RESULTS

During ERCP, 854 (24.11%) patients experienced immediate post-ES bleeding. All patients underwent epinephrine injection, and 32 had additional endoscopic therapy. By definition, delayed bleeding occurred in 26 (3.04%) of the 854 patients. The time to onset of delayed bleeding was not significantly different between patients with and without immediate post-ES bleeding

(2.8 \pm 2.7 d *vs* 3.3 \pm 2.7 d, *P* = 0.5).

Clinical characteristics of the 59 patients with delayed post-ES bleeding are outlined in Table 1. There were no significant differences in the mean age, sex distribution, and indications for ERCP between the two groups. None of the participants used anticoagulants from 3 d before or till 3 d after ERCP, and all the ES procedures were performed by experienced endoscopists. Thus, the established risk factors of post-ES bleeding included coagulopathy, bile duct stones, precut sphincterotomy, periampullary diverticulum, immediate post-ES bleeding, and cholangitis before ERCP^[9,21]. There was no statistical difference between the two groups with regard to these parameters. The drop in hemoglobin from baseline was 31 \pm 22 g/L in the epinephrine injection group and 37 \pm 22 g/L in the combination therapy group (*P* = 0.26). The time period between ES and hemorrhage ranged from 9 h to 16 d, and was not statistically different between the two groups (3.5 \pm 3.6 d *vs* 2.8 \pm 1.6 d, *P* = 0.32).

Data regarding bleeding severity and bleeding stigmata at initial endoscopy are listed in Table 2. Bleeding severity was classified according to the established criteria^[10]. There were 9, 10 and 7 cases of mild, moderate, and severe bleeding, respectively, in the epinephrine injection group, and 9, 17 and 7 cases, respectively, in the combination therapy group (*P* = 0.6). At initial endoscopy for delayed post-ES bleeding, the bleeding stigmata were classified as active oozing, oozing under an adherent clot, non-bleeding visible vessel, non-bleeding adherent clot, and non-bleeding red spots. There was no statistically significant difference between the two groups when the bleeding stigmata were compared with respect to these parameters (*P* = 0.70).

Clinical outcome data are summarized in Table 3. The total injected volume of dilute epinephrine was 7.8 \pm 5.8 mL (range: 3-30 mL) in the epinephrine injection group and 9.1 \pm 6.2 mL (range: 3-30 mL) in the combination therapy group (*P* = 0.48). Initial hemostasis was successfully attained in 25 patients from the epinephrine injection group and 33 patients from the combination therapy group (96.2% *vs* 100%, *P* = 0.44). Initial hemostasis was not achieved in 1 patient treated with epinephrine injection alone and the patient went directly to surgery.

The re-bleeding rate was 16% (4 of 25) for the epinephrine injection group and 12.1% (4 of 33) for the combination therapy group. The difference, however, was not significant (*P* = 0.72). The treatment for the four patients with re-bleeding from the epinephrine injection group was as follows: 2 underwent 1 session of endoscopic treatment and the bleeding stopped; 1 went directly to angiographic embolization at re-bleeding; and 1 underwent 1 session of endoscopic treatment for the first re-bleeding - surgery rather than endoscopic treatment was performed to control bleeding at the second re-bleeding. The treatment for the four patients from the combination therapy group was as follows: 1 underwent 1 session of endoscopic treatment and the bleeding stopped; 2 underwent 3 sessions of endoscopic

treatment due to repeated re-bleeding and the bleeding was finally controlled, and 1 underwent 2 sessions of endoscopic combination therapy and surgery was required to finally control bleeding.

None of the patients from the epinephrine injection group experienced any complications of endoscopic hemostasis. One of the patients from the combination therapy group experienced mild pancreatitis after initial endoscopic hemostasis (epinephrine injection plus APC). Another patient from the combination therapy group developed mild pancreatitis after endoscopic treatment (epinephrine injection + heat probe + APC + hemoclip) for the third episode of re-bleeding. The total number of patients requiring angiographic embolization or surgery to control bleeding was 3 in the epinephrine injection group and 1 in the combination therapy group (11.5% *vs* 3.0%, $P = 0.31$). The total number of blood transfusions was not significantly different between the two groups (3.5 ± 4.6 U *vs* 3.5 ± 4.5 U, $P = 0.94$). There was no bleeding-related death in either group.

DISCUSSION

Although the endoscopic approach for post-ES bleeding is similar to that for peptic ulcer bleeding, there is no consensus with regard to the optimal endoscopic hemostasis for treating post-ES bleeding^[7]. For peptic ulcer bleeding, epinephrine injection is the most commonly used, and highly effective, method for control of bleeding; its hemostatic efficacy is comparable to that of epinephrine in combination with additional thermotherapy^[14,19]. From the literature review, it appears that epinephrine injection is the most widely used method for hemostasis of post-ES bleeding. Its success rate in the cases reported in two large series was 97.5% and 100%^[5,9]. The present study shows that epinephrine monotherapy is also highly effective for controlling delayed post-ES bleeding. In addition, the results demonstrate that epinephrine monotherapy is as effective as epinephrine injection combined with thermotherapy, similar to that for peptic ulcer bleeding.

Data regarding bleeding peptic ulcer management suggest that epinephrine injection alone does not achieve permanent hemostasis, and an additional endoscopic treatment such as thermotherapy can reduce the re-bleeding rate^[14]. There are only a few studies that discuss re-bleeding after endoscopic treatment for post-ES bleeding. Ferreira *et al*^[13] reported a re-bleeding rate of 28.4% for 74 patients undergoing various endoscopic treatments for delayed post-ES bleeding. The present study found that the re-bleeding rate between epinephrine monotherapy and combination therapy is not significantly different (16% *vs* 12.1%, $P = 0.72$), implying that additional thermotherapy does not seem to reduce the risk of re-bleeding. Interestingly, the additional thermotherapy used by the endoscopists in this study was most likely performed with the intention of reducing the re-bleeding risk rather than primary

hemostasis, since epinephrine injection alone was highly effective for initial hemostasis. This practice was probably due to the experience of the endoscopists; they applied lessons learned in treating bleeding peptic ulcers.

Thermotherapy alone using multipolar electrocoagulation or a heat probe device has been reported to be effective for controlling post-ES bleeding^[16,17]. Contact thermal therapy, however, has an accurate placement problem, as has been described in bleeding peptic ulcers^[19,22]. In our experience, using a duodenal scope to perform contact thermal therapy is technically difficult when massive bleeding obscures the visual field. In contrast, epinephrine injection does not require accurate targeting. Injection close to the bleeding point will suffice to control bleeding, resulting in a better endoscopic view for more accurate targeting of the additional contact thermal therapy. Under such circumstances, combination therapy is a reasonable alternative.

In this study, none of the patients developed any clinically significant complications after endoscopic epinephrine injection therapy alone. This result confirms those reported in the literature that epinephrine monotherapy is very safe for hemostasis of post-ES bleeding^[5,9,13]. Pancreatitis was the most common complication of endoscopic combination therapy for delayed post-ES bleeding^[13]. In the present study, the only two patients who experienced pancreatitis after endoscopic hemostasis also underwent combination therapy. It is reasonable to consider that an additional thermal procedure would increase risk of complication(s), as has been described in the management of bleeding peptic ulcers^[14,22].

Any bleeding that occurs during ES increases the risk for occurrence of delayed bleeding, and it is suggested that treating "endoscopically significant" immediate bleeding may reduce the risk of delayed bleeding^[11,5,9]. However, the results of the present study do not support this idea: 24.11% of the patients had undergone endoscopic hemostasis for immediate post-ES bleeding, but the rate of clinically significant delayed bleeding was still high (1.81%). The discrepancy between this result and others is possibly because there is no consensus on what is endoscopically significant bleeding and who should receive endoscopic treatment. Furthermore, endoscopically significant bleeding may not become clinically significant^[9,23].

There were more patients requiring angiographic embolization or surgery in the epinephrine injection group (3/26 *vs* 1/33). This result should be interpreted with caution. At re-bleeding, endoscopic treatment was not offered to two of the three patients from the epinephrine injection group: one patient went directly to angiographic embolization at re-bleeding and the other one patient received surgery at the second re-bleeding. In contrast, two patients from the combination therapy group underwent three sessions of endoscopic treatment rather than surgery at their repeated re-bleeding, and the bleeding episodes were finally controlled. Surgery was once the only treatment choice for post-ES bleeding

in early ES, but its usage has fallen from 3% to less than 0.1% because of the improvements in endoscopic techniques and equipment^[1,10,24]. Therefore, endoscopic treatment may be offered to patients with re-bleeding prior to more invasive therapy.

The current study has several limitations. Firstly, it is not a prospective, randomized study. We do not know if there were any of the patients undergoing dual therapy because of epinephrine monotherapy failure. However, as discussed above, an additional thermotherapy was performed possibly to reduce re-bleeding risk rather than epinephrine monotherapy failure. Secondly, four different thermal methods resulted in the heterogeneity of the combination therapy group. It is not known whether different thermal methods would have had similar hemostatic efficacy, although there are no published data indicating that one method is superior to the others.

In summary, the present results show that epinephrine injection is as effective as epinephrine in combination with thermotherapy for treating delayed post-ES bleeding. Considering that epinephrine injection is safe and easy to perform, and that an additional thermotherapy may increase the risk of complications, we would suggest epinephrine injection alone as the first-line therapy for patients with delayed post-ES bleeding.

COMMENTS

Background

With the improvements of endoscopic techniques and equipment, the management of post-endoscopic sphincterotomy (ES) bleeding has shifted from surgery to endoscopic therapy. Delayed post-ES bleeding is less prevalent than immediate post-ES bleeding but it is often of clinical significance and requires more invasive intervention. The endoscopic treatments for delayed post-ES bleeding mirror those for peptic ulcer bleeding. However, the optimal method for treating this type of bleeding has not been determined.

Research frontiers

This is the first study to compare the hemostatic efficacy between epinephrine injection alone and epinephrine injection combined with thermotherapy for delayed post-ES bleeding.

Innovations and breakthroughs

From the literature review, epinephrine injection is the most commonly used and highly effective method to control post-ES bleeding. The study results further demonstrate that epinephrine monotherapy is as effective as epinephrine injection combined with thermotherapy for controlling delayed post-ES bleeding. In addition, an additional thermotherapy does not seem to reduce the risk of re-bleeding.

Applications

The results of this study suggest that epinephrine injection alone can be the first-line therapy for patients with delayed post-ES bleeding.

Terminology

Immediate post-ES bleeding: Any hemorrhage induced by ES and warranting endoscopic hemostasis within the procedure of endoscopic retrograde cholangiopancreatography (ERCP). Delayed post-ES bleeding: Any hemorrhage occurring after completion of ERCP and manifested by melena, hematemesis or hematochezia associated with a decreased hemoglobin level from baseline.

Peer review

Title reflects the major topic and contents of the study. Abstract gives a clear description of the materials and methods, results and conclusions. Significant points have been convincing. Detailed description of methods is provided and statistical methods used are appropriate. Results provide sufficient data to draw firm conclusions. In discussion valuable conclusions are provided. References are appropriate, relevant, and updated. Tables are appropriately presented.

Abstract

AIM: To compare the analgesic properties and efficacy of transnasal butorphanol with intramuscular meperidine after anal surgery.

METHODS: Sixty patients who underwent fistulectomy were enrolled in the study from January 2006 to December 2007. They were randomly divided into transnasal butorphanol ($n = 30$) or intramuscular meperidine ($n = 30$) treatment groups. Assessment of postoperative pain was made using a visual analogue scale (VAS). The VAS score was recorded 6 h after the completion of surgery, before receiving the first dose of analgesic, 60 min after analgesia and the next morning. Any adverse clinical effects such as somnolence, dizziness, nausea or vomiting were recorded. Satisfaction with narcotic efficacy, desire to use the particular analgesic in the future and any complaints were recorded by patients using questionnaires before being discharged.

RESULTS: Forty-two men and eighteen women were included in the study. There were no significant differences in VAS scores between the groups within 24 h. Length of hospital stay and the incidence of adverse effects between the groups were similar. In addition, most

patients were satisfied with butorphanol nasal spray and wished to receive this analgesic in the future, if needed.

CONCLUSION: Butorphanol nasal spray is effective for the relief of pain after fistulectomy. However, it offered patients more convenient usage and would be suitable for outpatients.

INTRODUCTION

Patients who undergo anal surgery always complain of intractable pain and appropriate analgesia is an important issue for these patients. Butorphanol is a synthetic opioid analgesic with agonist activity for the κ opioid receptor and antagonist activity for the μ opioid receptor^[1,2]. Butorphanol nasal spray is an alternative method which avoids hepatic metabolism and provides easier use^[1]. Several reports have demonstrated that butorphanol nasal spray is beneficial in treating pain after cesarean section, migraine headache, dental surgery, acute musculoskeletal pain and biliary colic^[3-10]. However, no studies have been reported for pain control after fistulectomy. The prospective objective of this study was to evaluate the analgesic properties and efficacy of butorphanol nasal spray after fistulectomy.

MATERIALS AND METHODS

After approval from the institutional review board of Tri-

Service General Hospital and on receipt of each patient's written informed consent, 60 patients (fistula in ano, intersphincteric type) scheduled for fistulectomy were enrolled from January 2006 to December 2007. Patients were randomly divided into the transnasal butorphanol treatment group ($n = 30$) and the intramuscular meperidine control group ($n = 30$) using a random number table. Exclusion criteria were an American Society of Anesthesiologists physical classification $> II$, any history of atrophy sinusitis or repeated epistaxis, previous anorectal surgery, inflammatory bowel diseases, hematologic disorders, significant cardiovascular disease, impaired renal function (serum creatinine > 1.5 mg/dL), hepatic disease (twice the upper normal limit of AST or ALT levels) or psychiatric disorders.

During surgery, a monitoring system was attached to each patient. This included pulse oximetry and noninvasive blood pressure measurement. A standardized heavy station intramuscular analgesia (meperidine 1 mg/kg, midazolam 0.08 mg/kg), local perianal anesthesia (2% lidocaine, 0.5% bupivacaine, 1:200 000 epinephrine) and surgical technique (fistulectomy) were prescribed for all patients. A gauze roll was placed in the anal canal for compression and this was removed 8 h later. At 6 h after completion of surgery, all patients were given oral analgesia (tolfenamic acid 10 mg). Subsequently, oral analgesia was prescribed regularly every 6 h. The patients in the butorphanol group received one spray (1 mg) at least every 4 h if they were in pain. In the control group, the patients received intramuscular meperidine (0.8 mg/kg) at least every 4 h if in pain.

Postoperative pain was assessed using a 10-point subjective visual analogue scale (VAS, 0 = "no pain" and 10 = "maximum pain"). The VAS score was recorded 6 h after the completion of surgery, before receiving the first dose of butorphanol or meperidine, 60 min after the analgesic prescribed and the next morning after removal of the gauze roll. Length of hospital stay and any adverse effects of the medicines such as somnolence, dizziness, nausea or vomiting were recorded. The VAS score and adverse effects were measured by an experienced nurse. Before discharge, the patients were asked three questions using questionnaires: (1) Are you satisfied with the narcotic efficacy? (2) How do you feel about the adverse effects? (3) Would you ask for the medicine again if necessary?

Statistical analysis was performed using SYSTAT (version 9.0, SPSS, Inc., Chicago, IL, USA). Each patient's demographic information and the VAS scores were compared between groups using Student's t or χ^2 tests. Side effects between groups were analyzed using the Fisher's exact test. The Wilcoxon rank-sum test was used to compare length of hospital stay between the groups and $P < 0.05$ was considered statistically significant.

RESULTS

Of the 60 patients, 42 (70%) were men and 18 (30%) were women. The mean age of the patients in the butorphanol group was 37.7 years and was 38.9 years in the meperidine

Table 1 Patient characteristics ($n = 30$, mean \pm SD)

	Butorphanol group	Meperidine group	<i>P</i> value
Age (yr)	37.70 \pm 10.76	38.90 \pm 10.89	0.669
Sex (%)			0.778
Male	20 (66.7)	22 (73.3)	
Female	10 (33.3)	8 (26.7)	
Weight (kg)	62.70 \pm 10.29	64.83 \pm 12.01	0.463
Height (cm)	164.57 \pm 7.03	165.73 \pm 7.18	0.528

Table 2 Results (mean \pm SD)

Variable	Butorphanol group	Meperidine group	<i>P</i> value
Operative time (min)	46.17 \pm 15.59	48.43 \pm 10.80	0.515
Frequent of analgesia (times)	3.03 \pm 1.67	1.23 \pm 0.504	< 0.001
VAS (6 h after surgery)	5.67 \pm 0.88	5.77 \pm 1.00	0.684
VAS (before analgesia)	8.17 \pm 1.66	8.31 \pm 1.36	0.719
VAS (after analgesia)	5.93 \pm 1.41	5.52 \pm 1.12	0.216
VAS (the next morning)	6.13 \pm 1.47	5.93 \pm 1.14	0.560
Hospital stay (d)	3.63 \pm 0.69	3.73 \pm 0.74	0.585

Table 3 Adverse effects n (%) ($n = 30$)

Adverse effect	Butorphanol group	Meperidine group	<i>P</i> value
Any side effect	16 (53.3)	10 (33.3)	0.192
Somnolence	10 (33.3)	5 (16.7)	0.23
Dizziness	6 (20.0)	4 (13.3)	0.73
Nausea	5 (16.7)	4 (13.3)	1.00
Vomiting	2 (6.7)	2 (6.7)	1.00

group. The mean surgical time was 46.17 min in the butorphanol group compared with 48.43 min in the meperidine group. The demographic details did not differ significantly between two groups (Table 1). The overall frequency of analgesic usage was 3.03 times in the butorphanol group compared with 1.23 times in the meperidine group ($P < 0.001$). The VAS scores were similar between the groups (Table 2). The mean VAS score 6 h after completion of surgery was 5.67 in the butorphanol group compared with 5.77 in the meperidine group. The mean VAS score before analgesic was 8.17 in the butorphanol group compared with 8.31 in the meperidine group. The mean VAS score after analgesia was 5.93 in the butorphanol group compared with 5.52 in the meperidine group. The mean VAS score the next morning was 6.13 in the butorphanol group compared with 5.93 in the meperidine group (Figure 1). The mean hospital stay was 3.63 d in the butorphanol group compared with 3.73 in the meperidine group.

Several adverse effects were recorded (Table 3). Sixteen patients complained of side effects in the butorphanol group and 10 patients complained of side effects in the meperidine group. The incidence of somnolence, dizziness and nausea was higher in the butorphanol group than in the meperidine group. However, no significant difference in adverse effects between the groups was observed. In the questionnaires, most patients reported good satisfaction with the analgesic they received; 22 patients in the butorphanol group (73%) would be happy

Figure 1 Pain level was scored from 0 to 10.

to receive butorphanol nasal spray for analgesia in the future if necessary. However, in the butorphanol group, two patients felt they had a poor analgesic response and four patients complained of multiple side effects. Three patients in the meperidine group complained of multiple side effects such as somnolence, dizziness and nausea.

DISCUSSION

Butorphanol nasal spray proved effective in relieving pain after fistulectomy. These data also demonstrate that butorphanol was equivalent to meperidine for analgesia. This is consistent with the literature on the treatment of moderate to severe pain^[3-10]. Butorphanol has been approved in an injectable formula in Taiwan since 1979. Initially, it was prescribed for intravenous or intramuscular administration to avoid the problem of hepatic first-pass metabolism^[1]. In 1992, a transnasal formulation was developed to avoid the reduced bioavailability of oral administration. Compared with the oral formulations, transnasal administration produces higher maximum concentration, rapid absorption and better pain relief^[1]. It is also 4-8 times more potent than morphine and 30-40 times more potent than meperidine^[11]. Peak plasma concentration is reached 30-60 min after 1 mg transnasal administration^[12,13]. Moreover, butorphanol nasal spray can be self-administered, is noninvasive and allows convenient usage for patients, especially outpatients.

In both treatment groups, the VAS scores were lower 6 h after completion of surgery. This could reflect the long anesthetic effect of bupivacaine. Subsequently, the VAS score increased and then decreased. The frequency of requests for butorphanol was higher than for meperidine ($P < 0.001$). However, the reduced VAS pain scores were similar in both groups. Moreover, transnasal butorphanol was noninvasive, convenient and more acceptable to patients. Thus, butorphanol nasal spray could be considered as an alternative device for patient-controlled analgesia.

From the questionnaires, we found that 22 patients (73%) would prefer to receive butorphanol nasal spray in the future, if necessary. However, two patients in the

butorphanol group felt that they had a poor analgesic response and these patients developed severe adverse effects. Therefore, to achieve the maximum benefit from butorphanol nasal spray, clinicians should inform patients about the possible adverse effects. Patients must also be alerted to the sedative properties of butorphanol. Most importantly, patients should be cautioned to avoid activities such as driving or operating equipment until the analgesia has worn off.

This study had several limitations, the main limitation being the small sample size. A larger sample size would have offered better information on efficacy and adverse effects of the medications. In addition, with a larger sample size statistically significant differences between the groups may have been observed. Secondly, the VAS pain scores were subjective, possibly reflecting inadequate instruction. Moreover, we did not design a placebo group as it would be unethical to withhold analgesia. Thus, we cannot draw any conclusion as to how butorphanol or meperidine might compare with placebo treatment.

In conclusion, butorphanol nasal spray was effective for relief of pain after fistulectomy. In addition, it offers patient-controlled and more convenient usage than intramuscular meperidine.

ACKNOWLEDGMENTS

The butorphanol nasal spray was donated by the Lotus Pharmaceutical Co., Ltd., Taipei, Taiwan, China.

COMMENTS

Background

Postoperative pain is the major patient complaint after anal surgery. Our purpose was to investigate the analgesic properties and efficacy of transnasal butorphanol after anal surgery.

Research frontiers

Postoperative pain was assessed using a visual analogue scale (VAS). However, VAS scales are subjective and the results possibly reflect inadequate instruction.

Innovations and breakthroughs

Several reports have demonstrated that butorphanol nasal spray is beneficial in treating postoperative pain. This is the first study to report that it is also effective for pain relief after anal surgery.

Applications

As butorphanol nasal spray is safe and effective for relief of pain after anal surgery, it might offer convenient usage for outpatients.

Peer review

It is a small and possibly worthwhile clinical trial with a novel analgesic regimen.

Abstract

AIM: To investigate the expression of leukemia related protein 16 (LRP16), and the possible relationship between LRP16 expression and clinicopathological indices in 336 gastric carcinoma patients.

METHODS: Immunohistochemistry was used to detect LRP16 expression in 336 cases of paraffin-embedded gastric carcinoma tissues and 60 cases of distal normal mucosa. The relationships between LRP16 expression and patients' age, tumor size, histological grade, clinical stage, metastatic status and prognosis were analysed.

RESULTS: The expression of LRP16 was 58.6% (197/336) in gastric carcinoma and 31.7% (19/60) in distal normal gastric mucosa. The expression of LRP16 in carcinoma was significantly higher than that in normal mucosa tissues ($\chi^2 = 14.929$, $P = 0.001$). LRP16 protein expression was found in 44.1% (63/143) carcinomas at stage I and II, and 69.4% (134/193) carcinomas at stage III and IV ($\chi^2 = 21.804$, $P = 0.001$), and in 56.9% (182/320) of cancers without metastasis but 93.8% (15/16) of those with metastasis ($\chi^2 = 8.543$, $P = 0.003$). The expression of LRP16 was correlated with tumor size, infiltrative depth, clinical stage, lymphatic invasion and distant metastasis (all

$P < 0.05$). Follow-up data showed that there was a significant difference in median survival time between cancer patients with expression of LRP16 (27.0 mo) and those without (48.0 mo, Log rank = 31.644, $P = 0.001$).

CONCLUSION: The expression of LRP16 may be associated with invasion, metastasis and prognosis of gastric cancer.

INTRODUCTION

Leukemia related protein 16 gene (*LRP16*), localized on chromosome 11q12.1, is an important estrogen-responsive gene^[1-5]. It has been found expressed at a high level in testicles, ovaries and mucosa of colon, at a moderate level in prostate, small intestine, spleen and thymus, and at a low level in peripheral blood leucocytes^[2,3]. LRP16 is also an estrogen receptor alpha ($ER\alpha$), coactivator^[6], and it may play an important role in ER signaling pathways. Since gastric cancer is the second leading cause of cancer-related death worldwide^[7], it is important for us to assess its prognosis according to the expression of some markers. It has been reported that ER is expressed in gastric cancer^[8], but no reports have ever evaluated the expression of *LRP16* gene in gastric carcinoma so far. In this study we retrospectively analyzed the relationships between the expression of LRP16 and clinicopathological factors in 336 Chinese patients with gastric cancer.

MATERIALS AND METHODS

Biopsy specimens

Paraffin embedded sections of 336 gastric carcinomas and 60 distal normal gastric tissues were obtained from the Department of Pathology, Chinese People's Liberation Army (PLA) General Hospital (Beijing, China) from 1998 to 2001. Of these patients, 17 were grade I, 65 grade II and 254 grade III, according to histological grading; 66 were stage I, 77 stage II, 147 stage III and 46 stage IV, according to clinical TNM stage revised by UIAC in 2003; and 75 were tubular adenocarcinoma (well-moderately differentiated adenocarcinoma), 32 were mucinous adenocarcinoma, 183 were poorly differentiated adenocarcinoma, 35 were signet-ring cell carcinoma, 11 were other gastric carcinoma according to histological type, respectively. By March, 2008 (the time of data analysis), 251 patients were dead, and 85 patients were alive. The median survival time was 36 mo (range, 0.17-120 mo).

Immunohistochemistry

All samples were fixed in 10% buffered formalin and embedded in paraffin. Sections were cut 4 μ m/L thick from wax blocks, mounted on to APES-coated glass slides. Slides were deparaffinized in xylene twice for 10 min, rehydrated through graded ethanols to distilled water before incubation for 10 min with 3% hydrogen peroxidase-methanol to inhibit endogenous peroxidase activity, and heated in 0.01 mol/L citrate buffer (pH 6.0) in a microwave oven for 5 min at 100°C after reaching boiling point for antigen retrieval. Then the slides were taken out of microwave oven to be cooled at room temperature for 15 min. After incubating for 20 min in a blocking solution containing 10% normal goat serum in PBS, sections were incubated at 4°C overnight in a humidified chamber with rabbit polyclonal antibody to human LRP16 (recognized and isolated in 1999 by Department of Molecular Biology of our hospital) diluted 1:400 in blocking solution. The sections were rinsed in PBS and incubated for 30 min with biotinylated secondary antibody (Poly peroxidase anti-mouse/rabbit IgG, Zymed). After washing in PBS, the sections were then incubated for 30 min at 37°C. 3,3'-Diaminobenzidine was used as the chromogen. Slides were counterstained for 3 min with hematoxylin solution. Normal ovarian tissue was used as a positive control for every lesion, whereas the primary antibody was replaced by PBS as a negative control.

Evaluation of score

In scoring LRP16 protein expression, both the extent and intensity of immunopositivity in the cell nucleus were considered. The intensity of staining was scored as follows: 0, negative; 1, weak; 2, moderate; 3, strong. The extent of staining was scored as follows: 0, < 5%; 1, > 5%-25%; 2, > 25%-50%; 3, > 50%-75%; 4, > 75% of the cells in the respective lesions. The final score was determined by multiplying the intensity of staining and the extent of staining scores, yielding a range from 0

Figure 1 Positive LRP16 expression in gastric adenocarcinoma (IHC, $\times 400$). The case received 3 scores (strong) relating to intensity of staining, and 3 scores (> 50%-75%) relating to extent of staining. Thus the final score was 9, which was defined as strong staining pattern (++).

to 12. Scores 9-12 were defined as preserved or strong staining pattern (++), 5-8 were defined as weak staining pattern (+) and 0-4 were defined as markedly reduced or negative expression (-).

Statistical analysis

For the statistical analysis, SPSS 13.0 for Windows (SPSS Inc, Chicago, Illinois) was used. The clinical variables were analyzed with the χ^2 test. The survival rates were calculated by the Kaplan-Meier method, and the outcomes of treatment were evaluated with the log-rank test. Finally, multivariate analysis was performed to determine the independent prognostic factors by Cox proportional hazards regression model. $P < 0.05$ was considered statistically significant.

RESULTS

LRP16 expression in gastric carcinoma and normal mucosas

LRP16 was assessed by IHC in 336 gastric cancer cases, with the following results: negative expression (-) in 41.4% (139/336) cases, weak staining (+) in 37.2% (125/336) cases, strong staining (++) in 21.4% (72/336) cases. In normal cases, LRP16 showed a negative expression in 68.3% (41/60) cases, a weak expression in 21.7% (13/60) cases, and a strong expression in 10.0% (6/60) cases. In total, LRP16 protein was expressed (+ or ++) in 58.6% (197/336) gastric carcinoma, but was expressed (+ or ++) only in 31.7% (19/60) of distal normal stomach mucosa (Figures 1 and 2). LRP16 protein was localized mainly in the nucleus of cancer cells or normal epithelial cells. A greatly significant difference was found in the expression of LRP16 protein between gastric carcinoma and normal gastric mucosa tissues ($\chi^2 = 14.929$, $P = 0.001$).

Relationships between LRP16 expression and histological grade, clinical stage and prognosis

The proportion of LRP16 expression showed an increasing trend from smaller tumor to bigger tumor. Significant positive correlations were found between

Figure 2 Negative LRP16 expression in normal gastric mucosa (IHC, $\times 400$). The case received 1 score (weak) relating to intensity of staining, and 0 scores ($< 5\%$) relating to extent of staining. Thus the final score was 0, which was defined as negative expression (-).

Tumor size	0.686	0.082	70.279	0.000 ^a	1.986
LRP16 expression	0.174	0.094	3.466	0.063	1.190

^a $P < 0.05$, statistically significant. B: Partial regression coefficient; RR: Relative risk.

median survival time between the carcinomas with LRP16 expression (27 mo) and those without (48 mo), and the overall 5-year survival rate (45.8%) of the LRP16 positive group was better than that of the LRP16 negative group (39.1%) (Log rank = 31.64, $P = 0.001$) (Figure 3).

LRP16 expression and Cox proportional hazards model

By Cox proportional hazards model, age, tumor size, histological type, depth of invasion, lymph node metastasis, and distant metastasis were proved to be statistically significant, but LRP16 was not an independent prognostic indicator (Table 2).

DISCUSSION

LRP16 was originally isolated from lymphocytes in order to identify a leukemia relapse-related gene, but there was no difference between patients primarily diagnosed with acute myeloid leukemia (AML)^[9]. Later some studies demonstrated that *LRP16* gene plays an important role in the carcinogenesis and progression of hormone-dependent breast cancer^[5,6]. LRP16 overexpression markedly promoted the proliferation of MCF-7 human breast cancer cells by promoting G1/S transition through increasing the cyclin E and cyclin D1 protein level^[4,6]. On the contrary, suppression of *LRP16* gene

expression inhibited MCF-7 cell growth and sensitized tumor cells to radiation^[10]. It has been proposed that estrogen affects the expression of *LRP16* gene, and its expression was strongly dependent on the estrogen activities^[9,11]. However, ectopic expression of *LRP16* in ER α -negative cells has no effect on proliferation^[6]. Among breast cancer patients, *LRP16* expression was significantly correlated with tumor size, lymph node metastasis, and clinical stage^[12]. Clinical data has shown that *LRP16* is overexpressed in primary breast cancer samples compared with their matched normal tissues^[12]. In our study, *LRP16* expression is in relation to tumor size, depth of invasion, lymph node metastasis, distant metastasis and TNM stage. The expression of *LRP16* in carcinoma is significantly higher than that in normal mucosa. Two types of ERs, ER α and ER β , have both been identified in non-cancerous and cancerous gastric tissue^[13,14]. Therefore, we propose that *LRP16*, a coactivator of ER α , may have a similar function on gastric cancer as on breast cancer. Activation of the ER signaling pathway plays important roles in multi-tissue development^[15-18], which implies that *LRP16* may display an important function in ER α target tissue development.

In conclusion, *LRP16* protein may play an important role in the carcinogenesis, progress and prognosis of Chinese gastric carcinoma and *LRP16* expression detected by immunohistochemistry may be a simple and useful molecular marker to predict the prognosis in gastric carcinoma patients. The association between *LRP16* and ER in gastric cancer development needs to be further investigated, from which *LRP16* targeting with anti-estrogen therapy may be applied in gastric cancer patients.

ACKNOWLEDGMENTS

The authors thank all colleagues (Department of Molecular Biology, Chinese People's Liberation Army General Hospital) who have done much work on *LRP16*. We greatly appreciate the comments from the reviewers for improving the manuscript.

COMMENTS

Background

Gastric cancer is the second leading cause of cancer death worldwide and it is important for us to assess its prognosis according to the expressions of some markers. The expression of *LRP16* may be associated with invasion, metastasis and prognosis of gastric cancer. Therefore, *LRP16* may play a significant role in the evolution of gastric carcinoma.

Research frontiers

LRP16 is an important estrogen-responsive gene. Some studies have demonstrated that *LRP16* gene plays an important role in the carcinogenesis and progression of hormone-dependent breast cancer. It has also been reported that ER is expressed in gastric cancer, but no reports have evaluated the expression of *LRP16* gene in gastric carcinoma so far. In this study the authors retrospectively analyzed the relationships between the expression of *LRP16* and the clinical and pathological factors for Chinese patients with gastric cancer.

Innovations and breakthroughs

Recent reports have demonstrated the important roles of *LRP16* in *in vitro* cell studies. Particularly in breast cancers, *LRP16* is over-expressed. This is the

first study to report that *LRP16* is also over-expressed in gastric carcinoma. Furthermore, our study shows that *LRP16* expression is in relation to tumor size, depth of invasion, lymph node metastasis, distant metastasis and TNM stage in gastric cancer.

Applications

The *LRP16* expression status detected by immunohistochemistry may be a simple and useful molecular marker to predict the prognosis in gastric carcinoma patients.

Terminology

LRP16, *Leukemia related protein 16* gene, localized on chromosome 11q12.1, is an important estrogen-responsive gene. It has been proposed that the expression of *LRP16* gene is strongly dependent on the estrogen activities. *LRP16* gene plays an important role in the carcinogenesis and progression of hormone-dependent breast cancer. Estrogen receptors (ERs), including ER α , ER β and the recently discovered ER β cx, have been identified in non-cancerous and cancerous gastric tissue. The biological mechanisms behind this are not yet clear.

Peer review

The authors examined the expression of *LRP16* protein, and the possible relationship between *LRP16* expression and clinicopathological indices in gastric carcinoma patients. It revealed that the expression of *LRP16* might be associated with invasion, metastasis and TNM stage of gastric cancer. The results are interesting and may provide us with a new molecular marker to assess the prognosis of gastric carcinoma.

Abstract

AIM: To investigate and evaluate the pathological features and diagnostic value of focal nodular hyperplasia (FNH) with multi-section spiral computed tomography (MSCT) and postprocessing.

METHODS: A total of 25 patients with FNH who had undergone MSCT and postprocessing were included in the investigation. All patients had been pathologically or clinically confirmed with FNH. A number of 75 cases of hepatic carcinomas, hemangiomas and adenomas were randomly selected at a same period for a comparative study.

RESULTS: There was a single focus in 22 cases and multiple foci in 3 cases. On the plain scan, 17 lesions showed hypodensity, 7 isodensity and 4 hyperdensity (the case with fatty liver). With contrast, 28 lesions were enhanced evenly or in the nodules in the arterial phase; 13 lesions still showed hyperdensity, 11 lesions isodensity and 4 lesions hypodensity in the parenchymatous phase; in the delayed phase only 5 lesions showed hyperdensity but 9 lesions showed isodensity or slight hypodensity and 14 lesions showed hypodensity. Twelve lesions of 28 had central asteroid scars. Thickened feeding arteries in postprocessing

INTRODUCTION

Hepatic focal nodular hyperplasia (FNH) was first described and proposed by Edmondson^[1] in 1958, then verified a decade later by the World Health Organization in 1975. At that time cases were too few to be investigated, and were considered as "local sclerotization", "hepatic hamartoma", "hepatic adenoma" and so on^[2]. With the improvement in imaging techniques, the number of cases diagnosed with FNH have been gradually increasing. At present, the incidence of FNH is just less than that of hemangiomas and has become the second most common benign hepatic disease^[3]. Although there have been a number of papers on FNH with different modalities in recent years^[4-7], multi-section spiral computed tomography (MSCT) was considered as one of the common facilities and could demonstrate some radiological characteristics

to diagnose with FNH^[8]. This article discusses more critical imaging findings on relating to the histological features in FNH through analyzing a total of 25 patients with 28 lesions and 75 cases of other hepatic tumors by MSCT and postprocessing.

MATERIALS AND METHODS

Study source

Authors collected and analyzed data of 25 FNH patients with 28 lesions within 2 institutions, the Cancer Center of Sun Yat-sen University and Peking University Shenzhen Hospital, from January 2005 to December 2007. The patients underwent CT examination and were confirmed with FNH pathologically or clinically. None of the patients had hepatitis, and all alpha-fetoprotein tests were normal. There were 14 men and 11 women, age range 14-59 years, and mean age 35.5 years. Of the 25 patients, 11 patients were confirmed with FNH by pathology after surgery resection, 14 patients were ascertained to have FNH by relative examinations and clinical follow-up for at least 18 mo with a stable shape and no marked change or diminution of the lesion. Meanwhile 30 hepatic carcinomas, 30 hemangiomas and 15 adenomas were randomly selected at a same period with MSCT and postprocessing for a control group.

CT scan protocols

All 25 patients underwent 16-section spiral CT scanning (Aquilion 16, Toshiba Medical Corporation). CT projection radiographs were scanned firstly for range confirmation, from the apex of the diaphragm to the base of the liver. After the plain scan, a bolus of about 100 mL (average 1.5 mL/kg body weight) contrast media of iodixanol (Iohexol, 300 mgI/mL) was injected into the antecubital vein at a flow rate of 3-5 mL/s for the enhanced scan. Bolus tracking was performed with the region of interest on the descending aorta at the level of diaphragm apex, and the arterial phase scan was automatically started 6 s after attenuation in the region of interest reached a pre-defined threshold of 120 HU. Three-phase scans were performed after contrast media injection: arterial phase scan (about 20-25 s), parenchymatous or vein phase scan (about 65-70 s), delayed scan (about 150-180 s). Scan parameters: tube voltage 120 kVp, tube current 300 mA, gantry rotation time 0.5 s per rotation, matrix 512 × 512, beam pitch 0.9375, detector collimation thickness 16 × 1 mm, abdomen standard reconstruction algorithm, and effective thickness of reconstruction images 1 mm.

Imaging postprocessing and analysis

To study the multi-phase images and analyze the dynamic changes in the lesions, the images from the arterial phase and parenchymatous phase were transferred to workstation (Vitrea2, Vital, USA) for postprocessing, with the use of volume rendering technique (VRT) and maximum intensity projection (MIP) to display the arteries supplying the lesions. Three radiologists evaluated the images in a double-blind manner, recorded the main parameters and analyzed the results.

RESULTS

Size and shape of FNH

A total of 25 patients with 28 lesions were studied, among them 22 patients with single lesions, the other 3 with multiple lesions. The sizes of the lesions ranged from 1.0 to 8.3 cm. All lesions assumed a circular or circular-type shape with a clear boundary except 2, which showed irregular lobulated shapes.

Location of FNH

There were 6 lesions at the right anterior lobe, 13 at the right posterior lobe, 6 at the left lobe and 2 near the diaphragm in the right lobe, one projecting outside the hepatic boundary.

Pathology of FNH

Specimens showed some pale yellow tubercular structures with many separations, part of which were found with asteroid scars, but no real fibrillar involucrem. Under microscopy fibroplasia, permeated with acute or chronic inflammation, could be seen. The center or periphery of the scars were rich in fibrous tissue and small vessels. No malignant tumor cytology was observed.

MSCT and postprocessing findings

Of the 25 patients with 28 FNH lesions, on plain CT 17 lesions showed hypodensity, 7 isodensity and 4 hyperdensity (in the 4 patients with fatty liver, one of whom had multiple lesions). With contrast, 28 lesions showed even or nodular enhancement in the arterial phase; 13 showed hyperdensity, 11 isodensity and 4 hypodensity in the parenchymatous phase; 5 showed hyperdensity, 9 isodensity or slight hypodensity and 14 hypodensity in the delayed phase. Of the 28 lesions, 12 were found to have a central asteroid scar (Figure 1A-D), with radiating form, and among these, 4 scars were reduced in size in the parenchymatous and delayed phases (Figure 2), 5 scars vanished in the parenchymatous and delayed phases with the lesions showing isodensity, and the other 3 scars showed high density (Figure 1D) in the late delayed phase; also, blood vessels could be seen in some central asteroid scars. The authors also found one example of FNH simultaneously accompanied by hemangiomas (Figure 3). Exceptionally, 6 lesions assumed a ring-like enhancement (Figure 4) in the parenchymatous and delayed phases which were likely mixed with a false involucrem as seen in some hepatic tumors. Thickened blood-supplying arteries were demonstrated in 24 lesions with VRT or MIP in postprocessing (Figure 5A and B), and the arteries followed a gentle line with gradual and direct entry into the body of the lesion. On comparative study, there were no such an artery penetrated into the lesion found in any of other hepatic carcinomas, hemangiomas or adenomas.

DISCUSSION

FNH manifestation and characteristics in this group

FNH pathogenesis was once thought to occur most

Figure 1 A patient with FNH on the left hepatic lobe. A: Hypodensity of the lesion with lower density of the central asteroid scar; B: High enhancement with a thickened blood-supplying artery detected in the arterial phase; C: Normal density of the lesion and lower density of the central scar in the parenchymatous phase; D: Normal density of the lesion and slightly higher density of the central scar in the delayed phase.

Figure 2 A FNH lesion located on the hepatic right posterior lobe was evenly highly enhanced except for the central asteroid scar in the arterial and parenchymatous phases (A), the scar being reduced in size in the delayed phase (B).

frequently in young women^[9], whereas in this study it occurred in more males than females, but the shape of the lesion was larger in females than in males. A relationship between FNH and oral contraceptives remains inconclusive. The use of contraceptives does not increase FNH incidence, but may possibly promote FNH growth^[10]. A recent report indicates that FNH is possibly linked with hereditary factors in an unusual manifestation of hepatic organization^[11].

This FNH group primarily appeared with a single lesion (22/25). Most of these cases had no marked clinical symptoms, and only a minority of this group presented with pain and feeling unwell, or a suspicious lump in the right upper abdomen, one of which was clinically thought to be in danger of rupture or hemorrhage. The majority of FNH cases were discovered on routine physical examination and then investigated further.

The FNH pathology has 3 major characteristics: (1) The pathological change is not a real tumor, but mainly normally functioning hepatic cells, with proliferation of the connectivum, the abnormal bile duct and

macrophages; (2) The existence of abnormal blood vessels and fiber structure, namely a scar in the center of the pathological change; (3) The blood supply pattern radiated from the inside to the periphery^[12-14]. Under the microscope may be seen fibrous divisions and an area of proliferating hepatic cells in FNH, which lacks a normal vein and portal vein, and sometimes has acute or chronic inflammatory cells^[15]. In addition there is a special type of FNH called multiple FNH syndrome^[16,17], which comprises more than 2 FNH lesions, simultaneously merged at least with one of the following pathological changes: hepatic angiocavernoma, artery structure damage, blood vessel abnormality in the central nervous system, meningioma or neurogliocytoma. This group included an example of multiple FNH combined with hepatic angiocavernoma (Figure 3).

It should be noted that on the border of the FNH lesions, there were expanded blood vessels or blood sinuses, which assumed an incomplete enhanced link round the tumor (Figure 4), and could easily be taken for a malignant tumor with involucrum enhancement.

Figure 3 A patient with FNH (hepatic right posterior lobe) accompanied by hemangiomas (left medial lobe). In the arterial phase a border nodular enhancement can be seen in the hemangiomas but even enhancement was demonstrated in FNH except for the central scar.

Figure 4 An arrow shows the ring-like enhancement mimicking a false involucreum.

Appearance of FNH in MSCT scanning with postprocessing

The majority of FNH showed as normal or slightly low density tumors in CT scans, demonstrating a clear boundary, even density, and no calcification^[18,19]. In enhanced scanning, the FNH characteristics alternated as follows: in the arterial phase the lesion quickly and obviously increased evenly or in the nodules from the central area; in the parenchymatous and delayed phases the contrast agent flowed out evenly and the low density lesion appeared. These enhanced characteristics were the result of the rich arterial blood supply and major vein drainage and generous blood sinuses within FNH. The center asteroid low density scar in 12 of 28 (42.8%) lesions has a distinctive feature to differentiate FNH from other tumors with a rich blood supply. MIP or direct volume rendering (DVR) could demonstrate the supplying artery to the central scar (Figure 5). In the parenchymatous and delayed phase the scars were enhanced gradually to equilibrium or to slightly high density, and only 2 remained at low density. The authors believe that it might be possible that scar proliferation could lead to obliteration of the vessel lumen, which could easily be confused with necrosis or a collagen scar within fibrous lamina-like cancer, hepatocellular carcinoma or cholangiocellular carcinoma^[20].

Figure 5 Imaging with use of MSCT postprocessing technology. A: A thickened blood-supplying artery was demonstrated in the FNH lesion on maximum intensity projection, and was centrifugal type with radiating blood supply within the lesion; B: Another case of FNH, the volume rendering technique showed the artery following a gentle line gradually entering into the body of the lesion.

The technology of DVR or MIP may directly demonstrate the pattern of blood supply in FNH with just the enhanced scanning raw data, the results of which provide new significant evidence for FNH diagnosis. The arteries supplying blood in FNH often appeared thickened, and had a smooth, gradual course, entering directly into the central area of the lesion. The pathology demonstrated that FNH has one or several blood-supplying arteries, which radiate from the center to the circumference^[21]. The major blood supply and drainage vessels have been demonstrated by color Doppler^[22,23]. In the scar center were vasa vasorum which proliferated and radiated throughout. All of these characteristics showed marked features different from hemangiomas or other cancers of the liver.

Differential diagnosis

The central scar may either appear in FNH or fibrous lamina-like hepatocellular carcinoma, and their imaging appears extremely similar. However, the FNH may occur as a single or multiple lesion, and in the arterial phase the lesions are markedly enhanced, their density approaching that of the aorta, whereas the fibrous lamina-like hepatocellular carcinoma usually appears as a single lesion with a diameter sometimes greater than 10 cm, with the central scar seldom or slightly enhanced. FNH may present false involucreum signs in certain case which could be confused with malignancy^[24], but, by

postprocessing, arterial vessels of hepatic carcinoma were revealed to be unevenly thickened, damaged, and discontinuous^[25].

Both FNH and hemangiomas of the liver could be markedly enhanced but in different ways. The typical enhancement of hemangiomas started from the periphery, with nodular or ring-like enhancement, advancing gradually to the center, with delayed phase backfill to equal density or high density. In contrast, enhancement of FNH started at the center of the lesion, rapidly and evenly spreading throughout, except for the central scar, which consistently strengthened then abated on the delayed phase. The process in hemangiomas enhanced slowly (representing slow bloodstream) and some atypical small hemangiomas may backfill completely in the arterial phase, but in the parenchymatous and delayed phases still assumed a high or equal density, which was a crucial difference from FNH^[26].

A patient with hepatic adenoma commonly has a history of taking contraceptives and/or has had celiacgia for a long time. Sometimes a ring-like bright band may be seen at the edge of an adenoma. As they bleed easily, some hematoma within the lesion result in a very different outcome of imaging compared with FNH^[27]. The peripheral enhancement in adenoma possibly indicated a wealth of blood-supplying vessels under the big involucre. The enhancement in adenoma was mostly centripetal, in contrast to the FNH centrifugal type^[28].

There are a variety of imaging techniques for visualizing FNH in different aspects^[29]: single photon emission CT (SPECT) can make a differentiation according to whether or not there are Kupffer cells in the lesion^[30]; color ultrasound may allow a rudimentary diagnosis based on finding radiating blood flow; magnetic resonance imaging emphasizes the special signal intensity in the FNH and its central scar and even its spectrum^[31]. However, MSCT with postprocessing technology provides a common mean of entirely recognizing the pathological characteristics of FNH, not only demonstrating the central asteroid scar and shape of the lesion, but also the tissue enhancing process, the blood-supplying model and hemodynamics^[32]. The following points should be used clinically to consider as FNH: (1) The MSCT plain scan presents a low or slightly low density lesion with an even, clear boundary and lower density central asteroid scar, which shows delayed enhancement; (2) In the arterial phase, the lesion is rapidly and evenly enhanced except for the central scar, in the parenchymatous phase, the lesion has normal or slightly high density, and in the delayed phase it has low density; (3) The lesion has a thickened but symmetrical blood-supplying artery^[33] entering gradually into the lesion. These are FNH pathological characteristics, on which clinicians could make a definite FNH diagnosis, no longer requiring further auxiliary investigations, biopsy or surgery.

diseases of the liver. As a benign disease, correct diagnosis of focal nodular hyperplasia (FNH) is vital for choosing the appropriate treatment protocol.

Research frontiers

Imaging techniques have been used to investigate the variants of FNH, e.g. single photon emission CT (SPECT) examined whether or not there were Kupffer cells in the lesion, color ultrasound investigated radiating blood flow, magnetic resonance imaging measured particular signal intensity in the central scar, whereas MSCT, by intravenous injection of contrast medium, can delineate the lesion shape, size, supplying arteries and hemodynamics, which could reflect the pathological manifestations of FNH.

Innovation and breakthroughs

On detailed FNH case observation, this paper has introduced different enhanced modes in the lesion and the central scar. By postprocessing in a workstation, the authors found a thickened but symmetrical artery entering into the lesion with a radiating blood supply, which is crucial in revealing the pathological characteristics of FNH and in making a conclusive diagnosis.

Applications

Based on the results of this study, a contrast method with postprocessing is recommended in diagnosis of hepatic lesions with MSCT, in order to reveal the features of enhancement, the central scar and supplying artery in FNH.

Terminology

FNH was one of the more recently recognized diseases, but its pathogenesis was still unknown. It is not a real tumor, but a mass of normal functional hepatic cells, with proliferation of the connectivum. FNH was often confused clinically with some other malignant and benign tumors such as hepatocellular carcinoma, hepatic hemangioma, etc.

Peer review

An important imaging technique has been addressed in this paper. Using a contrast method and postprocessing in a workstation, multi-section spiral computed tomography offers significant features which may reveal the characteristics of FNH pathology, and therefore the technique could make a reliable FNH diagnosis before biopsy or surgery.

Ma HQ, Liang XT, Zhao JJ, Wang H, Sun JC, Chen YB, Pan K, Xia JC. Decreased expression of *Neurensin-2* correlates with poor prognosis in hepatocellular carcinoma. *World J Gastroenterol* 2009; 15(38): 4844-4848 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4844.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4844>

Abstract

AIM: To investigate the expression of *Neurensin-2* (*NRSN2*) in hepatocellular carcinoma (HCC) and its prognostic values in predicting survival.

METHODS: The expression and prognostic significance of *NRSN2* in HCC was examined by performing immunohistochemical analysis using a total of 110 HCC clinical tissue samples, and Western blotting analysis to further confirm the result.

RESULTS: Decreased *NRSN2* expression was shown in 70.9% cases. Loss of *NRSN2* expression in HCC was significantly related to tumor size ($P = 0.006$). Larger tumor size was related to negative expression of *NRSN2*. Patients showing negative *NRSN2* expression had a significantly shorter overall survival than those with positive expression ($P = 0.008$). Multivariate Cox regression analysis indicated that *NRSN2* expression level was an independent factor of survival ($P = 0.013$). Western blotting analysis further confirmed decreased expression of *NRSN2* in tumor tissues compared with non-tumorous tissues.

CONCLUSION: Our study indicated that *NRSN2* could be a tumor suppressor gene for HCC and a candidate biomarker for long-term survival in HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide and the third most common cause of cancer-related death in the world^[1,2]. In China, it is the second leading cause of cancer death among males^[3]. Factors associated with increased risk of HCC include HBV infection, HCV infection, chronic alcohol consumption, cirrhosis, hemochromatosis and aflatoxin *etc.* Among them, chronic HBV infection is the most common cause of HCC especially in China. However, there are currently very limited therapeutic options for advanced or metastatic HCC. It is therefore critical to understand the genetic background and molecular pathogenic processes involved in the carcinogenesis of HCC, to aid the development of rational, targeted therapies^[4,5].

In a recent publication, Zender *et al*^[6] combined an integrated cancer genomic analysis, RNA interference (RNAi) technology and cancer-susceptible mouse models to discover and validate tumor suppressor genes contributing to HCC. The approach resulted in the functional validation of 13 tumor suppressor genes, including *Exportin 4* (*XPO4*), *DEAD box polypeptide 20* (*DDX20*), *Gap junction protein, delta 4* (*GJD4*), *Follistatin-like 5* (*FSTL5*) and *Neurensin-2* (*NRSN2*) *etc.*

Interestingly, the vast majority of these identified genes had not previously been linked to cancer.

To validate and further study the potential value of these tumor suppressors, we randomly selected *NRSN2* from those genes showing a higher possibility of being tumor suppressors, and performed immunohistochemical analysis and Western blotting analysis to determine the expression of *NRSN2* in HCC, further identified its relationship to clinicopathological features and evaluated its prognostic value to post-resectional survival in HCC.

MATERIALS AND METHODS

Patients and tumor tissue sample

A total of 110 HCC surgical resection specimens were collected at the Sun Yat-sen University Cancer Center between January 2001 and December 2002. The 110 patients included 96 males and 14 females with a median age of 45 years (range, 22-74 years). None of the patients had received radiotherapy or chemotherapy prior to surgery. Both tumor and corresponding non-tumorous tissues not less than 2 cm away from the HCC were sampled, respectively, and proved by pathological examination. All tissue samples were fixed in 10% formalin and embedded in paraffin, and consecutive 4 μ m sections were cut. The histological types were assigned according to the criteria of the World Health Organization classification. The diagnosis of liver cirrhosis was based on the case records and pathological data of HCC patients from Sun Yat-sen University Cancer Center.

Immunohistochemical analysis

The sections were deparaffinized and rehydrated through graded ethanol, then endogenous peroxidase was inhibited with 0.3% hydrogen peroxide. For antigen retrieval, slides were boiled in EDTA (1 mmol/L, pH 8.0) for 15 min in a microwave oven. After rinsing with PBS, the sections were incubated with primary antibody (rabbit anti-NRSN2, Sigma-Aldrich, Inc. USA) in PBS (1:100) at 37°C for 3 h, and then incubated with horseradish peroxidase (ChemMate™ DAKO EnVision™ Detection Kit) at 37°C for 30 min. Finally, the visualization signal was developed with 3,3'-diaminobenzidine tetrahydrochloride (DAB) and then all of the slides were counterstained in hematoxylin. For negative controls, tissue sections were immunoreacted without anti-NRSN2 antibody under the same experimental conditions.

Semi-quantitative method

The total *NRSN2* immunostaining score was calculated as the sum of the percent positivity of stained tumor cells and the staining intensity. The percent positivity was scored as "0" (< 5%, negative), "1" (5%-25%, sporadic), "2" (25%-50%, focal), "3" (> 50%, diffuse). The staining intensity was scored as "0" (no staining), "1" (weakly stained), "2" (moderately stained), and "3" (strongly stained). Both percent positivity of cells and staining intensity were decided under double-blind conditions. The final *NRSN2* expression score was calculated using

the value of percent positivity score \times staining intensity score, which ranged from 0 to 9. We defined *NRSN2* expression level as follow: "-" (score 0-1), "+" (score 2-3), "++" (score 4-6) and "+++" (score > 6).

Western blotting analysis

The frozen HCC samples including tumor or non-tumorous tissue were homogenated in a RIPA lysis buffer, and lysates were cleared by centrifugation (14000 rpm) at 4°C for 30 min. About 40 μ g protein samples were run on a 15% SDS-PAGE gel and transferred to PVDF membrane. After blocking non-specific binding sites for 60 min with 5% non-fat milk, the membranes were incubated overnight at 4°C with primary polyclonal antibody against *NRSN2* (at 1:200 dilution). The membrane was then washed three times with TBST for 10 min and probed with HRP-conjugated secondary antibody (at 1:2000 dilution) for 30 min at room temperature. After being washed three times, the membrane was developed by an enhanced chemiluminescence system (ECL, Pierce).

Statistical analysis

Quantitative values were expressed as mean \pm SD or median (range). Categorical variables were enumeration data from counting the number of samples. The χ^2 test for proportion and Pearson's correlation were used to analyze the relationship between *NRSN2* expression and various clinicopathologic characteristics. For survival analysis, the main outcome was overall survival rates which were calculated from the date of surgery to the date of death. Follow-up time was censored if the patient was lost to follow-up. Survival curves were calculated using the Kaplan-Meier method and compared by the log-rank test. Cox proportional-hazard analysis was used for univariate and multivariate analysis to explore the effect of clinicopathological variables and *NRSN2* expression on survival. The SPSS 16.0 software (SPSS Inc., Chicago, IL, USA) was used for all statistical analyses and a *P*-value < 0.05 was considered significant.

RESULTS

Expression of NRSN2 in HCC tissues

NRSN2 immunostaining was mostly in the cytoplasm. Overall, 32 of 110 (29.1%) cases had positive expression (*NRSN2* + or ++) in tumor cells (Figure 1A and B), 78 of 110 (70.9%) cases had negative expression (*NRSN2*-). In cases with adjacent hyperplastic tissue, we often observed a sharp contrast between infiltrative tumor areas of negative staining and the adjacent non-tumorous tissue of positive staining (Figure 1C). In addition, we further performed Western blotting analysis to detect the expression of *NRSN2* and the result was consistent with that of immunohistochemical analysis (Figure 2). Correlations between the expression of *NRSN2* and various clinicopathologic parameters are listed in Table 1. The *NRSN2* expression was significantly related to tumor size (*P* = 0.006). Negative expression of *NRSN2* was associated with larger tumor size. However, there was

Figure 1 Immunohistochemical staining of *NRSN2* in HCC. A and B: Positive staining of *NRSN2* at two different magnifications ($\times 100$ and $\times 400$), respectively, scored as *NRSN2* (++); C: Immunostaining of HCC and adjacent surrounding non-tumorous tissue showing a sharp contrast between infiltrative tumor area of negative staining ("T") and the adjacent non-tumorous tissue of positive staining ("N") ($\times 200$). The length of the bar in A, B and C is 500, 100 and 200 μm , respectively.

Table 1 Correlations between *NRSN2* expression and clinicopathologic variables of 110 cases of HCC

Clinicopathologic variables	n	<i>NRSN2</i> expression		χ^2	P-value
		Negative	Positive

no statistically significant difference between *NRSN2* expression and age, gender, histological differentiation, liver cirrhosis, metastasis, HBsAg status, or serum AFP.

Univariate and multivariate analyses of prognostic variables in HCC patients

The 5-year overall survival rates were 61.2% and 29.8%, respectively, in patients with positive and negative *NRSN2* expression. Patients showing negative *NRSN2* expression had a significantly shorter overall survival than those with positive expression ($P = 0.008$, log-rank test; Figure 3). Univariate Cox regression analysis also identified that clinical variables including tumor size, liver cirrhosis, serum AFP and *NRSN2* expression were significantly associated with overall survival (Table 2).

Table 2 Overall survival Cox regression analysis

Variables	Relative risk (95% CI)	P-value
Univariate		
Gender	0.674 (0.308-1.474)	0.320
Age	0.689 (0.423-1.123)	0.133
Tumor size	1.752 (1.028-2.986)	0.037 ^a

Liver cirrhosis	1.739 (1.076-2.808)	0.024 ^a
Serum AFP	1.957 (1.086-3.528)	0.025 ^a
<i>NRSN2</i>	0.481 (0.270-0.854)	0.013 ^a

^a $P < 0.05$.

Figure 2 Western blotting analysis of *NRSN2* expression in HCC. Protein extracted from paired tumor tissues (T) and surrounding non-tumorous liver tissues (N) in four patients with HCC.

Furthermore, to evaluate the potential of *NRSN2* expression as an independent predictor for overall survival of HCC, multivariate Cox regression analyses (Forward: LR) were performed. While the others failed to demonstrate independence, liver cirrhosis, serum AFP level and *NRSN2* expression may play a role in predicting the overall survival in HCC ($P = 0.024$, 0.025 , and 0.013 , respectively, Table 2).

DISCUSSION

HCC is one of the most deadly human carcinomas. Even with improved diagnosis and compositive therapy, the prognosis of HCC remains dismal^[7]. Therefore, prognostic molecular biomarkers are invaluable for the clinician to evaluate patients and to aid in tumor control.

Recently, Zender *et al*^[6] introduced a new, effective and high-yield approach for identifying liver tumor

Figure 3 Kaplan-Meier survival analysis of primary hepatocellular carcinoma patients ($n = 110$) after surgical resection with negative *NRSN2* expression ($n = 78$) and positive *NRSN2* expression ($n = 32$). The survival rate for patients in the *NRSN2* negative group ("−") was significantly lower than that for patients in the *NRSN2* positive group ("+") (log rank, $P = 0.008$).

suppressors. They first used representational oligonucleotide microarray analysis (ROMA), a high-resolution array-based comparative genomic hybridization (CGH) platform, to narrow down the field of potential candidate genes. To further accelerate the study of cancer genes *in vivo*, they adapted stable RNAi technology, utilizing microRNA-based short hairpin RNAs (shRNAs), that are potent triggers of the RNAi machinery and can efficiently suppress gene expression when expressed from a single genomic copy^[8,9], to downregulate tumor suppressor genes in mice^[10]. In addition, to facilitate a more rapid and cost-effective analysis of cancer gene action *in vivo*, they developed a "mosaic" mouse model of HCC^[11]. In this mouse model, HCCs with different oncogenic lesions can be rapidly produced by genetic manipulation of cultured embryonic liver progenitor cells (hepatoblasts) followed by their retransplantation into the livers of recipient mice^[11,12].

According to Zender^[6], they selected 16 shRNAs targeting 14 different genes for validation. The result showed that many of the candidate shRNAs triggered tumor growth above background, with those targeting *Xpo4*, *Ddx20*, *Gjd4*, *Fstl5*, and *Nrsn2* showing the most prominent acceleration of tumor growth. Interestingly, most of these genes previously have not been linked to cancer.

To validate and further study the potential value of tumor suppressors in the results of Zender, we randomly selected *NRSN2* as a sample, and performed immunohistochemical analysis and Western blotting analysis to determine the expression of *NRSN2* in HCC and evaluate its potential clinical relevance.

To our knowledge, there are no studies of *NRSN2* in cancer, not to mention HCC. *NRSN2* encodes a 21 983 Da protein composed of 204 amino acids, belongs to the vesicular membrane protein (VMP) family, and shows a high sequence homology to Neuensin-1. So far, there is no definite function for *NRSN2*. After retrieval in UniProt Knowledgebase, it may play a role in maintenance and/or transport of vesicles, according to its sequence similarities with Neuensin-1, and it is uncertain whether Met-1 or Met-2 is the initiator (<http://www.uniprot.org/>

[uniprot/Q9GZP1#section_comments](http://www.uniprot.org/entry/UniProtKB:Q9GZP1#section_comments)).

In the present paper, using immunohistochemistry technology, we demonstrated that negative *NRSN2* protein expression was found in 70.9% of HCC samples (78/110). This was significantly associated with larger tumor size ($P = 0.006$) and was significantly correlated with poor patient outcome ($P = 0.008$). Regardless of whether *NRSN2* has prognostic significance, decreased expression of *NRSN2* was observed in larger tumors, which does support the hypothesis that *NRSN2* may play a role in inhibiting tumor progression. Metastasis is one of the characteristics of progression of HCC. However, in our studies, no significant correlation was observed between *NRSN2* expression and metastasis, indicating that some other mechanisms may be more important in moderating the metastasis of HCC, since hepatocarcinogenesis is a multi-step and complex process associated with accumulation of genetic and epigenetic changes^[13]. Further multivariate Cox regression analysis indicated that *NRSN2* expression level was an independent factor of survival and may constitute a prognostic factor for patients with HCC after surgery. Western blotting analysis further confirmed decreased expression of *NRSN2* in tumor tissues compared with paired non-tumorous tissues.

At the same time, we also performed some experiments with the gene *XPO4* to investigate its expression and prognostic values in HCC, and the result was similar to that of *NRSN2* (data not shown). All these data supported the result of Zender and further validated the utility of this new approach. Therefore, we have reason to believe other genes identified by Zender are tumor suppressors, although more studies are still needed to further confirm this.

What's more, in the study of Zender, *NRSN2* was also found to be frequently deleted in human breast cancer, indicating that *NRSN2* may be relevant to other epithelial malignancies as a tumor suppressor. However, to elucidate the molecular mechanism role of *NRSN2* in liver carcinogenesis and its relation with other tumor types, more studies still should be done.

ACKNOWLEDGMENTS

We gratefully acknowledge Professor Min-Shan Chen for his help in collecting tumor tissue samples.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the most deadly human carcinomas. Even with improved diagnosis and compositive therapy, the prognosis of HCC remains dismal. Therefore, prognostic molecular biomarkers are invaluable for the clinician to evaluate patients and to aid in tumor control.

Research frontiers

A research article published on November 26, 2008 in "Cell" introduced a new, effective and high-yield approach for identifying liver tumor suppressors by combing an integrated cancer genomic analysis, RNA interference (RNAi) technology and cancer-susceptible mouse models. The approach resulted in identification of 13 tumor suppressor genes, including *Exportin 4* (*XPO4*), *DEAD box polypeptide 20* (*DDX20*), Gap junction protein, delta 4 (*GJD4*), *Follistatin*

like 5 (*FSTL5*) and *Neurensin-2* (*NRSN2*) etc. Interestingly, the vast majority of these identified genes had not previously been linked to cancer. Therefore, more work is needed to validate and further study the potential value of these tumor suppressors.

Innovations and breakthroughs

In the present study, for the first time, by using immunohistochemistry technology, *NRSN2* expression was found to be decreased in 70.9% of cases ($n = 110$). Loss of *NRSN2* expression in HCC was significantly related to tumor size ($P = 0.006$). Larger size tumors were related to negative expression of *NRSN2*. Patients showing negative *NRSN2* expression had a significantly shorter overall survival than those with positive expression ($P = 0.008$). Multivariate Cox regression analysis indicated that *NRSN2* expression level was an independent factor of survival. Western blotting analysis further confirmed decreased expression of *NRSN2* in tumor tissues compared with paired non-tumorous tissues.

Applications

Because *NRSN2* down-regulation frequently occurs in HCC, the authors propose that *NRSN2* may be a candidate tumor suppressor gene for HCC, and may be used as a candidate biomarker for long-term survival in HCC.

Terminology

NRSN2 encodes a 21983 Da protein composed of 204 amino acids, belongs to the vesicular membrane protein (VMP) family, and shows a high sequence homology to *Neurensin-1*. So far, there is no definitive function for *NRSN2*.

Peer review

Ma *et al* investigated the expression of *NRSN2* in 110 cases of HCC immunohistochemically and by Western blotting, and found a correlation between its negative expression and tumor progression. Although the function of *NRSN2* has not been clarified, their result was interesting and this molecule might be a new prognostic marker of HCC.

Abstract

We report a case of acute chylous peritonitis mimicking acute appendicitis in a man with acute on chronic pancreatitis. Pancreatitis, both acute and chronic, causing the development of acute chylous ascites and peritonitis has rarely been reported in the English literature. This is the fourth published case of acute chylous ascites mimicking acute appendicitis in the literature.

INTRODUCTION

Chylous ascites is the accumulation of chyle in the peritoneal cavity. It develops following disruption of the lymphatic system caused by traumatic injury or by either benign or malignant processes^[1]. It is usually a chronic process. This phenomenon is rarely associated with the symptoms and signs of peritonitis. Acute abdominal pain with peritonism due to sudden extravasation of chyle into the peritoneal cavity is rare but has been described in the literature.

CASE REPORT

A 38-year-old indigenous Australian man presented to the emergency department of our institution with a 24-h history of generalised abdominal pain localizing to the right iliac fossa. Associated symptoms included anorexia and nausea but no vomiting or diarrhoea. On examination he was systemically unwell with a temperature of 38.6 and was tachycardiac with a pulse of 115 beats per minute. On examination the patient was exquisitely tender in the right iliac fossa with rebound tenderness and peritonism, consistent with a diagnosis of acute appendicitis. His medical history was significant for chronic alcohol dependence and chronic pancreatitis. The patient admitted to drinking in excess of 120 g of alcohol daily but denied alcohol consumption for the two days prior to presentation. He had no significant surgical history.

Haematology and biochemistry investigations on presentation demonstrated deranged liver function, a macrocytosis and thrombocytopenia. Gamma glutamyl transaminase was elevated at 1392 U/L, with lesser elevations of alkaline phosphatase and alanine transferase, consistent with his known history of alcohol (ETOH) abuse and probable underlying alcoholic liver disease. C reactive protein (CRP) and white cell count (WCC) were not elevated. Blood film was normal and blood cultures negative. Lipase was elevated at 153 U/L.

The patient was taken to theatre with a clinical diagnosis of acute appendicitis. Subsequently a grid-iron incision was made revealing "milky" peritoneal fluid which at the time was presumed to be pus secondary to a perforated viscus despite its atypical appearance.

The appendix was not inflamed. Specimens were taken for biochemistry and microbiology. The decision was then made to perform a laparoscopy with a view to identifying the source of the fluid. When no obvious cause could be found, a midline laparotomy incision was made. The duodenum and stomach were mobilized, the lesser sac entered to exclude a perforated peptic ulcer while the remainder of the small bowel and colon were examined with no evidence of perforation. The only significant finding was that of a malrotated pancreas with an indurated and erythematous head consistent with acute pancreatitis. At this stage a presumed diagnosis of chylous peritonitis was made. Drain tubes were inserted and the midline incision was closed. The patient was discharged on day 4 after an uneventful post-operative course. In the initial few days post-operatively, there was significant drainage of the small blood-stained milky fluid seen at laparotomy. Interestingly, after several hours of stasis there was sedimentation of the blood from chyle within the drain tube bags. Fluid was sent for lipoprotein electrophoresis to confirm the diagnosis of chylous ascites.

A CT scan was completed on day 1 post-operatively to define the anatomy of the pancreas and exclude other pathology. The CT report confirmed an annular pancreas with changes surrounding the pancreatic head representing focal pancreatitis. There were no pancreatic calcifications seen.

The peritoneal fluid was significant for cholesterol of 7.3 mmol/L and triglycerides of 26.0 mmol/L (2280.7 mg/dL), highly suggestive of chylous effusion. Fluid amylase and lipase levels were elevated at 115 U/L and 2165 U/L, respectively, suggesting pancreatitis as the aetiology in this case. Plasma triglyceride levels were not measured.

DISCUSSION

Pathophysiology and aetiology

Chylous ascites is the accumulation of a milk-like peritoneal fluid rich in triglycerides, due to the presence of thoracic or intestinal lymph in the abdominal cavity^[1]. Causes of chylous ascites (Table 1) relate to disruption of the lymphatic system due to traumatic injury or obstruction.

Chronic chylous ascites is usually asymptomatic, however, abdominal pain from chylous peritonitis, with sudden outpouring of chyle into the peritoneum, has been described in the literature. A review of 140 cases of all forms of chylous ascites showed that 21% of adults and 14% of children with chylous ascites have the acute form^[2].

Pancreatitis is a recognised but rare cause of chylous effusion. In most published cases pancreatitis, usually chronic, results in the development of chronic chylous ascites without acute abdominal pain. Until 1984 only two cases of pancreatitis, both chronic, had been reported as causes of chylous effusions^[3]. Goldfarb^[4] described the first case of acute pancreatitis associated with acute chylous ascites, abdominal pain and

peritonism in 1984.

In his review of the literature, Goldfarb discussed three other cases of chylous effusion which were likely secondary to pancreatitis. Acute abdominal pain and peritonism were not features of these presentations. Since 1984 few cases of pancreatitis associated chylous ascites have been described. In 1999, Ben-Ami *et al*^[5] described acute chylous ascites secondary to acute pancreatitis. This was diagnosed during elective cholecystectomy and did not present with symptoms of peritonitis. In 2006, Chuang *et al*^[6] described a case of hypertriglyceridemia-associated acute pancreatitis with chylous ascites in pregnancy. In this

Table 2 Characteristics of ascitic fluid in chylous ascites^[1]

Cytology	Positive in some cases of malignancy

review there appeared to be a lack of correlation between the formation of chylous ascites and the severity of the pancreatitis.

Aalami proposed two mechanisms believed to play a role in the development of acute chylous ascites in the setting of pancreatitis. These are: the compression of lymphatic channels by an inflamed pancreas and the direct damage of channels by pancreatic enzymes^[3].

Clinical features

Chronic chylous ascites frequently presents with progressive and painless abdominal distension. As with other types of ascites, respiratory embarrassment is a common feature secondary to diaphragmatic splinting. Constitutional symptoms such as anorexia, weakness and malaise are very common, but non-specific^[1]. Other features include abdominal pain, weight loss, diarrhoea and steatorrhoea, malnutrition, oedema, enlarged lymph nodes, early satiety, fevers and night sweats^[1].

In cases of acute chylous ascites symptoms of anorexia, nausea, vomiting and severe abdominal pain are reported. A high fat meal has been reported in the literature as a common precipitant in the development of symptoms. Examination findings of peritonism have been described in the literature. Interestingly, symptoms are often maximal in the right iliac fossa^[7] and most likely a result of pooling of chylous fluid in the right paracolic gutter, mimicking acute appendicitis. Three cases have been reported in which acute chylous peritonitis presented clinically with acute appendicitis. In two cases, the patient underwent open appendectomy, while, in the third patient a midline laparotomy was performed for what was suspected to be appendicitis complicated by appendiceal perforation. In all three cases a white milky fluid was found in the peritoneal cavity, biochemical assessment of this fluid confirmed chylous ascites. The appendix was normal and exploration of the abdomen could not find any cause for the acute chylous effusion in all of the three cases described^[7-9].

Diagnosis

Laboratory testing is rarely useful. The white cell count may be elevated, but other findings are non-specific^[10]. Radiological investigations are of limited benefit although CT of the abdomen has been reported as being useful in identifying pathological lymph nodes and masses and in determining the extent and localisation of the fluid.

Paracentesis is the most useful diagnostic test. Typically chyle has a cloudy and turbid appearance. Table 2 shows the characteristics of ascitic fluid in chylous ascites.

Blood tests including a complete blood count, electrolytes, liver function tests, total protein, albumin, lactate dehydrogenase (LDH), triglycerides, cholesterol, amylase and lipase should be preformed but are by no means diagnostic.

Management

The underlying cause should be addressed whenever feasible. In patients with an acute abdomen, immediate exploration should be performed^[9]. Laparotomy usually allows a definitive diagnosis and provides an opportunity to address the underlying cause.

In chronic chylous ascites which cannot be managed surgically, the goals of treatment are (1) the maintenance of adequate nutrition, (2) decreasing the rate of chyle formation and (3) correcting the underlying disorder^[3]. Considerable controversy exists regarding the effectiveness of a high-protein, low-fat diet with medium-chain triglycerides and diuretics, or total parenteral nutrition (TPN) alone as a means to reducing chyle formation. Guidelines for management published by Aalami in 2000 recommend the commencement of TPN only if no improvement is observed after three weeks on a low-fat, medium-chain triglyceride diet. Multiple case reports describe the use of octreotide in the management of chylous ascites. Somatostatin receptors have been described in the lymphatic vessels of the intestine and it may be that octreotide is effective in managing chylous ascites because it helps to decrease lymph flow through these vessels. The use of octreotide with TPN for the treatment of chylous ascites has been described with clinical improvement in the ascites and reduction in TPN requirements and paracentesis frequency^[11].

In patients with a large amount of ascites a large volume paracentesis to relieve discomfort and dyspnoea can be performed and repeated as needed, however, the risk of infection and fat emboli should be noted^[9]. Peritoneo-venous shunting may be an option, although this is controversial. Although there is some evidence of high initial success rates after insertion, as high as 75%^[3], these shunts carry a high rate of complications which include fever, sepsis and DIC. The high viscosity of chyle has rendered shunt patency disappointing with an eventual occlusion rate approaching 100%.

In conclusion, acute chylous ascites can present with symptoms and signs of peritonism and can mimic acute appendicitis. Chylous effusions, both acute and chronic, are a complication of pancreatitis and may confuse clinical assessment and diagnosis.

INTRODUCTION

Upper gastrointestinal (GI) bleeding in children accounts for approximately 10% of all GI bleeding in children^[1,2]. Gastric and duodenal ulcers are infrequent causes of GI bleeding in children^[3-5]. The majority of children with active gastritis and ulcers of the stomach or duodenum have an associated systemic condition, such as overwhelming sepsis, severe head or body trauma, or burns^[6]. A history of taking medications such as corticosteroids or nonsteroidal anti-inflammatory drugs (NSAIDs) is also important. However, in the absence of such significant history, symptoms of childhood peptic ulcer disease can easily be overlooked in the initial stages, which can result in catastrophic consequences such as perforation or hemorrhage^[3,7].

We report here on a 30-month-old boy with duodenal perforation due to an ulcer. The patient presented to the emergency department (ED) with massive hematochezia (gastrointestinal bleeding) and ongoing active bleeding, and was subsequently found to have a perforated duodenal ulcer. This patient had an atypical presentation in that there were no antecedent signs or symptoms of peptic ulcer disease before the perforation.

CASE REPORT

A 30-month-old boy visited the ED with acute massive hematochezia. Two days before, he had watery diarrhea twice per day for 2 d, and was successfully managed with fluid therapy without any other medications at the ED. The patient was doing well before the incident except for a mild decrease in appetite. On arrival to the ED, he

Abstract

Peptic ulcer disease is uncommon in children and rarely suspected as a cause of abdominal complaints in this age group; the diagnosis is therefore made almost exclusively when complications develop. Peptic ulcer disease is usually not considered in the differential diagnosis of pediatric patients. We present the case of a 30-month-old boy with duodenal perforation due to a peptic ulcer without a known etiology. The patient was admitted through the emergency department due to severe hematochezia and ongoing anemia; he presented with neither abdominal pain nor abdominal distension. There were no medical problems, and no drugs, such as corticosteroids or nonsteroidal anti-inflammatory drugs, had been prescribed or administered recently. We tried to control the active bleeding by medical treatment including arterial embolization, but the active bleeding was not controlled. Finally, an exploratory laparotomy was performed. A discrete anterior perforation with active bleeding of the duodenal wall was found. After the operation, there were no complications and the patient recovered fully.

was alert, but he looked acutely ill. The patient presented with only hematochezia without abdominal pain or abdominal distension.

The medical history revealed that he was delivered vaginally at term, and otherwise had no significant prenatal or postnatal complications. There were no previous hospitalizations or medical problems, his immunization status was up-to-date, and no drugs had been prescribed or administered recently (especially NSAIDs).

On admission, the body weight was recorded to be 11.0 kg (25-50th percentile), height was 84 cm (3-10th percentile), and head circumference was 53.5 cm (25-50th

percentile). His vital signs were as follows: blood pressure 110/60 mmHg; pulse rate 80 beats/minute (bpm); respiration rate 20 breaths/min; temperature 36.6°C.

The patient looked acutely ill and had pale conjunctiva. Chest examination revealed regular heart beats without murmurs and clear breath sounds. Bowel sounds were hyperactive without localized tenderness or rebound tenderness. The abdomen was flat and soft without palpable mass.

The hemoglobin (Hb) was 11.9 g/dL two days ago, but dropped to 7.9 g/dL when checked on ED arrival. However, after 2 h, it dropped further to 7.3 g/dL. Therefore, an ongoing loss of blood was suspected and a transfusion started. Despite massive transfusions, Hb continued to decrease and fell to 4.8 g/dL, and platelets were also reduced to 75 000/mm³ after 2 h. Blood pressure could not be measured and heart rate was more than 160 bpm. A femoral central line catheter was inserted to transfuse packed red blood cells (P-RBC) and platelets. Even with ongoing transfusions, vital signs remained unstable and hematochezia was not improving.

Emergency abdominal CT was performed, which revealed an air-fluid level with distension of the small bowel and colon; in addition, the diameter of the abdominal aorta was decreased. Based on the CT scan, acute blood loss was strongly suspected (Figure 1). To determine the bleeding focus, angiography was performed, which showed extravasation at the duodenal branch of the gastroduodenal artery. Embolization was attempted with 3 coils; however, this could not stop the continuous arterial bleeding (Figure 2). The patient was transfused with 19 pints of P-RBC, 16 pints of platelets and 7 pints of fresh frozen plasma (FFP) because his vital signs were unstable before the operation started.

On hospital day #2, an exploratory laparotomy was performed 20 h after arrival at the ED. On entering the peritoneum, a large amount of blood-stained fluid was encountered. A discrete anterior perforation of the duodenal wall was found; there was a perforation injury that was half the size of the whole duodenal diameter at the anterior wall of the second portion of the duodenum. Serosal ulceration and active arterial bleeding were also seen at the gall bladder neck which was in contact with the perforation site. It showed an ulcer base of about 1.5 cm and bleeding in the posterior wall of the perforation site (Figure 3).

After the operation, the vital signs were stable. Hb was maintained in the normal range. We confirmed that the *Helicobacter pylori* (*H. pylori*) IgM was negative. The patient fully recovered and was eventually discharged without any sequelae.

DISCUSSION

Peptic ulcer disease is uncommon in children and rarely suspected as a cause of abdominal complaints in this age group^[2,4,8]. The diagnosis is therefore made almost exclusively when children develop complications; peptic ulcer disease is rarely included in the differential diagnosis of pediatric patients^[2,6,9,10]. Peptic ulcer disease is classified as either gastric or duodenal, based on the

location, and either primary (intrinsic) or secondary (extrinsic), depending on the etiology. Ulcer disease in children less than 10 years of age is usually secondary and is located predominantly in the duodenum. However, if a primary ulcer is present in this age group, it is usually gastric in origin. In children 10 years or older, primary ulcer disease is more common^[3,4,11,12].

The vast majority of primary duodenal ulcers are associated with *H pylori* infection of the gastric antral mucosa^[7,12-16]. Wong *et al*^[17] reported that patients with perforation underwent laparoscopic patch or open repair. All patients had a course of proton pump inhibitors postoperatively and in 90% of the patients *H pylori* was identified. In Hong Kong^[2], acute upper gastrointestinal bleeding in children was dominated by duodenal ulcers in 75% of the patients and *H pylori* infection was identified in 55% of the patients.

Secondary ulcer disease occurs as a result of some external predisposing cause, such as medications or stress. Associated medications include aspirin, NSAIDs, and steroids. In infants, stress-induced ulcers are often caused by traumatic delivery, respiratory or cardiac distress, sepsis, hypoglycemia, or dehydration. In older children, life-threatening illness and trauma are the main causes; ulcers associated with intracranial pathology (Cushing's ulcer) or burns (Curling's ulcer) have been well described. Since secondary ulcer disease predominantly occurs in the duodenum, it is more likely to present catastrophically, with hemorrhage or perforation as the initial features^[5,11,12]. In one study, 30% of patients had perforation on initial presentation^[8]. Often, exploratory laparotomy is the only way to diagnose patients with secondary ulcer disease because of the presentation of patients with an acute abdomen.

Moon *et al*^[3] reported the case of a 3-year-old boy presenting with shock who was diagnosed as having a perforated duodenal ulcer. Wilson *et al*^[4] reported the case of a 7-year-old boy who was admitted with gastroenteritis that was complicated by an acute perforated duodenal ulcer. In addition, Sisil Kumara *et al*^[6] reported on a 3-year-old boy who had taken prednisolone for a skin eruption and was diagnosed with a perforated duodenal ulcer. In all three of the above cases, chest radiographs showed air under the diaphragm. However, in our case, the gallbladder shielded the perforation site, and we did not see signs of a perforation. Barandica *et al*^[9] reported that CT was associated with a 26% false-negative rate in the detection of hollow viscus injuries in children.

Chan *et al*^[18] reported that 32 children with endoscopically proven ulcers of the duodenum were evaluated for their long-term outcome after H₂-receptor antagonist (H₂RA) treatment. In that study, 12.5% of the patients presented with a perforation. All four patients that had perforations were initially treated with a patch repair; two had persistent ulceration despite H₂RA treatment and required a proximal gastric vagotomy.

In summary, our patient did not have any of the known causes to explain the development of secondary

ulcer disease such as medications and stress, and *H pylori* infection was not detected in the duodenum. The patient did not exhibit symptoms of a bowel perforation such as abdominal tenderness or rebound tenderness; he presented with lower gastrointestinal bleeding symptoms including massive hematochezia rather than hematemesis or melena. The upright abdominal radiographs did not show free air under the diaphragm. Because the gallbladder wall covered the site of the duodenal perforation, the symptoms associated with bowel perforation were not apparent.

Abstract

Mesothelioma develops most commonly in the pleura, and less frequently in the peritoneum. Usually, it manifests as diffuse peritoneal thickening and multiple nodules, and rarely as a solitary mass. We report a rare case of primary malignant mesothelioma of the greater omentum, which mimicked omental infarct. A 54-year-old Korean man was admitted because of severe abdominal pain of sudden onset. A tender mass with indistinct margins was palpated in the upper abdomen. Abdominal ultrasound and computed tomography showed an ill-defined mass in the greater omentum and little ascites in the peri-hepatic space, and neutrophil-dominant exudates were documented on paracentesis. Intravenous antibiotics and analgesics were given for omental infarction with superimposed infection, which resulted in symptomatic improvement. The imaging studies after a week revealed a growing mass and ascites. Laparoscopic surgery was performed and an 8 cm × 3.3 cm greater omental mass was found, with multiple small nodules on the peritoneum, diaphragm, and pelvic cavity wall. Histological examination showed proliferating malignant epithelioid cells that stained strongly for calretinin, which was compatible with malignant mesothelioma. We recommend that primary omental mesothelioma should be included in the differential diagnosis of patients with omental infarction, despite its rarity.

INTRODUCTION

Malignant mesothelioma originates from the mesothelial lining cells of serous cavities. The disease develops most commonly in the pleura, but the peritoneum is involved in 20%-40% of cases^[1-4]. Besides its rarity, the disease has no specific clinical or radiological manifestations, therefore, diagnosis is very difficult in the absence of a history of exposure to asbestos^[4]. Usually, it manifests as multiple peritoneal nodules or plaques, which may later coalesce to produce diffuse neoplastic thickening of the peritoneum, with encasement of the abdominal viscera. However, a solid mass-like presentation is unusual, and furthermore, primary greater omental tumor is rare. Only a few cases of malignant mesothelioma of the greater omentum have been reported in the English-language literature^[5,6]. The omentum is composed mainly of adipose tissue; however, tumors that arise from adipose tissue are less common than smooth muscle tumors, and those that originate from the mesothelial lining are very rare^[7,8].

We report here a case of primary malignant mesothelioma that originated from the greater omentum, which manifested as omental infarction.

CASE REPORT

A 54-year-old Korean man was admitted to Gyeongsang National University Hospital because of severe abdominal pain of sudden onset. He had been suffering from vague abdominal pain of unknown cause during the previous 3 mo. He was given thorough medical examinations including abdominal ultrasonography (US) and computed tomography (CT) at several hospitals and clinics, but no cause for abdominal pain had been found. On the day prior to admission, the pain exacerbated suddenly and did

Figure 1 Abdominal computed tomography (CT) and ultrasonography (US). A: Initial abdominal CT revealed a mass-like lesion of about 7 cm × 3 cm at the greater omentum; B: Abdominal CT follow-up after 1 wk antibiotic therapy showed an increased omental mass lesion, with a shift to the right lower abdomen, and ascites; C: Abdominal US showed a heterogeneous echoic mass at the greater omentum, and ascites; D: Multiple round nodules at the peritoneum and ascites.

not subside with analgesics. The patient was working at a construction company as a chief executive officer but had no apparent history of exposure to asbestos. He had diabetes mellitus controlled with an oral hypoglycemic agent but had no specific family history. He was a nonsmoker and denied drinking alcohol. He looked very nervous and agitated. An indistinct mass-like lesion was palpated, which showed severe tenderness in the upper abdomen. The blood count was normal. Serum glucose was 252 mg/dL (normal range: 70-110 mg/dL), total protein 5.8 g/dL (6.4-8.3 g/dL), albumin 3.1 g/dL (3.4-4.8 g/dL), and C-reactive protein 252 mg/L (0-5 mg/L), but there were no remarkable abnormalities in the other biochemical tests including renal and hepatic function tests. Cancer antigen 125 (CA 125) was 186.7 U/mL (0-5 U/mL). A chest X-ray film was normal, while abdominal sonography and CT revealed an ill-defined mass with heterogeneous echogenicity/attenuation, about 3 cm × 7 cm in size, located in the greater omentum, and a little ascites in the peri-hepatic space (Figure 1). Diagnostic paracentesis of ascites yielded polymorphonuclear neutrophil (PMN)-dominant exudates (white blood cells 2525/mm³, PMN 79%, protein 4.4 g/dL, glucose 234 mg/dL, lactate dehydrogenase 136 U/L). Broad-spectrum antibiotics and analgesics were given for omental infarction with superimposed infection, which resulted in symptomatic improvement. However, the imaging studies after administration of antibiotics for 1 wk showed increased mass size and ascites. Laparoscopic surgery was performed and an 8 cm × 3.3 cm greater-omental mass was found (Figure 2A), with a moderate amount

of turbid ascites. Multiple, variable-sized, nodular lesions were scattered diffusely on the surface of the parietal peritoneum, mesentery, diaphragm, and pelvic cavity wall (Figure 2B). No visceral neoplastic lesion was detected. Partial omentectomy and excisional biopsy of nodules were performed. The main omental mass and nodules were composed of proliferating epithelioid cells that showed tubular, cystic or papillary structures. The tumor cells were strongly positive for calretinin (Figure 3), cytokeratin and vimentin, and negative for S-100 and carcinoembryonic antigen (CEA) upon immunohistochemistry. Diagnosis of malignant mesothelioma was made based on histopathological findings.

The patient recovered uneventfully and was referred to an oncologist for adjuvant therapy. He underwent eight cycles of treatment with pemetrexed and cisplatin. Serum CA 125 after three cycles of chemotherapy decreased to 14.9 U/mL, and positron emission tomography performed after six cycles showed no demonstrable abnormal fluorodeoxyglucose uptake. He has been followed every 3 mo on an outpatient basis after completion of eight cycles of palliative therapy. He is alive and well almost 14 mo after operation.

DISCUSSION

The occurrence of mesothelioma is known to be associated with environmental factors and carcinogens. The association between mesothelioma and asbestos exposure was first reported by Wagner *et al*^[1] in 1960. However, the relationship between peritoneal mesothelioma and asbestos

Figure 2 Laparoscopic findings. A: Greater omental mass of 8 cm × 3.3 cm with coarsely nodular surface; B: Variable-sized metastatic nodules adhered to the parietal peritoneum.

is less obvious than that of pleural mesothelioma^[10]. Liu *et al*^[6] also have reported a non-asbestos-related primary mesothelioma of the greater omentum. Another causative etiology is the simian virus 40 (SV40) TAG sequences^[11]. A multi-institutional international study has revealed that mesothelioma frequently expresses SV40 TAG sequences^[12]. Although our patient had no history of direct exposure to asbestos, he worked in a construction company, so that asbestos could not be excluded as a possible etiological factor. Unfortunately, SV40 studies were not performed in our case.

Primary greater omental tumors are rare, while metastatic tumors in the greater omentum are not uncommon. Several types of primary greater omental tumor have been reported: leiomyosarcoma, hemangiopericytoma, myosarcoma, fibrosarcoma, rhabdomyosarcoma, leiomyoma, leiomyoblastoma, lipoma, fibroma, mesothelioma, and endothelioma^[13-16]. In particular, greater omental malignant mesothelioma is very uncommon.

Although patients with primary greater omental tumors may be asymptomatic, most present with abdominal discomfort, nausea, early satiety, weight loss, and a palpable abdominal mass^[5,13]. Our patient presented with a greater omental mass with severe pain and PMN-dominant exudative ascites. Furthermore, he showed symptomatic improvement with antibiotic therapy. These findings made us suspect initially complicated omental infarction, making preoperative diagnosis difficult. US and CT of the abdomen can provide important information during the diagnostic process, as in the present case. Short-term follow-up imaging showed no improvement with regard to

Figure 3 Photomicrographs of laparoscopically resected omental mass. A: Proliferating epithelioid tumor cells formed tubular, cystic or papillary structures (HE, × 100, bar 100 μm); B: Tumor cells were strongly positive for calretinin upon immunohistochemical staining (× 100, bar 100 μm).

omental mass and ascites despite symptomatic amelioration, and we therefore decided to perform a laparoscopy to make a definitive diagnosis.

A definitive diagnosis can be established only by laparoscopy or open surgery with biopsy. Histological examination may reveal an epithelial, sarcomatoid, or biphasic pattern^[17]. Epithelial-type neoplasms account for 75% of cases and vary from a relatively well-differentiated tumor with a tubulopapillary pattern to solid sheets of rounded or polygonal cells. This type may mimic carcinoma, such that the distinction between epithelioid mesothelioma and metastatic carcinoma, particularly adenocarcinoma, is perhaps the most frequently encountered diagnostic dilemma^[18]. The sarcomatoid-type neoplasms also may be indistinguishable from fibrosarcoma upon histology alone. Immunohistochemistry can be helpful in differential diagnosis of sarcoma and adenocarcinoma. Positive immunoreactivity for calretinin markedly increases the accuracy of diagnosis^[18-21]. Mesothelioma cells are diffusely positive for calretinin, cytokeratin and epithelial membrane antigen, and negative for S-100 protein, Leu-M1, CEA, thrombomodulin and placental alkaline phosphatase^[22]. The tumor cells in our case also showed positive immunoreactivity for calretinin, cytokeratin and vimentin, but were negative for S-100 and CEA.

The prognosis of this malignant tumor is extremely poor because of the lack of effective treatment, with most patients dying within 1 year of diagnosis^[3]. Retrospective studies have shown that median survival after palliative

surgery and systemic and/or intraperitoneal chemotherapy is about 1 year, ranging from 9 to 15 mo^[23-25]. Recently, however, several independent phase I / II prospective trials have reported improved survival with an intensive loco-regional treatment strategy, including cytoreductive surgery along with perioperative intraperitoneal chemotherapy in the form of hyperthermic intraperitoneal chemotherapy, with or without early postoperative intraperitoneal chemotherapy^[23]. The median survival after aggressive surgery combined with hyperthermic intraperitoneal chemotherapy has approached 5 years and seems to improve with subsequent reports^[22,23,26-28]. Meanwhile, Vogelzang *et al.*^[29] have demonstrated in a multicenter, controlled, randomized phase III trial that pemetrexed-cisplatin is the gold standard for the non-operable malignant pleural mesothelioma. The combination of pemetrexed and cisplatin chemotherapy yielded an objective response in the present case.

Yan *et al.*^[28] have found by multivariate analysis that a small nuclear size is the only good independent prognostic determinant. The 3-year survival rate with a nuclear size of 10-20, 21-30, 31-40 and > 40 μm were 100%, 87%, 27% and 0%, respectively. The present patient survived for 14 mo without clinical and radiological evidence of recurrence, but his prognosis was poor because he was only able to undergo palliative surgery, despite his cells having a small nuclear size. We recommend that primary omental mesothelioma should be included in differential diagnosis of cases of omental infarction, despite its rarity.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (World J Gastroenterol ISSN 1007-9327, DOI: 10.3748) is a weekly, peer-reviewed, online, open-access (OA) journal supported by an editorial board of 1126 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in *WJG* will include the following. (1) Editorial: to introduce and comment on major advances in rapidly developing areas and their importance. (2) Frontier: to review recent developments and comment on current research status in important fields, and propose directions for future research. (3) Topic Highlight: this column consists of three formats, including: (a) 10 invited review articles on a hot topic; (b) a commentary on common issues associated with this hot topic; and (c) a commentary on the 10 individual articles. (4) Observation: to update the development of old and new questions, highlight unsolved problems, and provide strategies for their resolution. (5) Guidelines for Basic Research: as suggested by the title. (6) Guidelines for Clinical Practice: to provide guidelines for clinical diagnosis and treatment. (7) Review: to review systemically the most representative progress and unsolved problems, comment on current research status, and make suggestions for future work. (8) Original Article: to report original and innovative findings. (9) Brief Articles: to report briefly on novel and innovative findings. (10) Case Report: To report a rare or typical case. (11) Letters to the Editor: to discuss and reply to contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest. (12) Book Reviews: to introduce and comment on quality monographs. (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities on basic research and clinical practice

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments,

References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS AND DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of *P* values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as 1F , 2F , 3F ; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No.62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Telephone: +86-10-59080039

Fax: +86-10-85381893

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Language evaluation

The language of a manuscript will be graded before it is sent for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

Drug-induced liver injury is a significant and still unresolved clinical problem. Limitations to knowledge about the mechanisms of toxicity render incomplete the detection of hepatotoxic potential during preclinical development. Several xenobiotics are lipophilic substances and their transformation into hydrophilic compounds by the cytochrome P-450 system results in production of toxic metabolites. Aging, preexisting liver disease, enzyme induction or inhibition, genetic variances, local O₂ supply and, above all, the intrinsic molecular properties of the drug may affect this process. Necrotic death follows antioxidant consumption and oxidation of intracellular proteins, which determine increased permeability of mitochondrial membranes, loss of potential, decreased ATP synthesis, inhibition of Ca²⁺-dependent ATPase, reduced capability to sequester Ca²⁺ within mitochondria, and membrane bleb formation. Conversely, activation of nucleases and energetic participation of mitochondria are the main intracellular mechanisms that lead to apoptosis. Non-parenchymal hepatic cells are inducers of hepatocellular injury and targets for damage. Activation of the immune system promotes idiosyncratic reactions that result

INTRODUCTION

Drug-induced liver injury is the leading cause of acute liver failure and transplantation in western countries. The detection of subtle mechanisms that lead to potential drug hepatotoxicity is of key importance and remains a major challenge in clinical practice.

The frequent involvement of the liver in drug-induced toxicity depends on its anatomical location (the liver is the primary port of entry for ingested drugs) and its physiological and biochemical functions because of the abundance of metabolizing enzymes.

The spectrum of injury secondary to drug reaction ranges from mild damage to massive hepatic destruction. However, if one considers the large consumption of drugs, the latter possibility is rather infrequent^[1]. While direct toxic damage is dose-dependent, predictable and experimentally reproducible, idiosyncratic damage is rather supported by the innate and the adaptive immune system. With few exceptions of intrinsic hepatotoxicity, most cases of drug-induced liver injury are idiosyncratic. Toxicity can be experimentally tested by administering the compound at increasing doses, in the presence of

metabolic inducers or inhibitors or toxicity enhancers, with depletion of protective systems, or by co-administering the drug with a known toxic compound. In general, *in vitro* tests precede *in vivo* experiments. Intracellular organelles and their functions are often the primary targets of hepatotoxicity^[2]. Not only hepatocytes, but also cholangiocytes, Kupffer cells, Ito cells and sinusoidal endothelial cells can be involved in the process of drug-induced hepatotoxicity. Some drugs can induce cholestasis by impairing bile secretion or by causing obstruction of extrahepatic bile ducts^[3].

This review deals with the main mechanisms associated with drug-induced hepatic injury, by discussing current views on intra- and extracellular mechanisms of damage and cell death with respect to different drugs. Future perspectives on emerging problems, namely liver steatosis and genetic polymorphisms, are also discussed.

RISK FACTORS

As toxicity is exerted mostly through metabolites rather than the parent drugs, factors affecting metabolite formation are of key importance. Accordingly, genetic polymorphisms and environmental influences on metabolizing enzymes play an important role. Of note, drug-induced hepatotoxicity occurs mainly in women^[4], and this points to the existence of hormonal conditioning factors. Additional genetic, metabolic and immunological factors also may have a role in idiosyncratic hepatotoxicity. All such mechanisms can occur if specific metabolic pathways are activated and previous exposure has sensitized the organ with the formation of specific antibodies (e.g. halothane). In addition, the intrinsic toxicity of some molecules can depend on the expression of genetic variants, as occurs for paracetamol^[5]. Although preexisting liver disease generally is believed to play a minor role as a risk factor for hepatotoxicity, there are some well-documented exceptions. Hepatotoxicity caused by isoniazid, for example, is more common among patients with viral hepatitis and/or human immunodeficiency virus (HIV) infection^[6]. Patients undergoing antiretroviral treatment for HIV infection are at higher risk for severe hepatotoxicity when co-infected with hepatitis B or C viruses, particularly if therapy includes protease inhibitors^[7]. Fatty liver is another condition that is particularly prone to stress damage^[8]. Further studies are needed urgently in this respect, linking toxic injury to liver steatosis, which is becoming an emerging health problem, because of the increasing epidemic of obesity and diabetes as part of the metabolic syndrome^[9].

GENERAL MECHANISMS OF DAMAGE

Although major pathways leading to drug-induced liver injury include necrosis and/or apoptosis, a net distinction between these two processes is sometimes difficult and both events often coexist in the same microscopic field^[10]. Several factors may influence the hepatocyte response to a toxic insult and the extent

of damage results from the intervention of intrinsic and extrinsic cell factors. A combination of age, sex, genetics, hormones, cell energetic status, underlying liver disease, environmental factors, and local O₂ supply, strongly contributes to the expression of cell death mediators^[11]. Less frequently, hepatocyte injury follows on from vascular damage as a consequence of the occlusion of the centrilobular vein (i.e. azathioprine, estrogens, progesterone, pyrrolidine alkaloids). Generally, hepatocytes react to toxic aggression by activating defense mechanisms that include hypertrophy of the endoplasmic reticulum, induction of protective systems (glutathione, GSH), and synthesis of heat shock and acute phase proteins.

Apoptosis and necrosis initially may follow common metabolic pathways. When the injury affects the maintenance of functional cell programs, hepatocytes preferentially die *via* apoptosis, thus limiting the extent of the injury. Necrotic damage generally begins at the cytoplasmic level and thus involves mitochondria and the nucleus in determining swelling and loss of plasma membrane integrity. It becomes irreversible when cytosolic Ca²⁺ concentration increases^[12,13] for increased release by mitochondria and endoplasmic reticulum, or increased extracellular influx. Apoptosis determines cytoplasmic and nuclear condensation and fragmentation without loss of membrane integrity. Drug-induced apoptosis is generally spotty, whereas necrosis is zonal.

The mechanisms of damage include interference with hepatic transport proteins (i.e. organic anion transporting polypeptides), bile salt export pump, or with the nuclear receptor-mediated regulation of drug metabolism and transport^[14,15].

MECHANISMS OF CELL DEATH

Hepatocyte death typically follows an apoptotic or necrotic pathway^[16], mainly depending on predisposing factors^[10]. General mechanisms of hepatotoxicity include reactive metabolite formation, antioxidant depletion, and protein alkylation. Intracellularly generated signaling can activate B-cell CLL/lymphoma 2 (Bcl-2) family members (Bax and Bid) which form pores in the outer mitochondrial membrane. This condition favors the release of intramembrane proteins and promotes chromatin condensation and DNA fragmentation. Alternatively, mitochondrial dysfunction, through reactive oxygen species (ROS) delivery and peroxynitrite formation, triggers membrane permeability transition and leads to membrane potential collapse with decrease of energy production and release of nucleases^[17].

Apoptosis

Apoptosis results from an ATP-dependent death program that is characterized by activation of specific pathways involving death ligands and death receptors (e.g. Fas ligand with Fas) with activation of the caspase cascade (Figure 1). There are two different activating pathways of drug-induced hepatocyte apoptosis. The “intrinsic way” is triggered by intracellular signals

Figure 1 Schematic representation of subtoxic damage of hepatocyte in response to moderate dose of drug. Drug molecule activates Kupffer cells is metabolically processed by hepatocytes. These events may result in hepatocyte stress which is worsened by the intervention of reactive oxygen species (ROS) and nitrogen species from activated endothelial cells. Final result is apoptotic death and Ito cells activation with promotion of fibrosis. EC-GF: Endothelial cell growth factor; IL1: Interleukin 1; $\text{IL1}\beta$: Interleukin 1 β ; RNI: Reactive nitrogen intermediates; ROS: Reactive oxygen species; TGF- β : Transforming growth factor β ; TNF: Tumor necrosis factor α .

Figure 2 Schematic representation of toxic damage of hepatocyte in response to high dose of drug. High drug amount is processed by hepatocytes with production of reactive metabolites which induce cell injury. Toxic products and chemotactic factors released by damaged hepatocytes stimulate the activation of Kupffer and endothelial cells with a subsequent delivery of reactive oxygen (ROS) and nitrogen species. The intracellular damages result in necrotic death. LPO: Lipid peroxidation; LTB_4 : Leukotriene B $_4$.

Figure 3 Schematic representation of mitochondrial oxido-reductase system. Several drug molecules directly or after metabolic release of toxic intermediates can cause mitochondrial alterations at different levels. The following impairment of the energetic and redox balance finally triggers apoptotic or necrotic processes according to a poor or sufficient ATP level. Important regulatory mechanisms rely on the glutathione dependent redox status of proteins. GSH: Reduced glutathione; GSSG: Oxidized glutathione; GSH-Px: Glutathione peroxidase; GSSG-RX: Glutathione reductase; iNOS: Inducible nitric oxide synthetase; NO: Nitric oxide; PSH: Protein sulphhydryls; PS-SG: Protein mixed disulfides; PS-SP: Protein-protein disulfides; TRx: Thioredoxin; TRx-R: Thioredoxin reductase; TR-S₂: Oxidized thioredoxin.

scattered directly by the drug or its metabolites, with activation of a cascade of reactions that damage nuclear and/or mitochondrial DNA directly. Single-stranded DNA subsequently will stimulate intracellular sensor systems and induce the expression of the effector p53. In the “extrinsic way”, new surface antigens on hepatocyte membranes work as receptors. The interaction with ligands, such as tumor necrosis factor alpha (TNF- α) or Fas, activates cytotoxic T cells and liver non-parenchymal cells, with release of cytokines^[18] that engage death receptors on the cell surface^[19]. After binding, the receptor trimerizes and leads to a clustering of death domains. Intrinsic and extrinsic ways finally promote the activation of interleukin (IL)-1 β converting enzyme, which activates caspases and nucleases.

Generally, hepatocytes are resistant to TNF- α -induced cytotoxicity^[20]. In fact, under normal conditions, the activation of membrane receptors stimulates the synthesis of anti-apoptotic molecules and enzymes (e.g. Bcl-2, NO synthase), mediated by the intervention of the nuclear transduction factor nuclear factor- κ B (NF- κ B). Therefore, increased cell sensitivity to TNF- α or to other specific ligands is required to trigger subsequent events^[21]: a strong signaling response with activation of the executioner caspases^[22], and the involvement of mitochondria to amplify death mechanisms in the presence of a poor caspase activation^[23].

Necrosis

Drug-induced cell necrosis results from an intense and massive perturbation of cell homeostasis, with ATP depletion (Figure 2) associated with cytoskeletal alterations, cellular swelling and bleb formation^[16]. The next steps include lysosomal breakdown, bleb rupture,

and irreversible collapse of electrical and ion gradients.

When a high amount of toxicant reaches the liver, necrosis occurs because of dramatic intracellular alterations, or as a consequence of oxygen and nitrogen radical attack from activated Kupffer and endothelial cells^[24]. On this occasion, drugs are oxidized by the cytochrome P-450 (CYP-450) enzymes, with release of a large amount of reactive metabolites, with promotion of lipid and protein oxidation and depletion of GSH. Oxidized proteins and protein adducts may have immunogenic properties and activate Kupffer and polymorphonuclear cells, with subsequent release of ROS. The formation of protein disulfides results in increased permeability of the inner mitochondrial membrane, with loss of membrane potential, decrease of ATP synthesis, inhibition of Ca^{2+} -dependent ATPase, decreased capability to sequester Ca^{2+} , oxidation of actin, microfilament breakage, and membrane bleb formation^[25].

Abnormal control of cell volume is a major factor that promotes hepatocyte necrosis. Oxidative stress, very fast consumption of cellular energy, and mitochondrial dysfunction activate anaerobic glycolysis, which results in decreased intracellular pH. The incoming acidosis is contrasted partially by H^+/Na^+ and Na^+/HCO_3^- exchanges with influx of Na^+ . As a result of low ATP availability, Na^+ cannot be further exchanged and accumulates within the cell. The consequent osmotic load results in cell swelling and blocks the apoptotic process, which requires a reduction of the cell volume. This osmotic stress is worsened by the increase of cytosolic Ca^{2+} and results in plasma membrane rupture^[26].

Additional mechanisms include nucleotide alterations

and protein synthesis disruption. In most cases, these actions follow drug-induced mitochondrial injury. However, discriminatory nucleotide alterations and oxidation of protein sulfhydryls (γ -glutamyl synthetase and glucose 6-phosphate dehydrogenase) are promoted selectively by some drugs; one example is the damage to the ATPase complex observed after cisplatin intoxication^[27].

CELLULAR AND INTRACELLULAR TARGETS OF DRUG HEPATOCELLULAR INJURY

Aspects to discuss include non-parenchymal hepatic cells, microsomes, mitochondria, and nuclear receptors. Much evidence suggests the participation of non-parenchymal hepatic cells in drug-induced hepatocellular injury^[28], which depends on factors such as the intrinsic characteristics of the drug, its dose, its metabolites, and the local O₂ supply^[29]. Activation of Kupffer cells results in the release of inflammatory mediators and ROS, and modulates hepatocyte injury^[30]. It has been shown that inhibition of macrophage activation or administration of TNF- α antagonists protects hepatocytes against paracetamol toxicity^[31], and that depletion of Kupffer cells attenuates thioacetamide hepatotoxicity^[32]. Indeed, both Kupffer and endothelial cells can be activated secondarily by chemotactic factors (i.e. leukotriene B₄) released by injured hepatocytes^[24,33], which in turn, can be damaged by TNF- α and IL-1 β released from activated non-parenchymal cells. Examples of drug hepatotoxicity that involves non-parenchymal cells are that seen with methotrexate (activation of hepatic stellate cells to myofibroblasts, and liver fibrosis may develop even in the absence of liver enzyme elevation); bosentan (inhibition of transport proteins including the bile salt export pump^[34]); sulindac (competitive inhibition of canalicular bile salt transport, a contributing factor to cholestatic liver injury^[35]); cyclophosphamide and azathioprine (sinusoidal obstruction syndrome, veno-occlusive disease, follows a severe depletion of GSH in sinusoidal endothelial cells. This damage results in fibrosis of the hepatic sinusoids).

Microsomes are another target of hepatocellular damage induced by drugs. Biotransformation of lipophilic drugs *via* CYP-450 metabolic pass and the subsequent excretion of their metabolites are essential to avoid intracellular accumulation of toxic compounds. Less than 10 CYP-450 enzymes accounts for > 90% of all drug oxidation. Most adverse drug reactions depend on the release of reactive metabolites and ROS, which may overwhelm lethal insult, sensitize the innate immune system, or haptenize, thus eliciting immunoallergic reactions^[36]. If metabolites have a particularly high reactivity, they can even bind and inactivate the metabolic enzymes^[37]. This occurs with drugs that show a narrow therapeutic index (e.g. terfenadine and astemizole). Several factors may affect the efficiency of the microsomal metabolism: namely

aging, liver disease, enzyme induction and inhibition, genetics (existence of slow and fast acetylators), and O₂ supply. Changes in the level of CYPs may have a dramatic impact on drug metabolism. P-450 enzymes are subjected to multiple levels of regulation and expression; the latter being dominant in zone 3 just surrounding the centrilobular vein. Expression of P-450 isoforms varies with age; therefore, the capacity for drug metabolism is a function of age^[38,39]. Polymorphisms in P-450s or induction/inhibition account for the appearance of adverse reactions. In this regard, it has been noted that the constitutive androstane receptor (CAR) binds drugs and regulates the expression of the genes that code for CYP3A and CYP2B^[40]. Also, induction or inhibition of CYPs by herbal remedies accounts for the increasing number of case reports of hepatotoxicity^[41]. In fact, some herbal components are converted to toxic metabolites by P-450 enzymes; this is the case of aristolochis acid, which generates the highly reactive cyclic nitrenium ions^[42]. Upregulation of specific P-450 enzymes has been described during rifampicin treatment^[43] in experimental models of obesity and fatty liver^[44] and in humans with nonalcoholic fatty liver disease (NAFLD)^[45].

Mitochondria are often a major target of drug toxicity, and therefore mitochondrial dysfunction represents a major determinant of hepatotoxicity^[46,47] (Figure 3). Indeed, mitochondria are the gateway at which signals that initiate cell death converge^[3,48]. By integrating signaling networks, mitochondria have an active role in several metabolic pathways^[49]. Signals may damage mitochondria directly or act indirectly by activating death receptors. In particular, reactive metabolite formation, GSH depletion and protein alkylation are associated with mitochondrial dysfunction, and represent critical initiating events for drug-induced toxicity. Opening of pores in the outer mitochondrial membrane, release of proteins and cytochrome c, imbalance in intracellular Ca²⁺ homeostasis, and intracellular accumulation of Na⁺ are essential steps in hepatocyte death^[17,50]. In this context, the maintenance of the mitochondrial GSH pool^[21,51] is important to detoxify ROS and maintain the reduced status of membrane protein sulfhydryls, including the ATP synthase complex and the Ca²⁺-dependent ATPase. A fall of total cellular GSH below 15% (< 1 μ mol/g) inevitably is associated with lethal cell damage by involving the mitochondrial stores^[52,53]. Common events that lead to apoptosis and necrosis act through mitochondrial permeabilization and dysfunction. In particular, it seems that the number of mitochondria that undergo pore opening is associated with apoptosis or necrosis, according to ATP availability or deficiency^[47]. Some drugs exert toxic effects on mitochondria only after their metabolic activation at the microsomal level (isoniazid/rifampicin), after inducing endoplasmic reticulum stress (paracetamol) or even lysosomal dysfunction. The study of these mechanisms has revealed intriguing relationships between mitochondria and other intracellular organelles^[54-56].

Recent advances in molecular biology have revealed

that nuclear receptors such as the pregnane X receptor (PXR) and CAR act as intracellular sensors for lipophilic compounds by encoding proteins and regulating the expression of enzymes^[57,58] that are involved in drug oxidative metabolism, disposition and transport^[15]. Their incorrect activation may result in drug metabolism disturbance. PXR can be activated or inhibited by a variety of structurally different drugs. Its activation is associated with downregulation of several genes^[59] that influence mitochondrial ketogenesis^[60] and favor mitochondrial imbalance and hepatic steatosis^[61]. These receptors also represent important drug targets. In fatty livers, peroxisome proliferator-activated receptor (PPAR) activation/deactivation is particularly important, not only for the switch from simple steatosis to steatohepatitis, but also for maintaining the efficiency of specific metabolic drug pathways^[62]. PPARs and other oxidative stressors can be activated also by macrophage-released molecules (i.e. Stat-3 and NF- κ B)^[63]. The existence of single-nucleotide polymorphisms is associated in humans with drug transport alterations as a predisposing factor for drug-induced cholestasis^[14].

COMMON PATHWAYS OF DRUG-INDUCED LIVER DAMAGE

Immune system

The liver is a site of intense immunological activity and represents a tolerogenic immune organ for lymphocytes. Activation of Kupffer cells, and recruitment of macrophages and immune cells result in inflammation and injury caused by cytokines release^[64]. These events are major factors in initiating and maintaining drug-induced liver injury^[65].

The drug itself and its metabolites can activate an immune response in the liver: the molecule is processed by antigen-presenting cells in the central lymphoid tissue directly, or after the appearance of haptens or new antigens on the hepatocyte membrane. The latter case follows a covalent binding of the drug molecule with membrane constituents or intracellular proteins^[66]. This hypothesis is supported by the observation that neutrophil depletion protects against paracetamol toxicity^[67]. Also, idiosyncratic reactions are more likely to occur in the presence of an inflammatory state^[68]. Effectors are dendritic cells, which act by sensing pathogens and triggering adaptive immune responses. These responses are characterized by activation of B lymphocytes, which release immunoglobulins and kinins and activate the complement cascade, and of T lymphocytes, which produce lymphokines (CD4) or determine direct cytotoxicity (CD8) *via* surface-molecule expression and the release of mediators (e.g. perforin and granzyme)^[69]. As a consequence, inhibition of lymphocyte activation reduces the extent of drug-induced hepatocyte injury^[70].

The local O₂ supply has an important role in the progression of immune-mediated toxic liver injury. For example, metabolism of halothane under the anaerobic

conditions of the reductive pathway may result in mild hepatitis, whereas, in the presence of a high O₂ supply, the oxidative pathway may induce massive liver necrosis^[29]. These different effects may be explained by the higher immunogenicity of oxidized metabolites that form adducts with proteins. This example suggests the potential capacity of some drugs to trigger autoimmune hepatitis in some patients. In fact, statins, hydralazine and procainamide may trigger autoimmune reactions in predisposed patients^[71]. Most of these patients are positive for HLA-DR3, 4 or 7, which are known to be associated with increased risk of autoimmunity. Halothane toxicity rarely occurs after first exposure; but antibodies against CYP 2E1-mediated trifluoroacetylated metabolite-protein adducts can be detected after frequent exposures to halothane.

Direct toxicity

Paracetamol hepatotoxicity is the classical example of direct liver injury. Given at recommended doses, paracetamol is generally safe, but its intrinsic toxicity at higher doses represents the most important cause of acute liver failure and transplantation. Predominantly metabolized by conjugation with sulfate and glucuronide (metabolites are excreted into bile by Mrp2 and extruded into blood through Mrp3), only a small amount is degraded by CYP 2E1 to the highly reactive metabolite N-acetyl-benzoquinoneimine (NAPQI). NAPQI is, in turn, detoxified by binding with GSH. If the amount of paracetamol that reaches the liver exceeds 12-15 g, the conjugating capacity is overwhelmed and the remaining unbound NAPQI covalently binds to cellular and mitochondrial proteins, which leads to cell necrotic death. In the presence of CYP 2E1 hypertrophy and/or decreased GSH availability (e.g. chronic alcoholism, malnutrition, and prolonged intake of barbiturates), NAPQI formation is increased even at therapeutic doses, and after overwhelming the GSH stores, it may cause severe liver injury^[72,73].

Events start with disturbances of intracellular Ca²⁺ homeostasis, with an increase in cytosolic Ca²⁺ levels, Bax and Bid translocation into mitochondria, and mitochondrial oxidative changes with accumulation of oxidized GSH and peroxynitrite^[74,75]. The latter induces membrane permeability transition, with collapse of mitochondrial membrane potential, inability to synthesize ATP, release of mitochondrial proteins with calpain activation, and release of cytochrome C and endonucleases. ATP deficiency prevents caspase activation but induces nuclear DNA damage, and activates intracellular proteases that lead to cell membrane rupture and hepatocyte necrosis^[76,77]. These intracellular events explain the massive cell death and liver failure observed after paracetamol poisoning^[17]. The recent observation that paracetamol toxicity is modulated by CAR gives rise to new concepts that are important for the general understanding of drug-induced liver injury^[78]. Accordingly, the presence of gene polymorphisms may explain inter-individual differences

in susceptibility to paracetamol toxicity. Finally, a role for hepatic non-parenchymal cells in paracetamol-induced hepatocellular injury also has been suggested. In fact, the chemical elimination of Kupffer cells by gadolinium chloride has been observed to reduce the extent of paracetamol-induced liver injury^[31].

Direct toxicity of the liver is also induced by another drug, valproate, a branched medium-chain fatty acid with eight carbon atoms. Its chronic intake is associated with weight gain and it causes insulin resistance and NAFLD in 61% of treated patients^[79]. Mechanisms of toxicity rely on mitochondrial β oxidation inhibition followed by the appearance of microvesicular steatosis^[80]. Mitochondrial dysfunction follows the microsomal production of toxic metabolites (4-ene-valproate, 2,4-diene-valproate)^[81], decreased activity of complex IV of the respiratory chain, and depletion of coenzyme A (CoA) and carnitine^[80]. Preexisting mitochondrial impairment or deficiency of cofactors involved with valproate metabolism (e.g. carnitine) may represent risk factors for hepatotoxicity^[82].

Idiosyncratic reactions

Unpredictable idiosyncratic reactions can follow the administration of virtually any drug. As a consequence, an enormous number of hepatic reactions have been registered for practically all drug classes. Several mechanisms have been elucidated, including TNF- α -induced apoptosis, inhibition of mitochondrial function, and neoantigen formation. Here, we report some of the most representative cases. Hepatotoxicity associated with the non-steroid anti-inflammatory drug (NSAID) nimesulide has led recently to its commercial withdrawal in some countries^[83]. The mechanism is unknown, although liver histology has shown centrilobular and bridging necrosis^[84]. Diclofenac potentially leads to zone 3 necrosis, autoimmune hepatitis, or even cholestasis^[85] in predisposed individuals. The major pathway of diclofenac metabolism is through 40-hydroxylation by CYP 2C9^[86]. Diclofenac also undergoes oxidative metabolism by CYP 2C8 to form reactive diclofenac acyl glucuronide and 5-hydroxydiclofenac^[87]. Nucleophilic displacement can then replace the glucuronic acid moiety to form adducts with free cysteine thiols^[88], and act as a potential hapten that triggers autoimmunity. Studies with diclofenac-protein conjugates have shown that diclofenac-treated hepatocytes carry antigens that are recognized by T-cell- and non-T-cell-enriched splenocytes^[89]. As a consequence, changes in the activity of CYP 2C8, its haplotype distribution, or impairment in the clearance of acyl glucuronide may potentially increase the risk of hepatotoxicity. Polymorphisms, such as the presence of UGT2B7*2 allele, favor the development of diclofenac hepatotoxicity^[90].

EXAMPLES OF LIVER DAMAGE INDUCED BY COMMONLY USED DRUGS

Aspirin induces hepatotoxicity that is different

from that of other NSAIDs. Aspirin is hydrolyzed into salicylic acid, which is transformed actively by mitochondria into its salicyl-coenzyme A derivative. This compound indirectly inhibits the β oxidation of long-chain fatty acids and increases NADH availability, thus resulting in increased capacity of mitochondria to decarboxylate branched chain amino acids^[91,92]. The negative effect on mitochondrial β oxidation probably is augmented by concomitant viral infection that affects mitochondrial function. This combination may determine microvesicular steatosis known as Reye's syndrome^[93].

Nefazodone, a triazolopyridine trazodone, an antidepressant drug, recently has been withdrawn from the market because of hepatotoxicity. Mechanisms include inhibition of mitochondrial respiratory complex I and IV, associated with accelerated glycolysis. This effect leads to mitochondrial membrane potential collapse, GSH depletion and oxidative stress^[94].

Hepatotoxicity exerted by isoniazid, an anti-tuberculosis drug is related to its metabolite monoacetyl hydrazine, which is activated at the CYP-450 level and detoxified by N-acetyltransferase 2. These enzymes undergo genetic variability and environmental alterations; slow acetylator status and CYP 2E1 genetic polymorphism are risk factors for isoniazid hepatotoxicity^[95,96]. Concomitant therapy with rifampicin, a CYP-450 inducer, significantly increases the risk of liver injury^[56].

Amiodarone is a commonly used antiarrhythmic drug that consists of a benzofuran ring coupled with two iodine and diethyl-ethanolamine side chains substituted with a p-OH-benzene structure. Amiodarone accumulates within mitochondria and causes toxicity by inhibiting state 3 glutamate and palmitoyl-CoA oxidation and by decreasing mitochondrial respiration^[55]. Electron transport chain complexes and β oxidation are also inhibited by amiodarone^[96]. The chemical structure of benzarone resembles that of amiodarone. Benzarone, a non-halogenated benzobromarone derivative, is used for the treatment of vascular disorders. It decreases mitochondrial membrane potential, as well as state 3 oxidation and respiratory control ratio, uncouples oxidative phosphorylation, and inhibits β oxidation. Benzarone increases the production of ROS, as well as the leakage of cytochrome C, with final induction of mitochondrial permeability transition^[97].

Troglitazone, a PPAR agonist, causes hepatocyte injury by dissipating the mitochondrial transmembrane potential, which favors superoxide generation, thioredoxin oxidation and activation of the kinase-1-dependent apoptosis signaling pathway^[98].

HIV-1 protease inhibitors are essential components of antiretroviral therapy. However, mitochondrial toxicity represents a serious problem for patients taking antiretroviral drugs. It occurs most often with administration of a full dose of ritonavir and saquinavir^[7]. Genetic HLA variants of the immune system seem to participate in the hepatotoxicity induced

Table 1 Mechanisms that favor high sensitivity of fatty liver to drug toxicity and necrotic cell death

Initial change	Intermediate effects	Consequences
Increased bioactivation (microsomal CYP 450s)	Higher amount of toxic metabolites	Consumption of antioxidants
Mitochondrial dysfunction	Increased release of ROS	Lipid peroxidation
	Decreased energy production (ATP) and cytochrome c content	Over-expression of uncoupling protein 2
	Increased release of ROS and NO derivatives	Increased Ca ²⁺ efflux
	Pores opening and increased membrane permeability	Protein oxidation and nitration
Impaired intracellular signaling and trafficking	Altered expression of nuclear receptors and sensors	Expression of FAS ligands
	Increased DNA fragmentation rate	Calpain activation and protein cleavage
Activation of non-parenchymal cells (Kupffer cells) and enzymes	Increased release of transforming growth factor- β 1, p53, TNF- α	Defective transcription of repair mechanisms
	Increased NADPH oxidase activity	Inflammation and pro-oxidant attack

ROS: Reactive oxygen species; TNF: Tumor necrosis factor.

by abacavir, another antiretroviral drug. Co-infection with hepatitis viruses is known to increase the risk of mitochondrial toxicity induced by these nucleoside compounds^[6].

CHOLESTASIS

Hepatic clearance of drugs depends on the activity of transport proteins that are located on the hepatocyte canalicular membrane. Alterations of these transporters by drugs or genetic polymorphisms increase the susceptibility to cholestatic injury^[14]. As a consequence, cholestasis is one of the most important features of drug-induced hepatotoxicity^[99]. Substrates for hepatic transport proteins include indomethacin, statins, digoxin, enalapril, midazolam, tamoxifen, diclofenac, methotrexate, and troglitazone. Selective inhibition of ATP-dependent bile salt transport proteins represents an additional mechanism of damage; therefore, co-administration of drugs at this level may enhance the risk of cholestasis. Examples are troglitazone plus lisinopril, itraconazole and verapamil, bosentan and glyburide^[100,101]. Changes in the expression of drug transporters in conditions of chronic liver disease can also result in marked alterations in drug disposition^[102]. Examples are increased bioavailability of drugs with high hepatic extraction, and decreased hepatic clearance of drugs with a low hepatic extraction and of those with biliary excretion^[103]. Finally, cholangiocytes can also be damaged directly by drugs. Flucloxacillin, an isoxazolyl-penicillin, can cause cholestasis by injuring bile duct epithelial cells^[104].

FUTURE PERSPECTIVES

Drug-induced liver injury occurs when the organ defense systems are overwhelmed. Preexisting conditions may contribute to the extent of damage. Two examples in this respect are the existence of fatty liver disease (liver steatosis), and genetic polymorphisms.

The mechanisms that favor high sensitivity of fatty liver to drug toxicity and necrotic cell death are depicted in Table 1. It is known that fatty liver has a reduced

tolerance towards stress conditions, i.e. ischemia-reperfusion, prolonged fasting, and exposure to *t*-butyl-hydroperoxide^[105,106]. Potential mechanisms that favor increased susceptibility of steatotic liver to drug-induced toxicity include mitochondrial imbalance^[107], increased mitochondrial ROS production^[108], and deficient repair capacity^[109]. Indeed, a high incidence of hepatotoxicity has been observed in patients with type 2 diabetes^[110], a condition that is associated inevitably with fatty liver^[111]. Therefore, it is conceivable that hepatotoxic drugs might produce injury even at non-toxic doses in patients with fatty liver, although in a recent study^[112], steatosis appeared to protect against paracetamol toxicity through preserving microcirculatory alterations. Defective hepatobiliary transport as well as the downregulation of Mrp2, as observed in rats with fatty liver, may represent additional predisposing factors for damage in these organs^[113].

Genetic polymorphisms are another important issue. Polymorphisms of CYP-450s account, at least in part, for the variability of efficacy and for the occurrence of adverse drug reactions, and may explain the variety of effects exerted by the same drug in different subjects. Genetic variations in the glutathione S-transferases (GSTT1 and GSTM1) have been associated with drug-induced hepatotoxicity^[114]. Subjects who display mutations in some alleles that code for manganese superoxide dismutase have a higher risk of developing drug-induced liver injury^[115]. Genetic mitochondrial abnormalities are a major determinant of the high susceptibility towards idiosyncratic liver injury caused by drugs that target mitochondria, especially in aged and female subjects^[116]. Genetic polymorphisms associated with alteration of hepatobiliary transporters have implications in drug-induced cholestasis^[14].

CONCLUSION

The search for the underlying mechanisms of damage is expected to lead to new intriguing perspectives for diagnosing and treating toxic liver injury. Today, certain microsomal and mitochondrial metabolic pathways can be assessed easily *in vivo* by performing breath tests with

substrates that release CO₂ during their metabolism. Methionine and α -ketoisocaproate breath tests assess mitochondrial functions and are altered after exposure to alcohol or drugs, thus reflecting specific metabolic alterations induced by exogenous compounds^[92,117]. Such noninvasive diagnostic tools may guide evaluation of the effect of therapeutic strategies.

Future issues might include the use of cytokine and death receptor antagonists, strategies directed at factors that cause mitochondrial damage, and approaches that promote survival gene expression that may overcome drug-induced cell death. In this regard, toxicogenomics, a combination of toxicology and genomics, attempts to identify the effects of drugs on gene expression, and the role of genetic polymorphisms in drug-induced liver injury. However, although recent developments in genetics and toxicology have provided some new insights into drug hepatotoxicity, the complex interactions of hepatotoxins with genetic and environmental risk factors responsible for the onset of toxic injury have yet to be elucidated. Severe drug-induced liver diseases therefore remain unpredictable for most drugs. The identification of new risk factors and a better understanding of pathogenetic mechanisms will certainly have implications for health care and pharmaceutical developments in the near future.

Abstract

Carcinosarcoma, which comprises less than one percent of all gall bladder neoplasms, is characterized by the presence of variable proportions of carcinomatous and sarcomatous elements. Recently, several reports have described patients suffering from carcinosarcoma of the gall bladder. However, there are no large studies regarding the clinicopathologic features, therapeutic management, and surgical outcome of this disease because the number of patients who undergo resection of gall bladder carcinosarcoma at a single institution is limited. A Medline search was performed using the keywords 'gall bladder' and 'carcinosarcoma'. Additional articles were obtained from references within the papers identified by the Medline search. Optimal adjuvant chemotherapy and/or radiotherapy protocols for carcinosarcoma of the gall bladder have not been established. Curative surgical resection offers the only chance for long-term survival from this disease. The outcome of 36 patients who underwent surgical resection for carcinosarcoma of the gall bladder was poor; the 3-year overall survival rate was only 31.0% and the median survival time was 7.0 mo. Since the postoperative prognosis of carcinosarcoma of the gall bladder is worse than that of adenocarcinoma, new adjuvant chemotherapies and/or radiation techniques are essential for improvement of surgical outcome.

INTRODUCTION

Adenocarcinoma is the most common type of malignant tumor generated in the gall bladder, whereas carcinosarcoma is rare with an incidence of less than one percent of all malignant gall bladder neoplasms^[1]. Carcinosarcomas are composed of variable proportions of both carcinomatous and sarcomatous elements. Recently, several reports have described patients suffering from carcinosarcoma of the gall bladder. However, there are no large studies that report the clinicopathologic features, therapeutic management, and surgical outcome for this disease because the number of patients who undergo resection at a single institution is limited.

In the literature, there are well-presented data from 36 reported patients who underwent surgical resection for carcinosarcoma of the gall bladder with intent to cure^[2-28]. The purpose of the present study was to analyze these 36 cases to clarify the factors that might influence surgical outcome, including survival rates after surgery, and to determine the prognostic factors of carcinosarcoma of the gall bladder.

PATIENTS

We analyzed data from 36 patients reported in the literature from 1971 to 2009^[2-28] who underwent surgical management for carcinosarcoma of the gall bladder (Table 1). These patients consisted of 10 male and 26 female with a mean age of 67.7 years (range 45 to 90

Table 1 Thirty six reported cases of surgical resection for carcinosarcoma of the gall bladder

years). The outcome of each case was obtained from the published data. We evaluated the clinicopathological findings including clinical symptoms, tumor location, tumor size, the number and size of gall bladder stones, depth of the tumor invasion, tumor stage according to International Union Against Cancer (UICC) criteria, pathological features, and survival rates. All patients had undergone attempted curative resection for carcinosarcoma of the gall bladder. Survival rates were estimated by using the Kaplan-Meier method and were compared by using the log-rank test^[29]. Values were expressed as mean \pm SD. Differences in proportions were evaluated by the Pearson χ^2 test. $P < 0.05$ was considered to be statistically significant.

DIAGNOSIS OF CARCINOSARCOMA OF THE GALL BLADDER

Table 1 lists the 36 patients who underwent curative surgical resection for carcinosarcoma of the gall bladder and summarizes the clinical features and outcome. In these patients, carcinosarcoma was not associated with

any specific clinical syndromes. All patients presented clinical symptoms, such as abdominal pain, fever, anorexia, nausea, vomiting, painless jaundice, anorexia, and/or body weight loss (data not shown). In 56% of cases in which carcinosarcoma of the gall bladder was diagnosed, it was recognized as a palpable mass. The size of gall bladder carcinosarcomas appears to be larger than that of gall bladder carcinomas. The mean size of carcinosarcomas of the gall bladder was 8.4 ± 3.7 cm (range, 2.5-16 cm) in 29 patients with available data (Table 1).

Accurate preoperative diagnosis of carcinosarcoma of the gall bladder is very difficult because imaging studies cannot differentiate it from carcinoma of the gall bladder. Abdominal angiography often shows neovascularity and staining of carcinosarcomas of the gall bladder, whereas computed tomography (CT) shows an enhanced solid mass lesion. Differential diagnosis includes gall bladder carcinoma when there is calcification, calcified gall stones, or porcelain gall bladder, and carcinosarcoma of the gall bladder is suspected when calcification is observed within the tumor on CT examination^[15]. However, more detailed imaging

data is needed to improve diagnosis of carcinosarcoma of the gall bladder. Carcinosarcoma of the gall bladder is not associated with specific radiological findings or serum data, including tumor markers (carcinoembryonic antigen, carbohydrate antigen 19-9, or squamous cell carcinoma antigen). Carcinosarcoma of the gall bladder should be considered as a differential diagnosis of neoplasms of the gall bladder, especially when patients present with severe abdominal symptoms and/or a large tumor size.

Table 2 summarizes the trends of the incidence of carcinosarcoma of the gall bladder. These data reveal that despite advancements in diagnostic techniques and equipment in recent years, the frequency of resections in patients with gall bladder carcinosarcomas has not increased.

PATHOLOGICAL FEATURES OF GALL BLADDER CARCINOSARCOMA

Carcinosarcoma is characterized by malignancy of both the epithelial and mesenchymal components of the same tissue. Its diagnosis requires the presence and intermingling of both histological components. In most reported cases of gall bladder carcinosarcoma the epithelial component is adenocarcinoma, although a squamous cell carcinoma component is also often present. The mesenchymal component varies from

homogeneous sarcoma to more heterotopic elements such as malignant bone, cartilage, and other mesenchymal tissues^[22,27]. Sarcomatous change or squamous change from adenocarcinoma leads to aggressive spread and metastasis. Squamous cell carcinomas grow at twice the speed of adenocarcinomas^[30-32]. Therefore, once an adenocarcinoma transforms to an adenocarcinoma with a squamous component, the carcinoma exhibits a high degree of malignancy. For our series of carcinosarcoma of the gall bladder patients, the presence of either cartilage, rhabdoid tumor or a squamous component was not a significant prognostic factor.

The homogeneous sarcoma was usually a spindle cell type in these cases. The pathogenesis of carcinosarcoma is poorly understood. Several theories have been proposed to explain the admixture of epithelial and mesenchymal tissues in these neoplasms: (1) mesenchymal reaction, (2) true sarcoma (including the collision neoplasm hypothesis), (3) malignant proliferation of epithelial origin (including the stromal induction/metaplasia model), (4) an embryonic cell rest origin, and (5) the totipotent stem cell hypothesis^[24,33]. The third theory is supported by reports based on immunohistochemical findings^[19,24]. Sarcomatous change of carcinoma can be induced by radiotherapy, alterations to the *p53* gene, and the production of bone morphogenetic protein by cancer cells^[34-36]. A recent report suggests that genetic and gene expression alterations may underlie the

Figure 1 Survival after surgical resection for carcinosarcoma of the gall bladder ($n = 36$).

sarcomatous change or epithelial mesenchymal transition in cholangiocarcinoma^[37]. On the other hand, it has been speculated that these neoplasms arise from totipotent stem cells, rest cells of myoblasts that retain the capability of transformation, primitive undifferentiated müllerian stroma, or paramesonephric tissue^[5,22,38].

MANAGEMENT OF RESECTABLE CARCINOSARCOMA OF THE GALL BLADDER

Since carcinosarcomas are uncommon tumors with a poor prognosis, the outcomes related to various therapeutic interventions are not well defined and no optimal postoperative adjuvant therapy has been established.

Table 1 shows tumor location and the clinicopathological features of the 36 reported cases of carcinosarcoma of the gall bladder. Six cases (25.0%) arose in the neck of the gall bladder, 12 in the body of the gall bladder (50.0%), and the other 6 cases arose in the fundus of the gall bladder (25.0%). Among these cases, the incidence of tumor invasion of the muscularis propria was 35.7%, and in the remaining 63.3% of cases the tumor had perforated the visceral peritoneum or had invaded other organs. Although carcinosarcoma of the gall bladder has different clinicopathological features from adenocarcinoma, the treatment strategies are similar. It is considered that surgical treatment remains the only curative management option for carcinosarcoma of the gall bladder. Simple cholecystectomy and extended cholecystectomy, including cholecystectomy with the adjacent liver bed, with the extrahepatic bile duct, with partial resection of the small intestine and/or colon, and with pancreaticoduodenectomy, were performed in 9 (36.0%) and 16 (64.0%) of cases, respectively. Extended cholecystectomy was performed for carcinosarcoma of the gall bladder because most of these cases presented with a large mass invading adjacent organs.

PROGNOSIS AFTER SURGICAL RESECTION

The overall 1-, 2-, and 3-year survival rates after surgery

were 37.2%, 31.0%, and 31.0%, respectively (Figure 1). By comparing the survival rate among the subgroups identified by each predictive factor with the univariate analysis of the prognostic factors, two factors, namely (1) the presence of serosal invasion and/or involvement into other organs, and (2) advanced stage according to the classification of UICC in resected specimens, were found to be significantly associated with a poor outcome after surgery (Table 2).

The cases examined in the current study were patients recruited for surgical treatment of carcinosarcoma of the gall bladder with intent to cure; however, the current overall 5-year survival rate of 31.0%, which included an in-hospital mortality rate of 8.3%, was comparable to or worse than the reported rates for adenocarcinoma of the gall bladder. It is likely that the overall and median survival is poor because two-thirds of the patients with carcinosarcoma of the gall bladder in this study had serosal invasion and/or involvement of other organs. This finding suggests that carcinosarcoma has greater malignant potential than adenocarcinoma of the gall bladder. The 5-year survival rate after curative resection for carcinosarcoma of the gall bladder was 88.9% when tumor invasion was restricted to the muscularis propria.

Due to limited experience, the staging system could not be defined, nor has any consensus been established on the management of carcinosarcoma of the gall bladder. Here, we used statistical analysis to support a correlation between the staging system for carcinoma of the gall bladder according to UICC and the classification of carcinosarcoma of the gall bladder. In addition, the 5-year survival rate was 87.5% even when resection with intent to cure was performed for stage II tumors. The three cases surviving more than 3 years included a patient where tumor involvement was limited to the muscularis propria^[13,27]. Although curative resection provides the best hope for long-term survival with early stage tumors, only 35.7% of gall bladder carcinosarcoma cases are discovered at the early stage (stage II). It is likely that the overall and median survivals are poor in this study because 64.3% of patients with carcinosarcoma of the gall bladder had tumors at stage III or IV. As shown in Table 2, curative resection and stage II tumors are significant factors for a favorable prognosis for patients with carcinosarcoma of the gall bladder, thus an early diagnosis is required for a better outcome after treatment.

Recurrence was evaluated for twelve patients in this study. The major sites of recurrence were the liver (10 patients), lymph nodes (5 patients), and peritoneal cavity (4 patients). The median time to recurrence was less than one year. From the time of surgery, recurrence occurred within half a year in 8 patients (80.0%). The median time to recurrence for patients who died was only 1.5 mo. The invasive nature and aggressive malignant biology of carcinosarcoma explains the limited number of resectable cases. The results of this study suggest that adjuvant strategies would be beneficial for pre- and post-operatively diagnosed carcinosarcoma. Previous studies reported the use of chemoradiotherapy after

surgical resection of carcinosarcoma of the gall bladder, but this treatment did not significantly improve patient prognosis^[10,18,19,22,25].

CONCLUSION

Prognosis is poor following curative resection for carcinosarcoma of the gall bladder because of recurrence as systemic metastasis of the liver and peritoneal dissemination. In addition, a large proportion of these patients have recurrence during the postoperative early period. Consensus of opinion as to surgical indication for this tumor has not yet been achieved. Surgical treatment strategies based on the appropriate surgical indication are essential for improvement of surgical outcome because curative resection is usually not possible for advanced disease. For these reasons, once a diagnosis of carcinosarcoma of the gall bladder is made it is important to inform patients and their family regarding the biological behavior of this uncommon disease and the proposed prognosis following curative surgical treatment.

Exploration of new radiation techniques and of chemotherapeutic regimens with new drugs is required for the treatment of carcinosarcoma of the gall bladder because conventional chemotherapy and radiotherapy do not increase patient survival. Novel 'molecularly targeted' agents may improve surgical outcome. The prognosis of carcinosarcoma of the gall bladder remains poor despite curative resection, thus efforts to improve surgical outcome should continue for this rare, worldwide disease. Furthermore, the collection of epidemiologic data and pathologic findings will be required to determine the appropriate surgical indication for this tumor.

Abstract

Several reports have described an apparently uncommon clinicopathological disorder that is characterized by multifocal stenosing small-intestinal ulceration. Compared to Crohn's disease, the ulcers are not transmural and typically remain shallow, and involve only the mucosa and submucosa. The disorder seems to be localized in the jejunum and proximal ileum only, and not the distal ileum or colon. Only nonspecific inflammatory changes are present without giant cells or other typical features of granulomatous inflammation. Most patients present clinically with recurrent obstructive events that usually respond to steroids, surgical resection, or both. With the development of newer imaging modalities to visualize the small-intestinal mucosa, such as double-balloon enteroscopy, improved understanding of the long-term natural history of this apparently distinctive disorder should emerge.

INTRODUCTION

A syndrome that is characterized by intermittent episodes of small-intestinal obstruction caused by benign multifocal ulcerated stenosis has been described, largely, but not entirely, in the French literature^[1-10]. This disorder has also been termed "cryptogenic multifocal ulcerous stenosing enteritis" (CMUSE) and has been reported to localize largely within the jejunum or proximal ileum. CMUSE typically is associated with shallow, rather than deep transmural ulceration, and has also been noted to be usually responsive to steroids, although occasionally, surgical resection is required. The location of ulceration and strictures in the more proximal small intestine, along with the absence of any associated granulomatous inflammatory changes in resected material are believed to differentiate this entity from Crohn's disease, which usually is localized in the distal ileum and the colon^[11]. CMUSE appears to be an entirely distinct disorder from other small-bowel disorders, which is characterized by multifocal ulceration with stricture formation. With new imaging modalities increasingly becoming available, particularly double-balloon enteroscopy, further appreciation of this entity and its natural history should result.

DIFFERENTIAL DIAGNOSIS

A number of other entities may cause multifocal small-bowel ulcers (Table 1). Idiopathic ulcerative jejunoileitis, described elsewhere in detail^[12], is a small-intestinal ulcerative disorder, often associated with celiac disease, or at least, with concomitant flattening of the villous architecture of the small bowel. Some believe that the disorder may represent a specific complication of celiac disease, but ulceration of the small intestine in this setting may also be caused by a difficult-to-diagnose focal lymphoma with lymphomatous cells localized at the ulcer edges^[13].

A variety of infectious agents, some common, may also cause small bowel ulceration^[7], but most of these (e.g. *Campylobacter*, *Shigella*, *Yersinia* and *Salmonella*) seem to resolve completely without stricture formation. Of course, the natural history of many infections in the small intestine are not particularly well defined (e.g. tuberculosis and cytomegalovirus infection), especially if immune

Table 1 Other causes of multifocal small-bowel ulceration and stenosis

Ulcerative jejunoileitis with celiac disease or sprue-like intestinal disease
Lymphoma (especially mucosa only), including T-cell enteropathy and α -chain disease (Mediterranean type)
Crohn's disease involving the small intestine
Infections (e.g. <i>Campylobacter</i> and <i>Shigella</i>)
Drug-induced type (especially with NSAIDs)
Zollinger-Ellison syndrome (gastrinoma) or other hypersecretory disorders
Traumatic injury (e.g. endoscopic or surgical treatment, seat-belt injury)
Ischemia related to vasculopathy (e.g. collagen vascular disease, coagulopathy, or inflammatory vasculitis)

NSAIDs: Nonsteroidal anti-inflammatory drugs.

suppression from a concomitant disease or drug treatment is present. Other infectious agents appear to cause a completely different pathological reaction, although ulceration may conceivably occur (e.g. *Tropheryma whipplei* or *Mycobacterium avium intracellulare*).

Drug-induced causes of small-bowel ulceration are numerous and include potassium, gold and chemotherapeutic agents. Currently, the most common causes of drug-induced mucosal injury are nonsteroidal anti-inflammatory drugs (NSAIDs) that may cause frank ulcers, erosions, broad strictures and so-called diaphragm disease^[8]. Alternatively, NSAIDs also have been associated with the small-bowel-mucosal lesion that is characteristic of untreated celiac disease in the absence of ulcer formation^[14].

Peptic ulceration may occur but this is unusual in the jejunum and proximal ileum^[7]. In this location, a peptic ulcer could hypothetically be a clue to an occult Zollinger-Ellison syndrome from a gastrinoma, or heterotopic functioning gastric mucosa. Meckel's diverticulum may be associated with small-bowel ulceration caused by heterotopic functioning gastric mucosa, but usually, the ulceration occurs in the more distal ileum.

Crohn's disease may occur in the jejunum without disease elsewhere, but this seems to be uncommon^[15], and as noted earlier, usually is associated with other clinical and pathological features of Crohn's disease (Table 2).

Traumatic injury may also occur. Surgical injury (including peri-anastomotic ulceration) and external trauma from seat belts in motor vehicle accidents are being increasingly recognized. Endoscopic biopsies for diagnostic purposes, therapeutic interventions (e.g. cautery for polypectomy) or foreign bodies (e.g. ingested suture materials) may induce or be associated with small-intestinal ulcerations.

Finally, ischemic pathogenesis that results from a variety of causes may occur. For example, some systemic diseases have been associated with multifocal ulcers and stricture formation including: thrombotic diseases, Dego's disease, pseudoxanthoma elasticum, myeloproliferative disorders, anti-thrombin III deficiency and vasculitis associated with an occult collagen vascular disease (e.g. systemic lupus erythematosus or polyarteritis nodosa).

CLINICAL FEATURES

A previous retrospective evaluation^[7] of reported

Table 2 Differentiation of CMUSE from Crohn's disease

Absence of clinical or laboratory features of an inflammatory syndrome
Absence of small-intestinal transmural inflammatory process or ulceration
Absence of small-intestinal giant-cell granulomatous inflammatory process
Absence of small-intestinal fistula formation despite recurrent chronic disease
Absence of disease in other parts of gastrointestinal tract (i.e. stomach or colon)
Absence of most extraintestinal features of Crohn's disease (e.g. skin manifestations)

CMUSE: Cryptogenic multifocal ulcerous stenosing enteritis.

cases of CMUSE has revealed that virtually all patients complained of abdominal symptoms and about 70% had extraintestinal symptoms that included weight loss, fever, malaise and joint symptoms. The lesions in the small intestine were considered characteristic of stenosis (1-25, mean 8) found in the jejunum or the proximal ileum. The remainder of the small intestine appeared to be completely normal. Ulceration was superficial, involved the mucosa, sometimes the submucosa, but did not extend deeper into underlying tissues. All of these stenosis were associated with a nonspecific inflammatory infiltrate only. About 40% had persistent pain. Abdominal pain appeared to resolve with steroids but ongoing treatment was reported to be required in 50% of patients. Surgical resection resulted in complete recovery in about 40% but a second resection for recurrent stenosis was needed in 25% of patients. Occasionally, some required multiple resection. Vascular changes and complement component deficiency also have been associated with CMUSE^[7].

FUTURE DIRECTIONS

CMUSE needs to be defined carefully and more precisely. Its etiology and pathogenesis are unknown. Diagnosis of CMUSE should be considered only after exclusion of each entity listed in the differential diagnosis above, especially Crohn's disease and drug-induced ulceration with stenosis. Nonspecific small-intestinal ulceration without stricture formation should be considered a separate entity. With the development of better imaging methods for the small intestine, especially double-balloon enteroscopy, the opportunity now may be present to further explore this intriguing entity.

Abstract

Constipation is a common gastrointestinal complaint in clinical practice, affecting an estimated 27% of the population. Many patients are disappointed by current conventional treatments and, therefore, seek help from complementary and alternative medicine (CAM). Traditional Chinese medicine, is the most important part of CAM and has been practiced for treating diseases and promoting the health of humans for thousands of years, and has become a popular alternative choice. Although there are many Chinese herbal medicine (CHM) interventions available, and some have been verified by clinical trials, their efficacy and safety are still questioned by both patients and health care providers worldwide. The purposes of this review are, first, to appraise the qualities of individual study designs in the new Cochrane approach. Second, the benefits of individual CHM interventions or individual types of CHM intervention for the treatment of functional constipation are analyzed. Finally, valid and comprehensive conclusions are drawn, if applicable, in order to make clinical recommendations.

Cheng CW, Bian ZX, Wu TX. Systematic review of Chinese herbal medicine for functional constipation. *World J Gastroenterol* 2009; 15(39): 4886-4895 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4886.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4886>

INTRODUCTION

Constipation is a common gastrointestinal complaint in clinical practice. It affects an estimated 12%-19% of Americans^[1], 14% of Asian^[2], and up to 27% of the general population depending on demographic factors, sampling, and definition^[3]. A variety of over-the-counter medications are available. It is estimated that in the US alone, more than \$800 million is spent annually on laxatives^[4], with each constipated patient spending approximately \$7900, accounting for 6.5% of the total medical expenditure on lower gastrointestinal diseases^[5]. However, many patients are disappointed by current conventional treatments^[6,7] and, therefore, seek help from complementary and alternative medicine (CAM)^[8].

Many traditional Chinese medicine (TCM) interventions have been used for the treatment of constipation. A recent review listed the current clinical research findings of TCM interventions on treating functional constipation (FC)^[9]. However, an analysis on the benefits of individual interventions or individual types of interventions, and the qualities of individual study designs has not been undertaken. To draw valid and comprehensive conclusions and make clinical recommendations, a systematic review of Chinese herbal medicine (CHM) for FC is necessary.

This review aimed to determine the efficacy and safety of CHM for the treatment of FC by summarizing current available randomized controlled trials (RCTs) according to the Cochrane approach, newly revised in 2008.

CRITERIA AND METHODS FOR LITERATURE SEARCH

Criteria for considering studies for this review

The criteria for considering studies for this review are as follows. (1) Types of studies. Only RCTs without

restriction on language and publication types were included; pseudo-RCTs were not considered; (2) Types of participants. Patients of both sexes and of any age or any ethnic group with diagnosed FC according to the Rome criteria (Rome I, II or III) were included while those with secondary constipation due to medication and/or other diseases were excluded; (3) Types of interventions. Any form of CHM in any dose or as add-on combination treatment was considered, including oral and external preparations. Comparisons could include placebo, no intervention, acupuncture, massage, Western conventional medication (WCM) or any other interventions. Studies comparing one kind of CHM to another CHM were also included; (4) Types of outcomes. The responder rate of patients with a mean increase of ≥ 1 complete spontaneous bowel movement (CSBM) per week was considered a primary outcome. This outcome by combining a subjective measure of the completeness of defecation with an objective measure of stool frequency was considered to be clinically meaningful^[10]. If this outcome measure was not used in the study, the overall effectiveness assessment according to the references of Criteria of Diagnosis and Therapeutic Effect of Diseases and Syndromes in Traditional Chinese Medicine^[11], Guidelines for Clinical Research on New Chinese Herbal Medication^[12], Guidelines for Clinical Research on New Chinese Herbal Medication (Draft)^[13] or criteria made by the authors with details and comparable definitions were also considered. Based on the above criteria, interventions which resulted in improvement in general constipated symptoms and/or objective examination indices, for general improvement $\geq 30\%$ compared to their baselines, were counted as effective. Secondary outcomes including (a) Changes in individual symptoms, such as stool frequency, straining, completeness of defecation; (b) Changes in examination indices, such as blood nitric oxide (NO) and substance P (SP) levels, total colon transit test (TCTT) and anorectal pressure; (c) Changes in quality of life assessment as assessed with the Health Related Quality of Life (HRQOL) or other validated scales; (d) Adverse events (AEs), such as functional injury of liver or kidney, nausea, vomiting, diarrhea and allergic reaction.

Search methods for identification of studies

All relevant studies regardless of language or publication status were identified by searching the following databases from 1994, the year of the establishment of Rome criteria, up to the May 18 of 2009. (1) Ovid SP, which included the databases of Cochrane DSR (Cochrane Database of Systematic Reviews), ACP Journal Club, DARE (Database of Abstracts of Reviews of Effects), CCTR (Cochrane Central Register of Controlled Trials), CMR (Cochrane Methodology Register), HTA (Health Technology Assessment), and NHSEED (NHS Economic Evaluation Database), AMED, BIOSIS Previews (2001-2006), Biological Abstracts (1994-2000), Ovid MEDLINE(R) In-Process & Other Non-Indexed Citations (1950 to Present), Ovid MEDLINE(R) (1950 to Present), Ovid MEDLINE(R) In-Process & Other Non-Indexed Citations Present, and Ovid MEDLINE(R) Daily Update

Present. Detailed search strategy presented in Table 1. (2) VIP Citation Databases (VIP); (3) Traditional Chinese Medical Database System (TCM Database System); (4) China Journal Net (CJN). The common search strategy for VIP, TCM Database System and CJN is listed in Table 2. The Chinese wordings were presented in Pinyin.

Data collection and analysis

The title and abstract of the search results were scanned and full articles for all potentially relevant trials were retrieved. A data extraction form was used to extract data on study characteristics including methods, participants, interventions and outcomes. The reasons for the exclusion of studies were recorded accordingly.

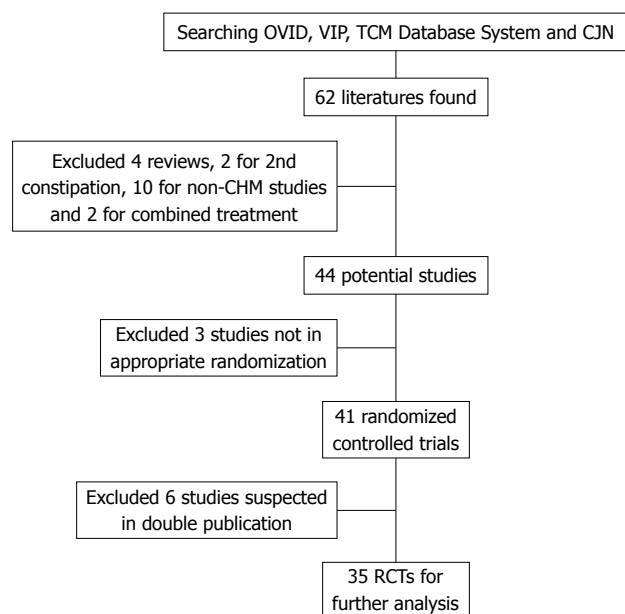

Figure 1 Flow diagram for literature search. TCM: Traditional Chinese medicine; CJN: China Journal Net; CHM: Chinese herbal medicine; RCTs: Randomized controlled trials.

The treatment effects of all CHM interventions were analyzed using Review Manager (Version 5.0). Mean difference with 95% confidence interval was used for continuous data while relative risks with 95% confidence interval was used for binary data. The risk of bias on sequence generation, allocation concealment, blinding, incomplete outcome data, selective outcome reporting and other potential threats to validity were assessed as “YES” (low risk of bias), “NO” (high risk of bias) and “UNCLEAR” (uncertain risk of bias) according to the criteria described in the Cochrane Handbook for Systematic Reviews of Interventions 5.0.1^[14].

SUMMARY OF LITERATURE

Description of studies

A total of 62 articles were identified. Of these, four articles were excluded because they were reviews^[9,15-17], two articles were excluded because they dealt with secondary constipation^[18,19], ten articles were excluded because they did not include CHM^[20-29], and two articles were excluded because they evaluated combination treatment of WCM and CHM by comparing with massage or WCM^[30,31]. This left 44 studies which claimed to be “randomized controlled” trials for FC.

Of these studies, three were not real RCTs because they used the admission sequence for treatment allocation, and thus were excluded^[32-34]. Six studies were suspected of being published more than once by the authors or publishers, and were excluded^[35-40]. This further screening left 35 studies for review. The screening process is summarized in a flow diagram (Figure 1).

Characteristics of included studies

A total of 3571 participants (ranging in age from 1 mo to 93 years) were included in these 35 studies. With the exception of two^[41,42] in 3 parallel groups, all studies used

CHM: Chinese herbal medicine.

a 2 parallel group design. Thirty six CHM interventions, including add-on with WCM treatment, were investigated by comparing with another CHM and/or WCM. The details of CHM interventions are listed in Table 3.

Risk of bias: The methodological quality of each study’s randomization sequence, allocation concealment, blinding, incomplete outcome data, selective outcome reporting and potential threats are summarized in Figures 2 and 3.

Randomization & allocation concealment: Only two studies clearly stated a random component in the sequence generation process, Liu *et al*^[43] used randomization software while Xie *et al*^[44] used an open random allocation schedule in sequence generated with a random number table. For the others, the words “random allocation” were cited in abstracts and/or main texts but without description.

Blinding: None of the participants, personnel or outcome assessors were blinded in any of these studies. Although minority outcome measures were based on the objective examination results, such as blood NO and SP levels, total colon transit time and anorectal pressure, the risk of both performance bias and detection bias with regard to general symptom improvement and safety issues were deemed very high.

Flow of participants and intention-to-treat: None of the trials reported the withdrawal, drop-out and/or loss to follow up rates. The method of handling missing data regarding intention-to-treat or per protocol analysis was not addressed.

Selective outcome reporting: Five studies had a high risk of bias with regard to selective outcome reporting^[45-49] because the data on individual symptoms, overall improvement and colon transit test pre-specified were reported incompletely in the results. Thus further meta-analysis could not be implemented.

Figure 2 Methodological quality graph: judgments about each methodological quality item presented as percentages across all included studies.

Other potential threats to validity: MaRen Capsule, which is derived from the ancient formula MaZiRenWan, was used as the control for treating FC in the Syndrome of Qi and Yin Deficiency in the study by Fan *et al.*^[50]. As MaZiRenWan is the representative formula for treating heat constipation (excessive constipation), it is therefore, not suitable for patients suffering from FC with Qi and Yin deficiency, and such a study design was a potential source of bias in assessing the efficacy and safety of MaRen Capsule.

Effects of interventions

None of the trials reported the responder rate on complete spontaneous bowel movement; instead overall effectiveness in which patients with improvement in general constipation symptoms and/or objective examination indices, was commonly used as a primary outcome measure.

CHINESE HERBAL MEDICINE VS PLACEBO/NO TREATMENT (COMPARISON 01)

None of the included trials used a placebo control, but one used no treatment as a control^[51]. General treatment was allowed for all participants in both groups, such as increased fibre and liquid intake, physical exercise and defecation habit training. The total effectiveness rates of Modified MaRenRunChang Pill and the control were 91.4% and 59.6%, respectively ($P < 0.01$). Reported AEs included two cases of diarrhea and one case of nausea and loss of appetite.

CHINESE HERBAL MEDICINE VS WESTERN CONVENTIONAL MEDICINE (COMPARISON 02)

Twenty-six studies, including two with three parallel groups^[41,42], tested 24 different CHM interventions compared with cisapride, polyethylene glycol 4000 (PEG), mosapride, phenolphthalein, itopride and bifidobacterium.

CHM vs cisapride

Nine studies compared nine different CHM interventions with cisapride or add-on with cisapride and/or

lactulose^[45,52-59]. Eight studies reported total effectiveness rates in the group using CHM which varied from 83.3%-96.7%, while these rates varied from 39.6%-80.5% in the cisapride group (RR 0.24, 95% CI 0.17 to 0.34). The difference suggested that CHM was more effective than cisapride (Figure 4).

The study by Li *et al.*^[55] showed that 92.6% of the CHM group and 68.3% of the cisapride group had normal stool consistency on the fifteenth day of treatment (half of treatment course) ($P < 0.01$). Sustainable improvement was

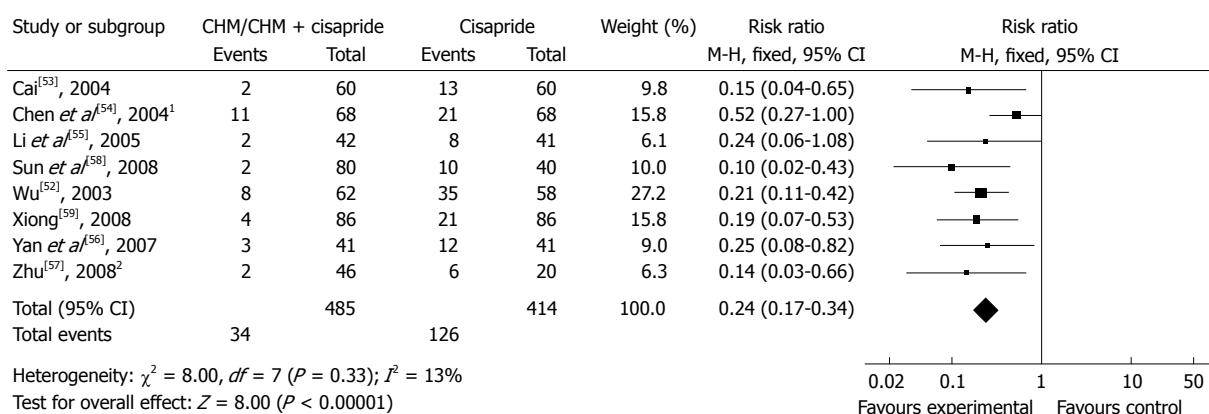

Figure 4 Comparison of CHM vs cisapride, failure to respond at endpoint. ¹Add-on treatment: CHM + cisapride vs cisapride; ²Add-on combined treatment: CHM + (cisapride + lactulose) vs cisapride + lactulose. CHM: Chinese herbal medicine.

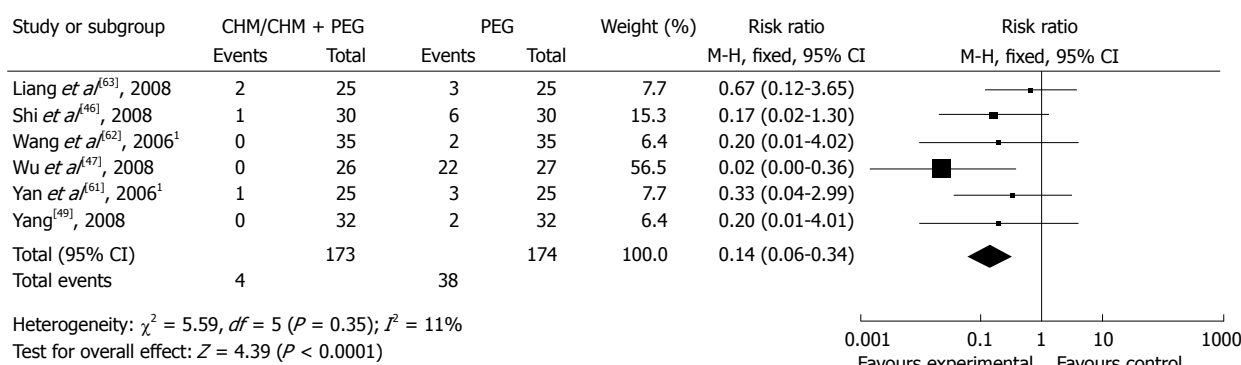

Figure 5 Comparison of CHM/CHM + PEG vs PEG, failure to respond at endpoint. ¹Add-on combined treatment: CHM + PEG vs PEG. PEG: Polyethylene glycol.

noted on the seventh day of the follow-up period when 95.2% and 80.3% of participants reported normal stool consistency, respectively ($P < 0.05$). The stool interval was shortened significantly from 4.4 ± 1.4 d to 2.2 ± 1.3 d during treatment and 2.1 ± 1.1 d during the post-treatment follow-up period for the CHM treatment group, but not for the cisapride control group. Both groups had shown a significant increase in barium strips excretion in the total colon transit test from $30.13\% \pm 9.2\%$ (before treatment) to $69.45\% \pm 11.32\%$ (during treatment) and $73.2\% \pm 12.16\%$ (after treatment) in the treatment group and from $29.86\% \pm 11.34\%$ to $41.43\% \pm 12.05\%$ and $48.01\% \pm 12.76\%$, respectively, for the controlled group ($P < 0.05$). In the study by Zhan *et al*^[45], patients showed a significant improvement in stool type, ease of defecation, stool frequency and total colon transit test in both groups ($P < 0.05$). Statistically significant differences between the groups were found only for stool type and difficulty of defecation ($P < 0.01$).

Six out of nine studies did mention safety measures. All adverse events were reported among patients receiving cisapride in two studies. 43 (43/68) cases in the study by Chen *et al*^[54] reported diarrhea, gas or abdominal pain and four needed to reduce the dose by half due to adverse reactions. In the study by Cai^[53], one (1/60) case reported headache and two (2/60) cases reported lassitude after taking cisapride. No cases were withdrawn due to adverse events.

CHM vs PEG

Eight studies compared seven different CHM interventions with PEG or add-on with PEG treatment^[43,46,47,49,60-63]. Six studies reported that the total effectiveness rates in the group using CHM or add-on with PEG varied from 92%-100%, while these rates were 18.5%-94% in the PEG group (RR 0.14; 95% CI 0.06-0.34). This finding suggested that CHM or add-on with PEG was more effective than PEG alone (Figure 5).

The study by Liang *et al*^[63] comparing CHM with PEG showed a statistically significant improvement with regard to abdominal bloating and TCM symptoms ($P < 0.05$), but not stool frequency, hardness of stool, straining and abdominal pain ($P > 0.05$). With the exception of time to defecation, the study by Wu *et al*^[47], showed that CHM, when compared with PEG significantly improved all symptoms, including stool frequency, sensation of urge to defecate, straining, dry stool, use of rescue drug and total symptom score ($P < 0.01$). The study by Yang^[49] comparing CHM with PEG control, reported that CHM resulted in significant benefit with regard to stool frequency, stool type, difficulty and time of defecation during treatment ($P < 0.05$). Liu *et al*^[43] showed that the effectiveness of the CHM intervention was equivalent to PEG with regard to stool frequency, stool type, straining, abdominal bloating, abdominal pain and loss of appetite and excretion rate of the total colon transit

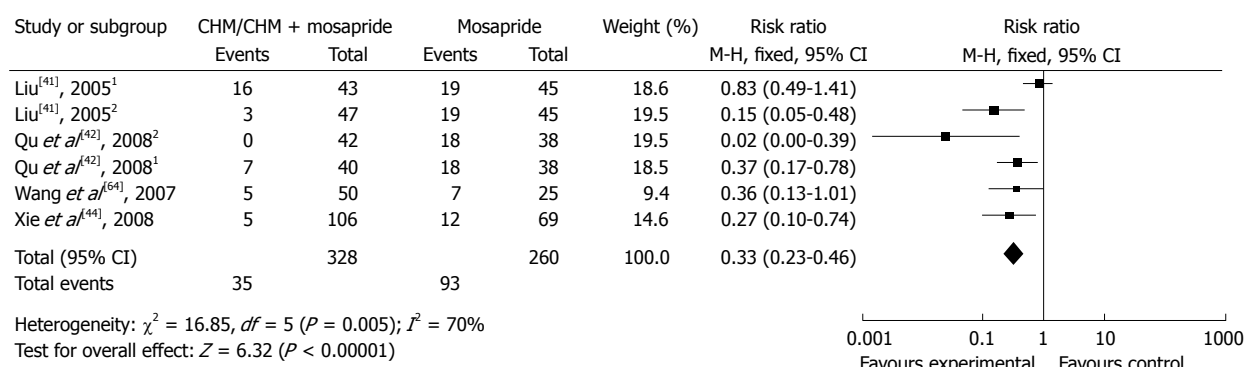

Figure 6 Comparison of CHM/CHM + mosapride vs mosapride, failure to respond at endpoint. ¹3 arms study: CHM vs mosapride; ²3 arms study: CHM + mosapride vs mosapride.

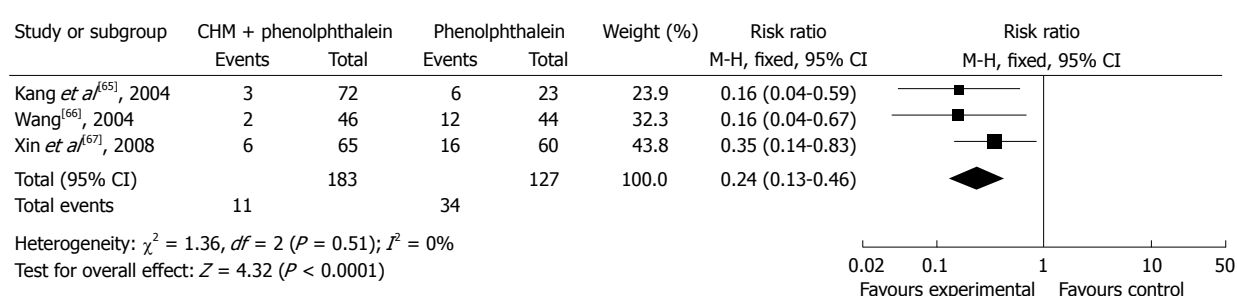

Figure 7 Comparison of CHM vs phenolphthalein, failure to respond at endpoint.

test. The LiuWeiAnXiao Capsule Collaboration Group^[60] reported that those who took CHM showed statistically significant improvement in QoL for components on general feeling, vitality, and daily activities ($P < 0.05$) and difficulty of defecation during follow-up ($P = 0.026$), but not on stool frequency, stool type, and excretion rate of the total colon transit test ($P > 0.05$). Since the outcome measures among these five studies were on different scales, further meta-analysis was not implemented.

Three studies mentioned the issue of safety^[43,60,61]. Only one AE (i.e. abnormal facial muscle tone) was reported by a patient receiving PEG from the study of LiuWeiAnXiao Capsule.

CHM vs mosapride

Four studies compared four different CHM interventions with mosapride^[41,42,44,64]. Two of them in three parallel groups included a CHM arm, a mosapride arm and a CHM plus mosapride treatment arm^[41,42]. All studies reported total effectiveness rates in the group using CHM or add-on with mosapride which varied from 65.2%-100%, while the effectiveness rate was 54.4%-82.6% in the mosapride group (RR 0.33; 95% CI 0.23 to 0.46). This suggested that CHM or add-on with mosapride was more effective than mosapride alone (Figure 6).

The study by Xie *et al*^[44] comparing CHM with mosapride showed a statistically significant improvement in the bothersome of constipation, straining and TCM Qi deficient symptoms ($P < 0.01$). The combined treatment group in Liu's study^[41] showed symptom relief with regard to abdominal pain, abdominal bloating and loss of appetite which was significantly better than both CHM

and mosapride alone ($P < 0.01$).

Two studies evaluated the safety of CHM interventions. Two patients (2/38) with abdominal pain from the CHM arm, two (2/40) with diarrhea from the mosapride arm and one (1/42) with diarrhea from the combined treatment arm were reported in the study by Qu *et al*^[42]. Liu^[41] reported 17 AEs, nine patients with abdominal pain (two from the CHM arm, two from the mosapride arm and three from the combined treatment arm), five with diarrhea (two from the CHM arm and three from the combined treatment arm), two with active bowel sounds and one with dry mouth (both of the latter from the mosapride arm).

CHM vs phenolphthalein

Three studies compared three different CHM interventions with phenolphthalein^[65-67]. The total effectiveness rates in the group treated with CHM were 90.8%-95.8%, while the comparable rates for phenolphthalein were 72.7%-73.9% (RR 0.24; 95% CI 0.13-0.46). Thus the results suggested that CHM was more effective than phenolphthalein (Figure 7). Only Kang *et al*^[65] mentioned that no AEs were observed.

Other

The study by Li *et al*^[68] showed that the total effectiveness of the combined treatment (a TCM intervention add-on with itopride) and itopride alone were 92% and 76%, respectively ($P < 0.05$). In total three cases of mild abdominal pain and two cases of loose stool were reported in the combined treatment arm while two cases of mild abdominal pain were reported in the itopride arm.

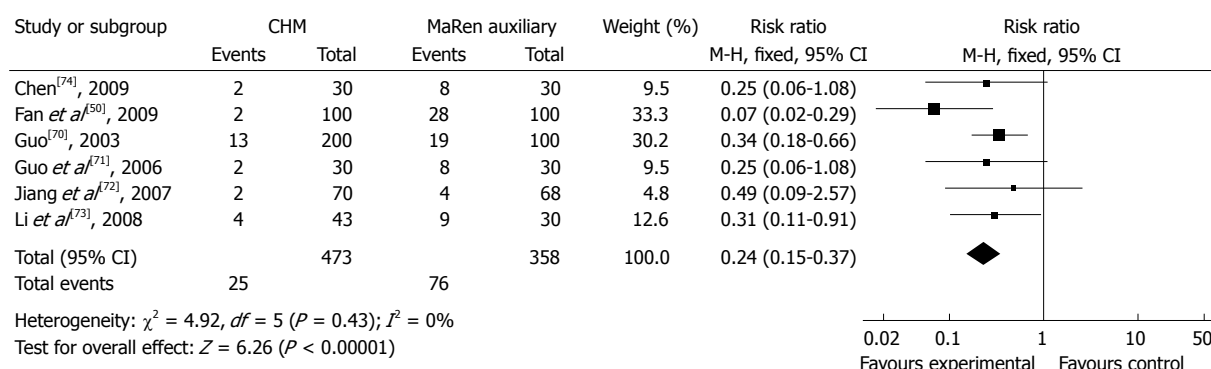

Figure 8 Comparison of CHM vs MaRen auxiliary, failure to respond at endpoint.

Figure 9 Comparison of RunChangTongBianNongSuo Pill vs MaRen Pill/MaZiRen Pill, failure to respond at endpoint.

The study by Meng^[69] showed that the total effectiveness of the combined treatment (a TCM intervention add-on with live bifidobacterium) and live bifidobacterium alone were 94% and 64%, respectively ($P < 0.01$). No studies reported safety issues.

CHINESE HERBAL MEDICINE VS CHINESE HERBAL MEDICINE (COMPARISON 03)

Ten different CHM interventions were tested in seven trials^[48,50,70-74]. Six of them used MaZiRenWan/MaRenWan or its modifications as control (MaRen auxiliary) while one used LuiWeiNengXiao capsules as control (LuiWei auxiliary).

CHM vs MaRen auxiliary

The total effectiveness rates in the group treated with CHM varied from 90.7%-98%, and was 70%-94.1% in the MaRen auxiliary (RR 0.24, 95% CI 0.15 to 0.37) (Figure 8). RunChangTongBian NongSuo Pill was the only intervention compared with the same control in two studies^[70,71] (RR 0.32, 95% CI 0.17 to 0.59) (Figure 9). These results suggested that the CHM interventions developed by the study authors were more effective than the MaRen auxiliary.

Li *et al*^[73] found that CHM resulted in a statistically significant improvement in time of defecation, abdominal bloating and pain, incompleteness of defecation, and total symptoms score by comparing QiLang Mixture with MaRenRuan Capsule ($P < 0.05$), but not on stool frequency, straining and stool type ($P > 0.05$). From the studies by Guo *et al*^[70,71] published in 2003 and 2006, RunChangTongBian NongSuoWan resulted in significant

improvement in the main constipation related symptoms, such as incompleteness and difficulty of defecation, when compared with MaRen Pill/MaZiRen Pill ($P < 0.05$), but it did not improve the minor symptoms of dry mouth, dizziness and palpitation, and blood NO and SP levels ($P > 0.05$).

Only two studies reported adverse effects^[50,70]. Three cases treated with YiQiRunChang Capsule reported diarrhea or abdominal pain while no AEs were observed in Guo's study.

CHM vs LiuWei auxiliary

The study by Gan *et al*^[48] compared TiaoChang Decoction with LuiWeiNengXiao capsules. The total effectiveness rates were 90% and 83.3%, respectively. Patients taking TiaoChang Decoction showed a significant improvement in constipation-related symptoms compared with LuiWeiNengXiao Capsule, and both were safe for consumption without any prominent AEs reported.

CHINESE HERBAL MEDICINE VS NON-PHARMACEUTICAL INTERVENTIONS (COMPARISON 04)

The study by Huang^[75] compared massage with FuFangLuHui capsules. The total effectiveness rates were 97.8% and 53.3%, respectively ($P < 0.05$). Massage was more effective in improving stool frequency, straining, lumpy or hard stool, time to defecation, sensation of anorectal blockage, manual maneuvers to facilitate the process, sensation of incomplete evacuation and stool weight for each defecation. No AEs were reported.

SUMMARY

This review analyzed 35 randomized trials that were conducted in China and published in Chinese medical journals. The results favored the tested CHM interventions in comparison with controls, WCM and some CHM interventions, but not when compared with massage; however, there was not enough replicable evidence to conclude that any specific CHM intervention is effective for FC.

Furthermore, the results of these trials should be interpreted with caution due to the generally low methodological quality of the included studies. First, all studies provided insufficient information on how the random allocation was generated and/or concealed, which is necessary to avoid selection bias. It has been shown that trials with inadequate concealment of allocation or unclear reporting of the technique used were on average 18% more “beneficial” than effect estimates from trials with adequate concealment (95% CI 5% to 29%)^[14]. Second, none of the studies used any blinding method. Lack of blinding to participants, healthcare providers and assessors can introduce performance bias and detection bias. Lack of blinding can also be associated with exaggerated estimated intervention effects-by 9% on average, measured as odds ratio^[14]. Third, none of the included studies addressed incomplete outcome data, such as missing data due to attrition or exclusions. Inadequate handling of missing data can compromise statistical analysis. Fourth, none of studies had been registered, despite a statement issued in 2004 by the International Committee of Medical Journal Editors (ICMJE) requiring that all clinical trials must be registered in order to be considered for publication^[76]. Therefore, protocols were not available to confirm free of selective reporting, especially for those trials which tended to address statistical conclusions instead of listing the details of individual outcomes^[46-48]. Fifth, the majority of experimental CHM interventions were prepared by the investigators without detailed information describing underlying rationales on formulation, dosage, manufacturing process, *etc.* The quality control processes of their tested interventions are unknown. For all these reasons, independent validation of the findings of these trials is necessary.

With regard to selection of an active control in the trials, it is necessary to consider whether there is evidence to support the efficacy of an active control. If no evidence supports the selection of a control, it may bias the trial results. Among all the active controls selected, only PEG had good supporting evidence for the treatment of constipation^[6]. Cisapride, mosapride and itopride have been used as gastroprokinetic agents for the symptomatic treatment of functional dyspepsia. They were thought to be useful for the treatment of constipation due to their stimulating effect on gastrointestinal motility as reported in recent research findings. However, cisapride was suspended by the US Food and Drug Administration in 2000 because of its side effects of heart rhythm disturbances, including QT prolongation^[77,78]. More

clinical data, especially evidence from systematic reviews, are urged to confirm the efficacy and safety of mosapride, itopride, phenolphthalein and bifidobacterium for the treatment of FC. Therefore, the effectiveness of tested CHM interventions is not conclusive, despite beneficial findings from meta-analyses.

The herbal medicines evaluated in this review generally appeared to be safe and well tolerated by patients. However, the safety of their use for FC could not be confirmed because only 48.6% studies (17/35) mentioned the safety of interventions or investigated AEs as one of the secondary outcome measures. It is recommended that more attention should be given to both recording and reporting the harmful effects of these interventions.

This systematic review has several methodological limitations. First, all the data were collected from the reports without directly contacting the trial authors. Therefore, many items of the “Risk of bias” assessment tool could only be classified as “unclear”. Second, most of the included studies were small and without formal sample size calculation. The results were likely to be underpowered. Third, in some cases, different CHM interventions were grouped together for analysis. The results might have been compromised by the heterogeneity within each CHM intervention and by the study design. Fourth, in general, the concept of TCM syndrome was not considered when analyzing the data, as some studies only targeted a WCM disease in a particular type of TCM symptom. Therefore, the actual therapeutic effect might not have been fully captured.

CONCLUSION

CHM interventions or CHM combined treatments showed benefit in the treatment of FC when compared with cisapride, PEG, mosapride, phenolphthalein, itopride and bifidobacterium alone, but not when compared with massage. However, the evidence and reliability of these conclusions are compromised by methodological flaws and lack of replicable validation. Further well-designed, randomized, double-blind, placebo-controlled trials need to be carried out and reported in detail according to the Consolidated Standards of Reporting Trials (CONSORT) and/or CONSORT for TCM Statements.

Abstract

AIM: To reveal the characteristics of CD133⁺ cells in the liver.

METHODS: This study examined the histological characteristics of CD133⁺ cells in non-neoplastic and neoplastic liver tissues by immunostaining, and also analyzed the biological characteristics of CD133⁺ cells derived from human hepatocellular carcinoma (HCC) or cholangiocarcinoma cell lines.

RESULTS: Immunostaining revealed constant expression of CD133 in non-neoplastic and neoplastic biliary epithelium, and these cells had the immunophenotype CD133⁺/CK19⁺/HepPar-1⁻. A small number of CD133⁺/CK19⁺/HepPar-1⁺ cells were also identified in HCC and combined hepatocellular and cholangiocarcinoma. In addition, small ductal structures, resembling the canal of Hering, partly surrounded by hepatocytes were positive for CD133. CD133 expression was observed in three HCC (HuH7, PLC5 and HepG2) and two cholangiocarcinoma cell

lines (HuCCT1 and CCKS1). Fluorescence-activated cell sorting (FACS) revealed that CD133⁺ and CD133⁻ cells derived from HuH7 and HuCCT1 cells similarly produced CD133⁺ and CD133⁻ cells during subculture. To examine the relationship between CD133⁺ cells and the side population (SP) phenotype, FACS was performed using Hoechst 33342 and a monoclonal antibody against CD133. The ratios of CD133⁺/CD133⁻ cells were almost identical in the SP and non-SP in HuH7. In addition, four different cellular populations (SP/CD133⁺, SP/CD133⁻, non-SP/CD133⁺, and non-SP/CD133⁻) could similarly produce CD133⁺ and CD133⁻ cells during subculture.

CONCLUSION: This study revealed that CD133 could be a biliary and progenitor cell marker *in vivo*. However, CD133 alone is not sufficient to detect tumor-initiating cells in cell lines.

Characterization of CD133⁺ parenchymal cells in the liver: Histology and culture. *World J Gastroenterol* 2009; 15(39): 4896-4906 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4896.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4896>

INTRODUCTION

CD133 (also known as prominin-1 or AC133) was the first identified member of the prominin family of pentaspan membrane proteins^[1-3]. In 1997, CD133 was reported as a marker of hematopoietic progenitor cells, using a novel monoclonal antibody that recognized the CD133 antigen^[1-3]. Subsequently, it was reported that CD133 was also expressed in epithelial and non-epithelial progenitor cells in murine or human tissues including brain, kidney, prostate, pancreas, and skin^[4-8].

The specific functions and ligands of CD133 have not been elucidated completely, although CD133 currently is recognized as a stem cell marker for normal and cancerous tissues in various organs^[9-13].

Until now, there have been several reports regarding CD133 expression in hepatocellular carcinoma (HCC)^[14-17]. Suetsugu *et al.*^[14] have examined CD133 expression in three cell lines of human HCC (HuH7, HepG2 and Hc). CD133 is expressed only on the surface of HuH7 cells. The CD133⁺ population of HuH7 cells is characterized by high proliferation activity and lower expression of mature hepatocellular markers. CD133⁺ cells can form tumors in SCID mice, whereas CD133⁻ cells induce a very small number of tumors or none at all. It has been concluded that CD133 could be useable as a marker of cancer stem cells in human HCC^[14]. Yin *et al.*^[15] and Ma *et al.*^[16] also have characterized CD133⁺ cells in HCC, and they have reached a conclusion similar to that of Suetsugu *et al.*^[14]. However, because these previous studies were mainly *in vitro*, the histological characteristics of hepatic CD133⁺ cells have not been fully examined so far. In particular, there are few data about CD133⁺ cells in non-neoplastic liver tissues and non-hepatocellular liver cancers.

In this study, CD133 expression in non-neoplastic and neoplastic liver tissues was examined. *In vitro* studies were also performed to examine the biological characteristics of CD133⁺ cells of HCC and cholangiocarcinoma cell lines. The goal of this study was to elucidate the histological and biological characteristics of CD133⁺ cells in non-neoplastic and neoplastic human livers.

MATERIALS AND METHODS

Histological studies

Case selection: A total of 52 samples of liver tissues were obtained from the hepatobiliary disease file of the Division of Pathology, Kanazawa University Hospital in Japan between 2005 and 2009. This study consisted of three cases of normal liver, five cases of chronic viral hepatitis or liver cirrhosis, 33 cases of HCC, six cases of intrahepatic cholangiocarcinoma, and five cases of combined hepatocellular and cholangiocarcinoma (combined carcinoma). All cases used in this study were surgically resected cases. Normal liver tissues used in this study were background liver tissues of metastatic colon cancers. Age, sex and clinicopathological characteristics are shown in Table 1.

Expression of CD133 (mRNA level): Total RNA was extracted from the frozen section of all 47 cases using an RNeasy Mini kit (Qiagen, Valencia, CA, USA). Total RNA was dissolved in 50 μ L of distilled water that contained 0.1% diethylpyrocarbonate, and quantitated using a spectrophotometer at OD₂₆₀. Isolated RNA was used for the subsequent reverse transcriptase-polymerase chain reaction (RT-PCR). The expression of CD133 mRNA was examined by nested RT-PCR using two sets of primers. The oligonucleotide sequences, numbers

of cycles, and annealing temperatures of these primers are shown in Table 2. After PCR, 5- μ L aliquots of the products were subjected to 1.5% or 2.0% agarose gel electrophoresis and stained with ethidium bromide.

Immunostaining of CD133, cytokeratin 19 (CK19) and hepatocyte paraffin-1 (HepPar-1): Frozen sections of 52 samples of non-neoplastic and neoplastic liver tissues were used for immunostaining. Immunostaining for CD133, CK19 and HepPar-1 was performed using a mouse monoclonal antibody against human CD133 (clone AC133; Miltenyi Biotec, Auburn, CA, USA), a mouse monoclonal antibody against human CK19 (Dako Cytomation, Glostrup, Denmark), and a mouse monoclonal antibody against human HepPar-1 (Dako Cytomation).

Serial sections were used in each case to examine the co-localization of CD133, CK19 and HepPar-1 expression. Sliced frozen sections were fixed with acetone for 20 min. After blocking endogenous peroxidases, the sections were incubated in protein block solution (Dako Cytomation) for 20 min and incubated at 4°C with each primary antibody. These sections were incubated for 1 h at room temperature with goat anti-mouse immunoglobulins, which were conjugated to peroxidase-labeled polymer (Envision+; Dako Cytomation). 3,3'-Diaminobenzidine tetrahydrochloride was used as the chromogen, followed by light counterstaining with hematoxylin. Negative controls were evaluated by substituting the primary antibody with similarly diluted non-immunized mouse serum.

Culture studies

Cell culture: Three human HCC cell lines (HuH7, PLC5 and HepG2) and two human cholangiocarcinoma cell lines (CCKS1 and HuCCT1) were used in this study. HuH7, PLC5 and HepG2 were obtained from the Health Science Research Bank (Osaka, Japan). HuCCT-1 was obtained from the Cell Resource Center for Biochemical Research, Tohoku University, Sendai, Japan. CCKS1 was established in our laboratory^[18]. HuH7 and PLC5 were cultured in Dulbecco's Modified Eagle's Medium (Invitrogen Corp., Carlsbad, CA, USA), and HepG2 was maintained in minimum essential medium (Invitrogen Corp.) with 1% nonessential amino acids (Specialty Media, Phillipsburg, NJ, USA). CCKS1 and HuCCT1 were cultured in RPMI-1640 medium (Invitrogen Corp.) Each medium was supplemented with 10% fetal bovine serum (Invitrogen Corp.) and 1% antibiotic-antimycotic (Invitrogen Corp.).

Dual fluorescent immunostaining of CD133/CK19 and CD133/ α -fetoprotein (AFP): Cell lines were cultured on Lab-Tek II chamber slides (Nalge Nunc International, Naperville, IL, USA) for fluorescent immunostaining. After culturing for 2 d, the specimens were fixed in 4% paraformaldehyde for 10 min at 4°C. After incubation in protein block solution (Dako Cytomation) for 10 min, the specimens were incubated

Table 1 Age, sex, and etiology of liver diseases in our study

	<i>n</i>	Age (yr)	Male/Female	Etiology
Normal liver	3	50	2/1	
Chronic hepatitis/cirrhosis	5	58	3/2	HBV (3), HCV (2)
HCC				
Well-differentiated	3	62	2/1	HBV (1), HCV (2)
Moderately differentiated	24	62	20/4	HBV (11), HCV (7), alcohol (3), NASH (1), cryptogenic (1) ¹
Poorly differentiated	6	54	4/2	HBV (3)
Cholangiocarcinoma	6	60	3/3	HCV (4)
Combined carcinoma	5	59	4/1	HBV (1), HCV (4)

¹The remaining one case had no etiology of liver diseases and showed histologically normal liver. NASH: Nonalcoholic steatohepatitis; HCC: Human hepatocellular carcinoma; HBV: Hepatitis B virus; HCV: Hepatitis C virus.

with antibodies against CD133 and CK19, or antibodies against CD133 and AFP for 1 h at room temperature. The antibodies used were as follows: CD133, mouse monoclonal, clone AC133, Miltenyi Biotec; CK19, goat polyclonal, clone G-14, Santa Cruz Biotechnology (Santa Cruz, CA, USA); and AFP, a rabbit polyclonal, Dako Cytomation. The reaction product was visualized with fluorescent goat anti-mouse and anti-rabbit IgG antibodies (1:500, Molecular Probes Inc., Eugene, OR, USA). Specimens were counterstained with DAPI (Molecular Probes Inc.), and fluorescent signals were observed using a fluorescence microscope (Olympus, Tokyo, Japan).

Fluorescence-activated cell sorting (FACS) with reference to CD133 expression: HuH7 and HuCCT1 cells were used for FACS. Cultured cells were harvested after treatment with 0.25% of trypsin-EDTA solution (Sigma Chemical Co., St Louis, MO, USA) for 20 min, and washed three times in Hanks' Balanced Salt Solution (Invitrogen Corp.). Cultured cells were stained live in a staining solution containing bovine serum albumin, insulin, and phycoerythrin (PE)-conjugated monoclonal antibody to CD133 (clone AC133; Miltenyi Biotec) for 30 min at 4°C. As negative controls, cultured cells were incubated similarly with non-immunized mouse

immunoglobulin. Samples were analyzed and sorted by JSAN (Bay Bioscience, Kobe, Japan). Cell debris and cell aggregates were gated out electronically. For the positive population, only the top 5%-10% of the most brightly stained cells were selected. For the negative population, only the bottom 5%-10% of the most dimly stained cells were selected. Then, 1.0×10^5 cells were sorted from the positive or negative population at the most specific mode. Sorted cells were plated on culture dishes for subculture. After sorting, CD133⁺ and CD133⁻ cells were cultured separately. After 4-wk culture, cultured cells were sorted again into CD133⁺ and CD133⁻ cells using flow cytometry to evaluate how the CD133⁺ cell ratios were altered in each subpopulation. After subculturing for 3 or 4 wk, cultured cells were sorted again into CD133⁺ and CD133⁻ cells to evaluate how the CD133⁺ or CD133⁻ populations changed during subculture. The percentages of CD133⁺ cells were calculated in a total of 1000-5000 cells in each group.

RNA expression in culture cells: Total RNA was extracted from five types of cultured cells using an RNeasy Mini Kit (Qiagen). Total RNA was similarly extracted from CD133⁺ and CD133⁻ cells. RT-PCR was performed for CD133, hepatocyte makers (AFP and albumin), biliary markers (CK19 and CK7 and β-actin.

The oligonucleotide sequences, numbers of cycles and annealing temperatures of these primers are shown in Table 2. After PCR, 5- μ L aliquots of the products were subjected to 1.5% or 2.0% agarose gel electrophoresis and stained with ethidium bromide.

Real-time RT-PCR: The alterations of CD133 expression levels were examined in non-sorted or sorted (CD133⁺ or CD133⁻) cultured cells time-dependently (days 0, 7, 14, 21 and 28) after the passage or sorting. Real-time analysis was performed using premade CD133 and β -actin-specific primers and probes with the ABI Prism 7700 sequence detection system (PE Applied Biosystems, Warrington, UK). RT-PCR was done with the TaqMan Universal PCR Master Mix (PE Applied Biosystems) using 2 μ L cDNA in a 25- μ L final reaction mixture. Cycling conditions were as follows: incubation at 50°C for 2 min, 10 min at 95°C, and 50 cycles of 15 s at 95°C and 1 min at 60°C. CD133 was normalized (Δ Ct) to β -actin from the Ct value of CD133. Each experiment was performed in triplicate, and the mean adopted.

Cell proliferation assay of CD133⁺ and CD133⁻ cells: CD133⁺ and CD133⁻ cells were plated on a Lab-Tek II chamber slide (Nalge Nunc International), and cultured for 7 d before the cell proliferation assay. Cell proliferation was assayed using BrdU. Cultured cells were incubated on slides with BrdU solution (10 mmol/L) at 37°C for 30 min. After fixing with 70% ethanol (50 mmol/L glycine buffer solution, pH 2.0) for more than 20 min, the slides were incubated with anti-BrdU solution at 37°C for 30 min. After additional incubation with IgG fluorochrome solution for 30 min, positive signals were detected by a fluorescence microscope (Olympus).

Relationship between side population (SP) and CD133⁺ cells: SP is currently estimated as one of the most reliable stem cell phenotypes^[19,20]. The relationship between SP and CD133⁺ cells was examined by FACS. After detaching and washing, the cultured cells were then incubated at 37°C for 90 min with 20 μ g/mL Hoechst 33342 (Sigma Chemical Co.), PE-conjugated monoclonal antibody to CD133 (clone AC133; Miltenyi Biotec), bovine serum albumin, in the presence or absence of 100 μ mol/L verapamil (Sigma Chemical Co.). After incubation, 1 μ g/mL propidium iodide (Sigma Chemical Co.) was added and the cells were filtered through a 40- μ m cell strainer (BD Biosciences, San Diego, CA, USA) to obtain single-cell suspensions. The relationship between SP and CD133 expression was analyzed by JSAN (Bay Bioscience). Hoechst 33342 was excited with a UV laser at 350 nm and fluorescence emission was measured with 405/BP30 (Hoechst blue) and 570/BP20 (Hoechst red) optical filters. Propidium iodide labeling was measured through a 630/BP30 filter for the discrimination of dead cells. Next, HuH7 cells were sorted into SP/CD133⁺, SP/CD133⁻, non-SP/CD133⁺,

Figure 1 Expression of CD133 mRNA. Nested RT-PCR revealed CD133 mRNA expression in all cases of non-neoplastic liver tissue, HCC, intrahepatic cholangiocarcinoma, and combined hepatocellular and cholangiocarcinoma. Only eight cases of HCC are shown, although the remaining cases also expressed CD133 mRNA.

and non-SP/CD133⁻. After 4 wk subculturing, each population was analyzed again with regard to CD133 expression by FACS.

Statistical analysis

Differences between two groups were analyzed using the Mann-Whitney *U* test or χ^2 test. Statistical analysis was performed using Statcel 2 software (OMS publishing, Tokorozawa, Japan). *P* < 0.05 was considered to be significant.

RESULTS

CD133 expression in non-neoplastic and neoplastic liver tissues

The expression of CD133 mRNA was identified in all non-neoplastic and neoplastic liver tissues examined in this study by nested RT-PCR (Figure 1). The results of immunostaining of CD133 are shown in Figures 2 and 3. In normal livers, CD133 was expressed constantly in biliary epithelium of intrahepatic large and small bile ducts. Mature hepatocytes were negative for CD133. In the livers of chronic hepatitis and liver cirrhosis patients, CD133 was expressed in bile ducts and proliferating bile ductules. In addition, small ductal structures, resembling the canal of Hering, partly surrounded by hepatocytes were also positive for CD133 (Figure 2). CD133 was expressed on cellular membrane with accentuation on the luminal side. Immunostaining of CK19 and HepPar-1 on serial sections revealed that CD133 and CK19 expressions were closely co-localized (Figure 2). In contrast, mature hepatocytes that expressed HepPar-1 were negative for CD133. CD133 expression was not evident in mesenchymal or inflammatory cells upon immunostaining.

In HCC, eight of 33 cases (24%) had CD133⁺ cells. CD133⁺ cells were small in number and randomly distributed in these tumors. There were no morphological differences between CD133⁺ and CD133⁻ cells. Serial sections stained with CK19 and HepPar-1 revealed that CD133⁺ cells in HCC were HepPar-1⁺ and CK19⁺ (Figure 3). CD133⁺ cells were observed more often in

Figure 2 CD133 expression in liver cirrhosis (immunostaining). CD133 was expressed in bile duct (black arrows), bile ductules (white arrows), and small parenchymal cells surrounded by hepatocytes. CD133 was expressed on the cellular membrane with an accentuation on the luminal side. CD133⁺ cells were also positive for CK19 but not HepPar-1. All images, $\times 400$.

Hepatocellular carcinoma

Figure 3 CD133 expression in HCC, intrahepatic cholangiocarcinoma, and combined hepatocellular and cholangiocarcinoma (immunostaining). In HCC, a few carcinoma cells expressed CD133, and those cells were CK19⁻ and HepPar-1⁺ (arrows). In cholangiocarcinoma, CD133 was expressed diffusely in carcinoma cells, and CK19 was also positive. In combined carcinoma, CD133 was expressed mainly in carcinoma cells positive for CK19, whereas some carcinoma cells were CD133⁺/CK19⁺/HepPar-1⁺ (arrows). All images, $\times 400$.

Intrahepatic cholangiocarcinoma

Combined hepatocellular and cholangiocarcinoma

less differentiated HCCs: 0/3 (0%) in well-differentiated, 4/24 (17%) in moderately differentiated, and 4/6 (67%) in poorly differentiated HCC cases. The expression of CD133 mRNA was detected in all HCC cases by nested RT-PCR, although CD133⁺ cells were identified in only

24% of cases by immunostaining. This discrepancy might have resulted from the small numbers of CD133⁺ cells in HCC.

In cholangiocarcinoma, CD133 was expressed diffusely in carcinoma cells in all cases examined (Figure 3).

Figure 4 Expression levels of mRNA in cell lines. CD133 mRNA was expressed in all cell lines examined. Biliary markers (CK19 and CK7) were expressed more often in cholangiocarcinoma cell lines (HuCCT1 and CCKS1), whereas hepatocellular markers (AFP and albumin) were expressed constantly in HCC cell lines (HuH7, PLC5, and HepG2).

Figure 5 Dual immunofluorescence of CD133/CK19 and CD133/AFP in HuH7 and HuCCT1 cells. CD133⁺ carcinoma cells were positive for CK19 or AFP in both HuH7 and HuCCT1 cell lines. All images, $\times 400$.

CD133 expression was mainly on cellular membranes. HepPar-1 expression was not observed in any cases of cholangiocarcinoma, and CD133⁺ cholangiocarcinoma cells were CK19⁺ and HepPar-1⁻. In combined carcinoma, all cases had CD133⁺ carcinoma cells. CD133 expression was observed mainly in adenocarcinoma components. Most CD133⁺ cells were CK19⁺ and HepPar-1⁻, although some CD133⁺ cells were CK19⁻ and HepPar-1⁺ (Figure 3).

CD133 expression in cultured cells

The expression of CD133 mRNA was identified in all cell lines by RT-PCR (Figure 4). Biliary markers (CK19 and CK7) were expressed strongly in CCKS1 and HuCCT1 cells, whereas hepatocellular markers (AFP and albumin) were expressed constantly in HuH7, PLC5 and HepG2 cells. In addition, a cholangiocarcinoma cell line, HuCCT1, also expressed AFP. Similarly, HCC cell lines also expressed CK19 or CK7. Next, the relationships between CD133 and CK19 or AFP expression levels were examined using HCC (HuH7) and cholangiocarcinoma (HuCCT1) cell lines, both of which expressed hepatocellular and biliary markers. Dual immunostaining of CD133/CK19 or CD133/AFP revealed that CD133⁺/

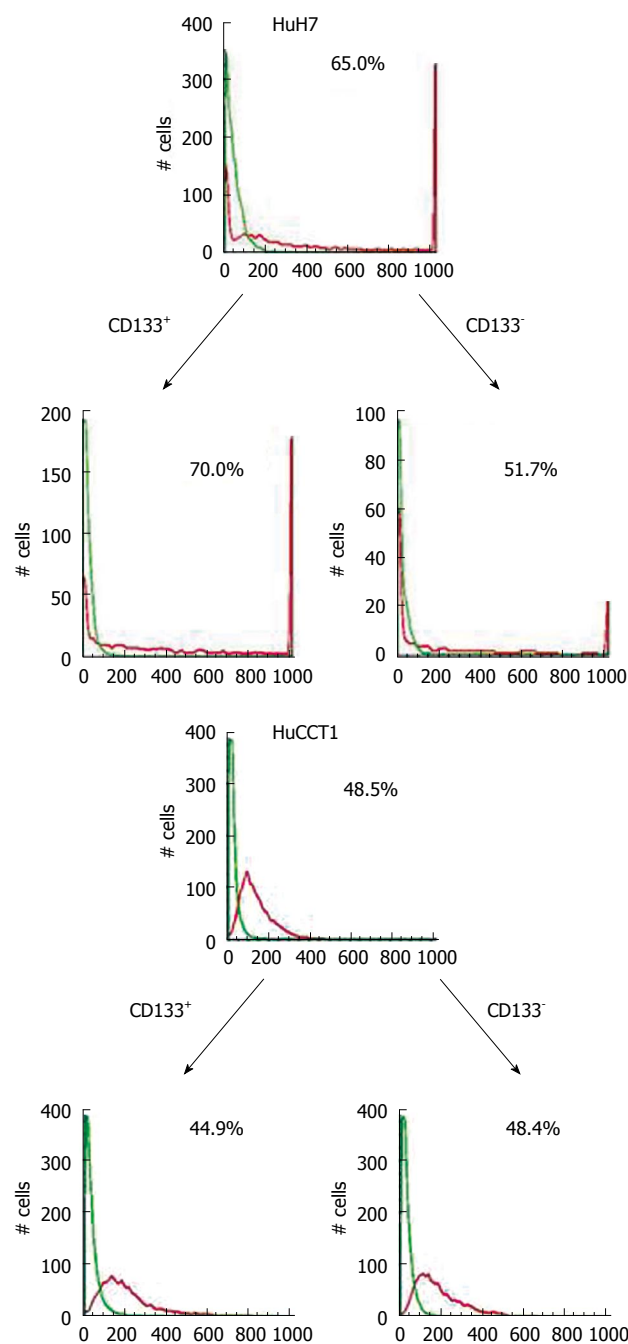

Figure 6 Flow cytometry analysis of CD133 in HuH7 and HuCCT1 cells. CD133⁺ cells comprised 65.0% of HuH7 and 48.5% of HuCCT1 cells. CD133⁺ and CD133⁻ cells could be generated from CD133⁺ and CD133⁻ subpopulations of HuH7 and HuCCT1 cells after 4 wk subculture.

CK19⁺ or CD133⁺/AFP⁺ cells were present in both HuH7 and HuCCT1 cells (Figure 5).

Cell sorting of cultured cells with regard to CD133 expression

FACS was performed using two cell lines (HuH7 and HuCCT1). The flow cytometry analysis with regard to CD133 expression is shown in Figure 6. The percentages of CD133⁺ cells from flow cytometry were 65.0% in HuH7 and 48.5% in HuCCT1 cells. After cell sorting, CD133⁺ and CD133⁻ cells derived from HuH7 or HuCCT1 cells were cultured separately for 4 wk. After

Figure 7 Expression CD133, CK19, CK7, AFP and albumin in HuH7 and HuCCT1 cells before sorting, just after sorting (day 0), and after 3 wk subculture (day 21). At day 0, expression of CD133 mRNA was observed in only the CD133⁺ population in HuH7 and HuCCT1 cells. However, CD133⁺ and CD133⁻ populations expressed similar levels of CD133 mRNA at day 21. At day 21, CD133⁺ and CD133⁻ HuH7 and HuCCT1 cells showed almost similar mRNA expression patterns.

4 wk subculturing, both CD133⁺ and CD133⁻ subpopulations returned to almost the pre-sorting cellular population that comprised both CD133⁺ and CD133⁻ cells (Figure 6). These results suggested that CD133⁻ HuH7 and HuCCT1 cells generated CD133⁺ and CD133⁻ progenies during subculture.

Expression patterns of mRNA in CD133⁺ and CD133⁻ cells

The expression patterns of CD133, CK19, CK7, AFP and albumin were examined in HuH7 and HuCCT1 cells before sorting, just after sorting (day 0), and after 3 wk subculture (day 21). At day 0, the expression of CD133 mRNA was observed in only the CD133⁺ population in both HuH7 and HuCCT1 cells. However, CD133⁺ and CD133⁻ populations expressed the CD133 mRNA at similar levels at day 21 (Figure 7). These results suggested that CD133⁻ cells began to express CD133 or produce CD133⁺ progeny during subculture. Acquisition of CD133 expression in CD133⁻ cells was consistent with the results of FACS.

On day 0, CK19 was expressed only in CD133⁺ HuH7 cells. However, CK19 expression was also identified in CD133⁻ cells at day 21. At day 21, CD133⁺ and CD133⁻ HuH7 or HuCCT1 cells showed similar expression patterns for mRNA, except for the slightly more intense expression of CK19 and albumin in CD133⁺ and CD133⁻ HuH7 cells, respectively (Figure 7).

Alteration of CD133 expression levels in CD133⁺ and CD133⁻ cells

Alterations of CD133 expression levels in HuH7 and

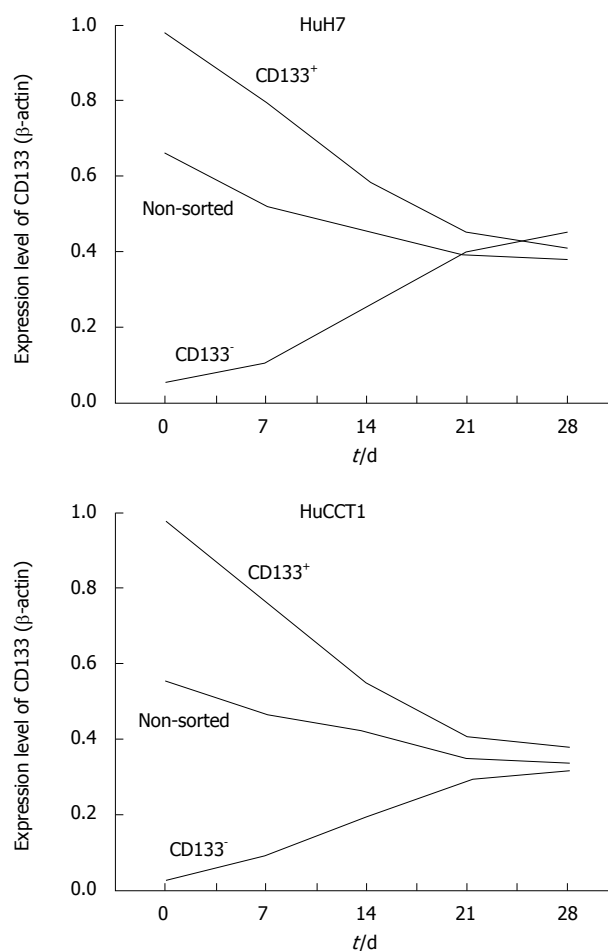

Figure 8 Time-dependent alteration of CD133 expression in HuH7 and HuCCT1 cells. Real-time quantitative RT-PCR revealed CD133 expression levels gradually decreased in non-sorted cells after passage. CD133⁺ HuH7 and HuCCT1 cells showed decreased expression of CD133. In contrast, CD133 expression increased in CD133⁻ cells in both cell lines. Around day 21-28, CD133 expression in three types of cells became similar to the level in both cell lines.

HuCCT1 cells were examined by real-time quantitative RT-PCR. HuH7 and HuCCT1 cells showed similar alteration patterns. As shown in Figure 8, CD133 expression levels in non-sorted HuH7 and HuCCT1 cells gradually decreased after passage. CD133 expression levels in CD133⁺ populations were high just after the sorting (day 0) in both cell lines. These expression levels decreased time-dependently. In contrast, CD133 expression levels in CD133⁻ cells were very low at day 0, and time-dependently increased. CD133 expression in CD133⁺ and CD133⁻ cells reached a similar level around day 21 or 28. In addition, their expression level was also similar to the level of CD133 expression in non-sorted cells at day 21 (Figure 8).

Proliferation assay of CD133⁺ and CD133⁻ cells

The proliferation of CD133⁺ and CD133⁻ cells were examined using BrdU after 7 d subculture. The percentages of BrdU-labeled cells were as follows: CD133⁺ HuH7 cells, 22%; CD133⁻ HuH7 cells, 24%; CD133⁺ HuCCT1 cells, 39%; and CD133⁻ HuCCT1 cells, 42%. No significant differences were observed in proliferation of CD133⁺ and CD133⁻ HuH7 and HuCCT1 cells.

Figure 9 Relationship between CD133⁺ cells and SP phenotype. A: The percentages of CD133⁺ cells in SP and non-SP fractions of HuH7 cells were examined using Hoechst 33342 and a PE-conjugated antibody to CD133. The ratio of CD133⁺ cells was almost the same in the SP and non-SP fractions; B: HuH7 cells were sorted into four populations: SP/CD133⁺, SP/CD133⁻, non-SP/CD133⁺, and non-SP/CD133⁻. After 4 wk subculture, CD133⁺ and CD133⁻ cells were generated at similar levels from all populations.

Relationship between SP and CD133⁺ cells

Previous studies have reported that CD133⁺ HCC cells have a greater colony-forming efficiency, higher proliferative activity, and greater ability to form tumors *in vivo*^[14-16]. It has been suggested that CD133⁻ cells are not capable of producing CD133⁺ cells. However, CD133⁺ and CD133⁻ HuH7 cells returned to almost identical cell populations after 4 wk subculture in this study. To resolve this discrepancy, the relationship between SP and CD133⁺ cells in HuH7 cells was examined because SP is one of the most reliable stem cell markers currently available.

As in the previous study^[21], an SP fraction was identified in HuH7 cells. The percentages of CD133⁺ cells in SP and non-SP fractions were examined using Hoechst 33342 and a PE-conjugated antibody against CD133. The ratios of CD133⁺ cells were almost the same in both the SP and non-SP fractions (Figure 9). HuH7 cells were sorted into four populations: SP/CD133⁺, SP/CD133⁻, non-SP/CD133⁺, and non-SP/CD133⁻. Each population was cultured separately for 4 wk and was analyzed again with regard to CD133 expression by FACS. CD133⁺ and CD133⁻ cells were produced at similar levels in the four populations (Figure 9). These results suggested no relationship between SP phenotype and CD133 expression.

DISCUSSION

This study involved the histological characterization of CD133⁺ cells in the liver and the biological characteristics of CD133⁺ cells derived from human HCC and cholangiocarcinoma cell lines. The results

obtained can be summarized as follows. (1) CD133 was expressed constantly in the biliary epithelium in non-neoplastic liver tissues. Most of the CD133⁺ cells were CK19⁺ and HepPar-1⁻ in non-neoplastic liver tissues. (2) In HCC, the expression of CD133 mRNA was observed in all cases by nested RT-PCR, whereas CD133⁺ cells were identified in only 24% of cases by immunostaining. CD133⁺ cells were small in number in all the cases of HCC examined. (3) In cholangiocarcinoma, CD133 was expressed diffusely in most carcinoma cells. (4) In combined carcinoma, most of the CD133⁺ cells were CK19⁺ and HepPar-1⁻, although some CD133⁺ cells were CK19⁻ and HepPar-1⁺. (5) In human HCC and cholangiocarcinoma cell lines, CD133⁺ cells co-expressed CK19 and AFP. (6) CD133⁺ or CD133⁻ cells derived from HuH7 and HuCCT1 cell lines similarly produced CD133⁺ and CD133⁻ progeny during subculturing. (7) There was no relationship between CD133⁺ cells and SP phenotype.

In the histological examination, CD133 expression was related closely to CK19 expression. CK19 has been used as not only a biliary marker, but also as a progenitor cell marker. CK19 is expressed usually in the bile ducts, bile ductules, and the canal of Hering^[22-24]. Small ductal structures partly surrounded by hepatocytes (the canal of Hering) are currently estimated as hepatic stem/progenitor cells, and these structures are also positive for CD133^[25,26]. Before starting this study, it was speculated that CD133 was expressed only in hepatic progenitor cells. However, this study revealed that CD133 is not only a progenitor cell marker, but can also be used as a novel biliary marker.

Some might argue about the discrepancy between the

results with nested RT-PCR and immunohistochemistry for HCC. Nested RT-PCR could detect CD133 expression in all HCC cases; whereas, its expression was observed in only 24% of cases by immunostaining. We speculate that this difference might have been caused by the low expression level of CD133 in HCC. Indeed, non-nested conventional PCR showed CD133 expression in less than half of HCC cases in the preliminary study. That is, it might be difficult to detect CD133 expression in HCC by immunostaining because of the low expression level or the lower number of positive cells.

Other investigators have examined CD133 expression in liver tissues. Yin *et al*^[15] have reported that CD133 expression is observed in a small subset of hepatocytes, biliary epithelium, and epithelial clusters in the portal tracts in cirrhotic livers, but CD133 expression is not seen in normal liver^[15]. In addition, Ma *et al*^[16] have also reported that CD133⁺ cells are almost absent in non-neoplastic liver tissues. The discrepancy between the previous and current studies might have been caused by the method of immunostaining. Both previous studies used a goat polyclonal antibody and paraffin-embedded specimens, but preliminary trials in the current study could not detect any positive signals for CD133 in paraffin-embedded specimens using any antibodies for CD133; therefore, frozen sections were used instead. In addition, CD133, which is usually expressed on the cellular membrane, was detected in the cytoplasm in previous studies. More recently, Shmelkov *et al*^[27] have examined CD133 in various organs using a unique transgenic mouse model, in which endogenous promoters for CD133 drove the expression of the reporter gene *lacZ*. CD133 was expressed widely in differentiated ductal structures in various organs including bile ducts in the liver^[27]. These previous results are consistent with the results of the current study.

CD133 expression was also related closely to CK19 expression in neoplastic liver tissues. In cholangiocarcinoma and combined carcinoma, CK19⁺ cells constantly co-expressed CD133. CD133⁺ cells comprised 48.5% of cells in the HuCCT1 cell line, and there were no differences between CD133⁺ and CD133⁻ cells in terms of proliferation or mRNA expression. We speculate that CD133 expression in cholangiocarcinoma reflects the biliary phenotype and not the progenitor phenotype. In contrast, some CD133⁺ cells in HCC and combined carcinoma were CK19⁻ and HepPar-1⁺. CD133⁺/CK19⁻/HepPar-1⁺ cells could not be identified in non-neoplastic livers, although this suggests that CD133⁺ cells are pluripotent and can differentiate into CK19⁺/HepPar-1⁻ and CK19⁻/HepPar-1⁺ cells. In particular, it is interesting that CD133⁺/CK19⁻/HepPar-1⁺ cells are observed in combined carcinoma because the involvement of hepatic progenitor cells is suggested in tumorigenesis of combined carcinoma^[28-30].

Until now, some investigators have examined the characterization of CD133⁺ cells in HCC, and have suggested that CD133⁺ HCC cells are characterized by higher proliferative activity, expression of "stemness"

genes, the ability to self-renew, and greater ability to form tumors *in vivo*^[14-16]. They have concluded that CD133⁺ cells are tumorigenic cancer cells, and located at a higher rank in the cancer-cell hierarchy. However, in the current study, CD133⁺ HuH7 cells were not different from CD133⁻ cells in terms of proliferation. In addition, CD133⁻ cells could generate both CD133⁺ and CD133⁻ cells in subcultures, which did not support the existence of a cancer-cell hierarchy with respect to CD133 expression. As noted in previous studies, CD133⁺ cells comprised about half of the carcinoma cells in the HuH7 cell line (65.0% in the current study, 46.7% or 65.0% in previous studies^[14,16]). The percentage of CD133⁺ cells seems too high to suggest that CD133 cells are tumor-initiating cells. Indeed, CD133⁻ cells were able to give rise to CD133⁺ cells in the subculture system in the previous study^[16]. Moreover, a more recent study has revealed that CD133 expression is not restricted to stem cells, and CD133⁺ and CD133⁻ cells derived from colon cancer are capable of initiating tumors in immunodeficient mice^[27].

To resolve the uncertainties regarding CD133 expression and tumor-initiating cells, the relationship between CD133⁺ cells and SP phenotype was examined in our study. SP is a minor population with extreme tumorigenic potential, and it is supposed that tumor-initiating cells exist in SP cells. If CD133⁺ cells are tumor-initiating cells, CD133⁺ cells should be related closely to the SP phenotype, and CD133⁻ cells should not exist in the SP fraction. However, there was no difference in the CD133⁺/CD133⁻ cellular population between SP and non-SP fractions. In addition, four cell populations (SP/CD133⁺, SP/CD133⁻, non-SP/CD133⁺, and non-SP/CD133⁻) could similarly produce CD133⁺ and CD133⁻ cells during subculture. It is speculated that CD133 expression might reflect the progenitor phenotype in HCC; however, CD133 alone is not sufficient to detect tumor-initiating cells.

It seems important to know that CD133 is one of the progenitor cell markers in the liver, but this is not specific. We have to determine the conditions to identify a pure hepatic progenitor or stem cell population, using multiple surface markers including CD133. From the biliary aspect, CD133 could become a useful marker, because this is a surface antigen. We can use this molecule for sorting or purification of biliary epithelium.

In conclusion, this study revealed that CD133 can be a biliary and progenitor cell marker in liver tissues. However, CD133 alone is not sufficient to detect tumor-initiating cells in cultured cells.

COMMENTS

Background

CD133 is recognized as a stem cell marker for normal and cancerous tissues in various organs. The histological characteristics of hepatic CD133⁺ cells have not been examined fully, especially in non-neoplastic liver tissues and non-hepatocellular liver cancers.

Research frontiers

Previous studies have shown that CD133 can be used as a marker of cancer stem cells in human hepatocellular carcinoma (HCC). The current study

elucidated the histological and biological characteristics of CD133⁺ cells in non-neoplastic and neoplastic human livers.

Innovations and breakthroughs

Immunohistochemical analysis showed that CD133 was expressed constantly in the non-neoplastic biliary epithelium. In cholangiocarcinoma, CD133 was expressed diffusely in most carcinoma cells, whereas CD133⁺ cells were identified in only a small number of cases of HCC. In combined carcinoma, most of the CD133⁺ cells were CK19⁺. In human HCC and cholangiocarcinoma cell lines, CD133⁺ cells co-expressed CK19 or alpha-fetoprotein. CD133⁺ or CD133⁻ cells derived from human HCC and cholangiocarcinoma cell lines similarly could produce CD133⁺ and CD133⁻ progeny during subculturing, and there was no relationship between CD133⁺ cells and the side population (SP) phenotype.

Applications

This study demonstrated that CD133 could be a biliary and progenitor cell marker *in vivo*. However, CD133 alone is not sufficient to detect tumor-initiating cells in cell lines. These results may provide insights into understanding the pathogenesis of various hepatobiliary diseases.

Terminology

CD133 (also known as prominin-1 or AC133) is a marker of hematopoietic progenitor cells. It has also been reported that CD133 is expressed in epithelial and non-epithelial progenitors in various tissues, in which the specific functions and ligands of CD133 have not been fully elucidated. SP is a minor population with extreme tumorigenic potential, and it is supposed that tumor-initiating cells exist in SP cells.

Peer review

The article presents interesting and novel data about CD133 expression in non-neoplastic and neoplastic liver tissues, and examines some biological characteristics of CD133⁺ cells in HCC and cholangiocarcinoma cell lines. Although the authors presented some controversial data about the presence of CD133 expression in HCC, the experiments were designed appropriately, the methodology was precise, and the discussion supports the results.

METHODS: One hundred and twelve MGs were divided into six groups (A-F). One hundred gerbils were inoculated with *H pylori* (groups A-E). Twelve gerbils were inoculated with vehicle broth only (group F). After 4 wk, they were given N'-methyl-N'-nitro-N-nitroso-guanidine (MNNG) (50 µg/mL) in the drinking water for 20 wk. In groups B-E, the animals were given the stock Celecoxib (10 mg/kg per day) diet from the 21st, 31st, 21st and 41st week respectively. The periods of administering Celecoxib were 30, 20, 20, and 15 wk respectively. On the 51st week, the animals were sacrificed for histological examination. Local PCNA expression was examined by the immunohistochemistry method. The expression of COX-2 protein was assessed by Western Blot. Analysis used the χ^2 test. The difference was regarded as significant when *P* value was less than 0.05.

RESULTS: Seventeen percent (17/100) of *H pylori*-infected MGs developed gastric cancer. All of these lesions were well-differentiated adenocarcinoma. The incidence rates of adenocarcinoma in groups A-F were 40%, 0%, 0%, 20%, 25%, and 0% respectively. The inflammatory scores were higher in group B than in other groups. There was no inflammatory response noted in group F. Celecoxib treatment resulted in a significant reduction in the proliferation of *H pylori*-infected mucosal cells (groups B, C and D) (*P* < 0.01). The expression of COX-2 protein was significantly attenuated in the groups which were Celecoxib-treated for more than 20 wk (groups B, C, D). The groups treated with Celecoxib had a significantly lower rate of advanced gastric cancer (34% vs 75%, *P* < 0.001). There were no sudden deaths in any of the groups.

CONCLUSION: Short-term treatment with Celecoxib has an anti-carcinogenic effect, and resulted in less severe inflammation and inhibited the invasive degree of gastric cancer.

Abstract

AIM: To evaluate the optimal intervention point of a selective cyclooxygenase-2 (COX-2) inhibitor, Celecoxib, for inhibiting *Helicobacter pylori* (*H pylori*)-associated gastric carcinogenesis in Mongolian gerbils (MGs).

China Medical University, 155 North Nanjing Street, Heping District, Shenyang 110001, Liaoning Province, China

Short-term Celecoxib intervention is a safe and effective chemopreventive for gastric carcinogenesis based on a Mongolian gerbil model. *World J Gastroenterol* 2009; 15(39): 4907-4914 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4907.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4907>

INTRODUCTION

Since the isolation and culture of *Helicobacter pylori* (*H. pylori*) in 1983, this bacterium has become accepted as an important human pathogen for the development of gastritis, peptic ulcer, and gastric cancer^[1]. The worldwide prevalence rate of *H. pylori* infection is approximately 50%, with the highest being in developing countries. In Taiwan, the overall prevalence rate is 54% and this rises with age^[2]. Seven-day triple therapy [proton pump inhibitor (PPI), amoxicillin and clarithromycin] has been the main first-line therapy for *H. pylori* infection in Taiwan, Europe and many other countries as guided by the Maastricht-22 000 consensus^[3,4]. Despite this, although the eradication of *H. pylori* is still the most cost-effective method for prevention of gastric carcinogenesis, the antibiotic treatment of *H. pylori* infection is confronting a significant challenge associated with resistance to antibiotics. The first-line regimen continues to have a 10%-23% failure rate^[5-10]. Unfortunately, several studies have shown that rescue regimens have failed in 5%-63% of patients whose *H. pylori* cannot be eradicated by standard PPI-based triple therapies^[11,12].

If refractory *H. pylori* infection persists, *H. pylori*-dependent induction of cyclooxygenase-2 (COX-2) is associated with enhanced production of multidrug resistance-1 (MDR-1) and Bcl-xL proteins that may contribute to gastric tumorigenesis and resistance to therapy^[13]. Therefore, it is important to find an alternative chemoprevention for these patients.

COX-2 is a prostaglandin-synthesizing enzyme. Elevated expression of COX-2 is observed in a wide variety of human malignancies, including gastric cancer. Various *in vitro* and *in vivo* studies strongly suggest that COX-2 is involved in a major early oncogenic event in these human malignancies^[14-18]. *H. pylori*-induced chronic gastritis also shows elevated levels of COX-2 expression in the stomach mucosa^[17-22]. Enhanced expression of COX-2 is also observed in intestinal metaplasia, dysplasia, and gastric adenoma, which are regarded as precancerous lesions^[14,23]. Moreover, previous studies showed that regular intake of either nonselective or selective COX-2 inhibitors reduces the risk of several human cancers^[24-26].

The selective COX-2 inhibitors have been reported to prevent chemical carcinogen-induced carcinogenesis in C57/BL6 mice^[22] and Mongolian gerbils (MGs)^[27-29].

However, the adverse effects of COX-2 inhibitors on the cardiovascular system inhibit the application of this chemoprevention^[30-33]. There is no animal study focusing on the optimal therapeutic period of COX-2 inhibitors to prevent these possible severe adverse events.

In the present study, our aim is to evaluate the optimal intervention point of Celecoxib in order to inhibit *H. pylori*-associated gastric carcinogenesis in MGs. In addition, we also investigated the effects on tumor invasion.

MATERIALS AND METHODS

The experimental design was approved by the Animal Research Committee of Kaohsiung Medical University. One hundred and twelve gerbils were divided into six groups (A-F), and were inoculated with *H. pylori* [CagA(+)/VacA(+)] (groups A-E; *n* = 20 in every group) or vehicle (Brucella broth) alone (group F; *n* = 12). After 1 wk, groups A-E were given N'-methyl-N'-nitro-N-nitroso-guanidine (MNNG) at a concentration of 50 µg/mL in the drinking water for 20 wk (as shown in Figure 1). Then, all groups were switched to autoclaved distilled water as drinking water. In groups B-E, the animals started to be given the stock Celecoxib diet from the 21st, 31st, 21st and 36th week. The periods during which Celecoxib was given were 30, 20, 20, and 15 wk respectively. However, the animals in groups A and F received the control diet. The daily-administered dosage of Celecoxib was 10 mg/kg per day in groups B-E. On the 51st experimental week, the animals were fasted for 24 h before being sacrificed.

Histological evaluation of the gastric mucosa in *H. pylori*-infected gerbils

Samples of the gastric mucosa were excised from each gerbil stomach for the assessment of the presence of *H. pylori* and gastric inflammation using Giemsa and hematoxylin-eosin (HE) staining for histological examination, respectively. The samples were fixed in 10% buffered formalin and embedded in paraffin^[34]. The paraffin sections were cut at a thickness of 5 µm and stained. Two experienced pathologists, unaware of the treatment given, performed histological examinations blindly. Histological features of mucosal inflammation and intestinal metaplasia were evaluated for each specimen under a light microscope according to the classification of the Sydney system. The degree of inflammatory cell infiltration and the area of intestinal metaplasia were scored as follows: 0, normal; 1, mild; 2, moderate; 3, marked. For the evaluation of mucosal cell proliferation, the proportion of PCNA-positive cells per 1000 mucosal cells was assessed in the antrum and corpus as in a previous study by Suzuki *et al.*^[35]. We also recorded the size, depth and location of tumor.

Analysis of anti-proliferating cell nuclear antigen (PCNA) in gastric mucosa

Half of the excised stomachs were fixed in 10% neutral-

Table 1 Effect of Celecoxib treatment period on incidence of gastric cancer in Mongolian gerbils

Group	Regimen	Period of Celecoxib treatment (wk)	n	Rate of gastric cancer (%)	Type of cancer

HP: *H. pylori* (intra-gastric); MNNG: N'-methyl-N'-nitro-N-nitroso-guanidine; Well: Well-differentiated adenocarcinoma; Poor: Poorly differentiated adenocarcinoma; Sig: Signet-ring cell carcinoma. ^a*P* < 0.05 vs group A.

Figure 1 Design of the study. At the beginning of the experiment, gerbils were inoculated (i.g.) with *H. pylori* (Grps A-E) or vehicle (Brucella broth; Grp F). Until the 21st week, the animals were given drinking water containing no Grp F (open bars) or 50 µg/mL MNNG (Grp A-E). All groups were then switched to distilled water and given a diet containing no drug (Grps A and F) or Celecoxib 10 mg/kg per day for 30 (Grp B), 20 (Grp C), 20 (Grp D) or 15 (Grp E) weeks. The gerbils were sacrificed at week 51.

buffered formalin and embedded in paraffin. Tissues sections were stained with HE and were analyzed by immunohistochemistry with anti-proliferating cell nuclear antigen (PCNA) serum (Dako).

Protein extraction and analysis of COX-2 expression in the gastric mucosa by Western blotting

Frozen gastric tissue was homogenized in lysis buffer (100 mmol Tris-HCl, pH 7.4, 15% glycerol, 2 mmol EDTA, 2% SDS, 100 mmol DDT) by the addition of 1:20 dilution of aprotinin and 1:50 dilution of 100 mmol PMSF as described in previous studies^[32]. Approximately 100 µg of cellular protein extract was loaded into a well, separated electrophoretically on 13.5% SDS-polyacrylamide gel and transferred onto Sequi-Blot TMPVDF membrane (Bio-Rad, Hercules, CA, USA) by electroblotting. Western blotting was performed with specific primary rabbit polyclonal antibody against COX-2 (dilution 1:500, Santa Cruz, USA) or anti-β-actin rabbit polyclonal antibody as primary antibody, and anti-rabbit IgG horseradish peroxidase-conjugated secondary antibody (dilution 1:2000, Santa Cruz, USA). Visualization of immune complexes was achieved by chemiluminescence using BM Chemiluminescence Blotting Substrate (Boehringer, Mannheim, Germany).

and the developed membrane was exposed to an X-ray film (Kodak, Wiesbaden, Germany). We did not perform Western blotting for group F.

Statistical analyses

We analyzed the collected data using the statistical software package STATA. An unpaired *t*-test or a Mann-Whitney *U* test was applied to determine the significance of differences between two groups. The incidence of cancer was assessed using χ^2 test. *P* < 0.05 was considered to be statistically significant.

RESULTS

In our study, all gerbils were alive till the end of this experiment; there was no significant difference in the survival rates among the various groups. Seventeen percent of *H. pylori*-infected gerbils developed gastric cancer. All of these lesions were well-differentiated adenocarcinoma (Figure 2). The incidence of cancer in every experimental group is shown in Table 1. As a result of long-lasting infection with *H. pylori*, 40% of the animals in group A developed cancer. There was no cancer found in groups B and C. However, the group treated with a shorter period of Celecoxib (group E) and the early-treatment group (group D) did not show obvious inhibitory effects on gastric carcinogenesis. Therefore, this meant that Celecoxib might have a chemopreventive effect on gastric carcinogenesis in some situations. Our data disclosed that the protective effect of Celecoxib might exist during long-term use or late-use of Celecoxib at a dose of 10 mg/kg per day (groups B and C).

We also evaluated the effect of Celecoxib on invasion of gastric cancer. Eight gerbils in the groups with no Celecoxib treatment and nine gerbils in groups with Celecoxib treatment developed gastric cancers. The incidence rate of advanced gastric cancer was higher in group A than groups D and E (75% vs 34%, *P* < 0.001).

In all of the *H. pylori*-infected animals (groups A-E), different degrees of infiltration of inflammatory cells were observed in the lamina propria and submucosa. The infiltration was predominantly lymphocytes, although some macrophages and neutrophils were also observed. The histological examination also revealed hyperplasia of the epithelia accompanied by erosions, lymphoid follicle formation, and intestinal metaplasia. These findings are mimicked in *H. pylori*-infected humans. The inflammatory

Figure 2 Typical adenocarcinoma in the pyloric mucosa of *H. pylori*-infected MGs. Shown is a typical well-differentiated adenocarcinoma (A, B) stained with HE. Images were obtained at $\times 100$ (A) and $\times 400$ (B).

Figure 3 Effect of Celecoxib on inflammation of the stomach mucosa. No obvious inflammatory change was found in group F. Significantly obvious inflammation was shown in *H. pylori*-infected groups (A-E) vs group F ($^aP < 0.05$), but there was no significant difference among *H. pylori*-infected groups. Group B showed higher inflammatory response than group A, C, D, E.

score was higher in group B than other groups. However, there was no significant difference between groups A, B, C, D and E. No definite evidence of inflammatory response was found in group F (Figure 3).

Our data revealed that Celecoxib could repress the development of intestinal metaplasia. Intestinal metaplastic changes were observed after *H. pylori* infection in our study (groups A-E) (Figure 4). These changes were significantly reduced in groups B and C. We did not find similar reductions in groups D and E. No intestinal metaplasia was found in group F.

In this study, we found that infection with

Figure 4 Effect of Celecoxib on the development of intestinal metaplasia (IM). Severe IM was found in group A. There was significantly lower rates of IM in groups B and C. A relatively lower rate of IM was found in groups D and E ($P > 0.05$ vs group A). There was no definite IM found in group F. $^aP < 0.05$ vs group A.

Figure 5 Effect of Celecoxib on the proliferation of gastric mucosal cells in gerbils. High PCNA positive ratio was found in group A, and the value decreased significantly after treatment with Celecoxib. The value was also lower in group F without *H. pylori* infection. $^aP < 0.05$ vs groups A.

H. pylori greatly enhanced the density of anti-PCNA immunohistochemistry in mucosal cells (groups A-E). This showed that proliferation of mucosal cells was promoted after *H. pylori* infection (Figures 5 and 6). Celecoxib treatment resulted in a significant reduction in the proliferation of *H. pylori*-infected mucosal cells (groups B, C, D and E), ($P < 0.01$). The group F showed lowest proliferation indices.

Results showed strong expression of COX-2 protein in those gerbils inoculated with *H. pylori*, but we did not detect any indication of this in gerbils treated with vehicle (Figure 7). Ratio of COX-2/ β -actin protein was significantly increased in group A, and the signal for COX-2 protein was significantly attenuated in the Celecoxib-treated groups (B, C, D). The value of COX-2 protein/ β -actin protein ratio was significantly lower in gerbils treated with long-term Celecoxib (groups B, C, D) compared to that treated with *H. pylori* alone (group A) or short-term Celecoxib (group E).

DISCUSSION

In this study, we attempted to evaluate the effect of short-term treatment of Celecoxib on prevention of

Figure 6 Expression of PCNA by immunohistochemistry method. A: Normal gastric mucosa; B: Intestinal metaplasia; C: Adenocarcinoma. Adenocarcinoma is pointed out by arrow. Images were obtained at $\times 400$.

gastric carcinogenesis in a Mongolian gerbil model. Our data support the concept that Celecoxib has a chemopreventive effect on *H. pylori*-associated stomach carcinogenesis. Besides this, we also showed that a short-term treatment period (20 wk) in the late infection phase could provide a similar chemoprevention effect as a longer treatment period (30 wk) reported in a previous study^[26]. According to this finding, we postulate that a COX-2 inhibitor could be used as chemoprevention for people older than about forty years old. However, this suggestion is not strongly definite due to the small scale of our study. The exact time-point of Celecoxib intervention needs further investigation.

This chemoprevention may play an important role for some people. For example, subjects with extensive metaplastic gastritis have the highest risk for the development of gastric cancer (annual cancer incidence,

Figure 7 Analysis of COX-2 protein expression in gastric mucosa of gerbils. The expression of COX-2 protein in group A was high. There was no detectable expression in group F. The expression of COX-2 was inhibited significantly by Celecoxib. There was a significant decrease in groups B, C and D. ^a $P < 0.05$ vs group A.

0.87%), but they cannot be treated with therapy to eradicate *H. pylori* because the infection is no longer present^[36]. In this small population, inhibition of COX-2 expression may be useful for the prevention of gastric cancer. Our study supports the fact that a COX-2 inhibitor has a chemopreventive effect by inhibiting expression of COX-2.

Eradication of *H. pylori* is a well-known effective prevention of gastric cancer^[37]. COX-2 inhibitors are expensive and less cost-effective than therapy aimed at eradicating *H. pylori*. However, there are still people with refractory infection despite rescue eradicating regimens. So this chemoprevention is very important for those patients with refractory *H. pylori* infections at high risk of gastric cancer.

Various mechanisms have been proposed to explain the anti-tumor action of NSAIDs, including cell growth suppression, inhibition of angiogenesis and metastasis, and NSAID-induced apoptosis in cancer cells^[38,39]. Persistent activation of COX-2 is associated with oncogenesis as well as with increased invasive potential of tumor cells^[40-42]. In our study, we found that Celecoxib could inhibit the tumor invasion even with short-term use. According to our results, Celecoxib may have effects including anti-oncogenic effect, inhibition of angiogenesis and metastasis, and it was shown that these effects were obtained by both late and short-term use of Celecoxib. In our study, the treatment began at 30-40 wk of age of the gerbils which is equivalent to 35 to 45-years old in humans.

With regard to PCNA results in our data; these disclosed that the inhibitory effect of Celecoxib was related to the inhibition of cell proliferation. This was comparable with previous studies' findings^[43,44]. It is well-known that carcinogenesis in the *H. pylori*-infected stomach also results from an inflammation-mediated

sequence. Chronic inflammation is thought to play a cardinal role in the accumulation of genetic damages leading to transformation and cancer by inducing the proliferation of target cells^[45-47]. Consequently, it is important to find the suitable time-point at which COX-2 inhibitors prevent the carcinogenesis.

In our study, group D had a higher incidence rate of gastric cancer than group C (20% *vs* 0%). This finding supports the theory that the protective effect of Celecoxib is involved in an early oncogenic phase not in an early inflammation phase. This was comparable with findings of previous studies^[14-17]. According to our findings, Celecoxib could be used latterly and short term for refractory *H pylori* infection in a clinical situation; a point which has been seldom discussed in previous reports. This short term use is very important for decreasing the possible side effects of COX-2 inhibitors.

In our study, different periods of treatment with Celecoxib produce different results in inflammatory score. The longer treatment period results in more obvious gastric mucosal damages. Previous studies which used long-term treatment indicated that COX-2 inhibitors were not a placebo and had toxic effects. Accordingly, COX-2 inhibitors should not be used too long for chemoprevention of gastric cancer. Although we did not find any sudden death resulting from cardiovascular events in the gerbils, this may be due to the small sampling size. However, we found that the average ventricular size was large in group B (data not shown). Therefore, subclinical cardiovascular events may occur. The above findings show that the treatment period of Celecoxib should be as short as possible.

It should be noted that there could be other COX-2-independent mechanisms involved in stomach carcinogenesis because a relatively high dose of Celecoxib is needed for the anti-carcinogenic effect. Further studies are required to survey these mechanisms.

In conclusion, our study supports the hypothesis that Celecoxib has a potent anti-carcinogenic effect, and that short-term use could result in an almost equal effect to longer term use with less side effects. The protective effect of Celecoxib could be involved in the early oncogenic phase not in the early inflammation phase. This chemoprevention may be suitable for subjects with high risk for the development of gastric cancer: such as people with extensive metaplastic gastritis or refractory *H pylori* infection. Thus we suggest that Celecoxib could be used short-term for high-risk patients.

COMMENTS

Background

Long-term high dose cyclooxygenase-2 (COX-2) inhibitors can inhibit gastric carcinogenesis in animal models, but the possible life-threatening cardiovascular events limit its popular application. Therefore, in the present study, we wished to evaluate the optimal intervention point of a selective COX-2 inhibitor, Celecoxib, for inhibiting *Helicobacter pylori* (*H pylori*)-associated gastric carcinogenesis in Mongolian gerbils (MGs).

Research frontiers

COX-2 is a prostaglandin-synthesizing enzyme. Elevated expression of COX-2 is observed in a wide variety of human malignancies, including gastric cancer.

H pylori-induced chronic gastritis also shows elevated levels of COX-2 expression in the stomach mucosa. The selective COX-2 inhibitors have been reported as preventing chemical carcinogen-induced carcinogenesis in C57/BL6 mice and Mongolian gerbils. It is important to evaluate the optimal therapeutic period of COX-2 inhibitors to prevent possible severe adverse events.

Innovations and breakthroughs

Chronic inflammation is thought to play a cardinal role in the accumulation of genetic damages leading to transformation and cancer by inducing the proliferation of target cells. Therefore, it is important to find the suitable time-point at which COX-2 inhibitors prevent the carcinogenesis. Previous studies used relatively long-term periods of chemopreventive treatment. However, COX-2 inhibitors were not a placebo and had a toxic effect, so COX-2 inhibitors should not be used too long for chemoprevention of gastric cancer. According to our results, Celecoxib may have effects including anti-oncogenic effect, inhibition of angiogenesis and metastasis, and it was shown that these effects were obtained by both late and short-term use of Celecoxib. In our study, the treatment began at 30-40 wk of age of the gerbils which is equivalent to 35 to 45-years old in humans. In our study, we found that the protective effect of Celecoxib could be involved in an early oncogenic phase not in an early inflammation phase. The short-term use also resulted in less severe inflammation and inhibited the invasion degree of gastric cancer. According to our findings, Celecoxib could be used latterly and short-term for refractory *H pylori* infection in a clinical situation; a point which has been seldom discussed in previous reports. This is very important for decreasing the possible side effects of COX-2 inhibitors.

Applications

Our study supports the theory that short-term treatment with Celecoxib has an anti-carcinogenic effect. Consequently, Celecoxib could be used in the later stages of *H pylori* infection to achieve safe and effective chemoprevention of gastric adenocarcinoma. In addition to this finding, The authors would like to suggest that COX-2 inhibitor should be used as chemoprevention for people older than about forty years old. This chemoprevention may play an important role for people who have extensive metaplastic gastritis with the highest risk for the development of gastric cancer, and it is also very important for those patients with refractory *H pylori* infections at high risk of gastric cancer.

Peer review

In the present study, the author investigated the optimal intervention point of Celecoxib for inhibiting *H pylori*-associated gastric carcinogenesis in MGs. They found the animals with extensive metaplastic gastritis or refractory *H pylori* infection may be suitable for celecoxib chemoprevention. This result provided us with some new information about personalized therapy for gastric cancer prevention and will prove beneficial for clinical application in the future.

Abstract

AIM: To study the association between serum levels of milk protein IgG and IgA antibodies and milk-related gastrointestinal symptoms in adults.

METHODS: Milk protein IgG and IgA antibodies were determined in serum samples of 400 subjects from five outpatient clinics in Southern Finland. Subjects were randomly selected from a total of 1900 adults undergoing laboratory investigations in primary care. All 400 participants had completed a questionnaire on abdominal symptoms and dairy consumption while waiting for the laboratory visit. The questionnaire covered the nature and frequency of gastrointestinal problems, the provoking food items, family history and allergies. Twelve serum samples were disqualified due to insufficient amount of sera. The levels of specific milk protein IgG and IgA were measured by using the ELISA technique. The association of the milk protein-specific antibody level was studied in relation to the milk-related gastrointestinal symptoms and dairy consumption.

RESULTS: Subjects drinking milk ($n = 265$) had higher levels of milk protein IgG in their sera than non-milk drinkers ($n = 123$, $P < 0.001$). Subjects with

gastrointestinal problems related to milk drinking ($n = 119$) consumed less milk but had higher milk protein IgG levels than those with no milk-related gastrointestinal symptoms ($n = 198$, $P = 0.02$). Among the symptomatic subjects, those reporting dyspeptic symptoms had lower milk protein IgG levels than non-dyspeptics ($P < 0.05$). However, dyspepsia was not associated with milk drinking ($P = 0.5$). The association of high milk protein IgG levels with constipation was close to the level of statistical significance. Diarrhea had no association with milk protein IgG level ($P = 0.5$). With regard to minor symptoms, flatulence and bloating ($P = 0.8$), were not associated with milk protein IgG level. Milk protein IgA levels did not show any association with milk drinking or abdominal symptoms. The levels of milk protein IgA and IgG declined as the age of the subjects increased ($P < 0.004$).

CONCLUSION: Milk protein IgG but not milk IgA seems to be associated with self-reported milk-induced gastrointestinal symptoms.

Milk protein IgG and IgA: The association with milk-induced gastrointestinal symptoms in adults. *World J Gastroenterol* 2009; 15(39): 4915-4918 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4915.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4915>

INTRODUCTION

More than 40% of adults in primary care suspect that milk ingestion is causative of their gastrointestinal symptoms^[1]. Furthermore, patients suffering from irritable bowel syndrome (IBS) often relate their symptoms to milk^[2]. To assess the impact of milk in

abdominal complaints is challenging. It is often difficult to distinguish the symptoms of milk hypersensitivity from other types of milk- or food-related gastrointestinal symptoms. Milk hypersensitivity in early childhood is mostly milk protein IgE-mediated^[3,4] causing immediate-type hypersensitivity reactions. The frequency of IgE-mediated cow's milk allergy decreases with increasing age and a high level of cow's milk-specific IgE is rare in adults^[5-8]. The impact of other types of immune reactions to cow's milk and, more specifically, the association of antibodies of IgG and IgA isotypes with cow's milk-induced adverse gastrointestinal symptoms in adults, is presently controversial^[9-13]. Ou-Yang *et al*^[14] have reported that an elimination diet based on the elevated level of food-specific IgG improved chronic diarrhea in children. Another recent study from China showed no association between symptom severity and food antigen-specific IgG in patients suffering either from IBS or functional dyspepsia (FD) although the levels of food-specific IgG titres were higher both in IBS and FD patients compared to healthy controls^[15].

The purpose of our study was to evaluate the association of serum level of milk protein IgG and IgA antibodies with gastrointestinal symptoms experienced by cow's milk ingestion in working age adults and to evaluate the milk IgA and IgG levels in relation to dairy consumption.

MATERIALS AND METHODS

We screened adults during spring 2004 in five different primary care centres for food-related symptoms, focusing on milk-related problems^[11,16]. Ethical approval was received from the Ethics Committee for outpatient clinics in Helsinki and surrounding areas (567/E1/03). Subjects who were referred to the laboratory for blood tests were invited to give a blood sample for the study purposes and to complete a questionnaire on gastrointestinal symptoms and dairy consumption as described recently^[1]. Of the 1900 adults who agreed to a blood sample within the three month study period, an exceptionally high proportion, 99%, returned the questionnaire. Randomly, serum samples from 400 of these subjects (198 women and 202 men) were selected for the measurement of milk protein IgG and IgA levels. Twelve samples were excluded due to an insufficient amount of sera. Thus, the study group comprised 388 adults (aged 18-64 years, mean age 40 years) of whom 119 informed us that they experienced gastrointestinal symptoms from consuming milk and 198 reported having no milk-related symptoms. The non-response rate was, in general, low per question. However, 71 (18%) did not answer the question on the presence of subjective milk-related symptoms, although they responded to questions on dairy consumption and gastrointestinal symptoms.

The reasons for laboratory testing were; gastrointestinal symptoms in 69/388 (18%), health check-up in 209/388 (54%), and follow up of an earlier diagnosed disease in 90/388 (23%). In 23/388 (6%) the indication for blood

test was not reported. All subjects had been genotyped for adult-type hypolactasia^[11] and screened for celiac disease^[16]. IgG antibodies to *Helicobacter pylori* (*H. pylori*) were determined with an in-house enzyme immunoassay as previously described^[17]. The lower limit for raised titres was 700 with a sensitivity of 99% and specificity of 93% as compared to histology^[17].

The milk protein IgG and IgA antibodies were measured by the ELISA technique using an adapted infant formula to coat the microtitre plates. Values are expressed as % of the standard with a very high titre of cow's milk antibodies^[18]. The major antigen in the formula was casein.

Statistical analyses

Kruskal-Wallis test, Spearman Rank Correlation, Mann-Whitney, Fisher's exact test, and ANOVA were used for analyzing the results. Significance was set at $P < 0.05$.

RESULTS

The levels of milk protein IgA and IgG antibodies declined as the age of the subjects increased, being lowest in the oldest age group, and the age-related decline was statistically significant with regard to milk protein IgG (ANOVA, $P < 0.004$; Table 1). Age and personally estimated milk-related gastrointestinal problems showed no correlation ($P = \text{NS}$, Spearman Rank). Men had higher milk protein IgA but not milk IgG levels in their sera than women (Mann-Whitney, $P = 0.04$; Table 1). Subjects drinking milk daily had higher levels of milk protein IgG in their sera than non-milk drinkers (Mann-Whitney, $P < 0.001$; Table 1). The daily consumption of milk was less frequent among subjects reporting gastrointestinal problems after drinking milk, but they had higher milk protein IgG levels than those who experienced no gastrointestinal symptoms (Table 1). Milk protein IgA levels did not show any association with milk drinking or abdominal symptoms (Table 1).

The association of high milk protein IgG levels with constipation was close to the level of statistical significance (Table 1). Diarrhea had no association with milk protein IgG level ($P = 0.5$). Regarding minor symptoms, flatulence and bloating ($P = 0.8$, Mann-Whitney), were not associated with milk protein IgG level. Subjects reporting dyspeptic symptoms had lower milk protein IgG levels than non-dyspeptics ($P < 0.05$). Furthermore, dyspepsia was not associated with milk drinking ($P = 0.5$, Fisher's exact test) or age ($P = 0.19$, Spearman Rank).

Milk protein IgG level was lower in subjects positive for antibodies to *H. pylori* ($n = 76/386$, $P < 0.05$ Mann-Whitney) although they drank milk more often than *H. pylori*-negative subjects ($n = 62/76$, $P < 0.006$ Mann-Whitney). However, the *H. pylori*-positive group was somewhat older (mean age 46 years) than the *H. pylori*-negative group (mean age 40 years, $P = 0.004$, ANOVA), which may explain the result. Accordingly, the presence of *H. pylori* antibodies in serum was associated

No dyspepsia	202 (52)	15.6 (12.6-18.5)		10.1 (6.8-13.3)	

¹The level of IgG decreased according to the age statistically significantly. ²The IgA level was statistically significantly higher in men than in women. ³The milk drinking was associated with IgG level statistically significantly. ⁴The IgG level was statistically significantly higher in subjects with symptoms from milk. ⁵The level of IgG was statistically significantly lower in subjects with dyspepsia.

in a statistically significantly manner with a lower level of milk protein IgA antibodies ($P = 0.03$, Mann-Whitney).

There was no correlation between milk protein IgG or IgA antibodies and C/T-13910 genotype associated with adult type hypolactasia. Unexpectedly, none of these randomly picked subjects was screen-positive for celiac disease^[16]. There was no association of milk-specific IgG or IgA with a reported history of a diagnosed gastrointestinal disorder [irritable bowel syndrome $n = 12/388$ (3.0%) or inflammatory bowel disease $n = 4/388$ (1.0%)], since none of these patients had high levels of cow's milk-specific IgG or IgA. Irritable bowel syndrome was reported less in the study group than in an average western population (5%-10%) and inflammatory bowel disease more often than in an average western population (0.1%)^[19,20].

DISCUSSION

Milk protein IgG but not milk IgA seems to be associated with self-reported milk-induced gastrointestinal symptoms. The nature of these symptoms, however, is unclear. There was a clear association of milk protein IgG with milk drinking in our study, supporting the view that the presence of milk protein IgG-specific antibodies may, to a certain level, be a normal physiologic reaction to ingested milk protein. Regarding the gastrointestinal symptoms, dyspepsia but not diarrhea or constipation showed a statistically significant association with milk protein IgG level. However, the association with milk protein IgG and dyspepsia was confounding as it was negative and not attributed to milk drinking or age.

The serum samples and questionnaires of the 388 patients included in this study were randomly picked from a group of 1900 volunteers attending a larger study of milk-induced gastrointestinal symptoms^[1]. The blood

samples were initially obtained during a short period of three months. Thus, seasonal variation had minimal effect on the results. An exceptionally high proportion, 99% of the 1900 participants, returned the questionnaire on abdominal symptoms and dairy consumption. The questionnaires were well completed and no samples needed to be excluded because of missing questionnaire data. However, as the number of samples included was limited there may be bias in the results. The information about milk-related gastrointestinal problems was derived from the questionnaires, not from milk challenge and subsequent observation of the participants. However, questionnaires were well-formulated and the participants were all working age people capable of understanding the questions. Furthermore, the most common causes for milk-related symptoms such as adult-type hypolactasia or celiac disease had been screened out by blood tests in the study group^[1,16].

There are only a few studies which have been conducted in adults regarding milk protein antibodies, especially involving IgG and IgA. Although there are a number of studies in children, extrapolation of results from pediatric populations requires caution. There are some recent pediatric studies which imply that determination of milk-specific IgG4 might have a role in this field^[13,21,22]. In this study we did not have the opportunity to measure milk-specific IgG4. However, the results of the earlier studies conducted in adults provided controversial results^[9-13].

In our previous study, we showed that IgE antibodies to milk did not correlate with the self-reported, milk-related symptoms^[5]. Consistent with this, Peltó *et al*^[11] have shown that hypersensitivity to cow's milk does also occur in adults but the mechanism is most likely not milk-specific antibody-mediated but rather due to an increase in serum reactivity to milk protein. Moreover, the positive association between milk protein IgG level

and reported gastrointestinal symptoms from milk are in accordance with earlier findings showing that bowel irritation had a correlation with high mucosal IgG levels to food antigens^[10,18].

The importance of milk protein IgG and IgA antibodies in the etiology of gastrointestinal symptoms following cow's milk ingestion remains uncertain. At present however, it would appear that measurement of these antibodies in routine clinical practice is of limited value and cannot be recommended.

ACKNOWLEDGMENTS

The skilful technical assistance of Ms Sirkku Kristiansen is gratefully acknowledged. Also, the patients who voluntarily took part in the study are thanked for their support.

COMMENTS

Background

Cow's milk-related gastrointestinal symptoms are often complained about by primary care patients. In adult populations "lactose intolerance" or, more precisely, adult-type hypolactasia, is the most common cause of cow's milk induced gastrointestinal symptoms. Celiac disease, the most common cause of secondary hypolactasia, is encountered in 1%-2% of western populations and thus should be considered when milk-related symptoms are being diagnosed. Allergy to cow's milk protein is relatively rare in adults and the mechanisms by which it is mediated are not yet known. Milk protein-specific immunoglobulin (Ig)E, the most common mediator of milk hypersensitivity in children, is hardly ever the mediator in adults. There are a number of studies regarding milk protein hypersensitivity in children, but only a few conducted among adults and the results achieved from children cannot be extrapolated to adults without caution. This study was conducted in order to evaluate the roles of milk protein specific IgG and IgA in cow's milk hypersensitivity in adults.

Applications

Milk protein IgG is associated with self-reported milk-related gastrointestinal symptoms, whereas milk protein IgA has no such association. Milk protein IgG antibody levels also correlate with drinking milk. These findings imply that milk protein-specific IgG has a role in the humoral reaction to ingested milk. However, the measurement of milk protein IgG provides no accurate information on milk hypersensitivity.

Peer review

This is an interesting work that is concerned with a controversial area of gastroenterology.

Abstract

AIM: To investigate whether children should undergo surgery without a long period of fasting after feeding.

METHODS: Eighty children with inguinoscrotal disorders (aged 1-10 years) were studied prospectively. They were divided into eight groups that each contained 10 children who were fed normal liquid food (NLF) and a high-calorie diet (HCD) 2, 3, 4 and 5 h before surgery, in two doses at 6-h intervals. NLF was given to four groups and HCD to the other four. In all groups, glucose, prealbumin and cortisol levels in the blood were measured twice: just after oral feeding and just before the operation. After the establishment of adequate anesthesia, gastric residue liquid was measured with a syringe.

RESULTS: Blood glucose levels in all patients fed NLF and HCD were high, except in patients in the HCD-4 group. There was no significant difference in the blood prealbumin levels. There was a significant increase in the blood cortisol levels in the NLF-2 (14.4 ± 5.7), HCD-2 (13.2 ± 6.0), NLF-3 (10.9 ± 6.4), and HCD-5 (6.8 ± 5.7) groups ($P < 0.05$).

CONCLUSION: The stress of surgery may be tolerated by children when they are fed up to 2 h before elective surgery.

INTRODUCTION

For many years, overnight fasting has been recommended before elective surgery. This fasting period is applied to reduce the risk of aspiration of stomach contents during anesthesia^[1]. The routine use of perioperative oral dietary supplements in patients about to undergo gastrointestinal surgery confers no clinical or functional benefit^[2].

However, this routine is now being questioned, because fasting causes discomfort and unnecessary problems with routine oral medication^[3,4]. The free intake of water is allowed up to 3 h before surgery in children^[5,6] and adults^[7]. Thirst and anxiety are reduced in comparison with overnight fasting. Feeding with clear fluids does not increase gastric contents^[7,8].

Although they do not diminish the risk of aspiration, clear liquids given enterally 2 h before surgery appear to pose no additional risk for aspiration of gastric contents in normal healthy children, and may provide some psychological benefit, as demonstrated by a decrease in irritability before induction of anesthesia^[9]. It has been reported that a high-calorie diet (HCD) given enterally 2 h before surgery makes the surgery more comfortable^[10,11].

Furthermore, Powell-Tuck *et al*^[12] and Beier-Holgersen *et al*^[13] have reported that early enteral feeding decreases postoperative complications, regulates wound improvement rapidly, decreases the cost of hospitalization, and increases quality of life and postoperative surgical success.

Recent studies have shown that perioperative insulin and glucose infusion maintains normal insulin sensitivity after surgery^[14]. Prealbumin (transthyretin) level is used often as an indicator of protein status because of its relatively short half-life, high tryptophan content, high

proportion of essential to nonessential amino acids, and small pool size. A sensitive acute phase reactant such as C-reactive protein always should be assayed along with prealbumin if levels are to be used to estimate nutritional status^[15].

Although some studies have investigated the duration of fasting, to the best of our knowledge, there has been no research published about the metabolic changes in children fed normal liquid food (NLF) and an HCD, depending on the duration of fasting before an operation.

The aim of our study, therefore, was to compare NLF and HCD depending on the duration of fasting before surgery, and to decide whether children should undergo surgery without a long period of fasting after feeding them with an HCD.

MATERIALS AND METHODS

Ethics

This work was carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. The study was approved ethically by Selcuk University Meram Medical School (2005/058). All families provided informed written consent for their children.

Patients

The study population consisted of 80 patients (58 male; mean \pm SD, 6.18 ± 1.25 years; range, 1-10 years). Blood samples were obtained from the patients by the same surgeon. The study was conducted as a randomized, single-blind clinical trial. The children included in the study were outpatients and they had inguinoscrotal disorders without any additional abnormality. Sixty-two (77.5%) patients who had inguinal hernias underwent high ligation (Ferguson procedure) and 18 (22.5%) who had undescended testes underwent orchidopexy. All patients were admitted on the day of surgery or underwent surgery as outpatients. Tracheal intubation was planned in all cases. General anesthesia was used. Patients taking medication or who had a disease known to delay gastric emptying or increase acid production were excluded.

Clinical design

The patients were divided into eight groups, each containing 10 patients who were fed NLF and an HCD 2, 3, 4 and 5 h before surgery. NLF was given to four groups and HCD to the other four (Figure 1). The food and liquid requirements of the children, which consisted of 10 mL/kg, were given orally in two doses at 6-h intervals, after calculating their carbohydrate, protein, lipid, and electrolyte needs according to body weight. Then, they were fasted for 2, 3, 4 and 5 h preoperatively. After the establishment of an adequate and stable level of anesthesia, a 14 or 16 Fr Levin multi-orificed gastric tube was passed orally into the stomach by the same investigator, who was unaware of the patient's fasting status, to determine whether there was any residue in the stomach before surgery. After confirmation of the gastric tube's position by auscultation, gastric fluid contents were

Figure 1 Groups, feeding procedures, and durations in the study design.

NLF: Normal liquid food; HCD: High-calorie diet; NLF-2: Fed with NLF 2 h before surgery; HCD-2: Fed with an HCD 2 h before surgery; NLF-3: Fed with NLF 3 h before surgery; HCD-3: Fed with an HCD 3 h before surgery; NLF-4: Fed with NLF 4 h before surgery; HCD-4: Fed with an HCD 4 h before surgery; NLF-5: Fed with NLF 5 h before surgery; HCD-5: Fed with an HCD 5 h before surgery.

obtained through the tube by gentle aspiration with a 60-mL syringe in several positions, with the patient tilted head-up, head-down, to the right, and to the left. Gastric residue liquid was measured using this syringe.

Biochemical analysis

Blood samples were obtained twice from the patients in all groups (Figure 1), when oral feeding was stopped and just before the operation (before the induction of anesthesia), to measure the values of blood glucose, prealbumin and cortisol. After all the blood samples were taken, blood glucose levels were determined in a Beckman Coulter Unicel DXC 800 Synchron Clinical System autoanalyzer (Beckman Coulter, Inc., Fullerton, CA, USA) using a Beckman Coulter test kit (catalog no: T709005). Prealbumin levels were determined using a Beckman Coulter test kit (catalog no: M605268) in a Beckman Array Protein System autoanalyzer. Cortisol levels were determined using a Beckman Coulter test kit (catalog no: 230) in Unicel DXI-800 Access Immunoassay System autoanalyzer (Beckman Coulter Inc. Immunodiagnostic Development Center, Chaska, USA).

Statistical analysis

Power was calculated as 100% with a sample size of 10 patients in each group. All data were presented as mean \pm SD for biochemical analysis. Two-way repeated measures of ANOVA were used to compare postprandial (PP) and starvation values for each parameter in the eight groups. Post-hoc tests were used to identify the origin of the difference when a significant difference was identified. For this purpose, Bonferroni-corrected one-way ANOVA and Tukey-HSD test were used to identify whether there was a difference among the groups during the PP and fasting periods. Moreover, Student's paired *t* test was used to compare the PP and starvation values in each dependent group. $P < 0.05$ was considered statistically significant. However, $P < 0.025$ was considered statistically significant when Bonferroni correction was made. For all calculations, SPSS version 13.0 was used, and for calculation of power PASS version 08.07 was used.

^a*P* < 0.004, NLF-2 vs HCD-5 group fasting values according to Tukey-HSD test; No significant difference according to PP vs fasting, *P* = 0.162. PP denotes values of blood glucose, prealbumin, and cortisol 2, 3, 4 and 5 h before surgery (when oral feeding was stopped). Fasting denotes values of blood glucose, prealbumin, and cortisol before just surgery (before the induction of anesthesia). NS: not significant; NLF: Normal liquid food; HCD: High-calorie diet; PP: Postprandial.

Figure 2 Boxplot graph of blood glucose (A), prealbumin (B), cortisol (C) levels in the eight study groups (*n* = 10 each) during PP and fasting periods.

RESULTS

PP blood glucose levels within and between groups were significantly lower compared to the fasting blood glucose levels, except for HCD-4. There was no significant difference regarding PP blood glucose (*P* = 0.570), but there was a significant increase in the fasting values of blood glucose in the NLF-2 group when compared with the HCD-5 group (*P* = 0.004) (Table 1 and Figure 2A).

There was no significant difference between or within the groups (*P* = 0.162) regarding blood prealbumin (Table 1 and Figure 2B).

PP blood cortisol levels in the NLF-2, HCD-2, NLF-3, NLF-5 and HCD-5 groups were significantly lower compared to fasting blood glucose levels (Table 1 and Figure 2C). The stomach residue liquids of all patients were at tolerable levels (1-2 mL). All anesthesia induction was uneventful, and no patient suffered from coughing, laryngospasm, or vomiting. There was no problem regarding the outcomes of surgery or wound healing.

DISCUSSION

Preoperative fasting has been applied before elective surgery to prevent the risk of aspiration of stomach contents during anesthesia^[1], but no study has examined whether there were negative effects of an HCD on the effects of duration of fasting and preoperative feeding on metabolic changes and anesthesia in children^[3,4].

The ingestion of unlimited clear fluids by healthy 2-12-year-old children up to 2 h before elective surgery does not affect gastric contents^[6]. In addition, there is no correlation between the fasting interval and gastric fluid pH or volume, and 2 mL/kg of water may be administered to healthy, non-premedicated children 2 h before surgery, without decreasing gastric fluid pH or increasing gastric fluid volume compared to those fasting for up to 6 h^[5]. Drinking clear liquids up to 2 h before anesthesia induction is unlikely to affect substantially the volume of gastric fluid contents or the percentage of patients with gastric fluid pH \leq 2.5. Clear liquids appear to add no additional risk for aspiration of gastric contents in normal healthy children, and may provide some psychological benefit, as demonstrated by a decrease in irritability before induction of anesthesia^[9]. Partial feeding in the immediate (up to 2 h before premedication) preoperative period may become routine in the future^[11].

The values of blood glucose and insulin are known to be increased significantly 40 min after ingestion of a carbohydrate-rich drink^[11]. Perioperative glucose and insulin infusions minimize the endocrine stress response and normalize postoperative insulin sensitivity and substrate utilization^[14]. To achieve standardization in our study, the food and liquid requirements of the patients were given in two doses at 6-h intervals, and blood samples were obtained from all groups twice before surgery. It is novel to evaluate metabolic changes in children fed NLF and an HCD, depending on the

duration of fasting before surgery. In the present study, blood glucose levels increased and stomach residue liquids were at a tolerable level in all patients fed NLF and an HCD. These results indicate that children can tolerate the stress of surgery when they are fed until 2 h before surgery, because there was no difference regarding stomach residue and metabolic changes among patients that underwent surgery after fasting for short and long periods.

In conclusion, there is no need for more than 2 h of fasting before inguinoscrotal region surgery. Further studies in surgical patients should help to substantiate the safety and clinical benefits of this new concept.

COMMENTS

Background

Preoperative fasting has been applied before elective surgery to prevent the risk of aspiration of stomach contents during anesthesia, but no study has examined whether there are negative effects of a high calorie diet (HCD) on the effects of duration of fasting and preoperative feeding on metabolic changes and anesthesia in children.

Research frontiers

Children can tolerate the stress of surgery when they are fed with normal liquid food (NLF) and HCD until 2 h before surgery, because there was no difference regarding stomach residue and metabolic changes among patients that underwent surgery after fasting for short and long periods.

Innovations and breakthroughs

For many years, overnight fasting has been recommended before elective surgery. This fasting period is applied to reduce the risk of aspiration of stomach contents during anesthesia. The routine use of perioperative oral dietary supplements in patients about to undergo gastrointestinal surgery confers no clinical or functional benefit. However, this routine is now being questioned, because fasting causes discomfort and unnecessary problems with routine oral medication. It is novel to evaluate metabolic changes in children fed NLF and an HCD, depending on the duration of fasting before surgery. In the present study, blood glucose levels increased and stomach residue liquids were at a tolerable level in all patients fed NLF and an HCD. These results indicated that children can tolerate the stress of surgery when they are fed until 2 h before surgery, because there was no difference regarding stomach residue and metabolic changes among patients that underwent surgery after fasting for short and long periods.

Applications

The study results suggest that there is no need for more than 2 h of fasting before inguinoscrotal region surgery in preventing the risk of aspiration of stomach contents during anesthesia.

Terminology

Glucose infusions minimize the endocrine stress response. Prealbumin (transthyretin) level is used as an indicator of protein status because of its relatively short half-life, high tryptophan content, high proportion of essential to nonessential amino acids, and small pool size. Cortisol preserves the completeness of the cell membrane, inhibits increased capillary permeability, and has an anti-inflammatory effect.

Peer review

This is an interesting paper, well-written and well-documented. The analysis of data has been done very carefully and the results are convincing.

Abstract

AIM: To evaluate the aspartate aminotransferase (AST) to platelet ratio index (APRI) as a predictive factor of early viral response in chronic hepatitis C naive patients.

METHODS: We performed an ambispective case-control study. We enrolled chronic hepatitis C naive patients who were evaluated to start therapy with PEGylated interferon α -2b (1.5 μ g/kg per week) and ribavirin (> 75 kg: 1200 mg and < 75 kg: 1000 mg). Patients were allocated into two groups, group 1: Hepatitis C patients with early viral response (EVR), group 2: Patients without EVR. Odds ratio (OR) and 95% confidence interval (CI) were calculated to assess the relationship between each risk factor and the EVR in both groups.

RESULTS: During the study, 80 patients were analyzed, 45 retrospectively and 35 prospectively. The mean \pm SD age of our subjects was 42.9 ± 12

years; weight 70 kg (± 11.19), AST 64.6 IU/mL (± 48.74), alanine aminotransferase (ALT) 76.3 IU/mL (± 63.08) and platelets 209 000 mill/mm³ ($\pm 84 429$). Fifty-five (68.8%) were genotype 1 and 25 (31.3%) were genotype 2 or 3; the mean hepatitis C virus RNA viral load was 2269 061 IU/mL ($\pm 7220 266$). In the univariate analysis, APRI was not associated with EVR [OR 0.61 (95% CI 0.229-1.655, $P = 0.33$)], and the absence of EVR was only associated with genotype 1 [OR 0.28 (95% CI 0.08-0.94, $P = 0.034$)]. After adjustment in a logistic regression model, genotype 1 remains significant.

CONCLUSION: APRI was not a predictor of EVR in chronic hepatitis C; Genotype 1 was the only predictive factor associated with the absence of EVR in our patients.

APRI as a predictor of early viral response in chronic hepatitis C patients. *World J Gastroenterol* 2009; 15(39): 4923-4927 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4923.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4923>

INTRODUCTION

According with the World Health Organization, 123 million individuals are infected with hepatitis C virus (HCV) worldwide, representing a prevalence of 2%^[1]. HCV can result in progressive hepatic injury and fibrosis, culminating in cirrhosis and end-stage liver disease. Chronic hepatitis C is a major indication for liver transplantation and increases the incidence of hepatocellular carcinoma^[2]. PEG-interferon and ribavirin

therapy during 24 to 48 wk leads to a sustained viral response (SVR, a sustained loss of serum HCV RNA)^[3].

There are factors identified as predictors of SVR among patients who received PEG-interferon and ribavirin, including HCV genotype other than 1, viral load less than 600 000 IU/mL, age of 40 years or less, and body weight of 75 kg or less. Sixty five percent of patients with early viral response (EVR) subsequently have an SVR^[4,5]. In addition, the absence of bridging fibrosis/cirrhosis has been significantly associated with SVR^[6,7]. Infection with genotype 2 or 3, low viral load, and absence of advanced hepatic fibrosis have consistently been identified as independent predictors of SVR^[8].

Percutaneous liver biopsy has been the gold standard for grading and staging liver disease; recently however, non-invasive methods have been developed to determine hepatic fibrosis, such as transient elastography, fibrotest, and the aspartate aminotransferase (AST) to platelet ratio index (APRI)^[9-11]. APRI is one of several markers that have been proposed to measure liver fibrosis. It is an inexpensive widely available tool^[11] that can predict accurately mild fibrosis in patients with a value < 0.42 and those with a value > 1.2 are diagnosed a significant grade of fibrosis. APRI establishes a 90% negative predictive value for the absence of fibrosis and a 91% of positive predictive value for its presence^[12-14]. Previous studies have not explored the usefulness of noninvasive tests to assess liver fibrosis for the prediction of viral response in hepatitis C naive patients. The purpose of this study was to evaluate APRI as predictive factor of EVR in hepatitis C chronic naive patients.

MATERIALS AND METHODS

Study design

We performed an ambispective case-control study with enrollment of APRI as a predictor of EVR in chronic hepatitis C naive patients prospectively from July 2006 to February 2008. We also reviewed retrospectively medical records of chronic hepatitis C naive patients from January 2004 to June 2006 who were evaluated to start therapy with PEG-interferon α -2b (1.5 μ g/kg per week) and ribavirin (> 75 kg: 1200 mg and < 75 kg: 1000 mg) at Hospital de Infectología "La Raza" National Medical Center at Mexico City. After the subjects were treated for 12 wk, they were allocated into two groups: patients with EVR and patients without EVR.

Study patients

Patients were eligible for the study if they were between the ages of 18 and 75 years old, had chronic HCV infection, had no history of treatment of HCV infection and had HCV RNA positive serum (at least > 50 IU/mL) according to a Real Time RT-PCR (Cobas Amplicor HCV v2.0, Roche Molecular Systems), serum aminotransferase levels and platelets measures. Patients were excluded if they had poorly controlled psychiatric

disease, a solid organ transplant, an autoimmune condition, thyroid disease, a hemoglobin level of 12 g/dL or lower, a neutrophils count of 1500 per cubic millimeter or lower, a platelet count of 75 000 per cubic millimeter or lower, drug abuse within the previous 12 mo, or alcohol abuse within the previous 6 mo, and an HBV or HIV coinfection.

The study was conducted in conformance with the principles of the Declaration of Helsinki. The institutional review board of the hospital approved the protocol and consent forms. All participants in the prospective way provided written informed consent.

Clinical assessments

Medical history was recorded for all patients (general attributes, medical problems, and medications), physical exam (height and weight), and laboratory results (blood cell count, liver function test, HCV RNA, and viral genotype).

We calculated the APRI using the following formula: $APRI = \frac{AST \text{ levels (} \times \text{ULN)}}{\text{platelets count (} 10^3/\text{L)}} \times 100$, where ULN means the upper limit of normal.

Fibrosis was established if the APRI was ≥ 1.2 . The primary efficacy end point was EVR, defined as ≥ 2 log reduction of the HCV RNA level compared to the baseline HCV RNA level (partial EVR) or HCV RNA negative at treatment week 12 (complete EVR). To evaluate APRI as a predictor of EVR, we stratified between genotype 1 and genotype other than 1 (genotypes 2 or 3).

Statistical analysis

Statistical analysis was performed with SPSS for Windows (version 12.0; SPSS Inc., Chicago, Ill). Categorical variables were compared using the Pearson's χ^2 or Fisher's exact test. Odds ratio (OR) and 95% confidence interval (CI) were calculated to assess the relationship between each risk factor. To adjust for the effects of potential confounders, we used logistic regression models. $P \leq 0.05$ were considered significant.

RESULTS

Patients

During the study, 84 patients were assigned to treatment; 80 patients completed the first 12 wk of therapy, three patients withdrew because of adverse events related to PEG-interferon, and one patient was lost during this period. Forty-five (56%) were evaluated retrospectively and 35 (34%) prospectively. Forty-one (51%) were female and 39 (49%) were male. The mean (± SD) age of our subjects was 42.9 ± 12 years. Fifty-five (68.8%) had genotype 1 and 25 (31.3%) had genotype 2 or 3 (Tables 1 and 2).

Virologic response and APRI findings

Analysis revealed EVR in 54 (67.5%) patients; 40 of them reached a complete EVR and 14 showed a partial EVR.

The APRI was calculated in all patients; 25 (31%) patients were ≥ 1.2; the mean ± SD APRI was 1.61 ± 0.090.

Independent factors associated with EVR

To identify predictors of EVR, in an univariate analysis, we observed the following: sex (OR 1.079, 95% CI 0.797-1.491, *P* = 0.624), age > 40 years (OR 1.57, 95% CI 0.609-4.090, *P* = 0.346), body weight > 75 kg (OR 1.29, 95% CI 0.491-3.437, *P* = 0.598), viral load > 600 000 IU/mL (OR 0.944, 95% CI 0.352-2.533, *P* = 0.910), genotype 1 *vs* genotype other than 1 (genotype 2 or 3) (OR 0.286, 95% CI 0.086-0.834, *P* = 0.034) and

APRI > 1.2	0.469	0.151-1.457	0.190

Logistic regression model.

APRI > 1.2 (OR 0.615, 95% CI 0.229-1.655, *P* = 0.334), (Table 3). Final multiple logistic-regression model, including the following factors, was entered in the final stepwise regression analysis: sex, age (< 40 years *vs* > 40 years), body weight (< 75 kg *vs* > 75 kg), pretreatment viral load (< 600 000 copies/mL *vs* > 600 000 IU/mL), pretreatment alanine aminotransferase quotient (> 3 *vs* < 3), pretreatment APRI score (< 1.2 *vs* > 1.2), and HCV genotype (1 *vs* non-1). Only one factor increased the odds of achieving an EVR independently and significantly: HCV genotype other than 1 (OR 0.304, 95% CI 0.087-0.946; *P* = 0.041, Table 4).

Among patients with genotype 1, APRI score (< 1.2 *vs* > 1.2) was evaluated and showed an OR of 0.65 (95% CI 0.20-2.09, *P* = 0.475). For patients with genotype other than 1 we found an OR of 0.40 (95% CI 0.045-3.57, *P* = 0.575).

DISCUSSION

Our results suggested that the APRI is not a predictor of EVR. We found no association when APRI was more than 1.2. In addition, when we stratified between genotype 1 and genotype other than 1 to evaluate APRI as a predictor of EVR, we found no association. Nevertheless, we found one predictor of absence of EVR (genotype 1 *vs* genotype other than 1) in patients who were treated with PEG-interferon α-2b and ribavirin.

A reasonable interpretation of these results is that, despite the possibility that biopsy could predict treatment response in HCV infected patients; an indirect measure of fibrosis with APRI is not an option to pre-

dict viral response.

We also found that in this Mexican population sex, age, weight, HCV viral load, and aminotransferase serum levels were not associated with viral response. One possible explanation for our results is that we adjusted ribavirin and PEG-interferon α -2b doses according to patient's weight.

Our findings are comparable with previous reports that evaluate predictors of sustained viral response.

Though our results might seem to differ with those of Fried *et al*^[4], who found age and weight as predictors of viral response, most of the patients in their study were Caucasians, and race has been shown to be a factor in the response to therapy for hepatitis C virus infection^[4,15].

In their study, Akuta and colleagues concluded that hepatocytes steatosis is a factor associated with virological non-response, however they measured liver steatosis by obtaining liver biopsy percutaneously, and did not use a noninvasive assessment of liver fibrosis^[16].

Our results are consistent with those of Nagaki *et al*^[17], who found no association among age, weight, and HCV viral load with sustained viral response in patients with chronic hepatitis C genotype 1b. Finally, similar to all prospective treatment studies, we found genotype as the strongest predictor of response^[5,18-20].

This was an ambispective study, and it has several limitations, more than half of patients were analyzed in a retrospectively way. In addition, rapid virological response was not measured in this group of patients, which now is a very important predictor of sustained viral response. In addition, these results could have been affected by the small sample size.

Another limitation in our study is that some of the patients are still undergoing treatment, for this reason, we still do not have the results for sustained viral response, which is the goal of treatment in patients with HCV infection. Thus, although EVR is a predictor of SVR in approximately 60%-80%, SVR is necessary to gain full results.

Previous studies have not explored the utility of non-invasive tests to assess liver fibrosis for the prediction of viral response in hepatitis C naive patients.

Despite the limitation of our study, we believe our results show that APRI is not a predictor of early viral response in HCV naive patients.

It is necessary to perform a study including sustained viral response as the final goal of treatment. In addition, other indirect liver damage measures (fibrotest or transient elastography) should be used to improve recognition, diagnosis, and management. Finally, future prospective research to study noninvasive assessment of liver fibrosis to predict sustained viral response should be developed.

biopsy has been significantly associated with sustained viral response (SVR). Despite its widespread use, performing a liver biopsy is not without due cautions and concern for physicians and patients alike. Significant complications, defined as requiring hospital admission or prolonged hospital stay, occurs in 1% to 5% of patients. AST to platelet ratio index (APRI) is an easy and non-invasive method to evaluate hepatic fibrosis. APRI as a predictive factor of early viral response in hepatitis C chronic naive patients has not been evaluated.

Research frontiers

The APRI is one of several markers that have been proposed to measure liver fibrosis; it is an inexpensive widely available tool; however it has not been used as a predictive factor in chronic hepatitis C. Further studies across more diverse cohorts of liver disease will be necessary, and further refinement will likely enhance accuracy. In this study, the authors demonstrated that APRI is not a predictive factor for early viral response (EVR) in patients with chronic hepatitis C.

Innovations and breakthroughs

Recent studies have shown the importance of this test to decrease the number of liver biopsies, particularly because patients with an APRI of less than 0.40 have very little chance of having significant fibrosis. This is the first study to evaluate the APRI as a predictive factor of early viral response in patients with chronic hepatitis C.

Applications

APRI is a good estimator of hepatic fibrosis. It could be used to decrease the number of liver biopsies, however it is not useful to predict EVR in chronic hepatitis C patients.

Terminology

The APRI is one of several markers that have been proposed to measure liver fibrosis; this index accurately predicts mild fibrosis in patients with a value < 0.42 and those with a value > 1.2 are diagnosed as a significant grade of fibrosis. APRI establishes a 90% negative predictive value for the absence of fibrosis and a 91% of positive predictive value for its presence. We calculated APRI with the following formula: $APRI = \frac{AST \text{ levels } (\times ULN)}{\text{platelets counts } (10^3/L)} \times 100$.

Peer review

It is necessary to investigate the utility of APRI as a predictor of sustained viral response.

Abstract

AIM: To compare the effects of *Helicobacter pylori* (*H. pylori*) infection on gastropathy between Indonesian and Japanese patients.

METHODS: Biopsy specimens were obtained during upper gastrointestinal endoscopy from 167 subjects (125 Indonesians and 42 Japanese) with uninvestigated symptoms of dyspepsia. The specimens were analyzed for the presence of *H. pylori* using urease analysis, histopathology, and cell culture. The grade and activity of gastritis was assessed using the updated Sydney system.

RESULTS: The percentages of Indonesian and Japanese patients who were *H. pylori*-positive at the antrum or body of the stomach were similar (68% and 59.5%, respectively; $P = 0.316$). Of those who were *H. pylori*-positive, more Japanese patients than Indonesian patients had high levels of polymorphonuclear cells ($P = 0.001$), mononuclear cells ($P = 0.013$), glandular atrophy ($P = 0.000$), and intestinal metaplasia ($P = 0.011$) in both the antrum and body of the stomach.

CONCLUSION: The grade of gastritis and prevalence of mucosal atrophy and intestinal metaplasia were higher in Japanese patients. The difference between Indonesian and Japanese patients was significant.

INTRODUCTION

There is abundant evidence of an association between *Helicobacter pylori* (*H. pylori*) chronic infection and gastric cancer^[1-5]. Some population-based studies show that high levels of *H. pylori* infection are not necessarily accompanied by high mortality from gastric cancer, the so-called African^[6-8] and Asian enigmas^[9].

Indonesia and Japan have a similar prevalence of *H. pylori* infection, but the incidence of gastric cancer is much higher in Japan than Indonesia^[10]. We conducted this cross-sectional study to compare the effects of *H. pylori* infection on gastropathy between Indonesian and Japanese patients.

We consider the old concept of a cascade of mucosal changes that develop from acute/chronic gastritis to atrophic gastritis with intestinal metaplasia, and finally to dysplasia and gastric cancer, as proposed by P. Correa before the discovery of *H. pylori* in the stomach^[11]. This is relevant because a difference in the pattern of *H. pylori*-associated gastritis may explain the difference in the incidence of gastric cancer between Indonesia and Japan.

MATERIALS AND METHODS

Selection of patients

Patients were eligible to participate in the study if they were aged 18 years or older and had experienced uninvestigated symptoms of dyspepsia for at least 3 mo before enrollment. We defined dyspepsia as epigastric pain or discomfort perceived to originate in

Table 1 Baseline characteristics of patients *n* (%)

Characteristic	Indonesian (<i>n</i> = 125)	Japanese (<i>n</i> = 42)	Total (<i>n</i> = 167)	<i>P</i>
Age (yr)	50.30 (18-82)	57 (20-79)		0.060
Sex				
Male	58 (46.4)	25 (59.5)	83 (49.7)	0.141
Female	67 (53.6)	17 (40.5)	84 (50.3)	
<i>Helicobacter pylori</i> (<i>H pylori</i>)-positive				
Antrum and/or body	85 (68)	25 (59.5)	110 (65.9)	0.316
Antrum	85 (68)	22 (52.4)	107 (64.1)	0.068
Body	5 (4)	20 (47.6)	25 (15)	0.000

the upper gastrointestinal tract, including heartburn, acid regurgitation, excessive belching, abdominal bloating, nausea, a perception of abnormal or slow digestion, and early satiety^[12,13]. Patients who experienced only heartburn and/or regurgitation were considered to have gastroesophageal reflux disease and were excluded. We also excluded patients who underwent upper gastrointestinal endoscopy and/or barium radiography less than 6 mo before the study or underwent these procedures on more than two separate occasions within the preceding 10 years, and patients who received eradication therapy for *H pylori* less than 6 mo before the study. We excluded patients who had undergone gastric surgery and those who had a documented history of ulcer disease, esophagitis, irritable bowel syndrome, or clinically significant abnormal results on laboratory analyses. None of the patients who enrolled in the study received treatment with nonsteroidal anti-inflammatory drugs, aspirin (> 325 mg/d), antibiotics, H2-receptor antagonists, proton pump inhibitors, misoprostol, sucralfate, prokinetic agents, or a bismuth compound within 14 d of the study.

From 1998 to 1999, 42 Japanese patients at Yamanashi Medical University Hospital, Koufu and 125 Indonesian patients at Metropolitan Medical Centre Hospital, Jakarta were diagnosed as having dyspepsia and were consecutively enrolled in the study. Informed consents were obtained from all of the patients. This study was reviewed and approved by the ethics committee of Faculty of Medicine University of Indonesia, who approved the protocol.

Intervention and measurements

All patients underwent an upper gastrointestinal endoscopy procedure to identify lesions and to obtain biopsy specimens from the antrum and body of the stomach. The grade and activity of gastritis was assessed using the updated Sydney system^[14]. The presence of *H pylori* in Indonesian patients was determined using histopathology, culture, and rapid urease test (RUT)^[15,16]. The presence of *H pylori* in Japanese patients was determined using urease analysis, histopathology, cell culture, and RUT.

Statistical analysis

SPSS for Windows version 14 software (SPSS Inc., Chicago, Illinois) was used to analyze data. The prevalence of *H pylori*, polymorphonuclear cells, mononuclear cells, glandular atrophy, and intestinal metaplasia in the antrum

Table 2 Comparison of the effects of *H pylori* infection on gastropathy in Indonesian and Japanese patients who were positive for *H pylori* at the antrum and/or body of the stomach *n* (%)

Characteristic	None or mild	Moderate or severe	<i>P</i>
Polymorphonuclear cells			
Indonesian (<i>n</i> = 85)	71 (83.53)	14 (16.47)	0.001
Japanese (<i>n</i> = 25)	12 (48)	13 (52)	
Mononuclear cells			
Indonesian (<i>n</i> = 85)	31 (36.47)	54 (63.53)	0.013
Japanese (<i>n</i> = 25)	2 (8)	23 (92)	
Glandular atrophy			
Indonesian (<i>n</i> = 85)	84 (98.82)	1 (1.18)	0.000
Japanese (<i>n</i> = 25)	16 (64)	9 (36)

Indonesian (<i>n</i> = 85)	85 (100)	0 (0)	0.011
Japanese (<i>n</i> = 25)	22 (88)	3 (12)	

and body of the stomach was analyzed using the χ^2 test or Fisher's exact test, as appropriate.

RESULTS

Baseline characteristics of patients

We studied 125 Indonesian patients and 42 Japanese patients (males, 49.7%; females, 50.3%), of whom 110 (65.9%) tested positive for *H pylori* at the antrum and/or body of the stomach. The percentages of Indonesian and Japanese patients who were *H pylori*-positive at the antrum or body of the stomach were similar (68% and 59.5%, respectively; *P* = 0.316). The percentage of Japanese patients (52.4%) positive for *H pylori* at the antrum of the stomach was similar to that of Indonesian patients (68%) (*P* = 0.068) but more Japanese patients were positive for *H pylori* at the body of the stomach (47.6%) than Indonesian patients (4%) (*P* < 0.000) (Table 1).

Comparison of the effects of *H pylori* infection on gastropathy in Indonesian and Japanese patients who were positive for *H pylori* at the antrum and/or body of the stomach

Of patients who were *H pylori*-positive at the antrum and/or body of the stomach, more Japanese patients had high numbers of polymorphonuclear cells (*P* = 0.001) and mononuclear cells (*P* = 0.013), glandular atrophy (*P* = 0.000), and intestinal metaplasia (*P* = 0.011) than Indonesian patients (Table 2).

DISCUSSION

The development of gastric cancer is a long process and caused by many factors. Although *H pylori* is an important risk factor for gastric cancer, it is not the only factor that is involved in the etiology of gastric cancer. The association between gastric cancer and *H pylori* infection should be considered from the perspective of the multi-agent compound etiological theory^[17]. The *H pylori* infection rate is very high both in Indonesian and Japanese populations. The reason why Indonesians with *H pylori* infection do not develop gastric cancer to

the same extent as their Japanese counterparts remains unknown.

The limitation of this study was that samples were obtained from a hospital population. Consequently, the results may not represent the community. However, this is the first study in which the effects of *H pylori* infection on gastropathy between Indonesian and Japanese patients were compared.

This study showed that the grade and activity of gastritis was higher among Japanese *H pylori*-positive patients. The prevalence of mucosal atrophy was also greater in Japanese *H pylori*-positive patients than in Indonesians. In addition, more Japanese *H pylori*-positive patients had severe atrophic gastritis and intestinal metaplasia than Indonesians. The difference between those two groups was significant statistically.

Japanese *H pylori*-positive patients had higher grade and activity of gastritis than Indonesian *H pylori*-positive patients. This finding was consistent with the study by Kang *et al*^[18] which observed differences in gastritis among Chinese, Malays, and Indians. This indicates that risk factors other than *H pylori*, such as genetic factors, are associated with the development of gastric cancer in Japanese patients. Moreover, atrophic gastritis in Japanese subjects originating from autoimmune gastritis may explain the high grade and activity of gastritis in these patients.

Another important risk factor is a dietary factor because this affects the rate of development of gastric cancer^[19,20]. Japanese dietary habits such as high consumption of nitrite-rich, salty pickled vegetables and dried fish, and alcohol, are associated with atrophic gastritis and gastric cancer^[21-24]. A low consumption of fresh fruit and raw vegetables may increase this risk. Such dietary habits may act in synergy with *H pylori* in causing gastric cancer^[25]. Migrants to countries with low gastric cancer rates have a diminished risk of gastric cancer^[26].

In conclusion, although the prevalence of *H pylori* infection was similar in Indonesian and Japanese patients, the grade and activity of gastritis was higher in Japanese *H pylori*-positive patients. Moreover, the prevalence of mucosal atrophy and intestinal metaplasia was also higher in Japanese group. The difference between Indonesian and Japanese *H pylori*-positive patients was found to be significant. That difference may be responsible for the disparity in the incidence of gastric cancer in Indonesia and Japan. Further studies will be needed.

COMMENTS

Background

Although *Helicobacter pylori* (*H pylori*) has been classified as a class I (or definite) carcinogen by WHO, the controversy as to why only a minority of infected patients develop distal adenocarcinoma still remains. Moreover, in Asian countries such as Indonesia, Japan, China, and Thailand, where the *H pylori* infection rates are similar, there is a significant difference regarding the outcome of gastric cancer. In the present study, the authors evaluated the transformation of gastric mucosa that is induced by *H pylori* infection prior to gastric cancer. The authors also compared the transformation between Indonesian and Japanese patients, the two countries that represent an "Asian paradox".

Innovations and breakthroughs

By means of this study, the authors revealed that there was a significant

difference in the grade and activity of gastritis and the prevalence of mucosal atrophy and intestinal metaplasia between Indonesian and Japanese *H pylori*-positive patients. These findings may be responsible for the difference in the incidence of gastric cancer in Indonesia and Japan.

Applications

This study indicates that there is a difference in host response between Indonesian and Japanese patients regarding *H pylori* infection.

Peer review

The study is a good idea. Patients were enrolled consecutively with no selection bias. There was no difference in patients' clinical features. The endoscopic features were assessed using OMED Database of Digestive Endoscopy. The histological differences were assessed using the Updated Sydney System by two observers with good interobserver degree of agreement.

group, anti-HAV seroprevalence was 32.3% in subjects < 10 years and 51.7% in those aged 11-20 years. Until now Bangladesh has been deemed to have high endemicity for HAV.

CONCLUSION: The transition from high to intermediate HAV endemicity may be underway; high SES adolescents and adults remain particularly at risk of symptomatic illness. Preventive measures need consideration.

Abstract

AIM: To elucidate the age-distribution of anti-hepatitis A virus (HAV) seroprevalence across different socio-economic status (SES) categories in Bangladesh which, despite scarce data, is generally deemed to have high endemicity.

METHODS: Blood samples of 818 subjects from a stratified sample of schools and hospitals, comprising different age categories and SES were collected. They were assayed for total anti-HAV antibodies. Social and medical history data were obtained using a questionnaire.

RESULTS: Overall anti-HAV seroprevalence was 69.6%, increasing with age from 1-5 years (40.4%) to > 30 years (98.4%). Seroprevalence was lowest (49.8%) in the high SES group and highest (96.5%) in the rural lower-middle SES group. Among subjects aged 6-20 years, anti-HAV seroprevalence was lowest in urban private school children (43.0%), followed by urban government school children (76.2%) and rural school children (96.5%) ($P < 0.01$). Within the high SES

INTRODUCTION

Hepatitis A virus (HAV) is the most common cause of acute viral hepatitis worldwide^[1]. Globally it is responsible for at least 1.4 million new infections each year^[2]. Although infection with HAV is often mild and asymptomatic in young children, the disease can be severe in adults^[3]. The distribution and prevalence of HAV infection is very closely related to local hygiene and sanitation conditions, and consequently may vary across countries depending on the socioeconomic status (SES) of the population^[4]. The highest incidence of hepatitis A infection has previously been reported in developing countries of Africa, Central and South America and South-East Asia^[5,6]. In these countries, virtually all children experience asymptomatic infection with hepatitis A before the age of 5 years. As the majority of children in these countries experience early exposure to infection,

the symptomatic disease that occurs in a small minority may still pose a significant disease burden^[7-9].

Ironically, with improving socioeconomic conditions, these countries are undergoing a transition phase in which the virus is still prevalent in the population but the improving hygiene and socioeconomic conditions delay the average age of infection^[10]. From a public health perspective, it is important to identify such epidemiological shifts, because the greater severity of the disease in older age groups can lead to an increased community disease burden^[11].

Bangladesh is considered to be a country where hepatitis A infection is hyperendemic with 100% of children ≤ 6 years of age exposed and immune to HAV^[3,12]. However, rapid improvements in hygiene and socioeconomic conditions, specifically in sections of the urban population, are taking place. This indicates a possible changing trend of hepatitis A epidemiology in Bangladesh. Neighbouring developing countries, such as India, Pakistan, Sri Lanka and Thailand, have passed, or are currently passing through a similar transition^[13-16]. Although there is some data indicating that 90% of the patients admitted with acute hepatitis are school children^[17], there is no data on seroprevalence of HAV in Bangladesh, which may be important in guiding the development of HAV prevention strategies.

This prospective, cross-sectional study aimed to determine the seroprevalence of HAV antibodies in a range of age groups, with different SES, living in urban and rural areas of Bangladesh.

MATERIALS AND METHODS

Study design and subjects

This hospital and school-based, cross-sectional seroprevalence study was conducted between October 2005 and December 2006 in Bangladesh in a number of sites selected at convenience. Healthy subjects aged > 1 year from different socioeconomic and educational backgrounds were enrolled in the study. To avoid information bias that might have arisen from the use of self-reported family income, we stratified according to age group and SES by choosing study sites where the study was feasible but which varied in terms of type of medical facility, type of school and residential locality, thereby allowing for recruitment of subjects from distinct SES. This methodology of using proxy markers for SES has been used in the past in Bangladesh^[18].

In the high SES group, subjects were recruited from the Popular Diagnostic Centre (a more costly private diagnostic centre in Dhaka city) and expensive urban private schools, with high tuition fees. In the lower SES group, subjects were recruited from Dhaka Shishu Hospital, a hospital which provides free treatment. Subjects in the lower-middle SES group were recruited from an urban government school, and subjects in the rural lower-middle SES groups were recruited from rural schools. This additional distinction between urban government and rural schools within the lower-middle SES group was deemed important because water supply

and sanitation in rural areas are often not of the same standard as in urban areas.

For analysis, enrolled subjects were stratified into five age groups: 1-5 years, 6-10 years, 11-20 years, 21-30 years and > 30 years. Different centres enrolled subjects of different age groups. Subjects between the ages of 1 and 5 years and > 20 years were enrolled from Dhaka Shishu Hospital and the Popular Diagnostic Centre. Subjects between the ages of 6 and 20 years were enrolled from urban private schools, urban government schools and rural schools.

Ethics

The study was conducted according to Good Clinical Practice of the International Council of Harmonization, and conforms to provisions of the Declaration of Helsinki. The research protocol was approved by the Ethical Review Committee of Dhaka Shishu Hospital.

Written informed consent was obtained from the subjects or (in the case of minors) from their parents/guardians, prior to conducting any study-specific procedure.

Laboratory assays

Two to three milliliters of blood was collected from each subject enrolled in the study. All the blood samples were assayed for total antibodies against HAV (anti-HAV IgG and IgM) at the Department of Microbiology of Dhaka Shishu Hospital using a commercial anti-HAV microparticle enzyme immunoassay (Abbott Laboratories, Illinois, USA). A sample optical density of 1.000 was considered as the assay cut-off value.

Data collection

All enrolled subjects were medically examined and checked for pre-defined inclusion/exclusion criteria. Subjects were excluded from participating in the study if they were suffering from hepatitis or if they had previously been vaccinated against hepatitis A. Information on age, height, weight, vaccination history, medical history, gender and various socioeconomic factors were collected on case report forms specifically designed for this study.

Sample size determination

The sample size was computed using nQuery by considering confidence interval (CI) for proportions using normal approximation with 95% CI level. Based on the various expected prevalences (30.0% for the age group 1-5 years, 31.0% for the age group 6-10 years, 64.0% for the age group 11-20 years, 89.0% for the age group 21-30 years and 90.0% for the age group > 30 years) of anti-HAV antibodies with the error margin at 0.1 (10.0%) among different age groups and SES, it was planned to enrol a total of 818 subjects in this study. The estimates considered for computing the sample size were published previously^[13,19]. The number of subjects planned for each stratum (combination of SES by age groups) is shown in Table 1.

Table 1 Group definition based on age and socioeconomic status classification

Socioeconomic status	Definition	Age group (yr)					Overall (n)

	Male	99 (65.6)	97 (64.2)	196 (64.9)

n: Total number of subjects.

Statistical analysis

All analyses were performed on subjects whose demographic and serological data were available and who abided with the protocol-defined procedures. Fisher's exact test was used to compare groups in the anti-HAV results between the SES groups for each age group. The exact 95% CI for the proportions of subjects seropositive for anti-HAV antibodies was used. All statistical analyses were performed using Statistical and Analysis Software version 8.2.

RESULTS

Study population

A total of 818 subjects were enrolled from different sites. Anti-HAV antibody status was studied in all 818 subjects. There were 161 (19.7%) subjects in the age group 1-5 years (mean: 2.6 ± 1.2 years) from the Popular Diagnostic Centre and Dhaka Shishu Hospital, 244 (29.8%) in the age group 6-10 years (mean: 7.7 ± 1.4 years) from urban private schools, urban government schools and rural schools, 272 (33.3%) subjects in the age group 11-20 years (mean: 13.7 ± 2.3 years) from

Figure 1 Overall seropositivity of anti-HAV antibodies by age group (n = 818). n: Total number of subjects with results. Percentage of seropositivity (anti-HAV antibodies) with 95% CI was calculated. The assay cut-off was sample optical density of 1.00.

urban private schools, urban government schools and rural schools, 77 (9.4%) in the age group 21-30 years (mean: 24.0 ± 2.7 years) from the Popular Diagnostic Centre and 64 (7.8%) subjects in the age group > 30 years (mean: 43.0 ± 9.7 years) (Table 1).

There were more males than females in the age groups 1-5 years, 21-30 years and > 30 years and more females than males in the age group 11-20 years. The male to female proportions were similar in the 6-10 years age group (Tables 2 and 3).

HAV seroprevalence

Overall anti-HAV seropositivity was 69.6% (569/818) with the 95% CI (66.28-72.70). Anti-HAV seropositivity increased considerably from lower age groups to older age groups, demonstrating a consistent trend (Figure 1).

Anti-HAV seropositivity was highest at 96.5% (166/172) with 95% CI (92.56-98.71) in the rural lower-middle group and lowest at 49.8% (161/323) in the high SES group.

Age groups and SES

Seropositivity for anti-HAV increased with age independently of the SES of subjects. Among the children aged 1-5 years, the seroprevalence was significantly high (50.0%) in the low SES group than in the high (31.0%) SES group ($P = 0.016$). Similarly, 64.0% and 88.0% of

Figure 2 Percentage of anti-HAV seropositivity assessed by age groups 1-5, 6-10, 11-20, 21-30 and > 30 years and SES (*n* = 818). 1: *n* = 81; 2: *n* = 80; 3: *n* = 83; 4: *n* = 83; 5: *n* = 78; 6: *n* = 89; 7: *n* = 89; 8: *n* = 94; 9: *n* = 38; 10: *n* = 39; 11: *n* = 32; 12: *n* = 32.

subjects were positive for HAV antibody in the urban lower-middle class group compared to 34.0% and 52.0% in the urban high SES group aged 6-10 years and 11-20 years, respectively. There was also a significant difference in the rate of seropositivity in the urban lower-middle class group (64.0% and 88.0%), compared with 93.0% and 99.0% of the rural population of the same SES in the 6-10 years and 11-20 years age groups ($P < 0.01$), respectively (Figure 2).

In subjects aged between 6-20 years, the anti-HAV seropositivity rates were lowest in the high SES group (49.8%), progressively increasing in the lower-middle group followed by the rural lower-middle group (Figure 2). A statistically significant difference was observed in anti-HAV seropositivity between the high and the rural lower-middle SES groups among both the young (6-10 years) and the adolescent age groups (11-20 years) ($P < 0.01$). A statistically significant difference in anti-HAV seropositivity was also observed between the urban private school (high SES group) and urban government schools (lower-middle SES group) among the age groups 6-20 years ($P < 0.01$).

A statistically significant difference in anti-HAV seropositivity was observed between the high and low SES groups for the age groups 1-5 years ($P = 0.016$) and 21-30 years (Figure 2).

DISCUSSION

Three epidemiological patterns of HAV endemicity are commonly observed worldwide: low, intermediate and high. Each pattern is different with respect to seroprevalence in different age groups, transmission mode and disease burden. Most developing countries have high endemicity, in contrast to the generally low seroprevalence found in the developed world. Furthermore, contrasting endemicity may exist in the same country, based on regional or local differences in SES, water supply and hygiene.

This study demonstrated a clear trend in anti-HAV seroconversion with age, where seropositivity progressively increased from 40.4% in the 1-5 years age group to over 98.0% in the > 30 years age group. As expected, there was also an inverse correlation between increased anti-HAV seropositivity and low SES; the exception was the low SES group which had lower seropositivity than the urban and rural lower-middle socioeconomic groups, a finding which can be explained partly by chance and partly by the fact that the majority of the subjects in this group were aged 1-5 years.

The very low anti-HAV seroprevalence of about 30.0% observed among children below the age of 10 years

in the high SES group is not surprising given that these children have grown up in environments where they are likely to have good access to clean water and sanitation. However, a similar pattern was observed in the low socioeconomic group, where almost half the population in the 1-5 years age group and 36.0% of the population in the 6-10 years age group continued to be susceptible to HAV infections. This finding reflects the effects of improvements in water supply and sanitation that have accompanied economic progress, with benefits for the general population in Bangladesh. This is in marked contrast to previous studies which have shown 100% seropositivity in children aged 6 years or less^[3,12].

Amid the very positive improvements in child health that have accompanied economic progress in Bangladesh, nearly 60.0% of children in the 1-5 years age group enrolled in our study and over one third of children aged 6-10 years remain at risk of developing HAV infection, with the risk of symptomatic disease and complications increasing with age. Nevertheless, our study suggests that rural Bangladesh, where the majority of the population resides, can still be considered highly endemic for HAV.

In the high SES group (especially in urban areas), anti-HAV seroprevalence remained low among adolescents aged 11-20 years (51.7%) and relatively low (when compared to rates traditionally observed in hyperendemic countries) among adults aged 21-30 years (81.6%). In other words, in the high SES group, one in two adolescents and one in five adults remains at risk of hepatitis A infection.

During the transition from high (anti-HAV seroprevalence > 90% by age 5 years) to low endemicity, populations undergo a phase of intermediate endemicity for hepatitis A, when more people are susceptible to HAV infection due to lack of exposure in early childhood and adolescence. Circulating HAV in the community means this group are at risk of symptomatic and potentially clinically severe acute hepatitis^[11,19]. Symptomatic disease could lead to significant illness, prolonged debility and is likely to require time off from studies or work during the active and economically productive years of adolescence and early adulthood.

Only in the population aged > 30 years did we observe a high anti-HAV seroprevalence rate (98.4%), regardless of SES. This was expected and reflects the cohort effect of a population that was exposed to HAV early in life due to the poor water quality and improper sanitation facilities that would have prevailed during their childhood^[11].

A limitation of our design was that the subjects enrolled in the study were from hospital-based and school-based sub-populations. Although not a population-based study, the complete coverage of age and SES made it reasonable to extrapolate these findings to the general population. Our findings that HAV seroprevalence is associated with age and SES are in line with HAV epidemiology documented in developing countries and previously described in the Indian subcontinent. Studies conducted in other countries in the region (India, Pakistan, Thailand, Sri Lanka, Korea, Philippines and Malaysia)^[20,21], have likewise shown higher seroprevalence rates in rural populations when compared to urban populations and

demonstrated strong evidence of epidemiological shifts, especially in the upper socio-economic groups^[14,15,22,23].

The most important mode of hepatitis A control is by improvements in hygiene, sanitation and drinking water supply, which accompany socioeconomic progress. However, the World Health Organization position paper on hepatitis A vaccines states that in countries under the category of intermediate endemicity, childhood vaccination occasionally targeted to specific risk groups may be considered in addition to health education and improved sanitation to contain HAV infections^[24]. Effective hepatitis A vaccination programs have helped to control the disease with proven social and economical benefits. Regional experts have also called for wider use of hepatitis A vaccines^[25]. Vaccines against hepatitis A have been available since 2001 in the Bangladeshi private market, but are not widely used currently and are not a part of the universal expanded programme of immunization in Bangladesh.

In conclusion, although disparities exist in anti-HAV seroprevalence between the upper and lower socioeconomic classes in Bangladesh, in conjunction with previous studies we found some evidence of a possible epidemiological transition taking place, especially among the upper classes. In view of these findings and as suggested by regional experts, the introduction of safe and effective vaccination against hepatitis A (with broader coverage), along with improvements in water supply, sanitation and hygienic conditions in Bangladesh may have the potential to reduce and hopefully prevent the severity of future HAV infection in older children and adolescents, with accompanying public health benefits.

COMMENTS

Background

Hepatitis A virus (HAV) is the most common cause of acute viral hepatitis in children worldwide. Although, HAV infection is often mild and asymptomatic in young children, the disease can be severe in adults. As the distribution and prevalence of HAV infection is closely associated with local hygiene and sanitation conditions, it was important to explore the impact of HAV infection in Bangladesh, which previously was considered hyperendemic. However, rapid improvements in hygiene and socioeconomic conditions, specifically in sections of the urban population have taken place. A research group in Bangladesh has predicted that a probable transition from hyperendemicity to intermediate HAV endemicity may be underway. In the high SES group, particularly adolescents

and adults are particularly at a higher risk of acquiring symptomatic illness, indicating the need for immunization against HAV, especially in this high risk group.

Research frontiers

Bangladesh is considered to be hyperendemic for HAV. However, rapid improvements in hygiene and socioeconomic conditions, specifically in sections of the urban population, are taking place. This indicates a possible changing trend of hepatitis A epidemiology in Bangladesh as has previously been observed in neighbouring countries, such as India, Pakistan, Sri Lanka and Thailand. During this transition from high to low endemicity, populations undergo a phase of intermediate endemicity for hepatitis A when more people are susceptible to HAV infection due to lack of exposure in early childhood and adolescence, despite circulating HAV in the community, and are consequently at risk of symptomatic and potentially clinically severe acute hepatitis. Prior to this study, no data were available on the seroprevalence of HAV in Bangladesh in different age groups and social classes, which are important parameters that guide the development of local HAV prevention strategies.

Innovations and breakthroughs

This is the first study to assess the entire population spectrum of Bangladesh for hepatitis A seroprevalence. The study demonstrates that a possible epidemiological transition is in progress among those of high socioeconomic status (SES). However, more than half of children aged < 10 years and almost half of individuals aged 11-20 years were still at higher risk of symptomatic hepatitis. Surprisingly, there are also some indications that an early epidemiological transition may be occurring in the lower SES groups.

Applications

The study results may help decision making on public health policies and vaccination strategies for the control of hepatitis A in Bangladesh.

Terminology

HAV, HAV seroprevalence, anti-HAV antibodies, Socioeconomic groups, Age groups.

Peer review

The authors described an epidemiological study investigating the anti-HAV seroprevalence of 818 subjects from hospital- and school-based subpopulations in Bangladesh, and found that anti-HAV seroprevalence was correlated with increasing age and inversely correlated with higher SES. They concluded that vaccination against hepatitis A should be considered to reduce the future burden of symptomatic HAV infection in this country. There are few reports on the seroprevalence of anti-HAV in Bangladesh where hepatitis A infection is hyperendemic and hence, this manuscript is worthy of publication.

was comparable to that in ICU patients without pancreatitis by case-control methodology ($P = 0.544$). Multivariate logistic regression analysis identified low $\text{PaO}_2/\text{FiO}_2$ (OR: 1.032, 95% CI: 1.006-1.059, $P = 0.016$) as an independent risk factor for mortality in patients with ventilator-related pancreatitis. The mortality rate in patients with ventilator-related pancreatitis was lower than that in patients with acute pancreatitis-related respiratory failure ($P < 0.001$).

CONCLUSION: We found that low $\text{PaO}_2/\text{FiO}_2$ was an independent clinical parameter predictive of ICU mortality in patients with ventilator-related pancreatitis.

Abstract

AIM: To identify risk factors predictive of intensive care unit (ICU) mortality in patients with ventilator-related pancreatitis. The clinical outcomes of patients with ventilator-related pancreatitis were compared with those of patients with pancreatitis-related respiratory failure as well as controls.

METHODS: One hundred and forty-eight patients with respiratory failure requiring mechanical ventilation and concomitant acute pancreatitis were identified from a prospectively collected dataset of 9108 consecutive patients admitted with respiratory failure over a period of five years. Sixty patients met the criteria for ventilator-related pancreatitis, and 88 (control patients), for pancreatitis-related respiratory failure.

RESULTS: Mortality rate in ventilator-related pancreatitis

INTRODUCTION

Mechanical ventilation is an important method for maintaining gas exchange in patients with respiratory failure until the underlying disorders are corrected. However, it is also associated with numerous organ-system disorders that can significantly affect the outcome of critically ill patients^[1]. Possible mechanisms include injurious ventilatory strategies, high pressure with hypovolemic status, and sympathetic stimulation. Injurious ventilatory strategies may induce the release of proinflammatory cytokines. High intrathoracic pressure with hypovolemic status can cause splanchnic hypoperfusion^[2]. Sympathetic stimulation can promote the release of catecholamines^[3] and result in organ ischemia. All of these mechanisms can result in a systemic inflammatory response and multiple organ dysfunction. Acute pancreatitis may also be induced during mechanical ventilation *via* these mechanisms.

Moreover, ischemia or organ hypoperfusion alone is considered an important common mechanism for the induction of pancreatic injury^[4,5]. Among the several mechanisms suggested to explain how mechanical ventilation can cause acute pancreatitis, splanchnic hypoperfusion appears to be of particular importance^[1].

Acute pancreatitis is an inflammatory process that usually occurs in a previously normal pancreas and is diagnosed mainly by acute abdominal pain associated with a concomitant increase in serum amylase and lipase concentrations^[6,7]. Alcoholism and gallstones are established as the most frequent causes of acute pancreatitis. Other risk factors - drugs, hypertriglyceridemia, hypercalcemia, viral infection, and connective tissue disease - are also common^[8-10]. Many studies have examined the clinical spectrum of lung injury associated with acute pancreatitis. Pulmonary dysfunction ranging from hypoxemia to acute respiratory distress syndrome (ARDS) is one of the most important systemic manifestations of severe acute pancreatitis^[11]. Patients with severe pancreatitis are frequently associated with acute respiratory failure that subsequently develops into ARDS^[12,13]. The development of ARDS is associated with a high mortality and is highly correlated with hypoxemic status^[14].

Acute lung injury and respiratory failure are frequent and potentially fatal complications of acute pancreatitis^[15,16]. Importantly, the institution of positive pressure mechanical ventilation can itself induce acute pancreatitis by exacerbating splanchnic hypoperfusion^[1,17]. Recent studies have reported that elevated serum lipase levels are frequently encountered in critically ill patients, and hypoperfusion and inflammatory processes associated with multiple-organ failure appear to result in pancreatitis. However, the incidence, natural history, and outcomes of ventilator-related pancreatitis (VRP) have not been characterized in humans.

The object of this study was to determine the risk factors predictive of clinical outcomes and intensive care unit (ICU) mortality in patients with VRP. We also compared the outcomes of patients who developed pancreatitis during mechanical ventilation (VRP) in patients admitted with equal physiological scoring severity without pancreatitis and those patients with a primary diagnosis of acute pancreatitis complicated by respiratory failure (PRRF) requiring mechanical ventilation. We sought to determine whether patients with VRP had a poorer prognosis than patients with PRRF.

MATERIALS AND METHODS

Study population and design

Nine thousand one hundred and eight patients with acute respiratory failure admitted to the medical intensive care units (ICUs) at Chang Gung Memorial Hospital (CGMH), a tertiary care hospital in Kaohsiung, were identified from a prospectively collected dataset over a period of five years. This study was approved by our hospital's institutional review board and was also in

compliance with the Helsinki Declaration.

In this study, acute pancreatitis was diagnosed in patients meeting at least two of the following three criteria as previously described^[18]: (1) acute abdominal pain and tenderness in the upper abdomen; (2) elevated levels of pancreatic enzyme (serum lipase and/or amylase) in the blood, urine, or ascitic fluid; and (3) abnormal imaging findings for the pancreas associated with acute pancreatitis. A search of medical records using a combination of the two diagnostic categories of acute respiratory failure and acute pancreatitis identified 163 patients. Among these, 75 patients were diagnosed with VRP. Fifteen patients with a history of alcoholism (alcohol consumption > 60 g daily for 10 years), gallstones (by hepatic sonography), hypertriglyceridemia (triglyceride > 500 U/L within 1 year), or the use of drugs that have been well documented to cause pancreatitis (such as propofol) were excluded to avoid confounding. We excluded other well-known etiologies of pancreatitis except for mechanical ventilation. Thus, 60 patients met the criteria for VRP and 88 patients were classified as having PRRF (Figure 1A). In the patients with PRRF, the principal cause of acute respiratory failure requiring intubation was acute respiratory distress syndrome (ARDS), as a complication of acute pancreatitis.

Due to the wishes of the patients' families and the medical culture in Taiwan, most patients were not receiving sedation. All patients with VRP complained of abdominal pain. The serum amylase and lipase levels were examined one day after the patients complained of abdominal pain following mechanical ventilation. Acute pancreatitis was confirmed by an elevated serum lipase level, three times the upper limit (> 570 U/L) with or without elevated serum amylase. Confirmatory imaging studies were not routinely used in this study. Among the VRP patients, only 28 (46.7%) underwent an imaging study for the diagnosis of pancreatitis. Fourteen patients (23.3%) underwent imaging studies but had indeterminate findings due to patient agitation or excessive bowel or respiratory distress. Eighteen patients (30%) underwent no imaging studies due to their critical condition.

Patient demographic characteristics, comorbidities, presence of ARDS, lowest PaO₂/FiO₂ ratio, acute renal failure, systemic inflammatory response syndrome (SIRS), vasopressor use, renal replacement therapy, serum amylase, lipase level, and ICU mortality were recorded. ARDS was diagnosed according to the criteria of the American-European Consensus Conference Committee^[19]. Acute renal failure was defined as normal renal function prior to admission that was impaired along with disease progression occurring before or after acute respiratory failure, and defined with a cutoff value of creatinine ≥ 1.5 mg/dL. SIRS was defined as a temperature ≥ 38°C or ≤ 36°C, heart rate ≥ 90 beats/min, respiratory rate ≥ 20/min, and a white blood cell (WBC) count ≥ 12000/mL or ≤ 4000/mL or > 10% immature neutrophils without a definite infection source and we noted this sign after pancreatitis had been diagnosed.

For the outcome analysis, each VRP subject was matched with 3 subjects from the cohort of 9108 pa-

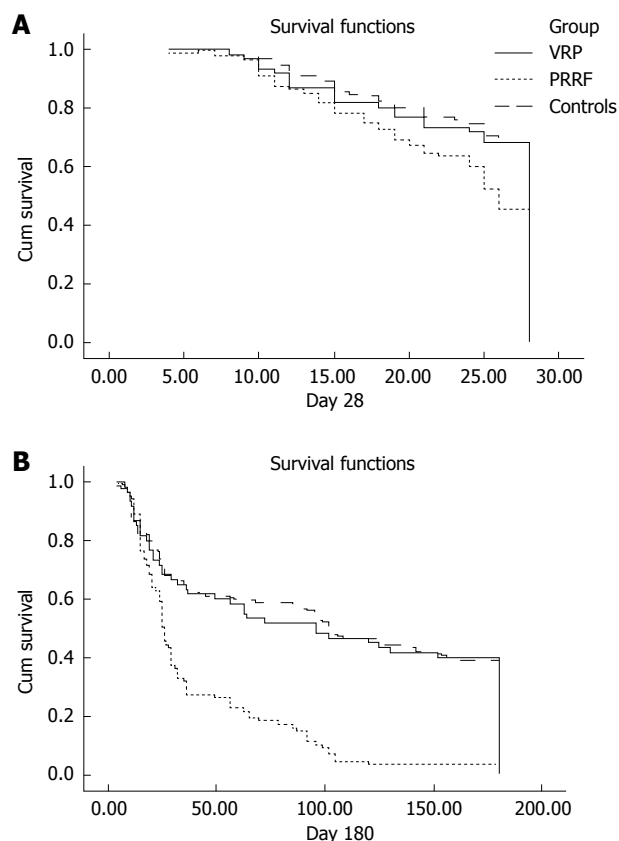

Figure 1 Kaplan-Meier estimates of short-term (A: 28 d) and long-term (B: 6 mo) survival of groups. A: $P = 0.007$ between VRP and PRRF, $P = 0.567$ between VRP and controls; B: $P < 0.001$ between VRP and PRRF, $P = 0.498$ between VRP and controls. VRP: Ventilator-related pancreatitis; PRRF: Pancreatitis-related respiratory failure.

tients with respiratory failure without pancreatitis by an investigator blinded to the outcomes. Matching was based on similarities in severity of illness as manifested by the Acute Physiology and Chronic Health Evaluation (APACHE) II score (± 2 points) at admission to ICU within 24 h, diagnostic category, status of lowest $\text{PaO}_2/\text{FiO}_2$, and diagnosis of ARDS. Among the matched cases, all patients had no abdominal pain described in their chart during admission to the ICU or if abdominal pain was noted, there was no elevation in serum amylase and lipase level.

Statistical analysis

Continuous variables were summarized using means and standard deviations (mean \pm SD), while categorical variables were summarized using counts and percentages.

Index cases and controls were compared using the Student's t -test or the Mann-Whitney U test, as appropriate for continuous variables, or the χ^2 test for categorical variables. Categorical variables were compared with the Pearson χ^2 test and, if appropriate, Fisher's exact test.

In patients with VRP, clinical parameters thought to be contributory to ICU mortality were analyzed by univariate regression analysis. Factors found to be statistically significant ($P < 0.1$) by univariate regression analysis were then retained for a multivariate logistic regression model to determine whether they remained predictive

for ICU mortality.

To assess the outcome between groups, survival time up to 6 mo post-admission was recorded, and Kaplan-Meier survival curves were constructed; comparison between the groups was by the log-rank test.

All testing was two-tailed and $P < 0.05$ were considered to be statistically significant.

RESULTS

Clinical characteristics associated with mortality in patients with ventilator-related pancreatitis

Among 60 patients with VRP, 35 patients (58.3%) were ICU survivors and 25 were ICU non-survivors (41.7%). The mean number of days to pancreatitis after mechanical ventilation in patients with VRP was 11.90 ± 7.22 d (range from 3 to 31 d). Of the 60 patients with VRP, amylase and lipase levels normalized and abdominal pain subsided in 51. The other 9 patients died before further blood sampling for amylase and lipase could be performed. The mean number of days to recovery from pancreatitis (duration from the onset of abdominal pain to the date of normalized amylase and lipase levels) was 7.08 ± 3.48 d (range from 2 to 15 d). Among the VRP patients, only 28 (46.7%) underwent an imaging study for the diagnosis of pancreatitis. Of those patients, all underwent an abdominal echo study, and 3 received both an abdominal echo and a CT study. After reviewing the images, we found that all cases showed mild-to-moderate swelling of the pancreas, and there were no cases of pancreatic necrosis or fluid retention in the abdominal cavity. High APACHE II score ($P = 0.001$), low $\text{PaO}_2/\text{FiO}_2$ level ($P < 0.001$), ARDS status ($P = 0.002$), SIRS occurrence ($P = 0.002$), acute renal failure status ($P = 0.005$), requirement for renal replacement therapy ($P = 0.003$), and male gender ($P = 0.040$) were significantly more frequent in ICU non-survivors than in survivors. High serum amylase ($P = 0.079$) and lipase level ($P = 0.072$) were not correlated with a poor prognosis. Interestingly, an underlying history of congestive heart failure ($P = 0.017$) was more frequent in survivors (Table 1). On univariate regression analysis, acute renal failure ($P = 0.006$), APACHE II score ($P = 0.003$), lowest $\text{PaO}_2/\text{FiO}_2$ ($P < 0.001$), ARDS status ($P = 0.003$), SIRS occurrence ($P = 0.003$), renal replacement therapy ($P = 0.008$), and male gender ($P = 0.044$) were predictors of death (Table 2). On multivariate analysis, only the lowest $\text{PaO}_2/\text{FiO}_2$ (OR: 1.032, 95% CI: 1.006-1.059, $P = 0.016$) predicted death and was, therefore, an independent risk factor for mortality in patients with VRP (Table 3).

Characteristics and outcomes of patients

Table 2 details the baseline characteristics of the 60 cases with VRP, 88 cases with PRRF, and 180 controls without pancreatitis. There were no statistically significant differences between the cases with VRP and the controls in any of the analyzed parameters. Between the patients with VRP and PRRF, there were no statistically significant differences in age, gender, or requirement for renal replacement therapy. More

Table 1 Comparison of the differences between ICU survivors and ICU non-survivors in patients with ventilator-related pancreatitis (mean \pm SD) *n* (%)

Characteristics	ICU survivors <i>n</i> = 35 (58.3)	ICU non-survivors <i>n</i> = 25 (41.7)	<i>P</i>

Amylase level	227.34 \pm 207.35	374.96 \pm 368.87	0.079
ARDS	5 (14.3)	13 (52)	0.002
SIRS	5 (17.2)	13 (52)	0.002
Vasopressor	12 (34.3)	9 (36)	0.891
Acute renal failure	11 (31.4)	17 (68)	0.005
RRT	2 (5.7)	9 (36)	0.003
CHF	26 (74.3)	11 (44)	0.017
CVA	12 (34.3)	10 (40)	0.651
Liver cirrhosis	8 (22.9)	7 (28)	0.650
COPD	12 (34.3)	8 (32)	0.853
Neoplastic disease	3 (8.6)	5 (20)	0.199
Diabetes mellitus	17 (48.6)	12 (48)	0.965
Hypertension	19 (54.3)	15 (60)	0.660

Variables are expressed as mean (standard deviation) and categorical data are expressed as number (percentage). Continuous variables were analyzed by Student's *t* test or Mann-Whitney *U* test, and categorical data by χ^2 test. ICU: Intensive care unit; Apache: Acute Physiology and Chronic Health Evaluation; ARDS: Acute respiratory distress syndrome; SIRS: Systemic inflammatory response syndrome; RRT: Renal replacement therapy; CHF: Congestive heart failure; CVA: Cerebrovascular disease; COPD: Chronic obstructive pulmonary disease.

subjects with VRP had congestive heart failure and liver cirrhosis than those with PRRF. PRRF patients were significantly sicker, with higher serum lipase ($P = 0.001$), serum amylase levels ($P < 0.001$), and APACHE II scores ($P < 0.001$), as well as ARDS status ($P < 0.001$), SIRS occurrence ($P < 0.001$), and vasopressor requirements ($P = 0.019$). PRRF was also associated with higher mortality than VRP ($P < 0.001$). However, there was no statistical difference in mortality rates between VRP patients and the control group ($P = 0.544$).

Short- and long-term outcomes

Short- and long-term outcomes were significantly better in patients with VRP. Patients with VRP were more likely to be alive at day 28 than patients with PRRF (68.3% *vs* 45.5%, $P = 0.007$), to be discharged from ICU (58.3% *vs* 26.2%, $P < 0.001$), and to have survived during the 6-mo follow-up period (40% *vs* 3.4%, $P < 0.001$). However, the 28 d survival ($P = 0.567$), ICU survival ($P = 0.544$), and 6 mo survival ($P = 0.498$) rates were comparable between patients with VRP and controls. Survival curves were constructed using the Kaplan-Meier method to explain the survival differences between the groups (Figure 1).

DISCUSSION

This retrospective analysis yielded three main findings. First, patients with respiratory failure needing ventilator support may develop acute pancreatitis. When patients

were diagnosed with VRP, clinical parameters such as a high APACHE II score, low PaO₂/FiO₂, SIRS occurrence, ARDS status, acute renal failure, renal replacement therapy, and male gender predicted mortality. Multivariate logistic regression showed that low PaO₂/FiO₂ was an independent risk factor for mortality. Secondly, the short- and long-term outcomes in patients with VRP were not worse than those in non-pancreatitis patients with an equal severity score, and were better than those in patients with PRRF, although both groups had respiratory failure and acute pancreatitis. Thirdly, patients with PRRF

had higher APACHE II scores, more frequent ARDS, lower $\text{PaO}_2/\text{FiO}_2$ levels, greater frequency of SIRS, and pressor-requiring shock, as well as higher serum lipase and amylase levels than VRP patients.

Using these diagnostic criteria, the incidence of acute pancreatitis in patients requiring mechanical ventilation was lower than we had anticipated. A possible reason is that intubated and sedated patients are frequently unable to indicate and localize serious abdominal pain and this may be overlooked by clinical staff. We speculate that the actual incidence of acute pancreatitis in the ICU is higher than appreciated and this entity would be more readily detected if comprehensive physical examination was conducted and laboratory testing initiated in patients with abdominal pain.

Numerous potential mechanisms could account for VRP. Mechanical ventilation, frequently with high levels of positive end-expiratory pressure (PEEP), can increase intrathoracic pressure and result in decreased venous return^[20]. Reduced preload in the return could result in decreased cardiac output and hypotension. Splanchnic blood flow is decreased in these settings in parallel with PEEP-induced reductions in cardiac output^[21]. Mechanical ventilation with PEEP is also associated with increased renin-angiotensin-aldosterone activity and elevated catecholamine levels because of sympathetic activation^[3,22]. Elevation of serum catecholamines can contribute to splanchnic hypoperfusion due to vasoconstriction and redistribution of blood away from the splanchnic vascular bed^[23]. The adverse effects of mechanical ventilation under injurious ventilatory strategies suggest an important role of cytokines in the pathogenesis of multiple organ complications. Pro-inflammatory cytokines can affect many organs and induce a variety of physiological and biochemical responses to critical illness^[24]. They can lead to a series of intracellular signaling events *via* highly specific cell surface receptors that typically result in elaboration of other cytokines within the target cell. If these processes are not attenuated, excessive amplification of the inflammatory cascade and overproduction of pro-inflammatory mediators can occur with the uncontrolled activation of the immune system and cause target organ damage. All of these mechanisms may result in organ ischemia and failure. If ischemic injury to the pancreas or pancreatic inflammation related to systemic inflammatory mediators occurs, it could account for the increased serum lipase and amylase levels observed in critically ill patients^[4,5]. Among several mechanisms suggested to explain how mechanical ventilation unfavorably results in acute pancreatitis, splanchnic hypoperfusion appears to be particularly important^[1].

A mortality comparison demonstrated a lower survival rate in PRRF than in VRP. Acute lung injury and ARDS, which have high mortality rates, are the most common manifestations of extra-abdominal organ dysfunction in patients with severe acute pancreatitis. The pathophysiology of ARDS is described as increased pulmonary vasculature leaking protein-rich transudate into the alveolar space and decreased lung compliance

clinically manifested as refractory hypoxemia, and radiologically as diffuse infiltration in the lungs. In the pathogenesis of systemic complications of pancreatitis, the role of active enzymes in circulation, the liberation of proinflammatory cytokines, decreased normal defense mechanisms, and the increased production of nitric oxide have been studied^[25,26]. The mortality and severity of the disease appear to be influenced by events occurring subsequent to the pancreatic injury as a result of the release of cytokines and other mediators. Hypoxemia is the most common sign presenting in patients with respiratory insufficiency resulting from severe acute pancreatitis; however, its presentation was not related to the development of atelectasis, pleural effusion, or pulmonary consolidation during the course of the disease. Severe hypoxemia is also a factor that predicts a poor prognosis. A recent study has shown that a baseline hypoxemia of less than 60 mmHg was a significant risk factor for pulmonary consolidation and ARDS, and can be used as a marker of poor outcome^[14]. Sustained systemic inflammatory states with multiple organ failure are frequently encountered and have a high attributable mortality rate^[27]. Progression to a shock state requiring vasopressor use or acute renal failure requiring renal replacement therapy is particularly ominous^[28,29].

Our study demonstrated that a high APACHE II score, low $\text{PaO}_2/\text{FiO}_2$, ARDS status, presence of SIRS criteria, acute renal failure, and the need for renal replacement therapy were predictors of outcome in patients with a diagnosis of ventilator-related pancreatitis; only a low $\text{PaO}_2/\text{FiO}_2$ level was an independent predictive factor as determined by multivariate logistic regression analysis. Thus, as mentioned above, hypoxemia or disease progression to ARDS are poor signs not only in PRRF patients but also in VRP patients.

To date, no specific management strategy has been proposed for acute pancreatitis with multiple organ failure other than intensive supportive treatment. The evidence available indicates that patients with severe acute pancreatitis do not benefit from therapy with available antisecretory drugs or protease inhibitors. Supportive therapy, such as vigorous hydration, analgesia, correction of electrolytes and glycemic disorders, and pharmacological or mechanical support targeted at specific organs, are still the mainstay of therapy^[30]. However, severe acute pancreatitis is still characterized by rapidly progressive multiple organ failure and high mortality, and both surgical and conservative therapies yield poor outcomes^[31]. Thus, most emphasis is placed on preventing the progression to multiple organ failure^[32,33].

Congestive heart failure was more common in VRP patients than in PRRF patients and was a good prognostic predictor for ICU mortality in patients with VRP. Acute pulmonary edema related to congestive heart failure was a frequent cause of respiratory failure in VRP patients; in contrast, the most common indication for intubation in patients with PRRF was ARDS. Heart failure-related pulmonary edema can often be reversed with diuretics and renal replacement therapy if there is concomitant renal failure. In contrast, there are no effective pharma-

cologic treatments for non-cardiogenic pulmonary edema associated with ARDS other than the treatment of the underlying disease. Conservative treatments with protective ventilatory strategies and fluid management may help to improve the hypoxemic status of patients with ARDS, however, these strategies had no benefit on mortality^[34,35]. This may explain, in part, why VRP patients in our study had better outcomes than PRPF patients and VRP patients with congestive heart failure had a better prognosis than those without congestive heart failure.

There are some limitations in this study. First, as this was a retrospective study, not every patient in the ICUs with abdominal pain had blood sampling for amylase and lipase levels. This ascertainment bias may have resulted in an overestimation of the incidence of VRP. Secondly, the Ranson score is widely used in predicting outcomes from severe acute pancreatitis^[36,38]. However, Ranson's criteria were not systematically collected in our cohort. Thus, we did not include Ranson's criteria as part of our analysis, therefore potentially limiting external validity. Third, although radiological imaging, particularly computed tomography, is valuable for diagnosis, risk stratification, and outcome prediction of acute pancreatitis^[36,39], not every patient had an imaging study to confirm acute pancreatitis in our study.

In conclusion, our findings suggested that low PaO₂/FiO₂ was an independent clinical parameter predictive of ICU mortality in patients with VRP. We also demonstrated that VRP was not associated with a higher mortality rate when compared with ICU patients with comparable disease severity but without pancreatitis and was associated with better outcomes than PRPF.

COMMENTS

Background

Mechanical ventilation is an important method in rescuing patients with respiratory failure, but it is also associated with numerous organ-system disorders. Acute pancreatitis may also be caused by mechanical ventilation, for which splanchnic hypoperfusion is considered the most important mechanism. However, the risk factors predictive of clinical outcomes and intensive care unit (ICU) mortality in patients with ventilator-related pancreatitis are still unclear. Thus, we conducted this study to clarify the clinical outcomes in patients with ventilator-related pancreatitis.

Research frontiers

Patients with severe acute pancreatitis may develop acute respiratory failure resulting in poor clinical outcomes. Such a concept is well documented. However, the notion of ventilator-related pancreatitis is not well understood, even though pancreatitis truly occurs after mechanical ventilation. We conducted this study to illustrate the different clinical outcome in patients with ventilator-related pancreatitis, pancreatitis related respiratory failure and equal severity ICU patients without pancreatitis.

Innovations and breakthroughs

The authors clarify the risk factors for predicting mortality in patients with ventilator-related pancreatitis. Short- and long-term outcomes in patients with ventilator-related pancreatitis are also illustrated by a comparison with patients who had pancreatitis-related respiratory failure and ICU patients admitted with equal physiological severity scoring without pancreatitis.

Applications

By understanding the nature of ventilator-related pancreatitis, the authors found that low PaO₂/FiO₂ was an independent clinical parameter predictive of ICU mortality in patients with ventilator-related pancreatitis. Despite the simultaneous diagnosis of acute respiratory failure and acute pancreatitis, patients with ventilator-related pancreatitis had better outcomes than patients

with pancreatitis-related respiratory failure.

Terminology

Ventilator-related pancreatitis is a disease in which pancreatitis occurs after mechanical ventilation by numerous mechanisms. Possible mechanisms include injurious ventilatory strategies, high pressure with hypovolemic status, and sympathetic stimulation mechanisms resulting in conditions such as pancreatic ischemia or pancreatic hypoperfusion are thought to be the cause of pancreatic injury.

Peer review

This interesting paper looks at a group of patients with a condition about which we know very little. They have coined the terms "ICU-related pancreatitis" and "ventilator-related pancreatitis", which are not terms currently in use but are reasonable. The findings of this study make sense.

Abstract

AIM: To investigate glue extrusion after endoscopic N-butyl-2-cyanoacrylate injection on gastric variceal bleeding and to evaluate the long-term efficacy and safety of this therapy.

METHODS: A total of 148 cirrhotic patients in our hospital with esophagogastric variceal bleeding (EGVB) were included in this study. N-butyl-2-cyanoacrylate was mixed with lipiodol in a 1:1 ratio and injected as a bolus of 1-3 mL according to variceal size. Patients underwent endoscopic follow-up the next week, fourth week, second month, fourth month, and seventh month after injection and then every 6 mo to determine the cast shape. An abdominal X-ray film and ultrasound or computed tomographic scan were also carried out in order to evaluate the time of variceal disappearance and complete extrusion of the cast. The average follow-up time was 13.1 mo.

RESULTS: The instantaneous hemostatic rate was 96.2%. Early re-bleeding after injection in 9 cases (6.2%) was estimated from rejection of adhesive. Late re-bleeding occurred in 12 patients (8.1%) at 2-18 mo. The glue cast was extruded into the lumen within one month in 86.1% of patients and eliminated within one year. Light erosion was seen at the injection position and mucosa edema in the second week. The glue casts were extruded in 18 patients (12.1%) after one week

and in 64 patients (42.8%) after two weeks. All kinds of glue clumping shapes and colors on endoscopic examination were observed in 127 patients (86.1%) within one month, including punctiform, globular, pillar and variform. Forty one patients (27.9%) had glue extrusion after 3 mo and 28 patients (28.9%) after six months. The extrusion time was not related to the injection volume of histoacryl. Obliteration was seen in 70.2% (104 cases) endoscopically. The main complication was re-bleeding resulting from extrusion. The prognosis of the patients depended on the severity of the underlying liver disease.

CONCLUSION: Endoscopic injection of cyanoacrylate is highly effective for gastric varices bleeding. The glue clump shape is correlated with anatomic structure of vessels. The time of extrusion was not related to dosage of the glue.

INTRODUCTION

Although the outcome of variceal hemorrhage has improved over the past two decades, variceal hemorrhage is still the most serious complication of portal hypertension and chronic liver disease^[1-3]. Gastric varices (GV) and their association with portal hypertension were first described in 1913^[4]. Since then, there have been reports on different aspects of gastric varices including prevalence, bleed tendency and treatment options. Gastric varices occur in 20% of patients with portal hypertension either in isolation or in combination

with esophageal varices (EV)^[5-6]. GV possibly bleed less frequently than EV, but GV bleeding is typically difficult to control, and is associated with a high risk for re-bleeding and high mortality. Fundal varices, large GV (> 5 mm), presence of a red spot, and Child's C liver status are associated with a high risk for bleeding^[7-8]. gastro-esophageal varices type 1 (GOV1) have a much lower risk for bleeding. A portosystemic pressure gradient of > 12 mmHg is not necessary for GV bleeding, probably related to the high frequency of spontaneous gastrosplenic shunts in these patients^[9]. There is no consensus for the optimum treatment of GV including drugs, endoscopy, and surgery. Optimal management of GV requires a multidisciplinary approach and close cooperation between gastroenterologists, interventional radiologists and the surgical team.

Histoacryl (N-butyl-cyanoacrylate) is the only endoscopic treatment that has been shown to be effective. Sohendra *et al*^[10] first reported in 1986 that bleeding from GV could be controlled by sclerotherapy using the tissue adhesive agent butyl cyanoacrylate. Since then several authors have used different sclerosing agents to achieve hemostasis in bleeding gastric varices, including N-butyl-2 cyanoacrylate (histoacryl)^[11,12], 2-octyl cyanoacrylate^[13], ethanolamine oleate injection^[14], gastric variceal banding^[15], thrombin^[1] and sodium tetradecyl sulfate^[16]. However, N-butyl 2 cyanoacrylate (NBC) is the only promising agent. Cyanoacrylate injection can achieve primary hemostasis in 70% to 95% of patients with acute GV bleeding, with an early re-bleeding rate ranging from 0% to 28% within 48 h^[17-19].

To date, there are many studies on the efficacy and hemostasis rate of NBC injection on gastric variceal bleeding. However, there are no reports on detailed gel extrusion after injection. In this study, we investigated the glue extrusion after endoscopic NBC injection for gastric variceal bleeding and evaluated the long-term efficacy and safety of this therapy to define its role in initial treatment.

MATERIALS AND METHODS

Materials preparation

A 1:1 (v/v) mixture of N-butyl-2-cyanoacrylate (Histoacryl blue; B. Braun-Melsungen, Germany, 0.5 mL per ampoule) and lipiodol (Laboratoire Guerbet, Aulnay-Sous-Bois, France) was prepared just before injection. An endoscopic injector (hemostasis catheter) with a 23-gauge needle (Optiflo, Boston Scientific, Boston, USA) was used.

Patients

From June 2007 to December 2008, total of 148 cirrhotic patients with or without concomitant hepatocellular carcinoma (HCC) who presented to our hospital with acute gastrointestinal bleeding, or who were already hospitalized and developed acute gastrointestinal bleeding, were subjected to injection of the mixture, except those with severe encephalopathy, severe hemodynamic instability, pregnancy, or those who refused treatment. Active hemorrhage was defined

as bleeding or oozing of blood from a gastric varix, a clot or blackish ulcer or rent over a gastric varix, or the presence of distinct large GV and absence of EV or other causes of gastrointestinal (GI) bleeding. Liver function was classified according to the Child-Pugh classification criteria. The most common cause of GV was viral hepatitis-related cirrhosis (74.5%). The modality and location of the GV were classified according to the system proposed by Hashizume *et al*^[19]; the modality was classified into 3 types: tortuous (F1), nodular (F2), and tumorous (F3); and location, 5 areas: anterior (La), posterior (Lp), lesser (Ll) and greater curvature (Lg) of the cardia, and the fundic area (Lf). Most of the GV were large. Associated EV were usually small or absent. The most common locations of these GV were the fundus (Lf) and the most proximal body on the posterior wall (Lp) (94.4%).

The location of GV was determined according to the classification described by Sarin *et al*^[20] and divided into gastroesophageal varices type 1 (GOV-1), GV continuing as an extension of EV on the lesser curve of the stomach), gastro-esophageal varices type 2 (GOV-2) on the greater curvature or fundal varices communicating with EV, isolated gastric varices type 1 (IGV-1) and fundal varices within a few centimeters of the gastric cardia, or isolated gastric varices type 2 (IGV-2) and isolated ectopic gastric varices.

NBC was mixed with lipiodol in a 1:1 ratio and injected as a bolus of 1 to 3 mL according to variceal size. Thirty patients had isolated GV, 38 had postoperative residual GV, and 72 had dominant GV. The actual volume of the injection was based on the variceal appearance. The injection was stopped when the varices became engorged. Lipiodol was used to flush the injection needle before and after the injection. The tip of the endoscope and the accessory channel were treated with silicone oil to prevent endoscopic damage. All patients received octreotide infusion (50 mg/h) at admission and was continued for 3 d. All patients were given a proton pump inhibitor, initially intravenously for 48 h and then orally for 4-6 wk.

Indices to evaluate the extrusion rule of glue

Indices to evaluate the extrusion rule of glue are as follows: (1) Information on each patient's gender, age, Child-Pugh classification, stage of GV, number of treatments, dosage of cyanoacrylate, outcome of GV, diameter of main portal tract, liver function and routine blood tests were collected; (2) An X-ray film was obtained three days after injection to determine the contour of the histoacryl cast. A chest X-ray was also obtained to ascertain whether any embolic material had migrated into the chest. Ultrasound and/or computed tomographic scan of the abdomen were carried out within one week; (3) Patients underwent endoscopic follow-up the next week, fourth week, second month, fourth month, and seventh month after injection and then every 6 mo to determine the cast shape. An abdominal X-ray film and ultrasound or computed tomographic scan were also obtained in order to

evaluate the time of variceal disappearance and complete extrusion of the cast; (4) The instant hemostasis rate, obliteration rate and re-bleeding rate were analyzed. Initial hemostasis was defined as a condition in which the vital signs were stable and no recurrent bleeding was noted for 48 h after the first injection. The definition of re-bleeding from GV included the following endoscopic conditions: spurting or oozing bleeding from GV or blood pools in the stomach accompanied by a fibrin cap on the GV. Primary success was defined as the absence of recurrent bleeding after the first histoacryl injection and during the entire follow-up period. Secondary success was defined as the absence of recurrent bleeding after the reinjection of histoacryl for recurrent bleeding. Definitive hemostasis included both primary and secondary success. Treatment failure was defined as failure to obtain definitive hemostasis.

Complications

Major complications included fever, chest pain, esophageal stricture, septicemia, mediastinum inflammation, pulmonary embolism, cerebral infarction, portal vein embolization, aspirated pneumonia and re-bleeding. The average follow-up time was 13.1 mo.

Statistical analysis

Statistical interpretation of data was performed using

Statistical Program for Social Sciences (SPSS) version 13. Results were expressed as mean ± SD, median (MD) for all continuous variables (e.g. age, gender, hospital stay, units of packed cells *etc*) and numbers (percentage) for categorical data (e.g. gender, Child's class, *etc*). Analysis was performed using the independent *t*-test, χ^2 test and Fisher's exact test wherever appropriate. *P* < 0.05 was considered statistically significant.

RESULTS

A total of 148 patients with liver cirrhosis and EGV at our hospital from June 2007 to December 2008 were subjected to the injection. This was a retrospective review of their records.

Clinical condition

According to Sarin's classification of GV, GOV-1 was detected in 68 patients (45.9%), GOV-2 in 49 (33.1%), IGV-1 in 30 (20.3%) and IGV-2 in 1 (0.67%). The common cause of GOV was liver cirrhosis and was segmental portal hypertension without liver disease in IGV. The majority of injections in this series were executed in selective cases, with the exception of 25 cases with acute bleeding who received emergent injections. The primary hemostatic rate was 96.2% (142/148). Among the 148 patients, 6 patients did not achieve hemostasis. The average number of sessions required to eradicate the GV was 2.9 ± 1.2 . It was observed that at follow-up (1-18 mo) the injected glue was rejected from GV, resulting in eradication. Early re-bleeding after injection in 9 cases (6.2%) was estimated from rejection of the adhesive. Late re-bleeding occurred in 12 patients (8.1%) at 2-18 mo. Some patients were treated with a second injection to successfully control the bleeding (Tables 1 and 2).

Vascular structure

Three-dimensional computed tomography was used in ten patients after injection in order to understand the vascular structure of GV. There were two types: one was composed of one blood vessel without obvious branches. The diameter of the influent vein and effluent vein were almost identical. The other was composed of many blood vessels with complex branches. Endoscopic feature of GV were related to their vascular structure. The former was common in regional GV (86%) and the latter in GV with a diffuse pattern (91%).

Glue extrusion

At follow-up (1-18 mo), it was observed that the injected glue was rejected from GV. The cast of glue was extruded into the lumen after one or two weeks, generally without resultant hemorrhage. An X-ray film was obtained three days after the injection to determine the contour of the histoacryl cast. It showed that all the GV were full of the histoacryl and lipiodol mixture, and 13 patients had mixture in the inferior segment of the esophagus. There were all kinds of glue clumping shapes including globular, trabs and flower shapes. The

Table 2 Results of histoacryl injection

Brown	48 (32.4)

X ray examination (Figure 1).

One hundred and twenty eight patients underwent endoscopic follow-up in the second week, fourth week, second month, fourth month, and seventh month after injection and every 6 mo thereafter to determine the cast shape. Light erosion was seen at the injection position and mucosa edema in the second week. The glue casts were extruded in 18 patients (12.1%) after one week and in 64 patients (42.8%) after two weeks. All kinds of glue clumping shapes and colors on endoscopic examination were observed in 127 patients (86.1%) within one month, including punctiform, globular, pillar and variform. Forty one patients (27.9%) had glue extrusion after three months and 28 patients (28.9%) after six months. The extrusion time was not related to injection volume of histoacryl (Tables 3 and 4, Figures 2 and 3).

Prognosis

Twenty one patients (14.1%) had re-bleeding. Five patients died from re-bleeding, hepatic failure or HCC aggravation. Lipiodol was seen flowing into lung vessels during injection in 1 with no serious cough or signs of ectopic embolism. The obliteration rate was 70.2% (104 cases) as shown on endoscopic examination. The determining factor for long-term survival was the underlying disease leading to portal hypertension.

DISCUSSION

The majority of patients with cirrhosis will develop varices during their lifetime. Once the diagnosis of cirrhosis has been made, the incidence of new varices is 5% per year and these will progress from small to large varices at a rate of 10 to 15% per year. Growth seems to be influenced by the progression of liver failure. At least

Figure 1 This 47-year-old female patient has isolated gastric varices. Expulsion of tissue glue on X-ray view. A: One day after injection; B: Two weeks after injection; C: One month after injection; D: Three months after injection. Lipiodol mass (intravascular) was in the stomach only and became smaller gradually. This indicated the extrusion process of glue.

contrast was smaller after one month in 132 patients and disappeared in 138 patients within one year as shown on

Figure 2 Different colors and shapes of contrast on endoscopic examination. A gastric mucosal defect can be seen with expulsion of the adhesive plug from the thrombosed gastric varix several weeks after endoscopic treatment with N-2-butyl-cyanoacrylate.

one-third of these patients will bleed from their varices and despite significant improvements in treatment and diagnosis, the mortality rate still remains high (30%).

China is one of the countries with the highest incidence of gastric variceal hemorrhage. Esophagogastric variceal bleeding (EGVB) is a serious and emergent condition and hemorrhage control in order to decrease death rate is important. Variceal bleeding results in considerable morbidity and mortality. Although GV bleeding occurs less frequently than EV bleeding^[20], whenever bleeding occurs it tends to be more severe and requires more red blood cell transfusions and has a higher mortality rate than EV bleeding^[21]; after control of acute bleeding, GV has a high re-bleeding rate of 34% to 89%^[22,23]. The principle of initial treatment is to achieve hemostasis and prevent bleeding-related complications such as renal failure, infection, and hepatic decompensation. Cyanoacrylate injection has been proved in large series to be a safe and effective therapy for gastric variceal bleeding.

A total 148 cirrhotic patients with EGV at our hospital from June 2007 to December 2008 were subjected to this treatment. Cyanoacrylate was injected intravariceally in a 1:1 mixture with lipiodal. Each patient underwent scheduled or emergent endoscopic injection of cyanoacrylate and were counterchecked on the 7th day, 1st month and 3rd month after the first treatment, respectively. Cyanoacrylate is a liquid with a consistency similar to water, which rapidly polymerizes on contact with blood. Although the adhesive is injected in a manner similar to sclerosants, extra precautions must be taken before its use to prevent damaging the endoscope. Silicone oil, oil-based contrast agents, simethicone or even olive oil should be used to flush the tip of the endoscope as well as the entire biopsy channel^[24,25]. The glue was rejected into the gastric cavity after one or two weeks without re-bleeding. The cast of glue was extruded into the lumen as a foreign body. Glue was extruded in 86.1% of patients within one month with all kinds of shapes and colors of contrast.

Figure 3 Different colors and shapes of contrast on endoscopic examination.

The rejection had no adverse effects. The glue was extruded in 18 patients (12.1%) within one week and in 64 patients (42.8%) within two weeks. All kinds of glue clumping shapes and colors were seen on endoscopic examination in 127 patients (86.1%) within one month, including punctiform, globular, pillar and variform. Forty one patients (27.9%) had glue extrusion after three months and 28 patients (28.9%) after six months. The extrusion time was not related to the injection volume of histoacryl. We did not observe contrast due to glue in six patients as a result of mucosal crimple.

We found re-bleeding in 9 patients due to glue extrusion. These patients were examined by endoscopy and erosion and ulcer at the injection site were noted. However, the volume of blood was not large. Time to re-bleeding was about one or two months. We administered antacid drugs, and in some, endoscopy therapy. All the patients recovered. Both follow up and supplementary treatment are important in maintaining and improving long-term outcomes. Repeated sclerotherapy using NBC is effective for remnant GV. The formation of collateral

veins around the cardia region after obliteration of gastric short veins or the posterior gastric vein may lead to new EV, which can be managed by conventional endoscopic or surgical measures.

Endoscopic injection of cyanoacrylate is highly effective in the treatment of gastric variceal hemorrhage, with only a few acute and long-term complications. This treatment modality may be referred to as the first choice for bleeding GV.

COMMENTS

Background

Esophagogastric variceal bleeding (EGVB) is a serious and emergent condition of portal hypertension and results in considerable morbidity and mortality. Gastric varices (GV) occur in 20% of patients either in isolation or in combination with esophageal varices (EV). GV possibly bleed less frequently than EV, but GV bleeding is typically difficult to control, and is associated with a high risk for re-bleeding and high mortality. There is no consensus on the optimum treatment of GV including drugs, endoscopy, and surgery. Optimal management of GV requires a multidisciplinary approach and close cooperation between gastroenterologists, interventional radiologists and the surgical team.

Sohendra *et al* first reported in 1986 that bleeding from GV could be controlled by sclerotherapy using the tissue adhesive agent butyl cyanoacrylate.

Research frontiers

Cyanoacrylate injection can achieve primary hemostasis in 70% to 95% of patients with acute GV bleeding, with an early re-bleeding rate ranging from 0% to 28% within 48 h. To date, there are many studies on the efficacy and hemostasis rate of N-butyl-2-cyanoacrylate injection on gastric variceal bleeding. However, there are no reports on detailed gel extrusion after injection.

Innovations and breakthroughs

Gastric variceal bleeding can be challenging to the clinician. Tissue adhesives can control acute bleeding in over 80% of patients, with re-bleeding rates of 20%-30%, and should be the first-line therapy where available. In this study, we investigated the glue extrusion after endoscopic N-butyl-2-cyanoacrylate injection for gastric variceal bleeding and evaluated the long-term efficacy and safety of this therapy to define its role in the initial treatment.

Applications

By understanding how the glue is extruded and the long-term efficacy and safety of endoscopic N-butyl-2-cyanoacrylate injection, this study may represent a better therapeutic intervention in the treatment of patients with gastric variceal bleeding.

Terminology

Gastroesophageal varices type 1 (GOV-1) are GV continuing as an extension of EV on the lesser curve of the stomach, gastro-esophageal varices type 2 (GOV-2) are found on the greater curvature or fundal varices communicating with EV. Isolated gastric varices type 1 (IGV-1) and fundal varices are found within a few centimeters of the gastric cardia, or isolated gastric varices type 2 (IGV-2) and isolated ectopic gastric varices.

Peer review

Looking at the rate of glue extrusion and its association with re-bleeding is quite a novel way of reporting the success of an old technique in arresting gastric variceal bleeding.

xenograft transplantation of hepatocellular carcinoma was also significantly suppressed by genistein. The number of pulmonary micrometastatic foci in the genistein group was significantly lower compared with the control group (12.3 ± 1.8 vs 16.6 ± 2.6 , $P < 0.05$).

CONCLUSION: Genistein appears to be a promising agent in the inhibition of metastasis of hepatocellular carcinoma.

Abstract

AIM: To investigate the inhibitory effects of genistein on metastasis of MHCC97-H hepatocellular carcinoma cells and to explore the underlying mechanism.

METHODS: MHCC97-H hepatocellular carcinoma cells were exposed to genistein. A cell attachment assay was carried out in a microculture well pre-coated with fibronectin. The invasive activity of tumor cells was assayed in a transwell cell culture chamber, and cell cycle and apoptosis were evaluated by a functional assay. In addition, the expression and phosphorylation of FAK were detected by Western blotting. *In situ* xenograft transplantation of hepatocellular carcinoma was performed in 12 nude mice and lung metastasis of hepatocellular carcinoma was observed.

RESULTS: Genistein significantly inhibited the growth of MHCC97-H cells *in vitro*. Adhesion and invasiveness of MHCC97-H cells were inhibited in a concentration-dependent fashion, and the inhibitory effect of genistein was more potent in the 10 μ g/mL and 20 μ g/mL genistein-treated groups. Genistein caused G₀/G₁ cell cycle arrest, an S phase decrease, and increased apoptosis. The expression and phosphorylation of FAK in MHCC-97H cells were significantly decreased. *In situ*

INTRODUCTION

As a common malignancy, hepatocellular carcinoma (HCC) is chemoresistant to most currently available chemotherapeutic agents, and is the leading cause of cancer related deaths in the world, with increasing incidence in many countries^[1]. In China, primary liver cancer, of which more than 90% is HCC, remains the second leading cancer killer. HCC mainly affects middle-aged people, those in the prime of their most productive years^[2]. The high incidence of metastasis accounts for the poor overall survival in HCC patients. Research into interventions for liver cancer metastasis has special priority in the anti-cancer campaign. The MHCC97-H hepatocellular carcinoma cell line has high metastatic potential and was established from a subcutaneous tumor in a high-metastatic-potential model of human HCC cells in BALB/c nu/nu mice (LCI-D20). Lung is the preferential metastasis target of MHCC97-H cells^[3].

In this study, we investigated the inhibitory effects of genistein on metastasis of human HCC cells and explored the underlying mechanism.

MATERIALS AND METHODS

Cell culture and genistein

The human HCC cell line, MHCC97-H, was obtained from the Liver Cancer Institute of Fudan University in Shanghai. The cells were cultured at 37°C in 50 mL/L CO₂ air in high glucose Dulbecco's Modified Essential Medium (DMEM; Hyclone, Logan, UT, USA) supplemented with 10% fetal bovine serum (FBS; Gibco BRL, Grand Island, NY, USA). Genistein (5,7,4'-trihydroxyisoflavone) purchased from Sigma Chemical Co. (St. Louis, MO, USA) was suspended in dimethyl sulfoxide (DMSO) for the experiments.

In vitro assays of MHCC97-H cell growth

A 96-well plate was incubated with exponentially growing cells at a density of 1×10^4 per well. Following incubation of MHCC97-H cells with or without genistein in different columns of 96-well microtiter plates, on day 1-6 methyl thiazol terazolium (MTT) was added to each well and incubated at 37°C for another 4 h before spectrophotometric detection (A_{595}). Each assay was performed in quadruplicate.

The inhibitory rate of tumor cell growth was calculated as: (average A_{595} value of control group-average A_{595} value of genistein group)/average A_{595} value of control group^[4].

In vitro assays of MHCC97-H cell adhesion and invasion

Pre-coating of 96-well microtiter plates was performed by incubating wells with 20 mg/L fibronectin at 4°C overnight. The wells were then blocked with 2% bovine serum albumin (BSA) for 45 min at 37°C. Cells were cultured in medium (DMEM with 2% FBS) for 24 h, then harvested at about 70% confluence, resuspended in serum-free DMEM medium supplemented with 0.1% BSA and distributed in the wells (8×10^4 cells/well). The cells were incubated at 37°C in a 50 mL/L CO₂ atmosphere for 20, 40, 60 and 90 min with or without genistein. The wells were washed 3 times with phosphate buffered saline (PBS) to remove unattached cells, and the attached cells were then incubated with MTT and the A_{595} was measured.

The invasive activity of MHCC97-H cells was assayed in Transwell cell chambers (Corning Inc., Corning, NY, USA), according to the method reported by Kido *et al*^[5]. Polyvinylpyrrolidone-free polycarbonate filters with an 8.0 µm pore size were pre-coated with 5 µg of fibronectin in a volume of 50 µL on the lower surface. The Matrigel was diluted to 100 µg/mL with cold PBS, applied to the upper surface of the filters (5 µg/filter), and dried overnight under a hood at room temperature. Log-phase cell cultures of MHCC97-H cells were harvested and washed 3 times with serum-free DMEM, then resuspended at a final concentration of 2×10^6 cells/mL in DMEM with 0.1% BSA. Cell suspensions (100 µL) with or without genistein were added to the upper compartment and incubated for 20 h at 37°C in a 50 mL/L CO₂ atmosphere. The filters were fixed with methanol and stained with Giemsa. The cells on the upper surface of the filters were removed by wiping with cotton swabs. The cells invading the lower surface of the filter through the Matrigel and

the filter were manually counted under a microscope at a magnification of $\times 400$. Each assay was performed in triplicate. The inhibitory rate of adhesion and invasion were calculated^[4].

Cell cycle analysis

MHCC97-H cells were seeded at a density of 5×10^5 cells/well in six-well dishes. After 24 h the cells were treated with or without genistein for 72 h and harvested by trypsinization. The cells were then centrifuged at 300 *g* for 10 min, washed in PBS, and resuspended in cold 70% ethanol. The cells were then subjected to flow cytometric analysis on a FACScan cytofluorimeter (Becton Dickinson, Franklin Lakes, NJ, USA) after propidium iodide labeling.

Western blotting analysis

Control and genistein-treated cell extracts were prepared and the proteins were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), followed by Western blot analysis using a FAK monoclonal antibody (1:1000; SC-713; Cell signaling, USA) and pFAK polyclonal antibody (1:500; SC-6243; Cell signaling, USA) as primary antibodies. Anti-rabbit/mouse immunoglobulin G (IgG)-HRP (Beyotime Biotech, China) was used as a secondary antibody, followed by the detection of chemiluminescence using chemiluminescence kits (Beyotime Biotech, China). The optical density was determined using a scanning densitometer and analyzed using Quantity One software (Bio-Rad). House-keeping gene β -actin was used as an internal standard.

In vivo experiments

Male athymic BALB/c nu/nu mice (46-wk-old), were obtained from the Shanghai Institute of Materia Medica, Chinese Academy of Science and maintained in specific pathogen-free (SPF) conditions and fed with sterilized MF pellets and distilled water. All studies on the mice were conducted in accordance with the National Institutes of Health "Guide for the Care and Use of Laboratory Animals". The mouse study protocol was approved by the Shanghai Medical Experimental Animal Care Commission.

MHCC97-H cells (5×10^6) in 0.2 mL of serum-free culture medium were injected subcutaneously into the upper flank region of nude mice, and the mice were observed for tumor growth. When a subcutaneous tumor had reached approximately 1.5 cm in diameter, a small piece was removed and cut into pieces of approximately 1 mm \times 1 mm \times 1 mm which were subsequently implanted into the livers of 12 new recipient nude mice by a method described previously^[6]. Of the 12 recipient nude mice, bearing an orthotopic tumor implant, 6 were randomly selected for treatment with genistein and the remaining 6, which did not receive genistein treatment, served as controls. Genistein (50 mg/kg) was administered intraperitoneally to each mouse in the genistein group daily for 20 d, while control animals were administered the same vehicle. The mice were observed for 35 d, and then killed by cervical dislocation. The liver and lungs were excised during autopsy, lungs were fixed and embedded in paraffin and coronal sections were cut.

Figure 1 Inhibitory effects of genistein on MHCC97-H cell proliferation. MHCC97-H cells were treated with various concentrations of genistein for 6 d, control cells were left untreated, A_{595} values were determined daily.

Table 1 Adhesion of MHCC97-H cells to fibronectin coated microtiter plates

	20 min	40 min	60 min	90 min
Control	0.309 ± 0.16	0.432 ± 0.17	0.548 ± 0.12	0.717 ± 0.06
5 µg/mL genistein	0.181 ± 0.04 ^a	0.267 ± 0.06 ^a	0.341 ± 0.02	0.341 ± 0.11 ^b
10 µg/mL genistein	0.108 ± 0.02 ^b	0.219 ± 0.01 ^b	0.257 ± 0.02 ^a	0.367 ± 0.01 ^b
20 µg/mL genistein	0.142 ± 0.07 ^a	0.201 ± 0.04 ^b	0.225 ± 0.04 ^a	0.298 ± 0.09 ^b

^a $P < 0.05$, ^b $P < 0.01$ vs control. The A_{595} for MHCC97-H cells treated with or without genistein in fibronectin pre-coated 96-well microtiter plates was measured at 20, 40, 60 and 90 min. Values are A_{595} mean ± SD from experiments.

After hematoxylin and eosin staining, micrometastatic foci were counted microscopically.

Statistical analysis

All data are the mean ± SD. The statistical significance of differences between the treated and control groups were determined by applying the one-way ANOVA and χ^2 test. The statistical analysis software package Stata 6.0 was used for the tests, and $P < 0.05$ was considered statistically significant.

RESULTS

Effects of genistein on MHCC97-H cell growth

Genistein significantly inhibited MHCC97-H cell growth over the 6-d experimental period. The inhibitory rate of tumor cell growth in the 5, 10 and 20 µg/mL genistein groups was 22.3%, 58.2%, and 80.1%, respectively. The inhibitory rate of MHCC97-H cell growth in the 10 and 20 µg/mL genistein groups was significantly higher than the 5 µg/mL genistein group ($P < 0.05$). The concentration-dependent effects of genistein on MHCC97-H cell growth are shown in Figure 1.

In vitro effects of genistein on adhesion and invasion of MHCC97-H cells

The A_{595} for MHCC97-H cells treated with or without

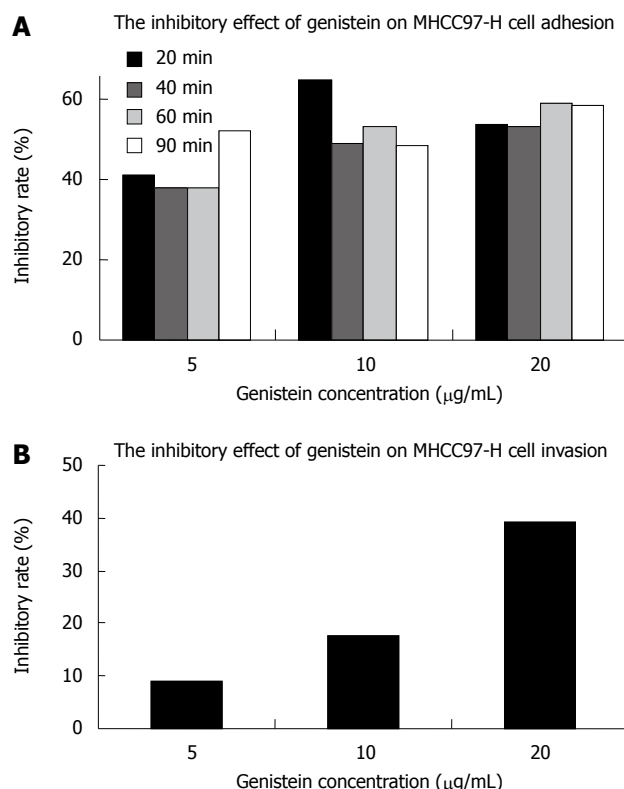

Figure 2 Inhibitory effects of genistein on adhesion and invasion of MHCC97-H cells. A: MHCC97-H cells were incubated for 20, 40, 60 and 90 min with various concentrations of genistein; B: MHCC97-H cells were incubated for 20 h with various concentrations of genistein.

genistein in fibronectin pre-coated 96-well microtiter plates at 20, 40, 60 and 90 min is shown in Table 1. Our results showed that genistein significantly inhibited tumor cell adhesion to fibronectin-coated substrates in a concentration-dependent fashion ($P < 0.05$), and the inhibitory effect of genistein on adhesion was more potent in the 10 and 20 µg/mL genistein groups. The inhibitory rate of genistein on MHCC97-H cell adhesion is shown in Figure 2.

We also investigated the capability of metastatic tumor cells to migrate through reconstituted basement membrane (Matrigel). The cells invading the lower surface of the filter through Matrigel in the control group, 5, 10, and 20 µg/mL genistein groups were 234.20 ± 12.36 /field, 213.60 ± 14.98 /field, 193.80 ± 19.92 /field, and 142.80 ± 23.66 /field, respectively. The inhibitory rate of invasion is shown in Figure 2. Our results showed that genistein inhibited the *in vitro* invasion of MHCC97-H cells. The inhibitory effect on invasion of MHCC97-H cells in the 20 µg/mL genistein group was more significant than that in the 5 and 10 µg/mL genistein groups ($P < 0.05$).

In vitro effects of genistein on cell cycle progression

The effects of genistein on the cell cycle in MHCC97-H cells were determined by flow cytometry. After treatment with genistein, the number of MHCC97-H cells in the G₀/G₁ phase increased significantly compared with control cells ($P < 0.05$). The number of cells in the G₂/M phase was decreased, but there was no statistical

Table 2 Effects of genistein on cell cycle progression in the MHCC97-H cell line

Treatment ($\mu\text{g/mL}$ genistein)	Cell cycle phase			Apoptosis (%)
	G ₀ /G ₁ (%)	G ₂ /M (%)	S (%)	
Control	59.12 \pm 3.89	10.95 \pm 6.41	29.93 \pm 2.52	1.18 \pm 0.01
5	67.86 \pm 2.36 ^a	4.08 \pm 1.82 ^a	28.06 \pm 0.55	3.92 \pm 1.63 ^a
10	69.53 \pm 2.13 ^a	6.80 \pm 0.48	23.65 \pm 1.76 ^b	7.84 \pm 1.72 ^b
20	71.85 \pm 3.60 ^a	8.84 \pm 4.07	19.31 \pm 1.51 ^b	18.90 \pm 4.98 ^b

^a $P < 0.05$, ^b $P < 0.01$ vs control. Cell cycle and apoptosis were evaluated by flow cytometric analysis on a FACScan cytofluorimeter. Values are mean \pm SD from experiments.

Figure 3 Western blotting analysis of protein expression and phosphorylation of FAK in MHCC97-H cells following genistein treatment. Lane 1: Genistein 5 $\mu\text{g/mL}$; Lane 2: Genistein 10 $\mu\text{g/mL}$; Lane 3: Genistein 20 $\mu\text{g/mL}$.

significance between the control group and the 10 and 20 $\mu\text{g/mL}$ genistein-treated groups ($P > 0.05$). S phase fractions decreased significantly in cells treated with 10 and 20 $\mu\text{g/mL}$ genistein ($P < 0.01$). The percentage of apoptotic cells in the genistein-treated groups increased significantly compared with the control group ($P < 0.05$). The results of the cell cycle analysis of MHCC97-H cells by flow cytometry are presented in Table 2.

Effects of genistein on protein expression and phosphorylation of FAK in MHCC97-H cells

The effect of genistein on expression and phosphorylation of FAK in MHCC97-H cells was determined using Western blotting. After treatment with genistein, the expression level of total FAK was decreased when the genistein concentration increased ($P < 0.05$). The optical density in the 10 $\mu\text{g/mL}$ and 20 $\mu\text{g/mL}$ genistein groups were significantly lower than that in the control group ($P < 0.05$). More interestingly, at the same time phosphorylated FAK also decreased. The 5 $\mu\text{g/mL}$ genistein treatment inhibited about 40% of FAK phosphorylation. These parameters were further significantly inhibited in the presence of genistein in a concentration-dependent fashion ($P < 0.05$). Data are shown in Figures 3 and 4.

Effects of genistein on tumor growth and metastasis in vivo

The anti-tumor activity of genistein was evaluated in nude mice bearing orthotopic tumor implants (Figure 5A). Treatment with genistein significantly inhibited local tumor growth, compared with the control

Figure 4 Effects of genistein on protein expression and phosphorylation of FAK. Black columns, protein expression of FAK; Open columns, phosphorylation of FAK. Values are mean \pm SD from experiments.

Figure 5 Autopsy and microphotographic appearance after orthotopic implantation. A: Autopsy of mice bearing orthotopic implantations. Rapid tumor growth occurred. Thirty-five days after tumor tissue implantation into the liver; B: Microphotography of lung metastasis by MHCC97-H cells. Thirty-five days after orthotopic implantation, MHCC97-H cells metastasized to the lungs, forming pulmonary metastatic lesions. HE, $\times 200$.

group. At the end of treatment, the tumor weight in the genistein group was significantly less than that in the control group (1.99 ± 2.07 g vs 2.63 ± 1.31 g, $P < 0.05$). Tumors in mice treated with genistein were reduced in weight by 24.3% compared with the control group.

After orthotopic implantation of tumor tissues, pulmonary metastases occurred in the recipient mice by day 35 (Figure 5B). Microscopy showed that the number of micrometastatic foci in the genistein group (12.3 ± 1.8) was significantly lower than that in the control group (12.3 ± 1.8 vs 16.6 ± 2.6 , $P < 0.05$).

DISCUSSION

Metastasis is a fundamental characteristic of cancer and the ultimate cause of most cancer mortality. Advances in surgical techniques and adjuvant therapies have proven useful in the treatment of primary tumors^[7]. However, metastasis remains a major cause of poor prognosis and death in cancer patients even after curative resection. The process of metastasis consists of sequential steps that include detachment, motility, invasion of the extracellular matrix, intravasation, circulation, adhesion, extravasation into the organ parenchyma and growth^[8]. The ability of cancer cells to form metastases depends on a set of unique biological properties that enable the malignant cells to complete all these steps of the metastatic process. Currently, only a few chemotherapeutic drugs are effective for the treatment of patients with malignant tumor metastasis, and there is a clear need to identify new anti-metastatic drugs^[9].

Genistein, an isoflavonoid abundant in soy beans, is a planar molecule with an aromatic A ring, has a second oxygen atom from that in the A ring, and has a molecular mass similar to those of the steroidal estrogens^[9-11]. Reports from epidemiological and experimental studies show that it plays an important role in the inhibition of tumors including breast cancer, prostate cancer, colon cancer, leukemia and melanoma^[12,13]. Genistein has a wide range of biological actions that suggest it may be of use in cancer treatment. Its molecular actions include: an inhibitory effect on protein tyrosine kinases, DNA topoisomerase I and II, and ribosomal S6 kinase; anti-estrogenicity; antioxidant activity; anti-angiogenesis activity; suppression of cell proliferation; induction of differentiation and modulation of apoptosis^[13-15]. However, few data are available on the effects of genistein on metastasis of HCC. The purpose of this study was to investigate the metastatic potential of genistein *in vitro* and *in vivo* in HCC and to gain primary insight into the underlying mechanism mediating the effects of genistein.

Several human and animal HCC cell clones have been established, but few of these have been suitable for the study of human HCC metastasis^[3,16,17]. However, most showed tumorigenicity when inoculated into experimental animals, and rarely did they demonstrate the full potential for distant metastases, as seen so frequently in patients. The metastatic HCC cell line MHCC97-H is characterized by high pulmonary metastasis potential and is a suitable cell line for the study of liver cancer metastasis^[3,18]. In this study, we found that genistein significantly inhibited MHCC97-H cell growth both *in vitro* and *in vivo*. The effect of genistein on MHCC97-H cells was concentration dependent; the *in vitro* inhibitory rates of tumor cell growth in the 10 µg/mL and 20 µg/mL genistein groups were about 58% and 80%, respectively. *In vivo*, tumor weight was significantly reduced by 24% in the genistein-treated group compared with the control group. We also found that genistein induced cell cycle progression arrest at the G₀/G₁ and G₂/M phases. These data are

in accordance with other reports which showed that genistein induced cell cycle progression arrest at the G₂/M phase and that the number of S phase cells decreased in a progressive way as the genistein incubation time was increased^[15,19,20]. Although the exact mechanisms of action of genistein have yet to be fully elucidated, induction of apoptosis may be partly responsible. In our studies, the percentage of MHCC97-H cells undergoing apoptosis was significantly higher in the genistein group than in the control group. This finding is consistent with apoptosis studies in breast, prostate and gastric cancer cell lines treated with genistein^[21,22].

The adhesion and invasiveness of tumor cells represents one of the several important steps necessary for the formation of metastases. Cell migration depends on adhesion between cells which is partly adjusted by integrin^[23]. We investigated the effect of genistein on the adhesive properties of MHCC97-H cells and found that genistein significantly inhibited MHCC97-H cell adhesion to fibronectin-coated substrates. The inhibition rate reached approximately 58% in the 20 µg/mL genistein group. This demonstrated that the reduction in cell adhesion caused by genistein may account for the ability of MHCC97-H cells to cross normal tissue boundaries and disperse to adjacent sites. Cell invasion was studied both *in vitro* and *in vivo* in our study. MHCC97-H cells which invaded the Matrigel to the lower surface of the Transwell filter were significantly inhibited in the genistein-treated groups compared with the control group. The inhibitory effect on invasion in the 20 µg/mL genistein group was 39%, which was significantly higher than that in the other groups. Our experiments with mice bearing orthotopic tumor implants further confirmed that treatment with genistein also significantly inhibited or halted lung metastasis of HCC, which correlated with the biological behavior *in vitro*.

FAK is a cytoplasmic tyrosine kinase which plays an important role in integrin-mediated signal transduction pathways closely related to cell adhesion, motility and growth. Upregulation of FAK expression is associated with oncogenesis, and a decrease in FAK is associated with loss of cell attachment, decreased migration and induction of apoptosis^[24]. We have reported that FAK is overexpressed in HCC, where the expression of FAK in invasive or metastatic HCC is significantly higher than that in non-invasive or non-metastatic HCC^[25]. Therefore, FAK seems to be an important pharmacologic target site. In this study, a significant downregulation of expression and phosphorylation of FAK after genistein treatment was observed, suggesting that genistein may serve as a potentially important anticancer agent for HCC progression by blocking the FAK signaling process, which plays a crucial role in the invasion and metastasis of HCC.

In conclusion, both *in vitro* and *in vivo* studies showed that genistein is a promising agent for inhibiting the metastatic potential of HCC. It may affect HCC progression as a result of its effects on cell cycle progression and apoptosis. However, because its precise mechanism of activity and its targets remain unclear, further in-depth studies of the molecular mechanism are

needed to establish the scientific basis for the possible use of genistein in the treatment of HCC metastasis.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the leading causes of cancer related deaths in the world. A high incidence of metastasis accounts for the poor survival of HCC patients, and research into interventions for liver cancer metastasis has special priority in the anti-cancer campaign.

Research frontiers

Genistein, an isoflavonoid abundant in soy beans, has a wide range of biological actions in the inhibition of tumors including breast cancer, prostate cancer, colon cancer, leukemia and melanoma. However, few data are available on the effects of genistein on metastasis of HCC. In this study, the authors demonstrate that genistein inhibited the metastasis of HCC *in vitro* and *in vivo*. Genistein appears to be a promising agent for inhibiting the metastatic potential of HCC.

Innovations and breakthroughs

In this study, genistein was found to significantly inhibit the growth, attachment and invasion of MHCC97-H cells *in vitro* in a concentration-dependent fashion. The expression and phosphorylation of FAK in MHCC-97H cells were also decreased by genistein. In addition, our study on nude mice bearing orthotopic tumor implants showed that genistein significantly inhibited lung metastasis of MHCC97-H cells.

Applications

The findings from this study support the idea that genistein may serve as a potentially important anticancer agent for HCC progression by blocking the FAK signaling process.

Terminology

Genistein is a planar molecule with an aromatic A ring, has a second oxygen atom from that in the A ring, and has a molecular mass similar to those of the steroidal estrogens. It binds to and inhibits protein tyrosine kinase, thereby disrupting signal transduction and inducing cell apoptosis and differentiation.

Peer review

This paper reports the effect of genistein exposure on the growth, adhesion, migration and metastases of a highly metastatic HCC cell line MHCC97-H. They observed that genistein exposure significantly inhibited growth, adhesion to fibronectin, and invasion of the cell line. The paper is well written and has novel data.

INTRODUCTION

Hepatitis B virus (HBV) is one of the major infectious diseases worldwide and is responsible for significant morbidity and mortality, particularly in developing countries^[1]. Of patients with chronic HBV infection, a quarter develop chronic liver disease, which can be associated with hepatoma in some cases^[2,3]. Increasing evidence indicates that genetic factors influence the natural history of HBV infection. Recent studies have proposed that a number of polymorphisms influence the progression of patients with HBV infection^[4,5].

The glucose-regulated protein 78 (*GRP78*), also called heat shock 70 ku protein 5, is a stress-inducible endoplasmic reticulum (ER) calcium-binding chaperone^[6]. The *GRP78* pathway is one of the most important responders to disease-associated stress^[7]. An elevated *GRP78* level generally correlates with HBV infection^[8-10]. As a stress-associated gene, *GRP78* may be a contributing factor or marker of stress-associated diseases, such as hepatitis B. HBV invasion and other physiopathologic changes cause a large amount of unfolding or false-folding protein accumulation in the ER, which in turn induces stress in the ER and expression of *GRP78*^[6,11].

Abstract

AIM: To examine the association between -86 bp (T > A) in the *glucose-regulated protein 78* gene (*GRP78*) and hepatitis B virus (HBV) invasion.

METHODS: DNA was genotyped for the single-nucleotide polymorphism by polymerase chain reaction followed by sequencing in a sample of 382 unrelated HBV carriers and a total of 350 sex- and age-matched healthy controls. Serological markers for HBV infection were determined by enzyme-linked immunosorbent assay kits or clinical chemistry testing.

RESULTS: The distributions of allelotype and genotype in cases were not significantly different from those in controls. In addition, our findings suggested that neither alanine aminotransferase/hepatitis B e antigen nor

The aim of the present study was to elucidate the potential association of -86 bp T > A, a new single-nucleotide polymorphism (SNP) from the estimated translation start site of *GRP78*, as a host genetic factor with the risk and acute exacerbation of HBV infection in a Chinese population.

MATERIALS AND METHODS

Subjects

A total of 382 unrelated HBV carriers (233 males and 149 females) between 24 and 39 years old (average age 30.5 ± 7.2 years) and a total of 350 sex- and age-matched healthy volunteers (203 males and 147 females) aged between 22 and 36 years old (average age 27.8 ± 7.0 years) who had no history of HBV infection or other conspicuous diseases from the Affiliated Tumor Hospital of Guangzhou Medical College were included in this study. The two groups had a similar frequency of distribution in age and gender ($P > 0.05$) (Table 1). The diagnosis of HBV infection was based on the presence of hepatitis B surface antigen and hepatitis B e antigen (HBeAg) or e antibodies, together with the absence of anti-HBs, for at least 36 mo prior to enrolment. The present study was approved by the Ethics Committee of Sun Yat-sen University and adhered to the tenets of the Declaration of Helsinki. Informed consent was also obtained from each participant.

PCR and resequencing

Blood samples were obtained and stored at -80°C until DNA extraction. Genomic DNA was extracted from peripheral blood leukocytes using the QIAGEN QIAamp DNA Mini Blood Kit (Hilden, Germany). The primers for PCR and resequencing were designed based on the published *Homo sapiens GRP78* DNA sequence (GenBank access No. NT_008470.18). Oligonucleotide primers were synthesized on a oligonucleotide synthesizer (Applied Biosystem, ABI) by Shanghai Sangon Biological Engineering Technology & Services Co., Ltd. (Shanghai, China).

PCRs were performed in 50 μL reaction systems containing 200 ng sample DNA, 5 μL of $10 \times \text{Ex Taq}$ buffer (Mg^{2+} free; Takara, Japan), 2 mmol/L MgCl_2 , 20 pmol of each primer (forward primer, AAGGGAGAACAAGCAGTAG and reverse primer, TGTCCCTGGAATTGTAAGC), 0.2 mmol/L of each deoxynucleoside triphosphate, and 5 U *Ex Taq* polymerase (Takara, Shiga, Japan). The amplification was performed using initial denaturation at 94°C for 10 min followed by 35 cycles of 94°C for 45 s, 56°C for 45 s and 72°C for 90 s on a GeneAmp 9700 thermal cycler (Perkin-Elmer Applied Biosystems, Inc., Foster City, CA, USA).

Resequencing was performed with the primer ATC CGC AAC CCC ACT TAC C, *Taq* polymerase, ABI PRISM® BigDye™ terminators on an ABI 3730xl DNA Analyzer (Applied Biosystems, Inc., Foster City, CA, USA).

¹The data were calculated by logistic regression with adjusted for age and gender. OR: Odds ratio; CI: Confidence interval; HBV: Hepatitis B virus; SNP: Single-nucleotide polymorphism.

Serological testing

Serological markers for HBV infection were determined by commercially available enzyme-linked immunosorbent assay kits (Sina-American Biotechnology Co., Ltd., China) or clinical chemistry testing. The normal range for serum alanine aminotransferase (ALT) is 0-40 IU/L. The extraction and quantification of serum HBV-DNA were carried out using a quantitative HBV PCR fluorescence diagnostic kit (Shenzhen PG Biotech., China) in the LightCycler Systems (Roche Diagnostic, Rotkreuz, Switzerland). HBV DNA levels were expressed as log copies/mL.

Statistical analysis

χ^2 test was used to determine whether there was a significant difference between cases and controls in terms of gender. Mann-Whitney *U*-test was used to test the difference among the age groups. Hardy-Weinberg equilibrium (HWE) of genotype distribution among cases and controls was carried out using the Pearson χ^2 test. A significant difference in polymorphism between cases and controls (or between different subgroup cases) was ascertained by unconditional logistic regression model adjusted for age and gender, in which the odds ratios (ORs) and 95% confidence intervals (CIs) were acquired synchronously. One way analysis of variance (ANOVA) and the Bonferroni test were used to evaluate the association between serum HBV DNA levels and alleles/genotypes in cases. All statistical tests were two-sided and *P* values less than 0.05 were considered statistically significant.

¹P values for ALT > 40 IU/L cases vs ALT ≤ 40 IU/L cases; ²P values for HBeAg positive cases vs HBeAg negative cases. +: Positive; -: Negative.

RESULTS

The observed genotype frequencies conformed to the HWE in both cases and controls (data not shown). According to the logistic regression analysis with adjustment for age and gender, the distributions of allelotype and genotype in HBV cases were not significantly different from those in the controls ($P > 0.05$, respectively) (Table 2).

To assess the possible association between the polymorphism and acute exacerbation of HBV infection, the cases were divided into two groups based on a normal or abnormal ALT value, or the absence or presence of HBeAg. There were no significant differences in allele frequencies or genotype distributions of -86 bp (T > A) between ALT abnormal cases (ALT > 40 IU/L) and ALT normal cases (ALT ≤ 40 IU/L), or between HBeAg positive cases and HBeAg negative cases ($P > 0.05$, respectively) (Table 3). In addition, the viral load demonstrated no significant differences among different alleles (OR: 3.96, 95% CI: 3.34-4.61, $P = 0.165$ for allele A) or genotypes (OR: 3.95, 95% CI: 3.33-4.64, $P = 0.175$ for AT) compared with the respective reference groups (OR: 3.60, 95% CI: 3.50-3.68 for allele T; OR: 3.57, 95% CI: 3.46-3.72 for genotype TT) by ANOVA and Bonferroni testing (Figure 1).

DISCUSSION

The findings in this study indicate that the -86 bp variation is not susceptible to HBV invasion and acute exacerbation.

As some of the polymorphisms may reflect the risk of onset and the severity of disease, assessing the effect of variations on the risk and progression of HBV invasion is important^[12,13]. The role of *GRP78* as a predisposing gene in the pathogenesis of viral diseases such as HBV has not been previously studied. Although no association was noted with *GRP78* using the -86 bp (T > A) SNP marker, there are a number of other loss/gain-of-function SNPs and haplotypes in the *GRP78* gene that have not been included in this study, which need further evaluation to conclusively exclude *GRP78* as a susceptibility locus.

The data presented in this study also demonstrate that neither ALT/HBeAg nor HBV-DNA were associated with the allele/genotype variation in HBV infected individuals. Because ALT, HBeAg and HBV-DNA are markers for acute infection of HBV^[14,15], we

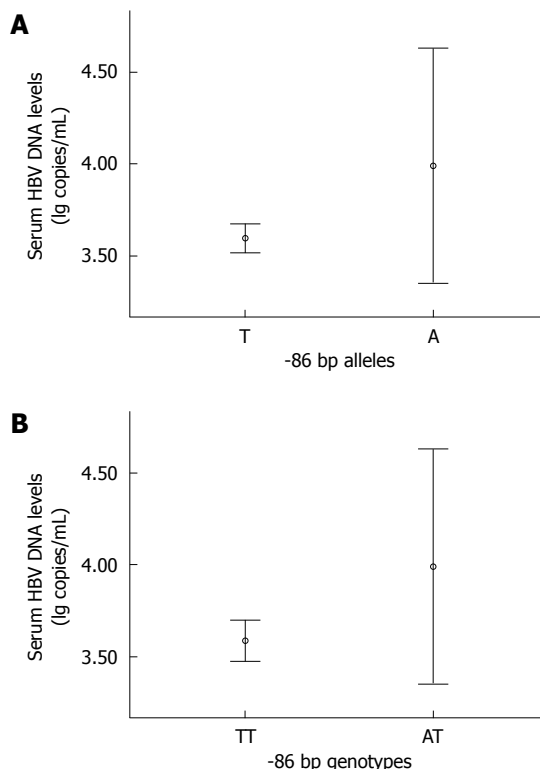

Figure 1 Association between serum HBV DNA levels and alleles and genotypes in the new SNP (-86 bp T > A) of *GRP78* gene. A: Compared with the reference group (allele T group, OR: 3.60, 95% CI: 3.50-3.68), allele A group (OR: 3.96, 95% CI: 3.34-4.61, $P = 0.165$) demonstrated no significant difference in HBV DNA levels; B: Compared with the reference group (genotype TT group, OR: 3.57, 95% CI: 3.46-3.72), genotype AT group (OR: 3.95, 95% CI: 3.33-4.64, $P = 0.175$) demonstrated no significant difference in HBV DNA levels.

can infer that -86 bp (T > A) is not associated with acute exacerbation of HBV invasion.

Moreover, a prospective study on the influence of polymorphisms on disease risk and progression mainly explored a statistical association between alleles/genotypes and clinical events^[16]. Therefore, the present study suggests a lack of association between the -86 bp and clinical risk as well as acute exacerbation. These data, however, do not exclude a possible physiopathological role of the *GRP78* in HBV progression.

To the best of our knowledge, this new found SNP in a Chinese Han population has not been deposited in a public database (<http://www.ncbi.nlm.nih.gov/SNP>). Although the functional effects of this polymorphism have not been elucidated, our data show that the specific

polymorphism evaluated in this study is not related to HBV susceptibility or acute exacerbation and suggest that, at least in this Chinese population, its role in HBV invasion could be less than expected. However, it must be underlined that this polymorphism should not be completely eliminated as studies with a larger sample size may demonstrate the small differences found in this study to be statistically significant.

ACKNOWLEDGMENTS

We greatly acknowledge the participants and their families, who took part in this study.

COMMENTS

Background

Highly variable disease outcomes in infected individuals cannot be fully explained by differences in viral or environmental factors but also involve host genetic susceptibility. Increasing data show that glucose-regulated protein 78 (GRP78) plays a crucial role in the proper folding of hepatitis B virus (HBV) protein. Therefore, we strongly believed that the influence of polymorphism on the risk and progression of HBV invasion should be studied so as to determine whether there is a statistical association between the -86 bp (T > A) genotypes and clinical events.

Research frontiers

In general, the present study is part of a series of research studies involving HBV infection and is aimed at mutational analysis of the *GRP78* gene among HBV carriers. To the best of our knowledge, this is the first study where an attempt has been made to correlate a new found gene mutation (-86 bp T > A) with HBV risk among Han Chinese.

Innovations and breakthroughs

The -86 bp T > A polymorphism in the *GRP78* gene is not related to the clinical risk and acute exacerbation of HBV invasion.

Applications

Genetic differences in the gene related to virus invasion may help us to predict an individual's susceptibility of developing serious disease and assist early detection which can substantially improve the cure rate. This study found that the -86 bp (T > A) is not a susceptible candidate locus, and future research should focus on its potential role in liver cancer risk.

Terminology

Human *GRP78* gene is located on 9q33-q34.1. GRP78 protein is a molecular chaperone that is critical to the folding, maturation and transport of proteins out of cells.

Peer review

The authors examined the association of a new polymorphism (-86 bp T > A) in the *GRP78* gene and risk of HBV infection. They did not find any association between this SNP and risk or acute exacerbation of HBV invasion. This study gives further evidence that *GRP78* is not directly involved in HBV infection.

(0.89-2.48, $P = 0.503$) for all treatment mortality, 1.33 (0.94-1.88, $P = 0.04$) for the rate of adverse treatment, 1.38 (1.23-1.63, $P = 0.0002$) for local-regional cancer recurrence, 1.28 (0.85-1.58, $P = 0.60$) for distant cancer recurrence, and 1.27 (0.86-1.65, $P = 0.19$) for all cancer recurrence. A complete pathological response to chemoradiotherapy occurred in 10%-45.5% of patients. The 5-year survival benefit was most pronounced when chemotherapy and radiotherapy were given concurrently (OR: 1.45, 95% CI: 1.26-1.79, $P = 0.015$) instead of sequentially (OR: 0.85, 95% CI: 0.64-1.35, $P = 0.26$).

CONCLUSION: Compared with surgery alone, neoadjuvant chemoradiotherapy can improve the long-term survival and reduce local-regional cancer recurrence. Concurrent administration of neoadjuvant chemoradiotherapy was superior to sequential chemoradiotherapy.

Abstract

AIM: To investigate the role of neoadjuvant chemoradiotherapy in prognosis and surgery for esophageal carcinoma by a meta-analysis.

METHODS: PubMed and manual searches were done to identify all published randomized controlled trials (RCTs) that compared neoadjuvant chemoradiotherapy plus surgery (CRTS) with surgery alone (S) for esophageal cancer. According to the test of heterogeneity, a fixed-effect model or a random effect model was used and the odds ratio (OR) was the principal measure of effects.

RESULTS: Fourteen RCTs that included 1737 patients were selected with quality assessment ranging from A to C (Cochrane Reviewers' Handbook 4.2.2). OR (95% CI, P value), expressed as CRTS *vs* S (values > 1 favor CRTS arm), was 1.19 (0.94-1.48, $P = 0.28$) for 1-year survival, 1.33 (1.07-1.65, $P = 0.69$) for 2-year survival, 1.76 (1.42-2.19, $P = 0.11$) for 3-year survival, 1.41 (1.06-1.87, $P = 0.11$) for 4-year survival, 1.64 (1.28-2.12, $P = 0.40$) for 5-year survival, 0.82 (0.39-1.73, $P < 0.0001$) for rate of resection, 1.53 (1.33-2.84, $P = 0.007$) for rate of complete resection, 1.78 (1.14-2.78, $P = 0.79$) for operative mortality, 1.12

INTRODUCTION

Esophageal cancer is one of the most frequently occurring malignancies and the seventh leading cause of cancer-related deaths in the world^[1]. The majority of patients present with an advanced stage of disease and long-term survival is poor^[2]. Esophagectomy remains a standard treatment for patients with resectable esophageal cancer, however, the 5-year survival rate is only 10%-20% in patients with advanced esophageal carcinoma

treated with surgery alone^[3-5]. Treatment failure mainly results from recurrence or metastasis. Most patients with seemingly resectable esophageal cancer have little prospect for cure. The proximity of the esophagus to vital mediastinal structures often compromises the completeness of cancer resection, and micrometastatic systemic disease is often present at the time of initial cancer diagnosis. These two limitations of surgical therapy set the stage for cancer recurrence, both local-regional and systemic. Radiotherapy can control local-regional esophageal cancer and chemotherapy, usually including cisplatin and 5-fluorouracil, has both local and systemic antineoplastic activity. Several studies have also suggested improved long-term survival rates with combined chemotherapy, radiotherapy and surgery in patients with resectable esophageal cancer^[6-8].

In addition, esophageal cancer patients seem to tolerate preoperative (neoadjuvant) chemoradiotherapy better than postoperative (adjuvant) chemoradiotherapy. And based on these premises, many phase III trials of neoadjuvant chemoradiotherapy followed by surgery have been done. Although many trials have generated promising results, there is a lingering concern, especially among surgeons, that neoadjuvant chemoradiotherapy may cause an unacceptable increase in perioperative morbidity and mortality. Randomized controlled trials (RCTs) have been performed to address these issues, but the results are not consistent. Many of the RCTs enrolled small numbers of patients, thus limiting their power to detect a treatment benefit.

So we performed a meta-analysis of RCTs that compared chemoradiotherapy plus surgery (CRTS) with surgery alone (S) in patients with resectable esophageal carcinoma.

MATERIALS AND METHODS

PubMed and manual searches were done (independently and in duplicate) to identify all published (manuscripts and abstracts) RCTs that compared CRTS with S for resectable esophageal cancer. Trials were not excluded because of cancer histology (squamous or adenocarcinoma) or language of publication. The PubMed search was done on PubMed (available at: <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi>). A set was created using the terms “esophageal neoplasms/surgery OR esophagectomy OR oesophagectomy OR esophageal cancer OR oesophageal cancer.” This yielded 37 604 citations (June 30, 2009). Another set was created using the terms “antineoplastic agents OR chemotherapy OR radiotherapy.” This yielded 2 448 725 citations. The two sets were combined using the Boolean operator “AND” to give 8974 documents on chemotherapy, radiotherapy, and surgery for esophageal cancer. This set was limited to “RCT” to yield 340 documents. These documents were reviewed to identify RCTs that compared CRTS with S. Fourteen studies were identified and retrieved^[9-22]. We did not attempt to identify unpublished RCTs. In total, 14 RCTs were found and these trials form the basis of the meta-analysis.

Given the limited number of RCTs, we designed the article selection process to be inclusive as opposed to exclusive. Meanwhile, trial validity assessment was done independently and in duplicate, and a trial quality assessment was assigned (A to C) according to the Cochrane Reviewers' Handbook 4.2.2^[23]. If reviewers disagreed on the quality assessment, discrepancies were identified and a consensus was reached. Trial data abstraction was also done independently and in duplicate, and any discrepancies in data abstraction were examined further and resolved by consensus.

Outcomes assessed by meta-analysis included 1-year survival, 2-year survival, 3-year survival, 4-year survival, 5-year survival, rate of resection, rate of complete (R0) resection, operative mortality, the rate of adverse treatment, all treatment mortality, local-regional cancer recurrence, distant cancer recurrence, and all cancer recurrence. The principle of treatment intention was used when calculating frequency of events, other than postoperative events (operative mortality, postoperative treatment complications). For all events, we used the most reliable data available. Raw data were considered the most reliable data, followed by percentages, and derivation of survival from graphically presented survival curves. Resection was defined as any resection, curative or palliative; esophageal bypass and exploratory surgery were not included. Complete resection was defined as a microscopically complete (R0) resection performed with curative intent. Most of the trials expressed operative mortality as a 30-d mortality, so a 30-d mortality was used for data analysis. Postoperative treatment complications included anastomotic leaks, pneumonia, respiratory failure, etc. All treatment mortality was obtained by adding preoperative deaths (usually secondary to chemoradiotherapy) and postoperative deaths. The most complete summation of these deaths was used from each individual trial. Local-regional cancer recurrence was defined as any local regional recurrence, as against isolated local-regional recurrence. Similarly, distant cancer recurrence was defined as any distant recurrence. All cancer recurrences were defined as any type (local, regional, distant), or combination of types, of cancer recurrence. Sensitivity analyses were performed on the 5-year survival data to identify the effects of cancer histology (squamous or adenocarcinoma) and scheduling of chemoradiotherapy (concurrent or sequential) on survival.

According to the test of heterogeneity, we selected a fixed effect meta-analysis model or a random effect model. This gives conservative confidence intervals and minimizes the risk of erroneously assigning benefit to the treatment group. Odds ratio (OR) was the principal measure of effect. ORs are presented as a point estimate with 95% confidence intervals (CI) and *P* values in parentheses. ORs are calculated as treatment (CRTS) vs control (S), and a number greater than one favors the CRTS group (higher frequency of desirable events). Funnel plot analysis did not suggest publication bias against negative trials^[24]. Review Manager 4.2 [Review Manager (Rev Man), (Computer program), Version 4.2 for Windows, Oxford, England: The Cochrane Collaboration, 2003] software was used.

Comparison: 01 CRTS vs S

Outcome: 03 3 yr-survival rate

Figure 1 Three-year survival (OR: 1.76, 95% CI: 1.42-2.19, $P = 0.11$). OR: Odds ratio; CI: Confidence interval; CRTS: Neoadjuvant chemoradiotherapy; S: Surgery alone.

Median survival data could not be combined using meta-analysis methods because there was insufficient documentation of original patient data in many trials.

RESULTS

The two trial investigators agreed on the selection of fourteen RCTs^[9-22]. Combining these trials yielded data on 1737 patients. The RCT quality assessments included ten B, but four A, due to the inherent difficulty in blinding a treatment such as chemoradiotherapy. Survival of the two patient groups was similar at 1-year, but 2-year, 3-year, 4-year and 5-year-survival in CRTS group was superior to that in S group (Figures 1 and 2). OR (95% CI, P value), expressed as CRTS *vs* S (values > 1 favor CRTS arm), was 1.19 (0.94-1.48, $P = 0.28$) for 1-year survival, 1.33 (1.07-1.65, $P = 0.69$) for 2-year survival, 1.76 (1.42-2.19, $P = 0.11$) for 3-year survival, 1.41 (1.06-1.87, $P = 0.11$) for 4-year survival, and 1.64 (1.28-2.12, $P = 0.40$) for 5-year survival.

Five-year survival meta-analysis was repeated with RCTs separated according to the histology (squamous or adenocarcinoma) and chemoradiotherapy scheduling (concurrent or sequential). If only RCTs addressing squamous cancer were considered, the 5-year survival advantage of neoadjuvant chemoradiotherapy and surgery was similarly apparent (OR: 1.53, 95% CI: 1.12-2.1, $P = 0.40$). Restricting the analysis to RCTs of adenocarcinoma was not feasible since there were just two trials of this type^[12,15], moreover, only one study reported the 5-year survival. If meta-analysis was restricted to RCTs using concurrent chemoradiotherapy, the 5-year survival

strongly favored the combination of CRTS (OR: 1.45, 95% CI: 1.26-1.79, $P = 0.015$). Conversely, RCTs using sequential chemoradiotherapy did not demonstrate a survival benefit at 5 years (OR: 0.85, 95% CI: 0.64-1.35, $P = 0.26$).

Although the patients treated with surgery alone tended to undergo an esophageal resection than those treated with CRTS, there was no significance (OR: 0.82, 95% CI: 0.39-1.73, $P < 0.0001$). However, patients treated with CRTS had a higher rate of complete resection than those treated with S (OR: 1.53, 95% CI: 1.33-2.84, $P = 0.007$). Data analysis for the CRTS showed a complete pathological response in 10%-45.5% of patients. In regard to the extent and quality of surgical resection and lymphadenectomy, it was difficult to discriminate from the included studies.

Moreover, the rate of adverse treatment events showed no significant difference between the two groups (OR: 1.33, 95% CI: 0.94-1.88, $P = 0.04$). However, there was a trend in favor of surgery alone for operative mortality (OR: 1.78, 95% CI: 1.14-2.78, $P = 0.79$; Figure 3) although there was no significant difference in all treatment mortality between CRTS and S groups (OR: 1.12, 95% CI: 0.89-2.48, $P = 0.503$).

As far as cancer recurrence is concerned, patients treated with CRTS had fewer local-regional cancer recurrences (OR: 1.38, 95% CI: 1.23-1.63, $P = 0.0002$). However, distant recurrence (OR: 1.28, 95% CI: 0.85-1.58, $P = 0.60$) and all cancer recurrence (OR: 1.27, 95% CI: 0.86-1.65, $P = 0.19$) were not statistically significant between the two groups of patients. A funnel plot, with regard to the publication bias of all analysis, showed the

DISCUSSION

Surgical resection is currently the preferred treatment for esophageal cancer if a patient is fit enough to un-

dergo major surgery and the tumor is considered to be resectable without evidence of distant metastases (cT₁₋₃ N₀₋₁ M₀). However, surgery as a solitary treatment modality for esophageal cancer remains dissatisfied. To date, assorted multimodality treatments have been investigated^[25-28]. Neither neoadjuvant radiotherapy and surgery, nor surgery and adjuvant radiotherapy, has

Figure 4 A funnel plot about 2-year survival with regard to the publication bias of all analysis, shows the basic symmetrical and inverted funnel-shaped graphics.

shown a significant survival advantage for these combinations of surgery and radiotherapy^[29,30]. Postoperative chemotherapy is frequently employed to prevent, delay or treat systemic metastases in patients with esophageal carcinoma, however, RCTs supporting the use of adjuvant chemotherapy are scarce, which showed no benefit for surgery followed by chemotherapy^[31,32]. In addition, some RCTs have compared neoadjuvant chemotherapy plus surgery with surgery alone^[33,34]. A complete pathological response after neoadjuvant chemotherapy was rare. Taken together, current neoadjuvant chemotherapy regimes remain not effective enough to improve the overall survival^[35,36].

The CRTS, an intuitively appealing treatment strategy, has brought about dramatic clinical and pathological responses in randomized esophageal cancer trials^[37,38]. Both chemotherapy and radiotherapy may be active against different tumor cell population, the chemotherapy may be effective against micrometastases while radiation is spatially cooperative. Neoadjuvant chemoradiotherapy can facilitate resection by down-staging tumors^[39,40]. However, whether or not CRTS actually increases long-term survival remains controversial, meanwhile CRTS seems to increase the morbidity and mortality of esophagectomy, so it is uncertain whether such a potential survival benefit outweighs the morbidity caused by such a treatment. A surgery alone is therefore still considered to be appropriate in randomized phase III studies for patients with esophageal cancer.

As yet only few meta-analyses examining the effectiveness of CRTS in patients with esophageal cancer has been published, and the previous analysis mainly focused on the 3-year survival^[55,36]. In contrast, our analysis pooled later survival data (up to 5-year survival) and more RCTs (up to 14 studies), which is more exhaustive. Our data contained the most cases (up to 1737 patients), meanwhile our funnel plot showed little publication bias. For all of these reasons, our findings may be more robust. Our meta-analysis of RCTs showed a long-term

survival benefit for the neoadjuvant chemoradiotherapy and surgery for resectable esophageal cancer. The survival benefit is involved in improved local-regional cancer control brought about by the neoadjuvant arm. Nevertheless, CRTS did not significantly reduce the incidence of distant recurrence. The sensitivity analysis of this regime showed the advantage of concurrent chemoradiotherapy, with maximal antineoplastic synergy between chemotherapeutic agents and radiation treatment, as compared with sequential chemoradiotherapy.

There was conspicuous difference between resection and complete resection rates for the two groups. More patients treated with S likely underwent esophageal resection, but more patients treated with CRTS likely underwent a complete resection. This indicates that CRTS downstages tumors and facilitates complete resection, which is also supported by the lower rate of local-regional cancer recurrence in the neoadjuvant chemoradiotherapy group. Although there was no significant difference for all treatment mortality between CRTS and S group (OR: 1.12, 95% CI: 0.89-2.48, $P = 0.503$) and adverse treatment events (OR: 1.33, 95% CI: 0.94-1.88, $P = 0.04$), our analysis showed a significant trend with respect to increased operative mortality (OR: 1.78, 95% CI: 1.14-2.78, $P = 0.79$) in the CRTS group. It is no doubt that surgeons will undertake a challenging esophagectomy resulting from operative difficulty and postoperative complications when performed after neoadjuvant chemoradiotherapy. For example, radiation might contribute to the failure of anastomotic leak and postoperative acute lung injury. Whether or not the survival benefit of neoadjuvant chemoradiotherapy can be negated by an increase in postoperative deaths has brought about extensive concerns.

In conclusion, this meta-analysis of RCTs that compared CRTS with S for resectable esophageal carcinoma showed a long-term survival benefit and reduced local-regional cancer recurrence for neoadjuvant chemoradiotherapy. Moreover, concurrent neoadjuvant chemoradiotherapy is more effective. CRTS has a higher rate of complete (R0) resection. There is no significant difference, but a trend of lowered rate of esophageal resection. In addition, it is concerned that this neoadjuvant approach is associated with increased mortality.

COMMENTS

Background

Esophagectomy is a standard treatment for resectable esophageal carcinoma but relatively few patients are cured. Combined neoadjuvant chemoradiotherapy with surgery may improve survival but there is concern about treatment morbidity.

Research frontiers

This meta-analysis investigated the survival data (up to 5-year survival) and RCTs (up to 14 studies).

Innovations and breakthroughs

Compared with surgery alone, neoadjuvant chemoradiotherapy and surgery improved the 3-year and 5-year survival and reduced local-regional cancer recurrence. It was associated with a lower rate of esophageal resection, but a higher rate of complete (R0) resection and operative mortality. There was a

nonsignificant trend toward the increased treatment mortality with neoadjuvant chemoradiotherapy. Concurrent administration of neoadjuvant chemotherapy and radiotherapy was superior to sequential chemoradiotherapy.

Applications

The study can be applied as a guidance of neoadjuvant chemoradiotherapy in prognosis and surgery for esophageal carcinoma.

Peer review

The manuscript gives results from a meta-analysis on the effects of neoadjuvant chemoradiotherapy on survival for esophageal carcinoma. The authors performed and reported a detailed literature search and analyzed 14 publications with regard to several survival end-points. The topic is interesting and statistical methods are appropriate. In the discussion, the authors describe that their meta-analysis is more detailed than previous ones which focus on the 3-year survival.

Abstract

AIM: To retrospectively evaluate the management and outcome of venous obstruction after living donor liver transplantation (LDLT).

METHODS: From February 1999 to May 2009, 1 intraoperative hepatic vein (HV) tension induced HV obstruction and 5 postoperative HV anastomotic stenosis occurred in 6 adult male LDLT recipients. Postoperative portal vein (PV) anastomotic stenosis occurred in 1 pediatric left lobe LDLT. Patients ranged in age from 9 to 56 years (median, 44 years). An air balloon was used to correct the intraoperative HV tension. Emergent surgical reoperation, transjugular HV balloon dilatation with stent placement and transfemoral venous HV balloon dilatation was performed for HV stenosis on days 3, 15, 50, 55, and 270 after LDLT, respectively. Balloon dilatation followed with stent placement *via* superior mesenteric vein was performed for the pediatric PV stenosis 168 d after LDLT.

RESULTS: The intraoperative HV tension was corrected with an air balloon. The recipient who underwent emergent reoperation for hepatic stenosis died of hemorrhagic shock and renal failure 2 d later. HV balloon dilatation *via* the transjugular and transfemoral venous approach was technically

successful in all patients. The patient with early-onset HV stenosis receiving transjugular balloon dilatation and stent placement on the 15th postoperative day left hospital 1 wk later and disappeared, while the patient receiving the same interventional procedures on the 50th postoperative day died of graft failure and renal failure 2 wk later. Two patients with late-onset HV stenosis receiving balloon dilatation have survived for 8 and 4 mo without recurrent stenosis and ascites, respectively. Balloon dilatation and stent placement *via* the superior mesenteric venous approach was technically successful in the pediatric left lobe LDLT, and this patient has survived for 9 mo without recurrent PV stenosis and ascites.

CONCLUSION: Intraoperative balloon placement, emergent reoperation, proper interventional balloon dilatation and stent placement can be effective as a way to manage hepatic and PV stenosis during and after LDLT.

INTRODUCTION

Vascular complications after liver transplantation (LT) include occlusion or stenosis at the site of anastomosis in the hepatic artery, portal vein (PV) and hepatic vein (HV). Venous obstruction after LT, including HV outflow obstruction and PV stenosis, is a relatively uncommon but important complication after LT especially living donor liver transplantation (LDLT) and split liver transplantation (SLT). The incidence of HV

obstruction varies from 5.3% in a series of LDLTs^[1] to 12.9% in a series of reduced-size livers^[2]. It occurs more frequently in pediatric liver transplants where a small graft may twist around the HV anastomosis. When hepatic outflow obstruction occurs, hepatic congestion can cause massive ascites and hepatic dysfunction. With the increase in cases of LDLT and SLT, management of HV outflow obstruction has become an important issue^[3-8].

PV stenosis is a relatively rare complication after LT and it sometimes leads to life threatening events due to gastrointestinal bleeding or graft failure. PV stenosis affect 2%-14% of transplant recipients in children^[5,9-11]. With LDLT, left lobe segments are frequently used as grafts^[12]. During left lobe graft transplantation, the extrahepatic PV slants to the right posterior, and the PV rotates backward to the left anterior into the liver. Stenotic areas almost always exist near the flexion. As the liver graft grows, it may kink or compress the flexion.

Recently, interventional procedures including balloon dilatation and stent placement have been widely accepted as treatments of choice for the management of venous obstruction after LT. Since the first successful treatment using percutaneous balloon dilatation by Raby *et al*^[13], several methods of portal venoplasty have been reported for the treatment of PV stenosis using percutaneous transhepatic^[14], transjugular intrahepatic^[15], transfemoral venous^[13], or transileocolic venous^[16,17] approaches. Stent placement has also been widely accepted as a treatment of choice for the management of venous obstruction after LT^[18,19]. Metallic stents have been used to treat recurrent and elastic stenosis^[20].

Thus, the aim of this study was to evaluate retrospectively the management and outcome of HV and PV stenosis after LDLT in one single center.

MATERIALS AND METHODS

Patients

Between February 1999 and May 2009, 223 cases of LDLT were performed in West China Hospital. A total of 7 male recipients developed postoperative hepatic and/or PV obstruction/stenosis (Table 1). Patients ranged in age from 9 to 56 years (median, 44 years). HV obstruction/stenosis was diagnosed in 6 adult male patients after LDLT, including 1 intraoperative HV tension, 3 early-onset HV-vena cava anastomosis stenosis, and 2 late-onset HV-vena cava anastomosis stenosis after LDLT. One intraoperative HV tension was suggested by hepatic congestion and confirmed at the same time during LDLT. HV tension was induced by the small right lobe liver graft falling into the deep right upper abdomen. Three early-onset HV stenosis was confirmed 3, 14 and 15 d post LDLT, respectively. Two late-onset HV-vena cava anastomosis stenosis was diagnosed 51 and 180 d after LDLT, respectively. Extrahepatic PV anastomotic stenosis was diagnosed in 1 male pediatric patient who was treated with left lobe LDLT 140 d post LDLT.

Postoperative HV and PV stenosis was suggested by

intractable ascites and confirmed by means of Doppler ultrasonography (HV flow velocity < 10 cm/s; PV flow velocity < 12 cm/s) and percutaneous portography followed by interventional procedures.

Management of HV obstruction

The treatment procedures were shown in Table 1. One intraoperative HV obstruction was corrected with a balloon filled with 75 mL air during LDLT; the balloon was placed under the liver to underlay the graft. Emergent laparotomy was performed for 1 patient with abdominal bleeding 3 d post LDLT, and HV stenosis was diagnosed during the operation. Abdominal bleeding came from liver incision rupture, which was the result of severe hepatic congestion induced by HV stenosis. Liver rupture repair and HV-vena cava re-anastomosis were performed. Transjugular HV balloon dilatation and metallic stent placement were performed for the other two early-onset HV stenosis on the 15th and 50th d post LDLT, respectively. Transfemoral venous balloon dilatation was performed for the two late-onset HV stenosis on the 55th and 270th d post LDLT, respectively.

Management of PV stenosis

As shown in Table 1, the pediatric patient with PV anastomotic stenosis received PV balloon dilatation and plastic stent placement 168 d post LDLT. All procedures were performed under general anesthesia. A new approach was employed for balloon dilatation and stent placement: the approach *via* the superior mesenteric vein. A small incision was made in the middle upper abdomen. Balloon dilatation and a 10 mm × 30 mm intravascular plastic stent placement were performed *via* superior mesenteric venous puncture. The diameter of the venous stent was about 1.0 cm. Immediately after the procedure, the patient underwent systemic anticoagulation with heparin-sodium for 7 consecutive days to maintain a partial thromboplastin time and INR of 1.5 times higher than normal levels. Follow-up data were obtained with routine clinical examination and Doppler sonography surveillance on days 1, 2, 3, and 7, at 2 wk and at 1 and 2 mo post procedure.

RESULTS

The results are shown in Table 1. The balloon underlying the liver graft during LDLT eliminated postoperative HV tension induced venous obstruction, and the balloon was removed on the 12th postoperative day. There was no outflow obstruction detected by ultrasonography before and after removal of the balloon. This patient has survived for 1.5 mo without ascites and hepatic congestion now.

The patient who underwent emergent operation for liver graft fracture bleeding induced by severe hepatic congestion died of hemorrhagic shock and renal failure 2 d later. Transjugular and transfemoral venous HV balloon dilatation was technically successful in each of 2 patients. In these 4 patients, the patient receiving

Table 1 Management and outcome of HV and PV obstruction/stenosis during and post LDLT

Case	V-O	LDLT	Age (yr)	Diagnosis and management time	Management	Survival	Complication
1	HV T	RL	46	Intraoperative	Balloon underlaying	> 1.5 mo, alive	-
2	HVS	RL	45	3, 3 d post LDLT	Re-anastomosis	2 d, dead	H-S, RF
3	HVS	RL	44	14, 15 d post LDLT	Transjugular BD + stent	off the trail	Bloody ascites
4	HVS	RL	56	14, 50 d post LDLT	Transjugular BD + stent	2 wk, dead	LF, RF
5	HVS	RL	43	51, 55 d post LDLT	Transfemoral vein BD	> 8 mo, alive	-
6	HVS	RL	39	180, 270 d post LDLT	Transfemoral vein BD	> 4 mo, alive	-
7	PVS	LL	9	140, 168 d post LDLT	trans-superior mesenteric venous BD + stent	> 9 mo, alive	-

BD: Balloon dilatation; H-S: Hemorrhagic shock; HV-H: Hepatic vein hemorrhage; HVS: HV stenosis; HV T: HV tension; LF: Liver failure; LL: Left lobe; PVS: Portal vein stenosis; RF: Renal failure; RL: Right lobe; V-O: Venous obstruction. LDLT: Living donor liver transplantation.

transjugular balloon dilatation and stent placement on the 15th postoperative day left hospital because of bloody ascites 1 wk later and disappeared, the patient receiving the same interventional treatment on the 50th postoperative day died of graft failure and renal failure 2 wk later, and the other two patients with late-onset HV stenosis receiving transfemoral venous balloon dilatation on the 55th and 270th postoperative day have survived for more than 8 and 4 mo without recurrent stenosis, respectively.

Balloon dilatation and stent placement *via* the superior mesenteric venous approach was technically successful in the pediatric patient with PV anastomotic stenosis. This child has survived for more than 9 mo without recurrent PV stenosis and ascites now. The liver function is normal, and the diameter of the venous stent is about 0.9 cm.

DISCUSSION

Although it is a relatively uncommon complication, venous obstruction after LT, including HV and PV stenosis, can induce severe complications such as hepatic congestion, portal hypertension, massive ascites, hepatic necrosis and hemorrhage, hepatic dysfunction, and even liver failure and death. Thus venous obstruction after LT is a critical problem for the recipient. Intraoperative HV or PV obstruction can be corrected with re-anastomosis. Tissue expanders or Foley catheters can also be employed to reposition the graft to improve HV and PV outflows induced by graft malposition during LT^[21,22]. Key points in HV and PV outflow reconstruction include: (I) size of anastomotic orifice, (II) length and orientation of vessels, and (III) position of the graft. Excluding vessel anastomotic techniques, the main factor in intraoperative venous outflow blockade is graft malposition. Severe HV obstruction shortly after transplantation is a surgical emergency, and reoperation is usually necessary for correction^[1,21]. On the other hand, because of fibrotic changes around the anastomotic site, surgical correction is usually difficult for the late-onset HV outflow obstruction and PV stenosis. Thus interventional procedures were a treatment of choice for the management of venous obstruction in that situation^[3,8,13,23,24]. Since the first report of percutaneous balloon angioplasty by Raby *et al*^[13], it has been widely accepted as a treatment of choice for

the management of venous stenosis after LT^[25-31]. The reported initial technical success rate was between 76% and 100%^[4-6,14,30].

In our study, the incidence rates of HV and PV stenosis was 2.7% and 0.04%, respectively. Several types of modified vascular reconstruction technology were used to avoid HV anastomotic stenosis^[32,33]: (1) the HV-HV anastomosis should be performed by a triangular opening of the inferior vena cava (IVC); (2) size matching of the donor HV to that of the recipient. If the donor HV is smaller than that of the recipient, patching of the great saphenous vein (GSV) graft could be used for the donor HV plasty; (3) a technique of “end-to-side vertical anastomosis” between the right HV or the inferior right HV (IRHV). The triangle-shaped hole has better stability, so the rate of stenosis and obstruction was very low. This also ensured the long-term patency of the anastomotic stoma. However, 7 patients with venous obstruction occurred at different phases: during the LDLT operation, in the early post-LDLT period (< 1 mo) and the late post-LDLT period (> 1 mo), respectively. One intraoperative HV obstruction was corrected with a balloon filled with air during LDLT, and the balloon was removed 12 d later without recurrent obstruction and any complications. One HV obstruction occurred 3 d after LDLT induced liver graft incision fracture and massive bleeding; although emergent hepatic rupture mending and HV-vena cava re-anastomosis were performed, this patient died of hemorrhagic shock and renal failure 2 d later. Both transjugular HV balloon dilatation and stent placement procedures for HV stenosis occurring in early phase were technically successful. Although balloon angioplasty has been accepted as the safe and effective initial treatment to manage HV outflow abnormalities, it may induce rupture of the fresh anastomosis and may be ineffective for eliminating various etiologies of venous outflow obstruction in the early post-transplant period. Thus, the outcome of balloon dilatation and stent placement for the 2 early-onset HV stenosis were bad in our study. The early (15 d post LDLT) transjugular balloon dilatation and stent placement induced massive bloody ascites 1 wk later, and the HV anastomosis bleeding may have been the cause of bleeding ascites. This patient left hospital and disappeared. Although the transjugular balloon dilatation and stent placement on the 50th postoperative day

in the other one patient prevented HV anastomosis bleeding, the preexistence of massive ascites, liver injury and renal dysfunction induced by the early-onset HV stenosis eventually resulted in the patient's death 2 wk later. However, the outcome of balloon dilatation for the two late-onset HV stenosis patients was good. These 2 patients have survived for more than 8 and 4 mo without recurrent stenosis and venous anastomosis bleeding, respectively.

The percutaneous transhepatic approach is the traditional method of PV stenosis interventional management. Our approach of preference was the trans-superior mesenteric venous approach. The first reason for this was the child's noncooperation for the percutaneous transhepatic approach under local anesthesia. The second reason was the risk of injury to the liver, the intrahepatic bile duct and artery, which could lead to liver damage, bile leakage, and hemorrhage, respectively. The good exposure of the superior mesenteric vein was the third cause, usually because of nonsevere adhesions or scar tissue surrounding the superior mesenteric vein after LT. As the PV is the linear prolongation of the superior mesenteric vein, superior mesenteric vein puncture, sheath intervention and placement of the guidewire into the PV, balloon dilatation and stent placement were easily performed. As the superior mesenteric vein puncture hole was sutured with 5-00 blood vessel suture (Proline), venous injury was not present. Postoperative paralytic ileus reported in the previous study^[16] was not present in this child. This child has survived for 9 mo with normal liver function, without venous thrombosis and recurrent venous stenosis now. This effective result suggested that a plastic stent could be used to treat pediatric venous stenosis after LDLT.

In conclusion, the results in our study suggested that the use of balloon filled with air to improve HV tension in malposed liver allograft is a simple and effective method during LDLT. Although balloon dilatation and stent placement is a safe and effective treatment to manage HV stenosis in the late post-transplant period, it may induce rupture of the fresh anastomosis in the early post-transplant period. The trans-superior mesenteric venous approach is clinically feasible and it is a safe and effective approach for PV stenosis intervention management after LDLT in children unfit for percutaneous transhepatic approach.

COMMENTS

Background

Hepatic vein (HV) and portal vein (PV) obstruction or stenosis during and after living donor liver transplantation (LDLT) is uncommon but critical complications may result in graft loss if not properly treated. Due to the technical difficulties of surgical management, interventional procedures including balloon dilatation via percutaneous transhepatic, transjugular intrahepatic, transfemoral vein and transileocolic vein approaches have been used to manage these complications. However, the direct trans-superior mesenteric venous approach is not in common use. Balloon dilatation followed by stent placement also has been widely accepted as a treatment of choice for the management of venous stenosis after liver transplantation (LT). Metallic stents have been used for recurrent and elastic stenosis.

Research frontiers

As there is a relatively high recurrence rate, i.e. 28.6%-36.8%, following balloon angioplasty, subsequent stent placement has been used to manage recurrent HV and PV stenosis after LT. However, some authors prefer to perform primary stent placement rather than balloon angioplasty in the early posttransplantation period (< 1 mo).

Innovations and breakthroughs

In this study, management and outcome of intraoperative HV obstruction induced by venous tension, as well as post-LDLT venous anastomotic stenosis in one single center were retrospectively analyzed. A balloon filled with air was employed for repositioning the graft to improve HV outflow obstruction induced by intraoperative graft malposition. Transjugular and transfemoral venous balloon dilatation were performed for treatment of 2 postoperative HV anastomotic stenosis, and immediately followed by stent placement via transjugular approach in 2 recipients. Plastic stent placement after balloon dilatation via the superior mesenteric venous approach was administered to manage a pediatric PV stenosis post living left lobe LT, and a good outcome was achieved.

Applications

A balloon filled with air could be used for repositioning the graft to improve HV outflow induced by intraoperative graft malposition. Emergent reoperation should be performed for HV obstruction shortly after LDLT. Proper interventional balloon dilatation and stent placement can be effective to manage HV and PV stenosis after LDLT. Balloon dilatation and stent placement via the superior mesenteric venous approach can be employed for treatment of PV stenosis after LDLT in children who do not cooperate with performance of the percutaneous transhepatic approach under local anesthesia.

Peer review

The single center study by the authors evaluated management and outcome of HV and PV obstruction after LDLT. Although venous obstruction post LDLT is a rare complication, choosing the ideal management is crucial since this complication can be life-threatening. Though the authors only report on 6 patients with venous obstruction following LDLT, the results and the conclusions drawn from their observations are quite interesting and important.

CASE REPORT

A 41-year-old female visiting from the Caribbean, the island of St. Vincent, presented initially to my office with abdominal pain. The history revealed she had been treated with antibiotics for her abdominal pain. Concurrently, she was prescribed birth control for presumed endometriosis for 5 mo without change in symptoms. A pelvic ultrasound revealed a leiomyomatous uterus and a 2.3 cm vascular umbilical mass. All laboratory data was within normal limits, except an elevated amylase level of 155, and a CA 19-9 level of 172 (normal < 35); CEA and CA27-29 were also normal. Since abdominal pain increased over the next 2 d she was admitted to the hospital. The CT of the abdomen/pelvis on admission revealed a large mass at the ileocecal junction with intussusceptions into the cecum without evidence of bowel obstruction. Also present were multiple large exophytic intramural and subserosal leiomyomas. Gastroenterology, Gynecology and Oncology were consulted. Since an umbilical vascular mass could not be biopsied, a colonoscopy was performed. Colonoscopy did not reveal any intra-luminal mass, however there was a significant intussusception of the ileum into the cecum. No obvious mass could be biopsied. At this time, there was still no diagnosis. It was recommended that an operative intervention was needed to excise the umbilicus for tissue diagnosis and also address the obstruction in the ileo-cecal region.

Umbilical mass and cecal mass with intussusceptions all revealed endometriosis on all frozen sections. A right hemicolectomy was performed. Intra operatively there were diffuse patches of endometriosis involving both ovaries, the cul-de-sac, the serosa of the uterus, and peritoneum. These areas were cauterized using the Bovie.

No malignancy was found in this patient.

DISCUSSION

Cutaneous metastases localized to the umbilicus are named "Sister Mary Joseph nodules". The historical perspective of this node and its namesake is quite interesting. Sister Mary Joseph, born Julia Dempsey in 1856 was assigned to St. Mary's Hospital (now the Mayo Clinic) in 1889 at the age of 33 years. Within 3 years she was appointed nursing superintendent. She worked with William W Mayo and his two sons, Charles H Mayo and William J Mayo. As first surgical assistant to son, William J Mayo she noted an umbilical nodule on a patient who

Abstract

Sister Mary Joseph nodule or node refers to a palpable nodule bulging into the umbilicus and is usually a result of a malignant cancer in the pelvis or abdomen. Traditionally it has been considered a sign of ominous prognosis. Gastrointestinal malignancies, most commonly gastric, colon and pancreatic cancer account for about 52% of the underlying sources. Gynecological cancers, most commonly ovarian and uterine cancers account for about 28% of the sources.

INTRODUCTION

Umbilical metastases (Figure 1), also named Sister Mary Joseph node are well documented in the adult population and most usually associated with gastrointestinal or gynecologic malignancy. The appearance of this node generally indicates a grave prognosis for the patient. malignant process, this case presents a rare, but reported non-malignant lesion^[1].

Figure 1 Sister Mary Joseph node.

was having surgery for an abdominal malignancy. She reported this to William J Mayo whom in 1928 reported it in the Proceedings of the Staff Meetings. It was then termed “pants button umbilicus”. By coincidence, Sister Mary Joseph, Charles H Mayo and William J Mayo all died within 3 mo of each other in 1939. These three people worked closely in developing what is now the Mayo Clinic. It was not until 1949, that Hamilton Bailey in his textbook, *Physical Signs in Clinical Surgery*, gave the name Sister Mary Joseph nodule to the umbilical metastasis, which usually is predictive of incurable abdominal malignancies^[2,3].

Metastasis to the umbilicus is very uncommon^[4]. When it does occur, the umbilical nodules are usually malignant with the common site being an abdomino-pelvic tumor^[5-7]. In Shetty's review^[8] of all cases of malignant disease to the umbilicus only 42% originated from either the abdomen or from the pelvis, whereas in

Powell's review^[9] of umbilical nodules, 32% of the cases were benign neoplasms.

This case demonstrates a non-malignant (benign) lesion that caused a metastatic umbilical nodule. In our case this was endometriosis^[10]. Although rare, this nodule ranges in color from dusky red to blue to purplish as in our case. It may change in size during the menstrual cycle and may be tender, and even bleed. The ultrasound demonstrated a vascular umbilical mass. Other benign causes of umbilical nodules are fibroma, keloid, and epithelial inclusion cysts^[11].

Abstract

The origin of myofibroblasts or myofibroblastic cells in the desmoplastic stroma associated with carcinoma invasion has been controversial. In the early invasive area of a rectal adenocarcinoma reported here, an obvious transition between the muscularis mucosa and the bundles of eosinophilic stromal cells observed in the carcinomatous stroma was demonstrated both in morphology and in their cytoskeletal phenotype, which conceivably suggests that the smooth muscle cells of the muscularis mucosa could convert to the eosinophilic stromal cells, namely myofibroblasts. Moreover, type I procollagen was demonstrated in both protein and mRNA levels in the areas of eosinophilic stromal cells with a lesser degree of differentiated smooth muscle phenotype that showed a transition from the muscularis mucosa, implying that the myofibroblastic cells converted from smooth muscle cells of the muscularis mucosa could be responsible for type I collagen production. These findings suggest that the muscularis mucosae may not be a passive barrier through which colorectal carcinomas infiltrate into the submucosa, but may play an active role in the formation and remodeling of tumor stroma.

INTRODUCTION

The invasion of some carcinomas is characterized by the induction of so-called desmoplastic stroma. The desmoplastic stroma is comprised of activated fibroblastic cells and the deposition of extracellular matrix (ECM) components^[1-3]. The activated fibroblastic cells commonly show some morphological and phenotypic features of smooth muscle cells, and are referred to as myofibroblasts or myofibroblastic cells^[4-6]. They would modulate the microenvironment and contribute to tumor invasion through production of extracellular matrices, proteases, and soluble factors^[1,3,7,8].

The origin of myofibroblasts or myofibroblastic cells has been controversial^[4,6]. With regard to myofibroblastic cells in the desmoplastic stroma, one experimental study of an organotypic assay using breast carcinoma cells and breast stromal cells stressed the local fibroblasts as the most frequent candidate for myofibroblasts, while it also observed the recruitment of vascular smooth muscle cells and pericytes^[9]. However, in contrast to those local resident precursors, bone marrow-derived circulating fibrocytes have recently been proposed to be myofibroblastic precursors^[10,11].

This case study of an early invasive rectal adenocarcinoma conceivably demonstrates that one of the precursors of myofibroblastic cells in the carcinomatous desmoplastic stroma is smooth muscle cells of the muscularis mucosa, and they are responsible for production of an ECM component around the invasive carcinomatous glands, reemphasizing the importance of local resident cells in the desmoplastic reaction, and giving a hint as to the implication and a role of the muscularis mucosa in the early invasive process of colorectal carcinomas.

Figure 1 Low power view of an early invasive rectal adenocarcinoma with bundles of eosinophilic stromal cells (a), which are continuous with the muscularis mucosa (arrows, HE stain, original magnification $\times 40$).

CASE REPORT

A rectal tumor was transanally removed from a 59-year-old Japanese male patient. The tumor was a broad-based sessile polypoid lesion of 20 mm in the largest diameter, which was fixed in 10% formalin, embedded in paraffin blocks, and stained with haematoxylin and eosin (HE) routinely. Serial sections were also made for immunohistochemistry and *in situ* hybridization (ISH).

Immunohistochemical staining was performed by an established indirect method using the following monoclonal antibodies (clone; source; dilution in parenthesis): anti- α -smooth muscle actin; α -SMA (1A4; Dako, Glostrup, Denmark; 1:25), anti-desmin (D33; Immunotech, Marseilles, France; 1:25), anti-high molecular weight caldesmone; h-CD (h-CD; Dako; 1:50), and anti-type I procollagen (M58; Chemicon, Temecula, CA, USA; 1:500). Antigens were retrieved by autoclaving at 121°C for 5 min in a citrate buffer before immunostaining for desmin and h-CD, and by 1% trypsin digestion for 20 min at room temperature for procollagen I. Negative control sections were incubated without primary antibodies. Submucosal arteries and part of the proper muscle layer could be available for internal positive controls for α -SMA, desmin, and h-CD. As a positive control for procollagen I, we also immunostained scar tissues which were fixed in formalin and embedded in paraffin in the same way as the present case.

For ISH to detect type I procollagen mRNA, the tissue sections were deparaffinized, rehydrated, and treated with 0.3% hydrogen peroxide in methanol for 30 min at room temperature. Then they were treated with protease K (Dako, Glostrup, Denmark) for 60 min followed by depurination in 0.2 N HCl for 20 min both at room temperature, dehydrated, and air dried. Hybridization was performed using a cocktail of two synthetic DNA oligonucleotide probes^[12] labeled with digoxigenin at the 3'-end in a solution consisting of 50% formamide, 10 mmol/L Tris-HCl pH 7.6, 200 μ g/mL yeast tRNA, 100 μ g/mL sonicated salmon sperm DNA, 1X Denhardt's solution, 10% dextran sulfate, 600 mmol/L NaCl, 0.25% SDS, 1 mmol/L EDTA pH 8.0, and

10 μ g/mL of each probe, at room temperature overnight. After posthybridization washes (two brief washes in 2X SSC at 47°C, two washes in 1X SSC at 47°C for 30 min each, one wash in 0.5X SSC at 47°C for 30 min, one wash in 0.1X SSC at 47°C for 60 min, and one wash in 0.05 mol/L Tris-HCl pH 7.6 with 0.1% Tween 20 at room temperature for 5 min), incubation with horseradish peroxidase-conjugated anti-digoxigenin antibody was performed at room temperature for 30 min followed by detection with TSA[™] Biotin System (PerkinElmer, Wellesley, MA, USA). As controls, prehybridization digestion with RNase and hybridization using the hybridization solution with non-labeled probes or without probes were performed.

Histologically, the rectal tumor was a well-differentiated adenocarcinoma showing papillotubular growth, microscopically infiltrating into the submucosal layer beyond the muscularis mucosa. In the stroma of the invasive area, continuing to the muscularis mucosa of the adjacent normal mucosa, bundles of eosinophilic stromal cells were seen, and it was not easy to determine whether they were disarrayed muscularis mucosa remains or stromal cells simulating muscularis mucosa (Figure 1). When observed in detail, the bundles of eosinophilic stromal cells were not morphologically homogeneous but different in parts, namely, from those more similar to the smooth muscle cells of the muscularis mucosa to those composed of less eosinophilic spindle cells with plumper nuclei, showing a morphological transition from the former to the latter (Figure 2A and B).

Immunohistochemical examination of the cytoskeletal phenotype revealed that the former was more constantly positive for α -SMA, whilst the latter was positive for α -SMA less constantly or in a few cells (Figure 2C). The former was positive in a few cells or almost negative for h-CD and desmin, and the latter was negative for both (Figure 2D and E). The cytoskeletal feature of the muscularis mucosa was that of differentiated smooth muscle cells, namely, positive for α -SMA, desmin, and h-CD. Therefore, corresponding to the morphological transition, a continuous transition apart from the differentiated smooth muscle phenotype of the muscularis mucosa was revealed in the bundles of eosinophilic stromal cells. The presence of type I procollagen, both in protein level by immunohistochemistry and in mRNA level by *in situ* hybridization, was demonstrated in the less eosinophilic stromal cells with a lesser degree of differentiated smooth muscle phenotype, that is, less constantly positive for α -SMA and negative for desmin or h-CD (Figure 2F-H).

DISCUSSION

In our experience of routine histopathological diagnosis of early invasive colorectal adenocarcinomas, we commonly see bundles of eosinophilic stromal cells, which are confused with disarrayed muscularis mucosa remains around invasive carcinomatous glands. In the present case, an obvious transition between the

Figure 2 Middle power view of the invasive area (A) indicated by dotted box in Figure 1 shows a transition from bundles of eosinophilic stromal cells more similar to smooth muscle cells of the muscularis mucosa (black arrows) to those composed of less eosinophilic stromal cells with plumper nuclei (white arrows) (HE stain, $\times 100$). Higher magnification of the former eosinophilic stromal cells (left) and the latter ones (right) is shown in B (HE stain, $\times 400$). Immunohistochemistry of the serial sections demonstrates the former being more constantly positive for α -SMA compared to the latter (C), and h-CD is positive in a few cells in the former, and negative in the latter (D). Desmin is almost negative for both the former and the latter (E). Immunohistochemical expression of type I procollagen (F) and the presence of type I procollagen mRNA by *in situ* hybridization (G, H) are demonstrated in the latter area (original magnification of C to G, $\times 100$). Higher magnification of type I procollagen *in situ* hybridization is shown in H, which demonstrates positive signals in plump stromal cells (H, $\times 400$).

muscularis mucosa and the bundles of eosinophilic stromal cells (both in morphology and in their cytoskeletal phenotype) was demonstrated, which we think conceivably suggests that the smooth muscle cells of the muscularis mucosa could convert to the eosinophilic stromal cells in the stroma of invasive colorectal adenocarcinomas. Moreover, considering their eosinophilic and α -SMA positive features, the eosinophilic stromal cells could be referred to as myofibroblasts or myofibroblastic cells, so we could paraphrase that the muscularis mucosa could convert to myofibroblasts or myofibroblastic cells, making it one of the sources of myofibroblasts in the stroma of invasive colorectal adenocarcinomas. This concept is supported by an ultrastructural morphological study

that showed the smooth muscle cells of muscularis mucosae or muscularis propria as a possible source of myofibroblasts in the stroma of invasive colorectal adenocarcinomas^[13].

The stromal change associated with carcinoma invasion has been called desmoplasia or desmoplastic reaction, which is characterized by modifications in the composition of stromal cells and ECM components, the latter being an excessive deposition of ECM components such as collagen, fibronectin, and proteoglycan, and type I collagen is one of the ECM components which deposits in desmoplastic tumor stroma^[1-3]. In the present case, type I procollagen was demonstrated in both protein and mRNA expression in the areas of eosinophilic stromal cells that showed

a transition from the muscularis mucosa and a lesser degree of differentiated smooth muscle phenotype, implying that the myofibroblastic cells converted from smooth muscle cells of the muscularis mucosa could be responsible for type I collagen production and play a role in the formation of desmoplastic stroma. This notion is supported by an *in vitro* study that showed the induction of proteoglycan production of smooth muscle cells derived from the colonic wall by colon carcinoma cells^[14].

Two different sources of myofibroblasts or myofibroblastic cells have been proposed, i.e. bone marrow-derived circulating fibrocytes and local resident cells such as fibroblasts^[8], the former being stressed recently^[15]. However, the result of this case study seems to reemphasize roles of local resident cells in the desmoplastic reaction associated with carcinoma invasion. During the early invasive process of colorectal carcinomas, the muscularis mucosae may not be a passive barrier through which colorectal carcinomas infiltrate into the submucosa. They may, rather, play an active role in the formation and remodeling of tumor stroma and facilitate the invasive process of carcinoma cells.

ACKNOWLEDGMENTS

We thank Mr. Yoshiya Goto and Mr. Koichi Kamada for their technical help with immunohistochemistry and *in situ* hybridization.

INTRODUCTION

Brunner's gland hamartoma is an infrequently encountered benign tumor in the proximal duodenum, accounting for approximately 5% of all duodenal masses^[1,2]. Fifty-seven percent of the tumors originate from the duodenal bulb and the incidence of the tumor decreases as the distance from the pyloric ring grows^[3].

Cystic lesions of the Brunner's glands are exceedingly rare. Only 12 cases have been documented in the literature under various terms such as Brunner's gland cyst, cystadenoma, mucocoele, and cystic Brunner's gland hamartoma^[4]. There has been no literature depicting predominant cystic lesions of Brunner's gland hamartoma in imaging modalities, except for two cases that were found at endoscopic ultrasonography. Although mild dilatation of the ducts may be present in Brunner's gland lesions, it is only detected in histologic test^[5,6].

Herein, we introduce a rare cystic Brunner's gland hamartoma with a long stalk arising from the duodenal third portion found on multidetector-row computed tomography (MDCT), magnetic resonance imaging (MRI), and a modified small bowel series, together with pathologic correlation.

CASE REPORT

A 30-year-old man with a 3-d history of aggravated episodes of nausea, vomiting, and epigastric pain was referred by a private clinic. He was healthy with no specific family or past medical history. Physical examination and laboratory evaluation revealed no abnormalities.

Upper tract endoscopy was not performed because endoscopic results reported by the private clinic were within the normal limits. MDCT showed a 4 cm × 4 cm polypoid mass with multifocal internal low densities in the proximal jejunum just below the Treitz ligament (Figure 1A), and the lesion's long stalk arising from the third portion of the duodenum (Figure 1B). Multifocal high-signal intensities on T2-weighted MRI reflected cystic components (Figure 1C), which were identical to the low densities on

Abstract

Cystic Brunner's gland hamartoma in the duodenum is exceedingly rare, although microscopic examination may sometimes reveal a Brunner's gland hamartoma containing dilated ducts in the duodenum. We present a case of large cystic Brunner's gland hamartoma in the duodenum with a long stalk, which is described in light of multidetector-row computed tomography, magnetic resonance imaging, and a modified small bowel series, together with pathologic correlation and differential diagnosis.

Park BJ, Kim MJ, Lee JH, Park SS, Sung DJ, Cho SB. Cystic Brunner's gland hamartoma in the duodenum: A case report.

Figure 1 CT and MRI findings. A: Axial portal venous-phase CT scan showing an intraluminal round mass (arrows) with internal multifocal low densities in the proximal jejunum; B: Coronal reformatted portal venous-phase CT demonstrating an identical configuration to the modified small bowel series showing a long stalk (arrowheads) and a well-defined mass with multifocal cystic lesions (arrows); C: A large, well-defined multi-chambered cystic mass showing high signal intensities (arrowhead) with its moved location in the third portion of the duodenum on axial T2-weighted images.

Figure 2 Modified small bowel series findings. A well-demarcated round filling defect (arrows) at the proximal jejunum just below the Treitz ligament and a tubular filling defect with a long stalk (arrowheads) originating from the proximal third portion of the duodenum.

MDCT (Figure 1A and B). The lesion's location moved to the third portion of the duodenum on MRI (Figure 1C). On the modified small bowel series, a mobile smooth lobular filling defect with a long stalk was visible in the proximal jejunum (Figure 2).

A pedunculated, well circumscribed mass was removed at laparoscopic enterotomy of the proximal jejunum, and the residual long remnant stalk was removed by post-operative endoscopy. The cut surface of the resected specimen revealed an approximately 4 cm × 3 cm whitish ovoid mass with multiple internal cystic spaces (Figure 3A). Histological examination of the specimen found that the

main body of the polyp contained a lobular collection of mature Brunner's glands with large multifocal areas of glandular cystic dilation (Figure 3B and C). There was no evidence of malignancy, and the lesion was diagnosed as a pedunculated cystic Brunner's gland hamartoma.

DISCUSSION

The etiology of Brunner's gland hamartoma has not been clearly elucidated. Brunner's gland hamartoma represents 5%-10% of all small bowel tumors and occurs most commonly in the fifth and sixth decades of life, with no gender or race predominance^[7]. Brunner's gland hamartoma is most commonly located on the posterior wall of the duodenum near the junction of the first and second portions. In a series of 27 patients described by Levine *et al*^[8], Brunner's gland hamartoma was located in the duodenal bulb, the second and third portions of the duodenum of 70%, 26%, and 4% of the cases, respectively. In the present case, the long stalk base was located in the proximal third portion of the duodenum.

Although Brunner's gland hamartoma is incidentally found, Levine *et al*^[8] reported that the most common presentations in symptomatic patients are gastrointestinal hemorrhage (37%) and obstructive symptoms (37%). Rarer presentations have been found in conjunction with recurrent pancreatitis^[9], obstructive jaundice^[10], and biliary fistula^[11]. Brunner's gland hamartoma is usually non-dysplastic and entirely benign. However, at least one recent report is available on a Brunner's gland hamartoma

Figure 3 Histologic findings of the specimen. A: Cut surface of the gross specimen showing a multiloculated cystic appearance filled with mucin-like material; B: Aggregated glands (arrows) are lined with cuboidal to columnar cells with abundant pale cytoplasm and a basally-located oval nucleus, resembling a normal Brunner's gland in histopathologic findings of cystic Brunner's gland hamartoma (HE, $\times 200$) while the large cystic dilated gland showing the same lining (arrowheads) as a normal Brunner's gland; C: Cystic Brunner's gland hamartoma showing a well-demarcated nodular lesion, composed of a lobular collection of tubuloalveolar glands separated by fibrous septa, beneath the muscularis mucosa, in the low power field ($\times 12.5$), while some glands showing cystic dilatation.

with malignant potential^[12]. Brunner's gland hamartoma of the duodenum can be removed endoscopically because it is usually benign. However, we performed laparoscopic enterotomy because endoscopic results reported by the private clinic were within the normal limits. It has been suggested that endoscopic or surgical removal of Brunner's gland hamartoma can prevent the development of complications and endoscopic polypectomy represents the ideal approach depending on the site and size of Brunner's gland hamartoma and the presence of a peduncle^[13]. In the present case, considering its size and distal location, the endoscopist was reluctant to perform the procedure, hence laparoscopic enterotomy was performed as our next treatment option.

Patel *et al*^[14] have reported seven cases of Brunner's gland hamartoma on CT. In that report, two lesions with homogenous enhancement correlated with histologic findings of solid glandular proliferation, and the remainder were found with heterogeneous enhancement and hypodensities. The latter cases revealed smooth muscle proliferation and small cystic dilatation of the Brunner's glands. Up to now, to our knowledge, no study has described predominant cystic lesions of Brunner's gland hamartoma found on imaging modalities such as MDCT and MRI, except for two cases that were found on endoscopic ultrasonography^[5,6]. Endoscopic ultrasonography provides additional information about the internal components of the duodenal mass. Imaging modalities such as MDCT, MRI, and modified small bowel series were useful for tissue characterization and localization of the mass in our case, because the large pedunculated mass of the jejunum was difficult to approach by endoscopic ultrasonography.

In the present case, large cyst lesions in a pedunculated mass were revealed by characteristic multifocal high-signal

intensities on T2-weighted MRI images, and large hypodensities on enhanced MDCT correlated with large cystic dilatation of the glands. Mobility due to its long stalk was confirmed by a modified small bowel series and positional change during serial imaging studies.

Diagnosis of Brunner's gland hamartoma is not always easy at present because radiological findings are often nonspecific^[15]. CT is useful only for confirming the absence of extra-luminal extension of a tumor^[16]. Radiologic findings of Brunner's gland hamartoma are extremely similar to those of several other lesions, including adenomatous polyps, lymphoma, carcinoid tumors, and mesenchymal tumors such as gastrointestinal stromal tumor, leiomyoma, and neurogenic tumor. Since duodenal tumors depicted in a cystic configuration through radiologic modalities are rare, the recognition of a cystic component in a solitary duodenal mass may be useful for preoperative diagnosis of Brunner's gland hamartoma.

In conclusion, cystic configuration of a solitary duodenal mass should be generally considered the clue to the diagnosis of Brunner's gland hamartoma.

Abstract

Foreign-body ingestion is a relatively common presentation at emergency departments, but long metallic spoon swallowing is an infrequent occurrence. Unlike most cases of foreign-body ingestion, there have been no reported cases of long foreign bodies reaching the jejunum. We report a rare case of a coffee spoon that was swallowed accidentally and passed through the pylorus and duodenal loop and reached the jejunum, with no complications.

INTRODUCTION

Foreign body ingestion is a frequent gastrointestinal emergency. However, long spoon swallowing is a rare

event. Most swallowed spoons have been found in the stomach^[1-4]. Previously, there has been no reported case of a long spoon reaching the jejunum. We present a rare case of a swallowed spoon with a length of 15 cm. The object passed through the pylorus and reached the jejunum, without clinical complications.

CASE REPORT

A 33-year-old woman presented to our emergency room after accidentally swallowing a spoon. She stated that she attempted to use the spoon to remove a fish bone, which was lodge in the pharynx 20 h previously. She had no abdominal pain, fever, vomiting, dysphagia, voice change, cough, or difficulty breathing. The patient was previously healthy and her past medical history was insignificant. General and abdominal examination was unremarkable. There was no abnormal finding in the laboratory tests.

An urgent plain abdominal radiograph revealed a metallic foreign body in the lower mid-abdomen (Figure 1). Inspection and removal was attempted by flexible gastroscopy. Gastroscopy found that a long spoon was resident in the stomach, together with a large volume of food (Figure 2). However, several attempts to remove the spoon failed because the patient could not tolerate the resultant nausea when the spoon was pulled to the cardia. There was a small amount of bleeding around the cardia. To follow-up the migration of the spoon, a second abdominal radiograph showed that the object position had changed (Figure 3). The second endoscopy confirmed that the foreign body disappeared from the stomach. She had to be taken to the operating room for an exploratory laparotomy, which disclosed that a 15-cm spoon had passed into the jejunum, following about 200 cm of the ligament of Treitz (Figure 4). Laparotomy demonstrated no free pus and fluid within the peritoneal cavity. Blood supply for the intestine was good. No bleeding and perforation was found in the stomach and intestine. After surgery, the patient was well and was discharged home on postoperative day 7.

DISCUSSION

Fortunately, most ingested foreign bodies pass spontaneously from the gastrointestinal tract. However, 10%-20% require nonoperative intervention, and ≤ 1% require surgery^[3,5,6]. Foreign bodies may cause serious complications such as impaction, obstruction, or perforation of the digestive or respiratory tracts. When complications occur, there is a relatively high rate of

Figure 1 Abdominal X-ray showing a radiopaque shadow in the lower mid-abdomen consistent with a spoon.

Figure 2 Laparotomy disclosing a metal spoon in the stomach.

mortality, with death rates as high as 1500 deaths per year in the United States^[7].

We tried to remove the spoon by endoscopy. However, our patient could not tolerate the discomfort associated with endoscopy, which had to be discontinued. Surprisingly, the spoon passed through the pylorus and duodenal loop several hours later. We had to remove the foreign body by surgery. In previous studies, long items such as forks or spoons, longer than 6-10 cm, have been unable to pass through the duodenal sweep^[5,6]. A Medline search indicated that other swallowed spoons have been found only in the esophagus and stomach. It has not been reported previously that a 15-cm spoon has passed through the pylorus and duodenal loop and reached the jejunum.

Abstract

We read with great interest the paper written by Shi *et al*, reviewing the molecular characteristics and stages of chronic hepatitis B virus (HBV) infection. We think that some points in the definition of occult HBV infection (OBI) and their conclusion about the management of OBI may need further considerations.

Ozaslan E, Purnak T. Controversies about occult hepatitis B virus infection. *World J Gastroenterol* 2009; 15(39): 4986-4987 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4986.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4986>

TO THE EDITOR

We read with great interest the paper written by Shi *et al*^[1], reviewing the molecular characteristics and stages of chronic hepatitis B virus (HBV) infection. We think that some points in the definition of occult HBV infection (OBI) and their conclusion about the management of OBI may need further considerations.

First, they defined OBI as the existence of HBV DNA in serum, at a level < 20000 IU/mL. However, a recent meeting report^[2], clarified the confusion about the definition of OBI, describing it as the presence of

HBV DNA in the liver (with detectable or undetectable HBV DNA in serum) of individuals with negative HbsAg, and introduced a cutoff value for serum HBV DNA (< 200 IU/mL). So, cases whose serum HBV DNA levels are comparable to those in the different phases of serologically evident (overt) HBV infection are generally due to infection with escape mutants and should be labeled as “false” OBI^[2].

Second, Shi *et al*^[1] stated that OBI is a common and long-term consequence of acute hepatitis B resolution and termed it as secondary occult infection (SOI). Actually, SOI is the major clinical form of OBI that represents the tails of acute or chronic HBV infection^[2]. Cross-sectional studies across the spectrum of HBV infection have revealed a marked increase in OBI prevalence towards cirrhosis or hepatocellular carcinoma (HCC)^[3,4]. So, the majority of OBI cases are secondary to overt HBV infection and represent a residual low viremia level suppressed by strong immune response together with histological derangements occurred during acute or chronic HBV infection. Moreover, immune response to hepatocytes sustaining a low HBV replication level may contribute to chronic liver damage in the setting of OBI. Berasain *et al*^[5] showed that approximately 50% of patients with persistent hypertransaminasaemia of unknown etiology have chronic hepatitis or cirrhosis due to occult HBV or hepatitis C virus (HCV) infection.

Third, the authors concluded that no reports are available on the treatment of OBI. However, therapy should be considered during reactivation and cirrhosis settings. The reactivation of OBI in hemato-oncological malignancies (< 5%), although at a lower rate than that of HBsAg positive cases, carries a significant risk of mortality and morbidity^[6], which is much higher in the setting of stem cell transplantation^[7]. Many fatalities especially due to rituximab containing regimens have also been reported^[8-11]. Although a definitive conclusion cannot be reached at the moment, targeted therapy *via* HBV DNA monitoring or even routine pre-emptive nucleoside analogue prophylaxis was offered to all HBsAg negative/anti-HBc positive patients in recent consensus reports^[12,13]. Moreover, recent guidelines offer therapy for cirrhotic patients with a detectable HBV DNA level^[14].

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (World J Gastroenterol ISSN 1007-9327, DOI: 10.3748) is a weekly, peer-reviewed, online, open-access (OA) journal supported by an editorial board of 1126 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in *WJG* will include the following. (1) Editorial: to introduce and comment on major advances in rapidly developing areas and their importance. (2) Frontier: to review recent developments and comment on current research status in important fields, and propose directions for future research. (3) Topic Highlight: this column consists of three formats, including: (a) 10 invited review articles on a hot topic; (b) a commentary on common issues associated with this hot topic; and (c) a commentary on the 10 individual articles. (4) Observation: to update the development of old and new questions, highlight unsolved problems, and provide strategies for their resolution. (5) Guidelines for Basic Research: as suggested by the title. (6) Guidelines for Clinical Practice: to provide guidelines for clinical diagnosis and treatment. (7) Review: to review systemically the most representative progress and unsolved problems, comment on current research status, and make suggestions for future work. (8) Original Article: to report original and innovative findings. (9) Brief Articles: to report briefly on novel and innovative findings. (10) Case Report: To report a rare or typical case. (11) Letters to the Editor: to discuss and reply to contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest. (12) Book Reviews: to introduce and comment on quality monographs. (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities on basic research and clinical practice

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments,

References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS AND DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of *P* values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as 1F , 2F , 3F ; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No.62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Telephone: +86-10-59080039

Fax: +86-10-85381893

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Language evaluation

The language of a manuscript will be graded before it is sent for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

Several studies have demonstrated that the outcome of chronic hepatitis C (CHC) infection is profoundly influenced by a variety of comorbidities. Many of these comorbidities have a significant influence on the response to antiviral therapy. These comorbidities negatively affect the course and outcome of liver disease, often reducing the chance of achieving a sustained virological response with PEGylated interferon and ribavirin treatments. Comorbidities affecting response to antiviral therapy reduce compliance and adherence to inadequate doses of therapy. The most important comorbidities affecting the course of CHC include hepatitis B virus coinfection, metabolic syndrome, and intestinal bacterial overgrowth. Comorbidities affecting the course and response to therapy include schistosomiasis, iron overload, alcohol abuse, and excessive smoking. Comorbidities affecting response to antiviral therapy include depression, anemia, cardiovascular disease, and renal failure.

INTRODUCTION

The prevalence of hepatitis C virus (HCV) infection varies throughout the world, with the highest number of infections reported in Egypt. The use of parenteral antischistosomal therapy in Egypt is thought to have contributed to a prevalence of antibodies against HCV in various regions ranging from 6% to 28% (mean, 22%)^[1]. An estimated 70% to 85% of infected patients are likely to develop chronic hepatitis, and up to 30% of these cases might progress to cirrhosis^[2].

When treating chronic hepatitis C (CHC), many clinicians do not take into consideration the presence of other comorbid conditions that lead to more progressive liver disease, such as cirrhosis and hepatocellular carcinoma (HCC)^[3-5]. In recent studies, it has been proved that such comorbidities might reduce the response rate to PEGylated interferon (PEG-IFN)/ribavirin (RBV) therapy in HCV patients^[6,7].

Eventually amelioration of these comorbidities before embarking on IFN-based therapy would improve the sustained virological response (SVR) and impair progression to cirrhosis and HCC.

COMORBIDITIES AFFECTING THE COURSE OF CHC

Hepatitis B virus (HBV) co-infection

Coexistent HCV infection has been estimated to be present in 10% to 15% of patients with chronic hepatitis B, and is more common among injecting drug users^[8]. Acute coinfection with HBV and HCV can shorten the duration of HBs antigenemia and lower the peak serum aminotransferase concentrations compared with acute HBV infection alone^[9,10]. However, acute coinfections of HCV and HBV, or acute HCV on preexisting chronic HBV, have also been reported to increase the risk of severe hepatitis and fulminant hepatic failure^[11].

However, combined chronic hepatitis B and C leads to more severe liver disease, an increased risk of hepatocellular carcinoma^[3,4] and lower response to IFN^[6]. Furthermore, co-infected patients represent a treatment challenge. No standard recommendations exist for treatment of viral hepatitis due to dual HBV/HCV infection, and therefore treatment must be individualized^[4].

Management: Treatment decisions should be based upon

Figure 1 HCV-induced insulin resistance. Dotted lines represent inhibition, continuous lines represent activation. PI3K: Phosphatidylinositol 3 kinase.

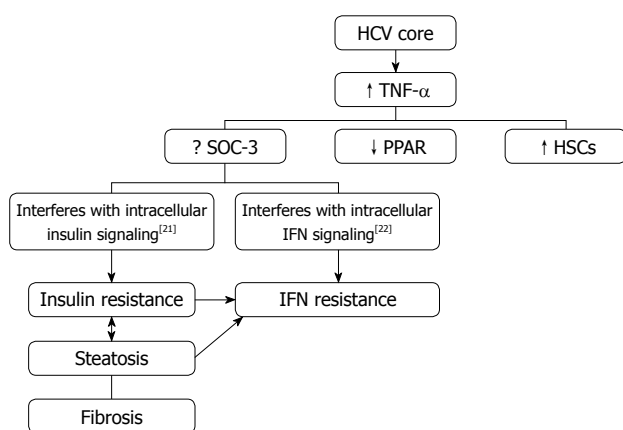

Figure 2 HCV-induced insulin resistance^[21-23]. SOC-3: Suppressor of cytokine-3; PPAR: Peroxisome proliferators activated receptor; HSCs: Hepatic stellate cells.

the determination of the "dominant" hepatitis virus. The more active virus should be treated using IFN plus RBV for hepatitis C and IFN plus Lamivudine for hepatitis B^[3,4]. Caution must be exercised in treating coinfecting patients, by observing reactivation of untreated virus as flares of the latter might occur.

Metabolic syndrome (MS)

MS is a cluster of abnormalities, including obesity, insulin resistance, type 2 diabetes mellitus, dyslipidemia, and hypertension. Moreover, patients with chronic HCV infection have increased prevalence of insulin resistance and of type 2 diabetes compared with age-, sex-, and liver disease-matched controls^[12].

It has been observed that overweight, insulin resistance, and liver steatosis have a negative impact on the course of CHC, being associated with more severe and progressive liver fibrosis^[5]. HCV proteins are associated with the dysfunction of mitochondria and endoplasmic reticulum that promote oxidative stress. The latter mediates signals that activate the expression of proinflammatory cytokines: tumor necrosis factor (TNF)- α , interleukin (IL)-6, IL-8, tumor growth factor- α , and the fas ligand..

Insulin resistance: HCV proteins activate the expression of TNF- α which inhibits the function of insulin receptor

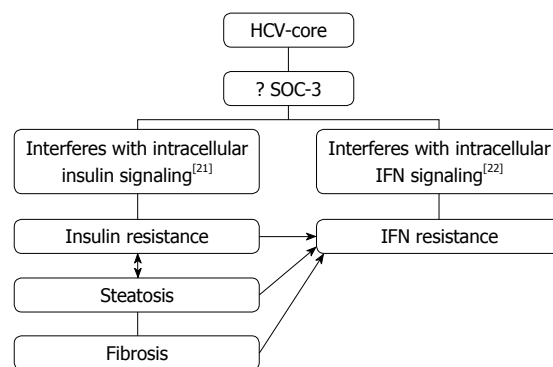

Figure 3 Core-protein induced insulin resistance^[21-23].

substrates (IRS) and decreases the expression of glucose transporter-4 and lipoprotein lipase in peripheral tissues, which are responsible for the promotion of insulin resistance (Figure 1).

Furthermore, reduced adiponectin levels, loss of adiponectin receptors, and decreased anti-inflammatory peroxisome proliferator-activated receptor α (PPAR- α) in the liver of HCV patients might contribute to reduced fatty acid oxidation, inflammation, and eventually, lipotoxicity^[12].

Insulin resistance has been clearly associated with steatosis, more severe and progressive fibrosis, and a reduced response to PEG-IFN and RBV therapy in HCV patients^[13]. Several recent studies have confirmed that SVR is impaired in patients with a high homeostasis model assessment index^[14].

Obesity/Hepatic steatosis: In hepatitis C infection, hepatic steatosis might be either metabolic [overweight & obesity (BMI ≥ 25), diabetes mellitus] or cytopathic due to the effect of the virus, as in genotype 3. However, genotype-4, which is predominant in Egypt, has no direct relation with the development of steatosis^[15]; however, it develops as a secondary metabolic effect as evidenced by HCV core protein promotes IR *via* TNF- α production^[16] (Figures 2 and 3). In addition, HCV non-genotype-3 induces insulin resistance through downregulation of IRS^[17-19]. HCV genotype-3 might induce a cytopathic effect and autoimmune aggression on β -cells of the pancreas^[20]. Furthermore, HCV produces necroinflammation of hepatocyte membranes with consequent malfunction of insulin receptors.

Several studies have recently confirmed that the SVR^[7] is impaired in patients with high body mass index and for those with hepatic steatosis. These data indicate that HCV carriers should avoid weight gain by diet and physical exercise before initiation of antiviral therapy, all efforts should be made to improve the metabolic steatosis of the patient.

Type 2 diabetes mellitus: Type 2 diabetes mellitus is frequently associated with hyperinsulinemia and fatty liver disease. The chronically elevated circulating insulin levels found in type 2 diabetic patients might be responsible for accumulation of fat in the liver by downregulating

Figure 4 Insulin-induced IFN resistance. Interaction between insulin and the PEG-interferon α -signaling pathway. PI3K activated by insulin seems to be responsible for the block of STAT1 translocation that avoids the antiviral effect of interferon. Dotted lines represent inhibition, continuous lines represent activation. IRS-2: Insulin substrate-2; 2',5'-OAS: 2',5'-oligoadenylate synthetase; PKR: Protein kinase.

mitochondrial β -oxidation and blocking secretion of triglycerides from the liver. Diabetic individuals are at higher risk to develop non-alcoholic steatohepatitis, which might progress to cirrhosis in up to 5% of cases^[24,25].

Intestinal bacterial overgrowth (IBOG): Chronic liver disease is associated with slow, transient, altered gut permeability and translocation of intestinal bacteria and toxins to portal and systemic circulation^[26,27]. These toxins contribute to liver cell injury by induction of proinflammatory cytokines (TNF- α , IL-6, and IL-8) in the liver. Concomitant IBOG with HCV infection will aggravate the risk of severe hepatitis and progressive liver disease as a result of the immune response against HCV infection.

Management: Intestinal decontamination by metronidazole and probiotics to prevent endotoxin formation, open bowel by synthetic disaccharides (lactulose), and trigger peristalsis by prokinetics.

COMORBIDITIES AFFECTING THE COURSE AND RESPONSE TO THERAPY OF CHC

Schistosomiasis co-infection

Schistosoma mansoni has been the major risk factor of liver diseases in Egypt, especially in rural areas. In many patients, HCV infection is associated with schistosomiasis because of iv anti-schistosomal therapy^[28,29]. Schistosomiasis is an immunological disease, which suppress cellular immunity, triggering Th2 cytokine response favoring chronicity of hepatitis C infection.

Patients with CHC and concomitant schistosomiasis respond poorly to IFN therapy and have higher relapse rates compared to patients with HCV infection only. This might be due to HCV genotype 4 *per se*, or to the negative influence of schistosomiasis on the immune system,

leading to higher HCV RNA titers, and more severe liver damage with a higher incidence of cirrhosis. The latter is promoted by the longer duration of both infections^[30].

Diagnosis of schistosomiasis was based on a history of *Schistosoma* infection, detection of *S. mansoni* ova in stool, or a rectal biopsy^[31]. At baseline, patients with CHC and schistosomiasis had higher HCV RNA titers compared to patients without schistosomiasis^[30].

Management: Praziquantel 40 mg/kg single dose (can be repeated up to three weekly consecutive doses) before initiation of antiviral therapy.

MS

Insulin resistance has been clearly associated with steatosis, a more severe and progressive fibrosis, and a reduced response to PEG-IFN and RBV therapy in HCV patients^[13].

How does concomitant MS with HCV infection impair the response to interferon?

In obese patients, subcutaneous fat impairs absorption of interferon at the site of injection. In addition, hepatic steatosis decreases contact between interferon and hepatocytes receptors^[16]. Steatosis interferes with the signaling cascade of interferon [Janus Kinase (JAK) activate signal transduction and activator of transcription (STAT) which express *IFN* genes]^[32]. On the other hand, the HCV core protein promotes insulin resistance *via* TNF-production and insulin resistance induces steatosis, fibrogenesis, and IFN-resistance^[16,33,34]. In addition, HCV core protein and TNF- α upregulate suppressor of cytokines-3 which binds to JAK, inhibiting phosphorylation of STAT1^[35] and eventually interfering with IFN signaling^[33]. Furthermore, obesity in general is associated with a suppressed immune response^[36,37] (Figures 3 and 4).

Management of MS: Amelioration of metabolic factors before starting interferon therapy favors a good response to interferon therapy. HCV patients should avoid weight gain by life style modification (hypocaloric diet/exercise), use of insulin sensitizers, in the form of Metformin, to reduce hepatic gluconeogenesis, and pioglitazone to sensitize insulin receptors and mobilize visceral fat to subcutaneous tissues. Antioxidants (vitamin E, betaine, silymarin, and β -carotene), hepatoprotective drugs (UDCA) might add therapeutic benefit to inhibit the toxic effects of free radicals. Gut decontamination with metronidazole and probiotics to prevent gut endotoxin formation should be considered; the later induce proinflammatory cytokines in the liver that promote steatosis and steatohepatitis.

Iron overload

In hepatitis C patients, increased iron absorption in cirrhosis and difficulty in excreting iron from the body contribute to development of iron overload^[38]. There is growing evidence that iron overload enhances the amount of liver injury and progression to cirrhosis and HCC. In addition, it decreases the SVR to IFN/RBV treatment^[39,40].

Management: Venesection, restrict diets rich in iron, give antioxidants such as silymarin, betaine and vitamin E to nullify the toxic effects of free radicals.

Alcohol abuse

Alcohol abuse favors the development of alcoholic steatosis, steatohepatitis, and subsequently cirrhosis. It plays a role in resistance to interferon therapy through immunosuppression of CD4+ and NK cells^[41], by increased hepatic iron load, and by inhibiting the IFN- α -activated signals^[42,43].

Most studies found that alcohol decreased the response to interferon-based therapy and this effect is alcohol dose-dependent^[42-44]. Median daily alcohol use > 30 g/d is associated with failure to respond to PEG-IFN and RBV for treatment of hepatitis C. Past alcohol use should be evaluated when considering treatment for hepatitis C^[42].

Management: Stop alcohol abuse, intestinal antibiotics and probiotics to prevent gut endotoxin formation; and antioxidants as vitamin E, betaine and silymarin to block lipid peroxidation. Pentoxifylline is an oral phosphodiesterase inhibitor which decreases expression of TNF- α (and other proinflammatory cytokines) and which may inhibit apoptosis. When the full course is completed, the SVR is similar, regardless of alcohol intake^[45].

Excessive smoking

Heavy smoking increases the severity of hepatic inflammation and fibrosis when associated with hepatitis C infection^[46]. Heavy smoking induces resistance to interferon therapy by suppression of CD4+ and NK activity^[41] inducing apoptosis of T-cells^[47], and increasing hepatic iron load^[48].

Management: Stop smoking, venesection to reduce iron level, limit diet rich in iron and use of antioxidants as silymarin, vitamin E, betaine, β -carotene, lecithin and selenium.

COMORBIDITIES AFFECTING RESPONSE TO INTERFERON THERAPY

These comorbidities reduce compliance and adherence to inadequate PEG-IFN or RBV doses.

Depression

Depression is significantly more prevalent in chronically HCV-infected patients than in the general population^[49], which negatively affect patients' functional health, ability to work, self-perceived health, health-related quality of life (HRQL) and well being^[50].

The presence of mild/moderate depression at baseline is not considered an absolute contraindication to initiate antiviral therapy with PEG-IFN and RBV. However, this condition is certainly associated with a higher risk of developing severe depression during therapy that might lead to higher rates of treatment discontinuation in the absence of adequate antidepressant therapy^[51].

It has been reported that IFN- α downregulated glucocorticoid receptor (GR) and serotonin receptor 1A (5-HTR1A) levels in cell lines. These levels of GR and 5-HTR1A, following IFN- α -induced downregulation, recovered after withdrawal of IFN- α or addition of desipramine or fluoxetine. These data provide insights regarding the pathogenesis of IFN- α -induced depression^[52].

The pharmacokinetics of PEGylated IFN are different from those of standard IFN^[53] and the time of depression occurrence also differs between PEGylated and standard IFN^[54]; therefore, it will be important to determine if the mechanisms described by Cai *et al*^[52] on GR and 5-HTR1A receptors also apply to PEGylated IFN. In addition, anxiety and depression impair the level and activity of B cells, T cells, and NK cells^[55]. No differences in depression rates were observed by Neri *et al*^[56] comparing PEGylated- α 2a and PEGylated- α 2b, and this finding has recently been confirmed in the large randomized comparison trial IDEAL^[57].

Depression and anxiety of significant severity can adversely effect compliance and tolerance to medication. Although anemia and depression were associated with HRQL impairment, depression was the most consistent predictor^[50]. Several studies concluded that individuals who experience significant worsening of depressive symptoms during IFN therapy are less likely to achieve a virological response during therapy and an SVR after therapy withdrawal^[13].

Management: Therapeutic intervention has been shown to be effective in the management of IFN-induced depression in a controlled study^[58]. The most effective and well-studied antidepressants in this setting are those of the selective serotonin reuptake inhibitor class, in particular citalopram 25 mg/d^[59]. Importantly, all patients who received antidepressant treatment were able to complete the full course of IFN therapy; while discontinuation was necessitated in patients in the placebo arm^[60].

Anemia

Anemia that develops in a patient receiving HCV therapy often has multiple potential contributing factors, including RBV, interferon or PEG-interferon, underlying liver disease caused by HCV infection, and co-morbid conditions, such as HIV infection or chronic renal failure^[61]. The anemia associated with RBV most often occurs as dose-dependent hemolytic anemia, typically developing within the first 4 wk of therapy^[62,63]. At higher doses of RBV (1000-1200 mg/d), hemoglobin levels frequently decline by 2-3 g/dL. In addition to causing hemolysis, RBV can also downregulate the number of erythropoietin receptors^[64]. Interferon can also contribute to the development of anemia by suppressing bone marrow production of erythrocytes, but this process is generally slower and might account for the continued decline in hemoglobin concentration during the second and third months of treatment. Finally, patients developing anemia during HCV therapy often have inappropriately poor serum erythropoietin responses^[65], probably related to their underlying liver disease. It is often not possible to

pinpoint one particular drug as the primary cause of the anemia, because of the mixed nature of HCV treatment-associated anemia.

Management of anemia associated with HCV Therapy:

The conventional standard of care for managing anemia during HCV antiviral therapy has consisted of reducing the RBV dose by half if the hemoglobin level decreases to less than 10 g/dL, and to completely stop the RBV if the hemoglobin level drops below 8.5 g/dL. A decrease in RBV dose, especially in the first several months of treatment, can diminish response rates considerably. Furthermore, the strategy of decreasing the RBV dose will only partially correct the anemia. On average, the hemoglobin level will increase 1 g/dL with RBV dose reduction^[66]. Finally, some patients who have co-morbid conditions, such as diabetes mellitus, coronary artery disease, and chronic obstructive pulmonary disease, might poorly tolerate even mild levels of anemia.

The recombinant erythropoietin hormone, epoetin α , has emerged as an excellent option for improving HCV treatment-related anemia while supporting optimal treatment doses of RBV and interferon. Recombinant erythropoietin hormone acts by increasing the number of erythroid progenitor cells, and has demonstrated efficacy and safety in patients with chronic renal disease, those with malignancies receiving chemotherapy. Patients receiving once weekly epoetin α (4000 unites) had significantly higher hemoglobin levels at week 16^[67]. The major drawbacks of using any of the recombinant erythropoietin medications are high cost and slightly increased risk of thrombotic events.

Cardiovascular disease

HCV RNAs were found in the hearts of patients with cardiomyopathies, and negative strands of HCV RNA were also detected in the hearts, suggesting that HCV replicates in myocardial tissues^[68].

A major subset of CHC patients currently considered ineligible for PEG-IFN/RBV is represented by those with co-existing clinically significant heart disease. Durante-Mangoni *et al*^[69] prospectively evaluated safety and efficacy of PEG-IFN/RBV treatment in CHC patients with heart disease. They concluded that treatment with PEG-IFN/RBV might be safely offered to CHC patients with co-existing, clinically significant, heart disease. In qualified centers, CHC patients with overt heart disease should not be denied treatment, whenever indicated^[69].

However, some patients with coronary artery disease poorly tolerate even mild levels of anemia. Hence, doses should be reduced in more than 25% of patients for both PEG-IFN/RBV to avoid the serious adverse events on the sick heart.

Renal failure

CHC and chronic renal failure might occur together because of the association of HCV infection with cryoglobulinemia and membranoproliferative glomerulonephritis, or by infection of chronic renal failure patients

from exposure to HCV-contaminated blood or hemodialysis equipment.

Those with renal failure and chronic HCV infection might have significant liver disease. Although patients on dialysis tend to have milder liver disease and normal liver enzymes compared with patients with normal renal function^[70], patients with end-stage renal disease (ESRD) and CHC might have severe chronic hepatitis on liver biopsy^[71].

A liver biopsy should be performed in patients with CHC who are receiving hemodialysis^[72] and do not have major comorbidities. Among dialysis patients who are not candidates for renal transplantation, antiviral therapy is recommended in those with fibrotic disease for viral eradication and potential reduction of the stage of fibrosis.

In candidates for renal transplantation, cirrhosis is a contraindication to renal transplantation^[73]; a combined liver and kidney transplantation might be indicated in patients who progress to decompensated cirrhosis. In candidates for renal transplantation, treatment is appropriate in the pre-transplant setting^[73]. Interferon therapy is ineffective and has an unacceptably high risk of precipitating rejection after transplantation. Even in patients with mild liver disease, antiviral treatment is recommended to obtain a SVR before transplantation^[73], which will avoid the risk of progressive liver disease after transplantation.

Management of HCV infection associated with renal failure:

RBV is cleared by the kidneys and thus contraindicated in patients with renal failure^[74,75]. There is a risk of enhancement of the RBV-related hemolytic anemia, with a marked fall in hemoglobin levels. Interferon monotherapy at the standard dosing schedule of 3 million units subcutaneously three times weekly, or PEG-interferon monotherapy (α -2a or α -2b) injected once weekly, is used in patients with renal disease. The pharmacokinetics are similar to patients with renal disease down to a creatinine clearance of 20 mL/min. Trials of PEG-interferon in patients with ESRD have used either 135 mcg of PEG-interferon α -2a or 0.5-1.0 mcg/kg of PEG-interferon α -2b. In dialysis patients, the sustained virologic response achieved with interferon monotherapy is at least as good as in the general population^[76]. Adverse events leading to drug discontinuation, in decreasing order of frequency, include flu-like symptoms, neutropenia, depression, and neurological symptoms. Drop-out rates seen with interferon given at 3 million units three times weekly are between 20% and 30%. PEG-interferon monotherapy trials in patients with ESRD are currently under way.

CONCLUSION

In chronic hepatitis C, control or amelioration of comorbidities before embarking on antiviral therapy represents the milestone for higher post-antiviral therapy response.

Abstract

Achalasia is a primary motor disorder of the esophagus, in which esophageal emptying is impaired. Diagnosis of achalasia is based on clinical findings. The diagnosis is confirmed by radiographic, endoscopic, and manometric evaluations. Several treatments for achalasia have been introduced. We searched the PubMed Database for original articles and meta-analyses about achalasia to summarize the current knowledge regarding this disease, with particular focus on different procedures that are used for treatment of achalasia. We also report the Iranian experience of treatment of this disease, since it could be considered as a model for medium-resource countries. Myotomy, particularly laparoscopic myotomy with fundoplication, is the most effective treatment for achalasia. Compared to other treatments, however, the initial cost of myotomy is usually higher and the recovery period is longer. When performing myotomy is not indicated or not possible, graded pneumatic dilation with slow rate of balloon inflation seems to be an effective and safe initial alternative. Injection of botulinum toxin into the lower esophageal sphincter before pneumatic dilation may increase remission rates. However, this needs to be confirmed in further studies. Due to lack of adequate information regarding the role of expandable stents in the treatment of achalasia, insertion of stents does not currently seem to be a recommended treatment. In summary, laparoscopic myotomy can be considered as the procedure of choice for treatment of achalasia. Graded pneumatic dilation is an effective alternative when the performance of myotomy is not possible for any reason.

INTRODUCTION

Achalasia is the most recognized primary motor disorder of the esophagus. In idiopathic achalasia, inhibitory ganglion cells in the myenteric plexuses of the esophagus undergo inflammatory degeneration. The term achalasia means “failure to relax”; the loss of ganglion cells leads to a defect in lower esophageal sphincter (LES) relaxation, which is the principal feature of idiopathic achalasia and causes functional obstruction of the esophagus, and reduced peristalsis in the esophageal body, which further impairs esophageal emptying. The functional obstruction in the LES is overcome only when the hydrostatic pressure of the retained material in the esophagus exceeds the LES pressure^[1]. Secondary achalasia may occur following several conditions, which are listed in Table 1.

The reported annual incidence of achalasia is approximately 1 per 100 000^[2]. Men and women are affected with equal frequency^[3]. Although achalasia is diagnosed mainly in people aged between 25 and 60 years, it may occur at any age^[2-4]. In general, achalasia has a subtle onset, and symptoms progress gradually. Therefore, patients experience symptoms for months or years before their disease is diagnosed. In a series of 87 patients with newly-diagnosed achalasia, the mean duration of symptoms was 4.7 years. The delay in diagnosis was due to misinterpretation of symptoms by physicians and atypical clinical manifestations^[5]. Many patients are treated for other disorders such as gastro-esophageal reflux disease (GERD) before the diagnosis of achalasia is made^[3]. The main symptom of achalasia is dysphagia^[3]. To relieve dysphagia and other symptoms of achalasia, several treatments have been introduced,

including medical therapy, myotomy, pneumatic dilation of the LES, and injection of botulinum toxin into the LES. Early treatment of achalasia may also reduce the reported increased risk of esophageal cancer among patients with achalasia^[6,7].

In this article, we report results of our review of medical literature on the subject of achalasia. Our aim is to summarize the current knowledge as regards this disease, with particular focus on different procedures that are used for treatment. Furthermore, several articles about achalasia have been published from Iran, mainly from the Digestive Diseases Research Center, Shariati Hospital of Tehran University of Medical Sciences, a nationwide referral center for the disease, where we provide follow-up care for 675 patients with achalasia. We present results of the Iranian studies, since our experience could be considered as a model for medium-resource countries.

PATHOPHYSIOLOGY

In achalasia, inhibitory ganglion cells in the myenteric plexuses of the esophagus, which produce nitric oxide, undergo inflammatory degeneration^[8-10]. The remaining ganglion cells are often surrounded by lymphocytes and, to a lesser extent, by eosinophils^[8,11]. Loss of inhibitory ganglion cells has two consequences: (i) basal LES pressure rises, which impairs normal relaxation of the sphincter and esophageal emptying, and (ii) the smooth muscle layer in the esophageal body loses normal peristalsis.

Several studies have suggested that a viral infection or some other environmental factor may initiate inflammation in the myenteric plexus. For example, a recent study suggested that the inflammatory reaction might be triggered by human herpes virus type 1^[12]. In certain individuals, the inflammation may lead to an autoimmune response against ganglion cells. Genetic susceptibility may play a role in this process^[13]. There are some reports of an association between some human leukocyte antigens and the presence of circulating antibodies to enteric neurons and the loss of ganglion cells^[14]. An hereditary association between achalasia and some other conditions such as adrenal glucocorticoid deficiency and alacrima has been reported^[15]. In our study on 25 children with achalasia, 2 cases (8%) had Achalasia, Alacrima, and Adrenal insufficiency (triple A syndrome or Allgrove syndrome) and 3 cases (12%) had Achalasia and Alacrima (double A syndrome). All of the 5 cases were siblings from two families^[16].

CLINICAL FEATURES

The prevalence of the main symptoms of achalasia is shown in Table 2. The most common symptom of achalasia is dysphagia to solid foods (over 99%), followed by dysphagia to liquids (90% to 95%)^[17]. Although dysphagia to liquids can occur in patients with other esophageal motility disorders (e.g. progressive systemic sclerosis), this symptom strongly suggests achalasia^[3].

Regurgitation, active or passive, occurs in 70% to

Symptom	Percentage (%)
Dysphagia to solids	99
Dysphagia to liquids	93
Active regurgitation	84
Passive regurgitation	68
Weight loss	61
Chest pain	59
Nocturnal cough	45
Heartburn	35
Nocturnal dyspnea	20
Hiccup	8

80% of cases. Regurgitation can be troublesome; this may lead to aspiration when patients lie down^[2,3]. Weight loss, chest pain, and heartburn occur in approximately 40% to 60% of patients. Although severe weight loss can happen, the usual weight loss is 5 to 10 kg.

Occasionally, chest pain is the presenting symptom of achalasia. This is more common in younger patients, and tends to diminish with advancing age^[17]. In our study of 213 achalasia patients, chest pain was the only symptom whose prevalence between the sexes was significantly different, being more common among women than men (70.9% *vs* 54.5%, $P = 0.03$, respectively)^[18]. In both sexes, chest pain did not relate to the duration of symptom and the LES pressure. Chest pain was less frequently reported by patients over 56 years of age compared to those younger than 56 years ($P < 0.05$)^[18]. It seems that chest pain is a distinctive symptom of achalasia which is affected by sex as well as age. Although chest pain was not improved following pneumatic dilation in some studies^[17], others reported significant improvement after the procedure^[18].

Heartburn occurs frequently in achalasia. Patients with heartburn have lower LES pressures than those without this symptom^[19]. Heartburn may occur as a result of gastro-esophageal reflux or other causes, such as direct irritation of the esophageal mucosa by foods, pills, and the lactate produced by bacterial fermentation of retained carbohydrates^[19,20]. Hiccup is also a frequent symptom in achalasia, partly because of the obstruction of the distal esophagus^[21]. Functional and structural abnormalities of the lung, such as tracheo-bronchial compression and abnormalities on high-resolution CT-scan, may occur in half of the patients^[22]. The frequency

Table 3 Frequency of cardinal symptoms in achalasia

Symptom	Frequency (%)			
	Each meal	Daily	Weekly	None
Dysphagia to solids	84	13	2	1
Dysphagia to liquids	60	25	8	7
Active regurgitation	33	36	15	16
Passive regurgitation	Daily	Weekly	Monthly	None
	20	44	4	32
Chest pain	12	39	8	41

of cardinal symptoms in achalasia is shown in Table 3.

Since patients with achalasia may experience retro-sternal fullness following a meal, they may eat more slowly and induce regurgitation to relieve the feeling. They may perform some maneuvers to augment esophageal emptying, such as lifting the neck or throwing the shoulders back^[3].

Compared to the general population, patients with achalasia are at substantially increased risk, even as high as 33-fold, of developing esophageal cancer. The cancer typically is of squamous cell type^[6,7]. However, some series did not find any increase in the risk, particularly with early treatment of achalasia. We followed up 365 patients with achalasia for a mean duration of 43 mo; no case of esophageal cancer was identified. This may be related to the fact that our study participants were fairly young (mean age, 38 years) and the duration of follow-up was not very long^[23].

DIAGNOSIS

Diagnosis of achalasia is based on clinical findings. The diagnosis is confirmed by radiographic, endoscopic, and manometric evaluations.

Radiography

The usual findings on a plain chest X-ray are widening of the mediastinum, due to esophageal dilation, and absence of the normal gastric air. When achalasia is suspected, barium swallow is the primary screening test. Barium swallow typically shows a dilated esophagus that terminates in a beak-like narrowing as a result of contraction in the LES. When dilation is very severe, the esophagus may have a sigmoid shape^[3]. The overall sensitivity of barium swallow for diagnosis of achalasia is approximately 95%^[24], but in early stages of the disease it may be reported as normal. For example, in a prospective study achalasia was suggested by barium examination in only 21 out of 33 patients who eventually were diagnosed with achalasia^[2].

The timed barium esophagogram, which assesses esophageal emptying at 1, 3 and 5 min after swallowing of barium, can be more helpful than usual barium swallow. Vaezi *et al*^[25] reported that assessing both symptom improvement and objective improvement in esophageal emptying can better identify the response rate to pneumatic dilation and need for repeated dilations in the future. In their study of 37 patients, there was a significant

association ($P < 0.001$) between improvement in patient symptoms and barium height. In 38 out of 53 (72%) pneumatic dilations, the degree of symptom and barium height improvement was comparable. In 8 out of 26 (31%) patients, however, there was $< 50\%$ improvement in barium height despite near complete symptom resolution. Age was the only difference between the groups and patients with improvement in both symptoms and barium height, i.e. the first group, were significantly older than the second. They concluded that the timed barium esophagogram before and after dilation may identify a subset of patients with poor esophageal emptying but with good improvement in symptoms who may benefit from early repeated pneumatic dilation^[25]. Similarly, Chuah *et al*^[26] found in their study of 32 patients with achalasia who received pneumatic dilation that the timed barium esophagograms correlated with symptomatic improvement in up to 71% of patients, although seven patients who noted complete symptom resolution showed less than 50% improvement in barium column height and esophageal diameter. In a study of 52 patients, we also found that the volume of barium retention at 5 min could predict the LES pressure before and after balloon dilation in achalasia^[27], and in a study of 43 patients, surface area of barium retention at 5 min appeared to be an even better predictor for resting LES pressure^[28]. In a randomized clinical trial of 51 patients who underwent surgery or pneumatic dilation, results of the timed barium esophagogram also correlated well with outcome. Poor improvement in barium height following the treatments was associated with an increased risk of treatment failure^[29].

Manometry

Manometry is the most sensitive tool for diagnosis of achalasia. Elevated resting LES pressure (usually > 45 mmHg), incomplete LES relaxation, and aperistalsis in the smooth muscle portion of the body of the esophagus are three characteristic manometric features of achalasia^[30]. Swallows may be followed by either no esophageal contraction or simultaneous contractions. Simultaneous contractions may also occur spontaneously. Another common feature is that resting pressure in the body of the esophagus is slightly higher than in the stomach^[3].

In most patients the amplitude of esophageal contractions is low. On the other hand, in vigorous achalasia the simultaneous esophageal contractions have high amplitudes (e.g. > 60 mmHg). Some studies have suggested that vigorous achalasia may represent an early form of achalasia in which some inhibitory ganglion cells may not yet be destroyed^[8], and that patients with vigorous achalasia may benefit more from botulinum toxin injection than those with classic achalasia^[31]. At present, however, the distinction between vigorous and classic achalasia seems to have little clinical significance.

Endoscopy

Endoscopy in achalasia typically reveals a dilated

esophagus that often contains retained material. The esophageal mucosa usually appears normal, although inflammation and ulceration may result from chronic inflammation caused by retained food or pills. Endoscopy may be reported as normal if it is carried out in the early stages of the disease or it is not performed by experienced endoscopists^[2]. Achalasia at early stages may also be misdiagnosed as GERD. Food stasis and GERD are main factors contributing to esophageal mucosal inflammation in achalasia. The association between endoscopic food stasis and histological inflammation is significant, but endoscopic signs of esophagitis and histological inflammation are poorly associated. Because of low sensitivity of endoscopy to detect inflammation, surveillance endoscopy with biopsy sampling and assessment of stasis is warranted to detect early neoplastic changes^[32]. The stasis may predispose the esophagus to *Candida* infection.

Although the LES in achalasia is contracted, the endoscope can usually be traversed easily into the stomach aided by gentle pressure on the scope^[3].

Endoscopic ultrasonography (EUS) may show widening of the mean longitudinal and circular smooth muscle layers of the LES; however, this finding is not specific for achalasia^[33]. We compared the esophageal muscularis propria thickness in achalasia patients with a control group using EUS and assessed the relationship between EUS findings and demographic features in both groups. The esophageal muscular layer was significantly thicker in patients with achalasia compared to control group ($P < 0.05$). Among patients with achalasia, the thickness at 5 and 10 cm above the gastro-esophageal junction appeared to be correlated with age, being higher among older people^[34].

Clinical and endoscopic features of some other conditions, such as neoplasms, may be similar to those of achalasia. Since gastric adenocarcinoma is the most common neoplasm associated with pseudo-achalasia, the esophago-gastric junction and the gastric fundus should be carefully examined for any evidence of neoplasm. With certain features, malignancy is more likely: duration of symptoms less than 6 mo; presentation after the age of 60 years; excessive weight loss in spite of short duration of symptoms; difficult passage of the endoscope through the gastro-esophageal junction^[35]. In these cases, repeated evaluations and biopsies are recommended.

Symptomatic scoring

Several scoring system have been proposed to evaluate the severity of the symptoms in achalasia. One of the scoring systems is shown in Table 4. In this scoring system, scores for the following five symptoms; dysphagia to solids, dysphagia to liquids, passive regurgitation, active regurgitation, and chest pain are summed up to calculate the total score. In a study of 116 patients with achalasia, we found a good correlation between this score and LES pressure ($r = 0.29$, $P < 0.01$)^[36]. Among the main symptoms, active and passive regurgitation and dysphagia to liquids were significantly correlated to the

Table 4 Scoring system for evaluation of clinical symptoms

Symptom	Score by frequency of symptoms			
	Each meal	Daily	Weekly	None
Dysphagia to solids	3	2	1	0
Dysphagia to liquids	3	2	1	0
Active regurgitation	3	2	1	0
Passive regurgitation	Daily	Weekly	Monthly	None
	3	2	1	0
Chest pain	3	2	1	0

LES relaxation pressure ($P = 0.001$, 0.002 , and 0.046 , respectively)^[36].

TREATMENT

The mainstay of therapy is to reduce LES pressure in order to improve esophageal emptying by gravity. Several therapeutic modalities have been introduced to achieve this goal, including medical therapy, surgical myotomy (open or laparoscopic), pneumatic dilation of the LES, injection of botulinum toxin into the LES, and insertion of self-expanding stents. There are 3 recent meta-analyses of publications which have investigated different treatment approaches. One of these included 105 articles involving 7855 subjects, and investigated symptom relief, prevalence of gastro-esophageal reflux, and complications following treatments^[37]. Pneumatic dilation was more successful in symptom relief than botulinum toxin injection (68% *vs* 41%, $P = 0.02$, respectively). Symptom relief with laparoscopic myotomy plus an anti-reflux procedure was better (90%) than with all other treatments. Furthermore, complication rate was low with this method (6.3%)^[37]. Likewise, another meta-analysis of randomized and controlled treatment trials, which included 17 articles with 761 participants and investigated remission and relapse rates and complications, found a better remission rate and lower relapse rate for laparoscopic myotomy compared to other treatments. There was no difference between open and laparoscopic myotomy, in the only trial that compared these two methods, regarding remission and relapse rates. Remission rate following pneumatic dilation was higher than after botulinum toxin injection^[38]. A meta-analysis of controlled and uncontrolled studies in the Chinese literature (43 articles with 1791 participants) also showed that myotomy was associated with higher initial and long-term remission rates than pneumatic dilation or botulinum toxin injection. Only 2 studies compared open myotomy with laparoscopic myotomy; there was no difference in remission rate^[39]. Since results after any treatment may deteriorate over time, life-long follow-up and objective assessment of the results are recommended.

Medical therapy

Nitrates and calcium channel blockers (e.g. nifedipine) relax the smooth muscles of the LES^[40]. These medications are usually taken sublingually 10 to 30 min before meals. Pharmacotherapy for achalasia, however, is often ineffective and frequently associated with side

effects (e.g. headache, hypotension, and tachyphylaxis). Therefore, nitrates and calcium channel blockers are primarily used for patients who are unwilling to undergo or unable to tolerate more effective, invasive forms of therapy^[3].

Surgical myotomy

Surgical myotomy was first introduced by Ernst Heller in 1913. Nowadays, a modified technique is commonly used^[41]. The standard “open” myotomy can be performed using either an abdominal or, more commonly, a thoracic approach^[42,43]. More recently, laparoscopic and thoracoscopic techniques have been used to perform myotomy^[39,44-46].

The modified Heller approach results in good to excellent relief of symptoms in 70% to 90% of patients with few serious complications. The mortality rate (approximately 0.3%) is similar to that reported for pneumatic dilation^[42]. The major disadvantages of surgery are the high initial cost, long recovery period, and the frequent development of GERD. Reflux esophagitis develops in approximately 10% of patients treated by surgical myotomy^[42]; however, the efficacy of proton pump inhibitor treatment minimizes its clinical significance. There is a debate with regard to the need for additional fundoplication in open myotomy. In some studies, gastro-esophageal reflux was relatively frequent even after combining myotomy with anti-reflux procedures^[47,48].

There is increasing experience with Heller myotomy performed by minimally invasive techniques (laparoscopy or thoracoscopy), and these techniques have become the procedure of choice by many experienced surgeons for uncomplicated cases in Western countries. These approaches in several trials were more successful in symptom relief than other treatments^[37]. They are associated with few major complications^[49] and shorten the duration of hospitalization and recovery^[44,45]. Some pre- and postoperative findings may be helpful in predicting the outcome. In a study of 407 patients who underwent laparoscopic myotomy, high preoperative LES pressure (> 30 mmHg) was a predictor of a good response, while severe chest pain and the presence of a decompensated sigmoid esophagus (class IV) was associated with poor outcome^[50]. In a study of 200 patients who underwent laparoscopic or thoracoscopic myotomy plus a partial fundoplication, low LES pressure, presence of sigmoid esophagus, and longer duration of symptoms were associated with failure of treatment in long-term follow-up^[51]. Preoperative LES pressure over 35 mmHg was also a strong predictor of excellent postoperative relief in dysphagia in another study of 200 patients^[52].

Objective analyses have shown a high rate of gastro-esophageal reflux in laparoscopic myotomy without an anti-reflux procedure. In a study of 50 patients with achalasia who underwent laparoscopic Heller myotomy without anti-reflux procedures, significant heartburn was reported in 30% of cases. Twenty-four-hour pH monitoring revealed abnormal findings in 11 out of 22 patients tested^[53]. However, use of a fundoplication procedure with laparoscopic myotomy

reduced the rate of gastro-esophageal reflux (8.8% with a fundoplication *vs* 31.5% without a fundoplication, $P = 0.003$)^[37]. In a study of 20 patients who underwent laparoscopic myotomy and fundoplication, 24-h combined multichannel intra-luminal impedance and pH monitoring did not show any evidence of postoperative pathologic reflux in both upright and recumbent positions^[54]. Few randomized trials have investigated the efficacy of different fundoplication techniques used with laparoscopic myotomy in treatment of achalasia. In a randomized, controlled study of 144 patients who underwent laparoscopic myotomy, the outcome when using Dor *versus* Nissen fundoplication was investigated. Both techniques were successful in long-term control of gastro-esophageal reflux, but the recurrence rate of dysphagia was higher with the Nissen method^[55]. Based on the published literature, Dor fundoplication seems to be performed more commonly as the anti-reflux procedure during laparoscopic myotomy than other fundoplication techniques.

Pneumatic dilation

Although some studies reported similar short- and long-term efficacy for myotomy and pneumatic dilation, particularly with graded dilation (1-3 dilations with progressively larger balloons)^[56,57], as mentioned earlier, myotomy has been shown to be a more effective treatment for achalasia in several trials^[37,38]. However, pneumatic dilation is less expensive than myotomy and still improves symptoms in a substantial number of patients^[58-60]. In a meta-analysis of uncontrolled studies, a single pneumatic dilation was found to be effective in 72% of patients during a mean follow-up of 4.9 years^[61]. In a study of 150 patients with achalasia, pneumatic dilations were performed until remission was achieved or symptoms recurred, using an “on-demand strategy” based on symptom recurrence, and a long-term remission was achieved in nearly all patients^[60]. Pneumatic dilation can also be applied for some patients in whom dysphagia persists after surgery^[62,63]. In a study of 27 patients with recurrent dysphagia following surgery, pneumatic dilation improved symptoms in 76% of the patients^[63]. If pneumatic dilation fails, laparoscopic myotomy with fundoplication can be performed; the outcome is not affected by previous pneumatic dilation^[50,64].

A number of different balloon dilators have been used over the years. A systematic review of the treatment of achalasia compared the results of using different dilators; pneumatic dilation was performed in 2418 patients with “old” dilators, in 234 patients with the “new” Witzel dilator, and in 359 patients with the Rigiflex dilator^[65]. Using old dilators and Witzel dilators, two-thirds of patients had good to excellent improvement after one or more dilations during a mean follow-up of 4.6 years and one year, respectively. Using Rigiflex dilators, an equivalent improvement was achieved in up to 90% of patients, depending upon the diameter of the dilator used (74% for 3.0 cm, 86% for 3.5 cm, and 90% for 4.0 cm)^[65]. At present, the most popular pneumatic dilator is the Rigiflex balloon, which is passed over a guidewire and positioned

fluoroscopically or endoscopically in the LES. This balloon is available in three different sizes (3.0, 3.5, and 4.0 cm). The thinnest balloon is typically used in the first dilating session. The standard approach to balloon dilation is one dilatation per session; further need for dilation is based on the symptomatic response. Patients are usually referred to a surgeon if three consecutive dilations over a few months do not provide clinical remission. In long-term follow-ups, more than three sessions can be applied if symptoms recur.

In our center we perform all dilations with the Rigidflex balloon dilator. After a clear liquid diet for 24 h and an overnight fast, patients receive intravenous diazepam (5-10 mg) and meperidine (25-50 mg). A guidewire into the stomach is placed under endoscopic visualization. In the first dilating session, a 3.0 cm balloon dilator is passed over the guidewire under endoscopic guidance. The midpoint of the balloon is positioned at the LES. The balloon is gradually inflated to 6 pounds per square inch (psi) over 20 s and then to 8 psi for the next 20 s and finally to 10 psi for 60 s. Then the balloon is deflated and removed along with the guidewire. Patients are discharged after a 6-h observation period. If severe or sustained chest pain occurs, a gastrografin swallow is performed to rule out perforation.

Using the above method we conducted a study of 99 patients to assess therapeutic outcome after pneumatic dilation. Initially, all symptomatic patients underwent pneumatic dilation with a 3.0 cm balloon. If symptoms recurred, dilation was repeated with a 3.5 cm balloon. In the case of further relapse, a third dilation was carried out with a 4 cm balloon. The patients were followed for an average length of 47 (range, 18 to 60) mo. Dilation was repeated in 35 patients; only 6 of them required a third dilation. After the third dilation two patients did not display improvement and underwent myotomy. Over the study period, cumulative remission rate was 65% without re-dilation and 94% with re-dilation. The mean remission period was 44.7 mo^[66].

To address the optimal method for performing pneumatic dilation, regarding the amount and rate of inflation pressure and balloon diameter, we conducted a large long-term prospective study and enrolled 262 achalasia patients over 10 years. In the first 62 patients (group A), dilation was done using a 3.5 cm balloon, which was inflated to the pressure of 10 psi over 10 s. In group B (200 patients), we initially used a 3.0 cm balloon with inflation pressure of 10 psi in 30 s. We used a Rigidflex balloon and maintained pressure for 60 s after inflation in both groups. If symptoms recurred, dilation was repeated with incrementally larger balloons (for second dilation, 4.0 cm in group A and 3.5 cm in group B; for third dilation, 4.0 cm in both groups). The cumulative proportional remission rates with single dilation after 6 mo were 83% and 75% in groups A and B, respectively; the corresponding rates decreased to 60% and 57%, respectively, after 30 mo. The difference between the 2 methods was not statistically significant. The remission rate following re-dilation was good; 1 year after the second dilation, it was 88% in group A and 89% in group B,

and 2 years after the second dilation, it was 70% in both groups. All perforations ($n = 3$) occurred in group A at the first dilation (62 dilations) with rapid inflation of balloon (10 psi over 10 s); while there was no perforation in group B (296 dilations), in which gradual increasing of pressure (10 psi over 30 s) and graded dilation method was used^[67].

In another Iranian study, 45 patients who underwent pneumatic dilation were compared with 19 patients who underwent open myotomy. Good to excellent relief was achieved in 68% of patients with myotomy and 80% of patients with pneumatic dilation. After over 2 years of follow-up, relapse rates in both groups were not significantly different (39% in surgery group and 25% in pneumatic dilation group). The mean length of hospital stay and days off from work were significantly lower in the pneumatic dilation group; these were discovered to be 9 and 39 d in the myotomy group and 1 and 2 d in the pneumatic dilation group, respectively^[57].

Some predictors for the outcome of pneumatic dilation have been suggested, including age of patients^[68,69] and a decrease in LES pressure following dilation^[69]. In a study of 111 patients, short- and long-term remission rates were good (98% and 75% at months 24 and 60, respectively), but young age (≤ 37.5 years), high esophageal body pressure, and high LES pressure (≥ 17.5 mmHg) following first dilation were negative predictive factors. Young patients who required more than 2 dilations seemed not to benefit from this kind of treatment^[70]. We did not find any significant association between age, gender, previous treatment, or severity of initial symptoms and the outcome of pneumatic dilation ($P > 0.4$)^[66].

Esophageal perforation is the most important complication of pneumatic dilation. It occurs in approximately 3% to 5% of patients in most series, although the range varies from 0% to 21%^[3,71]. Patients with esophageal perforation usually present in the first hours after dilation. A high index of suspicion should be maintained in patients complaining of sustained pain or discomfort after the procedure. Some patients respond to conservative treatment with antibiotics and parenteral nutrition but others need a surgical repair. Other complications of pneumatic dilation include development of intramural hematomas, esophageal mucosal tears, and diverticula at the gastric cardia^[72]. Severe transient and intermittent post-procedural chest pain has been reported in approximately 15% of patients during the 24-48 h after dilation^[73,74]. Although this symptom is disturbing, it is not harmful.

Botulinum toxin injection

Botulinum toxin is a potent inhibitor of acetylcholine release from nerve endings. The toxin theoretically relaxes the LES by decreasing unopposed cholinergic stimulation of the LES^[75]. Although the effect of botulinum toxin injection generally is shorter than some other procedures, it can be useful under certain conditions. In patients with multiple medical problems who are poor candidates for more invasive procedures, as well as those unwilling to undergo either surgery or pneumatic dilation, botulinum toxin injection is the preferred approach. Older patients

and those who suffer from vigorous achalasia may benefit more from botulinum toxin^[76]. A multicenter randomized study suggested that dose of botulinum toxin may be a predictor of outcome: the higher the dose, the better the response^[77].

The use of botulinum toxin in achalasia was first introduced by Pasricha *et al*^[78]. Several studies indicate that 65% to 90% of patients respond to a single injection within 1 mo. The effect of botulinum toxin lasts from 3 mo to more than one year^[79-82]. Those who respond to the injection may do equally well after a second or even a third injection. In one series, for example, symptom relief was achieved in 75% of 57 patients who received repeated injections, as needed, during up to 2 years follow-up^[31]. However, the effect decreases over time; some studies reported clinical remission rates of 50% and 30% at 6 and 12 mo, respectively, following botulinum injection^[83]. Although a few studies reported that botulinum toxin injection could provide an efficacy equal to that of pneumatic dilation over a one year period^[84], several randomized clinical trials have shown that while initial symptomatic remission rates by pneumatic dilation and botulinum injection may be similar in some cases, pneumatic dilation is associated with a significantly higher long-term remission rate^[85,86]. In some studies, only pneumatic dilation was associated with improvement in objective measures of esophageal function, including esophageal manometry and barium studies^[85,87]. In our trial of 40 patients, pneumatic dilation was more efficient than botulinum injection in providing sustained symptomatic relief over a 12 mo period. The remission rates for pneumatic dilation and botulinum injection after 12 mo were 52% and 15%, respectively^[88].

Several formulations of botulinum toxin are available. A comparison between 100 U of Botox and 250 U of Dysport showed a similar efficacy for up to 6 mo of follow-up^[89]. In the most common method for injection therapy, 1 mL aliquots (20 to 25 units/mL) of the toxin are injected into each of four quadrants, approximately 1 cm above the Z line, using a standard sclerotherapy needle. We use and recommend the following method. After an overnight fast, patients are sedated with intravenous diazepam (5-10 mg) and meperidine (25-50 mg). The LES is identified by visualization of the sphincter rosette at the squamo-columnar junction during upper gastrointestinal endoscopy. Four hundred units of Dysport are diluted in 4 mL normal saline. Two 50-unit aliquots (0.5 mL) of Dysport are injected through a 5 mm sclerotherapy needle into each quadrant of the LES. Patients are discharged when routine post-sedation care is completed and allowed to eat later on the same day. Improvement in symptoms is usually observed after only 24 h; peak effects occur even later in some patients.

Reported complications after botulinum toxin are not major and include post-procedural transient chest pain (25%) and heartburn (5%)^[90]. Transient chest pain, the main complication, can be controlled by sedatives. Neutralizing antibodies have been detected in approximately 5% of patients treated chronically with botulinum toxin for skeletal muscle conditions; however,

their significance in relapse of dysphagia in achalasia is uncertain. These antibodies, however, might be a possible cause of the rapid relapse of dysphagia following botulinum toxin injection^[91]. Surgical treatment of achalasia in patients who previously received botulinum toxin may encounter some technical problems, but no significant difference in the outcome between patients with and without previous use of the toxin has been reported^[92].

Pneumatic dilation after botulinum toxin injection

Only a few studies have investigated the effect of botulinum toxin injection on the outcome of pneumatic dilation. In a retrospective study of the effect of the combined therapy, we studied 12 patients who underwent dilation following botulinum toxin injection and 12 patients with achalasia who underwent only pneumatic dilation (control group). With combined therapy, only one of the patients relapsed 30 mo after dilation, while all the others were in remission for an average of 25.6 mo. In the control group, all the patients relapsed after a mean period of 12.6 mo and needed further dilation. The cumulative remission rate was significantly higher in the combined therapy group than in the control group ($P < 0.01$). One month after dilation, the mean symptom score decreased by 76% in the combined therapy group and by 53% in the control group. Age, sex, duration and severity of symptoms were not correlated with response to treatment^[93].

We also conducted a prospective trial. Twenty seven patients were randomly assigned to receive botulinum toxin 1 mo before pneumatic dilation and 27 patients were assigned to undergo pneumatic dilation alone. One-year remission rates of patients in the botulinum toxin-pneumatic dilation group and the pneumatic dilation group were 77% and 62%, respectively ($P = 0.1$). In the pneumatic dilation group, the esophageal barium height significantly decreased at 1 mo ($P < 0.001$), but this reduction did not persist over 1-year follow-up. The botulinum toxin-pneumatic dilation group showed a significant reduction in barium height at both 1 mo and 1 year after treatment ($P < 0.001$). In the botulinum toxin-pneumatic dilation group, 91% of patients older than 40 years were in remission at 1 year, compared with only 55% of this age group in the pneumatic dilation group ($P = 0.07$)^[94].

We found an abstract in English that reported a series of 9 patients with achalasia who were treated with application of 250 IU Dysport into the LES and balloon dilation 7 d later. Two patients underwent myotomy because of poor relief of symptoms. Seven other patients, however, were in good symptomatic remission after one year. The remission was even observed for as long as 36 mo, which was the longest follow-up period^[95].

Insertion of stents

Only a few studies have investigated the role of expandable stents in treatment of achalasia^[96-99]. The results are controversial. Therefore, insertion of stents does not seem to be a currently recommended treatment for achalasia.

CONCLUSION

First stages of achalasia may be misdiagnosed as other diseases, such as GERD. Myotomy, particularly laparoscopic myotomy with fundoplication, is the most effective treatment for achalasia and can be considered as the procedure of choice. Compared to other treatments, however, the initial cost of myotomy is usually higher and the recovery period, particularly following open myotomy, is generally longer. When performing myotomy is not possible for any reason, e.g. medical contraindication, patient's unwillingness, when patients cannot afford surgery, or experienced centers for surgery or post-operative care are not easily accessible (situations that may not be rare particularly in some low- or medium-resource countries), graded pneumatic dilation (using 3.0 cm balloons initially) with slow rate of balloon inflation seems to be an effective and safe initial alternative. The duration of remission can be extended by repeated dilation with larger-sized balloons. Injection of botulinum toxin into the LES before pneumatic dilation seems to increase remission rates. However, this needs to be confirmed in further studies. The timed esophagogram may be used as a non-invasive objective tool for initial and post-operative or post-dilation assessment.

INTRODUCTION

Liver disease caused by chronic hepatitis C virus (HCV) infection is the most common indication for liver transplantation in the United States. Unfortunately, HCV is universally recurrent in the transplanted liver and is a major cause of graft failure and decreased patient survival^[1]. 10%-30% of patients who have recurrent infection develop advanced fibrosis or cirrhosis within the first 5 years post-transplantation^[2,3].

The combination therapy of interferon and ribavirin has been shown to be the most effective therapy for HCV recurrence after liver transplantation with sustained virologic response rates between 20%-40%^[4]. Further studies are needed to determine whether treatment should be started preemptively, at the time of acute hepatitis, or at the early stages of chronic hepatitis in the graft. The ability to treat patients with adequate doses of interferon and ribavirin or even to initiate treatment is often limited by leucopenia, anemia, and thrombocytopenia. Chang *et al*^[5] reported in their study that almost 50% of patients (109 out of 216) had a platelet count below 50 000/ μ L before liver transplantation. At one year of follow-up, 21% of transplanted patients (45 out of 216) continued to have moderate to severe thrombocytopenia. Clinical factors associated with sustained thrombocytopenia were pretransplant severe thrombocytopenia ($< 50\,000/\mu\text{L}$) and pretransplant large spleen volume ($> 2000\text{ mm}^3$).

Splenectomy and partial splenic embolization represent two interventional therapies to improve thrombocytopenia which could potentially allow treatment of HCV. In this review we examine the effectiveness and risks of these approaches in liver transplant patients.

SPLENECTOMY

Splenectomy has been performed routinely in the past in liver and kidney transplant patients for immunologic reasons. It allowed patients to tolerate azathioprine therapy for episodes of rejection^[6]. This practice continued

Abstract

Hepatitis C is the most common indication for orthotopic liver transplantation in the United States. Unfortunately, hepatitis C recurs universally in the transplanted liver and is the major cause of decreased graft and patient survival. The combination therapy of interferon and ribavirin has been shown to be the most effective therapy for recurrent hepatitis C. However, pre- and post-transplant hypersplenism often precludes patients from receiving the antiviral therapy. Splenectomy and partial splenic embolization are the two invasive modalities that can correct the cytopenia associated with hypersplenism. In this report we review the two treatment options, their associated outcomes and complications.

until the early 1980s when cyclosporine was introduced. Current accepted indications for post-transplant splenectomy include recurrent ascites, splenic infarction, large aneurysms of the splenic artery, thrombocytopenia secondary to hypersplenism prior to or after liver transplantation, and small-for-size syndrome in recipients of living donors with associated thrombocytopenia and impaired liver function. Splenectomy was also performed at the time of liver transplantation for ABO incompatibility and preemptive HCV treatment with interferon and ribavirin in thrombocytopenic patients^[7-9]. Tashiro *et al*^[10] advocated performing concurrent splenectomy with liver transplantation in all patients who had a pre-transplant platelet count of less than 60000 mm³ so that this group of patients could tolerate preemptive administration of combination therapy in the post-transplant period.

Although successful results have been reported, splenectomy is potentially associated with multiple complications. It is an invasive procedure that can be technically difficult, with a high risk of bleeding in patients with portal hypertension, varices, and enlarged spleen. Portal vein thrombosis and pancreatic leaks requiring surgical reexploration have been described as complications^[9,11]. However, in our opinion, the risk of infection post-splenectomy is the most serious and potentially life-threatening complication in the immunosuppressed population. Troisi *et al*^[12] reported that 4 out of 10 liver transplant patients who underwent splenectomy developed sepsis, which led to their demise. Samimi *et al*^[13] reported 17.5% *vs* 2.7% one-month and 30% *vs* 11.5% one-year sepsis-related mortality in patients who underwent concomitant splenectomy with liver transplantation *vs* those who underwent liver transplantation alone. Neumann *et al*^[14] reported an increased risk for opportunistic pneumonia in patients who underwent simultaneous splenectomy and liver transplant. Splenectomy also places patients at risk for overwhelming post-splenectomy sepsis syndrome (OPSS), usually due to encapsulated organisms. It is recommended by the Center for Diseases Control to immunize patients prior to splenectomy to decrease the risk of OPSS from *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, and *Neisseria meningitidis*^[15]. According to guidelines issued by the American Society of Transplantation in 2004, these vaccines are administered to all candidates prior to liver transplantation^[16]. Unfortunately, the response rate is only 40%-80%^[17,18].

Despite vaccinations, fulminant bacterial sepsis carries a high risk of morbidity and mortality, especially in immunocompromised patients. The risk is greatest in the early months and years after splenectomy, but a period of as long as 45 years after the procedure has been reported in the literature^[19].

invasive treatment of hypersplenism. It is usually performed *via* a percutaneous femoral artery approach. The embolization catheter is advanced into the splenic hilum as far as possible in order to avoid injury to the pancreatic circulation. Gelatin sponge slurry suspended in an antibiotic solution, coils, microspheres, and polyvinyl alcohol particles are used for embolization of approximate 60%-70% of spleen parenchyma. Splenic embolization procedures date back to 1973, when the entire spleen parenchyma was ablated. At that time the procedure was associated with high rates of complications, including splenic abscesses, rupture, and pancreatic infarction, resulting in a high mortality rate^[20]. Subsequently, this procedure became more successful with selective ablation of the spleen. In 1984, Mozes *et al*^[21] showed in a prospective randomized trial that partial splenic embolization was as effective as splenectomy for treatment in renal transplant candidates on hemodialysis with a low platelet count prior to administration of immunosuppression. In this study excessive infarction of the spleen was avoided with a mean of 65% of spleen parenchyma ablated. Partial splenic embolization is an effective method to reduce the platelet pool and improve platelet count and is greatly dependent on the infarcted splenic volume. Hayashi *et al*^[22] reported that splenic volume was the best predictive factor for increase in platelet count at one month and one year in patients with liver cirrhosis and hypersplenism.

In several reports in the literature, partial splenic embolization has been described in patients after liver transplantation. It has been successful in patients with thrombocytopenia and recurrent HCV who were able to undergo treatment with interferon and ribavirin as a result of ablation^[23-25].

Most patients develop post-embolization syndrome, including symptoms of fever, left upper quadrant pain, pleural effusion, pneumonia, and atelectasis. Splenic abscesses and rupture are infrequent and are more commonly encountered and less tolerated by immunocompromised cirrhotic patients with a greater area of embolization^[26]. The risk is greatly reduced with aseptic technique, antibiotic prophylaxis, and careful control of pain. Extent of embolization is important as well, with more complications following greater than 70% area of ablation. In partial splenic embolization, achieving the intended target embolization area remains challenging. Graded partial splenic embolization at several settings has been entertained in order to avoid excessive embolization and severe complications associated with it^[27].

DISCUSSION

Hepatitis C is the most common indication for liver transplantation in the United States and Europe, but unfortunately the virus almost always recurs with up to a third of patients developing cirrhosis within the first 5 years. Interferon and ribavirin therapy has been widely accepted as the treatment for recurrent disease. Cytopenia, including thrombocytopenia, which often

PARTIAL SPLENIC ARTERY EMBOLIZATION

Partial splenic embolization is a non-surgical, less

afflicts liver transplant patients, leads to failure to initiate this antiviral regimen, dose reduction, or discontinuation of therapy, which ultimately decreases the likelihood of sustained virological response^[28].

Although, hemolytic growth factors, such as erythropoietin and growth colony stimulating factors, are used to counter the anemia and neutropenia associated with interferon and ribavirin treatment, there is no approved therapy for low platelet count in HCV infected patients.

A new group of synthetic thrombopoietic agents, including romiplostim and eltrombopag, have been found to be effective in stimulating platelet production^[29]. In 2008, romiplostim was approved by the FDA for the treatment of thrombocytopenia in patients with chronic idiopathic thrombocytopenic purpura (ITP). These agents are now being investigated in clinical trials for the treatment of thrombocytopenia in cirrhotic patients with hepatitis C infection^[30,31].

CONCLUSION

Currently, splenectomy is the more popular choice of treatment for hypersplenism and thrombocytopenia. The question is whether it is the optimal choice. Partial splenic embolization is an alternative option that is often overlooked. It is less invasive and potentially carries fewer infectious complications since there is a remnant of functional splenic parenchyma remaining after the procedure. Although it diminishes with time, the risk of OPSS in asplenic patients is life-long. It carries a high mortality rate and therefore, we feel, other options should be seriously considered. Thus, further prospective studies are needed to investigate both modalities in this select group of patients.

Abstract

The hepatitis C virus (HCV) induces lipid accumulation *in vitro* and *in vivo*. The pathogenesis of steatosis is due to both viral and host factors. Viral steatosis is mostly reported in patients with genotype 3a, whereas metabolic steatosis is often associated with genotype 1 and metabolic syndrome. Several molecular mechanisms responsible for steatosis have been associated with the HCV core protein, which is able to induce gene expression and activity of sterol regulatory element binding protein 1 (SREBP1) and peroxisome proliferator-activated receptor γ (PPAR γ), increasing the transcription of genes involved in hepatic fatty acid synthesis. Steatosis has been also implicated in viral replication. In infected cells, HCV core protein is targeted to lipid droplets which serve as intracellular storage organelles. These studies have shown that lipid droplets are essential for virus assembly. Thus, HCV promotes steatosis as an efficient mechanism for stable viral replication. Chronic HCV infection can also induce insulin resistance. In patients with HCV, insulin resistance is more strongly associated with viral load than visceral obesity. HCV seems to lead to insulin resistance through interference of intracellular insulin signalling by HCV proteins, mainly, the serine phosphorylation of insulin receptor-1 (IRS-1) and impairment of the downstream Akt signalling pathway. The HCV core protein interferes with *in vitro* insulin signalling by genotype-specific mechanisms, where the role of suppressor of cytokine signal 7 (SOCS-7) in genotype 3a

and mammalian target of rapamycin (mTOR) in genotype 1 in IRS-1 downregulation play key roles. Steatosis and insulin resistance have been associated with fibrosis progression and a reduced rate of sustained response to peginterferon plus ribavirin.

INTRODUCTION

Hepatocyte steatosis, defined as accumulation of fat droplets in hepatocytes, is a histological feature of a group of liver diseases including not only metabolic or alcoholic disorders but also chronic hepatitis C virus (HCV) and drug-induced liver disease^[1,2]. Steatosis is a very common lesion in chronic HCV, seen in more than half of patients, with a prevalence of 40% to 86% according to the genotype. The majority of patients show simple steatosis, but features of non-alcoholic steatohepatitis have been found in approximately 10% of patients with chronic HCV^[3]. Two main types of steatosis have been defined in HCV: metabolic steatosis found in patients infected by genotype 1 and associated with metabolic syndrome, and viral steatosis reported in patients with genotype 3a, without other known steatogenic cofactors and directly linked to a cytopathic effect of the virus. In the same way, chronic HCV infection can also induce insulin resistance^[4,5]. Epidemiological data support an association between HCV infection and a risk for the development of type 2 diabetes mellitus, both in cross-sectional and longitudinal cohorts. The majority of

transgenic mice expressing the HCV core protein developed insulin resistance and type 2 diabetes. Indeed, patients with HCV showed a higher insulin resistance index than healthy controls or patients with liver diseases other than HCV matched by sex, body mass index and age. Insulin resistance could be promoted by viral proteins and the intrinsic mechanism seems to be genotype-specific^[5]. In this sense, HCV replicons - genomic or subgenomic constructs expressing the viral replicase complex and capable of autonomous viral replication - constitute a powerful tool to investigate the molecular mechanism leading to steatosis and insulin resistance in host cells.

In this review, we aim to analyse the role of HCV in the pathogenesis of steatosis and insulin resistance as a possible “way out” mechanism of the virus, together with the impact of both metabolic abnormalities on the clinical course of the disease.

PATHOGENESIS OF STEATOSIS IN HEPATITIS C

HCV infection is characterized by a high rate of progression to fibrosis, chronic hepatitis, leading to cirrhosis and ultimately to hepatocellular carcinoma. In addition, various observations suggest that hepatic steatosis is a common histological feature of chronic HCV infection. Furthermore, increasing evidence indicates that hepatic steatosis is a more vulnerable factor that leads to liver inflammation and fibrosis. These suggest that HCV has a direct role in the development of steatosis and/or that the presence of steatosis affects the progression of HCV-related liver disease. The core protein component of HCV is known to contribute to hepatic steatosis^[6], hepatic fibrosis, and hepatic carcinogenesis^[7]. Some studies suggest that HCV core protein causes hepatic steatosis through inhibition of microsomal triglyceride transfer protein (MTP) activity and very low density lipoprotein (VLDL) secretion, and impairment of the expression and transcriptional activity of peroxisome proliferator-activated receptor (PPAR) α ^[8]. Sterol regulatory element binding protein 1s (SREBP1s) belong to the basic helix-loop-helix-leucine zipper family of transcription factors. A key role of two SREBP1 isoforms in regulating fatty acid synthesis in liver is suggested by study of transgenic mice overexpressing the constitutively active mature forms of SREBP1 isoforms^[9]. The transgenic mice study suggests that SREBP1s increase the transcription of genes involved in hepatic fatty acid synthesis [including fatty acid synthase (FAS); acetyl-CoA carboxylase (ACC); and stearoyl-CoA desaturase (SCD)], inducing massive hepatic steatosis through increased accumulation of triglycerides.

PPAR γ is a transcription factor, belonging to the nuclear receptor superfamily, is a master regulator of adipocyte differentiation, and is important in regulation of a number of genes involved in fatty acid and glucose metabolism^[10]. There is evidence suggesting that liver PPAR γ increases the transcription of genes involved in hepatic fatty acid synthesis (including FAS, ACC and SCD) and fatty acid uptake (including FAT/CD36 and

fatty acid translocase). Thus, liver PPAR γ contributes to regulation of lipid synthesis, transport and storage within hepatocytes, causing the development of hepatic steatosis.

Using a cell culture based model, Kim and coworkers^[11] have shown that HCV core protein is able to induce the gene expression and transcriptional activity of SREBP1, thereby causing the increase of fatty acid synthesis. They also observed that HCV core protein elevates PPAR γ activity, inducing the expression of fatty acid uptake-associated gene. These results suggest that SREBP1 and PPAR γ may represent a new potential therapeutic target in the pathogenesis in HCV infection.

Steatosis development is due to both viral and host factors. Viral steatosis is mostly reported in patients with genotype 3a, in whom fat accumulation correlates with HCV replication levels in serum and liver and disappears after successful antiviral therapy, strongly suggesting a direct role of specific viral products in the fat deposition. To address the role of specific HCV genotype on lipid accumulation in cells, Abid and coworkers^[12] developed an *in vitro* model to study the effect of the core protein belonging to several viral genotypes (1b, 2a, 3a, 3h, 4h and 5a). They concluded that the pattern observed in Huh7 cells upon expression of the six core proteins largely corroborated the phenotype seen *in vivo*. The genotype 3a-derived core protein was about three-fold more efficient than the corresponding protein from genotype 1b at inducing triglycerides accumulation in transfected cells, and is proposed as the ideal candidate to study the pathogenesis of HCV-induced steatosis. This group also reported the role of PPAR γ expression on triglyceride accumulation in Huh7 cells transfected with genotypes 1b and 3a core proteins^[13]. They found that the expression of HCV 3a core protein was associated with an increase in triglyceride accumulation and with a significant reduction of PPAR- γ mRNA compared with HCV 1b. Moreover, Fukasawa and coworkers^[14] showed that ACC1 and FAS, enzymes responsible for *de novo* lipid biosynthesis, are induced in Huh7 cells transfected with HCV core protein. Using microarray analysis Paziienza *et al*^[15] compared the gene expression profile of Huh7 cells transfected with the core protein of HCV genotype 1b and 3a, leading to the conclusion that several genes involving lipid transport and metabolism were up- or down-regulated in a genotype-specific manner. This fact could explain the variable disease expression associated with HCV infection. Taking all these observations together, we can conclude that there is a direct link between virus infection and steatosis development.

It has been shown that genotype 3 infected patients had lower expression of PPAR α or MTP mRNA in the liver and fat accumulation was three times higher in comparison with non-genotype 3 patients^[16]. Although the mechanism by which genotype 3a induces steatosis more efficiently than others genotypes is not completely understood, some differences in the amino acid sequence in the core protein could explain, at least in part, these differences. Indeed, a specific polymorphism in core protein from genotype 3 has been associated with

lipid accumulation in hepatocytes. Amino acid substitution at positions 182 and 186 caused intracellular lipid accumulation in hepatic cells and contributed to steatosis development^[17]. Indeed, single polymorphisms in the core gene promoting an amino acid change from tyrosine to phenylalanine (Y164F) has been associated with greater cumulative lipid droplet area in cultured cells than in cells producing the wild-type core protein^[18].

The immune response against HCV releases reactive oxygen species (ROS) from sequestered phagocytes and activated Kupffer cells in the liver. Increased oxidative stress caused by HCV may result in the activation of Kupffer cells^[19]. The change in H^+ concentration alters the balance in the Na^+/H^+ exchanger, causing the Kupffer cells to swell and eventually burst. This releases ROS and an arsenal of inflammatory mediators such as $TNF-\alpha$, $TGF-\beta$, IL-6 and IL-8. The rising concentrations of ROS induce lipid peroxidation and damage triglycerides. The process of lipid peroxidation disrupts cellular membranes and can induce mitochondrial dysfunction^[20].

Metabolic and viral steatosis share the same pathophysiological pathways, although metabolic abnormalities are more often seen in genotype 3a resulting in greater steatosis. A predominant but not exclusive metabolic or viral mechanism could be associated with each genotype, and steatosis could appear as a consequence of the interplay between both host and viral factors.

Recently, steatosis has been implicated in viral replication. The disruption of the association between core protein and fat droplets impairs viral fitness^[21]. In infected cells, core protein is targeted to lipid droplets, which serve as intracellular storage organelles. According to their results, two facts show the relationship between lipids droplets and viral replication: first, the change in the distribution of the core protein from wild sites juxtaposed to lipids droplets at an early stage, which later agreed with a peak production of virus. Secondly, JFH1_{DP}, a mutant strain obtained from JFH1, which did not give rise to virus progeny, expressed a core protein that was targeted to punctuate sites indistinguishable from those identified for the wild type protein at early times, but JFH1_{DP} core did not proceed to coat lipid droplets. In such cases, an association between core protein and lipid droplets would be essential for virus assembly. Furthermore, alteration of a phenylalanine in domain 2 of the core protein generates an unstable form of protein associated with reduced replication rates. Lastly, Shavinskaya *et al*^[22] identified the lipid droplet binding domain of HCV core as the major determinant for efficient virus production. They show that D2 in HCV core is a critical determinant for efficient virus assembly and that small numbers of variations (mutations) in this highly conserved domain can exert a significant effect on production of infectious HCV. Thus, HCV promotes steatosis as an efficient mechanism for stable viral replication.

From a clinical perspective, the negative impact of severe hepatic steatosis on graft dysfunction during the immediate post-transplant period has long been recognized^[23]. Donor livers containing greater than

30%-50% steatosis are at increased risk of developing primary nonfunction and delayed function and are associated with reduced graft and patient survival. Since chronic HCV is the most common indication for liver transplantation (LT), several studies have examined the impact of steatosis within the donor graft on the severity of recurrent HCV and/or survival following LT^[24,25]. From those studies, a direct relationship between marginal donors, graft steatosis and more frequent and earlier recurrence for HCV-related cirrhosis has been established^[25]. The putative relationship between steatosis and viral replication could explain this fact.

INSULIN RESISTANCE IN HEPATITIS C

Liver fibrosis has been considered for a long time to be responsible for the appearance of insulin resistance and type 2 diabetes in patients with chronic liver diseases. Hyperinsulinemia in liver cirrhosis has been reported to be due to diminished hepatic insulin extraction by liver dysfunction and not to pancreatic hypersecretion. C-peptide (a peptide resulting from the split of proinsulin into insulin and C-peptide) and insulin are secreted in equimolar quantities, and more than 50% of insulin is degraded in the liver at first pass, whereas C-peptide is degraded in the kidneys. Simultaneous measurements of C-peptide and insulin revealed that both insulin resistance and insulin secretion contribute to glucose intolerance in patients with chronic HCV^[26]. From a clinical point of view, the insulin resistance index was higher in patients with chronic HCV showing mild or no fibrosis than matched healthy controls. Moreover, insulin resistance was found to be higher in patients with chronic HCV than patients with other causes of chronic hepatitis matched by age, sex, body mass index, family history of type 2 diabetes and fibrosis staging^[27]. On the other hand, Homeostasis Model Assessment of Insulin Resistance (HOMA-IR) correlated with HCV RNA level and was found to be higher in patients with HCV than healthy controls in spite of a lower body mass index. Indeed, in patients with HCV, insulin resistance is more strongly associated with viral load than visceral obesity^[4]. Insulin resistance is a common metabolic disorder in the pre-diabetic state. Thus, if HCV promotes insulin resistance it should be linked to type 2 diabetes. Indeed, diabetes was more often seen in HCV than other liver diseases (20%-25% in patients with HCV and in 10% of those with hepatitis B)^[28]. Moreover, in a recent systematic review an increased risk of type 2 diabetes mellitus in patients with hepatitis C in comparison with non-infected people has been reported^[29].

HCV seems to cause metabolic syndrome, but the mechanisms by which HCV promotes insulin resistance have not been completely understood^[30]. HCV induces several complex mechanisms that lead to oxidative stress, insulin resistance, steatosis, fibrosis, apoptosis, altered gene expression and hepatocellular carcinoma. HCV seems to lead to insulin resistance through interference of intracellular insulin signalling by HCV proteins, mainly the serine phosphorylation of IRS-1

and impairment of the downstream Akt signalling pathway^[31].

Transgenic mice expressing core HCV protein developed insulin resistance, which does not occur in wild-type animals^[32]. During HCV replication, core protein has been found to localize to the outer mitochondrial membrane and is also associated with the endoplasmic reticulum (ER)^[33]. In the mitochondria, HCV core protein induces mitochondrial permeability transition, calcium accumulation, stimulation of electron transport and ROS production, as well as promoting glutathione depletion and release of cytochrome C^[34]. Moreover, HCV proteins are assembled and correctly folded by chaperones in the ER, but in some circumstances the ER fails to export synthesized proteins properly leading to an accumulation of misfolded proteins^[35]. The misfolded protein response causes ER dysfunction and promotes inflammation and ER stress^[36]. Of the HCV nonstructural proteins, NS3 and NS5A act as key mediators in the induction of oxidative stress and inflammation. The association of NS5A with the ER has been suggested to stimulate mitochondrial ROS production by releasing calcium from the ER^[37]. In addition, NS3 has been shown to activate nicotinamide adenine dinucleotide phosphate (NADPH) oxidase 2 (Nox2) that generates ROS^[38]. Nox2 can nitrosylate proteins within cells and can lead to a large number of pathological processes. Consequently, a role for NOX enzymes in hepatic fibrosis, characterized by hepatic stellate cell (HSC) proliferation and accumulation of extracellular matrix proteins, has been suggested^[39,40].

HCV core protein inhibits PPAR α and γ expressed in hepatocytes and adipocytes promoting IRS-1 degradation and insulin resistance^[13]. HCV core protein induces the over production of TNF α , responsible for phosphorylation of serine residues of IRS-1 and IRS-2 and down-regulation of glucose transporter gene expression. TNF correlates with the hyperinsulinemic state and the blockade of TNF production by anti-TNF drugs like infliximab inhibits the development of insulin resistance. Thus, TNF promotes hyperinsulinemia and hyperglycaemia and has been linked to an increased risk of diabetes development^[41]. Moreover, non-structural proteins such as NS3 and NS5 interact with the ER. NS3 enhances Nox2 activity and increases nitrosylated proteins and ROS^[42]. NS5A and NS5B proteins activate toll-like receptor-4 and the NF κ B pathway enhances TNF and IL-6 production and promotes insulin resistance^[43]. IL-6 is a cytokine that is secreted from Kupffer cells, adipocytes, B cells, and hepatocytes. HCV-infected patients are known to have elevated levels of IL-6 due to the virus-induced inflammatory state^[44]. Increased IL-6 derived from adipocytes leads to an ongoing acute-phase response that acts on hepatocytes and promotes hepatic insulin resistance. IL-6 is able to inhibit the expression of LPL in mice^[45]. Unlike TNF- α , IL-6 circulates at high levels in plasma, perhaps representing a hormonal role of IL-6 that may induce insulin resistance in other tissues besides liver.

The HCV core protein interferes with *in vitro* insulin

Figure 1 Hepatitis C core induces insulin resistance promoting proteasomal degradation of insulin receptor substrate-1 (IRS-1).

signalling by genotype-specific mechanisms (Figure 1). Pazienza *et al*^[46] used the previously described model of transient expression of the core protein of different genotypes of HCV to assess the interaction of HCV genotype 3a with the insulin signaling, using as comparison the genotype 1b. They found that Insulin Receptor-1 (IRS-1) protein level was significantly reduced in Huh-7 cells expressing the core protein of both genotypes 3a and 1b. However, while the core protein of genotype 3a promoted IRS-1 degradation through the down-regulation of PPAR γ and by up-regulating the suppressor of cytokine signal 7 (SOCS-7), the core protein of genotype 1b activated the mammalian target of rapamycin (mTOR), demonstrating that interaction between viral core protein and IRS-1 degradation is genotype-specific.

Enhanced SOCS production after HCV infection seems to play a crucial role in inducing interferon resistance by inhibiting interferon- α intracellular signalling^[47]. Moreover, SOCS inhibit the phosphorylation of Akt and phosphatidylinositol 3 kinase (PI3K), impairing intracellular insulin signalling, blocking the transactivation of GLUT-4 and avoiding glucose uptake by cells. Over-expression of SOCS-3 has also been linked to interferon and insulin resistance^[48]. Indeed, in transgenic mice unable to express SOCS-3 and expressing HCV core protein, insulin resistance did not appear in the absence of SOCS-3^[49]. Therefore, as previously reported in steatosis, patients with HCV could suffer from viral or metabolic insulin resistance. HCV itself induces insulin resistance by several factors also implicated in interferon resistance, allowing the virus to resist antiviral treatment and to promote fibrosis progression^[50]. However, some controversial results support the presence of additional mechanisms in the development of insulin resistance in patients with chronic HCV and metabolic or viral type insulin resistance. Pazienza and coworkers^[46] have shown that SOCS-1 and SOCS-3 mRNA levels did not change following transfection with both core proteins from genotypes 1b and 3a. However, SOCS-7 mRNA levels were found to be significantly higher in cells expressing the core protein 3a (but not in those transfected with core protein 1b). Their results were corroborated at the protein level by immunoblot. The role of SOCS-7 in IRS-1 downregulation in genotype 3a-transfected cells was con-

firmed using siRNA. They found that the mechanism of IRS-1 degradation by genotype 3a seems to be quite different from that possessed by genotype 1b. The latter is apparently mediated neither by PPAR γ or SOCS-7 nor by SOCS-1 or SOCS-3, as suggested by other authors.

In chronic HCV infection, steatosis up-regulates hepatocyte CD95/Fas and thus increases apoptosis, which facilitates inflammation and fibrosis^[51]. It has been recently shown that adiponectin reduced FFA-induced CD95/Fas expression and apoptosis of HepG2 hepatoma cells, which suggests a protective role for this hormone with promising therapeutic implications^[52].

There are still many molecular mechanisms and open questions to uncover on the HCV-host interaction for the development of effective drugs for the treatment of this disease. In this regard, cell culture based replication systems described so far will help in this task. The availability of systems for replication of all known HCV genotypes together with animal models is highly desirable, in order to find out the importance of the virus genome in disease development.

CONCLUSION

Steatosis development is linked to HCV infection. There is evidence for the accumulation of lipids in the infected cell that could play a determinant role for efficient virus assembly. Thus, HCV promotes steatosis as an efficient mechanism for stable viral replication. HCV itself induces insulin resistance by several factors also implicated in interferon resistance, allowing the virus to resist antiviral treatment and to promote fibrosis progression.

For those subjects with longitudinal assessment of HCV viremia prior to and while on statins, there were no significant differences between pre- and post-HCV viral titers. Additionally, no differences in HCV titers were observed at any dose level of the most prescribed statin, simvastatin. However, hypertriglyceridemia independently correlated with HCV titers, and niacin exposure was associated with significantly lower viral titers ($P < 0.05$).

CONCLUSION: There was no apparent effect of statins on HCV viral replication in this analysis. Further investigation is warranted to explore the possible antiviral properties of triglyceride-lowering agents and their potential role as adjuncts to standard HCV therapy.

Abstract

AIM: To compare hepatitis C virus (HCV) titers in patients with chronic hepatitis C with and without exposure to 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins).

METHODS: Medical records were reviewed for 6463 patients with documented HCV infection at a single center between March 2004 and September 2006. Patients with confirmed viremia and meeting inclusion criteria were assigned to one of three groups: Group A ($n = 50$), dyslipidemic patients with statin usage during HCV RNA polymerase chain reaction (PCR) determination; Group B ($n = 49$), dyslipidemic patients with prior or future statin usage but not at the time of HCV RNA PCR determination; and Group C ($n = 102$), patients without statin usage during the study period. The primary analysis explored the effect of statin therapy on HCV viremia. Secondary analyses assessed class effect, dose response, and effect of other lipid-lowering therapies on HCV viral titers.

RESULTS: Median HCV RNA titers did not significantly differ among the three groups (Group A: 4550000 IU/mL, Group B: 2850000 IU/mL, Group C: 3055000 IU/mL).

INTRODUCTION

Hepatitis C virus (HCV) infection affects approximately 1.8% of the United States population^[1,2]. The burden of disease is markedly increased in the United States Veteran population with 4%-19% of veterans being seropositive for antibodies against the virus^[3-5]. Pegylated interferon combined with ribavirin is the current standard therapy for HCV and is curative in approximately 40%-50% of patients. However, the adverse effects and contraindications to therapy limit the applicability and utilization of this regimen in many infected persons^[6]. The potential sequelae of chronic HCV infection, the limitations of current therapy, and the large economic burden of this disease provide a critical impetus for the pursuit of novel therapeutic agents.

Recent studies using HCV replicon systems suggest a potential therapeutic role for the lipid-lowering agents 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, commonly referred to as statins, in chronic HCV infection. These studies are predicated on cardinal observations of the HCV life cycle. Firstly, HCV virions circulate in plasma in association with low density lipoprotein (LDL) particles. Secondly, the LDL receptor and the high density lipoprotein (HDL) scavenger receptor B1 putatively facilitate HCV entry into hepatocytes^[7]. Thirdly, and perhaps more importantly, HCV replication depends on the formation of a “membranous web” replication complex^[8,9]. Within this endoplasmic reticulum-based replication complex, host proteins are found to be closely associated with HCV nonstructural proteins. The process which links these host and HCV proteins, termed prenylation, appears to depend on two distinct host protein pools, farnesyl and geranylgeranyl, both protein products of the cholesterol synthesis pathway. Therefore, statins, agents which block the formation of the lipid precursors for prenylation, could theoretically interfere with viral replication^[10].

Indeed, *in vitro* studies using HCV replicon-bearing hepatoma cell lines do suggest that statins inhibit HCV replication by disrupting the formation of viral replication complexes, an effect that can be reversed by the addition of mevalonate or geranylgeraniol, synthetic proteins in the cholesterol pathway^[10-12]. Further, the combination of interferon- α and fluvastatin in experimental models exhibited strong synergistic inhibitory effects on HCV RNA replication suggesting that fluvastatin, in particular, but potentially other statins, could be useful as an adjunct to interferon- α based therapy^[11]. While the findings from these studies have been invaluable, the applicability to human use remains in question.

The effect of statins on HCV replication in human subjects has been prospectively addressed in two small studies with mixed results^[13,14]. O’Leary *et al.*^[13] found no reduction in HCV RNA titers at week 4 and week 12 relative to baseline levels. In contrast, another study identified a non-sustained, non-dose-related, reduction in HCV RNA titers in 50% of those treated^[14]. Neither study, however, explicitly addressed the efficacy of individual statin drugs, viral genotype, or controlled for exposure to non-statin lipid-lowering agents. In order to examine a larger number of exposed subjects, to assess the relative efficacy of individual statin formulations, to control for potential confounders, and to determine whether further prospective trials might be warranted, we performed a cross-sectional and longitudinal analysis of HCV RNA viral loads in chronic HCV patients who received a statin for therapy of dyslipidemia.

MATERIALS AND METHODS

Ethics

This study protocol was reviewed and approved by the Institutional Review Board of the Philadelphia Veterans Affairs Medical Center (VAMC).

Selection of patient groups

We performed a retrospective analysis of chronic HCV-infected patients who were seen at the Philadelphia VAMC from March 14, 2004 to September 14, 2006 and who had at least one quantitative HCV RNA polymerase chain reaction (PCR) test performed using the Taqman[®] assay (Roche Diagnostics, Indianapolis, IA). Screening for viral hepatitis is part of routine intake for all primary care clinic patients at the Philadelphia VAMC. Patient level data was extracted from the facility’s Hepatitis C Registry, an automated system that registers all patients with positive HCV antibody testing from clinical laboratory data and facilitates acquisition of additional clinical information from the Computerized Patient Record System (CPRS) and Veterans Health Information Systems and Technology Architecture databases. Charts of patients identified as HCV antibody-positive were queried as to the presence and type of confirmatory PCR testing. Those without confirmatory PCR testing and those without detectable viremia by quantitative Taqman[®] HCV PCR assay were excluded. Patients were also excluded if HIV antibody, HIV RNA and/or HBsAg were positive or if antiretroviral drugs were present in the medication profile. Patients with acute HCV, defined as seroconversion within 2 years of exposure, and patients with chronic kidney disease, defined as serum creatinine greater than 2 mg/dL, were also excluded.

Pharmacy records were then examined to identify the start and stop dates of HMG-CoA reductase inhibitors, niacin, clofibrate, ezetimibe, and interferon- α preparations. Interferon- α based therapy was confirmed through review of progress note documentation in the CPRS. HCV RNA titers obtained during interferon- α therapy were annotated. Utilizing refill data and chart review, patients in whom the HCV RNA determination date(s) occurred at least 30 d after initiation of HMG-CoA reductase inhibitor therapy, in whom exposure to the statin drug spanned at least 60 d, and in whom the duration of statin therapy included the date of HCV RNA determination were designated as Group A. Two control groups who also met the inclusion criteria were selected for comparison. Subjects with hypercholesterolemia for whom a statin medication was prescribed but either had HCV RNA titers drawn prior to the statin initiation date or in whom statin therapy was discontinued at least 60 d prior to the HCV RNA determination were selected as dyslipidemic controls Group B. Group C was chosen from a pool of HCV positive subjects without documented statin exposure during the evaluation period. Analysis of this group was performed with and without exclusion of subjects with total cholesterol levels greater than 200 mg/dL. Using the date of closest correlation to the HCV RNA titer obtained, laboratory data, including basic chemistries, liver associated enzymes, coagulation panels, and lipid profiles were extracted for each group. The longitudinal results of HCV RNA titers during ongoing statin therapy were also recorded for those patients in Group A with more than one HCV RNA determination within the study period.

Table 1 Patient characteristics

Variables	Median (range)			P-value		
	Group A (n = 50)	Group B (n = 49)	Group C (n = 102)	All	Group A vs Group B	Group A vs Group C
Gender (male/female)	50/0	49/0	100/2	0.38		
Race (white/black/other/unknown)	15/28/0/7	11/31/0/7	18/64/0/20	0.74

Group A: Cases (HCV PCR+ with concomitant statin exposure); Group B: Dyslipidemic control (HCV PCR+ with non-coincident statin exposure); Group C: Unexposed control (HCV PCR+, no statin exposure).

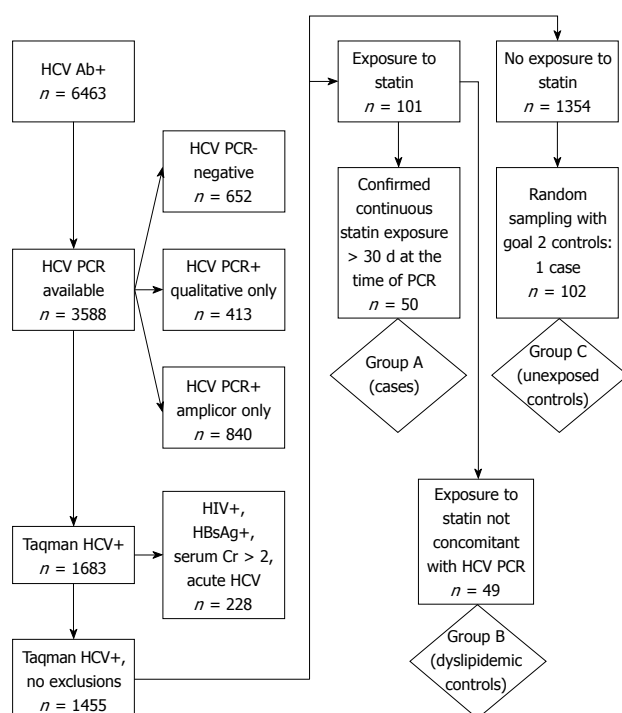

Figure 1 Patient assignment algorithm.

Statistical analysis

Comparisons of frequency data were performed with χ^2 or Fisher's exact testing as appropriate. All group-wise comparisons were performed using non-parametric tests including Kruskal-Wallis or Mann-Whitney *U* tests. Regression analysis was conducted to explore the effect of potential confounders on the primary study endpoint, HCV RNA titers. All analyses were conducted with JMP 7 software (SAS Institute, Cary, NC) and/or STATA 9.2

(College Station, TX). *P*-values < 0.05 were considered significant.

RESULTS

Patient selection and characteristics

A total of 6463 patients were found to be HCV antibody-positive (+). Fifty HCV-infected patients who met criteria for statin exposure with concomitant HCV RNA determination (Group A), 49 HCV-infected dyslipidemic patients not on a statin at the time of HCV RNA determination (dyslipidemic controls, Group B) and 102 statin-unexposed HCV-infected controls (Group C), were analyzed (Figure 1).

Patients in the three groups were similar in terms of age, gender, race, ethnicity, HCV genotype, serum albumin, alanine aminotransferase (ALT), alkaline phosphatase, total bilirubin, creatinine, international normalized ratio, platelets, HDL cholesterol, triglyceride levels and exposure to non-statin lipid-lowering agents (Table 1). Among Group A, the median duration from first statin exposure to HCV RNA determination was 288 d (range 34-1435, data not shown). Group A, when compared to Group C, had a significantly higher median body mass index (BMI) (29.1 *vs* 26.8, *P* < 0.01), platelet count ($243 \times 1000/\text{mL}$ *vs* $208 \times 1000/\text{mL}$, *P* < 0.05), total cholesterol level (177 mg/dL *vs* 161 mg/dL, *P* < 0.01), and LDL levels (114.3 mg/dL *vs* 93.4 mg/dL, *P* < 0.01). However, there were no significant differences between Group A and Group B. Group C had a significantly higher median aspartate aminotransferase level (54 U/L *vs* 37 U/L, *P* < 0.01) and ALT level (53 U/L *vs* 46 U/L, *P* < 0.05) when directly compared with Group A.

Figure 2 Hepatitis C RNA titers relative to HMG-coA reductase inhibitor exposure. Log HCV RNA viral load (IU/mL) in Group A, Group B, and Group C subjects. A: Entire cohort; B: Genotype 1 patients; C: Genotype 2 patients; D: Patients in which genotype was not available. Box plots indicate median, 25th and 75th percentiles (box), and 5th and 95th percentiles. *P*-value obtained by Kruskal-Wallis test.

HCV RNA titers and statin usage

Median HCV RNA titer in Group A was 4550000 IU/mL *vs* 2850000 IU/mL in Group B *vs* 3055000 IU/mL in Group C (Figure 2A). The similarity in serum titers suggest that in this cohort there was no evidence that as a class HMG-CoA reductase inhibitors exhibit antiviral properties *in vivo*. To confirm that there was no genotype-specific effect of HMG-CoA reductase inhibitors, we analyzed each known HCV genotype separately for genotype 1, genotype 2 and untyped subjects in all groups. We again found no significant differences between these groups for any genotype (Figure 2B-D).

Statin preparations, HCV RNA titers, and dose response

Among Group A, 42 (84%) received simvastatin, 5 (10%) lovastatin, 2 (4%) pravastatin and 1 (2%) fluvastatin. When comparing HCV RNA titers among patients receiving any of the four statin agents, there were no differences observed (Figure 3A). Furthermore, there was no apparent antiviral effect of simvastatin, the most prescribed statin in this cohort, at any dose level (Figure 3B). However, when comparing the two most commonly used agents in our cohort, there was a trend towards lower HCV RNA titers in subjects who received lovastatin relative to simvastatin. To further investigate whether or not the trend towards lower HCV RNA titers in lovastatin users might be significant, we compared

HCV RNA titers in active lovastatin users in Group A and former or future lovastatin users in Group B. However, no significant trend towards a lower HCV viral load could be identified (Figure 3C). Thus, there was no class effect of HMG-CoA reductase inhibitors and further conclusions regarding specific statin formulations cannot be made.

Serum total cholesterol and HCV RNA titers

The lack of apparent anti-viral effect of statins theoretically could have resulted from neutralization from a pro-viral effect of hypercholesterolemia rather than a lack of effect of the statin in individual patients. To control for this potential confounder, we correlated viral titers and total cholesterol for Group A (Figure 4A), Group B (Figure 4B), and Group C subjects (Figure 4C) and found no evidence of a relationship between total serum cholesterol and HCV RNA titers in any group. Further, there was no correlation of HCV RNA titers and HDL, LDL, or triglyceride levels (data not shown). Thus, hypercholesterolemia itself did not appear to mediate a pro-viral effect or to be related to cholesterol metabolism in a fashion that may negate any anti-viral effect of statin preparations.

BMI and HCV RNA titers

As noted above, Group A subjects had a significantly

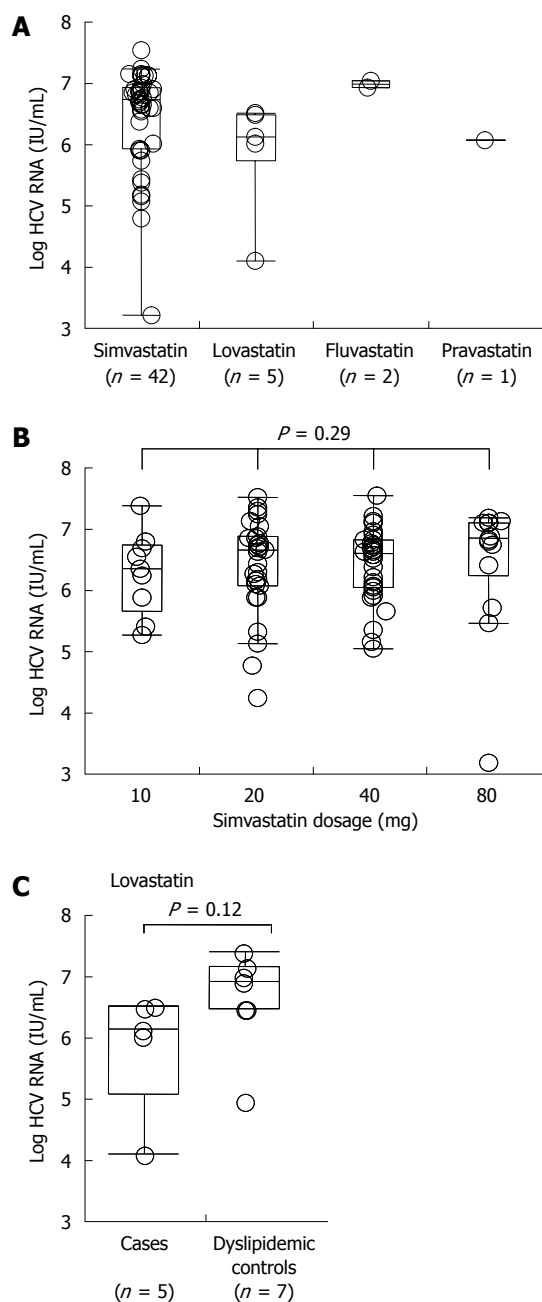

Figure 3 Antiviral effects of individual HMG-CoA reductase inhibitors. A: Log HCV RNA viral load (IU/mL) for Group A subjects who received simvastatin ($n = 42$), lovastatin ($n = 5$), fluvastatin ($n = 2$) and pravastatin ($n = 1$); B: Log HCV RNA viral load (IU/mL) for simvastatin-exposed subjects who were receiving 10 mg ($n = 4$), 20 mg ($n = 8$), 40 mg ($n = 20$), 80 mg ($n = 10$). P -value obtained by Kruskal-Wallis Test; C: Pairwise comparison of median HCV RNA titers in lovastatin-exposed Group A subjects and Group B subjects who received lovastatin but were not being treated at the time of the RNA determination. P -value from Wilcoxon sign rank test.

higher median BMI (29.1 *vs* 26.8, $P < 0.01$) than Group C, but no significant difference in BMI was found between Group A and B. To assess any potential interaction of BMI on HCV RNA titers, we performed regression analysis that demonstrated no association between BMI and HCV RNA titer in either Group A or Group C.

Hypertriglyceridemia, other lipid lowering agents and HCV RNA titers

In order to assess serum triglyceride levels as a confo-

ounding variable, we analyzed the association between serum triglycerides as well as triglyceride-directed therapy on HCV RNA titers. As shown in Table 1, 6/50 in Group A, 2/49 in Group B and 5/102 in Group C received non-statin lipid lowering therapy at the time of HCV RNA determination. Of these, a total of 10 exposures were to niacin (5/6 in Group A, 2/2 in Group B, and 3/5 in Group C). After excluding patients on niacin and gemfibrozil, the presence of triglyceride levels greater than 250 mg/dL was associated with a higher median HCV RNA titer (> 250 mg/dL: 6 760 000 IU/mL *vs* < 250 mg/dL: 3 130 000 IU/mL, $P < 0.05$, Figure 4D) and triglycerides were weakly but significantly correlated with HCV viral titers ($R^2 = 0.023$, $P < 0.05$, data not shown). After excluding two patients taking gemfibrozil, niacin-exposure, irrespective of statin exposure, was associated with lower median HCV RNA titers (exposed: median 835 000 IU/mL *vs* unexposed: 3 350 000 IU/mL, $P < 0.05$, Figure 4E). Compared to 13 patients with untreated hypertriglyceridemia (defined as triglycerides > 250 mg/dL), niacin-exposure was associated with a 1.16-log reduction in median HCV RNA titer ($P < 0.05$). Similar analyses for fibric acid derivatives or ezetimibe were not possible due to the limited number of exposed patients.

Longitudinal effect of statin therapy

Twenty-eight Group A subjects (23 simvastatin, one fluvastatin and four lovastatin) had more than one determination of HCV RNA titer, allowing for longitudinal assessment of changes in HCV viremia during the duration of HMG-CoA reductase exposure. In the vast majority of non-interferon-treated subjects, there was either a modest increase or no change in HCV RNA titers during such therapy (Figure 5). In 11 of these 28 subjects, an HCV RNA determination was made prior to and after the institution of statin therapy. Within this subgroup, there was no significant difference between pre- and post-statin levels of HCV viremia. In two of three lovastatin-exposed subjects with initial HCV RNA testing within 1 mo (range: -15 to +17 d) of initiation of interferon, HCV RNA titers declined by 0.7-1.1 log between 9-16 mo. Only two subjects with repeated assessments were exposed to interferon during the observation period. These data imply that statin exposure in this cohort was not associated with significant inhibition of viral replication for individuals with longitudinal follow-up.

DISCUSSION

The sustained virologic response rate of chronic hepatitis C in registration trials with currently approved interferon- α based antiviral therapy ranges from 44%-54%^[15,16], but varies widely by genotype, ethnicity and underlying histology. In practice, at centers similar to the study site, HCV treatment response rates range from 20% for genotype 1 to 43%-52% for genotypes 2-3^[17]. Suboptimal response and significant toxicity continue to spur the development of novel anti-HCV therapies.

The capacity of HMG-CoA reductase inhibitors

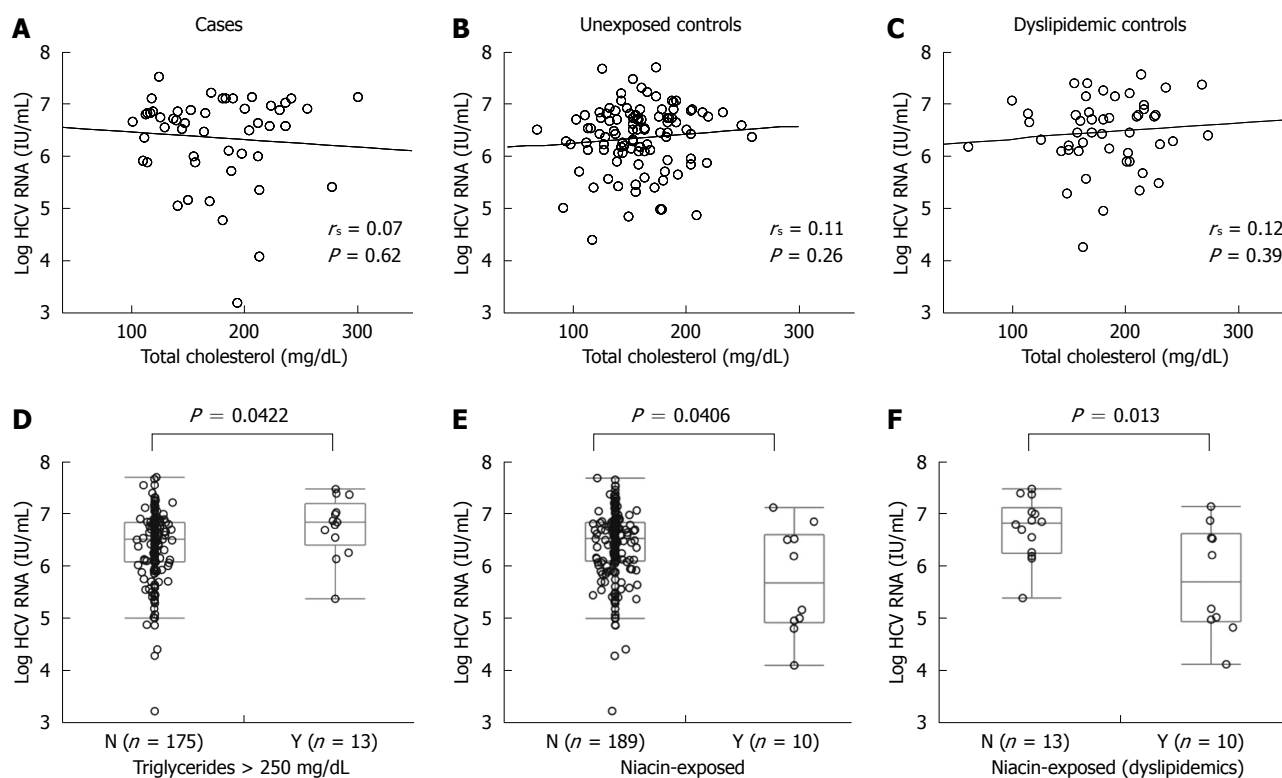

Figure 4 Lack of correlation between serum cholesterol and HCV RNA viral load, but apparent association with hypertriglyceridemia. Linear correlation of log HCV RNA titers (IU/mL) and serum total cholesterol (mg/dL) in Group A (A), Group B (B), and Group C (C). *P*-values obtained by Spearman correlation; D: Log HCV RNA titers for patients with serum triglycerides greater than or below 250 mg/dL excluding patients on gemfibrozil or niacin (> 250 mg/dL: median 6 760 000 IU/mL vs < 250 mg/dL: median 3 130 000 IU/mL, $P = 0.042$); E: Log HCV RNA titers for patients with or without exposure to niacin, excluding patients on gemfibrozil (exposed: median 835 000 IU/mL vs unexposed: median 3 350 000 IU/mL, $P = 0.041$); F: Log HCV RNA titer among patients with hypertriglyceridemia, excluding gemfibrozil therapy, with and without exposure to niacin shows lower HCV RNA viral load in niacin-treated patients (niacin-exposed: median 835 000 IU/mL vs unexposed: median 6 760 000 IU/mL, $P = 0.013$).

Figure 5 Longitudinal effect of statin therapy. Log HCV RNA titer plotted against days relative to the statin initiation date for simvastatin (black lines, $n = 21$), simvastatin plus interferon ($n = 2$), lovastatin (grey lines, $n = 4$), and fluvastatin (big dotted line, $n = 1$) for patients with more than one determination of HCV RNA titer. Eleven subjects had HCV RNA titers measured before and after the initiation of statin therapy.

to impede HCV replicon replication *in vitro* in a dose-dependent fashion raised hope that this commonly prescribed and acceptably safe class of medications could serve as an adjunct to standard interferon-based therapy. Data from such *in vitro* studies further demonstrated a hierarchy of statin-induced viral inhibition, with the greatest effect demonstrated with fluvastatin followed by atorvastatin, simvastatin, and lovastatin, respectively. These *in vitro* findings prompted a pilot study in which

10 subjects with chronic hepatitis C and laboratory evidence of dyslipidemia were treated with atorvastatin 20 mg daily. However, no significant changes in HCV RNA titers were demonstrated at the atorvastatin dose administered though such subjects did have a significant lowering of LDL and total cholesterol^[13]. This first study did not examine the effect of fluvastatin, the most potent statin identified in *in vitro* experiments. A more recent small, uncontrolled study of 22 patients given fluvastatin at doses ranging from 20-80 mg/d found transient, 0.5-log reductions in HCV RNA titers in 50% of treated subjects^[14], but did not correlate these responses with the lipid lowering therapeutic effect of statins or specifically explore viral genotypes and other medications used.

In order to validate the need for further prospective study of the effect of statins on HCV viral replication in clinical practice, we performed a cross-sectional study of a larger number of subjects and controlled for potential confounders such as viral genotype, cholesterol levels, triglyceride levels and exposure to other lipid lowering medications. We found exposure to different statin preparations, primarily simvastatin, during routine clinical use, was not associated with a change in HCV viral titers. In a limited number of subjects with longitudinal measures of HCV viral load pre- and post-initiation of statin therapy, our data suggested that there was no evidence of clinically significant change in HCV

RNA titers. Specifically for simvastatin, the statin for which we had the most data, we were unable to show a dose-dependent association with reduced HCV titers, contrasting with *in vitro* studies^[11]. Given the small number of fluvastatin-exposed subjects at our institution ($n = 2$), we were unfortunately not able to analyze the effect of exposure to the most potent *in vitro* inhibitor.

A plausible explanation for the discrepancy between our *in vivo* and others' *in vitro* results may rest with the pharmacokinetic properties of statins. There is a significant first pass effect for all statins with the exception of pravastatin^[18]. Intrahepatic concentrations of statins with routine use, however, have not been to our knowledge well documented in the literature. Serum levels of such agents after prolonged therapy are significantly lower than the statin concentrations that were used in replicon systems. For example, the maximal serum concentration of fluvastatin dosed at 40 mg daily is approximately 0.589 $\mu\text{mol/L}$ ^[19], approximately 10-fold lower than effective statin concentrations for inducing viral inhibition in the replicon systems^[10-12].

Additionally, replicon-bearing cell lines are highly adapted and behave quite differently from *in vivo* hepatocytes. For instance, Huh7 cells exposed to interferons are exquisitely responsive to the agent regardless of viral genotype^[20]. This is in direct contrast to the disparate rates of sustained virologic response observed clinically with interferon therapy. It is possible that the adaptations that confer interferon sensitivity also confer statin sensitivity, explaining the *in vitro* results. Alternatively, the specific dependence on prenylation of nonstructural proteins for establishment of the viral replication complex might be a feature of cell-culture models for which alternative pathways may be present *in vivo*. The HCV might also develop resistance mutations under selection pressure induced by statin therapy, an effect that could be demonstrated *via* sampling at regular intervals early after initial statin exposure for early viral load changes and sequence evolution. Lastly, pro-viral effects of statins might occur *via* induction of LDL-receptor expression which may paradoxically facilitate viral uptake into uninfected hepatocytes^[21].

Another possible explanation for the lack of difference between our study groups could be the presence of a significant confounding variable. For example, obesity, which is associated with non-response to interferon-based antiviral therapy^[22], and hypercholesterolemia, were significantly more prevalent in Groups A and B than C. We, however, did not find within any of the groups an association of HCV RNA titers with height, weight or body-mass index (data not shown) nor with total cholesterol; therefore we do not believe that differences in these variables could explain our negative findings. Since hypertriglyceridemia was directly associated with viral titer, the excess of hypertriglyceridemia cases in Group A could contribute to a type II error. However, when we controlled for triglycerides in the regression analysis, statin exposure remained insignificantly associated with HCV RNA titer.

While not powered for an analysis of non-statin lipid lowering medications and their effect on HCV

viral load, our analysis unexpectedly identified a possible direct association of triglycerides and viremia and a suggestion that niacin may have antiviral properties *in vivo*. Recent work with human serum^[23] and with primary hepatocytes^[24] suggests that HCV is co-secreted with VLDL, implicating triglyceride metabolism as an additional critical step in the viral lifecycle. Given these preliminary findings as well as a biologically plausible mechanism for the action of triglyceride lowering medications on HCV replication, these findings merit further investigation in a larger dataset and, if confirmed, in a prospective clinical trial.

There are several limitations of this analysis that we would like to acknowledge. First, the cross-sectional design inherently precludes determining causality and is inherently weaker than prospective evaluation. Further, given the limited number of subjects with measurements prior to and after the initiation of statin therapy, we cannot definitively rule out an association between statins and reduction in HCV viral replication. Secondly, the sample size remained relatively small after applying our exclusion criteria, raising the possibility of a type II error and specifically that of finding no association when one does indeed exist. Thirdly, there were no direct measurements of patient adherence with prescribed statin therapy, an important factor since poor adherence may make the medication in question appear to be less efficacious. Fourthly, the preferred statin agent on the formulary during the observation period was not the most highly active agent *in vitro*. Lastly, there is a small possibility that patients in Group B could have received a statin agent prescribed by a non-VA physician, which was not recorded in the VA electronic medical record. Since there is significant financial incentive for most veterans to obtain medications through the VA, we believe the impact of this factor is quite small.

In summary, in this single center, retrospective analysis, there was no evidence of an apparent effect of statins on HCV viral replication. Unexpectedly, we found that triglyceride lowering agents such as niacin may have HCV antiviral properties *in vivo*. Therefore, we suggest exploration of this result. Additionally, the potential antiviral efficacy of drugs such as niacin in chronic hepatitis C as adjuncts to interferon-based therapies merit further investigation.

ACKNOWLEDGMENTS

This material is based upon work supported in part by the Office of Research and Development, Department of Veterans Affairs and with the resources and the use of facilities at the Philadelphia VA Medical Center. We also thank Kyong-Mi Chang, MD for her review of the manuscript and for development of the hepatitis C registry at the Philadelphia VAMC.

COMMENTS

Background

Interferon and ribavirin are the mainstay of treatment for chronic hepatitis C

infection. Unfortunately, this combination is only effective in approximately 50% of all-comers. Therefore, novel therapies must be explored. Cardinal observations of the hepatitis C virus (HCV) life cycle have demonstrated that the lipid metabolism pathway is implicated in viral entry and replication within the hepatocyte. 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, referred to commonly as statins, have been shown to not only disrupt lipid metabolism within the hepatocyte but also halt HCV viral replication in *in vitro* models of chronic HCV infection. Relatively few studies have explored the effect of statins on HCV viral replication *in vivo*.

Research frontiers

Though *in vitro* studies using HCV replicon-bearing hepatoma cell lines do suggest that statins inhibit HCV replication, the applicability of use in humans with chronic hepatitis C infection remains in question. In this study, the authors attempt to, but are unsuccessful in, demonstrating a significant reduction in HCV viral titers with routine use of statins in a cohort of patients infected with hepatitis C.

Innovations and breakthroughs

The results did not suggest an effect of statins on HCV viral replication. However, the investigators did find preliminarily that triglyceride lowering agents may in fact lower levels of HCV viremia. Though significant, this finding was noted in a small number of patients and given that the study was not powered for this question, this should be viewed as hypothesis generating.

Applications

By continuing to explore potential adjunct therapies to current HCV anti-viral therapies, it is likely that some highly effective adjunct(s) will be discovered. This study, while not demonstrating a significant effect of statins in this cohort, does provide some preliminary data to support further investigation of lipid altering medications and their potential effect on HCV.

Terminology

The process which links host and HCV proteins during intrahepatic viral replication is termed prenylation. Prenylation is dependent on two distinct host protein pools, farnesyl and geranylgeranyl, both protein products of the cholesterol synthesis pathway.

Peer review

This is a well written manuscript. The study suffers from the limitations of a retrospective cohort study and may have not detected a difference in HCV viral titers because longitudinal assessment was not made for all subjects prior to and after initiation of statin therapy. The authors need to comment on these limitations in the discussion.

complications. In 1 patient, the thrombi did not respond to the interventional treatment and resulted in intestinal necrosis, which required surgical treatment. In 3 patients with interventional treatment, thrombi re-formed 1, 3 and 4 mo after treatment. In these 3 patients, indirect PV-SMV thrombolysis was performed again and was successful.

CONCLUSION: Interventional treatment, including direct or indirect PV-SMV thrombolysis, is a safe and effective method for patients with symptomatic acute-subacute PV-SMV thrombosis.

Abstract

AIM: To summarize our methods and experience with interventional treatment for symptomatic acute-subacute portal vein and superior mesenteric vein thrombosis (PV-SMV) thrombosis.

METHODS: Forty-six patients (30 males, 16 females, aged 17-68 years) with symptomatic acute-subacute portal and superior mesenteric vein thrombosis were accurately diagnosed with Doppler ultrasound scans, computed tomography and magnetic resonance imaging. They were treated with interventional therapy, including direct thrombolysis (26 cases through a transjugular intrahepatic portosystemic shunt; 6 through percutaneous transhepatic portal vein cannulation) and indirect thrombolysis (10 through the femoral artery to superior mesenteric artery catheterization; 4 through the radial artery to superior mesenteric artery catheterization).

RESULTS: The blood reperfusion of PV-SMV was achieved completely or partially in 34 patients 3-13 d after thrombolysis. In 11 patients there was no PV-SMV blood reperfusion but the number of collateral vessels increased significantly. Symptoms in these 45 patients were improved dramatically without severe operational

Interventional treatment for symptomatic acute-subacute portal and superior mesenteric vein thrombosis. *World J Gastroenterol* 2009; 15(40): 5028-5034 Available from: URL: <http://www.wjgnet.com/1007-9327/15/5028.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.5028>

INTRODUCTION

With the development of imaging technology, the rate of diagnosis of portal and superior mesenteric vein thrombosis has gradually increased^[1]. When thrombosis occurs only in the portal vein, clinical symptoms such as abdominal pain, nausea, anorexia, and weight loss are usually not serious. When thrombosis involves the superior mesenteric vein, patients may have cramps in the upper middle or lower middle abdomen, nausea, anorexia, vomiting, diarrhea, and/or bloody stool^[2-4]. Conservative medical treatment is often unsatisfactory. Surgical treatment is accompanied by more tissue damage, more complications, and a high recurrence rate. Therefore, it is seldom used as a standard treatment unless intestinal necrosis occurs. Recently, interventional and minimally invasive techniques were introduced to treat portal vein and superior mesenteric vein thrombosis (PV-SMV) thrombosis. The results have been

excellent^[5,6]. Herein we summarize the interventional treatment of 46 patients with symptomatic acute-subacute PV-SMV thrombosis. Our goal was to describe how to choose a specific interventional treatment, and how to enhance the effect of the treatment and reduce complications.

MATERIALS AND METHODS

General information

We reviewed the case histories of 46 patients including 30 males and 16 females, with an average age of 48 years (range: 17-68 years). All patients had different degrees of abdominal pain, fullness, and anorexia. Other symptoms and signs included diarrhea (25 cases), vomiting (11 cases), and ascites (8 cases). There was no obvious abdominal rigidity and rebound tenderness. Causes of the disease were clearly defined in 42 patients, including 18 who had splenectomies within one year, 8 who had a recent history of pancreatitis, 14 who had liver cirrhosis with portal hypertension (6 of them accompanied by esophageal and gastric varices), 1 who had the condition secondary to duodenal surgical repair for traumatic injury within the last 24 h, and 1 who had appendicitis within the last month.

The period of the disease included 28 acute cases (thrombosis occurred within 1 wk of onset) and 18 subacute cases (1-3 wk from onset). The number of platelets was higher ($500-980 \times 10^9/L$) than standard scores in 28 patients. The number of white cells was higher ($12-20 \times 10^9/L$) than normal standards in 17 patients. Red cell number and hemoglobin levels were in the normal range. Liver function tests showed 42 with Child A, and 4 with Child B. Renal function and plasma electrolytes were in the normal range. All patients were clearly diagnosed as having PV-SMV thrombosis by Doppler ultrasound scan, computed tomography (CT) and magnetic resonance imaging (MRI). They were fast and gastrointestinal decompressed.

Interventional treatment

Direct PV-SMV thrombolysis: Twenty four patients were seen within 1 wk of the onset of disease and diagnosed as having acute PV-SMV thrombosis without obvious lateral branch angiogenesis by imaging. Eight patients were seen between 1 and 2 wk from the onset of disease and diagnosed as subacute PV-SMV thrombosis without obvious lateral branch angiogenesis by imaging.

Thrombolysis through transjugular intrahepatic portosystemic shunts (TIPS): In 26 patients, a 10F long sheath (RUPUS 100 system, COOK Corp, USA) was used to puncture the right internal jugular vein according to Seldinger's method and then advanced into the hepatic vein *via* the superior vena cava, right atrium, and inferior vena cava. A shell-type needle was introduced into the hepatic vein through the sheath and it was advanced into the right branch of the PV under X-ray guidance. When PV branches were filled with thrombi and blood flow was interrupted, it was not possible to determine whether PV was punctured or not using the aspirate puncture-cannula. Under such conditions, the contrast should be injected slowly *via*

the puncture-cannula while the puncture-cannula is withdrawn gradually. When the puncture was successful, the contrast remained in the PV branches and the shape of vessels could be seen clearly. An ultra-smooth guide wire was easily introduced into the PV-SMV system. Once it was in the right branch of the PV, a 4F Cobra Catheter (Cordis Corp. USA) or an inferior vena cava angiographic catheter (COOK Corp, USA) was advanced to the distal SMV for direct PV-SMV angiography.

Before thrombolysis, 30-50 mg sodium heparin was injected intravenously into patients without any contraindications. An 8F large thin-walled introducer catheter (90 cm Cordis Corp., USA, or a 100 cm Boston Scientific Corp. USA) was used to aspirate the thrombi and a 4F pigtail catheter (Cordis Corp. USA) was used for mashing the thrombi. A 4F inferior vena cava catheter with multiple lateral holes (COOK Corp. USA) was inserted into the PV-SMV and used to deliver sodium heparin and urokinase (average doses of 0.8 MIU, 0.5-1.5 MIU) intermittently for local thrombolysis. After most of the thrombi in the PV-SMV had been removed, the catheter was maintained for continuous thrombolysis with urokinase (0.5-1.5 MIU/d) and sodium heparin (30-200 mg/d) for 3-13 d. Clopidogrel (75-150 mg/d) or enteric-coated aspirin (100-150 mg/d) were administered to patients with platelet counts greater than $300 \times 10^9/L$. During treatment, thrombin time (TT) and activated partial thromboplastin time (APTT) were monitored to maintain TT at 1.5-2.5 times the normal range, and APTT at 2-2.5 times the normal range. In the meantime, levels of D-dimer were monitored^[7]. The duration of indwelling catheters, which depended on the improvement of symptoms and thrombolysis, usually lasted less than 2 wk. After the catheter was withdrawn, intravenous sodium heparin was continued for 2 additional weeks, and then changed to oral warfarin sodium (for not less than 1 year). Treatment with warfarin and heparin should overlap for 3 d. After being discharged from the hospital, patients were monitored with standard blood tests and we maintained the international normalized ratio (INR) at 2.0-3.0. Abdominal ultrasound scans were repeated every 1-3 mo and CT or MRI scans as necessary.

Thrombolysis through percutaneous transhepatic portal vein cannulation: In 6 patients, a percutaneous transhepatic puncture was performed with a 22-gauge Chiba needle (COOK Corp, USA) into the right branch of the PV, at the midline through the right armpit. Then an 8F artery sheath (Cordis Corp. USA) was introduced into the PV for thrombolysis. The following thrombolysis procedure was the same as the TIPS method. After treatment, the punctured tract was broken by a gelatin sponge and a steel ring (COOK Corp, USA) was used to prevent secondary liver bleeding.

Indirect PV-SMV thrombolysis

Patients who received indirect PV-SMV thrombolysis included: (a) 4 with acute PV-SMV thrombosis diagnosed by imaging tests within one week of the onset of the disease and who refused direct PV-SMV thrombolysis, (b) 4 with subacute PV-SMV thrombosis diagnosed within 1-2 wk,

Figure 1 The figure shows a male, 43-year-old patient, 2 mo after splenectomy, with abdominal fullness for 6 d. He had thrombolysis through a transjugular intrahepatic portosystemic shunt (TIPS). A: Direct PV-SMV angiography showed extensive thrombosis in the PV and SMV. Contrast agent remained. No lateral branch angiogenesis (arrow); B: Mash and suck thrombi with intermittent injection of urokinase and heparin sodium. Repeated angiography 30 min after thrombolysis showed blood reperfusion in the PV-SMV and normal PV-SMV branches (arrow). Symptoms disappeared.

including 3 who refused and 1 who failed direct PV-SMV thrombolysis, (c) 6 with subacute PV-SMV thrombosis diagnosed within 2-3 wk, including 3 showing lateral branch angiogenesis around the PV-SMV system in the CT scan, suggesting a long duration of the disease.

Thrombolysis through the femoral artery to the superior mesenteric artery cannulation

In 10 patients, a 4F artery sheath (Terumo Corp. Japan) was used to puncture the right femoral artery according to a modification of Seldinger's technique, and then a 4F Cobra Catheter was inserted to perform celiac artery, superior mesenteric artery and indirect PV-SMV angiography. When angiography was completed, 3-6 holes were drilled at the front of the Cobra Catheter with a microdriller. An intensive dose of urokinase (0.2 MIU) was administered into the superior mesenteric artery through the catheter. Afterward, the catheter remained in the superior mesenteric artery in order to continue the thrombolysis with urokinase (0.75-1.5 MIU/d) and sodium heparin (30-200 mg/d) for 3-11 d. All treatments during and after indwelling catheters and review were the same as those performed in the TIPS method.

Thrombolysis through the radial artery to superior mesenteric artery catheterization

The left radial artery in 4 patients was punctured with a radial puncture system (COOK Corp, USA) using a modified Seldinger's method. A 5F artery sheath (COOK Corp, USA) was inserted and then an extended (120 cm) 5F Cobra Catheter (Terumo Corp. Japan) was introduced for celiac artery, superior mesenteric artery and indirect PV-SMV angiography. All other procedures were the same as those through the femoral artery to the superior mesenteric artery cannulation thrombolysis methods.

RESULTS

Direct PV-SMV thrombolysis was performed in 32 pa-

tients, taking 80-180 min each. In 22 of the 32 patients, direct PV-SMV angiography showed extensive thrombosis in the PV and SMV with contrast agent remaining in the vessels and without lateral branch angiogenesis (Figures 1A, 2B, 3C). Ten patients had thrombosis mainly in the PV, SMV and splenic vein. After thrombolysis, repeated angiography showed normal PV-SMV systems in 26 patients (Figure 1B) while thrombosis partially remained in the PV-SMV in 6 patients. Symptoms such as abdominal pain, fullness, and diarrhea disappeared or were significantly relieved. Hospital stays lasted from 2 wk to 2 mo. One patient whose thrombosis was secondary to duodenal surgical repair had PV-SMV reperfusion and symptomatic improvement but died because of an abdominal abscess and multiple organ failure. In 3 patients with interventional treatment, thrombosis recurred (at 1, 3 and 4 mo, respectively) after the treatment. For these 3 patients, indirect PV-SMV thrombolysis was performed again and repeated angiography showed increased lateral branch angiogenesis in the PV-SMV branches. Their symptoms were improved. All other patients had good PV-SMV circulation without abnormal symptoms. Ultrasound and CT scans did not show signs of recurrence.

In 14 patients treated with indirect PV-SMV thrombolysis, one patient with acute thrombosis and another one with subacute thrombosis had partial recovery of PV-SMV flow, partial thrombolysis, and complete symptomatic relief (Figure 2C). Eleven patients had intact thrombosis in the PV-SMV and obvious lateral branch angiogenesis. Their symptoms were dramatically improved with only slight abdominal pain and fullness, and less diarrhea remaining (Figure 3D). One patient with acute thrombosis had no improvement in symptoms 3 d after continuous thrombolysis and developed exudation around the remaining sheath. Ileum segmental necrosis was found on laparotomy 2 d after the catheter was withdrawn. Bowel resection was performed and treatment was continued with an anticoagulant treatment. Six patients with esophageal-gastric varices had obvious improvement confirmed by gastroscop examination after treatment. During follow-up, one patient had upper gastrointestinal bleeding 22 mo after the interventional treatment and was treated with endoscopic sclerotherapy (EIS). Other patients did not develop symptoms of PV-SMV thrombosis again.

DISCUSSION

PV-SMV thrombosis has a concealed onset without any specific symptoms and signs. The diagnosis is therefore, easily delayed. If the following conditions occur, the possibility of PV-SMV thrombosis should be considered in order to achieve early diagnosis and treatment. (1) unexplained abdominal pain, abdominal distension, especially with nausea, vomiting, and bloody stool; (2) intractable ascites; (3) unexplained bloody ascites; (4) unexplained portal hypertension; (5) unexplained upper gastrointestinal bleeding or progressive spleen en-

Figure 2 The figure shows a female, 22 year old patient who had abdominal pain for 17 d. A: A CT scan showed a high density of superior mesenteric vein thrombosis (characteristic of subacute thrombosis) (arrow); B: A Cobra catheter was inserted via the femoral artery into the superior mesenteric artery. Indirect angiography showed extensive thrombosis in the PV-SMV. Angiographic contrast agent remained (arrow); C: Indwelling catheters for 8 d. Angiography showed partial blood reperfusion in the PV-SMV. PV branches in the liver were intact (arrow). Symptoms were relieved.

Figure 3 A 24 year old male with abdominal pain for 8 d. A: The CT scan showed a low density SMV thrombosis (arrow); B: An enhanced CT scan still showed a low density of thrombosis (arrow). This fulfilled the symptoms and signs of acute thrombosis; C: An extended Cobra catheter was introduced into the superior mesenteric artery via the radial artery. The indirect angiography shows extensive thrombosis in the PV-SMV without lateral branch angiogenesis (arrow); D: Indwelling catheters for 10 d. The indirect angiography showed that the lateral vessels of the PV-SMV had significantly increased (arrow). Symptoms were relieved.

largement without apparent splenic hyperfunction; (6) unexplained paralytic intestinal obstruction, necrosis or peritonitis, *etc*^[8,9]. The diagnosis of PV-SMV thrombosis relies on imaging. Color Doppler ultrasound is very simple, noninvasive, and has a high negative predictive value. It should be chosen first. If a positive result is found, CT or MRI scans should be considered for further investigation. Accurate judgment of the PV-SMV thrombosis duration - acute, subacute, or chronic - is extremely important for disease management^[10]. According to our experience, thrombosis shown in a CT scan has a low density during the acute period (within 1 wk of the onset of the disease) (Figure 3A). It has a high density during the subacute period (1-3 wk after disease onset) with a CT value of 5-15 HU which is higher than values for the abdominal aorta and inferior vena cava (the so-called CT scan mesenteric vein angiographic phenomenon, an important piece of diagnostic evidence). It has a low density during the chronic period (> 3 wk) and is accompanied by lateral branch angiogenesis. The density of the thrombosis is not increased with contrast (Figure 3B)^[11]. In the MRI scan, PV-SMV thrombosis is shown as a T1WI low signal and a T2WI high signal during the acute period. During the sub-acute period, both T1WI

and T2WI signals are high. During the chronic period, T1WI gives mixed signals and T2WI gives low signals. After Gd-DTPA injection, the signal for thrombosis is not increased^[12].

Traditional PV-SMV thrombolysis treatment includes conservative internal treatment and surgical treatment. Medical treatments include thrombolysis and anticoagulation, and others, which can improve symptoms in some patients. But conservative treatment cannot directly remove the obstruction due to the thrombosis. Therefore, its efficiency is very limited and the mortality rate due to gastric bleeding is high^[13]. The application of surgical treatment is limited by tissue damage and additional complications^[14-17]. With the development of interventional radiology, minimally invasive technology has become one of the predominant means of treating acute-subacute PV-SMV thrombosis without obvious intestinal necrosis, perforation, and peritonitis^[18-26]. The method includes direct and indirect PV-SMV thrombolysis^[27]. In our study, 46 patients with acute-subacute PV-SMV thrombosis were treated interventionaly. The thrombolysis was effective without severe complication.

Our study showed that the effect of direct thrombolysis is better than indirect treatment. Injecting throm-

bolytic agents directly into a PV-SMV thrombus can dramatically increase the effect of thrombolysis, reduce the dose of thrombolytic agent, and reduce the complication of bleeding. Using a mechanical method such as aspirating and mashing to eliminate the thrombi, balloon expanding, stent implantation, etc. can result in reperfusion within a short time and recover blood circulation^[28]. However, when the disease duration is too long (> 2 wk) or angiography shows some lateral branch angiogenesis around the main vessels, there is no indication for TIPS and surgical treatment; or, if the treatment *via* TIPS fails, indirect PV-SMV thrombolysis is still an option^[24]. Evaluation of the efficacy of indirect PV-SMV thrombolysis should rely not only on reperfusion of the main vessels. The improvement in clinical symptoms and lateral branch angiogenesis with treatment are also important indications of efficacy. We found that indirect PV-SMV thrombolysis is simple and easy. When direct thrombolysis is difficult to perform, indirect thrombolysis can dissolve some thrombi, promote lateral branch angiogenesis and relieve symptoms for acute-subacute patients. With thrombolysis through the radial artery, one can achieve superior mesenteric artery indwelling catheters. Patients with such indwelling catheters do not need to rest in bed. Complications such as bleeding at the puncture point and infection are significantly reduced. Therefore, the procedure does not introduce any inconveniences into the patient's daily life and is easily accepted by patients.

Regarding the choice of pathways for direct PV-SMV thrombolysis, the way through TIPS does not pass through the intraperitoneal cavity. Hence, it is suitable for patients with existing ascites, coagulative dysfunction and catheters that have been indwelling for a long time^[22]. It has a specific advantage in prevention of bleeding, not only avoiding hepatic surface injury, but also reducing bleeding due to thrombosis being aspirated through the big vessel sheath (> 7F) because the cannula is inside the liver. Moreover, cannulation through TIPS can also divert portal blood flow and effectively relieve portal hypertension^[29,30]. Therefore, it is very suitable for patients requiring a portosystemic shunt for portal hypertension and embolism for esophageal-gastric varices. The disadvantages of TIPS are its complexity and difficulties in performing it^[31]. The procedure for percutaneous transhepatic portal vein cannulation is simpler, easier and cheaper than TIPS^[25,32]. It is suitable for patients without ascites and coagulative dysfunction^[33]. Recently, this procedure has been improved in several ways. Ultrasound was used to guide a fine needle to the puncture. A steel coil and a gelatin sponge were used to fill the puncture channel to reduce intraperitoneal haemorrhage^[25,34]. This method can be an alternative for cases of unsuccessful TIPS or cases that are unsuitable for TIPS but that require direct PV-SMV thrombolysis.

During the time that the catheter is indwelling, determining safe and effective doses of urokinase and heparin is fundamental for the success of the treatment. Our study suggests doses for urokinase (0.5-1.5 MIU/d) and heparin sodium (30-200 mg/d). Urokinase should be rapidly injected through the catheter within half an

hour, twice a day. Heparin sodium can be admitted *via* peripheral veins when urokinase treatment is performed *via* the catheter. It must be administered *via* the catheter to the thrombosis in the time gap between urokinase treatments. Patients with PV-SMV thrombosis usually have complications of chronic hepatic disease, clotting factor insufficiency, and generally low coagulation conditions but high coagulation conditions in the portal vein. The direct injection of urokinase and heparin into the PV is more effective. Clopidogrel or enterically-coated aspirin are administered for patients with platelet counts more than $300 \times 10^9/L$. In our study, one patient had a platelet count of $600-970 \times 10^9/L$ while they had indwelling catheters after splenectomy and was treated with hydroxycarbamide to inhibit platelet formation.

Urokinase is a plasminogen activator. Its half-life is short (15-20 min). Quickly administering urokinase can instantly lead to its penetration into the thrombosis and cause thrombolysis. In our study, urokinase was injected within 30 min. If the injection is too slow, the effect of thrombolysis becomes weak. Urokinase can also cause degeneration of some clotting factors such as fibrinogen (FIB). FIB is an important clotting factor and a reflective index for activation of the fibrinolysis system. It is also a fundamental factor for plasma viscosity and platelet aggregation. The elevation of plasma FIB can promote blood coagulation and form clots. Because the half-life of urokinase is very short, FIB will increase after 24 h of urokinase administration and return to previous levels after 48 h. If it is not combined with other anticoagulation treatments, it will increase the incidence of vascular thrombosis obstruction after thrombolysis. Therefore, anticoagulation treatment during thrombolysis is necessary.

Heparin sodium affects blood clotting by inhibiting synthesis of fibrous protein factors and the extension of existing clots within the blood. In our study, all patients had anticoagulation treatment with a combination of urokinase and heparin sodium. The prevalence of hemorrhage is high (23%-28%)^[21,35-38]. Therefore, an emergency treatment including ECG monitoring and blood pressure control for bleeding must be prepared. All indexes for coagulation and anticoagulation should be monitored. Presently, most researchers suggest that maintaining TT at 1.5-2.5 times the normal range and APTT at 2-2.5 times the normal range can not only achieve the best treatment efficacy, but also avoid severe bleeding. In our study, only three patients had exudation around the catheter sheath. Their symptoms were relieved with a compression bandage without any severe organic bleeding. This is related to understanding the time window of urokinase and heparin, and monitoring the dose for both medications according to all factors involved in coagulation and anticoagulation.

COMMENTS

Background

With the development of imaging technology, the rate of diagnosis of portal and superior mesenteric vein thrombosis has gradually increased. Thrombosis of

portal vein and superior mesenteric vein thrombosis (PV-SMV) is a severe disease. The consequences of these thromboses can be severe, including mesenteric ischemia and variceal bleeding, with high mortality rate. There are no uniform protocols for the effective treatment of PV-SMV thrombosis. Conservative medical treatment is often unsatisfactory. Surgical treatment is accompanied by more tissue damage, more complications, and a high recurrence rate.

Research frontiers

The treatment of symptomatic acute thrombosis of the PV and SMV is controversial due to unsatisfactory results obtained in some cases with medical treatment, as well as the difficulty in performing surgical procedures in some cases. Recently, interventional and minimally invasive techniques were introduced to treat PV-SMV thrombosis.

Innovations and breakthroughs

The authors summarize the interventional treatment of 46 patients with symptomatic acute-subacute PV-SMV thrombosis, which demonstrated the feasibility of this method in the management of this challenging illness. Compared to conservative medical and surgical treatment, interventional treatment has the least tissue damage, complications, invasive and a high success rate.

Applications

Interventional endovascular thrombectomy with direct or indirect thrombolysis can offer a non-surgical alternative for the treatment of symptomatic acute-subacute PV-SMV thrombosis. This technique can be performed in patients who do not present with bowel ischemia and infarction, or who are not at risk for bleeding, and have persistent symptoms or worsening of symptoms despite anticoagulation.

Terminology

PV-SMV: Portal vein and superior mesenteric vein thrombosis. TIPS: Transjugular intrahepatic portosystemic shunts. TT: Thrombin time. APTT: Activated partial thromboplastin time. INR: International normalized ratio.

Peer review

This study summarizes the interventional treatment of 46 patients with symptomatic acute-subacute PV-SMV thrombosis.

Abstract

AIM: To investigate the expression pattern of γ -synuclein in colorectal cancer (CRC) tissues, and to study the effects of γ -synuclein on CRC cell line HCT116 biological features *in vitro*.

METHODS: The expression pattern of γ -synuclein was determined in 54 CRC tissues and 30 tumor-matched nonneoplastic adjacent tissues (NNAT) 5 cm away from the tumor *via* real-time quantitative reverse transcription PCR (RT-PCR) and immunohistochemistry. The relationship between γ -synuclein protein expression and clinicopathological factors of CRC tissues was analyzed. Three small interfering RNA (siRNA) targeting γ -synuclein mRNA plasmids were constructed and transfected into the CRC cell line HCT116. The stable

cell lines were selected with G-418 for 28 d, and the biological features of these cells were examined by cell growth curve, soft agar assay, and cell migration and invasion assays *in vitro*.

RESULTS: The expression of γ -synuclein mRNA and protein was much higher in CRC tissue samples than in NNAT samples ($P = 0.02$, $P = 0.036$). There was a significant correlation between the γ -synuclein protein expression and clinical stage and lymph node involvement of CRC ($P = 0.02$, $P = 0.033$). In functional analysis we found that down-regulation of γ -synuclein expression in HCT116 cells could inhibit the growth, colony formation rate, and migration and invasion ability of HCT116 cells.

CONCLUSION: Increased expression of γ -synuclein in CRC tissues and the biological effects of reduced γ -synuclein expression on HCT116 cells suggest that γ -synuclein may play a positive role in the progression of CRC.

Expression of γ -synuclein in colorectal cancer tissues and its role on colorectal cancer cell line HCT116. *World J Gastroenterol* 2009; 15(40): 5035-5043 Available from: URL: <http://www.wjgnet.com/1007-9327/15/5035.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.5035>

INTRODUCTION

The synucleins are a family of small, soluble, highly conserved neuronal proteins that consist of α -, β -, and γ -synuclein. They are a natively unfolded group of proteins that are characterized by 5-6 repeats of the amino acid motif (KTKGV), constituting most of the N-terminal half of the proteins^[1-3]. The synucleins

have attracted considerable attention due to their involvement in neurodegenerative diseases. α -synuclein is the major component of Lewy bodies in Parkinson's disease and has also been identified as the non-amyloid component of amyloid deposition, the hallmark of Alzheimer's disease^[4,5]. β - and γ -synuclein are assumed to have a neuroprotective role by inhibiting α -synuclein aggregation and toxicity^[6,7].

γ -synuclein gene [also referred to as breast carcinoma specific gene 1 (BCSG1)] initially was cloned from infiltrating breast carcinoma cells by using the expressed sequence tag-based differential cDNA sequencing approach^[8]. γ -synuclein maps to chromosome region 10q23, and is composed of five exons and transcribed into an mRNA of about 1 kb, coding 127 amino acids^[9]. γ -synuclein expression is usually highly tissue-specific and restricted to brain tissue and presynaptic terminals^[2]. However, the tissue-specificity appears to be lost, and γ -synuclein is abnormally expressed in a high percentage of advanced breast and ovarian cancers, but not in normal or benign tissues^[10]. Furthermore, overexpression of γ -synuclein can stimulate proliferation, and induce invasion and metastasis of breast cancer cells^[11]. γ -synuclein has also been shown to compromise normal mitotic checkpoint controls, resulting in multinucleation as well as faster breast cancer cell growth^[12,13]. Liu *et al*^[14] found that γ -synuclein protein was also abnormally expressed in a high percentage of tumor tissues of other cancer types, including liver, gastric, lung, prostate, cervical *etc.*, but rarely expressed in tumor-matched nonneoplastic adjacent tissues (NNAT). However, Zhou *et al*^[15] had an opposite conclusion in esophagus cancer, in which low expression levels of γ -synuclein in human esophageal squamous cell carcinoma (ESCC) and biological effects of γ -synuclein overexpression on ESCC 9706 cells suggested that γ -synuclein might play a role as a negative regulator in the development of human ESCC. Therefore, further study in cancer tissues and cell line culture is needed to understand the roles of γ -synuclein in the development of other human neoplastic diseases.

Recent reports demonstrate that colorectal cancer (CRC) has been the third most common malignancy and the third leading cause of cancer-related deaths worldwide^[16]. The conventional therapies involving surgery and adjuvant therapy seem to give rise to improvements in progression-free and overall survival; nevertheless about 50% of patients die within 5 years owing to metastasis or recurrent disease. Patients with early stage CRC have an estimated 5 year survival rate of 91%, compared to only 6% for those with later stage disease. Early detection remains the most important factor in improving long-term survival. Furthermore, tumor invasion and regional lymph node metastasis are important factors for determining CRC prognosis^[17-19].

To further determine whether aberrant expression of γ -synuclein is involved in the development of CRC, and identify a new biomarker or a potential target for diagnosis and treatment, we examined expression patterns of γ -synuclein in CRC tissues, analyzed the

relationship between γ -synuclein protein expression and clinicopathological factors of CRC, and then studied the effects of γ -synuclein down-regulation on colorectal cancer cell line HCT116 biological features *in vitro*.

MATERIALS AND METHODS

Tissue samples and cell lines

Fifty-four CRC samples and 30 NNAT samples 5 cm away from the tumor were obtained from patients undergoing CRC surgery between January 2005 and October 2008 at the Department of General Surgery, Ruijin Hospital, Shanghai, China. After washing with RNase-free 9 mL/L NaCl to remove blood after surgery, one half of each sample was snap-frozen in liquid nitrogen immediately and stored at -80°C for RNA extraction, and the other half was fixed in 40 g/L formalin for histological assessment. For tumor samples, non-tumor portions were trimmed off from the frozen tumor blocks and the selected areas had more than 80% tumor cells as shown by histological assessment. Tumors were staged using the TNM and World Health Organization classification systems. The ethics committee at Ruijin Hospital approved the use of these tissues for research purposes. The colorectal cancer cell line HCT116 (ATCC No. CCL-247) was grown in Dulbecco's modified Eagle's medium (DMEM) (Gibco BRL, Life Technologies Inc, USA) supplemented with 10% heat inactivated fetal bovine serum (FBS) (Summit Biotechnology, Fort Collins, CO, USA). The HCT116 cells were maintained in a humidified incubator at 37°C with 50 mL/L CO₂, fed every 3 d with complete medium, and subcultured when confluence was reached.

Total RNA extraction and real-time quantitative reverse transcription PCR (RT-PCR) of γ -synuclein mRNA

Cultured cells were washed twice with phosphate-buffered saline (PBS) and harvested, and tissues were ground into fine powder in liquid nitrogen before extraction of RNA. Total RNA was extracted using TRIzol Reagent (Invitrogen, Carlsbad, CA, USA). cDNA synthesis from 1 μ g of RNA was performed with a reverse transcription system kit (Promega, Madison, WI, USA) according to the manufacturer's instructions. Real-time quantitative PCR was carried out in 96-well polypropylene microplates on an ABI Prism 7000 (Applied Biosystems, Foster City, CA, USA) using SYBR Green Realtime PCR Master Mix (TOYOBO, Tokyo, Japan) according to the manufacturer's instructions. Amplification was carried out with the following profile: 1 cycle at 95°C for 1 min, and 40 cycles each at 95°C for 15 s, 59°C for 15 s, 72°C for 45 s. All PCR reactions were performed in triplicate wells. Specificity of the resulting PCR products was confirmed by melting curves. H₂O was used as a negative control. Data were analyzed by using the comparative Ct (Δ Ct) method and the amount of γ -synuclein relative to GAPDH was expressed as 10000 \times 2^{-(Δ Ct)}. Table 1 provides the sequences of the primers used in these studies.

Table 1 Sequences of γ -synuclein gene-specific primers

Primer	Sequence (5'-3')	Product size (bp)
γ -synuclein-5'	GGAGGACTTGAGGCCATCTG	73 (339 to 411)
γ -synuclein-3'	CTCCTCTGCCACTTCCTCTTTC	
GAPDH-5'	GGACCTGACCTGCCGTCTAG	100 (831 to 930)
GAPDH-3'	GTAGCCCAGGATGCCCTTGA	

Immunohistochemistry (IHC) analysis

Unstained 4 mm sections were cut from the tissue paraffin-embedded block and deparaffinized in xylene, and the slides were bathed in 0.01 mol/L sodium citrate and heated in a microwave oven for 12 min. The sections were incubated with mouse anti- γ -synuclein monoclonal antibody (SantaCruz, CA, USA) at a dilution of 1:100 and kept at 4°C overnight. Negative control slides were treated with non-immunized mouse immunoglobulin fraction under equivalent conditions. For the secondary developing reagents, a labeled streptavidin-biotin kit (DAKO, CA, USA) was used. Slides were developed with diaminobenzaminidine and counterstained with hematoxylin. Positive cases were defined by the presence of intracellular staining with red/brown color in epithelial cells. Negative cases were defined by the absence of specific intracellular staining as seen in negative controls. Samples were evaluated under light microscopy independently by two pathologists without prior knowledge of the patients' clinical data.

Plasmid construction

The pGCsi-U6/neo/GFP plasmid (Shanghai GeneChem., Ltd, Shanghai, China), a siRNA expression vector containing a green fluorescent protein gene (GFP) under a separate promoter for tracking the transfection efficiency, was used for the cloning of small synthetic oligonucleotides that encode two complementary sequences of 19 nucleotides separated by a short spacer region of 9 nucleotides. Three sequences (as shown in Table 2) unique to the coding region of γ -synuclein were designed and inserted between the *Bam*H I and *Hind*III sites of the pGCsi-U6/neo/GFP plasmid. The positive clones were confirmed by sequencing.

siRNA transfection and selection of HCT116 stable transfectants

One day before transfection, HCT116 cells were plated in a six-well plate with 1×10^5 cells per well using culture medium without antibiotics. The cells were transfected with 3.0 μ g/well of pGCsi-U6/neo/GFP-vector and pGCsi-siRNA plasmids, respectively, using Lipofectamine (Invitrogen) according to the manufacturer's protocol. Cells transfected with medium but lacking DNA served as controls. Fresh growth medium was replaced after 4 h of transfection. Cells were passaged at a 1:10 dilution at 24 h after transfection and cultured in medium supplemented with G418 (Promega, Madison, WI) at 1000 μ g/mL for 4 wk. Stably transfected clones were picked and maintained in medium containing 400 μ g/mL G418 for further study.

Western blotting analysis

Cells were harvested and lysed with mammalian protein extraction reagent (Pierce Rockford, IL, USA). Protein concentrations were determined with a bicinchoninic acid (BCA) protein assay kit (Pierce Rockford, IL, USA). Samples containing 50 μ g of protein were mixed with $2 \times$ sodium dodecyl sulfate (SDS) gel-loading buffer (100 mmol/L Tris-CL, 200 mmol/L dithiothreitol, 4% SDS, 0.2% bromophenol blue, and 20% glycerol), boiled for 5 min, loaded onto each lane of 15% acrylamide gel in a minigel apparatus (Bio-Rad, Richmond, CA, USA), and separated by SDS-PAGE. The separated proteins were electrophoretically transferred to a Sequi-blot PVDF membrane (Bio-Rad Laboratories, Hercules, CA, USA). After being incubated with mouse anti- γ -synuclein monoclonal antibody (SantaCruz, CA, USA) (1:500), and goat anti-mouse IgG-AP antibody (SantaCruz, CA, USA) (1:5000) respectively, immune complexes were detected using BCIP/NBT Alkaline Phosphatase Color Development Kit (Sigma, St. Louis, MO). GAPDH served as a loading control.

Cell proliferation analysis

Cells were seeded onto 96-well plates at a density of 2×10^3 cells per well in 100 μ L medium containing 10% FBS. The number of viable cells was determined daily with WST-8 cytotoxicity assay using the Cell Counting Kit-8 (Dojindo, Japan). Briefly, 10 μ L of the CCK-8 solution was added to each well of the microplate, and the absorbance at 490 nm was measured by a microplate reader (μ Quant, Bio-Tek, USA) after 4 h incubation.

Soft agar colony formation assay

Cells (1×10^3) were trypsinized to a single-cell suspension and then plated in triplicate onto six-well plates in complete culture medium containing 0.3% agar on top of 0.6% agar in the same medium. Cultures were maintained at 37°C in the 50 mL/L CO₂ incubator for 15 d. The colonies were fixed with 70% ethanol, and stained with 0.2% crystal violet. The colonies containing at least 50 cells were counted. Colony formation rates were calculated as the number of colonies relative to that of cells initially plated in a well (1×10^3), and expressed as mean \pm SD.

Cell migration and invasion assay

Boyden chambers with 8 μ m polycarbonate membranes in 24-well dishes (Nucleopore, Pleasanton, CA) were used for migration assay, and chambers coated with 4 mg/mL growth factor reduced Matrigel (50 μ g; Collaborative Biomedical, Becton Dickinson Labware) were used for the invasion assay. Cells (1×10^5) were resuspended in serum-free DMEM and added to the upper chamber in triplicate. Consecutively, DMEM with 10% FBS was added to the lower chamber. Chambers were incubated at 37°C in the 50 mL/L CO₂ incubator for 24 h. After incubation, the chambers were fixed with 70% ethanol, and stained with 0.2% crystal violet. Cells on the surface of the upper chamber were removed by

swiping with cotton swabs. The amount of migration and invasion cells in the lower chamber was determined under light microscopy. The data are means \pm SD of counting ten random fields of vision.

Statistical analysis

Statistical analyses were performed using SPSS11.0 software (Shanghai jiaotong University School of Medicine, Shanghai, China). Mann-Whitney *U*-test was used to analyze γ -synuclein mRNA expression in paired CRC and NNAT samples. The Fisher's exact test was used to test the significance of the difference in frequency of

γ -synuclein protein expression between CRC and NNAT samples, and to assess the relationship between the protein expression and clinicopathological characteristics of CRC. Two-way analysis of variance (ANOVA) was performed to detect the effects of γ -synuclein knockdown on cell proliferation, soft agar colony formation, cell migration and invasion, and Student-Newman-Keuls test was used to detect the difference between any two groups. *P* < 0.05 was selected as the statistically significant value.

RESULTS

Examination of γ -synuclein mRNA and protein expression in CRC and NNAT samples

γ -synuclein mRNA expression in 54 CRC and 30 NNAT samples was examined using Q-RT-PCR. Table 3 shows the results of Q-RT-PCR. γ -synuclein mRNA expression in CRC samples ranged from 1.12 to 39.36 with a median value of 11.06, while in matched NNAT samples it ranged from 0.81 to 30.21 with a median value of 6.11. The γ -synuclein mRNA expression levels in CRC samples were significantly higher than those in NNAT samples (*P* = 0.02).

The expression and subcellular localization of γ -synuclein protein were evaluated *via* IHC in 54 CRC and 30 NNAT samples. NNAT sections showed either no protein expression (*n* = 23) or relatively weak protein expression (*n* = 7) in the cytoplasm of epithelium cells (Figure 1A). Conversely, the immunoreactive patterns of γ -synuclein were predominantly positively identified in the cytoplasm, sometimes in the nucleus of cancer cells (Figure 1B) with a relatively high frequency of 48.1% (Table 3, *P* = 0.036).

In the analysis of γ -synuclein protein expression in CRC tissues and various CRC patients' clinicopathologic variables, the results clearly showed a close association of γ -synuclein staining with clinical stage and lymph

Figure 1 γ -synuclein protein expression detected by IHC. A: Negative γ -synuclein immunostaining in NNAT; B: Positive γ -synuclein immunostaining in the cytoplasm of CRC cells (original magnification $\times 200$). IHC: Immunohistochemistry; NNAT: Nonneoplastic adjacent tissues; CRC: Colorectal cancer.

node involvement (Table 4). The frequency of positive γ -synuclein staining was much higher in later stage tumors than in earlier stage tumors ($P = 0.02$), and was much higher in lymph node-positive tumors than in lymph node-negative ones ($P = 0.033$). However, there was no significant correlation between the γ -synuclein protein expression and other clinicopathologic characteristics.

Identification of the effective siRNA target sequence

We first investigated three recombinant γ -synuclein-specific siRNA plasmids, pGCsi-siRNA1, pGCsi-siRNA2, and pGCsi-siRNA3. These γ -synuclein-specific siRNA plasmids and pGCsi-U6/neo/GFP-vectors were transfected into HCT116 cells. After 24 h, these cells were examined for γ -synuclein expression by Q-RT-PCR. As shown in Figure 2A, γ -synuclein levels were different in the transfected HCT116 cells containing siRNA1, siRNA2, siRNA3 and the vector. There were no significant changes of γ -synuclein mRNA expression in pooled HCT116/vector, HCT116/siRNA1, and HCT116/siRNA3 cells. However, in HCT116/siRNA2 cells, γ -synuclein mRNA levels were significantly low, compared with parental HCT116 cells and HCT116/vector cells. Then stable transfected clones of HCT116/siRNA2 cells were selected with G418. After 4 wk of the selection, stable transfected clones were established (Figure 2B). These clones were examined for γ -synuclein expression by western blotting, the result of which suggested that pGCsi-siRNA2 plasmid could specifically

Figure 2 The siRNA plasmid can specifically knock down γ -synuclein expression in the HCT116 cells. A: γ -synuclein mRNA expression detected by Q-RT-PCR after transient transfection. Values were γ -synuclein/GAPDH expression of one group cells relative to that of parental HCT116 cells; B: The vision of HCT116 stable transfectants in fluorescence microscopy and light microscopy; C: γ -synuclein protein expression detected by western blotting after selection of stable transfectants. Control: Parental HCT116 cells; pGCsi-vector: HCT116/vector cells; siRNA1 (2,3): HCT116/siRNA1 (2,3) cells.

knock down γ -synuclein protein expression in the stable transfected HCT116 cells (Figure 2C).

Inhibition of cell proliferation and colony formation by γ -synuclein knockdown

In vitro cell proliferation tests, two clones derived from stable transfectants with control vector, siRNA2 plasmids, and parental HCT116 cells were chosen for further study. As shown in Figure 3A, γ -synuclein knockdown suppressed cancer cell growth significantly in regular medium. The number of pooled HCT116/siRNA2 cells was significantly reduced by 48, 72, 96, and 120 h after plating, respectively, compared with the HCT116/vector and parental HCT116 cells ($P < 0.05$).

Subsequent soft agar colony formation assay was

Control: Parental HCT116 cells; pGCsi-vector: HCT116/vector cells; siRNA2: HCT116/siRNA2 cells.

done to evaluate the tumorigenicity of γ -synuclein down-regulated cells *in vitro*. Colony formation rates were $29.4\% \pm 4.5\%$, $32.1\% \pm 5.8\%$ and $9.6\% \pm 2.9\%$ in parental HCT116 cells, HCT116/vector and HCT116/siRNA2 cells (Figure 3B, $P < 0.05$). The size of colonies formed by HCT116/siRNA2 cells was much smaller than that of two control cells, and there were no significant differences between parental HCT116 cells and HCT116/vector cells colonies both in number and size (Figure 3C).

Inhibition of cell migration and invasion by γ -synuclein knockdown

The close correlation of γ -synuclein protein expression and CRC staging suggests that γ -synuclein might be involved in advanced stage tumor progression and metastasis. We used an *in vitro* reconstituted basement membrane (Matrigel) invasion assay to determine the effect of γ -synuclein on cell migration and invasion

(Figure 4A). The results showed that the amount of migration HCT116/siRNA2 cells in the lower chamber was much less than that of parental HCT116 cells, and HCT116/vector cells (Figure 4B, $P < 0.05$). It was demonstrated that γ -synuclein down-expression led to suppression of cell motility in HCT116 cells. Similarly, we observed that γ -synuclein down-expression led to decreased cell invasion in HCT116 cells. HCT116/siRNA2 cells showed a significant decrease in the number of invasive cells compared to that of two control cells (Figure 4C, $P < 0.05$).

DISCUSSION

γ -synuclein belongs to the synuclein protein family, consisting of α -, β -, and γ -synuclein, which are abundantly expressed in nervous tissues^[9]. Although there has been a report that showed down-regulation of γ -synuclein in human ESCC, more studies support the statement of over-expression of γ -synuclein in more types of cancer^[14,15,20-22]. The loss of tissue-specificity raises questions about the involvement of γ -synuclein in the process of tumorigenesis and metastasis, and presents the possibility to use γ -synuclein as a potential target for early diagnosis and treatment. However, little is known about the expression and biological effects of γ -synuclein in CRC.

In the current study, we showed that γ -synuclein expression levels were higher in CRC tissues than those in matched NNAT. IHC analysis also confirmed that CRC tissues exhibited abundant γ -synuclein expression in the cytoplasm of cancer cells, in contrast to NNAT, which did not appear to exhibit γ -synuclein expression or exhibit faint expression.

To further investigate how γ -synuclein contributes to the biological behavior changes in CRC, we constructed specific γ -synuclein siRNA plasmids and established permanent transfected HCT116 cells to investigate the potential role of γ -synuclein in the progression of CRC. Consistent with our observation that the γ -synuclein expression levels were lower in NNAT than in CRC tissues, the cell growth and colony formation rate decreased in HCT116/siRNA2 cells with reduced expression of γ -synuclein, compared with parental HCT116 cells, and HCT116/vector cells, which gave evidence that γ -synuclein indeed had the ability to promote cell growth. Previous studies have demonstrated that ectopic expression of γ -synuclein increased breast cancer cell growth in anchorage dependent and independent conditions through interaction with BubR1, a mitotic checkpoint kinase, which led to inhibition of the mitotic checkpoint control^[12,13,23]. It has also been shown that γ -synuclein could constitutively activate ERK1/2, and increase ER- α transcriptional activity through an HSP-based multiprotein chaperone complex, which led to an increase in breast cancer or ovarian cell survival and proliferation^[24-28].

In addition to the effects on cell growth, γ -synuclein is associated with cell invasion and metastasis. In previous *in vitro* studies, retinoblastoma cell lines

Figure 4 Inhibition of cell migration and invasion by γ -synuclein knockdown. A: Boyden chambers with 8 μ m polycarbonate membranes coated with or without 4 mg/mL growth factor-reduced Matrigel were used for migration or invasion assay. The chambers were stained with 0.2% crystal violet and analysed by photography, and the stained cells were migration or invasion cells in the lower chamber; B, C: The migration or invasion cells were counted in ten random fields of vision. Values were the number of cells relative to that of parental HCT116 cells, and expressed as mean \pm SD for three independent experiments; ^a $P < 0.05$. Control: Parental HCT116 cells; pGCSi-vector: HCT116/vector cells; siRNA2: HCT116/siRNA2 cells.

overexpressing γ -synuclein were shown to have higher MMP9 protein levels and activity, which were enhanced in cell motility and invasion^[29]. In *in vivo* studies, γ -synuclein was also shown to cause metastasis in nude mice on implanting γ -synuclein expressing MDA-MB 435 breast cancer cells in fat pads of these mice. IHC results showed mice given implants of γ -synuclein positive cells displayed an increase in tumor growth, and metastasis into axillary lymph nodes and lungs, compared with mice given control implants^[11]. In the current study, we presented the clinical evidence and experimental data to indicate that γ -synuclein played a key role in CRC invasion and metastasis. We analyzed the relationship between γ -synuclein protein expression in 54 CRC tissues and the clinicopathologic characteristics of patients with CRC, and found that the frequency of positive γ -synuclein staining was much higher in tumors with lymph node-positive or later stage than in lymph node-negative or earlier stage tumors ($P < 0.05$).

Our results also showed that there was a tendency for high γ -synuclein expression with metastasis. However, this difference is not significant ($P = 0.095$), possibly because of our relatively small sample size. Consistent with the clinical evidence, we also observed that reduced γ -synuclein expression led to decreased cell motility and invasion in HCT116 cells. All these results gave evidence that γ -synuclein may indeed function as key mediators of cancer cell growth and metastasis and will be a promising target for CRC treatment. Biological treatment targeting γ -synuclein has been studied in breast cancer, and Singh *et al.*^[30] have designed and characterized a γ -synuclein targeting peptide inhibitor, which associates with γ -synuclein and enhances sensitivity of breast cancer cells to antimicrotubule drugs.

In summary, we have shown that strong expression of γ -synuclein occurred in CRC tissues and correlated with the advancement of tumor stage and lymph node involvement. With a vector-based siRNA method, we

showed that stable down-regulation of γ -synuclein expression inhibited CRC cell growth, colony formation, motility and invasion. Therefore, γ -synuclein is likely to play an important role in the progression of CRC. Further study is needed to prove the value of γ -synuclein as a biomarker or molecular target for CRC diagnosis, prognosis evaluation and therapy. The following research may encompass: 1. Examination of γ -synuclein expression in serum or stool samples from patients with CRC; 2. Relationship between γ -synuclein expression and 5-year survival rate of CRC patient; 3. Delineation of the interaction between γ -synuclein and other proteins, and γ -synuclein targeting biotherapy in cell culture and animal model.

ACKNOWLEDGMENTS

We are grateful to Dr. Feng Zhang (Institute of Digestive Surgery, Ruijin Hospital, China) for excellent technical assistance and advice.

COMMENTS

Background

Colorectal cancer (CRC) is the third most common malignancy and the second leading cause of cancer-related deaths worldwide. The conventional therapies involving surgery and adjuvant therapy do not significantly prolong the survival period. It is necessary to identify a reliable biomarker or a potential target for diagnosis and treatment.

Research frontiers

γ -synuclein, a member of synuclein protein family, is abundantly expressed in brain tissue and presynaptic terminals. However, the tissue specificity of γ -synuclein expression appears to be lost in some types of cancer. Particularly in breast cancers, γ -synuclein promotes malignancy of breast cancer cell lines in *in vitro* studies and animal models. However, little is known about γ -synuclein in colorectal cancer.

Innovations and breakthroughs

The results of this study provide strong evidence suggesting that γ -synuclein expression is up-regulated in CRC tissues, and is significantly correlated with clinical stage and lymph node involvement of CRC. The authors also constructed specific γ -synuclein siRNA plasmids and established a permanent transfected colorectal cancer cell line HCT116, and found that down-regulation of expression of γ -synuclein in HCT116 cells could inhibit the growth, colony formation rate, and migration and invasion ability of HCT116 cells.

Applications

These results demonstrate that γ -synuclein indeed may function as a key mediator of cancer cell growth and metastasis and will be a promising target for CRC diagnosis, prognosis evaluation and biotherapy.

Terminology

Mitotic checkpoint is a cellular inherent mechanism, which strictly controls the cell division cycle and makes sure there is faithful cell replication. G418, a kind of aminoglycoside antibiotic, is a most common resistance selection reagent, used for stable transfectants in molecular biology tests.

Peer review

The paper investigated expression pattern of γ -synuclein in CRC tissues, and the effects of γ -synuclein on CRC cell line HCT116 biological features also were studied *in vitro*. The study is well conducted and the results is clear.

Abstract

AIM: To investigate the effects of class I phosphatidylinositol 3-kinase (PI3K) inhibitor LY294002 on the invasiveness and related mechanisms of implanted tumors of SGC7901 human gastric carcinoma cells in nude mice.

METHODS: Nude mice were randomly divided into model control groups and LY294002 treatment groups. On days 5, 10 and 15 after treatment, the inhibitory rate of tumor growth, pathological changes in tumor specimens, expression levels of matrix metalloproteinase (MMP)-2, MMP-9, CD34 [representing microvessel density (MVD)] and vascular endothelial growth factor (VEGF), as well as apoptosis indexes in tumor samples were observed.

RESULTS: In this study, we showed that treating

the tumors with LY294002 could significantly inhibit carcinoma growth by 11.3%, 29.4% and 36.7%, after 5, 10 and 15 d, respectively, compared to the control group. Hematoxylin & eosin staining indicated that the rate of inhibition increased progressively ($23.51\% \pm 3.11\%$, $43.20\% \pm 3.27\%$ and $63.28\% \pm 2.10\%$ at 5, 10 and 15 d, respectively) along with apoptosis. The expression of MMP-2 was also downregulated (from $71.4\% \pm 1.6\%$ to $47.9\% \pm 0.7\%$, $31.9\% \pm 0.9\%$ and $7.9\% \pm 0.7\%$). The same effects were observed in MMP-9 protein expression (from $49.4\% \pm 1.5\%$ to $36.9\% \pm 0.4\%$, $23.5\% \pm 0.9\%$ and $7.7\% \pm 0.6\%$), the mean MVD (from $51.2\% \pm 3.1\%$ to $41.9\% \pm 1.5\%$, $30.9\% \pm 1.7\%$ and $14.9\% \pm 0.8\%$), and the expression of VEGF (from $47.2\% \pm 3.1\%$ to $25.9\% \pm 0.5\%$, $18.6\% \pm 1.2\%$ and $5.1\% \pm 0.9\%$) by immunohistochemical staining.

CONCLUSION: The class I PI3K inhibitor LY294002 could inhibit the invasiveness of gastric cancer cells by downregulating the expression of MMP-2, MMP-9, and VEGF, and reducing MVD.

Effects of LY294002 on the invasiveness of human gastric cancer *in vivo* in nude mice. *World J Gastroenterol* 2009; 15(40): 5044-5052 Available from: URL: <http://www.wjgnet.com/1007-9327/15/5044.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.5044>

INTRODUCTION

Gastric cancer is the fourth most frequently diagnosed malignancy worldwide, accounting for 12% of all cancer-related deaths. In Asia and parts of South America in particular, gastric cancer is the most common epithelial malignancy and a leading cause of cancer-related death^[1,2]. The major cause of death from gastric cancer

is metastasis that is usually resistant to conventional treatment.

Invasiveness and metastasis are the leading biological characteristics of a malignant tumor, and have a close relation with factors such as movement of tumor cells, apoptosis and metastasis-associated genes. Matrix metalloproteinase (MMP)-2, MMP-9, intratumoral microvessel density (MVD) and vascular endothelial growth factor (VEGF) are important angiogenic factors, which have a higher expression in tumor tissues, may induce angiogenesis in the tumor and play an important role in metastases, invasion and prognosis of gastric cancer^[3-7]. However, the underlying mechanism remains uncertain.

The phosphatidylinositol 3-kinase (PI3K) pathway plays a central role in the regulation of cell proliferation, growth, differentiation and survival^[8,9]. Dysregulation of this pathway is frequently observed in a variety of tumors, including brain tumors and breast, ovarian and other carcinomas^[10-12]. Therefore, inhibition of PI3K signaling is under investigation as a potentially useful approach for cancer treatment. However, the detailed mechanisms are poorly understood.

LY294002 is a specific inhibitor of class I PI3K. The antitumor activity of LY294002 may be related to the induction of apoptosis of tumor cells, but the precise mechanism of its antitumor activity is not well understood.

In the present study, we investigated whether the inhibition of class I PI3K by LY294002 restricted the growth and invasiveness of implanted tumors of SGC7901 cells in nude mice. Through this research, we would suggest that the class I PI3K inhibitor LY294002 could play an important role in the inhibition of progression of gastric carcinoma, and may be of value in effective clinical antitumor therapy.

MATERIALS AND METHODS

Materials

SG7901 cells and female Balb/c nude mice (4 wk old, 16-18 g) were purchased from the Chinese Academy of Sciences (Shanghai, China). RPMI-1640 medium was purchased from Gibco (Rockville, MD, USA). Fetal bovine serum was purchased from Hangzhou Sijiqing Biological Engineering Material Co. (Hangzhou, China), anti-MMP-2 (sc-13595), anti-MMP-9 (sc-21733), anti-CD34 (sc-19621) and anti-VEGF (sc-57496) monoclonal antibodies were purchased from Santa Cruz Biotechnology, Inc. (USA). SP kit was purchased from Maixin Biotechnology (Fuzhou, China).

Drug preparation

LY294002 was purchased from Cell Signaling Technology (Beverly, MA, USA) and diluted in phosphate buffered saline (PBS) to create a stock solution that was stored according to the manufacturer's instructions. The final concentration of the LY294002 solution used was 500 $\mu\text{mol/L}$. This concentration of LY294002 was selected on the basis of our experiments on implanted tumors of human SGC7901 cells in nude mice.

Cell culture

SGC7901 cells were maintained in RPMI-1640 medium (Gibco) containing 10% heat-inactivated fetal bovine serum (Hangzhou Sijiqing Biological Engineering Material Co.), 0.03% L-glutamine (Sigma) and incubated in a 5% CO₂ atmosphere at 37°C. Cells in the mid-log phase were used in the experiments.

Inhibitory rate of tumor growth

A transplanted tumor model was established by injecting 1×10^9 cells/mL human SGC7901 into the subcutaneous tissue in the armpit of nude mice. After 10 d, 25 nude mice were randomly divided into four groups, and 0.2 mL normal saline solution, LY294002 (500 $\mu\text{mol/L}$) was directly injected adjacent to the tumor, twice at a 2 d interval (5 d group), three times at 2 d intervals (10 and 15 d group). There were six nude mice given saline, 19 nude mice given LY294002 (six in the 5 d group, six in the 10 d group, seven in the 15 d group). Changes in tumor volume = $(\pi/6) \times abc$ (a: the length of the tumor, b: the width of the tumor and c: the depth of the tumor) were measured at 5, 10, 15 d after LY294002 treatment and the tumor inhibition rate of each group was calculated.

Inhibitory rate of tumor growth = $[C(V_1 - V_0) - T(V_1 - V_0)]/C(V_1 - V_0)$

Where C is the control group, T is the treated group, V_1 is the volume before treatment (mm^3), and V_0 is the volume after treatment (mm^3).

Hematoxylin and eosin (HE) and immunohistochemical staining

Tumor specimens were taken from areas next to the margin of the tumors as well as from more central areas. All the specimens were formalin-fixed, paraffin-embedded and pathologically diagnosed to be gastric carcinoma and evaluated using HE for conventional histological assessment. Histological characteristics were reviewed by two pathologists.

The tumor samples were cut into 4 μm thick slices and fixed in acetone. After washing in PBS, slices were incubated in 0.3% H₂O₂ solution at room temperature for 5 min. Slices were then incubated with anti-MMP-2 or anti-MMP-9 or anti-MVD or anti-VEGF monoclonal antibody at a 1:300 dilution at 4°C overnight. After washing in PBS, the second antibody, biotinylated anti-rat IgG, was added and the cells were incubated at room temperature for 1 h. After washing in PBS, avidin-biotin complex was added and then incubated at room temperature for 10 min. Diaminobenzidine was used as the chromogen. After 10 min, the brown color signifying the presence of antigen bound to antibodies was detected by light microscopy. Controls were prepared in the same manner as the experimental group, except for incubation with the primary antibody. The positive rate (PR) was calculated as follows: PR = (number of positive cells/total number of cells) \times 100%.

Immunohistochemical assessment

The cytoplasm with MMP-2, MMP-9 and VEGF

appeared as brown in color. Immunohistochemical staining was independently evaluated by two pathologists, who were blinded to the experimental data. Two hundred cells were chosen under the microscope to evaluate the stained cell number against the total cell number in the field. Based on the positive cell number, the criteria were set as follows: negative (-) having a positive cell number < 10%; (+) having 11%-50% positive cells; (++) having 51%-75% positive cells; and (+++) having > 75% positive cells. The results of staining of MMP-2, MMP-9 and VEGF were classified into negative (staining of \leq 10% of cells) or positive (staining of > 10% of cells).

Evaluation of MVD

MVD-CD34 of tumor tissues were evaluated at low power field ($\times 40$). The tissue sections were screened and five areas with the most intense neovascularization (hot spots) were selected. Microvessel counts of these areas were performed at high power field ($\times 200$). Cases with discrepancies in scores between the two investigators were evaluated jointly to obtain a common consensus score. Any positively stained endothelial cell or endothelial cell cluster that was clearly separated from the adjacent microvessels, tumor cells and connective elements was counted as one microvessel, irrespective of the presence of a vessel lumen. An automated microvessel count/field was computed in each hot spot and the mean microvessel count of the 5 most vascularized areas was taken as the MVD-CD34, which was expressed as the absolute number of microvessels per 0.74 mm^2 ($\times 200$ field). The microvessel count that was higher than the median of microvessel count was taken as high MVD-CD34 and the microvessel count that was lower than the median of microvessel count was taken as low MVD-CD34.

Statistical analysis

All data are presented as mean% \pm SD. Statistical analysis was carried out using ANOVA followed by Dunnett's *t*-test, with $P < 0.05$ taken to indicate significance.

RESULTS

Effect of the LY294002 on tumor growth

SGC7901 cells (1×10^5) were injected subcutaneously into the armpit of nude mice. Within 1 wk, visible tumors had developed at the injection sites. To determine the therapeutic effectiveness of LY294002, intratumoral injection of LY294002 was started after the volume of the implanted tumor reached 20 mm^3 , and was repeated every 2 d for a total of three times. As shown in Table 1, LY294002 markedly suppressed tumor growth compared with PBS alone ($P < 0.01$). No gross adverse effects, i.e. the loss of body weight, were observed during the experimental periods. Moreover, LY294002 inhibited the proliferation of the implanted tumor of human SGC7901 cells in nude mice in a time-dependent fashion. The inhibition rate of the tumors

15 d	5	5	20.4 \pm 1.7	379.2 \pm 9.3	36.7 \pm 2.12 ^a

^a $P < 0.05$ vs control.

was 11.31% \pm 13% on day 5, 29.4% \pm 1.47% on day 10 and reached 36.7% \pm 2.12% on day 15.

LY294002 reduced cell viability and induced apoptosis of transplanted SGC7901 tumor cells

Treatment with LY294002 for 5, 10 and 15 d in SGC7901 cells produced intensive HE staining indicating apoptosis. A significant increase in apoptosis was observed along with the time that tumors were treated (Figure 1). After 5 d, the rate of inhibition reached 23.51% \pm 3.11%. The rate of inhibition rose when the experimental time increased, reaching 43.20% \pm 3.27% on day 10 and 63.28% \pm 2.10% on day 15 after LY294002 treatment. All the results indicated that LY294002 induced apoptosis (Figure 1E-H).

Similarly, in the lymphatic vessels, the effect of the drug increased with time. The invasion rate of the tumor cells in the lymphatic vessels decreased from 75.69% \pm 3.5% to 63.78% \pm 4.3%, 45.62% \pm 3.1% and 28.17% \pm 2.7% at 5, 10 and 15 d, respectively, after treatment with LY294002 (Figure 1A-D).

LY294002 inhibited the expression of MMP-2 and MMP-9 proteins

Positive staining was distributed in the cell membrane and cytoplasm (Figures 2 and 3). The PR of MMP-2 protein downregulated was from 71.4% \pm 1.6% in the control group to 47.9% \pm 0.7%, 31.9% \pm 0.9% and 7.9% \pm 0.7% at 5, 10 and 15 d, respectively, after treatment with LY294002 for (Figure 2E-H). Significant differences in the expression were observed between the 500 $\mu\text{mol/L}$ LY294002 group and the control group at every time point ($P < 0.05$). Similarly, the expression of MMP-9 decreased from 49.4% \pm 1.5% to 36.9% \pm 0.4%, 23.5% \pm 0.9%, 7.7% \pm 0.6%, respectively (Figure 3E-H).

In the lymphatic vessels, we found that the expression of MMP-2 in the tumor cells also decreased from 59.23% \pm 6.2% to 45.46% \pm 7.3%, 32.14% \pm 1.9%, 14.01% \pm 3.9% at the various time points (Figure 2A-D). Interestingly, MMP-9 shared the same characteristics in expression as that of MMP-2, which fell from 39.95% \pm 5.7% to 25.32% \pm 6.5%, 12.84% \pm 2.8%, 4.01% \pm 5.9% (Figure 3A-D).

LY294002 decreased the expression of MVD and VEGF

Positively stained particles of MVD-CD34 were mainly distributed in the plasmalemma of cells, though some

Figure 1 Pathological changes in lymphatic vessels and SGC7901 tumor cells in the model control groups (A, E) and treatment groups (B-D, F-H). Lymphatic vessels (A-D) (HE, $\times 200$) and tumor cells (E-H) (HE, $\times 100$); control groups (A, E); LY294002 groups on days 5 (B, F), day 10 (C, G), day 15 (D, H).

were expressed in the cytoplasm (Figure 4). The mean MVD was much lower in the tumors treated with LY294002 than in the control group.

According to the PR of MVD protein of the control group and the experimental group after treatment with LY294002 5, 10, 15 d, the expression of MVD was downregulated from $51.2\% \pm 3.1\%$ to $41.9\% \pm 1.5\%$, $30.9\% \pm 1.7\%$ and $14.9\% \pm 0.8\%$ after 5, 10 and 15 d, respectively (Figure 4E-H). A significant difference in positive expression was observed between the 500 $\mu\text{mol/L}$

LY294002 group and the control group at every time point ($P < 0.05$). Similarly, the expression of VEGF decreased from $47.2\% \pm 3.1\%$ to $25.9\% \pm 0.5\%$, $18.6\% \pm 1.2\%$ and $5.1\% \pm 0.9\%$, respectively (Figure 5E-H).

In the vascular area, we found that the effect of the agent increased with time, and the MVD of the tumor cells decreased from $37.65\% \pm 2.7\%$ to $27.24\% \pm 5.3\%$, $10.64\% \pm 3.5\%$, $5.26\% \pm 1.3\%$ at 5, 10 and 15 d, respectively (Figure 4A-D). The VEGF expression was also downregulated from $34.25\% \pm 1.7\%$ to $25.21\% \pm$

Figure 2 Pathological changes of the expression of MMP-2 in lymphatic vessels and SGC7901 tumor cells in the model control groups (A, E) and treatment groups (B-D, F-H). Lymphatic vessels (A-D) (HE, $\times 200$) and tumor cells (E-H) (HE, $\times 100$); control groups (A, E); LY294002 groups on days 5 (B, F), day 10 (C, G), day 15 (D, H).

2.3%, $11.34\% \pm 5.1\%$ and $3.26\% \pm 0.3\%$, respectively (Figure 5A-D).

DISCUSSION

Currently only a few chemotherapeutic drugs are effective for the treatment of human gastric carcinoma^[13] and there is an increasing interest in the use of drugs to prevent its occurrence or invasiveness. The lipid kinase PI3K is a proto-oncogene that generates 3'-phosphoinositides at the

cell membrane. The best-characterized inhibitors of PI3K are LY294002 and wortmannin. LY294002 effectively inhibits the growth of many types of tumor cells *in vitro* and *in vivo*, via the inhibition of PI3K and downstream components of the pathway^[14-17]. It is possible that LY294002 inhibits proliferation and induces apoptosis in SGC7901 cells through inhibiting class I PI3K. However, the downstream molecules involved in the apoptotic death of tumor cells following inhibition of PI3K/Akt by LY294002 remain to be identified^[1,18].

Figure 3 Pathological changes of the expression of MMP-9 in lymphatic vessels and SGC7901 tumor cells in the model control groups (A, E) and treatment groups (B-D, F-H). Lymphatic vessels (A-D) (HE, $\times 200$) and tumor cells (E-H) (HE, $\times 100$); control groups (A, E); LY294002 groups on days 5 (B, F), day 10 (C, G), day 15 (D, H).

Tumor metastasis involves a series of complex processes in which many gene products take part in regulating MMPs, which play an important role in breaking the extracellular matrix, are overexpressed in malignant tumors and are believed to contribute to tumor proliferation, invasion, and metastasis^[19]. Among the MMPs, MMP-2 and MMP-9 are closely related to the metastasis of tumors, and have been specifically considered to be important factors in facilitating lymphatic invasion and metastases in gastric carcinoma^[20-22].

MVD is a quantitative index for carcinoma angiogenesis, which indicates the regulation of the progress and metastasis of primary gastric carcinoma, and can therefore serve as a marker for carcinoma prognosis^[23-25]. VEGF is one of the agents accelerating the formation of blood vessels, and plays a vital part in tumor-associated microvascular invasion^[26-28]. It has been found that tumor metastasis is speeded up by VEGF, which is highly expressed in gastric carcinoma, thus may be used as an index for poor prognosis of gastric carcinoma^[29-31].

Figure 4 Pathological changes of the expression of MVD in lymphatic vessels and SGC7901 tumor cells in the model control groups (A, E) and treatment groups (B-D, F-H). Lymphatic vessels (A-D) (HE, $\times 200$) and tumor cells (E-H) (HE, $\times 100$); control groups (A, E); LY294002 groups on days 5 (B, F), day 10 (C, G), day 15 (D, H).

In the present study, there was a significant difference in the expression of MMP-2, MMP-9 and VEGF, and in MVD between the transplanted gastric tumor tissues treated by the class I PI3K inhibitor LY294002 and that of the control group ($P < 0.05$), indicating that LY294002 may inhibit the gene expression of MMP-2, MMP-9, MVD, and VEGF. We also showed that LY294002 reduced the viability and induced apoptosis in the implanted tumor of human SGC7901 cells, thus demonstrating the cytotoxic effects of LY294002. Both

the *in vitro* invasion assay and the *in vivo* nude mice assay suggested that LY294002 had the potential to inhibit the invasion and metastasis of gastric cancer. This may be the result of the decrease of the expression of MMP-2, MMP-9, MVD and VEGF together with the cytotoxicity towards the tumor cells, both induced by LY294002. Moreover, no gross adverse effects, i.e. loss of body weight, were observed during our experimental periods. These findings suggest that inhibition of the class I PI3K signaling pathway is a potent and safe strategy for

Figure 5 Pathological changes of the expression of VEGF in lymphatic vessels and SGC7901 tumor cells in the model control group (A, E) and treatment group (B-D, F-H). Lymphatic vessels (A-D) (HE, $\times 200$) and tumor cells (E-H) (HE, $\times 100$); control groups (A, E); LY294002 groups on days 5 (B, F), day 10 (C, G), day 15 (D, H).

managing gastric cancers, and further indicated that development of LY294002-based therapies may be an emerging approach for the next step in gastric cancer management.

COMMENTS

Background

The phosphatidylinositol 3-kinase (PI3K) pathway plays a central role in the regulation of cell proliferation, growth, differentiation, and survival. Dysregulation of

this pathway is frequently observed in a variety of tumors, including brain tumors and breast, ovarian and other carcinomas. Currently only a few chemotherapeutic drugs are effective for the treatment of human gastric carcinoma and there is an increasing interest in the use of drugs to prevent its occurrence or invasiveness.

Research frontiers

LY294002 is a specific inhibitor of class I PI3K. The antitumor activity of LY294002 may be related to the induction of apoptosis of tumor cells, but the precise mechanism of its antitumor activity is not well understood.

Applications

The research indicated that development of LY294002-based therapies may be an emerging approach for the next step in gastric cancer management.

Terminology

Matrix metalloproteinases (MMPs) are a family of structurally related zinc-endopeptidases. MMP-2 contributes to cell proliferation, migration, and matrix invasion in a number of cell types such as tumor cells and fibroblasts. MMP-9 is directly involved in tumor metastasis, and more recently MMP-9 activity has been linked with the process of tumor cell invasiveness. High MVD is an indirect measure of tumor aggressiveness. Vascular endothelial growth factor is a potent regulator of placental vascular function. Endothelial dysfunction is a key factor associated with preeclampsia.

Peer review

Overall, the experiment was well performed and the authors have presented interesting data to provide a mechanistic insight into the antitumor effect of LY294002.

predominance of CD8+ cells in the tumor tissue (52.6/10 HPF) and of CD4+ cells in the interface region (223.1/10 HPF). CD56+ cells of the innate immune system were scarce. There was no significant difference between hepatocellular or cholangiolar carcinoma. No correlation with the clinicopathological data was seen.

CONCLUSION: Liver TIL consists of intratumoral CD8+ T cells and peritumoral CD4+ T cells independent of histogenetic origin. Different functions of lymphocytes in these regions seem possible.

Abstract

AIM: To investigate the role of tumor infiltrating lymphocytes (TIL) in primary hepatocellular and cholangiolar carcinomas of the liver.

METHODS: Immunohistochemical analysis was performed including antibodies to CD3, CD4, CD8, CD20, CD56 and TIA-1 in formalin-fixed and paraffin-embedded tissue of 35 liver resection specimens of hepatocellular or cholangiocellular carcinomas. Semiquantitative evaluation was performed with emphasis on the area of the tumor itself and of the tumor/liver interface.

RESULTS: All hepatocellular carcinomas showed infiltration of lymphocytes predominantly around the tumor in the tumor/liver interface consisting mainly of CD3+ CD4+ T lymphocytes [164.3/10 high power fields (HPF)] and in the tumor itself of CD8+ cells (54.9/10 HPF). Cholangiocarcinomas contained a heterogeneous amount of TIL, composed mainly of CD3+ T cells with a

INTRODUCTION

Tumor infiltrating lymphocytes (TIL) are part of the tumor surveillance system^[1]. This immune response is thought to be a result of changes of surface components of tumor cells. The innate as well as the adaptive immune system is involved in tumor destruction with cell-mediated mechanisms playing the main role. They are frequently present in human solid tumors. Some CD8+ T cells are seen as final effector cells with the ability to induce apoptosis of cancer cells. Subpopulations of CD4+ T cells have a helper function, activating other immune cells *via* cytokine secretion or antigen processing. TIL are a target for immunotherapeutic strategies^[2].

The liver can be regarded as an immunological organ, specially equipped with liver-associated lymphocytes, mainly T lymphocytes and natural killer cells^[3]. They play an important role in the barrier function of the liver between the gastrointestinal tract and an organism. They

do not only function as part of the defense system but also as a regulator of immune tolerance.

Hepatocellular carcinoma is the leading cause of malignant cancer deaths worldwide and the morbidity is increasing year on year. It accounts for approximately 6% of all human cancers and up to 1 million deaths per year. The second most common primary malignancy of the liver, cholangiolar carcinoma also has a bad prognosis. Its resectability rate is very low, but surgical resection is the only treatment which can change outcome significantly^[4,5].

We studied the frequency and composition of TIL in primary liver cancers with special attention to the morphological distribution. The subtyping was performed to clarify their putative role in host response, immunotolerance and as a therapeutic target.

MATERIALS AND METHODS

Patients

Formalin-fixed and paraffin-embedded tissue of 35 liver resection specimens were investigated. The specimens were obtained from 8 women and 27 men with a median age of 60.5 years (38-82 years). Twenty seven of the cases were diagnosed as hepatocellular carcinoma (8 × T1, 3 × T2, 12 × T3 4 × T4; 6 × G1, 14 × G2, 7 × G3) and 8 as cholangiolar carcinoma (2 × T1, 1 × T2, 2 × T3, no T-stage available in 3; 6 × G2, 2 × G3) with a mean diameter of 7.9 cm and 8.3 cm, respectively.

Immunohistochemistry

A panel of immunohistochemical stains was performed including antibodies to CD3, CD4, CD8, CD20, CD56 and TIA-1. The specifications and titers are given in Table 1.

Routinely processed formalin-fixed and paraffin-embedded tissue sections of the tumor and the tumor/liver interface with a thickness of 4 μm were used. Sections were mounted onto capillary gap slides (DAKO, Glostrup, Denmark), dried overnight at 30°C, deparaffinized with xylene and rehydrated with ethanol in a graded series to distilled water. Staining was performed using an automated immunostainer (Techmate, DAKO, Glostrup, Denmark) with AEC (3-amino-9-ethylcarbazole) for visualization. The slides were counterstained with hemalaun and a coverslip placed on top. Appropriate positive and negative tissue control samples were used throughout. Tonsils served as positive controls.

Statistical analysis

Ten high power fields (HPF) of the tumor and the tumor-liver interface were randomly selected and the frequency of TIL was counted using an ocular grid. Results are reported as mean value and standard deviation per 10 HPF. Comparison of the groups was performed using the two-tailed Students *t*-test (SPSS for windows). The significance level was set as *P* < 0.05.

RESULTS

TIL in hepatocellular carcinoma

All hepatocellular carcinomas showed an infiltration of

Table 1 List of antibodies

Name	Clone	Pre-treatment	Titer	Manufacturer
CD3	PS1	10 min autoclave 120°C, citrate buffer pH 6	1:50	DAKO, Glostrup, Denmark
CD4	1F6	10 min autoclave 120°C, citrate buffer pH 9	1:10	Novocastra, Newcastle, UK
CD8	C8/144B	10 min autoclave 120°C, citrate buffer pH 6	1:100	DAKO, Glostrup, Denmark
CD20	L26	none	1:500	DAKO, Glostrup, Denmark
CD56	123C3	2 × 7 min microwave citrate buffer pH 6	1:500	Zymed, San Francisco, CA, USA
TIA-1	TIA-1	2 × 7 min microwave citrate buffer pH 6	1:500	Coulter Immunol., Hialeah, FL, USA

lymphocytes which was mainly localized around the tumor in the tumor/liver interface, with less among the tumor cells (Table 2, Figure 1). The TIL consisted mainly of CD3+ T lymphocytes. CD20+ cells and CD56+ cells were rarely found. In the tumor itself, the infiltration was dominated by CD8+ cells. In contrast, in the peritumoral area the amount of CD4+ cells was higher than the amount of CD8+ cells. TIA-1 containing cells were more frequent in the peritumoral region.

TIL in cholangiolar carcinoma

Cholangiocarcinomas contained a heterogeneous amount of TIL, composed mainly of CD3+ T cells. The relationship of the subpopulations was comparable to that of hepatocellular carcinoma, with a predominance of CD8+ cells in the tumor tissue and of CD4+ cells in the interface region. CD56+ and CD20+ cells were found only in a minor proportion. Cells containing the cytotoxic granula TIA-1 occurred often in the interface region. The details are summarized in Table 2 and Figure 2.

No statistical differences were found in the frequency and distribution according to age, sex, size or grade of the tumor.

DISCUSSION

Liver carcinoma evolves over a long period of time from precursor lesions to invasive cancer and metastases. The exact mechanisms of this pathway are not fully understood^[6]. It is known, however, that TIL have the potential to modulate this process. The extent of this modulation and the real effects of tumor growth and dissemination remain unclear.

Several methodical approaches have been used to measure TIL. Most often flow cytometry and immunohistochemistry is used. Flow cytometry is a rapid method, in which a higher amount of cells and a panel of markers can be investigated. Fresh tissue, however, is necessary. Therefore retrospective studies, especially with human tissue from pathological files, are not possible. An exact localization of the TIL cannot be determined. Immunohistochemistry can identify different cell populations and has the advantage of direct localization of the lymphocyte subsets. Manual counting and automated counting

HPF: High power fields; TIL: Tumor infiltrating lymphocytes.

Figure 1 Lymphocytic infiltration in the tumor tissue of hepatocellular carcinoma. A-D: Intratumoral region; E-H: Tumor/liver interface (peritumoral); A and E: CD3+ T cells are the main infiltrate with a higher amount in the interface region; B and F: CD4+ cells were mainly located in the peritumoral area; C and G: In the tumor tissue, CD8+ cells were more often seen; D and H: CD20+ cells were scarce.

Figure 2 The distribution of tumor infiltrating lymphocytes in cholangiocellular carcinoma. A-D: Intratumoral region; E-H: Tumor/liver interface (peritumoral); A and E: CD3+ T cells were the dominant infiltrate; B and F: The quantity of CD4+ and CD8+ cells were opposite with a higher level of CD4 cells in the peritumoral region; C and G: CD8+ cells were more often found in the tumor tissue; D and H: CD20+ cells were scarce.

of digital images are possible^[7,8].

Using a histological approach we were able to localize TIL and could differentiate between lymphocytes in the tumor itself and in the environs of the tumor. In the

tumor, CD8+ cells were more frequent, showing a closer contact with the tumor cells. As these cells can have a cytotoxic function, a direct apoptotic effect *via* different pathways such as the FAS/FAS-ligand pathway seems

possible. Large numbers of CD8+ TILs are associated with a favorable prognosis in several solid carcinomas such as colorectal, ovarian, pancreatic and esophageal carcinoma^[9-14]. Other entities such as nasopharyngeal cancer, renal cell carcinoma and non-small cell lung cancer show opposite behavior^[15-17]. For hepatocellular carcinoma, further investigation is necessary.

In contrast, TIL in the interface are mostly of the CD4+ type. As CD4+ cells include helper T cells, their infiltration could activate cytotoxic killer cells by cytokine secretion or antigen presentation. Other authors, however, found an involvement of these cells, also known as regulatory cells, in immune tolerance^[18]. Tumor cells adapting to these mechanisms of the CD4+ lymphocytes could use these cells to induce a tumor-friendly environment. The infiltration of CD4+ T-cells could be a sign of tumor adaptation known as enhancement^[19].

Unitt *et al*^[20,21] indicated that lymphocytic infiltration of the tumor and a high CD4+/CD8+ T cell ratio were associated with a reduced risk of tumor recurrence after liver transplantation for hepatocellular carcinoma. This ratio was beneficial in hepatocellular carcinoma. A decreased ratio was shown to imply poor tumor response^[22]. CD4+ T lymphocytes can activate monocytes, macrophages and natural killer cells and can help CD8+ T lymphocytes to kill tumor cells. Thus, a positive effect of those infiltrations seems to exist. On the other hand, however, CD4+ T cells were also involved in tolerance mechanisms. As the liver is particularly involved in tolerance induction to food antigens, a supportive role of these infiltrates cannot be ruled out.

A lower quantity of CD8+ cells in the tumor and in the tumor periphery could signal a low level of T cell activation by tumor specific antigens in the liver. Primary reasons for this can be in the immune system itself such as development of self tolerance in the thymus or in the periphery^[23]. The tumor can also develop various evasion strategies like converting T helper cells or lowering the expression of tumor specific antigens to below the required threshold^[24-26]. These mechanisms would lead to a low quantity of TIL. Janicki *et al*^[27], however, could show that TIL can lose their effector function even after infiltrating the tumor. One reason could be a loss of adhesion capability^[28]. These results have critical implications for vaccination studies.

The liver normally contains a higher quantity of cells of the innate immune system such as natural killer cells. The lack of CD56+ cells in the tumor and in the interface to the liver is surprising. This cell type is thought to be involved in tumor defense. This is in contrast to a recent study investigating human glioblastomas^[29]. Half of all TIL in these tumor types were CD56+ cells, in particularly CD4+CD56+ T cells. Whether this cell type is unique for brain tumors has to be clarified by further studies.

In the liver, a primary defect or lack of cells of the innate immune systems could be regarded as an aid to tumor development. On the other hand, there is the possibility that a manifest tumor can suppress the innate immune system.

For cholangiolar carcinoma, only scarce data are

available regarding TIL. Takagi and coworkers found that patients with high numbers of TIL (CD8+ or CD4+) had significantly better prognosis^[30]. In our study, the amount of TILs was heterogeneous. In the tumor tissue itself, the CD8+ cells can act as cytotoxic cells. In this entity, regulatory cells are also found in the tumor environs. As in hepatocellular carcinoma, there is a lack of CD56+ cells of the innate immune system.

Earlier we investigated the lymphocytic reaction of the liver with liver metastases from different primary neoplasms^[31]. In this investigation, the results were similar to those demonstrated here. Also, in liver metastases, the frequency of TIL in the interface between the liver and tumor was higher than in the tumor itself. The infiltrate in the interface was also composed mainly of CD4+ T cells. Thus, a general rule can be seen in the reaction of the liver. A manifest tumor is accompanied by a CD4+ reaction in the liver. Whether this is a defense mechanism or more like an induced protection by the tumor cells needs further clarification.

In summary, we could demonstrate for hepatocellular carcinoma and cholangiolar carcinoma that TIL consists, in the tumor itself, of CD8+ T cells and, in the peritumoral region, of CD4+ T cells such as helper cells or regulatory cells. CD20+ cells and TIA-1+ cells were scarce. There was a lack of CD56+ cells of the innate immune system. The functional interaction of TIL in liver carcinomas needs further investigation especially if considered as a target for immunotherapeutic strategies.

COMMENTS

Background

Tumor development is based on an interaction between the tumor cells and the immune system of the body. Tumor infiltrating lymphocytes (TIL) are part of the tumor surveillance system. This immune response is thought to be a result of changes of surface components of tumor cells. TIL are a target for immunotherapeutic strategies in cancer treatment.

Research frontiers

Immune therapy is one of the newer strategies in cancer therapy. The main aim is vaccination against carcinomas. A prerequisite for the development of these vaccines is an understanding of the immunological tumor reaction.

Innovations and breakthroughs

Recent reports have shown different functions of lymphocyte subsets in tumor surveillance. These cells not only have antitumor potential but growth promotion by certain lymphocytes is also documented.

Applications

This study suggests that the immune reaction to liver cancer consists of different lymphocyte subtypes. Some can enhance tumor growth, others can destroy tumor cells. A complex strategy would be necessary for successful immune therapy of liver cancer.

Peer review

The authors investigated the role of TIL in primary hepatocellular and cholangiolar carcinomas of the liver. They found that liver TIL consist of intratumoral CD8+ T cells and peritumoral CD4+ T cells independent of histogenetic origin. This article is well written and deserves publication.

Abstract

AIM: To investigate the correlation between *uridine diphosphate glucuronosyl transferase 1A1 (UGT1A1)* gene polymorphisms and irinotecan-associated side effects and parameters of drug efficacy in patients with metastatic colorectal cancer (mCRC) receiving a low-dose weekly irinotecan chemotherapeutic regimen.

METHODS: Genotypes were retrospectively evaluated by gene scan analysis on the ABI 310 sequencer of the TATAA box in the promoter region of the *UGT1A1* gene in blood samples from 105 patients who had received 1st line irinotecan-based chemotherapy for mCRC.

RESULTS: The distribution of the genotypes was as follows: wild type genotype (WT) (6/6) 39.0%, heterozygous genotype (6/7) 49.5%, and homozygous genotype (7/7) 9.5%. The overall response rate (OR) was similar between patients carrying the (6/7, 7/7) or the WT genotype (6/6) (44.3% vs 43.2%, $P = 0.75$). Neither time to progression [(TTP) 8.1 vs 8.2 mo, $P = 0.97$] nor overall survival [(OS) 21.2 vs 18.9 mo, $P = 0.73$] differed significantly in patients who carried the

(6/6) when compared to the (6/7, 7/7) genotype. No significant differences in toxicity were observed: Grade 3 and 4 delayed diarrhoea [(6/7, 7/7) vs (6/6); 13.0% vs 6.2%, $P = 0.08$], treatment delays [(6/7, 7/7) vs (6/6); 25.1% vs 19.3%, $P = 0.24$] or dose reductions [(6/7, 7/7) vs (6/6); 21.5% vs 27.2%, $P = 0.07$].

CONCLUSION: This analysis demonstrates the non-significant influence of the *UGT1A1* gene polymorphism on efficacy and rate of irinotecan-associated toxicity in mCRC patients receiving low-dose irinotecan based chemotherapy.

INTRODUCTION

Irinotecan (Camptosar®, CPT-11, Pfizer Oncology, New York, NY, US) is one of the most effective chemotherapeutic agents in the treatment of metastatic colorectal cancer (mCRC)^[1,2]. Data from phase III studies indicated an improved clinical outcome of patients who had received an irinotecan-based regimen when compared to those who had received 5-FU/LV alone. As reported by Saltz *et al*^[3], the irinotecan-based combination therapy not only improved the response rate (39% vs 21%), but also the progression free (PFS) (7.0 vs 4.3 mo; $P = 0.004$) and overall survival (OS) (14.8 vs 12.6 mo; $P = 0.04$).

Irinotecan is a semisynthetic derivative of camptothecin and acts as an inhibitor of intracellular topoisomerase- I^[4]. *In vivo*, the pro-drug is metabolized by carboxylesterase into its active metabolite SN-38. SN-38 is inactivated by uridine diphosphate glucuronosyl transferase 1 (UGT1A1) into SN-38G which is excreted with bile^[5].

The most common side effects of irinotecan include neutropenia, febrile neutropenia, nausea, alopecia and delayed diarrhoea which particularly often represents the main and dose-limiting toxicity. This major side effect is because betaglucuronidase in the bowel re-activates SN-38G into the active metabolite SN-38^[6-8].

UGT1A1, an essential enzyme for the inactivation of SN-38, is also involved in the metabolism of bilirubin. Changes in the metabolism of bilirubin result in several clinical disorders. They range from the clinically harmless condition of mild jaundice to the deadly disease Crigler-Najjar that may have a lethal outcome in adolescence^[9]. Patients with Gilbert's syndrome present with a mild unconjugated hyperbilirubinaemia without any structural liver disease or haemolysis. The activity of UGT1A1 is reduced in these individuals compared to those without a comparable defect^[10,11].

Molecular analyses have revealed that in the Caucasian population Gilbert's syndrome is most commonly caused by a polymorphism in the *UGT1A1* gene^[12]. It consists of a TA insertion in the TATAA element of the 5'-promotor region. Genotypes are defined (6/6), (6/7) and (7/7) according to the number of TA repeats. Therefore patients with the wild type (WT) genotype (6/6) (33% in the Caucasian population) are homozygous with 6 repeats of the TA insertion. Patients with the (7/7) genotype are homozygous with 7 TA repeats while the heterozygous genotype (6/7) consists of 1 allele with 6 TA repeats and of 1 with 7 TA repeats. Patients being heterozygous or homozygous for this variant allele (also named UGT1A1*28) show a reduced expression of the UGT1A1 enzyme resulting in lower rates of bilirubin and SN-38 glucuronidation^[13]. Compared to the wild type genotype (6/6) patients carrying the (7/7) genotype displayed a 70% reduction in transcriptional activity and are, by the attenuated expression of UGT1A1, theoretically predisposed to SN-38 associated side effects^[14]. Apart from that, there are rare genotypes with less than five or more than seven TA repeats leading to variable enzyme levels.

A number of trials have provided evidence of an association between UGT1A1 gene polymorphism and increased toxicity in patients who received irinotecan^[15-18]. Comparability and appliance of the results of these trials is difficult because of the various regimens and irinotecan dosages used. Due to the widespread use of irinotecan and the associated risk of severe side effects the question of defining subgroups of patients susceptible to irinotecan-related toxicities is of eminent clinical importance.

This retrospective analysis included a subgroup of 105 patients with mCRC who were treated with an irinotecan-based chemotherapy within a large prospective randomized multicenter phase III study which investigated the role

of a low-dose irinotecan-based chemotherapy in patients with metastatic or advanced colorectal cancer (FIRE-trial)^[19]. Patients underwent UGT1A1 genotyping in order to evaluate UGT1A1 as a predictor for drug efficacy and/or toxicity for patients with low-dose irinotecan-based chemotherapy and to provide a future tool for a patient tailored chemotherapy.

MATERIALS AND METHODS

Patient selection

One hundred and five Caucasian patients with mCRC were included in this analysis. The study population represents a subgroup of patients treated within the FIRE-trial. In the FIRE-trial a total of 492 patients from 56 centres were included, of which 478 patients could be evaluated for efficacy and toxicity. After an amendment UGT1A1 genotyping was offered and 105 patients were included in this subgroup analysis within the ongoing main study. The local ethics committees of the participating centres approved both the study protocol of the FIRE-trial and the amendment for UGT1A1 genotyping. Since the trial was a multicentre trial, monitoring for consistency was done by an external monitoring expert (ClinAssess GmbH, Leverkusen, Germany). Patients gave written informed consent prior to any study-specific procedures.

Patients with known Gilbert's syndrome or known DPD-deficiency were not allowed to enter the trial.

Treatment regimen

Patients within the FIRE-trial were randomly assigned to a modified FOLFIRI (mFOLFIRI) or modified IROX (mIROX) protocol. Randomisation was done by the external monitoring expert after an eligibility check. Inclusion criteria included serum bilirubin ≤ 1.25 or ≤ 1.5 of the upper institutional limits without or with hepatic metastasis. The modified FOLFIRI consisted of irinotecan 80 mg/m² i.v. over 30 min, folinic acid 500 mg/m² i.v. over 120 min, followed by 5-FU 2000 mg/m² i.v. over 24 h weekly for 6 wk. The modified IROX consisted of oxaliplatin 85 mg/m² i.v. over 120 min every 2 wk and irinotecan 80 mg/m² i.v. over 30 min weekly. For both arms, treatment cycles were repeated on day 50. Pre-medication with atropine (s.c.) was given routinely to prevent acute anti-cholinergic syndrome. Antiemetics were given according to good clinical practice and the local standards of the participating centres (generally 5-HT₃ antagonists). Treatment continuation was intended until progression, until unacceptable toxicity or confirmed complete response (CR).

Therapy was postponed for at least one week until bone marrow recovery or resolution of side effects (diarrhoea \geq grade 1, mucositis \geq grade 1, leucocytopenia \geq grade 2, thrombocytopenia \geq grade 1 or any other toxicity \geq grade 2). In case of toxicity, defined as diarrhoea \geq grade 3, mucositis \geq grade 3, leucocytopenia grade 4, thrombocytopenia \geq grade 3, severe obstipation \geq 96 h or hand-foot-syndrome \geq grade 3, a dose reduction of irinotecan and 5-FU to 80%

Figure 1 Electropherograms/gene scanning: Example results of TA promoter region of the *UGT1A1* gene. A: Control heterozygous genotype (6/7); B: Patient homozygous genotype (6/6); C: Patient homozygous genotype (7/7); D: Negative control.

was mandatory. Doses of irinotecan and oxaliplatin were reduced to 80% for obstipation \geq grade 3. Moreover, a dose reduction of oxaliplatin was required in cases of persistent paraesthesia (dose reduction 25%), painful paraesthesia with duration of > 7 d (dose reduction 25%) or paraesthesia with functional impairment with duration of > 7 d (dose reduction 50%).

In case of any toxicity as described above, following cycles were begun at a reduced dose level as defined by the scheme above.

***UGT1A1* genotyping**

Genotyping studies were performed by an independent laboratory (OncoScreen GmbH, Jena, Germany). Prior to any chemotherapy blood samples were collected for DNA isolation and determination of genotypes. DNA extraction, preparation and genotyping was performed using the methods as previously described^[12,14,16]. DNA was extracted from peripheral blood leucocytes using standard methods. A two-extra-nucleotide insertion (TA) within the TATA box resulting in the sequence (TA)₇TAA (-39 to 53) was researched. Genotypes were identified by gene scan analysis on the ABI 310 sequencer of the TATAA box in the promoter region of the *UGT1A1* gene. Figure 1 displays an electropherogram with typical overlapping peaks to distinguish the WT genotype from the heterozygous and homozygous genotype (Figure 1). The design of the primers to specifically amplify the TA expansion was done with support of GenBank AF297093.

Data collection

Standard evaluation by history, physical examination and routine laboratory tests (including complete blood count, chemical profile and electrolyte determination) were performed prior to the beginning of each cycle.

Drug administration, performance status and toxicity or adverse events were recorded after each cycle of chemotherapy. Toxicity was graded according to the NCI-CTC Classification (version 3.0). Imaging studies using computed tomography (CT) or magnetic resonance imaging (MRI) were performed prior to the beginning of each following cycle as well as for confirmation 4 wk after the end of chemotherapy. Data collection was monitored by an independent monitoring expert (ClinAssess GmbH, Leverkusen, Germany) and was done by an external data manager (Estimate GmbH, Augsburg, Germany).

Response evaluation

Patients' response was assessed by standard WHO criteria, as follows: complete response (CR) was defined as the disappearance of all known disease, documented by at least two observations not less than 4 wk apart, while partial response (PR) was defined as a decrease by at least 50% of the sum of the products of the largest perpendicular diameters of all measurable lesions, as determined by two observations not less than 4 wk apart. Stable disease (SD), lasting for at least 6 wk from the start of the study (i.e. first drug administration), was defined as a $< 50\%$ decrease and $< 25\%$ increase in the sum of the products of the largest perpendicular diameters of all measurable lesions. Progressive disease (PD) was defined as a $> 25\%$ increase in the size of at least one bidimensional or unidimensional measurable lesion, or the appearance of a new lesion.

Endpoints and statistical methods

The primary endpoint of the FIRE-trial was time to progression (TTP). Secondary endpoints included response rate (RR), overall survival (OS), resectability rate, toxicity and quality of life. TTP was defined as the interval

Table 1 Patient characteristics and UGT1A1 status (%)

	Total (<i>n</i> = 103)	WT (6/6) (<i>n</i> = 41)	(6/7) (<i>n</i> = 52)	(7/7) (<i>n</i> = 10)

LDH > 240 U/L	44.8	39.0	51.9	30.0

KPS: Karnofsky performance status; LDH: Lactate dehydrogenase.

between the start of therapy and first documentation of disease progression. OS was measured from the date of starting treatment to the date of death from any cause (intent-to-treat). Probability of survival and TTP were estimated using the Kaplan-Meier method^[20]. Statistical comparisons between different genotypes were determined by using the χ^2 -test. Differences in OS and TTP were analyzed using the log-rank test. A difference of $P < 0.05$ was considered statistically significant.

RESULTS

Baseline characteristics

The median age was 64 years with a gender distribution of 70.5% male and 29.5% female patients. 59% of the patients suffered from metastatic colon and 41% from metastatic rectal cancer. Performance status and adjuvant pre-treatment was similar between WT and heterozygous genotype patients. Detailed patient characteristics are provided in Table 1. Patients in the main trial were stratified according to performance status, lactate dehydrogenase (LDH) and adjuvant pre-treatment. These patients were well balanced between the two treatment arms.

Distribution of the UGT1A1 status

The distribution of the *UGT1A1* genotypes was analysed in 105 of 478 patients evaluated within the FIRE-trial. The majority of the patients (49.5%) had the heterozygous genotype (6/7), 39.0% showed the WT genotype (6/6) and the homozygous genotype (7/7) was found in 9.5% of the analyzed patients. There were also two single cases of the rare genotype (5/7) which were not included for further evaluation due to the low frequency. Results of the distribution of the genotypes are given in Table 2.

Response to chemotherapy with regard to UGT1A1 genotype

The overall response rate (ORR = CR + PR) was similar between the WT genotype (6/6) and the (6/7, 7/7) genotypes (43.2% *vs* 44.3% $P = 0.75$). However, the disease control rate (DCR = CR + PR + SD) appeared to be lower within patients carrying the WT genotype (6/6) as compared to those patients with the (6/7,

7/7) genotypes (73.0% *vs* 91.8%, $P = 0.008$). Detailed response data are presented in Table 3.

There are no efficacy data for the 2 patients carrying the rare genotype (5/7). One patient quit the trial while the other died early during therapy.

Toxicity with regard to UGT1A1 genotype

Overall toxicity according to genotype and treatment arm is given in Table 4. The incidence of grade 3-4 toxicity did not differ significantly between the treatment arms mFOLFIRI and mIROX both for patients with the WT (6/6) and those carrying the (6/7), (7/7) and (5/7) genotypes.

Haematological toxicity was generally mild (grade 3 and 4 < 5%). Comparing the incidence of grade 1-2 and grade 3-4 haematotoxicity in patients with the WT (6/6) genotype to those with the (6/7, 7/7) genotypes, there were no significant differences regarding leucocytopenia, anaemia or thrombocytopenia ($P > 0.05$) (Table 5).

Regarding non-haematological toxicity, the incidence of grade 3-4 delayed diarrhoea appeared higher in patients with the (6/7, 7/7) genotypes compared to the WT (6/6) genotype even though this difference did not reach the statistical level of significance (13.0% *vs* 6.2%, $P = 0.08$) (Table 6).

Both cases with the rare genotype (5/7) were excluded from the statistical evaluation. However, they experienced grade 3-4 toxicity in the course of the treatment (delayed diarrhoea and leucocytopenia, per cycle analysis).

There were no significant differences regarding toxicity-related treatment discontinuations or dose adjustments. Dose delays in patients with the WT (6/6) were observed in 27.2%, compared to 21.5% in patients with the (6/7, 7/7) genotypes ($P = 0.071$). Dose reductions

were more frequently observed in patients with the (6/7, 7/7) genotypes compared to patients who carried the WT (6/6) genotype (25.1% *vs* 19.3%, $P = 0.24$) (Table 7).

TTP and survival with regard to UGT1A1 genotype

TTP was similar between the WT (6/6) and the (6/7, 7/7) genotypes with 8.1 mo and 8.2 mo respectively ($P = 0.971$) (Figure 2). Moreover, there was no difference in survival between the WT compared to the genotypes [WT (6/6) *vs* (6/7, 7/7); 21.2 mo *vs* 18.9 mo, $P = 0.725$] (Figure 3).

DISCUSSION

More than 50 genetic alterations of the UGT1A1 gene locus have previously been described^[21]. Among the Caucasian population the UGT1A1*28 genotype (7/7) plays the most important role for the development of Gilbert's syndrome and an increased toxicity related to irinotecan-based chemotherapy.

The distribution of the UGT1A1 genotype in this retrospective analysis was comparable to that described by Iyer and co-workers^[15]. They reported a frequency of the WT (6/6) genotype in 45% of the patients (39% in the

present analysis), the (6/7) genotype in 35% (49.5% in the present analysis), and the (7/7) genotype in 20% (9.5% in the present analysis) respectively^[15]. Moreover, another analysis of 51 patients suffering from non-small cell lung cancer (NSCLC) showed a comparable distribution of the genotypes WT (6/6) 49%, (6/7) 36% and (7/7) 15%^[22].

Prior to discussion of an association of toxicity and UGT1A1 genotype the following preliminary remarks are inevitable: patients randomized within the FIRE-trial received different irinotecan-based regimes. The incidence of delayed diarrhoea, neurotoxicity, leucocytopenia and thrombocytopenia was more frequent in the IROX arm compared to the FOLFIRI arm^[19]. Differences in the frequency of adverse events might therefore partly influence the present analysis. Moreover, 7.3% of the patients (mainly with rectal cancer) had previously received locoregional radiotherapy prior to study entry. Local irradiation may also play a role in the development of severe diarrhoea or may at least worsen it, independent of the UGT1A1 genotype^[23]. Finally, in analogy to the study of Ando *et al*^[14], there is a certain bias by excluding patients with elevated pre-treatment bilirubin levels.

Among non-haematological toxicities, the incidence of grade 3 and 4 delayed diarrhoea was twice as high in our study population with a homozygous (7/7) or heterozygous (6/7) genotype compared to those carrying the wild type genotype WT (6/6), even though the difference did not reach the level of significance (13.0% *vs* 6.2%; $P = 0.08$). Nevertheless, this trend is supported by the data provided by Marcuello *et al*^[23] who found a significant correlation of the UGT1A1 genotype and

Figure 2 Time to progression and UGT1A1 status. WT (6/6) 8.1 mo (range = 5.7-10.5) vs (6/7, 7/7) 8.2 mo (range = 6.3-9.4), $P > 0.05$; WT: Solid line, (6/7, 7/7): Dashed line.

Figure 3 Overall survival and UGT1A1 status. WT (6/6) 21.2 mo (range = 12.3-41.0) vs (6/7, 7/7) 18.9 mo (range = 16.4-34.1), $P > 0.05$; WT: Solid line, (6/7, 7/7): Dashed line.

the frequency of severe delayed diarrhoea [WT (6/6) 17%, (6/7) 33%, (7/7) 70%; $P = 0.005$]. Moreover, Ando *et al.*^[14] reported on a 3.5-fold higher frequency of the UGT1A1*28 genotype in patients who suffered from severe diarrhoea and leucocytopenia during irinotecan-based chemotherapy. Taking the UGT1A1*28 genotype as a significant risk factor for the development of severe toxicity the authors suggest that UGT1A1 genotyping serves as a useful tool in predicting toxicity in patients receiving irinotecan. It is critical to state that the majority of these analyses were done retrospectively. In contrast, an exploratory analysis presented by Seymour *et al.*^[24] could not confirm such an association of UGT1A1 to irinotecan-related toxicity. Moreover comparability is hampered by the different doses of irinotecan applied within these trials. The interpretation of our data is limited by a slight imbalance with more patients with the (6/7) and (7/7) genotype being treated with the modified FOLFIRI protocol. Therefore, a tendency towards an increased rate of diarrhoea which might be associated with exposure to 5-FU can not be ruled out.

Comparing the incidence of severe haematotoxicity in patients with the WT (6/6) genotype to those with the (6/7, 7/7) genotype in our analysis, there were no significant differences regarding leucocytopenia, anaemia or thrombocytopenia ($P > 0.05$). The incidence of haematological toxicity was generally low, as expected from other trials with comparable doses of weekly scheduled irinotecan^[25,26]. Nevertheless, these findings are in contrast to previously published results of patients with mCRC treated with IRIFUFOL or FOLFIRI^[18]. In the study of Rouits *et al.*^[18] grade 3-4 neutropenia was significantly associated with the genotypes (6/7, 7/7). The results of a retrospective analysis of 128 Chinese patients with mCRC who received biweekly irinotecan indicate that the heterogenous and homogenous genotype UGT1A1 (6/7) and (7/7) predicts severe neutropenia and diarrhoea but not treatment efficacy^[27]. Necessity for dose reduction was significantly associated with the (6/7) or (7/7) genotype (42.3% vs 12.7%; $P < 0.01$).

Moreover, Innocenti *et al.*^[16] also observed no case of grade 4 neutropenia among patients with the wild type genotype WT (6/6), whereas 50% among patients with the homozygous genotype (7/7), and 12.5% of those with the heterozygous genotype (6/7) experienced grade 4 neutro-

penia. In their study irinotecan was administered at a dose of 350 mg/m² every 3 wk. Accordingly, data from Roth *et al.*^[28] indicated that the risk of severe neutropenia was higher among patients carrying the homogenous genotype (7/7). Interestingly, female sex was superior to UGT1A1 in predicting grade 4 neutropenia. Contrary, Marcuello *et al.*^[23] found an increased, but not significantly increased, haematological toxicity among patients with the genotypes (6/7, 7/7) during single-agent or combination chemotherapy with irinotecan given at a dosage of 350 mg/m² every 3 wk or 180 mg/m² every 2 wk.

The literature regarding UGT1A1 genotyping and irinotecan-related toxicity is heterogeneous and to some extent conflicting which may be partly explained by the retrospective character of most studies^[14,16,18,23,24]. Another aspect contributing to the heterogeneity of the results is due to the variety of irinotecan dosages and schedules which also applies for the present study. Patients within our trial received dose reduced and modified FOLFIRI and IROX. Patients in both treatment arms received weekly scheduled irinotecan (80 mg/m²) in combination with 5-FU 2000 mg/m² weekly or oxaliplatin 85 mg/m² biweekly. We assume that the mild toxicity and the absent impact of UGT1A1 genotype on toxicity in our study are a result of the low irinotecan dose. Stewart *et al.*^[29] concluded from their study of low-dose protracted irinotecan in pediatric patients that UGT1A1 genotyping is not a useful prognostic factor in predicting toxicity. Hoskins *et al.*^[30] advised a genotype-tailored therapy only for those patients who receive irinotecan at higher doses. Patients carrying the genotype UGT1A1*28 who receive irinotecan up to a dose of 150 mg/m² are at the same risk of experiencing severe neutropenia as any patients. Consequently, UGT1A1 genotyping is not generally recommended.

The response rate in the present analysis was similar between the WT (6/6) genotype and the (6/7, 7/7) genotypes (43.2% vs 44.3%, $P > 0.05$). Interestingly, the disease control rate appeared to be higher in patients with the (6/7, 7/7) genotypes compared to those with the WT (6/6) genotype (91.8% vs 73.0%, $P = 0.008$). However, this finding did not result in any advantage regarding TTP or OS.

Douillard *et al.*^[31] reported a TTP of 6.7 and an OS of 17.4 mo in previously untreated patients with mCRC who had received irinotecan and FU/FA. A large Italian study reported a comparable TTP of 7 mo and an OS of 14 mo

for the FOLFIRI regimen given as 1st line chemotherapy for mCRC^[32]. Ashley *et al*^[33] have found a TTP of 6.7 mo and an overall survival of 17.3 mo in previously untreated patients with mCRC who had received an IROX regimen consisted of oxaliplatin 85 mg/m² and irinotecan 200 mg/m² every 3 wk. These data are supported by the findings of Goldberg *et al*^[34] who found a similar TTP of 6.5 mo and an overall survival of 17.4 mo for patients who were treated with IROX. Comparing these data to those of our study a loss of activity due to the dose modifications with low-dose irinotecan dosage can be ruled out.

In a large prospective study conducted by Toffoli *et al*^[35], the response rate was higher in mCRC patients with the homozygous genotype (7/7) compared to the wild type genotype WT (6/6). These patients experienced a slightly improved survival of approximately 2 mo ($P > 0.05$). One may argue that in patients with the (6/7) or (7/7) genotype there is less detoxification of SN-38 resulting in higher blood levels of the active compound, more anti-tumor effect and therefore a better response rate. However, Marcuello *et al*^[23] observed no statistically significant impact of UGT1A1 gene polymorphism on response rate but a trend towards an improved OS in patients with the WT (6/6) genotype compared to patients with the (6/7) or (7/7) genotype (33 *vs* 21 mo; $P = 0.09$). This is partly explained by dose reductions in patients with homozygous or heterozygous genotypes (6/7, 7/7) because of severe diarrhoea. Another recent study reported on prospectively genotyped patients suffering from mCRC who had received either 1st line irinotecan/capecitabine or 2nd line single-agent irinotecan. Response rates, numbers of dose reductions and applied chemotherapy cycles were similar within the different genotypes^[36].

An important factor contributing to irinotecan metabolism is the existence of several UGT1A1 isoforms and their distribution among different patient populations^[37]. There exist an increasing number of reports on genetic variants of UGT1A1 as well as SNPs in the coding region of the gene locus potentially influencing drug metabolism. Moreover, other enzymes of the UGT1 family like UGT1A7 and UGT1A9 are also involved in the glucuronidation of SN-38^[38-40]. Patients of African, Caucasian and Asian descent show a different gene frequency of the UGT1A1*28 gene variant^[12]. When analysing UGT1A1 genotypes and irinotecan-related adverse events the different variants of the UGT1A1 gene locus among an ethnic population must be taken into consideration^[41]. Moreover, there is strong evidence that several other individual factors apart from ethnic affiliation may influence the irinotecan metabolism^[42].

In conclusion, UGT1A1 genotyping alone does not allow characterizing subgroups of patients who are at an increased risk of life threatening toxicity during low-dose irinotecan-based chemotherapy. Due to the incoherent findings of several small trials, a larger prospective phase III trial is warranted. The metabolism of irinotecan is highly complex with different UGT enzymes and drug transporters involved. Distinction between high-dose and low-dose irinotecan is of eminent importance when considering the use of UGT1A1 genotyping. There is

a need for a diagnostic panel including the testing of multiple gene polymorphisms that more reliably predicts toxicity. On the other hand, beside a comprehensive patient education, and the escalation of supportive therapy, dose modifications and alternative treatment schedules may help to provide patients who are at high risk with a safe irinotecan-based chemotherapy.

COMMENTS

Background

Irinotecan is one of the most effective chemotherapeutic agents in the treatment of colorectal cancer. Among other side effects irinotecan can lead to neutropenia and delayed diarrhoea. The active metabolite of irinotecan, SN-38, is inactivated by uridine disphosphate glucuronosyl transferase 1 (UGT1A1), the same enzyme by which bilirubin is metabolised. Genetic polymorphisms of the UGT1A1 gene result in variable levels of the enzyme. According to the number of TA repeats in the enhancer region of the gene a wild type genotype (6/6) can be differentiated from the heterozygous genotype (6/7) and the homozygous genotype (7/7).

Research frontiers

Preclinical and clinical studies have revealed a close dependency of the activity of UGT1A1 enzyme and the occurrence of irinotecan-associated side effects. Existing data are contradictory to some extent or are derived from heterogenous or small study populations. Therefore and against the background of other metabolic ways of toxification and detoxification the research hotspot is how to apply genetic testing of UGT1A1 gene polymorphisms to predict toxicity and efficacy of an irinotecan-based chemotherapy.

Innovations and breakthroughs

Recent studies have emphasized the impact of UGT1A1 genotyping to predict toxicity and outcome in patients undergoing an irinotecan-based chemotherapy. Distribution of the genotype in this study was well in line with data in the literature. No significant differences could be noticed between the homozygous and the heterozygous genotype compared to the wild type genotype in terms of efficacy, toxicity of higher grades, treatment delay or dose reduction. This is a retrospective study to report that UGT1A1 genotyping appeared not to be useful for predicting treatment efficacy and irinotecan-associated side effects in patients receiving low-dose irinotecan for mCRC. Furthermore, our analysis supports the idea that UGT1A1 genotyping should be considered when using irinotecan at a higher dosage.

Applications

By understanding the limitations of UGT1A1 genotyping and by understanding the complexity of irinotecan metabolism, this study may just add another piece of the puzzle for the future development of a patient-tailored chemotherapy with genotyping as one tool among others.

Terminology

The chemotherapeutic agent irinotecan is metabolised by the enzyme UGT1A1, the same enzyme by which bilirubin is metabolised. Genetic polymorphisms resulting in a decreased amount of the enzyme can lead to enhanced irinotecan-associated toxicity. Pre-existing data have partly shown genetic subgroups of patients with different toxicity and treatment efficacy under chemotherapy with irinotecan.

Peer review

The manuscript by Schulz *et al* describes the impact of UGT1A1 gene polymorphism on toxicity and efficacy of irinotecan-based regimens in metastatic colorectal cancer. The authors demonstrate that the genetic polymorphism of the UGT1A1 gene does not influence treatment efficacy. The manuscript is well written, the methods are adequately chosen.

Abstract

AIM: To assess the patient-reported outcomes (PROs) of pancreatic neuroendocrine tumor (PNET) patients.

METHODS: Fifty-one consecutive patients (21 male, 30 female, 61.0 ± 10.3 years) with proven PNETs were studied. An SF-12 questionnaire capable of exploring the physical (PCS) and mental (MCS) aspects of daily life was used. Four questionnaires were also used [12 items General Health Questionnaire (GHQ-12) for non-psychotic psychiatric disorders, State Trait Anxiety Inventory (STAI) Y-1 and Y-2 for anxiety and BDI-II for depressive symptoms] to explore the psychological aspects of the disease. Forty-four sex- and age-matched Italian normative subjects were included and evaluated using the SF-12, STAI Y-1 and Y-2 questionnaires.

RESULTS: Seven patients refused to participate to the study; they were clinically similar to the 44 participants who agreed to complete the questionnaires. PNET patients had a PCS score (44.7 ± 11.0) were not significantly different from the norms (46.1 ± 9.9 , $P = 0.610$), whereas the MCS score was significantly lower in patients (42.4 ± 13.0) as compared to the norms (48.2 ± 9.8 , $P = 0.036$). GHQ-12 identified 11 patients (25.0%) as having non-psychotic psychiatric disorders.

The STAI scores were similar in the patients and in the normative population. Finally, BDI-II identified eight patients (18.2%) with moderate depression and 9 (20.5%) with mild depression whereas 27 patients (61.4%) had no depression.

CONCLUSION: The PNET patients had a good physical but an impaired mental component of their quality of life; in addition, mild or moderate depressive symptoms are present in about 40% of PNET patients.

INTRODUCTION

Pancreatic neuroendocrine tumors (PNETs) are a heterogeneous group of rare neoplasms, occurring in fewer than one in 100 000 people per year^[1]. These tumors have attracted considerable attention in recent years, both because they are relatively easy to palliate and because they demonstrate the chronic effects of the particular hormone whose level is elevated. In about 10%-50% of cases, the tumors are not associated with obvious signs or symptoms of hormone hypersecretion and are called non-functioning tumors^[2]. We have recently demonstrated that radical surgery continues to have a central role in the therapeutic approach to PNETs^[2], and

that medical treatment has a precise role in functioning neuroendocrine tumors. Even if the survival rate is good, especially in those patients who were resected, there is no extensive data available on the quality of life (QoL) in these patients compared to the general population. In addition, the majority of studies published on this topic until now examined a Scandinavian population^[3-10], and it is well known that some differences in perceiving well-being exist among different cultures^[11]. Finally, there are no studies specifically focusing on the localization site of neuroendocrine tumors such as PNETs. Therefore, we carried out this prospective study on a large series of subjects with PNETs in order to assess the patient-reported outcomes (PROs), using different questionnaires capable of exploring the physical and mental aspects of their QoL as well as various psychological factors.

MATERIALS AND METHODS

Patients

Fifty-one consecutive patients with pathological confirmation of PNET who were admitted as outpatients to our Department from January to April 2009 were enrolled in the study. The histological specimens were obtained at surgery in 41 patients and at percutaneous biopsy using computed tomography/ultrasonography/endoscopic ultrasonography in the remaining 10 patients. The epidemiological and clinical data of the 51 patients studied are reported in Table 1. There were 21 males (41.2%) and 30 females (58.8%). The mean age of the patients was 61.0 ± 10.3 years (range, 34-86 years) and the duration of the disease was 5.8 ± 5.2 years (range, 1-28 years). Forty-one patients (80.4%) were married and 10 (19.6%) were single. Thirteen patients had finished elementary school (25.5%), 18 had finished middle school (35.3%), 13 had a high school diploma (25.5%) and seven had a university degree (13.7%). The majority of the patients were still working (38, 74.5%) while 13 were retired (25.5%). Twenty patients in the present series were drinkers (39.2%) while 22 (43.1%) were smokers. Thirty-five patients (68.6%) had one or more comorbidities (arterial hypertension in 21 patients, cardiac diseases in nine patients, chronic obstructive pulmonary diseases in four patients, gastrointestinal diseases such as peptic ulcers, gallstones and/or colon polyposis in eight patients, neuroendocrine diseases such as thyroid or hypophysis diseases in five patients, urogenital diseases in three patients, and other diseases in the remaining four patients) and 41 (80.4%) received drugs for causes not related to the PNET. Forty patients (78.4%) had undergone surgery at least once for causes unrelated to the neuroendocrine neoplasia (cholecystectomy in eight patients, appendectomy in 22 patients, inguinal hernioplasty in seven patients, other abdominal surgery in three patients, tonsillectomy and other otorhinolaryngological procedures in 17 patients, urological surgery in seven patients, gynecologic procedures in 10 patients and other surgical procedures in three patients). Forty-one of the 51 patients (80.4%) underwent surgery for their neuroendocrine pancreatic

Data are reported as absolute and relative frequencies or mean \pm SD.

disease: resective surgery was performed in 36 patients and enucleation of the cancer in the remaining 5 patients. At the time of the study, 29 patients were disease-free (56.9%) and the remaining 22 had advanced disease (lymph node involvement or liver metastases). Seventeen patients (33.3%) were currently being treated medically: 11 (21.6%) with somatostatin analogues alone, and 6 (11.8%) with somatostatin analogues and radiometabolic treatment. Nineteen patients (37.3%) had experienced pain in the month prior to the interview whereas 30 patients (58.8%) had dyspeptic symptoms evaluated according to the Rome III criteria^[12]. Among the 30 patients with dyspeptic symptoms, the majority (25, 83.3%) had experienced post-

prandial distress syndrome and five had had heartburn (16.7%). Finally, 14 patients (27.5%) had diabetes secondary to pancreatic surgery.

The mean body mass index (BMI) was 25.7 ± 4.1 kg/m²; in particular, according to the WHO criteria^[13], 1 patient (2.0%) was underweight (BMI < 18.5 kg/m²), 22 (43.1%) had normal weight (BMI between 18.5 and 24.9 kg/m²), 21 (41.2%) were pre-obese (BMI between 25.0 and 30.0 kg/m²) and the remaining 7 (13.7%) were obese (BMI > 30 kg/m²).

Questionnaires

The Italian versions of the SF-12™ Health Survey (SF-12), State Trait Anxiety Inventory (STAI) Y-1 and Y-2, 12 items General Health Questionnaire (GHQ-12), and Beck Depression Inventory-II (BDI-II) were used for the purpose of the study.

The SF-12 questionnaires had previously been developed and tested on the Italian population in general^[14]. It consists of 12 items which generate two summary scales capable of exploring the physical and mental components. High scale scores of the SF-12 physical (PCS) and mental (MCS) component summaries represent a good QoL. The normative population tested with the SF-12 questionnaire included 61 434 Italian subjects; these subjects were randomly sampled from the electoral lists, regardless of their health status^[14]. The values of this group represent the average of the health-related QoL of the general Italian population. The stratified mean \pm SD values of the PCS and the MCS referring to 44 sex- and age-matched Italian subjects of this population were used as a normative group.

The GHQ-12 is a measure of current mental health and since its development^[15], it has been translated into the Italian language and has been used for the Italian population^[16,17]. The GHQ-12 has become a commonly used instrument for detecting psychiatric disorders^[18]. The scale asks whether the respondent has recently experienced a particular symptom or behavior. Each item is rated on a four-point scale (less than usual, no more than usual, slightly more than usual or much more than usual). The score ranges from 0 to 12^[19]; subjects with a score from 0 to 4 have a > 80% probability of having non-psychotic psychiatric disorders and they are generally considered cases (i.e. those subjects who needed psychological support) while those subjects with a score > 4 should be considered not affected by non-psychotic psychiatric disorders^[20].

Due to the fact that the GHQ-12 is a general questionnaire regarding the psychological aspects of daily life, we used the following two specific questionnaires: the STAI^[21] and the BDI-II^[22] to better evaluate anxiety disorders and depressive syndrome.

Regarding the assessment of anxiety, both state and trait anxiety can be assessed by using the 40 items of the STAI-Y-1 and Y-2^[21]. The state (Y-1) and the trait (Y-2) portions of the inventory each consist of 20 item Likert format statements. The STAI has been extensively validated and the Italian version has already been used^[23]. The scores of the two 20 item scales range from 20 to

80 and high scores represent a high level of anxiety^[21]. In brief, the state of anxiety can vary in intensity and fluctuate over time depending on the perceived threat. The trait of anxiety is a tendency to perceive a wide range of living conditions as threatening and to react to them with a high intensity; this trend remains latent until it is activated by stress associated with real or imagined dangers. The normative population tested with the STAI questionnaire included 2363 Italian working people sampled regardless of their health status^[23]. The stratified mean \pm SD values of the STAI Y-1 and the STAI Y-2 used with 44 sex- and age-matched Italian subjects of this population were used as a normative group.

The BDI-II^[22] is a 21-item self-report instrument which assesses the severity of depressive symptoms in adolescents and adults over the 2 wk prior to its use. Each item is rated on a 4-point scale (0-3) with total scores ranging from 0 to 63. For interpretation of the BDI-II, Beck *et al.*^[22] present a table of scores indicative of: severe (> 28); moderate (score ranging from 20 to 28) and mild (score ranging from 14 to 19) depression. Scores of ≤ 13 suggest an absence of depression. These scores observed in an American population having depressive symptoms can also be used for the respective Italian population^[24]. The Italian version of this questionnaire was used^[24].

All patients included in our study were fluent in the Italian language and the questionnaires were administered according to the recommendations suggested by the user manuals^[14,19,23,24].

Ethics

The study was approved by the Senior Staff Committee of the Department of Digestive Diseases and Internal Medicine of the University of Bologna and was carried out in accordance with the Helsinki Declaration of the World Medical Association. All study participants gave oral informed consent.

Statistical analysis

The descriptive statistics applied were: mean, SD and ranges as well as absolute and relative frequencies. Three-way ANOVA was applied in order to estimate the various effects related to the SF-12 and STAI scores by adjusting for age (increasing trend among the age categories) and gender (males *vs* females). The 95% confidence intervals (95% CIs) of the estimates were also calculated. One-way ANOVA, one-way linear term ANOVA, Pearson correlation, Fisher exact test, Pearson chi-squared and linear-by-linear association chi-square were also applied where appropriate.

All statistical evaluations were carried out by running the SPSS version 13.0 for Windows. Two-tailed *P* values less than 0.05 were considered statistically significant.

RESULTS

Forty-four (86.3%) of the 51 patients answered the questionnaires; the demographic and clinical characteristics of these patients are reported in Table 1. Seven patients

Table 2 Effects of neuroendocrine tumors of the pancreas on the SF-12 physical (PCS) and mental (MCS) component summaries estimated by means of three-way ANOVA adjusted for age (increasing trend among the age classes) and gender

	PCS		MCS

(13.7%) refused to participate in the study: no significant differences among the demographic and clinical data were found between participants and those who refused to answer the questionnaire (data not shown for brevity).

Overall analysis of the SF-12 questionnaire in the 44 patients showed that the values of the PCS score are representative of a relatively good physical QoL and they were not significantly different from those of the normative population (PCS: 44.7 ± 11.0 *vs* 46.1 ± 9.9 , $P = 0.610$). The MCS score was significantly lower in patients (42.4 ± 13.0) as compared to the norms (48.2 ± 9.8 , $P = 0.036$). Moreover, a stratified analysis (Table 2) failed to show any significant interaction between sex and age and the effect of the disease on the MCS of PNET patients.

Regarding the GHQ-12 questionnaire, we identified 11 patients (25.0%) having non-psychotic psychiatric disorders. Shown in Table 3, the results of the STAI demonstrated that anxiety was similar in patients and the normative population.

Finally, in order to explore the depressive syndrome in detail, the BDI-II identified eight patients (18.2%) with moderate depression, nine patients (20.5%) with mild depression and 27 patients (61.4%) with no depression.

We also explored the relationships between the results of the various questionnaire scores. The MCS was highly related ($P < 0.001$) to both anxiety state and trait (STAI Y-1 and Y-2, respectively) whereas the PCS was only significantly related to anxiety trait ($P = 0.043$) but not to the anxiety state ($P = 0.222$). As shown in Table 4, only the STAI scores were significantly associated with the presence of non-psychotic psychiatric disorders as

evaluated by the GHQ-12 while both the SF-12 and the STAI were significantly related to the depressive symptoms as assessed by the BDI-II. In addition, a significant ($P = 0.011$) positive relationship was also found between the presence of non-psychotic psychiatric disorders and the depressive state (absence of depression: 4/27, 14.8%; mild depression: 2/9, 22.2%; moderate depression: 5/8, 62.5%).

Table 5 shows the possible relationships between the demographic and clinical characteristics of the PNET patients and the results of the questionnaires investigated. MCS significantly improved with age ($P = 0.042$), and anxiety state (STAI Y-1) significantly decreased with age ($P = 0.038$). Workers had an MCS (39.8 ± 13.1) significantly lower than retired people (49.2 ± 10.7 , $P = 0.032$). The patients that did not receive non-specific disease drugs had a PCS score (51.7 ± 8.6 , $P = 0.032$) significantly higher (42.9 ± 11.70) than those who were taking non-disease specific drugs; PCS was also significantly higher in patients who underwent surgery for PNET (46.4 ± 10.8) compared with those who were not operated on (38.3 ± 10.0 , $P = 0.049$). Pain worsened both the STAI Y-1 (patients with pain had a score of 48.9 ± 12.7 and those without 41.5 ± 11.0 , $P = 0.046$) and Y-2 (patients with pain had a score of 45.8 ± 12.0 and those without 39.1 ± 9.7 , $P = 0.049$) scores. Finally patients with dyspeptic symptoms had a worse MCS (patients with dyspepsia had a score of 38.4 ± 13.2 and those without 47.1 ± 11.4 , $P = 0.025$). The frequency of dyspepsia was 37.0% (10/27) in patients without depressive symptoms evaluated with the BDI-II, 88.9%

Table 4 Relationships between SF-12 and STAI scores, and GHQ-12 and BDI-II scores in the 44 patients with neuroendocrine tumors of the pancreas (mean \pm SD)

DISCUSSION

The correct management of neuroendocrine tumors of the pancreas includes diagnosis, management of the functional hormonal syndrome when present and management of the potentially malignant tumor. Control of the hormonal syndrome, when present, is achieved preoperatively in order to stabilize patient status for the operation^[25] whereas, in the case of recurrence and in the case of a non-surgical approach to these tumors,

medical treatment is the main option^[26].

In the present study, approximately 57% of the patients were disease-free at the time of the interview whereas, as previously reported^[2], patients with advanced disease were treated medically. Thus, especially in this latter group of subjects, PRO assessment seems to be important for evaluating the impact of this chronic disease^[27] in order to understand how biology interacts with cultural, social, interpersonal and psychological aspects. In fact, QoL also plays a central role in how the variety of symptoms and the medical management of disease are perceived by those affected. However, there are a limited number of studies evaluating the patient point of view regarding his own disease^[3-10,28]. All

these studies evaluated the QoL in patients with various neuroendocrine tumors of the gastrointestinal tract and almost all^[3-6,8-10,28] used the European Organisation for Research and Treatment of Cancer Quality of life Questionnaire-C30 (EORTC) questionnaire for quantifying the QoL of the patients; only one study explored the PROs using a different questionnaire such as the SF-36^[7]. Only two studies compared the EORTC results of neuroendocrine tumor patients with a normative population^[6,9], but the patients enrolled had carcinoid tumors which represent only a part of the neuroendocrine tumors of the gastrointestinal tract. Thus, we focused our attention on the PROs in a well defined group of patients, i.e. those with a diagnosis of PNET. For this purpose, we utilized the SF-12 questionnaire. The choice of this questionnaire in evaluating the PROs was based on the following assumptions: the simplicity of this questionnaire (it is based on 12 questions only whereas the EORTC contains 30 questions); the two SF-12 component summaries have a high level of reliability in evaluating the QoL similar to that of the domains/scores of the EORTC questionnaire^[29]; it is also possible to compare the data of patients with a nationwide normative population (there is no Italian normative population for EORTC) and, finally, SF-12 has been already tested in patients with neuroendocrine tumors of the ileum^[30]. Thus, from a practical point of view, the SF-12 questionnaire is more reliable and easier to use in routine clinical practice than the EORTC. Only a few studies have also explored psychological aspects of the disease, mainly using the Hospital Anxiety and Depression Scale (HADS) for evaluating this topic^[3,6,7,9,10]. Thus, we planned the present study in order to evaluate not only the presence of generic psychological distress by using the GHQ-12 questionnaire but also to determine whether the psychological distress eventually present is related to anxiety or depressive syndrome, and to compare these psychological aspects to those of the normative Italian population. For this purpose, we utilized two specific questionnaires, the STAI and the BDI-II, which are largely used in this setting.

The values of the SF-12 summary scores as compared to the norms showed that the 44 patients in the present study seemed to perceive their physical QoL as relatively good even if they had a tumor, and this finding agreed with previous reports^[4,5,9,10] whereas mental aspects were significantly impaired as compared to the norms. This seems to be due to the disease itself and is not related to the effects of gender and age. In fact, we carried out a stratified analysis which showed no significant interaction between age and sex, and the effect of the disease. We also attempted to identify the factors capable of modifying the mental component of QoL of patients with PNET. Surprisingly, we found that our patients were not affected by anxiety, but mild and moderate depressive symptoms were present in about 40% of the patients studied. Our data differed from those previously published which showed that patients

with neuroendocrine tumors had anxiety and depression in varying proportions from low, as reported by Larsson *et al*^[4], to high, as reported by Fröjd *et al*^[10]. These results may be due to the fact that we compared the data to the general population. In fact, when we analyzed the questionnaire score within the group of patients without comparison to the normative population, we found that the MCS and the anxiety state were better in older patients, and that workers had an MCS significantly lower than retired people. PCS was significantly higher in patients that did not receive non-disease specific drugs as compared to those who were taking non-disease specific drugs; this score was also significantly higher in patients who underwent surgery for PNET as compared to those who were not operated on. Furthermore, we also found that pain worsened both the anxiety state and trait (STAI Y-1 and Y-2) scores. Finally, patients with dyspeptic symptoms had worse MCS scores and they also presented with more depressive symptoms than those without. In clinical practice, these red flags should also be taken into consideration; even if the tumor does not affect physical condition (only 2% of patients were underweight), the workers were worried about their condition which could limit their daily activity and they probably needed psychological support.

Furthermore, these patients needed more intensive medical treatment for alleviating the pain flares and the dyspeptic symptoms.

Finally, the seven patients who refused to participate in the study were similar in demographic and clinical variables to the 44 subjects who completed the questionnaires; thus, we can assume that the results obtained can be extended to the entire Italian PNET population, at least under our experimental conditions.

In conclusion, knowledge of the patient's reported outcome in patients with PNET may help in decision-making providing important information about the long-term effects of depressive symptoms in cancer survivors, and help to identify potential adjustment problems. Current workers and especially those with dyspeptic symptoms are those patients who need specific and intensive medical and psychological support because of the presence of depressive symptoms.

COMMENTS

Background

Pancreatic neuroendocrine tumors (PNETs) are generally slow growing and patients may have prolonged survival. There are no studies specifically focusing on the localization site of neuroendocrine tumors such as PNETs.

Research frontiers

patient-reported outcome (PRO) assessment is important for evaluating the impact of this chronic disease in order to understand how biology interacts with the cultural, social, interpersonal and psychological aspects. In fact, quality of life (QoL) also plays a central role in how the variety of symptoms and the medical management of the disease are perceived by those affected.

Innovations and breakthroughs

Of the patients affected by PNETs, current workers and especially those with dyspeptic symptoms are those subjects who need a specific and intensive medical and psychological support because of the presence of depressive symptoms.

Applications

Knowledge of the patient's reported outcome in patients with PNETs may help in decision-making providing important information about the long-term effects of depressive symptoms in cancer survivors, and help to identify potential adjustment problems.

Terminology

Patient-reported outcomes provide a means of gaining an insight into the way patients perceive their health and the impact that treatments or adjustments to lifestyle have on their QoL.

Peer review

The paper by Pezzilli *et al* assessed the physical and mental status of patients with PNETs. They conclude that patients had a comparable physical but a lower mental score than these 44 individuals. The idea is rather innovative and the results are interesting.

Abstract

AIM: To evaluate serum levels of N-terminal pro-brain natriuretic peptide (NTproBNP) and tumor necrosis factor α (TNF- α) in a large series of patients with hepatitis C associated with mixed cryoglobulinemia (MC+HCV).

METHODS: Serum NTproBNP and TNF- α levels were assayed in 50 patients with MC+HCV, and in 50 sex- and age-matched controls.

RESULTS: Cryoglobulinemic patients showed significantly higher mean NTproBNP and TNF- α levels than controls ($P < 0.001$; Mann-Whitney U test). By defining high NTproBNP level as a value higher than 125 pg/mL (the single cut-off point for outpatients under 75 years of age), 30% of MC+HCV and 6% of controls had high NTproBNP (χ^2 , $P < 0.01$). With a cut-off point of 300 pg/mL (used to rule out heart failure (HF) in patients under 75 years of age), 8% of MC+HCV and 0 controls had high NTproBNP (χ^2 , $P < 0.04$). With a cut-off point of 900 pg/mL (used for ruling in HF in patients aged 50-75 years; such as the

INTRODUCTION

The most common clinical features of hepatitis C associated with mixed cryoglobulinemia (MC+HCV) are correlated with vasculitis in the various organs and sometimes with increased viscosity of the plasma^[1,2]. Signs and symptoms include purpura, ulcers of the extremities, arthralgia, proteinuria, hepatic damage, abdominal pain, mental confusion, oligo-anuria, hemorrhagic diathesis, and sometimes congestive heart failure (HF)^[1-4]. Furthermore, HF has been described as heralding the clinical onset of essential mixed cryoglobulinemia (MC)^[5]. Moreover, many MC+HCV patients experience symptoms such as fatigue, dyspnea and reduced physical activity. However, in many patients, these symptoms are not proportional to the liver involvement and resemble symptoms of HF.

Several studies have shown that plasma levels of brain natriuretic peptide (BNP) and N-terminal proBNP (NTproBNP) are reliable diagnostic and prognostic

markers for cardiac disease^[6,7] that correlate with symptoms of HF and the severity of systolic and diastolic dysfunction^[8]. Some authors have recently stated that NTproBNP appears superior to BNP for the evaluation of suspected acute HF in patients with preserved left ventricular ejection fraction^[9,10]. In the study by O'Donoghue *et al*^[9], NTproBNP seems to correlate with HF severity better than BNP and is more sensitive.

Cytokines play an important role in chronic HF, and it has been shown that TNF- α and NTproBNP are independent predictors of long-term risk of death^[11,12] for HF. Circulating TNF- α has been recently shown to be high in patients with MC^[13].

However, to our knowledge, until now no study has evaluated circulating NTproBNP together with TNF- α levels, as possible markers of HF, in MC+HCV patients affected by cryoglobulinemic vasculitis.

The aim of this study was to evaluate serum levels of NTproBNP in a series of MC+HCV patients, and to correlate this parameter with the clinical features of the disease, and with the circulating levels of TNF- α .

MATERIALS AND METHODS

Patients

Fifty MC+HCV patients (37 females and 13 males; mean age 57 ± 9 years; mean disease duration 10 ± 11 years), consecutively referred to our Rheumatology Unit, were recruited for the study between 2001 and 2006. The diagnosis of MC+HCV was based on the presence of serum mixed (IgG-IgM) cryoglobulins and the classical clinical triad, purpura, weakness, arthralgias, and on the exclusion of other well-known systemic disorders, such as immuno-rheumatic and neoplastic diseases^[1,2,14-16].

The study included only patients with MC+HCV, without liver cirrhosis or hepatocellular carcinoma (assessed by histology, laboratory evidence of liver failure and/or ultrasound-proven portal hypertension)^[17,18]. None of the patients had evident signs of HF, organic renal disease (patients with serum creatinine > 1.2 mg/dL and/or proteinuria > 0.5 g/24 h were excluded), thyroid disease, diabetes, cancer or any other major diseases. All patients had normal cardiac physical examinations and normal blood pressure.

Thirty eight out of 55 (76%) MC+HCV patients underwent liver biopsy for diagnostic purposes; liver histology activity index (grade) or stage of liver fibrosis were evaluated according to Ishak *et al*^[19]. The mean activity index (grade) in MC+HCV patients was 5.0 ± 1.2 , and the mean stage was 2.0 ± 0.9 . Main demographic and clinico-serological features of MC+HCV patients are reported in Table 1.

Among the patients, 17 had been previously treated with interferon-alpha (IFN- α) for an average of 7 mo (range, 1-13 mo), at a mean dosage of 10.4 MU/wk; the time elapsed from the last course of IFN- α treatment ranged from 6 to 69 mo (mean 40 ± 22 mo). No statistically significant differences were observed in the main demographic and clinico-serological features of MC+HCV patients treated or untreated with IFN- α .

Table 1 Demographic and clinico-serological features of 50 MC+HCV patients

Age (yr)	57 \pm 9
Male/female	13/37
Disease duration with MC (yr)	10 \pm 11
Purpura	82%
Active vasculitis	31%
Weakness	91%
Arthralgias	83%
Arthritis	14%
Raynaud's phenomenon	51%
Sjogren's syndrome	45%
Peripheral neuropathy	59%
Aminotransferase elevation and/or histologic activity ¹	71%
Cryocrit (%)	4.2 \pm 8.9
CH50 (normal: 160-220 U)	111 \pm 36
C3 (normal: 60-130 mg/dL)	81 \pm 36
C4 (normal: 20-55 mg/dL)	14 \pm 18
Autoantibodies ²	25%

¹Increase of the liver enzyme (alanine aminotransferase) and/or liver histological alterations. ²Presence of anti-nuclear and/or anti-mitochondrial and/or anti-smooth muscle and/or anti-extractable nuclear antigen autoantibodies. MC+HCV: Hepatitis C associated with mixed cryoglobulinemia.

At the time of study, 35 MC+HCV patients were taking low doses of corticosteroids, 8 had previously been on corticosteroids and 7 had never been treated with corticosteroids. No MC+HCV patient had had plasma exchange treatment in the last year before the study. In both patients and controls, a careful medical history was collected, in particular with regard to family history of thyroid disease, smoking habits, and drugs. The presence of Raynaud's phenomenon, Sjogren's syndrome, skin ulcers, peripheral neuropathy, and renal and liver involvement in MC+HCV patients was evaluated as previously described^[16]. Routine blood chemistry was carried out by standard methods.

Controls

Each of the 50 MC+HCV patients eligible for the study was matched, by sex and age, one-to-one with a control group of healthy subjects of the general population from the same geographic area (North-West Tuscany). This control group was extracted from a larger sample of 1640 subjects taking part in a population-based survey of thyroid disorders; only HCV-negative subjects, without clinical and laboratory evidence of thyroid and liver disorders or autoimmune diseases and not treated with immunomodulators were included.

None of the controls had signs of HF, organic renal disease, thyroid disease, diabetes, cancer or any other major diseases. All patients had normal cardiac physical examination results and normal blood pressure.

Extraction of the control group from the original population was performed by finding the closest age match (± 2 years) to each case within either gender. When more than one age-match was available per case, the choice was made at random.

The study protocol was approved by the local Ethics Committee. All subjects gave their informed consent to enter the study.

Figure 1 Plasma NTproBNP circulating levels (were significantly higher in MC+HCV patients than in controls; Mann Whitney *U* test). ^a*P* < 0.05 vs control.

Immunological studies

Cryocrit was measured as the percentage of packed cryoglobulins after cold centrifugation of the serum; cryoglobulin composition was determined by the incorporation in cryoprecipitates of monoclonal or polyclonal IgM-rheumatoid factor (i.e. MC type II or MC type III); hemolytic complement C3-C4 fractions were measured as previously described^[16], anti-nuclear, anti-smooth muscle, and anti-mitochondrial autoantibodies were detected by current techniques^[16]. Sera with a titre > 1:40 were considered positive. Anti-extractable nuclear antigen antibodies, including anti-Scl70, -Sm, -RNP, -SSA/SSB, -PCNA, -SL and -Jo1 specificities, were detected by counter-immuno-electrophoresis according to the methods described by Bunn *et al*^[20].

Virological studies

Antibodies against HCV (anti-HCV) and HCV-RNA were determined in serum clotted and centrifuged at 37°C and stored at -70°C. Anti-HCV and HCV-RNA levels [assayed by polymerase chain reaction (PCR) technique] in the serum were investigated as previously described^[21,22].

Cytokines, chemokines and analytical assays

Blood samples for analysis of plasma NTproBNP were collected, centrifuged and plasma was stored at -80°C until analysis. Plasma concentrations of NTproBNP were measured by a sandwich immunoassay on an Elecsys 2010 (Roche Diagnostics, Mannheim, Germany).

Serum TNF- α concentrations were measured using commercially available kits (R&D Systems, Minneapolis, MN). The mean minimum detectable dose was 0.12 pg/mL for TNF- α ; the intra- and inter-assay coefficients of variation were 5.8% and 10.2%. Samples were assayed in duplicate. Quality control pools of low, normal, or high concentration for all parameters were included in each assay. Alanine aminotransferase (ALT) was assayed by conventional methods^[18].

Statistical analysis

Values are given as mean \pm SD for normally distributed variables, or as median \pm IQR for not normally distributed variables (NTproBNP, TNF- α). Group values

were compared by univariate ANOVA, for normally distributed variables; or by Kruskal-Wallis (≥ 3 groups) or Mann-Whitney *U* (2 groups) tests. Proportions were compared by the chi-square test. *Post-hoc* comparisons on normally distributed variables were carried out using the Bonferroni-Dunn test. Univariate analysis was performed by simple regression. A multivariate logistic regression analysis considering age, gender, ALT, and presence or absence of active vasculitis as independent variables and presence or absence of high levels of NTproBNP or TNF- α as dependent variables was performed in MC+HCV patients.

RESULTS

Plasma NTproBNP concentrations were significantly (*P* < 0.001; Mann-Whitney *U* test) higher in MC+HCV patients (mean 123 ± 112 pg/mL; median 36 pg/mL, range 8-1547 pg/mL) than in controls (mean 11 ± 12 pg/mL; median 3.1 pg/mL range 2-145 pg/mL) (Figure 1).

By defining high NTproBNP level as a value higher than 125 pg/mL (the single cut-off point for outpatients under 75 years of age^[23]) 15/35 MC+HCV and 3/47 controls had high NTproBNP (χ^2 , *P* < 0.002).

With a cut-off point of 300 pg/mL (used to rule out HF in patients under 75 years of age^[23]) 4/46 MC+HCV and 0/50 controls had high NTproBNP (χ^2 , *P* < 0.041).

With a cut-off point of 900 pg/mL (used for ruling in HF in patients with age 50-75; such as the patients of our study^[23]) 3/47 MC+HCV and 0/50 controls had high NTproBNP (χ^2 , *P* = 0.08).

In order to better define the role of increased serum NTproBNP in MC+HCV, mean levels of this chemokine were separately evaluated (by Mann Whitney *U* test) among MC+HCV patient subgroups defined according to main demographic and clinical features (age > 55 years; gender; disease duration > 10 years; presence or absence of purpura, active vasculitis, weakness, arthralgias, arthritis, Raynaud's phenomenon, Sjogren's syndrome, peripheral neuropathy, aminotransferase elevation and/or histologic activity in the liver), but no significance was found. No significant correlations were observed between NTproBNP levels and serological findings of MC+HCV (levels of cryocrit and complement, presence/absence of autoantibodies) or previous/ongoing treatments.

Serum TNF- α was detectable in 85% of controls and in all MC+HCV patients; mean levels were significantly (*P* < 0.01; Mann Whitney *U* test) higher in MC+HCV patients (mean 26 ± 65 pg/mL; median 8.3 pg/mL, range 1.3-269 pg/mL) than in controls (mean 1.6 ± 1.1 pg/mL; median 1.2 pg/mL, range 0.6-3.4 pg/mL). No correlation was found between serum TNF- α and any of the following; ALT level, liver histology activity index, stage of liver fibrosis, the presence of active vasculitis, or the other demographic, serological and clinical features of MC.

MC+HCV patients had, obviously, raised ALT enzymes (*P* < 0.0001), in comparison with controls.

No association was observed between NTproBNP or TNF- α levels and ALT levels in the MC+HCV patients.

DISCUSSION

Our study demonstrates the presence of significantly high serum levels of NTproBNP in patients with MC+HCV compared to healthy controls. Furthermore, our study confirms significantly high serum levels of TNF- α in patients with MC+HCV compared to healthy controls.

Some authors have recently stated that NTproBNP appears superior to BNP for the evaluation of suspected acute HF in patients with preserved left ventricular ejection fraction^[9,10]. Furthermore^[9], NTproBNP seems to correlate with HF severity better than BNP and appears more sensitive. The International Collaborative for NTproBNP Study (ICON) helped in defining appropriate cut-off points for NTproBNP in the emergency department^[23]: 300 pg/mL should be used to rule out HF, while 450 pg/mL, 900 pg/mL, or 1800 pg/mL, depending on age (< 50, 50-75, or > 75 years; respectively), should be applied for ruling in HF. The age stratifications do offer significant positive predictive value. For outpatient evaluation the manufacturer suggested a single cut-off point of 125 pg/mL for patients under 75 years of age and 450 pg/mL for patients above 75 years of age^[23].

The levels of NTproBNP found in MC+HCV are included in a gray zone (125-900 pg/mL) that is not necessarily associated with HF, however in 3/50 (6%) of MC+HCV patients the NTproBNP levels were higher than 900 pg/mL, which is the cut-off value for ruling in HF for patients of age 50-75 years, such as the patients of our study. Since NTproBNP level seems to correlate with HF severity, the values in the gray zone may be suggestive of a subclinical cardiac impairment. The exclusion of patients with renal failure from the study suggests that the NTproBNP increase is not related to any kidney involvement in the MC+HCV patients.

In a previous work, Matsumori *et al*^[24] showed there was a significantly higher NTproBNP level in HCV patients and observed that the presence of anti-HCV antibodies in sera was more prevalent in patients with myocarditis and HF than in the general population. Future studies comparing NTproBNP levels between HCV and MC+HCV patients will be needed to evaluate the specific influence of the cryoglobulinemic vasculitis.

The findings of the present study may have important implications for patients with MC+HCV. Most patients complain about fatigue, dyspnea and reduced physical capacity. The pathogenesis of these symptoms is not well understood and sometimes attributed to the liver injury. However, it seems possible that these patients experience cardiac impairment which could at least contribute to these symptoms. Furthermore, among signs and symptoms of MC+HCV, sometimes congestive HF may be found, which in some cases has been described as heralding the clinical onset of essential MC^[3-5].

Testing of NTproBNP level may serve as a screening marker for cardiac insufficiency in the differential diagnosis of fatigue and dyspnea and may aid the decision for further diagnostic testing of cardiac function as has been described for other groups of patients^[25-28]. Besides diagnostic consequences, evaluation of NTproBNP may have therapeutic consequences for patients with MC+HCV. In patients with known congestive HF, elevated plasma BNP concentrations could be reduced by treatment with ACE inhibitors^[29] or angiotensin II receptor antagonists^[30] as well as treatment with diuretics and vasodilators^[31]. As a consequence, plasma NTproBNP concentration may guide the intensity of pharmacotherapy as some interventional studies have suggested^[32,33].

Cytokines play an important role in chronic HF, and it has been shown that TNF- α and NTproBNP are independent predictors of long-term risk of death^[11,12] for patients with HF.

Our study confirms a high serum TNF- α level in HCV+ve patients, as previously demonstrated in other studies of HCV+ve patients^[34-36]. The increase of TNF- α in MC+HCV patients is unlikely to be due to a more aggressive liver disease; in fact, no correlation was found between TNF- α levels and ALT levels, or with degree of liver inflammation in our study^[13]. Other studies have shown an increased production of TNF- α by lymphocytes in MC+HCV patients^[37,38], suggesting that the increase of TNF- α may be due to activation of lymphoid cells.

The fact that TNF- α and NTproBNP are independent predictors of long-term risk^[11] is in agreement with the results of our study; in fact, no relationship has been observed between TNF- α and NTproBNP.

It has been shown that combining measurements of pro-inflammatory cytokine TNF- α and NTproBNP seems a promising tool in the prognostic assessment of HF patients^[12]. However, even if we have shown that NTproBNP and TNF- α are both high in the circulation of MC+HCV patients, we cannot exclude that different pathogenetic pathways may be differentially implicated in the increase of each of these factors.

The interest in finding reliable markers of cardiac dysfunction is intensified by studies that strongly suggest an association between HCV chronic infection and atherosclerotic disease in the carotid or coronary artery^[39-41].

In conclusion, our study shows elevated levels of NTproBNP in patients with MC+HCV, in association with TNF- α . This may indicate the presence of cardiac dysfunction and explain, at least in part, some of the clinical symptoms of patients with MC+HCV. Further larger, possibly multicenter prospective studies quantifying symptoms and correlating these with echocardiographic parameters are needed to confirm this association.

COMMENTS

Background

The most common clinical features of hepatitis C associated with mixed

cryoglobulinemia (MC+HCV) are correlated with vasculitis in various organs and heart failure (HF) has been described as heralding the clinical onset of essential mixed cryoglobulinemia (MC). To our knowledge, until now no study has evaluated circulating NTproBNP together with TNF- α levels as possible markers of HF, in MC+HCV patients affected by cryoglobulinemic vasculitis.

Innovations and breakthroughs

This study demonstrates elevated serum levels of NTproBNP in patients with MC+HCV, in association with high TNF- α levels. This may indicate the presence of cardiac dysfunction and explain, at least in part, some of the clinical symptoms of patients with MC+HCV who have no evident signs of HF. Further larger, possibly multicenter prospective studies quantifying symptoms and correlating these with echocardiographic parameters are needed to confirm this association.

Applications

NTproBNP evaluation may serve as a screening marker for cardiac insufficiency in the differential diagnosis of fatigue and dyspnea, may aid the decision for further diagnostic testing of cardiac function and may have therapeutic and diagnostic consequences for patients with MC+HCV. In patients with known congestive HF, elevated plasma BNP concentrations could be reduced by treatment with ACE inhibitors, angiotensin II receptor antagonists and treatment with diuretics and vasodilators. As a consequence, plasma NTproBNP concentration may guide the intensity of pharmacotherapy as some interventional studies have suggested.

Terminology

Plasma levels of BNP and NTproBNP are reliable diagnostic and prognostic markers for cardiac disease which correlate with symptoms of HF and the severity of systolic and diastolic dysfunction. TNF- α is a cytokine involved in systemic inflammation and is a member of a group of cytokines that stimulate the acute phase reaction. Circulating TNF- α has been recently shown to be high in patients with MC.

Peer review

The study by authors has evaluated the circulating levels of NTproBNP and TNF- α in patients with HCV-related cryoglobulinemia. They found higher levels of both proteins in these patients as compared with normal controls and conclude that they may have a potential role in cardiac dysfunction of cryoglobulinemic patients. Though crude, these data are interesting.

the development of HCC. The time from HCV infection to appearance of cancer was 10-50 years. In the HCC patient population, broader distributions of genotypes were present with genotype 3a as the predominant genotype. Using the type-specific genotyping method, we found HCV genotype 3a in 40.96%, 3b in 15.66%, 1a in 9.63%, and 1b in 2.40% of HCC tissue samples. About 28% of cases were found with mixed genotypes. Two cases were unable to be genotyped because of low viral load. Sixty-six percent of treated patients with cirrhosis had an end of treatment response, but unfortunately they relapsed quickly when the treatment was discontinued, and HCC developed during a median 3.8 years.

CONCLUSION: There was a strong association between chronic HCV infection and HCC in Pakistan, and between HCV genotype 3a and HCC.

Abstract

AIM: To assess the association between chronic hepatitis C virus (HCV) infection and hepatocellular carcinoma (HCC) in Pakistan, and the genotype distribution among these HCC patients.

METHODS: One hundred and sixty-one subjects with HCC were included in this study. Liver biopsy was performed on 145 of the patients; sixteen were excluded because they failed to fulfill the inclusion criteria. Qualitative polymerase chain reaction (PCR) was performed for hepatitis B virus and HCV. Samples positive for HCV RNA were genotyped using genotype-specific PCR and confirmed by HCV 5' noncoding region sequencing analysis.

RESULTS: Chronic HCV infection was identified a major risk factor (63.44% of tested HCC patients) for

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the commonest cancers in the world, with an estimated incidence of 5000000 to 10000000 new cases every year^[1]. Hepatitis C virus (HCV) infection, hepatitis B virus (HBV) infection, alcoholic liver disease, and non-alcoholic fatty liver disease are the major causes of cirrhosis in patients with HCC^[2,3].

Chronic HCV infection frequently leads to liver cirrhosis and is associated with an elevated risk for progression into HCC^[4,5]. Epidemiological surveys have identified HCV in 10%-80% of HCC patients reported in different populations^[5,6]. HCV has also been reported to be the major cause of HCC in Japan^[7], Italy^[6] and Spain^[8], but is less important in South Africa^[9] and Taiwan^[10]. Association of HCV infection with HCC has also been well documented in the United States^[11].

Etiology, clinical features, and survival of HCC vary considerably in different populations^[12]. In Pakistan, HCC is a leading cause of death and accounts for 60%-90% of all primary liver malignancies^[13]. Some studies have shown hepatitis B surface antigen (HBsAg) positivity in 60% of patients with HCC^[14,15]. However, some other studies have reported positivity for HCV infection in up to 80% of patients with HCC^[16]. It is believed that HCV infection is a major etiological factor for HCC^[17], however, not all patients with HCV infection develop HCC. A number of host factors such as male sex, older age at infection, long disease duration, excessive alcohol consumption, and high liver iron overload have been reported to influence disease progression^[18,19]. Several additional studies have noted variables such as chronic co-infection with HBV and human immunodeficiency virus (HIV)^[20], obesity and steatosis^[21], type 2 diabetes^[22], and asymptomatic cryoglobulinemia^[17,18,23]. In addition to these host factors, several viral factors such as genotype and peripheral viral load have also been reported to influence disease progression^[24]. Some studies have identified that cirrhotic patients infected with HCV type 1b carry a significantly higher risk of developing HCC compared to those infected with other HCV types^[25,26]. However, the results of other studies^[27,28] are in disagreement with these studies, and demonstrate no association of a particular HCV genotype with the development of HCC.

No such studies on the association or otherwise of HCV genotype with the development of HCC are available from Pakistan. Therefore, this study was performed to: (1) study various risk factors for the development of HCC; (2) investigate the prevalence of HCV in patients with HCC; and (3) evaluate if there is any association between particular HCV genotypes and HCC.

MATERIALS AND METHODS

Patients

For initial examination, 161 subjects with chronic hepatitis managed as end-stage liver disease patients at various hospitals of Punjab and North West Frontier Province of Pakistan were enrolled. All these patients underwent ultrasound-guided liver biopsy. Of these 161 subjects, 145 satisfied the inclusion criteria such as: HCC was confirmed by liver imaging (ultrasonography and computed tomography); histologically confirmed HCC; chronic liver disease of any etiology, with ascites and encephalopathy. Sixteen patients were excluded from the study because they failed to fulfill the study

criteria (14 subjects) or were unwilling to participate in the study (two subjects). The study was started in March 2001 and ended in April 2009. The clinical records of these patients were examined to identify the etiology of HCC. Documentation of the histology of liver tissue surrounding the cancer, together with possible sources of transmission and duration of blood-borne infectious hepatitis, was made. The time of transmission of HCV infection was calculated from the time of first major/minor surgery or first blood transfusion; only these patients were used to calculate the range/median duration of infection. Serum samples were collected and stored at -20°C, at the time of diagnosis of HCC. All the liver biopsies were transported in liquid nitrogen and stored at -70°C. Liver function tests such as alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase and bilirubin levels of all the samples were estimated using an auto-analyzer (Hitachi, Tokyo, Japan). Serum α -fetoprotein (AFP) concentration was determined by solid-phase, two-site chemiluminescent immunometric commercial diagnostic assay, using an Immulite-100 automated immunoassay system (Diagnostic Products, Los Angeles, CA, USA). From all the subjects, written informed consent was obtained. The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Ethics Committee and Institutional Review Board of the Centre.

ELISAs for HBsAg, anti-HBsAg, anti-hepatitis B core antigen (HBc), anti-HCV and anti-HIV 1 and 2

All the patients were screened for HBsAg, anti-HBsAg, anti-HBc, anti-HCV and anti-HIV 1 and 2 using third-generation ELISA kits (DRG Instruments, Germany) as described by the manufacturer.

HBV qualitative polymerase chain reaction (PCR)

Hepatitis B viral DNA was extracted from 200 μ L of stored serum and 2-5 mg of liver tissue of each of the patients using Gentra DNA Isolation Kit (PUREGENE, USA). Qualitative detection of serum HBV DNA was done by PCR amplification of the surface antigen gene using specific forward (5'AGAACATCGCATCAGGAC TC-3'; nt: 159-178) and reverse (5'CATAGGTATCTTG CGAAAGC-3'; 642-623) primers. One microliter of the first-round products was re-amplified using nested PCR with internal forward (5'AGGACCCCTGCTCGTGTT AC-3'; 181-200) and reverse (5'AGATGATGGGATG-GGAATAC-3'; nt: 619-600) primers. The amplified products were detected on agarose gel electrophoresis after staining with ethidium bromide and visualization on a UV transilluminator.

Qualitative and quantitative detection of HCV RNA

HCV qualitative RT-PCR was carried out as described previously^[29]. HCV RNA was quantified using a SmartCycler II Real-time PCR (Cepheid, USA), using HCV RNA quantitative kits (Sacace Biotechnologies, Italy) according to the kit protocol.

Table 1 Characteristics, biochemistry and etiology of HCC patients (*n* = 145) *n* (%)

No known etiology	6 (4.13)

HCC: Hepatocellular carcinoma; ALT: Alanine aminotransferase; AST: Aminotransferase; AFP: α -fetoprotein; HCV: Hepatitis C virus; HBV: Hepatitis B virus.

HCV genotyping

Core HCV genotyping were performed as described previously^[30] for all HCV-RNA-positive sera and tissues. Genotypes were confirmed by HCV 5' noncoding region (5' NCR) sequencing using ABI PRISM 3100 Genetic Analyzer (Applied Biosystem Inc., Foster City, CA, USA) in both directions. Sequences of isolates were aligned with representative sequences for each major genotype and subtype selected from the GenBank database with the help of the Multalign program. The phylogenetic analysis of HCV isolates was performed with MEGA 3.0 software^[31], and phylogenetic trees were constructed by the neighbor-joining method, using the bootstrap-resampling test from the MEGA program (1000 bootstrap replications).

HCV treatment

The medical records of the HCV-related HCC patients showed that a total 21 patients had been treated previously for HCV infection. These treated patients had received 3 MU recombinant interferon- α three times weekly, subcutaneously, and ribavirin (10 mg/kg per day) for a total of 24 wk.

Statistical analysis

The data were analyzed and summary statistical analysis was carried out using SPSS for Windows version 10.0. The results for all variables were given in the form of averages (SD). The χ^2 /Fisher's exact test and independent sample *t* test were used for categorical/continuous variables.

RESULTS

Characteristics and biochemistry of HCC patients

Patient demographics and biochemical and clinical data are shown in Table 1. HCC patients were older (58 \pm 11 years), were predominantly male (73.8%), and had no history of chronic alcoholism. Data collection was

incomplete for one aspect, namely, exact duration of illness. The time of HCV transmission was calculated from the time of first major/minor surgery or first blood transfusion, which might not have been the exact date of virus acquisition. All the patients with HCC had raised levels of serum bilirubin (> 1.0 mg/dL) and alkaline phosphatase (> 300 U/L). ALT and AST levels were abnormal (ALT > 40 IU/mL, AST > 35 IU/mL) only in 42% of patients. AFP level was elevated (> 15 IU/mL) in 86.2% of patients with HCC. Cirrhosis was present in 67.6% of HCC patients. All the patients were found to be negative for anti-HIV.

Etiology of HCC

Out of the 145 patients with HCC, HCV antibodies were present in 92 (63.4%) serum samples. Two patients were found to be tissue-positive by PCR but no anti-HCV antibodies were present. Eighty-one patients were found to be tissue- positive by PCR out of 92 anti-HCV-positive patients (88.04%). Of these patients with HCC caused by HCV, 68 were male and 13 were female. The mean age was 55 \pm 10 years for HCV-related HCC. HCV RNA was detected in the serum of all these 81 tissue-positive patients. All the patients with HCV-related HCC had a history of chronic HCV infection. The peripheral HCV RNA loads were as low as 10000 copies to as high as 3.7×10^8 copies/mL. No significance difference was found between the viral loads in serum and tissues of the same patients. Twenty-eight cases were caused by HBV, of whom 18 (19.31%) also had markers for current HBV infection (HBsAg-positive), and two patients (1.37%) had markers for past infection (HBsAg-negative; anti-HBsAg-positive; anti-HBc positive). The age was 65 \pm 12 years for HBV-associated HCC patients. Nineteen (13.1%) of the HCC cases had markers for HCV and HBV. Out of these 19 cases with dual infection, two were HBV-DNA-positive and HBsAg-negative. In 6 (4.13%) cases, the etiology of liver cancer could not be determined from the medical records or serology. All these six HCC patients with unknown etiology were younger than the HCV-related HCC patients (45-50 years).

Distribution of HCV genotypes in HCC patients

Table 2 shows the results of HCV genotyping. A total of 83 tissue samples (81 positive for HCV RNA and anti-HCV, and two positive for HCV RNA and negative for anti-HCV) were used for HCV genotyping. Using the type-specific genotyping method, we found HCV genotype 3a in 40.96%, 3b in 15.66%, 1a in 9.63%, and 1b in 2.40% of HCC tissue samples. Twenty-four tissues (28.91%) were found with mixed genotypes. Of the 24 mixed genotypes, 10 were infected with genotypes 3a and 3b, eight with 1a and 3a, and six with 1a and 3b. Two tissue samples were found to be untypable as no genotype was detected. Both of the untypable patients had no cirrhosis and had a low viral load (< 10^4 IU/mL). The genotyping results for all single genotypes were confirmed by sequencing. The sequence data of the sequences were submitted to GenBank. The Accession

Table 2 Results of HCV genotype determination in HCC patients (*n* = 83)¹

HCV genotype	No. of HCC cases	Percentage
1a	8	9.63
1b	2	2.40
3a	34	40.96
3b	13	15.66
3a + 3b	10	12.48
1a + 3a	8	9.63
1a + 3b	6	7.22
NT	2	2.40

¹Eighty-one were positive for tissue/serum RNA by PCR and positive for serum anti-HCV, and two were positive for tissue/serum RNA by PCR but negative for serum anti-HCV. Eleven patients with HCC caused by HCV were not genotyped, as these were anti-HCV-positive by ELISA, but were HCV-RNA-negative, thus they could not be genotyped utilizing the molecular genotyping method. NT: Not typed.

Numbers provided for our nucleotide sequences by GenBank are EF173955-EF174011.

Anti-viral treatment history

The medical records of the patients showed that 21 of 94 patients with HCV-associated HCC had received previous standard interferon therapy for a total of 24 wk. Of these treated patients, 13 were male and eight were female. Cirrhosis was present in all of these 21 treated patients. Twenty of these patients had genotype 3a (12 male and eight female) and one 3b (male). Fourteen (66.7%) of these patients (eight male and six female; all with genotype 3a) had an end of treatment response but relapsed after discontinuation of treatment, with no sustained viral response.

DISCUSSION

Several viral and host factors have been studied extensively since the identification of HCV infection as a major risk factor for the development of HCC^[4,9,17]. Among the viral factors, the presence of some HCV genotypes adds to the list of risk factors for HCC. In the present study, the etiology of 145 patients with HCC was assessed with special emphasis on HCV genotype. More than 73% of the enrolled patients with HCC were male. It has been reported already that men have a higher liver cancer rate than women, with a ratio between 2:1 and 4:1^[32]. The reasons for the higher proportion of male patients with HCC might be the possibility that more men are infected with HBV and HCV, consume alcohol, smoke, have increased iron stores, higher body mass index, and a possible involvement of male sex hormones in the onset of HCC^[33]. Most patients (96.5%) in the current study were elderly and their ages ranged from 58 to 68 years. They were possibly infected on receiving injections or major/minor surgery at a median time of 20 years previously. Our observation of late onset of HCC is in agreement with earlier reports from other parts of the world where the transition from acute infection to cirrhosis and detection of HCC took 20-30 years^[34]. It is important to mention here that, in

recent years, with the increasing incidence of HCC, the age of patients with HCC has been decreasing among persons aged 45-60 years^[2]. AFP elevation was observed in the present study in about 86% of patients with HCC. Cirrhosis was present in > 67% of HCC cases studied. Previous studies have shown that cirrhosis underlies HCC in > 80% of affected individuals^[35,36]. Therefore, any agent that leads to cirrhosis should be seen as a risk factor for the development of HCC. It has also been reported that the risk among those with cirrhosis increases in parallel with the impairment of liver function, and in subjects with increased AFP concentration^[35].

Thirty-two percent of our patients with HCC were without liver cirrhosis, which showed that infection with HCV and HBV could be correlated with the emergence of HCC, even in the absence of liver cirrhosis. It has been established that the mechanism for the development of HCC in HBV-related cases is associated with the integration of HBV DNA into hepatocytes^[37]. However, such a mechanism has not been established for HCV, because to date, integration of HCV RNA into cellular DNA has not been reported, even when there has been evidence for the direct involvement of HCV in oncogenicity. According to recent reports, the possible risks are involvement of various viral proteins such as core, NS3 and NS4 in the induction of liver cell proliferation, by interfering directly with the major cellular transduction networks^[38,39].

Several major findings have emerged from the current study. The first finding is the identification of chronic HCV infection as a major risk factor for the development of HCC in Pakistan, because anti-HCV was observed in > 63% of patients with HCC. The overall anti-HCV prevalence rate is 14%-15% and HBV carrier rate is 2%-3% in the general population of Pakistan^[29,40]. Overall, our data are consistent with the results of studies already reported from high-risk areas for HCC such as Japan, Italy and Spain, where majority of reported HCC cases are HCV-related^[6-8]. It is clear from the present study and from others that the greatest proportional increases have occurred recently in HCV-related HCC worldwide, and that HBV-related HCC has been stable and at its lowest rate^[16]. The rate of HCV-related HCC is likely to continue to increase, and it is estimated that this increase will peak around the year 2010, not only in North America and Europe^[41], but also in the rest of the world including Pakistan. Presently, the annual incidence of HCV-related HCC ranges between 2% and 8%^[38].

The second major finding of the current study is the evidence that links HBV with HCC, with about 19% of cases caused by HBV. This link was expected and is unquestionable, as has been reported previously^[40]. Co-infection with HBV was also found as an additional etiological factor for HCC in the current study, which supports other published studies^[42,43]. In two HCV-RNA-positive patients, HBV DNA was detected even in the absence of serological markers for HBV in serum. Previously, it has also been reported that the rate of

occult infection in such patients can be as high as 63%^[44]. It has been reported that the implementation of HBV vaccination has resulted in a significant decrease in the incidence of HBV-related HCC^[45]. In 4.13% cases in the present study, the etiology of liver cancer could not be determined from medical records or from serology and molecular biology. All these patients were non-drinking males, but were chain smokers.

Another more interesting and somewhat surprising finding in the present study was the observation that HCV genotype 3a was the predominant genotype in 41% of HCC cases. This suggests that genotype 3a is a major risk factor associated with the development of HCC compared with other HCV genotypes. However, the question whether HCV genotype plays a role in the development of liver cirrhosis and HCC is still debatable. Previously, the effect of HCV genotype 1b has been scrutinized as a risk factor for HCC^[25,26]. However, some other studies have revealed no preferential role of individual HCV genotypes in HCC^[27,28]. Although in our study HCV genotype 3a was predominant in HCV-related HCC, this genotype has been reported previously to induce a high sustained response, and has been less responsible for severe disease as compared to genotypes 1a, 1b and 4^[46]. It seems that the high percentage of HCC in patients with HCV genotype 3a might result from the fact that genotype 3a can equally cause increased oncogenicity, as can other genotypes such as 1a and 1b. Finally, patients with cirrhosis had no sustained response rates and treatment did not reduce the incidence of HCC. However, more studies with a large number of cirrhotic patients, along with adequate controls, are required to confirm this observation of the current study.

In conclusion, HCC was found mostly in patients with chronic HCV infection and with liver cirrhosis in Pakistan. There also seemed to be a strong association between chronic HCV infection with genotype 3a and HCC, as the high prevalence of genotype 3a in the HCC population reflected increased oncogenicity. Treatment did not stop the development of HCC. However, studies with larger numbers of patients could confirm that HCV genotypes vary in their propensity to produce clinically significant liver disease.

ACKNOWLEDGMENTS

We thank all the clinicians and patients for their cooperation in the study. We thank Dr. Saleem Kamili, Chief, Reference Laboratory, Division of Viral Hepatitis CDC for critically reading the manuscript. This project was partially supported by the Ministry of Science & Technology, Government of Pakistan.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is currently one of the fastest growing causes of cancer-related deaths worldwide. The geographical prevalence varies considerably from country to country and Pakistan is a high-risk area for the

disease. A strong association has been established between chronic hepatitis C virus (HCV) infection and hepatocarcinogenesis. A specific HCV genotype could play a role in the development of HCC.

Research frontiers

In Pakistan, HCC is a leading cause of death and accounts for 60%-90% of all primary liver malignancies. Positivity for HCV infection is up to 80% in HCC. Are HCV genotypes playing a role in the development of liver cirrhosis and HCC? This question remains debatable. Previously, the effect of HCV genotype 1b has been scrutinized as a risk factor for the development of HCC. However, some other studies have revealed no preferential role of individual HCV genotypes in HCC. Therefore, the current study was carried out to assess if there was any association between chronic hepatitis infection with various HCV genotypes and HCC.

Innovations and breakthroughs

In the current study, the authors identified various risk factors for the development of HCC and particularly investigated the prevalence of HCV in patients with HCC. They further assessed the association between chronic hepatitis infection with various HCV genotypes and HCC, and found a strong association between chronic HCV infection with genotype 3a and HCC. Previously, the effect of HCV genotype 1b has been scrutinized as a risk factor for HCC.

Peer review

This paper describes the relationship between HCV genotype 3a infection and HCC development. Although there have been many studies on the difference among HCV genotypes in hepatocarcinogenesis, there has not been a sufficient number of reports on genotype 3a. Therefore, this paper deals with an interesting issue.

malignancy to the diagnosis of LMC was 6.3 mo, ranging between 0 and 73.1 mo. Of the initial endoscopic findings for the 45 available patients, 23 (51%) of the patients were Bormann type III and 15 (33%) patients were Bormann type IV. Pathologically, 94% of cases proved to be poorly differentiated adenocarcinomas. Signet ring cell component was also observed in 40% of patients. Headache (85%) and nausea/vomiting (58%) were the most common presenting symptoms of LMC. A gadolinium-enhanced magnetic resonance imaging was conducted in 51 patients. Leptomeningeal enhancement was noted in 45 cases (82%). Intrathecal (IT) chemotherapy was administered to 36 patients—primarily methotrexate alone (61%), but also in combination with hydrocortisone/± Ara-C (39%). The median number of IT treatments was 7 (range, 1-18). Concomitant radiotherapy was administered to 18 patients, and concomitant chemotherapy to seven patients. Seventeen patients (46%) achieved cytological negative conversion. Median overall survival duration from the diagnosis of LMC was 6.7 wk (95% CI: 4.3-9.1 wk). In the univariate analysis of survival duration, hemoglobin, IT chemotherapy, and cytological negative conversion showed superior survival duration ($P = 0.038$, $P = 0.010$, and $P = 0.002$, respectively). However, in our multivariate analysis, only cytological negative conversion was predictive of relatively longer survival duration (3.6, 6.7 and 14.6 wk, $P = 0.030$, RR: 0.415, 95% CI: 0.188-0.918).

CONCLUSION: Although these patients had a fatal clinical course, cytologic negative conversion by IT chemotherapy may improve survival.

Abstract

AIM: To identify the clinical features and outcomes of infrequently reported leptomeningeal carcinomatosis (LMC) of gastric cancer.

METHODS: We analyzed 54 cases of cytologically confirmed gastric LMC at four institutions from 1994 to 2007.

RESULTS: The male-to-female ratio was 32:22, and the patients ranged in age from 28 to 78 years (median, 48.5 years). The majority of patients had advanced disease at initial diagnosis of gastric cancer. The clinical or pathologic tumor, node and metastasis stage of the primary gastric cancer was IV in 38 patients (70%). The median interval from diagnosis of the primary

INTRODUCTION

Leptomeningeal carcinomatosis (LMC) is defined as malignant infiltration of the pia mater and the arachnoid membrane. LMC is one of the most serious complications that can occur in cancer patients^[1]. According to the results of a large autopsy study, the incidence of LMC was 5%-8% in cancer patients^[2]. As a significant proportion of these patients have asymptomatic microscopic disease, the clinical diagnosis of LMC has been established in 2%-4% of patients during the course of their malignancy^[1]. LMC is frequently detected in patients with leukemia, breast cancer, lymphoma, and lung cancer^[3]. Among solid tumors, LMC is observed more frequently in cases of disseminated and progressive disease. Although a subset of patients, particularly those with lymphoma or breast cancer, may survive for more than 12 mo with a reasonable quality of life, leptomeningeal metastasis from solid tumors is associated with a poor overall prognosis. The treatment of LMC is palliative and unsatisfactory. No evidence demonstrating the superiority of intrathecal (IT) treatment compared to best palliative care is currently available from clinical trials.

Furthermore, the development of LMC from a gastric cancer is a very rare occurrence. Some articles have reported that the incidence of LMC in patients with gastric cancer was responsible for 0.16% of all cases of gastric cancer^[4]. Due to its rarity, the clinical features and prognostic factors of LMC as a metastasis from gastric carcinoma have yet to be clearly characterized. The benefits of IT chemotherapy are also currently a matter of some contention.

Gastric cancer is the most common malignancy in Korea^[5]. Because of the high prevalence of gastric cancer in Korea, we took the opportunity to study gastric cancer patients with LMC. The principal objective of this study was to review our experience with LMC associated with gastric cancer, and to evaluate its clinical features and the efficacy of a variety of treatment modalities in terms of neurological status and overall survival (OS).

MATERIALS AND METHODS

Patients

From 1995 to 2007, 22154 patients were diagnosed with gastric cancer at four independent institutions. Among them, 54 patients who were diagnosed with leptomeningeal seeding metastasis of gastric cancer were analyzed. Although it is not representative of the cohort of patients, the prevalence of LMC was 0.24%.

Eligibility for this study included: (1) patients with histologically confirmed adenocarcinoma of the stomach; (2) cytologically confirmed malignancy on cerebrospinal fluid (CSF) analysis, patients with

suspected LMC by magnetic resonance imaging (MRI) and negative cytology were excluded; (3) no history of any other malignancies.

We retrospectively analyzed the patients' medical records including the patients' characteristics, clinical symptoms, laboratory and radiologic findings, treatment modality and outcomes, final follow-up, and survival duration.

Statistical analysis

Comparisons of categorical variables among groups were conducted using the chi-square test and Fisher's exact test. OS was calculated from the cytological confirmation of LMC and plotted *via* the Kaplan-Meier method. Comparison of survival according to prognostic factors was evaluated *via* a log-rank test, and forward stepwise Cox proportional hazard models were employed to evaluate the joint effect of predictive variables. $P < 0.05$ was considered significant. Analysis of the data was conducted using SPSS for Windows V. 15.0 (SPSS Inc., Chicago, IL, USA) statistical software.

RESULTS

Patients' characteristics

We analyzed 54 cases of cytologically confirmed gastric LMC at four institutions from 1994 to 2007. The clinical characteristics of these patients are summarized in Table 1. The male-to-female ratio was 32:22, and patients ranged in age from 28 to 78 years (median, 48.5 years). The majority of patients had advanced disease at initial diagnosis of gastric cancer. The clinical or pathologic tumor, node and metastasis stage of the primary gastric cancer was IV in 47 patients (87%). Stage I - III patients received curative operation. Among the stage IV patients, 13 patients had T4N1-2 or N3 (No. of nodes > 15) by pathologic features through curative operation. M1 node positive patients were counted as palliative surgery. Of the initial endoscopic findings in the available 45 patients, Bormann type III and IV were reported for 23 (51%) and 15 (33%) patients, respectively. Pathologically, 94% of cases proved to be poorly differentiated adenocarcinomas. Signet ring cell component was also observed in 40% of patients.

LMC patterns

The median interval from diagnosis of the primary gastric cancer to the diagnosis of LMC was 6.3 mo, ranging from 0 to 73.1 mo. Five patients presented with initial LMC. The majority of patients (59.3%) initially presented with metastatic gastric cancer without LMC, and then progressed to LMC. One-third of the patients presented with curable disease at the initial diagnosis of gastric cancer (Table 2).

Clinical symptoms

The most frequently observed presenting symptoms of LMC were nonspecific symptoms such as headache (85%) and nausea/vomiting (58%). In addition, various neurological clinical signs and symptoms were noted

including altered mental status, seizure, motor weakness, sensory change, diplopia, hearing loss, and facial palsy (Table 3).

CSF analysis and image findings

Lumbar puncture and analysis of CSF is a crucial laboratory test in the diagnosis of LMC. All the patients presented with malignant cells on cytological analysis *via* the inclusion criteria. An elevated opening pressure on lumbar puncture was noted in 58% of the subjects. The mean CSF pressure in the patients was 222.1 mm CSF. 78.8% and 53.8% of patients had elevated white blood cells and protein in CSF, respectively (Table 4).

Brain computed tomography was assessed in eight patients and leptomeningeal enhancement was observed only in one patient. A gadolinium-enhanced MRI was

conducted in 51 patients. Leptomeningeal enhancement was noted in 45 cases (82%).

Treatment modalities and outcomes

IT chemotherapy was administered to 36 patients, principally with methotrexate (MTx) alone (61%) or in combination with hydrocortisone/± Ara-C (41%). The median number of IT treatments was 7 (range, 1-18). Seventeen patients (46%) achieved cytological negative conversion (Table 5).

Thirteen patients were treated with whole brain irradiation coupled with IT chemotherapy. Six patients received radiation treatment alone.

Additional systemic chemotherapy was given to 10 patients. Three patients were treated with the orally available 5-fluorouracil (5-FU) drugs - capecitabine, S-1, and tegafur-uracil. Irinotecan/leucovorin/5-FU, 5-FU/cisplatin, and paclitaxel/cisplatin were administered to four, two and one patients, respectively. Seven patients were treated with chemotherapy plus IT chemotherapy. Three patients received chemotherapy alone. The median number of cycles administered was 2 (range, 1-6). Among the treated patients, only one exhibited a detectable response to treatment.

Survival and prognostic factors

Median OS duration from diagnosis of LMC was 6.7 wk (95% CI: 4.3-9.1 wk) (Figure 1). In the univariate analysis of survival duration, hemoglobin, IT chemotherapy, and cytologic negative conversion showed superior

LMC, the most frequently encountered solid tumors are breast (12%-34%), lung (14%-29%), and melanoma (17%-25%)^[3]. Unlike Western reports, gastric cancer is the principal etiology of LMC in solid tumors in Korea^[7].

CNS metastasis is a very rare complication of gastric cancer, and occurs in 0.16%-0.69% of gastric cancer patients in general, including Korean reports^[4,8,9]. Although all the included patients demonstrated CSF cytologically confirmed malignancy, the prevalence of LMC in this study was 0.24% in all gastric cancer patients.

Consistent with other studies, the majority of patients had Bormann type III or IV advanced gastric cancer of poorly differentiated or signet-ring cell histopathology, which increased the tendency for distant metastasis and poor prognosis^[4,10,11]. Similar to the results of a previous study, LMC patients presented with an advanced stage and Bormann type III or IV advanced gastric cancer of poorly differentiated or signet-ring cell histopathology.

LMC is an ultimately fatal disease^[12-15]. A minority of patients, usually those with breast cancer or lymphoid malignancies, may achieve disease-free survival of a year or more, however, the median OS for patients with LMC is only 4-6 wk if untreated and 2-4 mo with therapy^[6,12,15]. In our study, the median survival duration was just

6.7 wk. Although LMC patients tend to have a poor performance status, approximately two-thirds of patients who receive IT chemotherapy and 47.2% patients who responded to therapy achieved longer survival duration. The independent prognostic factor for survival was cytologic negative conversion by IT chemotherapy. Although the small sample size and inherent selection bias of the retrospective design of this study makes any conclusions regarding the outcomes of treatment somewhat difficult, the findings of our study indicate that cytologic negative conversion by IT chemotherapy may improve survival by arresting neurologic progression in selected patients.

MTx remains the most frequently utilized drug for IT administration, despite its limited success and serious complications^[16,17]. Combination IT chemotherapy with MTx, arabinoside and hydrocortisone has been reported to be more effective than MTx alone in solid tumor LMC^[18]. However, approximately 10% of gastric cancer patients were enrolled in this study, and the efficacy of arabinoside against gastric cancer is questionable.

Craniospinal irradiation may be a one-treatment modality. However, the additional or sequential role of radiation has been controversial^[19]. In our study, additional effects of radiotherapy were not observed. As response to radiation is associated with the sensitivity or resistance of primary tumors and malignant cells circulating in the CSF space, radiation is occasionally not feasible for palliative treatment.

Systemic chemotherapy was also administered to a limited number of patients who had better performance status^[6,15,20]. In our study, patients who were treated with systemic chemotherapy showed the best median OS duration (21.6 wk, 95% CI: 3.2-40 wk). However, all the treatments were administered sequentially after IT chemotherapy and the patients responded to treatment.

COMMENTS

Background

Leptomeningeal carcinomatosis (LMC) occurs in approximately 5% of cancer patients. The most common cancers involving the leptomeninges are breast and lung cancer. However, gastric adenocarcinoma has been infrequently reported in conjunction with LMC. This retrospective analysis was performed to identify the clinical features and outcomes of infrequently reported LMC of gastric cancer.

Research frontiers

This is the first large scale study on gastric LMC. LMC is a rare component in the clinical manifestation of gastric cancer. LMC usually presents at a relatively young age, at an advanced stage, and is of a poorly differentiated pathologic type.

Innovations and breakthroughs

Although gastric LMC had a fatal clinical course, the findings of our study suggest that cytologic negative conversion by intrathecal (IT) chemotherapy may improve survival by arresting neurologic progression in selected patients.

Applications

These results could provide basic clinical data on gastric LMC for physicians and demonstrate the role of IT chemotherapy.

Terminology

Leptomeninges (literally thin meninges) is a term referring to the pia mater and arachnoid mater. LMC is a condition in which a tumor diffusely spreads to the leptomeninges. Intrathecal chemotherapy involves anticancer drugs injected

into the fluid-filled space between the thin layers of tissue that cover the brain and spinal cord.

Peer review

The results are interesting and suggest that cytologic negative conversion by IT chemotherapy may improve survival by arresting neurologic progression in selected patients.

Abstract

AIM: To investigate the gastroprotective effect of vardenafil against indomethacin-induced gastric damage.

METHODS: Forty-eight female Wistar albino rats were randomly divided into 6 groups. Group 1 received saline only. Group 2 (indomethacin) received indomethacin. Rats in group 3 and 4 were pretreated with different doses of famotidine. Group 5 and 6 were pretreated with different doses of vardenafil. Rats in groups 3 to 6 received 25 mg/kg indomethacin 30 min after pretreatment. The animals were sacrificed 6 h later and their stomachs were opened. Gastric lesions were counted and measured. The stomach of each animal was divided in two parts for histopathological examinations and nitric oxide (NO) and malondialdehyde (MDA) assays, respectively.

RESULTS: There were no gastric mucosal lesion in the saline group but all rats in the indomethacin group had gastric mucosal ulcerations (ulcer count; 6.25 ± 3.49 , and mean ulcer area; 21.00 ± 12.35). Ulcer counts were

diminished with famotidine 5 mg/kg (4.12 ± 2.47 , $P > 0.05$), 20 mg/kg (2.37 ± 4.43 , $P < 0.05$), vardenafil 2 mg/kg (4.37 ± 3.06), and vardenafil 10 mg/kg (1.25 ± 1.38 , $P < 0.05$) compared to the indomethacin group. Gastric mucosal lesion areas were diminished with famotidine 5 mg/kg (8.62 ± 2.97 , $P < 0.001$), famotidine 20 mg/kg (0.94 ± 2.06 , $P < 0.001$), vardenafil 2 mg/kg (6.62 ± 5.87 , $P < 0.001$), and vardenafil 10 mg/kg (0.75 ± 0.88 , $P < 0.001$) compared to the indomethacin group. MDA levels were significantly higher in indomethacin group (28.48 ± 14.51), compared to the famotidine 5 mg/kg (6.21 ± 1.88 , $P < 0.05$), famotidine 20 mg/kg (5.88 ± 1.60 , $P < 0.05$), vardenafil 2 mg/kg (15.87 ± 3.93 , $P < 0.05$), and vardenafil 10 mg/kg (10.97 ± 4.50 , $P < 0.05$). NO concentration in gastric tissues of the famotidine groups were significantly increased ($P < 0.05$), but the NO increases in the vardenafil groups were not statistically significant. Histopathology revealed diminished gastric damage for pretreatment groups compared to the indomethacin group ($P < 0.05$).

CONCLUSION: Vardenafil affords a significant dose-dependent protection against indomethacin induced gastric mucosal lesions in rats.

INTRODUCTION

Gastric mucosal damage is a common disorder of the gastrointestinal system. The pathogenesis of gastric ulcers is based on complex interactions between aggressive and protective factors. Nonsteroidal anti-inflammatory drugs

(NSAID) are known to be aggressive agents for gastric ulcer development. People of advancing age need many drugs, including NSAIDs, for the treatment of pain and inflammation due to rheumatological disturbances.

Vardenafil is a phosphodiesterase (PDE) V inhibitor that has been used for the treatment of erectile dysfunction^[1] and, more recently, for pulmonary hypertension^[2,3]. Recent laboratory studies demonstrated successful effects of PDE V inhibitors on cardioprotection after ischemia reperfusion injury^[4,5], as well as in ischemic injury of other organs, such as the colon, liver, and brain^[6,7]. Deibert *et al*^[8] revealed that vardenafil had increased portal flow and lowered portal pressure in patients with cirrhotic livers.

Diminished mucosal circulation has been blamed as one of the etiological factors in gastric ulcer formation. Like prostaglandins, the L-Arginine/nitric oxide (NO) pathway is a major protective system in gastric mucosa^[9] via relaxation of the arterial smooth muscles. Inhibition of nitric oxide synthase aggravates the injury in animal models of gastric ulcers^[10].

In this study, we have studied the effects of vardenafil on the acute gastric injury caused by administration of indomethacin.

MATERIALS AND METHODS

The study was approved by the Zonguldak Karaelmas University (ZKU) Animal Experiments Local Ethic Committee. The study was carried out on 48 female Wistar albino rats weighing 200-250 g, obtained from the Experimental Animal Laboratory of Medical Faculty of ZKU. The rats were kept under standard conditions (temperature; 22-24°C, and 12:12 h light/dark). The experimental procedures were carried out in accordance with international guidelines for the use and care of laboratory animals. All animals were fed with pellet food produced especially for experimental animals. Water was available ad libitum. All experiments were performed at the same time of the day to avoid diurnal variations of putative regulators of gastric functions.

Famotidine and vardenafil were dissolved in distilled water. All drug solutions and suspensions were freshly prepared. Gastric ulcers were inflicted by oral administration of indomethacin 16-18 h after starvation.

Animals were randomly divided into six groups. In Group 1 (n:8) rats received only 8 mL/kg of saline by gavage. Rats in Group 2 (n:8) received 25 mg/kg indomethacin in a volume of 8 mL/kg of saline. The rats in group 3 and 4 were pretreated with famotidine, 5 mg/kg and 20 mg/kg, respectively. Rats in groups 5 and 6 were pretreated with 2 mg/kg and 10 mg/kg vardenafil, respectively. After 30 min, 25 mg/kg indomethacin in a volume of 8 mL/kg of saline were administered by gavage. Six hours after oral administration of indomethacin, all rat groups were anesthetized with an intramuscular injection of 100 mg/kg Ketamine (Ketalar®, Parke Davis-Eczacıbaşı, Istanbul, Turkey). A midline abdominal incision was then performed. All rat groups were sacrificed *via* cardiac puncture, and their stomachs rapidly removed, opened by an incision along the lesser curvature, and rinsed in ice-cold distilled water^[11]. Gastric tissues were pinned out on a

wax platform. Macroscopic damage to the gastric mucosa was assessed. Hemorrhagic and ulcerative lesions were counted and their lengths were measured on square millimeter paper. Gastric mucosal lesions were expressed as the sum of the lengths (mm) of all lesions for each stomach, which was used as the ulcer index (UI)^[12,13]. Gastric lesions were judged by two independent researchers who were blinded to the protocol. The average score of the two independent observers were taken into account, and the sum of the total scores was divided by the number of animals to obtain the mean UI for each group.

The stomach of each animal was divided into two parts. One part of the stomach was excised, immersed in saline, and immediately stored at -40°C for measurement of NO and MDA levels.

Gastric tissues were homogenized in ten volumes of 150 mmol/L ice-cold KCl using a glass teflon homogenizer (Ultra Turrax IKA T18 Basic) after cutting the tissues into small pieces with scissors (for 2 min at 5000 r/min). The homogenate was then centrifuged at 5000 × *g* for 15 min. The supernatant was used for analysis. High-performance liquid chromatographic analysis was performed using a Shimadzu HPLC system (Kyoto, Japan) with an MDA kit (Immundiagnostik AG, Bensheim, Germany). Spectrophotometric measurements of total antioxidant status (TAS) (Randox, Crumlin, UK) was performed using a Shimadzu UV-1601 (Kyoto, Japan) spectrophotometer. Serum nitric oxide levels (nitrite + nitrate) were measured, after conversion of nitrate to nitrite by copperized cadmium granules, by a spectrophotometer at 545 nm (Shimadzu, Tokyo, Japan)^[14]. Protein assays were measured on an Advia 2400 chemistry analyzer (Bayer Healthcare Instruments, Tarrytown, NY, USA). Results were expressed as μmol/g protein for NO and nmol/g protein for MDA.

The other part of the stomach was fixed in 10% neutral formalin, embedded in paraffin, and cut into 5 μm sections. The sections were stained with hematoxylin eosin (HE) and examined under the light microscope by a blinded pathologist for histological changes.

The results obtained from vardenafil groups were evaluated by comparing them with those of sham, indomethacin, and famotidine groups.

Statistical analysis

The statistical analysis was performed using Statistical Package for the Social Sciences (SPSS) version 12.0 for Windows. All data are expressed as the mean ± SD. Mann-Whitney *U* and χ^2 tests were used for statistical analysis of data among all groups. *P* < 0.05 was considered as statistically significant.

RESULTS

Macroscopic analysis showed that there was no gastric mucosal lesion in the sham group. There were gastric mucosal lesions in all stomachs of the indomethacin 25 mg/kg treated group. The mean ulcer area was 21.00 ± 12.35 in the indomethacin group. Gastric mucosal damage was significantly reduced by famotidine 20 mg/kg and vardenafil 10 mg/kg pretreatments. In both groups, the mean count of ulceration and the mean count of

The values are presented as mean ± SD, (min-max). ^a*P* < 0.05 *vs* the other group; ^c*P* < 0.05 *vs* indomethacin group; ^e*P* < 0.05 *vs* famotidine groups (F5 and F20); ^g*P* < 0.05 *vs* group F20; ^h*P* < 0.01 *vs* group F20.

ulcer area were significantly lower than the control group. Gastric mucosal lesion areas were significantly diminished in rats pretreated with famotidine 5 mg/kg and vardenafil 2 mg/kg, when compared with the control group, but this did not reach statistical significance in respect to ulcer count. The mean ulcer area in the vardenafil 2 mg/kg group and vardenafil 10 mg/kg group were 6.62 ± 5.87 and 0.75 ± 0.88 , respectively. Macroscopic evaluation of gastric mucosal lesion counts and gastric mucosal lesion areas for each group are presented in Table 1. In damaged stomachs, mucosal lesions of various sizes and forms were dispersed to all stomach surfaces. Those lesions consisted of elongated bands parallel to the long axis of the stomach. Lesions of the gastric mucosa in each group are shown in Figure 1. Tissue MDA and NO levels are presented in Table 2 for each group.

On histopathological examination, erosion, inflammation, hemorrhage, and necrosis were abundant in the indomethacin group. Those lesions were encountered with increasing frequency in the Famotidine 20 mg/kg, vardenafil 10 mg/kg, famotidine 5 mg/kg, and vardenafil 2 mg/kg groups. There were statistically significant (*P* < 0.05) differences between the indomethacin group and pretreatment groups. Famotidine 20 mg/kg pretreatment had the most efficient protective effect against indomethacin-induced gastric mucosal lesions. Minimal hemorrhage, minimal focal necrosis, and superficial erosions were observed in 25% of the rats given 2 mg/kg vardenafil. A high dose (10 mg/kg) of vardenafil had a potent protective effect against indomethacin-induced gastric mucosal lesions, but vardenafil in low doses (2 mg/kg) did protect the gastric mucosa against the harmful effects of indomethacin, similarly famotidine 5 mg/kg did. Microscopic views of the normal and damaged gastric mucosa are shown in Figure 2. In our

study, vardenafil has gastroprotective effects against indomethacin-induced gastric mucosal damage. The potency of this effect is stronger in high doses than low doses.

DISCUSSION

Despite the great progress in the treatment protocols, peptic ulcers are still a major ongoing health problem. The gastric barrier protects the mucosa against damage of its deeper structures by noxious substances. Mucosal microcirculation of the stomach has an important role in gastric mucosal protection^[15]. Prostaglandins and NO are the main factors that regulate gastric blood flow. NSAIDs cause gastric mucosal damage by inhibiting endogenous prostaglandins due to inhibition of COX-1 and COX-2^[16,17]. Prospective data from the Arthritis, Rheumatism, and Aging Medical Information System (ARAMIS) states that 13 of every 100 patients with rheumatoid arthritis treated with NSAID for one year suffer from serious gastrointestinal complications related to the NSAIDs^[18]. Indomethacin administration increases aggressive factors but decreases protective factors^[19,20].

There is no doubt on the protective effect of H₂ blockers. The gastroprotective effects of H₂ blockers are significantly greater when given in high doses than in low doses. The results in our experiment, either in low or in high doses of H₂ blockers, were in accordance with the literature. Widespread use of H₂ blockers could not prevent peptic ulcer related disorders. Therefore, the search for new alternatives with novel mechanisms of action is ongoing.

PDE type-5 inhibitors, which were developed as cardioprotective drugs, are commonly used in the treatment of erectile dysfunction. Sildenafil citrate

Figure 1 Gross appearance of the opened stomachs in the experimental groups. A: Appearance of normal mucosa of the stomach (Saline); B: Severe mucosal injury (Indomethacin); C: Diminished mucosal injury (Group F5); D: Gastric mucosa without any lesion (Group F20); E: Partially protected gastric mucosa against the harmful effect of indomethacin (Group V2); F: Lesion free gastric mucosa (Group V10).

Figure 2 Normal rat gastric mucosa in the saline group and Group V10 (A and C, HE; × 100); gastric mucosal hemorrhage and necrosis in indomethacin group and Group V2 (B and D, HE; × 200, × 100) are shown.

has shown gastroprotective effects in experimental studies^[21-23], and its gastroprotective effect was dose-

dependent. Vardenafil is more potent than sildenafil. The gastroprotective effect of vardenafil has not yet been

studied. In our study, the antiulcer activity of vardenafil was investigated against indomethacin-induced gastric mucosal damage. Vardenafil decreased indomethacin-induced gastric mucosal lesions significantly at high doses (10 mg/kg). Macroscopically, vardenafil at a dose of 2 mg/kg has a protective effect on the gastric mucosa similar to famotidine at 5 mg/kg.

Macroscopic evaluations of gastric tissues revealed that vardenafil given in 2 mg/kg protects gastric mucosa better than famotidine at a dose of 5 mg/kg. Vardenafil has clinically important gastroprotective effects at high doses (10 mg/kg). Thus, the gastroprotective effect of vardenafil was dose dependent. In the stomach tissue of rats given indomethacin, the level of the lipid peroxidation product, MDA, increased significantly compared to the sham operated group. Tissues exposed to oxidative stress include large amounts of toxic oxygen radicals, which induce lipid peroxidation leading to MDA formation^[24,25]. The lowest MDA values were detected in the famotidine groups. The mean MDA values in the vardenafil groups were similar to the sham group (Table 2). Thus, vardenafil pretreatment has inhibited MDA production in indomethacin treated rats.

Possible mechanisms of gastroprotection of PDE V inhibitors are increased production of tissue NO^[23,26-28] or increased tissue cGMP level without modifying NO content^[22,25,29,30]. The NO levels are slightly elevated in vardenafil pretreated rats in our study; however, the level of NO in either of vardenafil groups did not surpass the level of NO determined in the sham group. Some studies revealed gastroprotective effects of some agents without significant alterations in NO or MDA levels^[31]. Determination of tissue cGMP level was not included in our study design. This is a short armcoming of our study design. PDE V inhibitors might prevent indomethacin-induced gastric mucosal damage in either mechanism.

In conclusion, vardenafil reduced gastric mucosal damage significantly at a high dose. Patients treated with PDE type-5 inhibitors might benefit from the additional gastroprotective advantages of these drugs, especially in high doses.

COMMENTS

Background

Peptic ulcer is a common disorder of the gastrointestinal system. The increase in non-steroid anti inflammatory drug (NSAID) ingestion in the treatment of inflammation, fever, and pain is one of the major etiological factors for peptic ulcers. Despite the many drug treatment protocols used to date, peptic ulcer still remains a major public health problem.

Research frontiers

Vardenafil has being used in the treatment of functional impotence; however, its effects on gastric mucosa have not yet been investigated. The research's aim was to determine its effectiveness in gastroprotection against NSAID-induced gastric lesions in comparison with famotidine.

Innovations and breakthroughs

Multiple agents have been used to prevent NSAID-induced peptic ulcer. This work is the first experimental study that show the beneficial effects of Vardenafil (a phosphodiesterase type V inhibitor) on NSAID-induced gastric ulcer. The gastroprotective effect of vardenafil against NSAID-induced peptic ulcer is dose dependent.

Applications

The study results suggest that vardenafil might be used as a potential therapeutic drug to prevent NSAID-induced gastric ulcer formation.

Peer review

This work might provide the first experimental data that directly shows the beneficial effect of a phosphodiesterase V inhibitor on gastric ulcers. In this manuscript, Karakaya et al report that administration of a phosphodiesterase V inhibitor (Vardenafil), dose-dependently suppresses indomethacin-induced gastric ulcers in rats. For comparison purposes, famotidine was used. There is only limited information suggesting the potential beneficial effect of vardenafil on ulcer healing, the data presented would be considered to provide attractive clinical information, although a clear mechanistic insight is not provided.

Abstract

AIM: To investigate the efficacy and safety of rabeprazole under continuous non-steroidal anti-inflammatory drug (NSAID) administration for NSAID-induced ulcer in Japan.

METHODS: Subjects comprised patients undergoing NSAID treatment in whom upper gastrointestinal endoscopy revealed an ulcerous lesion (open ulcer) with diameter ≥ 3 mm, who required continuous NSAID treatment. Endoscopies were performed at the start of treatment, during the treatment period, and at the conclusion (or discontinuation) of treatment. Findings were evaluated as size (maximum diameter) and stage based on the Sakita-Miwa classification. An ulcer was regarded as cured when the "white coating" was seen to have disappeared under endoscopy. As criteria for evaluating safety, all medically untoward symptoms and signs (adverse events, laboratory abnormalities, accidental symptoms, *etc.*) occurring after the start of rabeprazole treatment were handled as adverse events.

RESULTS: Endoscopic cure rate in 38 patients in the efficacy analysis (endoscopic evaluation) was 71.1% (27/38). Among those 38 patients, 35 had gastric ulcer with a cure rate of 71.4% (25/35), and 3 had duodenal ulcer with a cure rate of 66.7% (2/3). Three adverse drug reactions were reported from 64 patients in the safety analysis (interstitial pneumonia, low white blood cell count and pruritus); thus, the incidence rate for adverse drug reactions was 4.7% (3/64).

CONCLUSION: The treatment efficacy of rabeprazole for NSAID-induced ulcer under continuous NSAID administration was confirmed.

INTRODUCTION

In clinical practice, non-steroidal anti-inflammatory drugs (NSAIDs) are widely prescribed for arthralgia and rheumatoid arthritis (RA)^[1,2]. NSAIDs exert potent anti-inflammatory and analgesic effects but are clinically problematic in that gastric mucosal injury can be induced as an adverse reaction^[3,4]. For example, up to 25% of patients using NSAIDs develop peptic ulcer^[5,6]. A United States study reported that the number of people taking NSAIDs has reached 13 million per year, with approximately 100 000 requiring hospital treatment for upper gastrointestinal injury and 17 000 reported deaths annually^[7]. The medical cost exceeds \$4 billion per year in the USA^[8].

In Japan, the Japan Rheumatism Foundation has reported the results of an epidemiological survey of the incidence of NSAID-induced gastric mucosal lesions in arthritis patients^[9]. According to that report, of the 1008 patients with arthritis who took NSAIDs for ≥ 3 mo, upper gastrointestinal tract lesions were observed in 62.2%, including 15.5% with gastric ulcer and 1.9% with duodenal ulcer. This suggests that NSAID-induced gastric ulcers occur at a higher rate than the incidence of gastric ulcer found by physical examination (2.2%-4.1%). Moreover, more than 40% of patients were asymptomatic despite the presence of a lesion. In Japan, which faces an increasingly aging society, chronic diseases requiring long-term treatment with NSAIDs (e.g. RA, low back pain and arthralgia) are expected to increase. Devising methods for coping with the expected associated increases in gastric mucosal lesions will thus become increasingly important.

Preparations like proton pump inhibitors (PPIs) and misoprostol are known for curing NSAID-induced gastrointestinal mucosal damage^[10-13]. However, misoprostol often induces some adverse reactions like diarrhea^[14].

Given this background, the “Evidence-Based Guidelines for Gastric Ulcer” were issued in 2003 (2nd edition in 2007) proposing policies for the treatment and prevention of NSAID-induced ulcers^[15]. The guidelines recommend the following therapies: (1) if possible, discontinuation of NSAIDs and initiation of conventional ulcer treatment^[16]; and (2) if NSAID treatment cannot be discontinued, initiation of treatment with a PPI or prostaglandin preparation. However, the evidence (clinical results) put forth in the guidelines was based entirely on foreign reports, with no evidence of use from Japanese studies^[15].

Rabeprazole, a newer PPI, provides reliable control of gastric acid secretion, with more potent antisecretory activity than that of other PPIs such as omeprazole and lansoprazole, a more rapid rise in intragastric pH, and less effect of CYP2C19 on its metabolism^[17-20].

Based on our belief in the importance of investigating the efficacy and safety of the PPI rabeprazole on NSAID-induced ulcers in Japanese individuals, we conducted this survey of 38 medical departments (primarily departments of gastroenterology and internal medicine) at 38 facilities nationwide. This survey was conducted between 1 August 2004 and 31 January 2006, in accordance with good post-marketing surveillance practice.

MATERIALS AND METHODS

Subjects

Subjects included in this survey were patients undergoing NSAID treatment in whom upper gastrointestinal endoscopy revealed an ulcerous lesion (open ulcer) with diameter ≥ 3 mm, who required continuous NSAID treatment. Patients taking low-dose aspirin to prevent clot/thrombus formation were excluded as subjects. Patients meeting any of the following criteria were also excluded: (1) history of hypersensitivity to rabeprazole components; (2) exposed blood vessels in the ulcer base; or (3) judged by an investigator as unsuitable for participation in this survey.

Methods

A central registration system was adopted. The registration form was mailed within 1 wk of the registration date. Rabeprazole were to be administered in accordance with the following dose: once daily oral administration of 10 mg of rabeprazole sodium, which can be increased to once daily oral administration of 20 mg, depending on the symptoms (Standard dosage for adults): Standard treatment duration is 8 wk in the case of gastric or anastomotic ulcer, and 6 wk in the case of duodenal ulcer. The Japanese standard dosages of the three most used NSAIDs in this study are as follows; diclofenac sodium, 25-100 mg/d; loxoprofen, 60-180 mg/d; lornoxicam, 12-18 mg/d.

Figure 1 Patient disposition. ¹Patients treated for longer than the allowed treatment period. The allowed treatment period was defined in the protocol as 8 wk for patients with gastric ulcer and 6 wk for patients with duodenal ulcer, + 2 wk for each (i.e. 10 wk for gastric ulcer and 8 wk for duodenal ulcer); ²Patients for whom endoscopic evaluation was performed prior to 31 d before the start of rabeprazole treatment or more than 31 d after the conclusion of rabeprazole treatment.

Evaluation

Endoscopic findings: Endoscopies were performed at the start of treatment, during the treatment period, and at the conclusion (or discontinuation) of treatment. Findings were evaluated as size (maximum diameter) and stage based on the Sakita-Miwa classification. When multiple ulcers existed in a single subject, only the largest one was recorded. An ulcer was regarded as cured when the “white coating” was seen to have disappeared under endoscopy.

Adverse events: As criteria for evaluating safety, all medically untoward symptoms and signs (adverse events, laboratory abnormalities, accidental symptoms, etc.) occurring after the start of rabeprazole treatment were handled as adverse events.

RESULTS

Patient disposition

One hundred three patients were enrolled in the present study. Due to violation of enrollment and patients meeting exclusion criteria like no concomitant use of NSAIDs, 38 patients were put in the efficacy analysis and 64 patients in the safety analysis (Figure 1).

Efficacy

Demographic and baseline characteristics: Demographic and baseline characteristics of the 38 patients in the efficacy analysis (endoscopic evaluation) are shown in Table 1. Well-used NSAIDs by patients were diclofenac sodium in 36.8% (14/38), loxoprofen 36.8% in (14/38) and lornoxicam in 13.2% (5/38). The main reasons for use of NSAIDs observed were RA in 39.5% (15/38) and low back pain in 36.8% (14/38).

Among 25 subjects undergoing examination for *Helicobacter pylori* (*H. pylori*) infection, 64.0% (16/25) were positive, and 36.0% (9/25) were negative.

Table 2 Endoscopic cure rate

	10 mg group	20 mg group	Modified dose group ²	Total
Gastric ulcer ¹	71.4% (15/21)	75.0% (9/12)	50.0% (1/2)	71.4% (25/35)
Duodenal ulcer	66.7% (2/3)	-	-	66.7% (2/3)
Total	70.8% (17/24)	75.0% (9/12)	50.0% (1/2)	71.1% (27/38)

¹The 2 patients with “gastric/duodenal ulcer” were included in tabulations for gastric ulcer; ²Modified dose group consisted of 1 patient changing from 10 mg to 20 mg and 1 patient changing from 20 mg to 10 mg.

Endoscopic cure rate: Endoscopic cure rate for the 38 patients in the efficacy analysis (endoscopic evaluation) was 71.1% (27/38) (Table 2). According to diagnosis, the cure rate was 71.4% (25/35) for gastric ulcer and 66.7% (2/3) for duodenal ulcer. In addition, the cure rate was lower in the gastric antrum (55.6%; 10/18) than in the gastric corpus (91.7%; 11/12).

graphic and baseline characteristics of 64 patients in the safety analysis are shown in Table 3. Well-used NSAIDs by patients were diclofenac sodium in 53.1% (34/64), loxoprofen in 31.3% (20/64) and lornoxicam in 10.9% (7/64). The main reasons for using NSAIDs were RA in 40.6% (26/64), low back pain in 28.1% (18/64) and osteoarthritis in 15.6% (10/64). Among 42 subjects undergoing examination for *H. pylori* infection, 59.5% (25/42) were positive, and 40.5% (17/42) were negative.

Incidence of adverse drug reactions: Among the 64 patients in the safety analysis, 3 adverse drug reactions were observed in 3 patients. The incidence rate for adverse drug reactions was thus 4.7% (3/64). Adverse reactions comprised 1 case of “interstitial pneumonia” (serious; outcome: recovering) (1.6%); 1 case of “low white blood cell count” (non-serious; outcome: recovered) (1.6%); and 1 case of “pruritus” (non-serious; outcome: recovered) (1.6%).

DISCUSSION

Endoscopic cure rate was 71.1% (27/38). By disease, the endoscopic cure rate in gastric ulcer patients after 8 wk of treatment was 71.4% (25/35) and the endoscopic cure rate in duodenal ulcer patients after 6 wk of treatment was 66.7% (2/3). In other clinical studies of rabeprazole, reported cure rates have been 93.5% (72/77 patients)^[21] and 96.4% (27/28) for gastric ulcer, and 100% (23/23) for duodenal ulcer^[22]. Endoscopic cure rate in this survey, at 71.1%, did not reach the general cure rates obtained for chronic gastric and duodenal ulcers. These results strongly suggest that continuous administration of NSAIDs may act to delay ulcer healing.

Conversely, in studies similar to this study relating to the healing of gastric and duodenal ulcers in the presence of NSAID treatment, according to the results of Shiokawa *et al*^[23] in the first such study in Japan, cure rates for gastric and duodenal ulcer were 70% (35/50) and 83.3% (5/6), respectively, when a prostaglandin was used at 800 µg/d. With regard to the healing effect of PPI use, only results from foreign studies are available^[24-27]. Hawkey *et al*^[26] conducted a comparative examination of the results of studies on the effects of 20 mg and 40 mg of omeprazole, and 800 µg of misoprostol. After 8 wk of administration, the gastric ulcer cure rate was 87.2% (102/117) with 20 mg of omeprazole and 79.5% (105/132) with 40 mg. The cure rate in the group administered 20 mg of omeprazole was significantly higher than the 72.8% (91/125 patients) in the control group administered 800 µg of misoprostol. In a study of lansoprazole, Agrawal *et al*^[27] compared the results of 15 mg and 30 mg of lansoprazole versus 300 mg of ranitidine hydrochloride. Gastric ulcer cure rates after 8 wk of treatment were 68.6% (81/118) with 15 mg lansoprazole and 72.6% (85/117) with 30 mg. Cure rates in both lansoprazole groups were significantly higher than the 53.0% (61/115 patients) obtained using ranitidine hydrochloride. The present survey found no significant difference between rabeprazole doses with respect to cure rates for NSAID-induced ulcer, with a cure rate of 70.8% (17/24) using a dose of 10 mg and 75.0% (9/12) at 20 mg. The cure rates observed here did not differ significantly from those obtained using the other PPIs described above.

Conversely, how *H pylori* infection affects healing of NSAID-induced ulcers remains controversial and is an important topic that should be considered in future studies, and a recently published guideline addressed this point^[28]. This survey investigated the dependency of cure rate on *H pylori* infection, but no significant difference was observed. The cure rate in *H pylori*-positive patients was 81.3% (13/16), compared to 77.8% (7/9) in *H pylori*-negative patients.

Symptoms and signs, and the conditions of occurrence of these presentations, are commonly considered to differ between NSAID-induced ulcer patients and patients with ordinary ulcers. Saigenji *et al* reported that the pretreatment incidence of epigastralgia was 100% (72/72 patients) in patients with gastric ulcer^[21]. However, the

Table 4 Clinical characteristics of NSAIDs-induced ulcer (safety analysis: *n* = 64)

Site of ulcer	<i>n</i>	%	Ulcer form	<i>n</i>	%	No. of ulcers	<i>n</i>	%
Ulcer condition								
Corpus	19	29.7	Round	27	42.2	Single	42	65.6
Angle	7	10.9	Elliptical	23	35.9	Multiple	21	32.8
Antrum	31	48.4	Irregular	11	17.2			
Bulb	4	6.3	Other	2	3.1			
Efferent loop	1	1.6						

pretreatment incidence rate for epigastralgia was 70.2% (33/41) in the present survey, which was comparatively lower than the incidence observed with ordinary gastric ulcer. In general, incidences for symptoms and signs are lower with NSAID-induced ulcers^[29], and the present results support this.

Data on the site, shape and number of NSAID-induced ulcers were also tabulated in this survey. For the 90 patients with NSAID-induced ulcer (not including the 9 patients in the dataset of patients analyzed who did not display NSAID-induced ulcer), the original ulcer site was most frequent at the gastric antrum (43.3%) and the most common shapes were round (35.6%) and elliptical (37.8%), although irregularly shaped ulcers were also observed (23.3%). In terms of the number of ulcers, multiple ulcers were present in 33.3% (30/90) of cases. The clinical characteristics of NSAID-induced ulcers that were confirmed in the 64 patients in the safety analysis were also tabulated. The gastric antrum was the site of the ulcer in 48.4% (31/64) of patients; the shape was round in 42.2% (27/64) and elliptical in 35.9% (23/64) while 32.8% (21/64) of cases displayed multiple ulcers (Table 4).

NSAID-induced ulcer in gastric antrum, the most common in the present study, seemed to be harder to cure compared to NSAID-induced ulcers in the gastric corpus or gastric angle, as reported by Mizokami *et al*^[30].

Measures for responding to NSAID-induced lesions found in normal medical examinations will become increasingly important as society continues to age. This survey, conducted in accordance with the guidelines, proposes one direction for treatment.

ACKNOWLEDGMENTS

This survey was conducted in 38 medical facilities nationwide under the direction of the late Professor Shinichi Ota. We wish to express sincere gratitude to all the participating physicians as follows: Hiroyuki Hisai, Date Red Cross Hospital; Toshimi Chiba, Iwate Medical University Hospital; Harufumi Oizumi, Oizumi Gastrointestinal and Medical Clinic; Yuji Mizokami, Tokyo Medical University Kasumigaura Hospital; Hideharu Miyabayashi, National Hospital Organization Matsumoto National Hospital; Naoshi Nakamura, Marunouchi Hospital; Akihiko Suzuki, Japanese Red Cross Azumino Hospital; Yoshihiro Matsukawa, Nihon University Itabashi Hospital; Kazuo Kashiwazaki, Kyosai Tachikawa Hospital; Norihiko Tono-

COMMENTS

Background

A non-steroidal anti-inflammatory drug (NSAID) is widely prescribed for patients with rheumatoid arthritis, low back pain, etc. However, NSAID damages gastrointestinal mucosa and induces peptic ulcers. Use of a proton pump inhibitor (PPI) is recommended to cure those peptic ulcers.

Research frontiers

This multicenter study all over Japan revealed the safety profile and efficacy of rabeprazole, a type of PPI, for NSAID-induced ulcer.

Innovations and breakthroughs

This is one of the studies to investigate the safety profile and efficacy of rabeprazole for NSAID-induced ulcer.

Applications

Safety and efficacy of rabeprazole was comparable to other types of PPIs, which means more diversity of treatment options for patients suffering from NSAID-induced ulcer, and this is important since the number of patients using NSAIDs is expected to increase in the aging society in Japan.

Peer review

The manuscript by Mizokami provides the results of studies on the efficacy and safety of rabeprazole for ulcerous lesions in patients undergoing NSAID treatment. This is a reasonable study and the data are well presented.

Abstract

Many studies have established the role of radiofrequency (RF) ablation as a minimally invasive treatment for liver metastases. Although relatively safe, several complications have been reported with the increased use of RF ablation. We describe here a case of unexplained liver laceration after a RF procedure. A woman who presented a solitary metachronous liver metastasis underwent RF ablation treatment for this lesion. Six hours later the patient displayed fatigue and pallor. Emergency blood tests showed a haemoglobin level of < 7 g/dL and markedly elevated transaminase levels. A computed tomography examination revealed two areas of liver laceration with haematoma, one of them following the path of the needle and the other leading away from the first. Following a blood transfusion, the patient was haemodynamically stable and completely recovered 24 h later. The patient remained in bed for 1 wk. No surgical intervention was required, and she was discharged 1 wk later.

INTRODUCTION

Many studies have demonstrated the benefits of radiofrequency (RF) ablation as a minimally invasive treatment for hepatic metastases from colon carcinoma^[1-3]. Good outcomes with low morbidity and mortality have been identified. Therefore, the use of RF ablation is increasing in the field of oncology^[4,5]. Although a wide spectrum of complications has been described, all of these complications occur at low frequencies. Haemorrhage is the most common complication, mainly related to mechanical injury of the blood vessels in patients with cirrhosis, and it is probably exacerbated by a coagulation deficit and the rich blood supply of the tumour^[6].

We present here a case of multiple liver haematomas occurring as a secondary response to RF ablation of a solitary metastasis.

CASE REPORT

A 72-year-old woman underwent RF ablation for the treatment of a metachronous solitary liver metastasis from rectal adenocarcinoma, which had been treated 18 mo before with preoperative chemoradiotherapy and anterior resection. The lesion was located in segment VIII.

The procedure went well and the patient was initially haemodynamically stable. One hour later her condition suddenly worsened. She was clinically dizzy and had fatigue and pallor. We detected hypotension and tachycardia. Emergency blood tests showed a haemoglobin level of < 7 g/dL and markedly elevated transaminase levels. A computed tomography examination revealed an accumulation of intraperitoneal fluid in the pelvis and two liver haematomas. The images showed two liver lacerations, one following the path of the needle (Figure 1A-C) and another, unexplained laceration leading away from the first (Figure 2). The patient had no serious coughing or hiccupping after the RF treatment, or any other complications that might have caused increased abdominal pressure and tumour rupture.

Figure 1 Secondary lacerations resulting from a radiofrequency ablation procedure to treat a liver metastasis from colorectal adenocarcinoma. A: Image of liver laceration grade III in a central location (arrow); B: Image showing the first laceration following the path of the RF needle (arrow); C: Image of the first laceration in a lower liver tomography cut (arrow).

Figure 2 The second and unexplained liver laceration located in segments V-VI (arrow).

Subsequently, the patient received a blood transfusion and close monitoring. She was haemodynamically stable after the second blood transfusion and completely recovered 24 h later. The patient remained in bed for 1 wk. No surgical intervention was required.

DISCUSSION

RF ablation is a minimally invasive treatment of hepatic metastases from colon carcinoma, and can achieve good outcomes with low morbidity and mortality rates. Therefore, the use of RF ablation is increasing in the field of oncology^[1,2]. Although some studies which included large numbers of patients have found low rates of complications after RF ablation of hepatic tumors (ranging from 2.4% to 8.9%), the rate of intraperitoneal haemorrhage is low (0.46%-1.6%) but relevant because this technique is increasingly used with few selection criteria for patients^[6]. The etiology of this potentially grave complication is variable.

The reported reasons for haemorrhage are usually related to mechanical injuries to the liver blood vessels and occur most often in patients with cirrhosis, and are probably due to a coagulation deficit and the rich blood supply of the tumour^[4,6]. Other cases have been attributed to serious coughing or hiccups after the RF treatment^[7]. These complications might cause increased abdominal pressure and tumour rupture, particularly if the tumour location is near the capsule^[6].

Liver laceration has rarely been described as a cause of haemorrhage. Although this latter complication is very infrequent, it has been reported, and has been associated with inappropriate electrode positioning or mechanical injury of the soft liver during the procedure^[8]. Such mechanical injury can be induced by coughing or position changes, causing increasing abdominal pressure, and possibly displacing the electrode slightly^[8].

In our case the procedure went well, without incident, and the patient did not present any of the complications described above, such as coughing or hiccups. The tumour was not located near the capsule but at a depth within segment VIII.

We suggest that these two lacerations might have resulted from direct mechanical injury due to penetration by the electrode into liver tissues that were soft and damaged as a result of prior treatment with chemotherapy. The second laceration may have occurred due to difficulty in positioning the electrode to access such a profound lesion, causing liver disruption away from the first laceration.

Most haemorrhages require blood transfusions or surgical intervention^[6]. In our case the patient recovered spontaneously after blood transfusion and bed rest without the necessity of surgical intervention.

It is absolutely essential to minimise complications associated with RF ablation treatments, and to correctly deal with complications which do arise^[6]. The close observation of patients after RF ablation treatments, and early intervention to minimise the damage and severity of complications, are warranted.

producing adenocarcinoma and separated adenocarcinoma. *World J Gastroenterol* 2009; 15(40): 5106-5108 Available from: URL: <http://www.wjgnet.com/1007-9327/15/5106.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.5106>

INTRODUCTION

Choriocarcinoma is a rapidly growing, highly invasive, widely metastasizing neoplasm that derives from either trophoblastic or totipotential germ cells. It often arises in the uterus in association with pregnancy, and its most common extragonadal sites are the mediastinum, ovary and testis^[1].

Primary gastric choriocarcinoma (PGC) is a rare neoplasm that constitutes less than 1% of all gastric cancers^[2]. It was first described by Davidsohn in 1905 and more than 140 cases have been reported in the international medical literature. Several studies have indicated that the pathogenesis of PGC can be explained by the dedifferentiation of malignant adenocarcinoma tissue to the level of the embryonal ectoderm, and the retention of an ability to form trophoblasts^[3]. However, the clinicopathological and prognostic factors of PGC are unreliable because of the small numbers of PGC cases reported.

α -fetoprotein (AFP) is a fetal serum protein that is produced by fetal liver and yolk sac cells, and some fetal gastrointestinal cells. AFP levels decrease gradually after birth and reach adult levels at 8-12 mo. However, AFP levels are elevated in patients with hepatocellular carcinoma and in those with non-cancerous liver disease associated with liver regeneration. AFP-producing tumors have been reported in several different organs, and commonly in the stomach^[4-8]. The proportion of gastric cancers that secrete AFP has been reported to be 2.7%-8.0%^[9]. AFP-producing gastric carcinomas have high proliferative activity and are associated with low levels of apoptosis and rich neovascularization. They are divided into three subtypes: hepatoid, yolk sac tumor-like, and fetal gastrointestinal^[10]. Here, we report the case of a 70-year-old man with gastric choriocarcinoma admixed with AFP-producing adenocarcinoma.

Abstract

We report a case of gastric choriocarcinoma admixed with an α -fetoprotein (AFP)-producing adenocarcinoma. A 70-year-old man was hospitalized for gastric cancer that was detected during screening by esophagogastroduodenoscopy (EGD). Initial laboratory data showed the increased serum level of AFP and EGD revealed a 5-cm ulcerofungating mass in the greater curvature of the gastric antrum. The patient underwent radical subtotal gastrectomy with D2 lymph node dissection and Billroth II gastrojejunostomy. Histopathological evaluation confirmed double primary gastric cancer: gastric choriocarcinoma admixed with an AFP-producing adenocarcinoma and separated adenocarcinoma. At 2 wk postoperatively, his human chorionic gonadotropin and AFP levels had reduced and six cycles of adjuvant chemotherapy were initiated. No recurrence or distant metastasis was observed at 4 years postoperatively.

CASE REPORT

A 70-year-old man was referred to our hospital for

Figure 1 Gross pathology showed a 5.8 cm × 3.2 cm ulcerofungating mass in the antrum, with extensive hemorrhage and light gray fibrosis, and a 2.5 cm × 2.0 cm ulcerative lesion.

Figure 3 Immunohistochemical staining showed positive immunoreactivity for β-human chorionic gonadotropin (A) and focal positivity for α-fetoprotein (B).

gastric cancer that was detected during screening by esophagogastroduodenoscopy (EGD). No significant medical history was identified, except dysuria caused by bladder contraction. Initial laboratory data showed a serum level of AFP of 32.3 ng/mL (normal range: 0-15 ng/mL), but no other abnormality, which included other tumor markers, such as, carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA19-9). EGD revealed a 5-cm ulcerofungating mass that was comprised of three septate ulcers in the greater curvature of the gastric antrum. A pathological examination of endoscopic biopsy tissues confirmed the presence of moderately differentiated tubular adenocarcinoma. Subsequent abdominopelvic computed tomography visualized a gastric mass with deep ulceration in the gastric antrum with perigastric lymph node enlargement. No metastatic lesions were observed in the liver, lung or peritoneum, and chest radiography showed no significant findings.

Radical subtotal gastrectomy with D2 lymph node dissection and Billroth II gastrojejunostomy were performed. Grossly, the resected specimen contained double lesions: the first was a 5.8 cm × 3.2 cm ulcerofungating mass in the antrum, with extensive hemorrhage and light gray fibrosis; and the second was a nearby 2.5 cm × 2.0 cm ulcerative lesion (Figure 1).

Microscopically, massive numbers of pleomorphic,

Figure 2 Microscopically, massive numbers of pleomorphic, bizarre tumor cells with hemorrhage were revealed: syncytiotrophoblasts and cytotrophoblasts (HE, A × 40, B × 100).

bizarre tumor cells with hemorrhage (syncytiotrophoblasts and cytotrophoblasts) were observed in the first lesion. Hematoxylin and eosin (HE)-stained tissues revealed a bubbly purple cytoplasm and giant nuclei at a magnification of 40 × (Figure 2A) and 100 × (Figure 2B). The tumor involved the proper muscle layer (T2a) and metastasis was found in four of 56 regional lymph nodes (N1). Immunohistochemical staining showed positive immunoreactivity for β-human chorionic gonadotropin (HCG) (Figure 3A) and focal positivity for AFP (Figure 3B). These findings confirmed the presence of gastric choriocarcinoma that contained small foci of an AFP-producing adenocarcinoma. The second lesion was moderately differentiated tubular adenocarcinoma, which extended to the submucosal layer (T1b). It was close to, but distinct from the first lesion, which was negative by immunohistochemical staining for β-HCG and AFP.

The patient had an uneventful postoperative course and was discharged on postoperative day 9. Two weeks later, his HCG level was 176 mIU/mL (normal range: 0-10 mIU/mL) and his AFP level was 10.0 ng/mL. Six cycles of adjuvant chemotherapy with capecitabine (Xeloda; Hoffmann-La Roche Inc., Nutley, NJ, USA) was started at 2500 mg/m² per day for 14 d/cycle. After two cycles, his β-HCG level had declined to < 3 mIU/mL, and has since remained at this level. No recurrence or distant metastasis had occurred at his 4-year postoperative follow-up.

DISCUSSION

Several theories have been proposed to explain the histopathogenesis of primary choriocarcinoma of the stomach. These hypotheses include an origin from a gonadal angle displaced in the abdomen^[1], a histological resemblance to choriocarcinoma^[1], an origin from an underlying gastric teratoma^[12], and the dedifferentiation or opisthoplatia of carcinoma cells to the level of the embryonal ectoderm with an ability to form trophoblasts^[13]. Of these, the dedifferentiation theory, proposed by Pick in 1926, is accepted most widely. Based on the observation that many cases of PGC have been found with coexistent adenocarcinoma, Pick proposed that choriocarcinoma could arise by overgrowth

and elimination of the original adenocarcinoma^[4]. Furthermore, the findings of a comparative genomic hybridization and fluorescence *in situ* hybridization study by Liu *et al*^[14] support this theory; they have concluded that PGC possesses genetic characteristics of adenocarcinoma and gestational choriocarcinoma.

Applying the dedifferentiation theory proposed by Pick to the present case, we are led to consider that β -HCG-producing choriocarcinomas is dedifferentiated from AFP-producing adenocarcinomas. However, this is supposition and further studies on the pathogenesis of choriocarcinoma are required.

Of the three subtypes of AFP-producing gastric cancers, the described case was of the fetal gastrointestinal type that appeared to develop as a result of fetal gastrointestinal epithelium recapitulation in a tubular adenocarcinoma. The clinical implications of the three subtypes have not been evaluated, although the best-characterized hepatoid type, which is the most common, is known to have a high malignant potential and to be associated with poor survival^[15].

The prognosis of PGC is poor because of its high metastatic potential, especially to the liver, lung and regional lymph nodes, and most PGC patients succumb within a year of operation. Therefore, the treatment of choice for PGC is controversial, especially palliative gastric resection. However, in several cases, curative resection and adjuvant chemotherapy (such as 5-fluorouracil and cisplatin combination) have been found to promote long-term survival^[1].

Furthermore, survival for AFP-producing gastric cancer is also dismal because of the high risk of liver metastasis^[16]. A high proportion of patients with AFP-producing early gastric cancer that underwent curable resection died from liver metastasis^[17]. In the described case, the patient survived recurrence free without distant metastasis for more than 3 years after surgery and adjuvant chemotherapy.

In conclusion, the described case suggests that gastric choriocarcinoma admixed with an AFP-producing adenocarcinoma has a good prognosis. Curative resection, appropriate chemotherapy, and the absence of synchronous liver metastasis are considered favorable prognostic factors in PGC. Further evaluations of its pathogenesis and of the cause of its good prognosis are necessary.

INTRODUCTION

Abdominal computed tomography (CT) is currently considered the most sensitive radiological method for confirming intussusception^[1,2]. However, it is quite possible for colonoscopy to be selected as the initial diagnostic method when intussusception presents primarily as hematochezia. Colonoscopy may be useful for confirming the presence of intussusception, localizing the disease, and demonstrating the underlying organic lesion serving as the lead point. Intussusception might be misinterpreted as another lesion, such as a hematoma or polyp, on a colonoscopic examination, especially by an inexperienced endoscopist. Here, we report a colonoscopic feature of an intussuscepted Meckel's diverticulum, presenting with hematochezia, which was initially misinterpreted as a hematoma on colonoscopic examination.

CASE REPORT

A 35-year-old woman presented to the emergency room with acute onset hematochezia that occurred over a weekend. She first noticed the hematochezia accompanied by transient, sharp, severe epigastric pain 6 h earlier. On physical examination, she was a lean young woman with stable vital signs. Her abdomen was soft with no tenderness or muscle guarding. Bowel sounds were hypoactive with a normal pitch. Digital rectal examination showed bright red stools on the glove. Laboratory tests revealed normal peripheral blood cell counts and blood chemistry, except for leukocytosis with a white blood count of $145\,000/\text{mm}^3$. Because she was admitted at a weekend, endoscopy was performed by an inexperienced endoscopist who had trained at

Abstract

We report colonoscopic features of an intussuscepted Meckel's diverticulum, presenting with hematochezia. A 35-year-old woman presented to the emergency room with acute onset, transient, sharp, severe epigastric pain that began 6 h earlier. Colonoscopy revealed a reddish, soft, fist-sized polypoid lesion in the terminal ileum. The lesion was misinterpreted as a hematoma by an inexperienced endoscopist. The patient began to complain of intermittent, severe periumbilical pain following the colonoscopic examination. Subsequent computed tomography showed an enteric intussusception. An exploratory laparotomy revealed an intussuscepted Meckel's diverticulum, with transmural infarction. Colonoscopy was of little use in assessing the intussusception. However, colonoscopic examination may be performed initially, especially in an intussuscepted Meckel's diverticulum presenting with hematochezia. Endoscopists should note the endoscopic features of an intussuscepted Meckel's diverticulum.

Figure 1 A polypoid lesion in the terminal ileum.

Figure 2 Contrast-enhanced abdominal CT showed massive invagination of long segmental ileal loops.

our endoscopic center for 2 years. Gastroscopy was negative. Colonoscopy revealed blood and mucus throughout the colon. At colonoscopy, a reddish, soft, fist-sized polypoid was found 30 cm into the terminal ileum (Figure 1). Forcing forceps against the lesion depressed the lesion. The endoscopist tried to remove the lesion using various endoscopic accessories, because it was misdiagnosed as a hematoma. The patient began to complain of intermittent, severe periumbilical pain following the colonoscopic examination. Subsequent CT showed a typical inhomogeneous target-shaped soft-tissue mass with a layering effect, suggestive of enteric intussusception (Figure 2). An exploratory laparotomy revealed enteric intussusception, with gangrene. Segmental resection of the small intestine was performed. The pathology revealed an intussuscepted Meckel's diverticulum with transmural infarction along the antimesenteric border (Figure 3). Microscopic examination disclosed an ectopic gastric mucosa and a complete proper muscle layer in the diverticular wall (Figure 4). The patient had an uneventful postoperative course and was discharged on the ninth post-operative day.

DISCUSSION

Adult intussusception constitutes 5% of all cases of intussusception and accounts for only 1%-5% of intestinal obstructions in adults^[3]. Almost 90% of the cases of intussusception in adults are secondary to a pathological

Figure 3 Macroscopically, a diverticular sac was noted along the antimesenteric border. The entire wall of both the diverticulum and intestine was affected by hemorrhagic infarction and the luminal surfaces were covered with a necrotic exudate.

Figure 4 Microscopically, the diverticular sac was totally involved in transmural infarction. Its wall had a continuous proper muscle layer and heterotopic gastric mucosa (Inset). (HE, × 40; inset × 200).

condition that serves as a lead point, such as carcinomas, polyps, Meckel's diverticulum, colonic diverticulum, and strictures or benign tumors, which are usually discovered intraoperatively^[4-6]. A Meckel's diverticulum is a remnant of the omphalomesenteric duct, which is normally obliterated by the 5th-8th wk of gestation. It is seen in 2% of the population. The lifetime risk of complications in patients with a Meckel's diverticulum is only 4%^[7]. Thus, an intussuscepted Meckel's diverticulum is very rare, despite the well-known association of enteric intussusception and Meckel's diverticulum.

Abdominal CT can help to confirm the presence of intussusception and distinguish between lead point and non-lead point intussusception and can potentially eliminate unnecessary surgery^[7]. Colonoscopy is of little use for assessing intussusception. There are few reports on the colonoscopic features of an intussuscepted Meckel's diverticulum^[8,9]. An inexperienced endoscopist might be unfamiliar with these features, which appear to depend on the severity, chronicity, and etiology of the intussusception. A spring-shaped polypoid mass with surface erosion or a large number of blood vessels has been seen at colonoscopy in intussuscepted Meckel's diverticulum without complications^[8,9]. Incidental snare polypectomy might be performed in patients with

chronic intussusception that presents as a polypoid mass on a barium or endoscopic examination^[10]. This poses a high risk of perforation in a background of chronic tissue ischemia and possible necrosis of the intussuscepted bowel segment wall. An intussuscepted Meckel's diverticulum, with gangrene, such as in our case, might be misdiagnosed as a hematoma at colonoscopy, because of the severe hyperemic and edematous mucosal changes. In conclusion, endoscopists should be aware of the endoscopic features of an intussuscepted Meckel's diverticulum, because a colonoscopic examination can be performed initially, especially in an intussuscepted Meckel's diverticulum presenting with hematochezia.

INTRODUCTION

A previous study has shown that liver or combined liver-kidney transplantation can be a valuable surgical technique for the treatment of polycystic liver disease^[1]. Here, we present the case of a 35-year-old woman with polycystic liver disease, who underwent orthotopic liver transplantation (OLT) on November 11, 2008.

CASE REPORT

In October 2008, a 35-year-old woman with a body weight of 52 kg was admitted to the Liver Transplantation Center, the First Affiliated Hospital of Nanjing Medical University to undergo liver transplantation. This patient had a significant family history of polycystic disease, and her mother had died of dyscrasia that resulted from polycystic liver and kidney diseases. She had normal liver function [alanine aminotransferase (ALT) 35.7 U/L, aspartate aminotransferase (AST) 21.7 U/L, total bilirubin 16.5 μ mol/L, and prothrombin time 13.8 s], and normal renal function (urea 4.33 mmol/L, creatinine 77 μ mol/L, glomerular filtration rate 62.4 mL/min), but had dyspnea, anorexia, abdominal pain, hypertension, increased abdominal girth, mild ascites, and a liver span of 20 cm below the left costal margin and 25 cm below the right costal margin before transplantation. OLT was performed on November 11, 2008, and the whole-size graft was taken from a 51-year-old man who had died of a heart attack. The blood phenotypes of the donor and recipient were type A, RH (+). OLT was performed, but resection of the massive hepatomegaly was very difficult, because the enlarged polycystic liver occupied nearly the whole epigastric zone and mid abdomen (Figure 1A), which resulted in a small surgical space, especially for

Abstract

A previous study has shown that liver or combined liver-kidney transplantation can be a valuable surgical technique for the treatment of polycystic liver disease. Herein, we present the case of a 35-year-old woman with polycystic liver disease, who underwent orthotopic liver transplantation (OLT) on November 11, 2008. The whole-size graft was taken from a deceased donor (a 51-year-old man who died of a heart attack). Resection in a patient with massive hepatomegaly is very difficult. Thus, after intercepting the portal hepatic vein, left hepatectomy was performed, then the vena cava was intercepted, the second and third porta hepatic isolated, and finally, right hepatectomy was performed. OLT was performed successfully. The recipient did well after transplantation. This case suggested that OLT is an effective therapeutic option for polycystic liver disease and left hepatectomy can be performed first during OLT if the liver is over enlarged.

Key words: Hepatectomy; Liver transplantation; Polycystic liver

Figure 1 The liver before and after liver transplantation. A: Polycystic liver after cyst fenestration. The liver was still very large; B: The excised polycystic liver contained innumerable cysts; C: After OLT, the donor liver was much smaller than the recipient liver.

manipulation of hepatic blood vessels behind the liver. Thus, after intercepting the portal vein and vena cava, left hepatectomy was performed, followed by isolation of the hepatic veins and short hepatic veins at the posterior of the liver, and finally, right hepatectomy. OLT was then performed successfully (Figure 1C). The excised liver weighed 10.2 kg (approximate 20% of the body weight), which contained innumerable cysts and a large amount of cystic fluid (Figure 1B). The recipient did well after transplantation, and the hospitalization period was 21 d.

DISCUSSION

Polycystic liver disease is a rare, benign disorder^[2].

Symptoms of polycystic liver disease are related mainly to the size of the liver. Patients with massive hepatomegaly may suffer from abdominal pain, vena caval obstruction, hypertension, hemorrhage, cyst infections, dyspnea, increased abdominal girth, and poor quality of life^[3-6]. Cyst fenestration can be used to ameliorate the symptoms of massive hepatomegaly, but symptom relief is only temporary. Previous studies have shown that cyst aspiration, liver or combined liver-kidney transplantation may be a valuable surgical technique for the treatment of polycystic liver disease^[1,7]. The first patient to undergo liver transplantation for polycystic liver-kidney disease was in 1988, however, the patient died intraoperatively from intractable bleeding^[1].

In the present case, resection of massive hepatomegaly was very difficult, because the enlarged polycystic liver occupied nearly the whole epigastric zone and mid abdomen, therefore, the surgical space was very small, especially for manipulation of the hepatic veins and short hepatic veins at the posterior of the liver. During transplantation, cyst fenestration was used, but the volume of the liver could not be reduced significantly. Thus, after intercepting the portal vein and the vena cava, left hepatectomy was performed, followed by isolation of the hepatic veins and short hepatic veins, and finally, right hepatectomy. OLT was performed successfully. Left liver resection may be an effective treatment of choice, if the space is too small for manipulation of liver blood vessels behind the liver.

Abstract

Epidemiologic studies have suggested a relation between hepatitis C virus (HCV) infection and diabetes mellitus. HCV infection is emerging as a metabolic disease, and diabetes mellitus as a risk factor for HCV infection. However, some data on the prevalence of antibodies to HCV in patients with diabetes are conflicting. These seroprevalence data should be interpreted with caution. Some potential bias may occur in those clinic-based studies that target a specific disease group. In this letter we explain some reasons for these conflicting studies.

TO THE EDITOR

We read with great interest the article of Kaabia and collaborators^[1] and we congratulate them for the originality

of this interesting study in the Maghreb area. In this study, Kaabia and colleagues performed hepatitis C virus (HCV) screening in 1269 diabetic patients and 1315 non-diabetic patients, attending in the same health centers in Sousse, Tunisia. Authors found that the frequency of HCV antibodies was low in diabetic patients and in the control group, with no significant difference between the groups (1.3% *vs* 0.6%, $P = 0.057$).

The results of this study do not match those of several studies performed in numerous areas in the world, which found a higher prevalence of hepatitis C in diabetic patients^[2,3]. Moreover, in Kaabia's study, anti-HCV seroprevalence was significantly higher in type 2 diabetes sub-group than in the control group (1.4% *vs* 0.6%, $P = 0.04$). Anti-HCV seropositivity was detected only in one patient of 121 patients with type 1 diabetes, which was lower than in type 2 diabetes group, but the difference was not statistically significant (0.82% *vs* 1.4%, $P = 0.50$).

Kaabia's study has several deficiencies; their results must be interpreted with precaution. The diabetic patients were more aged than non-diabetic patients, it will be more interesting if the authors have compared the HCV seroprevalence between the two groups with age adjustment. Another bias of selection was introduced in this study by using the prevalence and not the incidence of HCV infection. Moreover, diabetes is an independent co-factor of fibrosis in chronic hepatitis C^[4], and in patients with cirrhosis the survival rate is reduced in case of associated diabetes^[5]. The hepatitis C prevalence is underestimated than in diabetic patients. Classification errors of diabetes could be made in the group of non-diabetics. Indeed the manner in which the diagnosis of diabetes was eliminated in this group was not specified in the article. Starting from the assumption that 50% of diabetics are not diagnosed, we wonder in which group the new cases of screening diabetes were classified? It is also impossible to establish a chronological relation between the diabetes and hepatitis C in this transversal study and it is possible that the infection by virus C precedes the occurring of diabetics. The authors have not compared the risk factors of hepatitis C in infected diabetic patients and in non-infected diabetic patients. Several studies found that diabetic patients infected with HCV had the same frequency in drug-addiction past and in blood transfusion than diabetic patients not infected with HCV. And these factors when they exist are present before the occurring of diabetes^[6].

Our group presented in 2006 in the ALFEDIAM Congress in Paris a study suggesting that the prevalence of hepatitis C is higher in Algerian diabetic patients^[7]. In

this retrospective study, we investigated hepatitis C virus markers in 739 patients attending internal medicine department of university hospital center of Batna (Algeria) from January to December 2005. One hundred and fifty nine patients (73 men and 86 women) with diabetes mellitus diagnosed by conventional criteria^[8] were studied. Their mean age was 60 years. Type 2 diabetes was present in 90% of patients. The control group consisted of 580 non-diabetic patients (229 men and 351 women). Their mean age was 50 years. Anti-HCV serology was determined in both groups using the third-generation micro-particle enzyme immunoassay. Anti-HCV seropositivity was 17.5% in diabetic patients and 8.4% in non-diabetic patients ($P < 0.01$). Despite our small size sample, we found a statistically significant higher prevalence of hepatitis C among diabetic patients. However, after adjustment for age, this difference is statistically significant only in patients aged between 40 and 65 years (22.2% *vs* 9.3%, $P = 0.024$).

Is diabetes mellitus a risk factor for HCV infection; or is this later a risk factor for type 2 diabetes mellitus? That is the question. Further studies are required to elucidate the mechanism of this interesting association.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (World J Gastroenterol ISSN 1007-9327, DOI: 10.3748) is a weekly, peer-reviewed, online, open-access (OA) journal supported by an editorial board of 1126 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in *WJG* will include the following. (1) Editorial: to introduce and comment on major advances in rapidly developing areas and their importance. (2) Frontier: to review recent developments and comment on current research status in important fields, and propose directions for future research. (3) Topic Highlight: this column consists of three formats, including: (a) 10 invited review articles on a hot topic; (b) a commentary on common issues associated with this hot topic; and (c) a commentary on the 10 individual articles. (4) Observation: to update the development of old and new questions, highlight unsolved problems, and provide strategies for their resolution. (5) Guidelines for Basic Research: as suggested by the title. (6) Guidelines for Clinical Practice: to provide guidelines for clinical diagnosis and treatment. (7) Review: to review systemically the most representative progress and unsolved problems, comment on current research status, and make suggestions for future work. (8) Original Article: to report original and innovative findings. (9) Brief Articles: to report briefly on novel and innovative findings. (10) Case Report: To report a rare or typical case. (11) Letters to the Editor: to discuss and reply to contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest. (12) Book Reviews: to introduce and comment on quality monographs. (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities on basic research and clinical practice

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments,

References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS AND DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of *P* values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as 1F , 2F , 3F ; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Patent (list all authors)

- 16 **Pagedas AC,** inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at <http://www.wjgnet.com/wjg/help/14.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No.62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Telephone: +86-10-59080039

Fax: +86-10-85381893

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Language evaluation

The language of a manuscript will be graded before it is sent for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.
