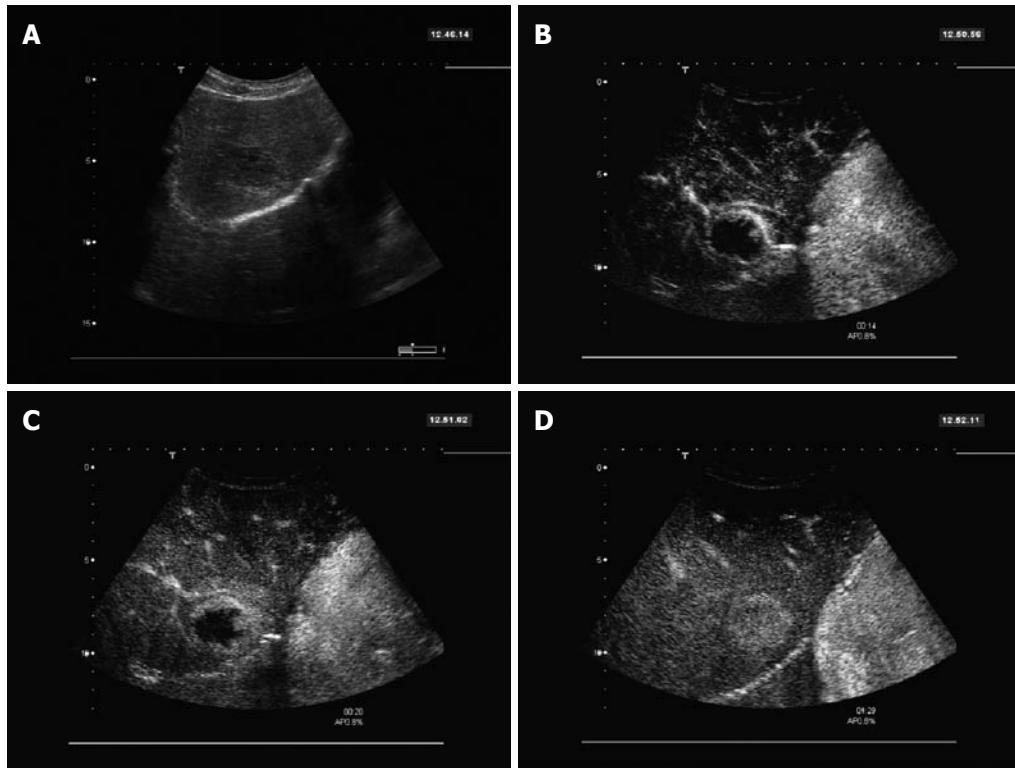

are real blood-pool agents not leaving the intravascular space and (2) a continuous imaging over the whole enhancement period with high temporal resolution is possible, not limited to distinct, pre-defined time points<sup>[18,19]</sup>. Furthermore contrast-enhanced ultrasound has many other advantages, such no exposure to radiation, and absence of nephrotoxic contrast agents and large availability of machines.

There are already several studies published, demonstrating the safety and efficacy of this method for the diagnosis of focal liver lesions, however most of these studies were single-center studies performed with just one type of machine<sup>[9,10,26]</sup>. This clinical study investigated the diagnostic performance of SonoVue®-enhanced ultrasound in the characterization of focal liver lesion in an international multicenter and multi-equipment setting in comparison to established CT and MRI examinations, using a final reference diagnosis based on all available imaging, histology and clinical information as gold standard.

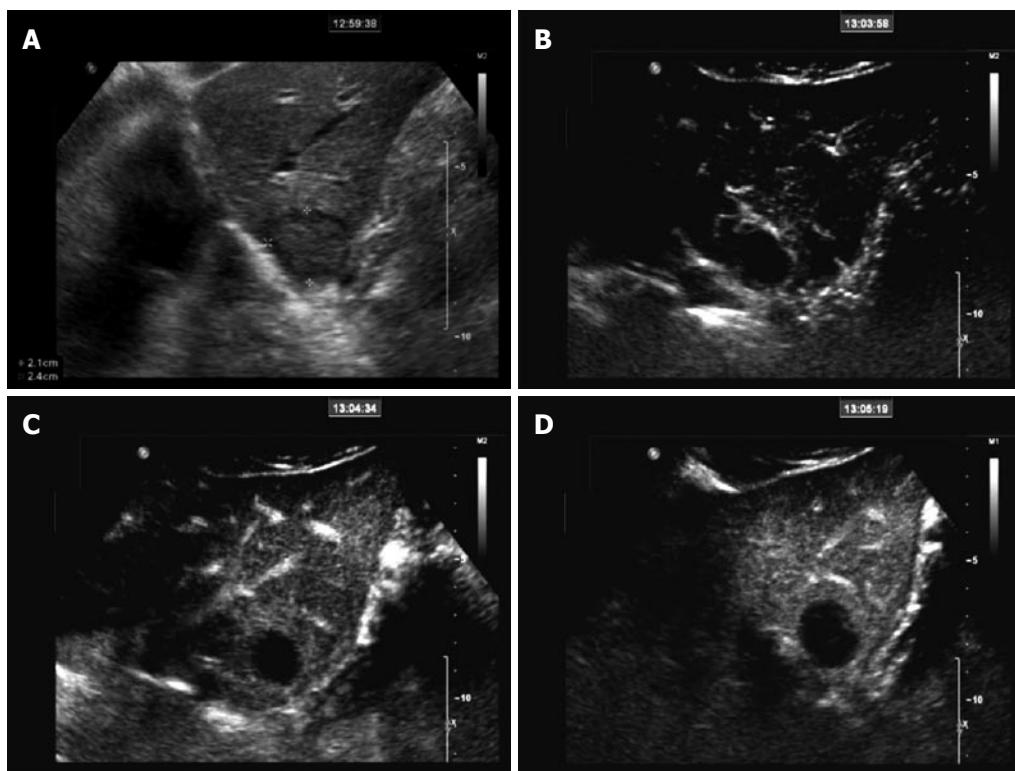

The results of this study confirm the excellent performance of real-time contrast-enhanced ultrasound for focal liver lesion characterization which is clearly superior to that of unenhanced ultrasound, as shown already in other studies with SonoVue® and other microbubble contrast agents<sup>[10-17,26-29]</sup>. Furthermore, this study demonstrates, that the diagnostic accuracy of SonoVue®-enhanced ultrasound is even better than that of contrast-enhanced CT and MRI. The markedly improved accuracy of SonoVue®-enhanced compared

to unenhanced sonography (+ 54.5%) is statistically significant ( $P < 0.0001$ , McNemar's test) and of high clinical relevance. Usually, sonography is the first-line examination for the assessment of focal liver lesions and the high number of 'indeterminate' evaluations found with unenhanced ultrasound causes the high number of follow-up examinations found in today's clinical practice, along with all the costs and discomfort for the patient. The comparable low accuracy for unenhanced sonography in our study could be explained by the high number of patients with malignant lesions (43.3%) in our study population, which was intended to obtain a balanced study population for characterization but does not reflect the distribution in an unselected study population. In our study population, benign lesions with typical B-Mode appearance (cysts, typical hemangiomas, typical FNH), which are easy to characterize based on morphological criteria, were less frequent, making the characterization more difficult compared to an unselected patient population. However, even in an unselected patient population unenhanced sonography is known to be clearly less accurate than the 92.7% accuracy obtained in our study with SonoVue®-enhanced Sonography<sup>[1-3]</sup>.

For the diagnosis of benign lesions (especially FNH and hemangioma), correct diagnosis is the only issue since usually no further activities are required. Therefore, incorrect classification of a malignant lesion is the main concern. In our study, there was only one false-negative characterization with SonoVue®-enhanced sonography

**Figure 2 36-year-old female.** A: 4.0 cm hypoechoic lesion in segment 8 found in B-Mode sonography; B: Contrast-enhanced sonography with SonoVue® showed a peripheral enhancement with nodular contrast accumulations 14 s after injection; C: Slow progression of the enhancement from the periphery towards the center of the lesion, with a broader peripheral enhancement zone seen at 20 s; D: After 1.5 min, the lesion is completely filled with contrast and appears hyperenhanced compared to the surrounding normal liver tissue. The enhancement pattern is typical for a hemangioma.

**Figure 3 44-year-old male patient with a history of rectal carcinoma.** A: 2.4 cm isoechoic lesion in segment 2/3 found in B-Mode sonography; B: Contrast-enhanced sonography with SonoVue® showed a distinct rim enhancement in the peripheral zone of the lesion 13 s after injection, representing the abnormal arterial supply of the lesion; C: Early washout of the contrast enhancement in the portal phase and lack of any portal enhancement resulted in a hypo enhancement of the lesion compared to the surrounding normal liver tissue; D: In the late phase, complete lack of enhancement within the lesion (black spot) allows a clear discrimination of the lesion from the strongly enhanced normal liver tissue. The enhancement pattern is typical for a hypovascular metastasis.

(1 out of 55 patients with malignancies), a lesion which was diagnosed as indeterminate instead of malignant. The tumor was an HCC with hypoenhancement in arterial and portal venous phase. The final diagnosis could only be obtained by histology, since also with CT just an indeterminate diagnosis could be made due to the non-characteristic enhancement pattern. For exclusion of malignancy we observed 5 indeterminate and 3 false malignant classifications out of 68 patients with benign lesion. All of these lesions corresponded to atypical enhancement patterns (4 FNH, 1 adenoma, 2 hemangioma, and 1 hepatic fibrosis).

SonoVue®-enhanced ultrasound turned out to be even more sensitive, specific, and accurate for the characterization of doubtful focal liver lesions compared to CT/MRI. Percentage point differences were 29.7% for sensitivity (recognition of malignancy), 13.6% for specificity (exclusion of malignancy), and 20.8% for accuracy. Sensitivity was nearly perfect for the SonoVue®-enhanced sonography (98.2%) in comparison to the much lower sensitivity of CT/ MRI (68.5%). The higher accuracy of SonoVue®-enhanced sonography may be explained by the real-time capabilities of dynamic low-MI contrast sonography, allowing a continuous assessment of the whole enhancement period, whereas in CT and MRI spiral scans at distinct time points (usually early arterial, late arterial, portal-venous and - in MRI - late phase)<sup>[4-6]</sup>. Especially the very early contrast period (8-12 s post injection) is usually missed with CT/MRI, but may provide crucial diagnostic information especially in highly arterialized lesions. For example, this early arterial phase was particularly useful for the FNH demonstrating the centrifugal hyper-enhancement with a central vessel and radial vascular branches (Figure 1), for haemangioma showing the very early nodular enhancement (Figure 2) or for hypovascular metastasis to demonstrate few isolated spots in the lesions with marked wash-out in portal and late phase (Figure 3). Furthermore, the blood-pool characteristics of SonoVue® prevent the extravasation of the contrast agent (present in conventional CT and MRI contrast agents), which may obscure vascular flow information especially at later time points (equilibrium phase in CT/MRI)<sup>[26]</sup>. The data collected in this study suggest that contrast-enhanced sonography is the best imaging modality for the characterization (malignant/benign) of focal liver lesions.

A limitation of this study is the lack of an off-site assessment with blinded and separated unenhanced and combined unenhanced/contrast-enhanced sequences, to evaluate the accuracy of the pure image sequences without any clinical patient information and with validated blinding with regard to reference examinations. Information about patient's characteristics (e.g. laboratory values) may influence the pre-test probability for malignancy and thus facilitate the classification by imaging. However, this reflects the situation in routine clinical practice. The improvement of the sonographic characterization with SonoVue® can be explained by the additional information on vascularity and perfusion obtained with the analysis of the dynamic enhancement pattern of the

lesions, which is standard in CT and MRI examinations (generally using contrast enhanced sequences for characterization) but not in conventional sonography (just assessing morphological criteria and Doppler signals in large vessels). An unenhanced examination should be considered as inadequate for the characterization of focal liver lesions, which can't be clearly classified as benign due to unequivocal morphological criteria. Contrast-enhanced ultrasound should be the preferred first-line examination for the characterization of such lesions, followed by supplementary CT/MRI examinations or histological confirmation, if required.

## COMMENTS

### Background

The characterization of liver lesions with imaging is based on the examination of the vascularity and enhancement pattern within the lesion. SonoVue® is an Ultrasonographic contrast agent allowing the assessment of vascularity and enhancement pattern of focal lesions with ultrasound in real-time.

### Research frontiers

The authors demonstrate the higher accuracy of contrast-enhanced sonography related to the real-time capabilities of dynamic contrast sonography, allowing a continuous assessment of the whole enhancement period, whereas in computed tomography (CT) and in magnetic resonance imaging (MRI) spiral scans at distinct time points (usually early arterial, late arterial, portal-venous and - MRI - late phase).

### Innovations and breakthroughs

There are already several studies published, demonstrating the safety and efficacy of contrast-enhanced ultrasonography for the diagnosis of focal liver lesions. However most of these studies were single-center studies performed with just one type of machine. This clinical study investigated the diagnostic performance of contrast-enhanced ultrasound in the characterization of focal liver lesion in an international multicenter and multi-equipment setting in comparison to established CT and MRI examinations.

### Applications

Contrast-enhanced ultrasound should be the preferred first-line examination for the characterization of liver lesions, followed by supplementary CT/MRI examinations or histological confirmation, if required.

### Terminology

SonoVue® is an ultrasonographic contrast agent composed by micro bubbles. It is used with specific contrast-enhanced sequences obtained using low-mechanical index (MI) imaging software ( $MI < 0.2$ ). Low-mechanical index or low acoustic pressure is used to do not destroy the microbubbles too fast to allow multiphasic imaging. The real-time capability of sonography in comparison with CT or MRI is related to a better temporal resolution of this technique.

### Peer review

The authors evaluated in a controlled multicenter study whether the characterization of focal liver lesions can be improved by using SonoVue®-enhanced sonography, as compared with unenhanced sonography, contrast-enhanced CT and contrast-enhanced MRI. Contrast-enhanced sonography emerges as the most sensitive, most specific and thus most accurate imaging modality for the characterization of focal liver lesions.

## Abstract

**AIM:** To investigate RNA interference targeting signal transducer and activator of transcription-3 (STAT3) on invasion of human pancreatic cancer cells.

**METHODS:** We constructed three plasmids of RNA interference targeting the STAT3 gene. After LV (lentivirus)-STAT3siRNA (STAT3 small interfering RNA) the vector was transfected into the human pancreatic cell line, SW1990 and cell proliferation was measured by the MTT assay. Flow cytometry was used to assess cell cycle. Vascular endothelial growth factor (VEGF) and matrix metalloproteinase-2 (MMP-2) mRNA and protein expression were examined by quantitative PCR and western blotting, respectively. The invasion ability of SW1990 cells was determined by cell invasion assay.

**RESULTS:** We successfully constructed the LV-STAT3siRNA lentivirus vector and proved that it can suppress expression of STAT3 gene in SW1990 cells. RNA interference of STAT3 by the LV-STAT3siRNA construct significantly inhibited the growth of SW1990 cells, in addition to significantly decreasing both VEGF and MMP-2 mRNA and protein expression. Moreover, suppression of STAT3 by LV-STAT3siRNA decreased the invasion ability of SW1990 cells.

## INTRODUCTION

Pancreatic cancer is a highly lethal disease that is usually diagnosed at an advanced stage for which there is little or no effective therapy. It remains the fourth most common cause of cancer-related death in the western world<sup>[1]</sup>. The annual incidence rate of pancreatic cancer is almost identical to the mortality rate; approximately 37 000 new cases are diagnosed each year in the United States, and approximately 33 000 patients die from this disease<sup>[2]</sup>. Due to the aggressive natural history of this disease, less than 10% of these cases constitute candidates for surgical resection at the time of diagnosis. Although an adjuvant treatment regimen after surgical resection seems to prolong survival, the precise treatment protocol including drug-of-choice is still debated and the focus of several ongoing clinical trials<sup>[3]</sup>. Effective systemic therapy capable of reversing the aggressive biology of this disease is currently not available. Thus, understanding the molecular mechanisms of pancreatic cancer is one of the most important issues for treatment.

Signal transducer and activator of transcription 3 (STAT3) is an oncogene that is activated by phosphorylation of a conserved tyrosine residue in response to extracellular signals and oncogenes. Once tyrosine is phosphorylated, STAT3 monomers form dimers through reciprocal phosphotyrosine-SH2 interactions. The dimers are phosphorylated STAT3 (P-STAT3), which translocate to the nucleus and bind to cognate DNA sequences, regulate the transcription of target genes and modulate fundamental cellular processes, such as proliferation and differentiation<sup>[4]</sup>. Inappropriate and constitutive activation of STAT3 may be responsible for pancreatic cancer progression through regulating the expressions of target genes, such as Bcl-xL, Mcl-1, Bcl-2, Fas, cyclin D1, survivin, c-Myc, VEGF, MMP-2 and MMP-9<sup>[5-7]</sup>. Many studies have indicated that the constitutive activation of STAT3 influences invasion and metastasis. Specifically, the level of activated STAT3 protein has been found to be associated with invasion in thymic epithelial tumors<sup>[8]</sup>, colorectal adenocarcinoma<sup>[9]</sup>, and cutaneous squamous cell carcinoma<sup>[10]</sup>. Conversely, inhibition of the STAT3 signaling pathway suppresses cancer cell growth, invasion and induces apoptosis in various cancers<sup>[11]</sup>. Thus, the STAT3 signaling pathway may be one of the common pathways involved in regulating cancer invasion.

Small hairpin RNA (shRNA) expression vector systems have been established to induce RNA interference (RNAi) in mammalian cells<sup>[12]</sup>. Although these vectors provide certain advantages over chemically synthesized siRNAs, some disadvantages remain, including transient shRNA expression and low transfection efficiency, especially in non-dividing primary cells. To overcome these limitations, shRNA delivery systems using retroviral vectors<sup>[13]</sup>, adenoviral vectors<sup>[14]</sup> and, more recently, lentiviral vectors<sup>[15]</sup> have been reported and proven to be safe for humans. Lentivirus vectors encoding antisense targeting sequence have been used in clinical trials with no obvious side effects<sup>[16,17]</sup>. Lentivirus-delivered shRNAs are capable of specific, highly stable and functional silencing of gene expression in a variety of human cells including primary non-dividing cells and also in transgenic mice<sup>[18,19]</sup>.

In our study, we constructed a lentivirus vector mediating RNAi targeting of STAT3 (LV-STAT3siRNA). The efficacy of LV-STAT3siRNA plasmids in interference with STAT3 was confirmed by real-time PCR and western blotting. We found that LV-STAT3siRNA suppressed growth and invasion by markedly decreasing the expression of VEGF and MMP-2 in SW1990 cells, but LV-Con (control) had no effect on SW1990 cells. Since the STAT3 signaling pathway is critical for growth and the invasive behavior of pancreatic cancer, silencing of the STAT3 gene with RNAi may provide a novel strategy for investigation of the role of STAT3 gene in the invasion of human pancreatic cancers.

## MATERIALS AND METHODS

### Construction and production of lentivirus vectors

We designed and cloned a shRNA template into a

lentivirus vector. A third generation self-inactivating lentivirus vector containing a CMV-driven GFP reporter and a U6 promoter upstream of the cloning restriction sites (*Hpa* I and *Xba* I) was used. The introduction of oligonucleotides encoding shRNAs (Figure 1A) between these restriction sites enables the production of the shRNA *in vivo*. Three coding regions corresponding to targeting human STAT3 starting at positions 466, 1638, and 1061 in the sequence (GenBank Accession: NM 39276) were selected as siRNA target sequences under the guide of siRNA designing software offered by Genscript. We constructed three shRNA-STAT3 lentivirus vectors, namely LV-STAT3siRNA-1, LV-STAT3siRNA-2 and LV-STAT3siRNA-3, respectively (Table 1). Briefly, oligonucleotides were annealed, digested and inserted between the *Hpa* I and *Xba* I restriction sites of the plasmid vector. Some mutations were introduced in the sense sequence of the hairpin structure to facilitate sequence and avoid destruction by bacteria during amplification in the bacterial host. Correct insertions of shRNA cassettes were confirmed by restriction mapping and direct DNA sequencing. We constructed a STAT3 over-expression vector, pEGFP-N1-STAT3 (Figure 1B), and co-transfected with recombinant lentivirus vectors into 293T cells using Lipofectamine 2000 (Invitrogen, Carlsbad, CA, USA). To detect the interference effects of different target, STAT3 protein expression was determined using western blotting. Recombinant lentivirus vectors and control lentivirus vectors were produced by co-transfecting 293T cells with the lentivirus expression plasmid and packaging plasmids (pHelper 1.0 including *gag/pol* and pHelper 2.0 including VSV-g). Infectious lentivirus vectors were harvested at 48 h post-transfection, centrifuged to remove cell debris, and filtered through 0.45 μm cellulose acetate filters. The infectious titer was determined by hole-by-dilution titer assay. The virus titers produced were approximately 10<sup>9</sup> transducing U/mL medium.

### Cell culture and infection

The human pancreatic cancer cell line, SW1990, and 293T cells were purchased from the American Type Culture Collection. Cells were grown in 5% CO<sub>2</sub> saturated humidity, at 37°C and cultured as monolayers in RPMI 1640 supplemented with penicillin/streptomycin, 2 mmol/L glutamine and 10% FBS. Cells were subcultured at 1 × 10<sup>5</sup> cells per well into six-well tissue culture plates. After 24 h culture, cells were infected with recombinant lentivirus vectors at a multiplicity of infection (MOI) of 40.

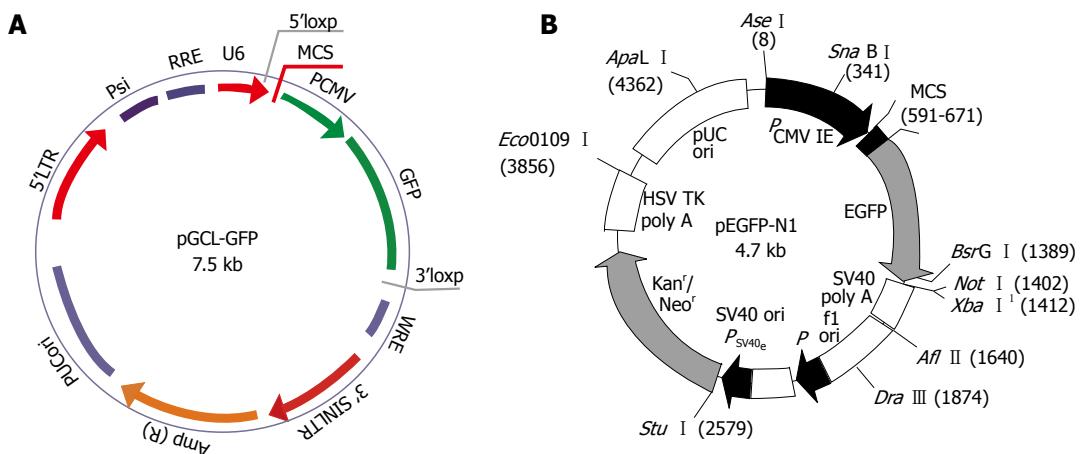

### Cell proliferation assay

Cell proliferation was determined by 3-(4,5-dimethylthiazole-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Pancreatic cancer cells were seeded in 96-well culture plates in culture medium at an optimal density (5 × 10<sup>3</sup> cells per well) in triplicate wells for the LV-STAT3siRNA, LV-Con and parental cells groups. After 1, 2, 3 and 4 d, cells were stained with 20 μL MTT (5 mg/mL) (Sigma, St Louis, MO, USA) at 37°C for 4

**Table 1** Interfering sequence specified for STAT3 gene

Number	Sequence

h and subsequently made soluble in 150 µL of DMSO. Absorbance was measured at 490 nm using a microtiter plate reader. Cell growth curves were calculated as mean values of triplicates per group.

### Flow cytometry

The cell cycle effects of LV-STAT3siRNA on human pancreatic cancer cells were analyzed by flow cytometry. Briefly,  $1 \times 10^5$  cells were trypsinized, washed with PBS, centrifuged at 800 r/min and fixed with 70% cold ethanol overnight. Ethanol was aspirated after centrifugation at 1000 r/min, and the cells were incubated in a solution of propidium iodide (PI) (100 µg), 0.5% Triton-X100 and RNase (2000 µg/mL) for 15 min and analyzed by flow cytometry (FCM).

### Quantification by real-time PCR

Total RNA was isolated using TRIzol LS (Invitrogen, Carlsbad, CA, USA). The concentration and purity of RNA was determined using a spectrophotometer. M-MLV reverse transcriptase (Promega, Madison, WI, USA) was used to create cDNA for further analyses. Quantitative real-time polymerase chain reaction (RT-PCR) assays were carried out using SYBR Green Real-Time PCR Master Mix (Toyobo, Osaka, Japan) and real-time PCR amplification equipment.

The PCR primers used to detect STAT3 and β-actin were as follows: STAT3, sense strand 5'-CCAAGGA

GGAGGCATTG-3', antisense strand 5'-ACATCG GCAGGGTCAATGG-3', with a product length of 147 bp; β-actin, sense strand 5'-TCGTGCGTG ACATTAAGGAG-3', antisense strand 5'-AAGGTA GTTTCGTGGATGCC-3', with a product length of 214 bp. The thermal profile consisted of one cycle at 95°C for 15 min, followed by 45 cycles at 95°C for 15 s and 60°C for 30 s. The expression of STAT3 was determined by normalization of the threshold cycle (C<sub>t</sub>) of these genes to that of the control housekeeping gene (β-actin). The delta Ct was determined using the following equation:  $(\Delta C_t) = (C_t \text{ of STAT3}) - (C_t \text{ of } \beta\text{-actin} \text{ in each group})$ . The  $\Delta C_t$  value obtained was used to find the relative expression of the STAT3 gene according to the following formula: Relative expression =  $2^{-\Delta C_t}$ ,  $\Delta C_t$  = (mean  $C_t$  of STAT3 genes in LV-STAT3siRNA groups) - ( $C_t$  of STAT3 genes in LV-Con group or parental SW1990 group).

The PCR primers used to detect MMP-2, VEGF and β-actin were as follows: MMP-2 sense strand 5'-TAGCATGTCCCTACCGAGTCT-3', antisense strand 5'-ATTGGATGGCAGTAGCTGC-3', with a product length of 151 bp; VEGF sense strand 5'-CTGTCTGGGTGCATTGGA-3', antisense strand 5'-ATTGGATGGCAGTAGCTGC-3', with a product length of 152 bp; β-actin sense strand 5'-CACCAACTGGGACGACAT-3', antisense strand 5'-ATCTGGGTCACTTCTCGC-3', with a product

length of 138 bp. PCR parameters were as follows: 95°C for 20 min, then 95°C for 30 s, 56°C for 30 s, 72°C for 40 s for 40 cycles, 72°C for 10 min. A standard calibration curve for the expression of each mRNA was generated using 8-fold dilutions of a control RNA sample. MMP-2 and VEGF mRNA expression was calculated as a ratio compared with that of β-actin.

### **Western blotting**

Whole-cell protein extracts and nuclear protein extracts from pancreatic cancer cells were prepared with RIPA Lysis Buffer (Santa Cruz Biotechnology, Santa Cruz, CA, USA) and Nuclear Extract Kit (Active Motif, Carlsbad, CA, USA), respectively, according to the manufacturers' instructions. Protein concentrations were determined using an assay kit (Bio-Rad, Hercules, CA, USA).

Lysates containing 100 μg of protein were mixed with loading buffer with 5% β-mercaptoethanol and heated for 5 min at 100°C. Samples were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and transferred onto nitrocellulose membranes by semi-dry blotting.

Membranes were incubated in blocking buffer [tris-buffered saline (TBS), 0.1% Tween 20, and 5% non-fat dry milk] for 1 h at room temperature, followed by hybridization with anti-P-STAT3 (tyr-705) antibody (Cell Signaling Technology, 1:1000 dilution), anti-STAT3 antibody (Cell Signaling Technology, 1:1000 dilution), anti-MMP-2 antibody (Santa Cruz Biotechnology, 1:500 dilution), anti-VEGF antibody (Santa Cruz Biotechnology, 1:500 dilution), GADPH antibody (Lab Vision, Fremont, CA, USA, 1:100 dilution) or anti β-actin antibody (Lab Vision, Fremont, CA, USA, 1:100 dilution) at 4°C overnight.

After 3 washes in TBS/0.1% Tween 20, the membranes underwent hybridization with a horseradish peroxidase-conjugated secondary antibody rabbit IgG (Santa Cruz Biotechnology, 1:5000 dilution) for 1 h at room temperature. After 3 washes in TBS/0.1% Tween 20, signals were detected by chemiluminescence using luminol reagent (Santa Cruz Biotechnology).

### **Invasion assay**

The cell invasion assay was performed using a specialized invasion chamber that included a 24-well tissue culture plate with 12 cell culture inserts (Chemicon, Temecula, CA, USA). The inserts contained an 8 μm pore size polycarbonate membrane with a precoated thin layer of basement membrane matrix (ECMatrix). Briefly, media supplemented with 10% fetal bovine serum was added to the lower chamber as a chemo-attractant. After reaching 60%-70% subconfluence, pancreatic cancer cells were trypsinized, re-suspended in DMEM at 1 × 10<sup>6</sup> cells/mL, and 300 μL of the cell suspension was added to each upper compartment.

After 24 h incubation at 37°C, non-invasive cells were removed from the upper surface of the membrane using a moist cotton-tipped swab. Invasive cells on the lower surface of the membrane, which had invaded the ECMatrix and had migrated through the polycarbonate

membrane, were stained with the staining solution for 20 min and rinsed with distilled water several times. Invasiveness was quantitated by selecting ten different views (400 times) and calculating the number of invading cells.

### **Statistical analysis**

All assays were conducted three times and found to be reproducible. Data were expressed as mean ± SD and the statistical correlation of data between groups was analyzed by Student's *t* test, where *P* < 0.05 were considered significant. These analyses were performed using SPSS 11.0 software.

## **RESULTS**

### **Selection of the most effective STAT3-specific siRNA expression vector**

Three plasmids containing shSTAT3 (pGCL-GFP-STAT3siRNA) and pEGFP-N1-STAT3 were co-transfected into 293T cells, respectively. GFP expression in 293T cells was observed under a fluorescent microscope 36-48 h after transfection with pEGFP-N1-STAT3 and pGCL-GFP-STAT3siRNA. Results of the western blotting assay showed that LV-STAT3siRNA-1 and LV-STAT3siRNA-2 could significantly suppress the expression of STAT3 at the protein level in 293T cells. According to the results of western blotting assay, LV-STAT3siRNA-2 was the most effective lentivirus vector and, thus, was used in the following research (Figure 2).

### **Expression of STAT3 suppressed by LV- siSTAT3-2 in SW1990 cells**

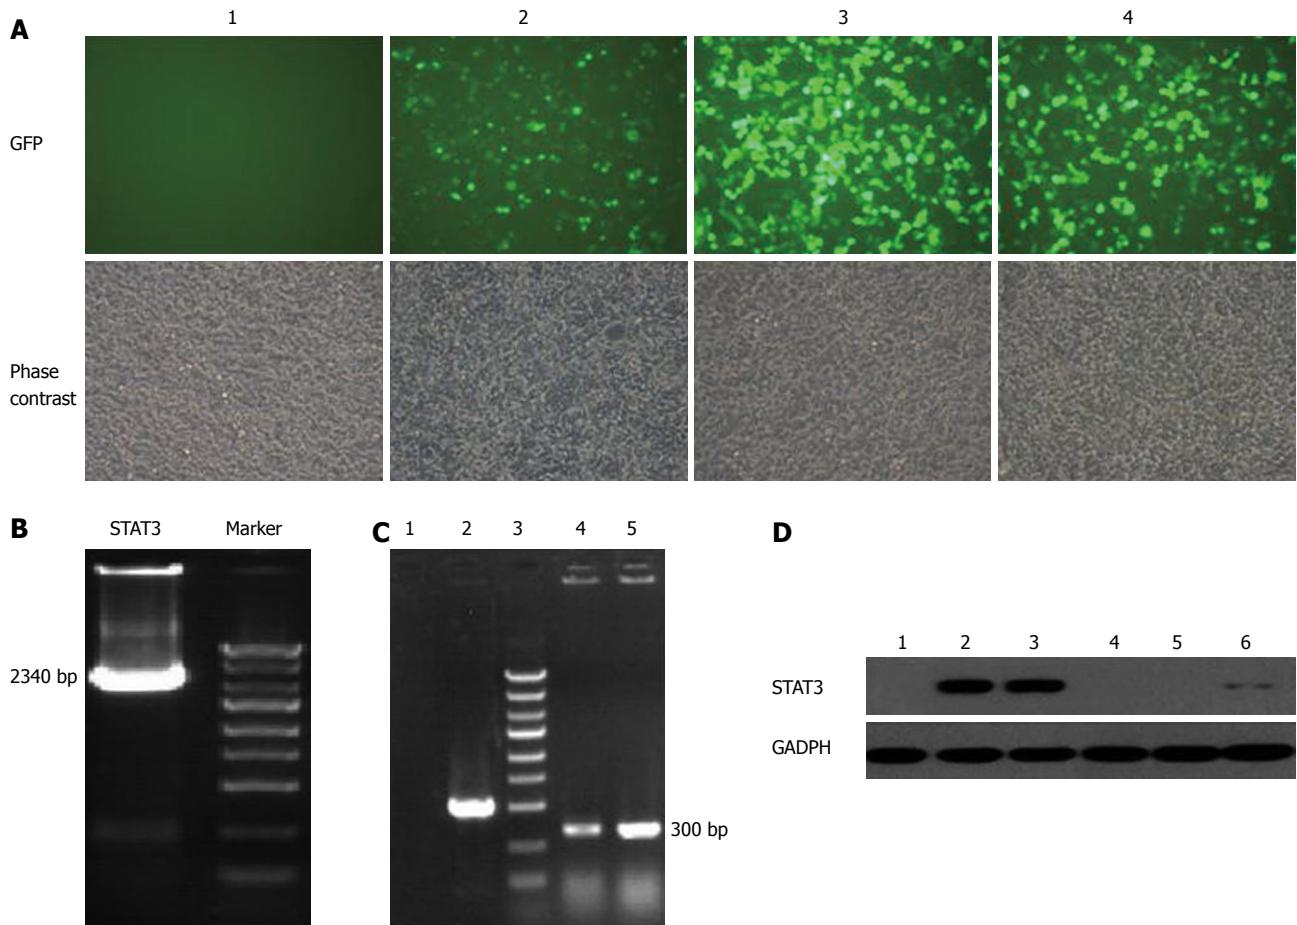

To determine the effect of LV-STAT3siRNA on the expression of STAT3, GFP expression was observed under a fluorescent microscope in SW1990 cells 72 h after infection with LV- siSTAT3-2 at an MOI of 40. Next, real-time PCR and western blotting were performed to determine the mRNA and protein levels of STAT3 in LV-STAT3siRNA-2, LV-Con and parental cell groups. These analyses demonstrated that LV-STAT3siRNA-2 significantly inhibited expression of STAT3 mRNA (*P* = 0.006, *P* = 0.007) and protein compared with SW1990 cells and the LV-Con group (Figure 3).

### **Effects of LV-shSTAT3 on cell growth of SW1990 cells**

Cell proliferation was monitored for four days after SW1990 cells were infected with LV-STAT3siRNA-2 and LV-Con. The growth of cells infected with LV-STAT3siRNA-2 was markedly inhibited compared with LV-Con and parental SW1990 (Figure 4).

### **Effects of LV-shSTAT3 on cell cycle in SW1990 cells**

To investigate the effects of LV-STAT3siRNA-2 on cell cycle, G1, G2 and S phase cells were detected by flow cytometric analysis. The total S phase plus G2 phase fraction was used to measure cell proliferation. SW1990 cells were infected with LV-STAT3siRNA-2 and cell proliferation after 72 h was detected by flow

**Figure 2 Selection of the most effective STAT3 specific siRNA expression vector in 293T cells.** A: Phase contrast and GFP expression under a fluorescent microscope was taken after 36–48 h in 293T cells, 1: 293T cells; 2: Transfection of pEGFP-N1 vector in 293T cells; 3: Transfection of pEGFP-N1-STAT3; 4: Co-transfected of pEGFP-N1-STAT3 and pGCL-GFP-siRNA vectors in 293T cells (original magnification  $\times 200$ ). B: STAT3 gene was cloned from the cDNA library with production of 2340 bp by PCR. C: pEGFP-N1-STAT3 was constructed after restricted enzyme cutting and connection with production of 300 bp by PCR. 1: pEGFP-N1 vector; 2: A special sequence was inserted in pEGFP-N1 vector; 3: Marker; 4-5: STAT3 gene over-expression vector pEGFP-N1-STAT3. D: Protein level of STAT3 in 293T cells was detected by western blotting. Lanes 1-6: 293T cells, STAT3 gene over-expression vector, non-silence control, LV-STAT3siRNA-1, -2, and -3 respectively. LV-STAT3siRNA-1 and LV-STAT3siRNA-2 can significantly knock down expression of STAT3 at the protein level.

**Table 2 Cell cycle detected by flow cytometry (%)**

Group	G1 fraction	G2 fraction	S fraction	G2 + S fraction
SW1990	$35.83 \pm 5.85$	$49.29 \pm 2.80$	$14.45 \pm 3.24$	$63.74 \pm 5.66$
LV-Con	$43.34 \pm 2.14$	$51.88 \pm 3.35$	$4.79 \pm 1.27$	$56.66 \pm 2.14$
LV-STAT3siRNA-2	$52.36 \pm 1.02$	$43.34 \pm 1.14$	$4.30 \pm 2.08$	$47.63 \pm 1.20^{a,c}$

Cell cycle detected by flow cytometry. The G2 + S phase fraction of the LV-STAT3siRNA-2 group was the lowest compared with LV-Con group and parental SW1990 group. This result was consistent with that of the MTT assay. <sup>a</sup> $P < 0.05$  vs SW1990 group, <sup>c</sup> $P < 0.05$  vs LV-Con group.

cytometry. Consistent with the MTT assay (Table 2), LV-STAT3siRNA-2 caused a significant reduction in cell proliferation compared with the control, LV-Con ( $P = 0.003$ ) and parental SW1990 groups ( $P = 0.008$ ).

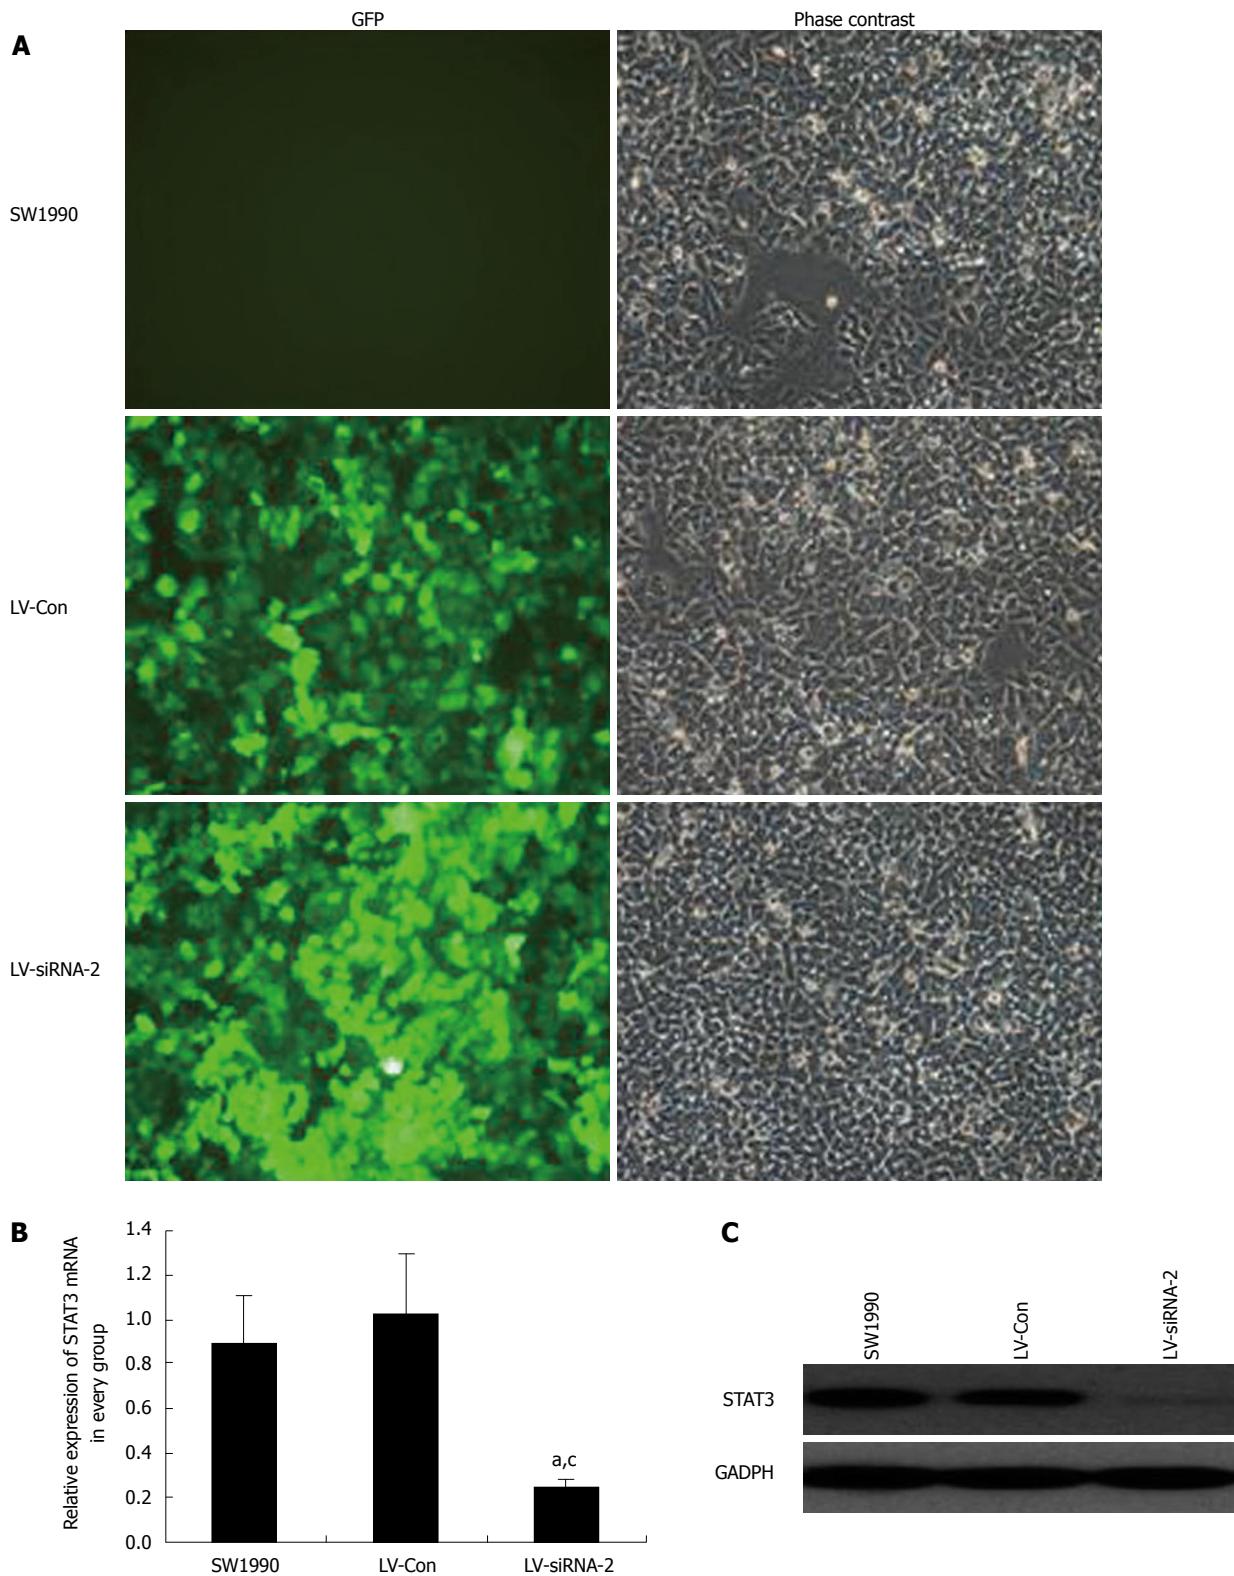

#### Effects of LV-shSTAT3 on VEGF and MMP-2 expression in SW1990 cells

The expression of P-STAT3, MMP-2 and VEGF was analyzed at the mRNA level by real-time PCR (Figure 5A and B). Protein expression was evaluated by western blotting (Figure 5C and D) in the human pancreatic cancer cell lines. Silencing of STAT3 expression by stable

transfection of LV-STAT3siRNA-2 significantly decreased the expression of MMP-2 ( $P = 0.004$ ,  $P = 0.008$ ) and VEGF ( $P = 0.006$ ,  $P = 0.0015$ ) mRNA compared with the control, SW1990 and LV-Con groups. LV-STAT3siRNA-2 could markedly downregulate protein levels of P-STAT3 ( $P = 0.001$ ,  $P = 0.000$ ), VEGF ( $P = 0.031$ ,  $P = 0.025$ ), and MMP-2 ( $P = 0.007$ ,  $P = 0.026$ ) in SW1990 cells compared with the SW1990 and LV-Con groups.

#### Effects of LV-shSTAT3 on invasion ability in SW1990 cells

An *in vitro* cell invasion assay was performed and the

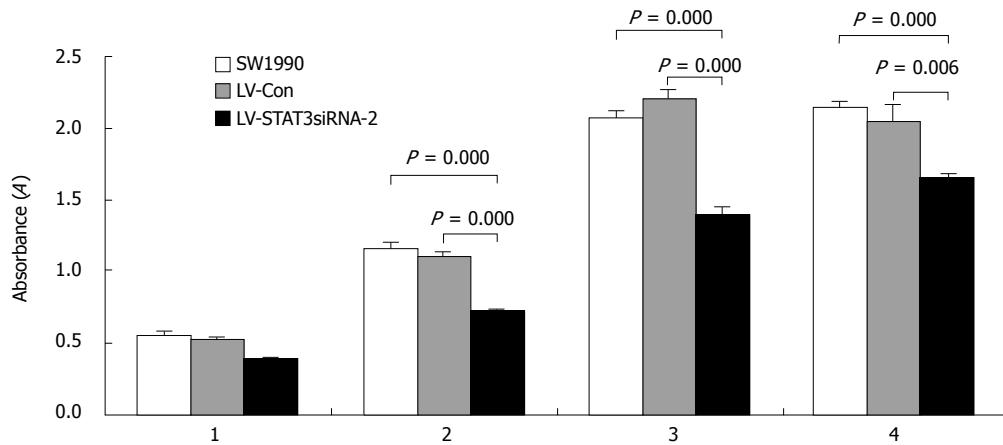

**Figure 3 Expression of STAT3 suppressed by LV-siSTAT3-2 in SW1990 cells.** A: SW1990 cells were infected with LV-Con or LV-STAT3siRNA-2; The cells were infected (MOI = 40), GFP expression and the phase contrast images were taken after 72 h (original magnification  $\times 200$ ). B: mRNA level of STAT3 after SW1990 cells were treated with LV-STAT3siRNA-2 and LV-Con detected by real-time PCR. LV-STAT3siRNA-2 significantly inhibited expression of STAT3 mRNA in SW1990 cells,  $^aP < 0.05$ , compared with SW1990 cells,  $^cP < 0.05$ , compared with LV-Con group. C: Western blotting analysis showed that STAT3 protein was markedly inhibited by LV-STAT3siRNA-2 in SW1990 cells.

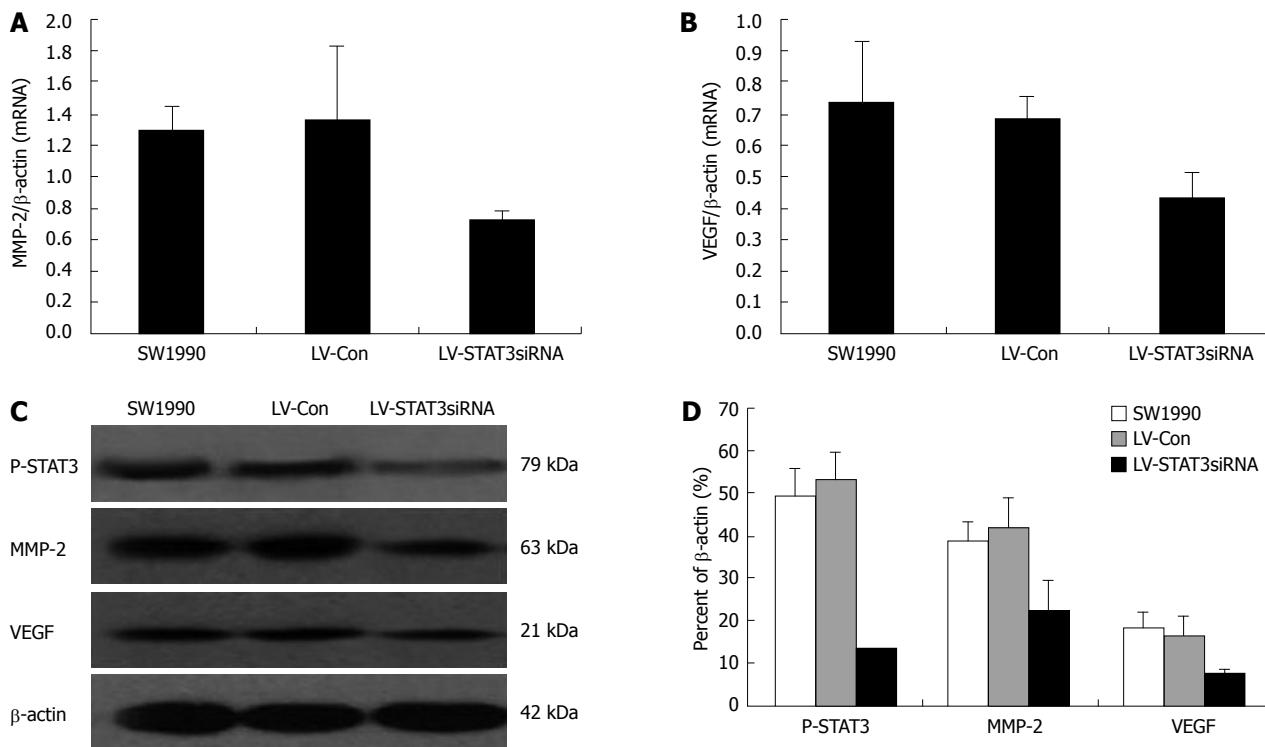

number of invading cells counted. The control group, LV-Con, had no effect on invasion of SW1990 cells, however, LV-STAT3siRNA-2 markedly reduced the invasion ability compared with LV-Con ( $P = 0.004$ ) and parental SW1990 ( $P = 0.001$ ) (Figure 6).

## DISCUSSION

STAT3 is a key signal transduction protein that mediates signaling by numerous cytokines, peptide growth factors, and oncproteins. The Janus kinase (JAK)/STAT3

**Figure 4 Pancreatic cancer cells growth was detected by MTT assay.** SW1990 cells growing in 96-well plates were infected with LV-STAT3siRNA-2 and LV-Con 1, 2, 3, 4 d respectively, and the MTT assay revealed that the cell growth was significantly suppressed by LV-STAT3siRNA-2 in SW1990 cells compared with LV-Con group and parental SW1990 group. Data are mean  $\pm$  SD.

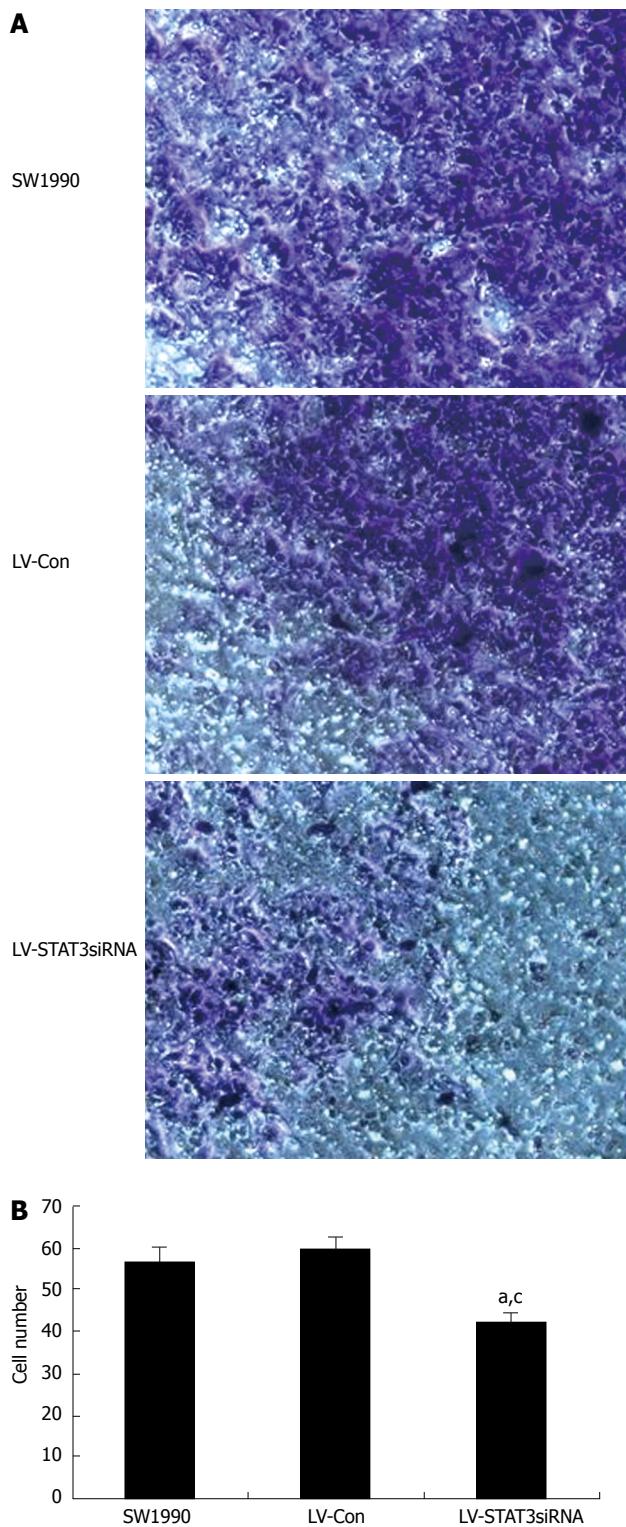

**Figure 5 The expression of MMP-2 and VEGF was analyzed by real-time PCR and Western blotting in the human pancreatic cancer cell lines.** LV-STAT3siRNA-2 significantly inhibited mRNA and protein expression of MMP-2 and VEGF in SW1990 cell. A: MMP-2 mRNA expression in every group. B: VEGF mRNA expression in every group. C: P-STAT3, MMP-2 and VEGF protein expression in every group. D: Densitometric analysis protein expression of P-STAT3, MMP-2 and VEGF in every group.

signaling pathway plays a significant role in various physiological processes, including immune function, cell growth, differentiation, and hematopoiesis<sup>[20]</sup>. However, STAT3 has been implicated in important roles for cell proliferation, invasion and metastasis in diverse human cancers, including pancreatic cancer. Recent studies have also revealed that the promotion of STAT3 activation can contribute to oncogenesis. For example, Huang<sup>[11,21]</sup> and coworkers reported that activation of the STAT3 signaling pathway plays an important role in the progression of pancreatic cancer. These published reports all demonstrated the crucial importance of the

JAK/STAT3 signaling pathway in tumorigenesis and progression. In this study, our aim was to determine the role of the JAK/STAT3 signaling pathway in pancreatic cancer progression and to test the hypothesis that the STAT3 gene could serve as a therapeutic target.

RNAi is the process by which double-stranded RNA induces potent and specific inhibition of eukaryotic gene expression through the degradation of complementary messenger RNA, and is functionally similar to the processes of post-transcriptional gene silencing<sup>[22,23]</sup>. In the past few years, RNAi has been widely used by researchers to silence the expression of many target

**Figure 6 Invasion assay was performed using a specialized invasion chamber.** A: The blue-stained cells are those that invaded the ECM matrix and migrated through the polycarbonate membrane to the lower surface of the membrane (original magnification  $\times 200$ ). B: Invasion assay indicated LV-STAT3siRNA significantly decreased the invasion ability of SW1990 cells. Bars indicate mean  $\pm$  SD. <sup>a</sup>P < 0.05 vs SW1990 group, <sup>c</sup>P < 0.05 vs LV-Con group.

genes because of their high specificity and apparent non-toxicity<sup>[24]</sup>. Furthermore, systems based on lentiviral vectors have provided new solutions to achieving stable shRNA-mediated knockdown<sup>[25]</sup>. In this research, we chose a lentivirus vector as our shRNA delivery vehicle

because they can infect both dividing and nondividing cells at a high efficiency and sustain long-term gene expression by integrating into the host genome. shRNA was proved to provide long-lasting silencing and maximal inhibition of gene expression at low concentration<sup>[26]</sup>. Since the potency of the inhibitory effect of shRNA is related to the specificity to its target sequence, we used RT-PCR and western blotting to confirm the efficacy of STAT3siRNA in SW1990 and 293T cells. The greatest STAT3 gene silencing effect was observed when LV-STAT3siRNA-2 was applied and the expression of STAT3 mRNA and protein were markedly inhibited. Given this result, we concluded that LV-STAT3siRNA-2 had a high specificity for STAT3 in SW1990 cells.

Constitutive activation of STAT3 is observed in many types of tumors and promotes cell proliferation and survival<sup>[27,28]</sup>. Inappropriate and constitutive activation of STAT3 may be responsible for pancreatic cancer progression by regulating the expression of target genes, such as c-Myc, Bcl-xL, p21WAF1 and cyclinD1. Moreover, functional inactivation of STAT3 by dominant-negative STAT3 or AG490 (a JAK-specific inhibitor) could inhibit proliferation and promote the apoptosis of pancreatic cancer cells<sup>[29,30]</sup>. In our study, cell cycle and proliferation assays revealed that LV-STAT3siRNA-2 markedly inhibited cell growth and proliferation.

An increasing number of studies suggest that the activation of STAT3 might play an important role in the invasion and metastasis of carcinomas<sup>[5]</sup>. Furthermore, disruption of the STAT3 signaling pathway has been reported to suppress cell invasion by decreasing cell-cell homotypic adhesions and increasing cell motility and scattering<sup>[31]</sup>. In the present study, the invasion ability of these cells with a cell invasion assay was examined and found that STAT3 silencing by RNAi in SW1990 cells resulted in a weak level of invasiveness. Therefore, there is a strong relationship between STAT3 and the invasive ability of human pancreatic cancer cells.

Tumor invasion and metastasis is dependent on angiogenesis, the formation of new blood vessels from a pre-existing network of capillaries. VEGF is known to be a potent angiogenic mitogen that plays an important role in tumor angiogenesis, invasion, and metastasis<sup>[32]</sup>. The role of STAT3 in angiogenesis was first shown when VEGF was found to be a direct target of STAT3 in mouse melanoma cells<sup>[6]</sup> and then confirmed by a study in a human pancreatic cancer system<sup>[33]</sup>. According to studies of clinical samples from pancreatic cancer and pancreatic cancer cell lines, MMPs play important roles in tumor cell invasion and metastasis by degrading components of the basement membranes and extracellular matrix<sup>[34-36]</sup>. Specifically, activated STAT3 regulates tumor invasion of melanoma cells by regulating the transcription of the MMP-2 gene<sup>[7,37]</sup>. In the present study, inhibition of the STAT3 gene by RNAi markedly decreased both MMP-2 and VEGF expression in the pancreatic cancer cell line, SW1990. This suggests that silencing of the STAT3 gene could suppress invasion ability based on the down-regulation MMP-2 and VEGF

gene expression in SW1990 cells.

Overall, the present study indicates that siRNA targeting of STAT3 mRNA via a lentivirus vector system effectively sustains knockdown of the STAT3 gene expression in SW1990 cells. Here we describe the successful construction of a lentivirus RNAi vector targeting STAT3 that will provide a useful tool to study the function of the STAT3 gene in pancreatic cancer cells. Our findings strongly suggest that the JAK/STAT3 pathway plays a significant role in pancreatic cancer cell invasion. Targeting of STAT3 activation may prove to be a more effective approach to controlling invasion than merely targeting individual molecules, such as VEGF and MMP-2, representing a novel approach to regulating pancreatic cancer invasion.

## COMMENTS

### Background

Signal transducer and activator of transcription 3 (STAT3) is a member of the JAK/STAT signaling pathway. Abnormal activation of STAT3 plays a critical role in metastasis and invasion in a variety of human tumors including pancreatic cancer. The authors aim was to study the effect of silencing of STAT3 on invasion in human pancreatic cancer cells.

### Research frontiers

Activated STAT3 has been shown to promote cell proliferation, metastasis, and angiogenesis, as well as protect tumor cells from apoptosis by regulating associated genes, such as Bcl-xL, Mcl-1, Bcl-2, Fas, cyclin D1, survivin, c-Myc, VEGF, MMP-2, and MMP-9. The authors sought to determine whether the STAT3 signaling pathway regulates the invasive potential of pancreatic cancer cells. The inhibition of STAT3 may offer a novel strategy for pancreatic cancer intervention.

### Innovations and breakthroughs

The authors successfully constructed the lentivirus LV-STAT3siRNA vector. Expression of LV-STAT3siRNA can suppress expression of STAT3 gene in SW1990 cells. Flow cytometry analysis showed that the cell cycle of SW1990 cells was inhibited by LV-STAT3siRNA compared with controls. Moreover, LV-STAT3siRNA significantly suppressed the invasion ability of SW1990 cells by down-regulating the VEGF and MMP-2 genes.

### Applications

Lentivirus vectors are safe for human use. Lentivirus vectors encoding the antisense targeting sequence have been used previously for treatment in clinical trials with no obvious side effects. Most recently, a lentivirus vector containing β-globin gene has been approved in phase I/II clinical trials for human β-thalassemia and sickle cell anemia gene therapy. Targeting of STAT3 activation may prove to be an effective approach to controlling invasion in pancreatic cancer cells.

### Peer review

This is an interesting manuscript. The authors utilized three different siRNAs against STAT3 and infected the pancreatic cell line SW1990. They show that siRNA is the most effective at suppressing protein levels of VEGF, MMP-9 downstream effector molecules of STAT3 signaling pathway as well as STAT3 itself. They also show siRNA suppressed the proliferative capacity of SW1990 cells and also its invasive ability.

## INTRODUCTION

Serrated colorectal polyps in the proximal colon are now recognized as precancerous lesions that should be removed during colonoscopy<sup>[1-3]</sup>. Previously, hyperplastic polyps have been considered innocuous when identified anywhere in the colon; however, some proximal colon serrated polyps are better classified as sessile serrated polyps (sessile serrated adenomas) and closer endoscopic follow-up may be appropriate<sup>[4-7]</sup>.

Much about hyperplastic polyps remains unknown. The extent to which they are recognized as polyps by endoscopists is uncertain, since miss rates for proximal colon hyperplastic polyps have not been reported<sup>[8]</sup>. Further, the extent to which they have been recognized endoscopically but not removed (their endoscopic appearance might initiate observation or sampling, rather than removal), or ineffectively removed, is uncertain and has not been reported. Finally, the extent to which proximal colon serrated lesions are distinguished as hyperplastic *versus* sessile serrated polyps (or sessile serrated adenomas) *versus* traditional serrated adenomas by pathologists is not known<sup>[9,10]</sup>.

In this report, we describe the results of a quality improvement project in which we sought to estimate the extent to which proximal colon polyps removed in prior years and designated as hyperplastic polyps by

## Abstract

**AIM:** To evaluate how proximal colon polyps interpreted as hyperplastic polyps in 2001 would be interpreted by expert pathologists in 2007.

**METHODS:** Forty consecutive proximal colon polyps ≥ 5 mm in size, removed in 2001, and originally interpreted as hyperplastic polyps by general pathologists at Indiana University, were reviewed in 2007 by 3 GI pathologists.

**RESULTS:** The gastrointestinal (GI) pathologists interpreted 85%, 43% and 30% of the polyps as sessile serrated polyps (sessile serrated adenomas). The overall Kappa was 0.16. When diagnoses were compared in pairs, Kappa values were 0.38 and 0.25 (fair agreement) and 0.14 (slight agreement).

**CONCLUSION:** Many polyps interpreted as hyperplastic in 2001 were considered sessile serrated lesions by GI pathologists in 2007, but there is substantial inter-observer variation amongst GI pathologists.

pathologists might now be considered more clinically significant lesions, such as sessile serrated polyps or serrated adenomas<sup>[11-13]</sup>. The issue was deemed pertinent to our colonoscopy callback process, since in prior years we had recommended routine colonoscopic follow up if only hyperplastic polyps were removed from the colon, including from the proximal colon. Recently, we began recommending follow up at shorter intervals if hyperplastic or other serrated polyps were removed from the proximal colon<sup>[14]</sup>. In order to assess whether we had patients who had serrated proximal colon polyps removed earlier and whom we should consider calling back earlier than we previously recommended, we evaluated histologic slides of 40 consecutive proximal colon "hyperplastic polyps" ≥ 5 mm in size removed at Indiana University Hospital in 2001 which were reviewed by three expert gastrointestinal (GI) pathologists.

## MATERIALS AND METHODS

We utilized an endoscopic database that includes histology of more than 10 000 consecutive colorectal polyps<sup>[15]</sup>. We selected 40 consecutive lesions originally diagnosed as hyperplastic polyps removed from the proximal to the sigmoid-descending junction that were at least 5 mm in size. The sample size was selected for feasibility of review in our quality improvement process and not on the basis of a power calculation. The original interpretation in each case was made by 1 of 8 attending pathologists at Indiana University Hospital, none of whom was a specialist in GI pathology. The review was performed by a specialist in GI pathology currently in GI practice at I.U. (OC) and two outside pathologists (J.G. and M.O.). Each of the reviewers was aware that the original slide had been interpreted as a hyperplastic polyp. Each pathologist performed their review independently without any knowledge of the other's findings. We did not supply the reviewing pathologists with standard terminologies to utilize in describing their findings. Permission to report the results of the quality study was granted by the Institutional Review Board of Clarian Health Partners. The Kappa statistic was used to determine agreement between the three specialists in interpretation of the polyps. For the purposes of the comparisons, we considered "sessile serrated polyp" and "sessile serrated adenoma" to be equivalent, but distinct from traditional serrated adenoma.

After the reviews, the pathologists were asked to provide the criteria they used to interpret the histology. Pathologist A indicated that he used the World Health Organization criteria<sup>[16]</sup> for serrated adenoma and published criteria from another source for sessile serrated adenoma and hyperplastic polyp<sup>[2]</sup>. Pathologist B utilized the criteria of Torlakovic *et al*<sup>[17]</sup> that described 3 variants of hyperplastic polyp (the microvesicular serrated polyp, the goblet cell serrated polyp, and the sessile serrated adenoma). The term serrated adenoma was used by pathologist B when some component of the polyp has serrated architecture and overt cytological dysplasia was present. Pathologist C provided two references that best described his criteria for diagnosis of serrated polyps<sup>[18,19]</sup>.

## RESULTS

The three GI pathologists interpreted 43%, 30% and 85% of the (cases) as sessile serrated polyps or sessile serrated adenomas (Table 1). Only one polyp was called a traditional serrated adenoma, and by only one of the pathologists.

Based on diagnoses for all three pathologists, the overall Kappa value was 0.16, indicating only slight agreement. When the pathologists' diagnoses were compared in pairs, the Kappa values for the comparisons were 0.38 and 0.25 (fair agreement) and 0.14 (slight agreement).

## DISCUSSION

In this report, we describe a quality improvement project in which we explored issues relating to pathologic interpretation of proximal colon polyps with serrated

histology. Our results indicate that polyps interpreted as hyperplastic in 2001 by non-specialist pathologists at a university hospital were frequently called sessile serrated polyps or sessile serrated adenomas by GI pathologists in 2007. To the extent that “sessile serrated polyp” triggers a recommendation for earlier colonoscopic follow-up compared to “hyperplastic polyps,” this could affect clinical outcomes for patients. The extent to which earlier follow-up by clinicians would be undertaken is unknown, as current postpolypectomy surveillance colonoscopy guidelines indicate that shorter intervals are appropriate for these patients but these guidelines do not make distinct interval recommendations for these patients<sup>[14]</sup>.

We found that each of three expert pathologists used different published references to support their criteria for sessile serrated adenoma (polyp) and serrated adenoma. A review of the various references<sup>[2,16-19]</sup> cited by the pathologists indicated that they utilize substantially similar but not identical language to describe these pathologic entities. The extent to which only slight-to-fair interobserver agreement in this report is the result of variations in criteria *vs* interobserver variation with essentially equivalent criteria is uncertain.

After examining these results, we elected not to systematically call back patients for earlier surveillance colonoscopy if they had undergone colonoscopy less than 10 years ago and had proximal colon polyps originally interpreted as hyperplastic and no adenomas anywhere else in the colon. Our rationale for this decision included (1) lack of clear recommendations on appropriate follow up intervals for this population and (2) the marked interobserver variation in the interpretation of these polyps among experts in GI pathology, and (3) no specific observation that patients with these polyps are a source of interval cancers in our endoscopy unit, and (4) no clear evidence that patients would benefit from being called back early for “sessile serrated polyp” or “sessile serrated adenoma.” We were reassured that only one polyp was called a true serrated adenoma, and this by only one pathologist. We acknowledge uncertainty regarding the appropriateness of the decision to not call patients back earlier than originally planned.

Others have also noted interobserver variation in the pathologic interpretation of serrated polyps<sup>[9,10]</sup>, even among specialists in GI pathology<sup>[9]</sup>, as well as variation in the terminology used to describe these lesions<sup>[9]</sup>. Certainly, recent evidence suggesting that colonoscopy is more effective at reducing the risk of distal compared to proximal cancers<sup>[20]</sup> has raised concerns in our unit that these polyps be carefully looked for, removed completely, and interpreted correctly by pathologists.

In summary, our results suggest that as recently as 2001, non-GI pathologists at a university hospital were uniformly interpreting proximal colon polyps with serrated histology as hyperplastic polyps that GI pathologists would now interpret as sessile serrated polyps (sessile serrated adenomas). If this phenomenon has occurred on a widespread basis (which seems likely)

it might have a negative effect on colorectal cancer prevention, but this is very uncertain. We elected not to bring patients with only proximal colon hyperplastic polyps diagnosed in the period around 2001 back for follow-up colonoscopy sooner than originally planned. However, we admit uncertainty regarding the optimal management of these patients, and physicians might reasonably choose to recall these patients for colonoscopy at earlier intervals<sup>[14]</sup>. Clinicians should be aware that substantial percentages of patients with lesions diagnosed as proximal colon hyperplastic polyps may have had lesions which would now be called sessile serrated polyps or sessile serrated adenomas by expert pathologists.

## COMMENTS

### Background

Serrated polyps in the proximal colon share molecular features with a group of proximal colon cancers and maybe precursors of these cancers. Subtypes of serrated polyps include hyperplastic polyps, sessile serrated polyps (also called sessile serrated adenomas) and serrated adenomas.

### Research frontiers

The clinical relevance of the distinction between hyperplastic and sessile serrated polyps is unknown. Possibly the number, size, and location of serrated polyps has as much relevance as the pathologic distinction between hyperplastic polyps and sessile serrated polyps. True serrated adenomas, however, are likely more important than hyperplastic polyps and sessile serrated polyps, and also are much less common. The accuracy of the pathologic distinction of these polyp types in clinical practice is probably quite low.

### Innovations and breakthroughs

Serrated polyps in the proximal colon often have molecular features in common with a subgroup of colon cancers, including *BRAF* mutations, the CpG island methylator phenotype, and microsatellite instability. These common molecular features underlie the hypothesis that some hyperplastic polyps become serrated adenomas and then cancers.

### Applications

The results indicate that clinical decision making regarding serrated polyps is complicated by variations in pathology terms and substantial interobserver variation in pathologic interpretation of serrated polyps, even among experts.

### Terminology

The term “serrated polyps” describes a set of polyps divided into subgroups believed to have variable risk for short term transformation into cancer. Hyperplastic polyps are believed to have the most benign behavior, while true serrated adenomas (which are dysplastic) have the greatest risk. Sessile serrated polyp is a term often used for a set of polyps called sessile serrated adenoma, and these lesions may be intermediate in the transformation of hyperplastic polyp to serrated adenoma.

### Peer review

Original evaluation of histologic features of hyperplastic polyps in different periods, with experienced pathologists applying new concepts. Several problems are highlighted in this paper: Missing polyps during colonoscopy; Absence of unique terminology; Difficulties in interobserver agreement in histologic interpretation.

= 421) and controls ( $n = 483$ ) aged  $\geq 30$  years to conduct a comprehensive tagSNP association analysis of the PTEN gene.

**RESULTS:** None of the PTEN SNPs were statistically significantly associated with colon cancer when controlled for age, gender, and race, or when additionally adjusted for other known risk factors ( $P > 0.05$ ). Haplotype analyses similarly showed no association between the PTEN gene and colon cancer.

**CONCLUSION:** Our study does not support PTEN as a colon cancer susceptibility gene.

## INTRODUCTION

The phosphatase and tensin homolog (PTEN) tumor suppressor gene is second only to p53 in mutation frequency in human cancers<sup>[1]</sup>. PTEN utilizes multiple mechanisms to control cellular growth, the most important of which is by inhibiting phosphoinositide 3-kinase (PI3K) activation<sup>[2]</sup>. The PI3K signaling cascade has been shown to play an important role in the development of colon tumors and other neoplasia<sup>[3-5]</sup>, suggesting that genetic variations in this pathway might confer susceptibility to colon cancer. PTEN is a likely candidate, because mutations<sup>[6-9]</sup>, deletions<sup>[10]</sup>, and loss of heterozygosity<sup>[11]</sup> in PTEN have been found in a variety of tumors. Although PTEN alterations were

## Abstract

**AIM:** To investigate the association between single nucleotide polymorphisms (SNPs) in the phosphatase and tensin homolog (PTEN) tumor suppressor gene and risk of colon cancer.

**METHODS:** We utilized a population-based case-control study of incident colon cancer individuals ( $n$

initially discovered in glioma, prostate, kidney, and breast carcinomas, more recent discoveries in gastrointestinal cancers suggest a likely association between PTEN and colorectal cancers<sup>[12-14]</sup>. PTEN expression is decreased in over 50% of colon tumors, and PTEN loss is associated with increased risk of local colon cancer recurrence<sup>[3,15]</sup>. In addition, PTEN missense and nonsense mutations occur in Cowden Disease, a hereditary cancer susceptibility syndrome involving multiple hamartomas of the gastrointestinal tract and other tissues<sup>[16,17]</sup>.

To date, three published studies have examined PTEN as a potential candidate susceptibility gene for four cancer types: breast and prostate cancer<sup>[18]</sup>, meningiomas<sup>[19]</sup>, and colorectal cancer<sup>[20]</sup>. These studies found no association with PTEN genetic polymorphisms. However, the colorectal cancer study included a relatively small number of predominantly Jewish patients and examined only two PTEN single nucleotide polymorphisms (SNPs) that did not cover the full PTEN gene region. Therefore, a more thorough investigation of PTEN and colon cancer is warranted. Here we carried out a comprehensive tagSNP association analysis to further clarify the relationship between PTEN genetic polymorphisms and the risk of colon cancer in a population-based case-control study.

## MATERIALS AND METHODS

### **Study design and data collection**

The study design, data collection and study population have been described in detail elsewhere<sup>[21]</sup>. Briefly, between 2003 and 2006, incident colon cancer cases identified from the Surveillance, Epidemiology, and End Results (SEER) Kentucky Cancer Registry (KCR) and population controls were recruited for an incident case-control of colon cancer. Histopathologically confirmed colon cancer cases were identified through regular queries of the KCR database. Random digit dialing using the same area codes and exchanges as cases was used to recruit population controls who were  $\geq 30$  years and had no personal history of cancer, with the exception of non-melanoma skin cancer. Those with known inflammatory bowel disease, a family history of familial adenomatous polyposis, or hereditary nonpolyposis colorectal cancer, were excluded. Participants provided a blood sample collected at approved medical facilities after an overnight fast. They also completed a self-administered questionnaire ([http://epi.grants.cancer.gov/CFR/about\\_questionnaires.html](http://epi.grants.cancer.gov/CFR/about_questionnaires.html)), which collected detailed information on personal and family history of colon (and other) cancers, lifestyle, and behavioral risk factors. Participation rates were 72.2% for cases and 62.5% for eligible controls. The study was approved by the Institutional Review Boards of Case Western Reserve University/University Hospitals of Cleveland, the University of Kentucky, Lexington, and the University of Southern California, Los Angeles.

### **Genotyping**

Fifty validated SNPs have been identified within the PTEN gene in HapMap (NCBI Build 36). Four tagging SNPs (rs2299939, rs12357281, rs2248293, and rs926091)

**Table 1 Descriptive characteristics of the CWRU/kentucky colon cancer genetic epidemiology study population**

	Cases (n = 421 )	Controls (n = 483)	P <sup>1</sup>
Age <sup>2</sup> (yr)	62.7 ± 10.6	57.6 ± 11.2	< 0.0001
Gender (%)			
Female	214 (50.8)	307 (63.6)	0.0001
Male	207 (49.2)	176 (36.4)	
Race (%)			
Caucasian	394 (93.6)	450 (93.2)	0.3
African-American	22 (5.2)	21 (4.4)	
Other	5 (1.2)	12 (2.5)	
BMI <sup>3,4</sup> (kg/m <sup>2</sup> )	29.2 ± 6.2	28.2 ± 6.0	< 0.0001
Family History <sup>3,5</sup>			
Yes	94 (26.8)	72 (17.1)	0.0015
No	257 (73.2)	349 (82.9)	
NSAID use <sup>3,6</sup> (%)			
Yes	235 (64.2)	306 (68.9)	0.18
No	131 (35.8)	138 (31.1)	
Physical activity <sup>3</sup> (%)			
Vigorous	165 (42.7)	247 (53.8)	0.006
Moderate	106 (27.5)	98 (21.4)	
Light	115 (29.8)	114 (24.8)	

<sup>1</sup>P-value of significance difference between cases and controls in a  $\chi^2$  test (discrete variables and genotypes) or t-test (continuous); <sup>2</sup>Age (mean ± SD) at diagnosis for cases and age at recruitment for controls; <sup>3</sup>Calculations based on cases and controls with available information; <sup>4</sup>BMI (mean ± SD); <sup>5</sup>Family history of first-degree relatives with colorectal cancer; <sup>6</sup>NSAID: Yes = either ibuprofen or aspirin use in the last 6 mo.

were selected for genotyping in our study. These tag SNPs were selected based on the following criteria: (1) minor allele frequency  $\geq 5\%$ ; (2) pair-wise  $r^2 \geq 0.8$ ; (3) spanning 5 kb upstream of the 5' end and 2 kb downstream of the 3'end of the PTEN gene. Genotyping was done using the TaqMan allelic discrimination assay with pre-designed primer/probe sets (Applied Biosystems). The failure rate for genotyping was less than 0.1%. For quality assurance, assays were repeated on 2% of random samples, with a concordance call rate of 100%.

In our analysis, in addition to age, gender, and race, we also included risk factors known to be associated with colon cancer. Body mass index (BMI) was computed by dividing self-reported weight in kilograms (kg) by height in meters squared (m<sup>2</sup>). A positive family history of colon cancer was defined as having at least one first-degree relative with colon cancer. Non-steroidal anti-inflammatory drug (NSAID) use was defined as using any NSAID at least twice a week for  $> 6$  mo. Physical activity was quantified using metabolic equivalents of energy expenditure units (METS), with light activity  $< 3.0$  METS, moderate 3-6 METS, and vigorous activity  $> 6$  METS.

### **Statistical analysis**

Unconditional logistic regression analyses were performed to test the association of each individual SNP with the risk of colon cancer. The higher frequency allele was considered the referent for each SNP. Association was assessed for dominant, additive, and recessive modes of inheritance by number of copies of the risk allele. For the dominant model, participants with at least one copy of the risk allele were coded as 1 and those with no risk allele

**Table 2** Associations of PTEN SNPs with colon cancer *n* (%)

<sup>1</sup>Base model adjusted for age, gender and race; <sup>2</sup>Full model further adjusted for BMI, family history of colorectal cancer, NSAID use, and physical activity based on 329 cases and 390 controls; <sup>3</sup>Five other haplotypes representing a total of six participants were removed due to rarity.

copies were coded as 0. Number of risk alleles present (0, 1, or 2) determined coding for the additive model. For the recessive model, participants with two risk alleles were coded as 1, and all others were 0.

Haplotypes and their frequencies were estimated using PROC HAPLOTYPE in SAS/Genetics version 9.1. Due to the high certainty of haplotype pairs for each individual (>98%), each haplotype was coded as 1 if estimated to be present in that individual (1 or 2 copies) and 0 otherwise. Haplotypes with a frequency < 5% in our study population were excluded from analyses due to small sample sizes. All univariate and multivariate analyses were conducted using SAS version 9.1 (SAS Institute, Cary, NC) with an  $\alpha = 0.05$  cutoff for statistical significance.

## RESULTS

Data from 904 participants (421 cases and 483 controls), of which 93% were Caucasian, were included in the analyses. Table 1 summarizes the descriptive characteristics of the study population. Cases were evenly split by gender, whereas controls were more likely to be female. A higher percentage of cases than controls reported a positive family history of colon cancer.

All SNPs were in Hardy-Weinberg equilibrium in both the case ( $P > 0.10$ ) and the control ( $P > 0.15$ )

groups. None of the four PTEN SNPs were statistically significantly associated with colon cancer when adjusted for age, gender, and race (Table 2). Further adjustment for family history, BMI, non-steroidal anti-inflammatory drug use, and physical activity did not alter the results. The additive model results are shown for the three SNPs that had sufficient numbers. The dominant model results are displayed for rs12357281, as only five participants had the rare genotype for this SNP.

Five haplotypes represented 99.2% of the variants for PTEN in this population (Table 3). Similar to the SNP results, none of the haplotypes were associated with colon cancer in the base model (adjusted for age, gender, and race) or the full model (further adjusted for BMI, family history, NSAID use, and physical activity). Odds ratios for the base model ranged from 0.75 (95% CI = 0.510-1.09) for the most frequent haplotype (C-G-T-C) to 1.44 (95% CI = 0.979-2.11) for the haplotype with the fourth highest frequency in our population (C-G-C-T).

When the above analyses were restricted to Caucasian only, the results did not substantially change (data not shown).

## DISCUSSION

Recent studies have shown changes in the PTEN

gene in colon cancer tumors, including mutations<sup>[6]</sup>, loss of heterozygosity<sup>[12]</sup>, and low or absent gene expression<sup>[15,22,23]</sup>, making it a strong candidate susceptibility gene for colon cancer. In the present study, we selected four tag SNPs covering the entire PTEN region to examine association between PTEN genetic variation and risk of colon cancer. We found no evidence for association for the individual SNPs or the haplotypes. Our results indicate that common inherited variations in PTEN are unlikely to predispose to colon cancer, despite the reported high frequency of somatic mutations of the PTEN gene in colon tumors<sup>[6,12]</sup>.

The importance of PTEN as a tumor suppressor and protector of chromosomal stability is well documented<sup>[24-28]</sup>. However, its particular function and mechanism in specific cancers is unknown. While PTEN might be necessary to prevent Akt from being phosphorylated in the PI3K pathway, its loss might not be sufficient for tumorigenesis. Recent studies suggest that mutations in other parts of the PI3K signaling pathway, such as PIK3CA and PIK3CB, might be more important in leading to tumor growth<sup>[21,23,29,30]</sup>. In addition, PTEN might be more influential in affecting local recurrence<sup>[15]</sup> or metastases<sup>[31]</sup> than primary tumors. These avenues warrant further investigation with regard to PTEN and colon cancers.

Although we only genotyped four tagging SNPs out of the total 61 (50 validated) possible SNPs on PTEN, they were spaced to cover the entire length of the gene, including both upstream and downstream regions, and the entire PTEN gene is in a single LD block for Caucasians. Analyses, excluding African Americans or other minorities, yielded similar results, indicating that population stratification is unlikely to have confounded our results. Our study has over 90% power to detect an odds ratio of 1.7 and > 80% power to detect an odds ratio of 1.5 with a type I error rate of 0.05, assuming a dominant model and a minor allele frequency of 16%.

To our knowledge, this is the first population-based study to examine PTEN genetic polymorphisms with risk of "sporadic" colon cancer. Taken together with other studies<sup>[18-20]</sup>, our results do not support PTEN as a colon cancer susceptibility gene.

## COMMENTS

### Background

Colon cancer is the third leading cause of cancer death in the United States and worldwide for men and women. Up to 30% of all colon cancer cases may be due to heritable factors, but only five percent are associated with known genes. The phosphatase and tensin homolog (PTEN) tumor suppressor gene is a likely candidate for association with colon cancer.

### Research frontiers

While the phosphoinositide 3-kinase (PI3K) signaling cascade has been shown to play an important role in the development of colon tumors, it is unclear which elements are controlling this association. PTEN controls cellular growth by inhibiting the PI3K pathway. In addition, PTEN expression is decreased in over 50% of colon tumors, and PTEN loss is associated with increased risk of local colon cancer recurrence. Therefore, PTEN is a promising candidate gene for colon cancer.

### Innovations and breakthroughs

This study has provided further insight into the role of the PTEN gene in colon cancer risk.

### Applications

In the process of identifying genetic causes of cancer, it is important to determine precisely which elements of a biologic pathway are responsible for affecting tumor suppression or development. Then, treatments and preventive measures can be tailored to those who would benefit most. The PTEN gene directly impacts a known signaling mechanism associated with colon cancer but has not been well-evaluated in a genetic association study. This study found that PTEN is not a likely colon cancer candidate gene, and future research should focus on other parts of the PI3K signaling pathway to understand its role in colon cancer risk.

### Terminology

PTEN is a gene located on chromosome 10 known to affect tumor cell growth.

### Peer review

Various genetic changes of PTEN gene in colon cancer have been described so far in the literature. In the present study, the authors examined the possibility of PTEN as susceptibility gene for sporadic colon cancer. However there was no association of individual single nucleotide polymorphisms or the haplotypes examined and therefore they concluded that common inherited variations in PTEN are unlikely to predispose to colon cancer. Although results of this study show no association of PTEN expression or susceptibility to sporadic colon cancer, and no-association results are not as attractive as positive associations, I feel they should be presented to the scientific audience in order not to create a literature bias towards publishing only studies with positive associations.
