Early symptoms of an iliopsoas hematoma include groin pain and femoral neuropathy. The present patient was in a drowsy state of consciousness due to shock when he was referred to our hospital. Stools were positive for blood, and therefore, only examinations for upper gastrointestinal tract were performed, and no specific findings were obtained. Unfortunately, the upper abdominal CT scan area did not involve the iliopsoas muscles.

As shown in Table 1, a review of the literature revealed 8 cases of spontaneous muscle hematoma associated with liver cirrhosis, including the present case (Table 1)^[6-11]. Of these cases, 4 involved the rectus abdominis muscle^[6-9], 3 (including the present case) involved the iliopsoas^[8,10], and one involved the gluteus maximus, the biceps femoris and the pectoralis muscles^[11]. The mean age of these patients was 55.8 years old. Five of the 8 cases were male (62.5%) and 3 were female (37.5%). Six of the 8 cases were Japanese and the others were Caucasian. Alcoholic cirrhosis accounted for 75% of the cases (6 of 8 cases), and virus-related cirrhosis (virus unknown) and a combination of hepatitis C- and alcohol-related cirrhosis each accounted for 12.5% of the cases (1 each out of 8 cases).

The mortality rate of muscle hematoma associated with cirrhosis was 75% (6 of 8 cases), which is extremely high. All 3 patients with iliopsoas hematoma and 2 of the 4 patients with rectus abdominis muscle hematoma (50%) died. Cherry and Mueller^[3] reported that rectus abdominis muscle hematoma is rarely fatal based on a large series of patients from a single institution (mortality rate 1.6%, 2 of 126 cases), most of whom were on various anti-coagulant therapies. Furthermore, the mortality rate of iliopsoas hematoma associated with hemophilia is extremely low after the induction of prophylaxis^[2]. According to a review of iliopsoas hematomas in patients receiving intravenous heparin^[5], only one of 54 patients (1.9%) died. In these

reports, it was generally accepted that early recognition and diagnosis of rectus abdominis and/or iliopsoas hematoma could reduce mortality.

As shown in Table 1, intramuscular hematoma in patients with liver cirrhosis was diagnosed on the day of onset in 6 of the 8 cases (75%). The exceptions included case #5 (diagnosed at 6 d after the onset) and case #7 (the present case, which was diagnosed by autopsy). The Model for End-stage Liver Disease (MELD)^[12] and recently reported MELD-Na^[13] scores could be calculated in 4 (#2, #5, #7, #8) and 3 (#5, #7, #8) patients, respectively. The mean MELD and MELD-Na scores were 23.5 (range: 16–29) and 23.3 (range: 16–29), respectively, thus suggesting that the probability of death at 90 d (%) ranged from about 4% to 25%^[13]. These findings indicate that intramuscular hemorrhage associated with cirrhosis is lethal despite an early diagnosis, even in patients with low MELD or MELD-Na scores.

Huang *et al*^[14] reported interesting findings concerning spontaneous intracranial hemorrhage (SICH) in 4515 hospitalized Chinese cirrhotic patients. Among these patients, 36 experienced SICH and 78% were male. The etiology of cirrhosis included alcoholic cirrhosis in 50% of the patients, virus-related cirrhosis in 27.8%, and combined virus- and alcohol-related cirrhosis in 22.2%. The mean age at onset of SICH in cirrhosis was 53 years. They reported that the overall incidence of SICH in cirrhosis was related to the etiology of cirrhosis, and the incidence of SICH was 6 times higher in alcohol-related cirrhosis than in virus-related cirrhosis. These results are consistent with the present findings on muscle hematoma associated with cirrhosis. It seems likely that a common risk factor, namely alcohol, plays an important role in the promotion of non-variceal hemorrhage in cirrhotic patients. Several actions of alcohol may promote hemorrhage, including the inhibition of platelet adhesion to fibrinogen^[15], dose-related ethanol suppression of platelet aggregation induced by extravasation^[16], and the promotion of atherosclerosis^[17]. However, the participation of these factors in the pathogenesis is still unknown in patients with alcoholic cirrhosis. Among these cases, 6 of 8 were

reported in Japan, thus suggesting that intramuscular hematoma and/or SICH with cirrhosis may occur more frequently in Asians than in other ethnicities.

Treatment of muscle hematoma in cirrhotic patients is often challenging. Many factors, including poor general condition due to cirrhosis, lead to poor outcomes. Hematomas might improve with conservative management, as observed in case #3 in Table 1. Zissin *et al*^[18] reported in a literature review that 19 of 26 patients (73%) recovered following transcatheter arterial embolization (TAE) in anticoagulant-related rectus abdominis and iliopsoas hematoma. TAE may be useful for patients in poor condition, although it was unsuccessful in a case of cirrhosis (case #6)^[8]. Urgent liver transplantation, which was performed in case #4^[9], may be a treatment choice in the future. The bleeding site was detected by angiography in only 1 case of iliopsoas hematoma (#6). In this case, two regions of extravasation of the ilio-lumbar arterial branches were observed and TAE was performed. In the other cases, the origin of the bleeding could not be detected even at autopsy. This difficulty is one challenge associated with the treatment of this condition. Additional cases could provide further insight into effective treatment methods.

In general, intramuscular hematoma is not mentioned as one of the bleeding complications occurring in cirrhotic patients^[1]. Intramuscular hematoma may occur easily by daily motion. For example, a case of rectus abdominis hemorrhage (#3) occurred after an episode of coughing. Taking into account the extremely high mortality rate despite early diagnosis and relatively low risk scores, intramuscular hematoma should be recognized as a rare but clinically important bleeding complication of cirrhosis, especially in cases of alcoholic cirrhosis.

In conclusion, a bilateral iliopsoas hematoma was observed in a patient with alcoholic liver cirrhosis. A review of the literature on intramuscular hemorrhage in cirrhotic patients suggested that alcohol is the common risk factor. In addition, a higher incidence was observed in Asians. This literature review also indicated that muscle hematoma in cases of cirrhosis has a serious prognosis that is quite different from the prognosis

of hematomas in patients with hemophilia or under anticoagulant therapy. We should therefore always include muscle hematoma in the differential diagnosis of acute anemia in liver, especially alcoholic, cirrhosis.

Abstract

Pneumatic dilation (PD) is considered to be a safe and effective first line therapy for achalasia. The major adverse event caused by PD is esophageal perforation but an immediate gastrografen test may not always detect a perforation. It has been reported that delayed management of perforation for more than 24 h is associated with high mortality. Surgery is the treatment of choice within 24 h, but the management of delayed perforation remains controversial. Hereby, we report a delayed presentation of intrathoracic esophageal perforation following PD in a 48-year-old woman who suffered from achalasia. She completely recovered after intensive medical care. A review of the literature is also discussed.

INTRODUCTION

Esophageal achalasia is an inflammatory disease characterized by esophageal aperistalsis and failure of complete LES relaxation due to loss of the inhibitory intrinsic neurons of the esophageal myenteric plexus^[1,2]. Pneumatic dilation (PD) is considered to be the first line therapy for achalasia^[3,4]. Esophageal perforation could be a hazardous event if left untreated after PD^[5]. Usually, gastrografen is ingested immediately after each PD to detect extravasations which imply perforation.

However, on rare occasions, immediate gastrografen ingestion may not always detect a perforation which could become clinically evident several hours later resulting in a delayed presentation (more than 24 h)^[6]. Hereby we report our experience in treating an achalasia patient who suffered from delayed clinical presentation of intrathoracic esophageal perforation after PD but healed after intensive medical care.

CASE REPORT

The 48-year-old female, who had a history of surgery for uterine myoma status for 2 years, was referred to our hospital due to esophageal stenosis. She suffered from progressive symptoms of dysphagia for liquid and solid foods, chest pain and food regurgitation for the previous 6 mo. She also complained of gradual body weight loss of 5 kg during this period. She had no family history of gastrointestinal cancer. Physical examination revealed an unhealthy, conscious woman with stable vital signs. The laboratory data were as follows: white blood cell count: 4.1×10^3 cells/ μ L (normal 3.5-11 cells/ μ L), hemoglobin: 10.5 g/dL (normal 12-16 g/dL), hematocrit: 32% (normal 36%-46%), mean corpuscular volume: $69.3 \mu\text{m}^3$ (normal $80-100 \mu\text{m}^3$), platelet count: $18.8 \times 10^3/\mu\text{L}$ (normal $15-40 \times 10^3/\mu\text{L}$), sodium: 142 mmol/L

Figure 1 Barium esophagogram before and after pneumatic dilations. A: Barium esophagogram before pneumatic dilations revealed a dilated distal esophageal lumen with bird-beak signs (arrow); B: Ingestion of gastrografin revealed no obvious immediate leakage of contrast medium immediately after pneumatic dilation (arrow).

Figure 2 Chest radiograph revealed left side pleural effusion, left lower lobe consolidation and air-fluid level over retrocardiac region air fluid level over the retrosternal area (arrow).

(134-148 mmol/L), potassium: 3.7 mmol/L (normal 3.0-4.8 mmol/L). A barium esophagogram revealed a dilated distal esophageal lumen with food retention at a narrowing of the gastroesophageal junction (Figure 1A). Achalasia was confirmed using manometric findings of esophageal aperistalsis and incomplete relaxation of the lower esophageal sphincter during wet swallowing. The residual pressure was about 10 mmHg but the basal lower esophageal sphincter pressure was about 45 mmHg. Achalasia caused by tumors was excluded by computed tomography (CT). The patient received PD with a 3-cm "Regiflex" dilator. Routine gastrografin ingestion showed no sign of immediate leakage of contrast (Figure 1B). She was fine after PD with only mild chest pain and asked to be scheduled for discharge. Her vital signs remained stable in the next 24 h following PD.

Unfortunately, severe chest pain occurred 6 h later with fever up to 38°C. Chest radiograph revealed left side pleural effusion, left lower lobe consolidation and air-fluid level over retrocardiac region air fluid level over the retrosternal area (Figure 2). The chest CT revealed esophageal dilatation suspicious of rupture of the lower esophagus with prominent pleural effusion and fluid collection over the middle and lower mediastinum (Figure 3). Due to rapid progression of the dyspneic condition and high fever to 40°C, a chest drainage tube was placed immediately. Intravenous broad-spectrum antibiotics were also given immediately. She was then

Figure 3 CT revealed esophageal dilatation and a rupture of the lower esophagus (arrow) with prominent pleural effusion (P) and fluid collection over the middle and lower mediastinum.

transferred to the cardiovascular surgery intensive care unit. She refused to receive any surgical intervention. Total parenteral nutrition was given via the venous route to ensure an appropriate nutrition supply. Fortunately, her condition improved gradually 2 wk later. A barium esophagogram revealed a dilated esophagus without any contrast leakage and absence of bird-beak signs. She was discharged safely another 2 wk later. She remained in clinical remission status 8 years after PD.

DISCUSSION

Esophageal perforation is a relatively uncommon complication even though many diagnostic and therapeutic procedures in daily practice require the passing of instruments through the esophagus, such as endoscope-guided PD for this lady who suffered from esophageal achalasia. The signs and symptoms of esophageal perforation are non-specific but may include pain, fever, dyspnea, vomiting, crepitus, and shock^[6]. Despite prompt treatment and improved management, the mortality of esophageal perforation is still significant^[7]. The esophagus lacks a serosal layer and the adventitia of the esophagus is contiguous with the connective tissue of the mediastinum. As a result, esophageal perforation allows the leakage of food residues, saliva, oropharyngeal bacteria and digestive enzymes into the mediastinum and chest cavity. Severe adverse events such as mediastinitis, pleural emphysema, empyema, or subdiaphragmatic abscess may occur rapidly in delayed diagnosed and managed patients^[8]. The impact of delayed recognition is decreasing despite the high incidence of complications. Reeder and colleagues reported a 29% mortality rate following late diagnosis^[9]. The most important predictor of treatment outcome depends on the time interval from perforation to treatment. It has been reported that delayed management of perforation for more than 24 h is associated with a 3-5 fold increase in mortality.

The diagnosis of delayed presentation of esophageal rupture remains a clinical challenge because of the non-specific findings of this rare clinical condition. Ingestion of water-soluble gastrografin immediately after each PD

is a standard examination to avoid possible extravasation of barium-containing agents that may cause serious mediastinitis^[10]. Imaging studies provide a reliable way to make a definite diagnosis of esophageal perforation. Contrast leakage on imaging studies suggests leakage of gastric juice and other substance into the mediastinum and causes the inflammatory process. Unfortunately, an immediate gastrografen test may not always detect a perforation which could become clinically evident several hours later and this must be kept in mind. Absence of contrast leakage may suggest a small or a sealed-off perforation. This may result in the tricky delayed clinical presentations following dilations. This explains the initial stable subjective and objective conditions that occurred in our patient following PD. Buecker and colleagues suggest that a negative gastrografen study should be followed-up with a barium study to increase sensitivity^[11] but then the patient may be at risk of severe mediastinitis.

The management of esophageal perforations includes fluid resuscitation, antibiotics, gastric decompression, and surgery. Broad-spectrum antibiotics that cover Gram-positive, Gram-negative, and anaerobic organisms should be started and tailored to culture results^[7]. Surgery is the treatment of choice within 24 h, but the management of delayed perforation remains controversial. Quintana and colleagues reported the mortality rate in patients with prompt surgical treatment ranged from 0% to 34%, and those without immediate treatment 68.7%-75%^[12].

However, Younes and colleagues advocated that patients with mild fever, absence of shock and sepsis might be considered for conservative management^[13]. There was no difference in mortality rate between surgery and medical treatment in these two publications^[12,13]. The other theoretical issue is whether the perforation would heal in the presence of distal obstruction, which this patient potentially had before PD as a result of her underlying achalasia; however the follow-up esophagogram revealed patency of the distal lumen. All the above favorable factors were probably the main reasons for the recovery of our patient despite her refusal of surgery. Therefore, intensive non-surgical treatment may be another option for treatment with a favorable outcome in selected patients with a good general health status.

The sizes of the balloons and the techniques of the procedure are relevant to esophageal perforation in treating achalasia under the guidance of a fluoroscope or endoscope^[3,14-16]. Graded PD with a 30 mm diameter and slower rate of balloon inflation is an effective and safe initial method of therapy for achalasia. The potential danger in increased risk of perforation is likely to interfere with the effect of dilation toward the side of the endoscope, and this can be compromising and lead to a decrease in overall efficacy of the procedure and the possibility of generating an unequal radial force on the sphincter^[17].

In summary, early identification of a delayed presentation of intrathoracic esophageal perforation requires premeditated consideration and is crucial for a favorable outcome. However, an immediate contrast study may not always detect a perforation which can

become clinically evident several hours later. Therefore, close observation of clinical symptoms and signs such as severe chest pain and fever implying potential perforations is mandatory after PD. Surgery is the treatment of choice within 24 h. Intensive non-surgical treatment could be another option for treatment with a favorable outcome in selected patients with a good general health status.

Abstract

A 55-year-old male patient with hepatitis B-related liver cirrhosis was found to have advanced hepatocellular carcinoma. His AFP was initially 9828 $\mu\text{g/L}$ and rapidly dropped to 5597 $\mu\text{g/L}$ in ten days after oral sorafenib treatment. However, he developed acute renal failure, hyperkalemia, and hyperuricemia 30 d after receiving the sorafenib treatment. Tumor lysis syndrome was suspected and intensive hemodialysis was performed. Despite intensive hemodialysis and other supportive therapy, he developed multiple organ failure (liver, renal, and respiratory failure) and metabolic acidosis. The patient expired 13 d after admission.

INTRODUCTION

Molecular targeted therapy is currently the new treatment modality for advanced cancer. Sorafenib is an oral multi-kinase inhibitor that blocks tumor growth and cell proliferation by targeting Raf kinase, VEGFR-2, VEGFR-3, and PDGFR- β ^[1]. Sorafenib was approved by the FDA in 2007 to treat hepatocellular carcinoma (HCC)^[2]. An uncontrolled sorafenib phase II study in 137 patients with advanced HCCs confirmed that the higher pERK patients had a longer time to progression compared to the lower pERK patients^[3,4]. Therefore, sorafenib is a specific target drug for the Raf/MEK/ERK pathway and pERK could be a useful biomarker. Sorafenib showed efficacy in prolonging patients' survival in a previous SHARP trial^[5]. The study obtained an overall 44.9% improvement and the sorafenib group had a partial response rate of 2.3% ($n = 7$) vs placebo of 0.7% ($n = 2$). Sorafenib opens a new era for advanced HCC treatment. However, that sorafenib might induce tumor lysis syndrome (TLS) had never been reported in previous studies. Here, we report sorafenib induced TLS in an advanced HCC male patient. This reported case developed multiple organ failure (liver failure, renal failure and respiratory failure) and metabolic acidosis. Despite intensive hemodialysis and other supportive therapy, he succumbed to the complication of tumor lysis syndrome.

CASE REPORT

A 55-year-old male hepatitis B carrier visited our Clinic with the symptoms of general fatigue, abdominal fullness, poor appetite and body weight loss of 5 kg over 2 mo. An abdominal sonography showed multiple mixed-hypoechoic masses (larger than 12 cm in aggregated diameter or more than 50% of whole liver capacity) involving both lobes of the liver. Additionally, there was left portal vein thrombosis and decompensated cirrhosis with ascites. Laboratory data showed that HBeAg was negative, creatinine was 106 (97-133) $\mu\text{mol/L}$. AST was 435 (0-38) U/L, ALT was 79 (0-44) U/L, total bilirubin was 74 (10-24) $\mu\text{mol/L}$, prothrombin time was 12.7 s (control was 10.7 s), albumin was 37 (35-50) g/L, and α -feto protein (AFP) was 9828.63 (1.09-8.04) $\mu\text{g/L}$. The Child-Turcotte-Pugh score was eight. His abdominal triphase computed tomography

Figure 1 Abdominal computed tomography showing bilateral multiple hepatic tumors with left side portal vein thrombosis and mild ascites.

(CT) confirmed the sonography findings, namely, advanced HCC in a background of liver cirrhosis (Figure 1). He was given oral sorafenib 400 mg twice every day and oral diuretics (furosemide 40 mg once, spironolactone 25 mg three times every day since February 28, 2009). Ten days later (March 9, 2009), his AFP level dropped to 5597.52 $\mu\text{g/L}$ and his creatinine level was 80 $\mu\text{mol/L}$. Thirty days after he received sorafenib treatment, he was found to have profound jaundice with total bilirubin of 344 (10–24) $\mu\text{mol/L}$, decreased urine output, and general weakness. Abdominal sonography showed no ascites. The laboratory data revealed a creatinine level of 177 $\mu\text{mol/L}$, BUN at 34 (3.6–7.1) mmol/L, serum sodium at 112 (135–148) mmol/L, potassium at 7.0 (3.5–5.3) mmol/L, ammonia at 92 (16–41) $\mu\text{mol/L}$, AST at 698 (0–38) U/L, and ALT at 297 (0–44) U/L. Acute renal failure with hyperkalemia was diagnosed and he was treated intravenously with calcium gluconate, sodium bicarbonate, glucose water with insulin, corticosteroid, and oral kalimate (calcium polystyrene sulfonate). The HBV DNA (Simens, VERSAN® HBV DNA 3.0, Australia) was shown to be 48 800 IU/ml (273 288 copies/mL) and antiviral therapy with entecavir (0.5 mg on day one, followed by 0.5 mg every 3 d) for the suspicion of liver failure secondary to hepatitis B exacerbation. On the next day, his serum potassium was 7.2 (3.5–5.3) mmol/L. Emergency hemodialysis began and sorafenib treatment was discontinued. On the next day, his serum potassium dropped to 4.5 mmol/L, sodium to 128 mmol/L, uric acid to 547 (238–506) $\mu\text{mol/L}$, and his creatinine level was 248 $\mu\text{mol/L}$. Half of the previous dose of sorafenib was restarted with hydration of 2000–3000 mL saline for suspicious dehydration and diuretics were discontinued. Two days later, his potassium level had increased to 5.0 mmol/L, uric acid was 851 $\mu\text{mol/L}$, phosphorus was 5.4 mmol/L (2.7–4.5) and his creatinine level was 309 $\mu\text{mol/L}$. Recurrence of TLS was suspected and sorafenib was discontinued. Allopurinol 300 mg (*po* st) and 600 mg (*po* every day) was started. Another course of emergency hemodialysis was performed after the patient failed to respond to the medication. His general

condition stabilized but multiple organ failure and metabolic acidosis persisted, despite another course of hemodialysis. He expired 13 d after admission.

DISCUSSION

Tumor lysis syndrome (TLS) is a life threatening oncological emergency. It is the result of rapid breakdown of tumor cells with release of cellular contents, such as potassium, uric acid, phosphate, purine, and proteins into the circulation^[6]. Risk factors for TLS include the following: (1) hematological malignancy; (2) high proliferation rate tumors; (3) chemo- or radio-sensitive tumors; (4) large tumor burden; and (5) dehydrated state or patients with preexisting renal impairment^[6,7]. In hematological malignancy, TLS may develop rapidly within 24–48 h or it may develop one week after effective chemotherapy. HCC is a solid tumor with slower growth rate than that of hematological malignancies. Therefore, the TLS developed one month after treatment with sorafenib in this case. His renal function was within normal limits before, and 10 d after, treatment. The occurrence of TLS in this patient could be the combination of effective therapy due to sorafenib chemosensitivity of the HCC, the use of diuretics with secondary dehydration, and advanced HCC with large tumor burden. Diuretics induced secondary dehydration could result in acute renal failure, but after effective hydration and supportive therapy, hyperkalemia and hyperuricemia persisted. Therefore, sorafenib induced TLS was the more likely cause of the symptoms described.

The degree of abnormalities in his uric acid and potassium fulfill the criteria of TLS as defined by Cairo-Bishop^[8]; however, our case had no initial calcium data due to hyperkalemia treated with calcium gluconate. The initial serum calcium was 2.32 (2.2–2.6) mmol/L and dropped to 1.65 mmol/L ten days later. The decrease of calcium level over 25% also matched the Cairo-Bishop definition of TLS^[8]. Hypophosphatemia did happen in the sorafenib treatment group (11/297) *vs* control group (2/302) ($P < 0.001$) in Llovet *et al*'s SHARP study^[5]. Phosphorus in our case was 5.4 (2.7–4.5) mmol/L and did not go over 6.5 mmol/L as Cairo-Bishop definition of TLS, which might be the result of sorafenib effect.

The prognosis of TLS is poor with a high mortality rate in solid tumor. Prevention of TLS by hydration, alkalization, or therapy to correct metabolic disturbance can be effective for some hematological malignancies^[6–9]. Based on previous reports, hemodialysis can be helpful in improving the clinical course and can even cure TLS in some patients^[6–10]. This case had a satisfactory initial course following the sorafenib therapy; however, his condition deteriorated after TLS developed. Llovet *et al*^[5] reported that sorafenib could significantly extend median survival and prolong the time of radiologically evidenced progression by approximately three months compared with a placebo in individuals with advanced hepatocellular carcinoma (HCC) with well-preserved

liver function, naive to systemic therapy. In comparison with the control group given the placebo, they reported that sorafenib was significantly associated with more diarrhea of any grade, weight loss, hand-foot skin reaction, alopecia, anorexia, and voice changes^[5]. However, in their report, TLS was not mentioned. We believed that TLS is a rare side effect of sorafenib treatment. Once it occurred, however, TLS can induce multiple organ failure with a catastrophic outcome.

In conclusion, in the therapy of HCC with sorafenib, especially in patients with high tumor burden and showing a good initial response, the possible occurrence of TLS should be kept in mind and appropriate laboratory data should be monitored. Once TLS developed, the prognosis was poor even when intensive hemodialysis was given.

Abstract

A patient with obstructive jaundice was examined by multidetector row helical computed tomography (MDCT) and magnetic resonance imaging (MRI), and his common bile duct was observed to be leading into the distal portion of the horizontal duodenum with a pancreaticobiliary union outside the duodenal wall. A mass was also found in the proximal jejunum. All the above findings were confirmed by subsequent surgery, thus contrast-enhanced MDCT and MRI with appropriate image post-processing could provide non-invasive and accurate information regarding anatomy and lesions of the pancreaticobiliary duct and duodenal union, which may improve the feasibility of surgery and reduce postoperative complications.

INTRODUCTION

Anomalous termination of the common bile duct

(CBD) is not an uncommon anatomical variation with incidence ranging from 5.6% to 23%^[1-3]. Pancreaticobiliary maljunction (PBM) is a congenital anomaly in which the pancreatic duct meets the bile duct outside of the duodenal wall. Previous studies using endoscopic retrograde cholangiopancreatography (ERCP) found some sporadic cases. As ERCP is invasive with serious complications, e.g. pancreatitis, computed tomography (CT) or magnetic resonance imaging (MRI) may be another diagnostic choice for these patients. However, few studies up till now have reported such cases by CT or MRI. This study reports findings of both multidetector row helical computed tomography (MDCT) and MRI in a patient with anomalous termination of CBD, PBM and proximal jejunal adenoma. Both MDCT and MRI provide non-invasive and accurate information about anatomy and lesions of the pancreaticobiliary duct and duodenal union (PDDU).

CASE REPORT

A 71-year-old woman presented with icteric skin and sclera for the past three months without fever, abdominal pain or distention, nausea or vomiting. Physical examination revealed no abdominal tenderness or mass. On admission, total and direct bilirubin levels were 138.5 $\mu\text{mol/L}$ and 120 $\mu\text{mol/L}$ respectively, alanine aminotransferase was 78 IU/L, aspartate aminotransferase was 184 IU/L, alkaline phosphatase was 1031 IU/L, and carcinoembryonic antigen and α -fetoprotein levels were within normal values. She had a history of cholecystectomy 18 years ago. MDCT and MRI were performed within a week. The scan parameters for the MDCT scanner (Sensation 16, Siemens Medical Solutions, Siemens, Germany) included 120 kVp, 121-124 mAs, 5-mm slice thickness, 1-mm reconstructive thickness, and a table speed of 24 mm/s (pitch, 1). Non-ionic contrast material 90 mL (Iohexol, 300 mg I/mL) was injected at a flow rate of 3 mL/s. The MR (1.5-T, Siemens Sonata, Siemens, Germany, Leonardo work station) scanning protocol included unenhanced axial T2W scan (HASTE; TR/TE, 6379 ms/83 ms), coronal T2W imaging (True-FISP; TR/TE, 3.8 ms/1.9 ms), magnetic resonance cholangiopancreatography (TSE; TR/TE, 100 ms/1.8 ms), axial T1W (GRE, TR/TE, 100 ms/1.8 ms, 70° flip angle) and Gadolinium-enhanced three-dimensional VIBE (TR/TE, 4.8 ms/2.2 ms, 70° flip angle) information. The images were retrospectively reviewed in consen-

Figure 1 Anomalous junction of the common bile duct and main pancreatic duct. A: CT scan shows the junction of the common bile duct and main pancreatic duct below the level of the uncinate process (arrow); B and C: Axial MR images show the junction of the common bile duct and main pancreatic duct (arrows). (These photographs were processed by Adobe Photoshop Creative Suite 2.).

Figure 2 Anomalous termination of the common bile duct. A: Axial image from CT scan shows the termination of the common bile duct at the distal portion of the horizontal part of the duodenum (arrow); B and C: MR images demonstrate a tapered configuration of the common bile duct (black arrows) and a mass located on the proximal jejunum (white arrows). (These photographs were processed by Adobe Photoshop Creative Suite 2.).

Figure 3 Dilated pancreatic and biliary ducts with ectopic drainage. A: Coronal MDCT image of CT reveals a low termination of the common bile duct (arrow); B and C: Coronal MR images show ectopic pancreaticobiliary junction, low termination of the common bile duct (black arrows), and the mass (white arrows) located on the proximal jejunum; D: MRCP shows dilated pancreatic and biliary ducts. (These photographs were processed by Adobe Photoshop Creative Suite 2.).

sus by two experienced radiologists who were unaware of other imaging and surgical findings.

On the continuous transverse images of MDCT and MR, the CBD which was joined by the main pancreatic duct (MPD) outside the duodenal wall below the level of the uncinate process (Figure 1) was found to terminate at the distal portion of the horizontal duodenum (Figure 2). The coronal images of MDCT and MR, as well as MRCP images, showed a more clear presentation than transverse images regarding the ectopic pancreaticobiliary junction and low termination of the CBD at the horizontal duodenum (Figure 3). Both MPD and extra-

and intrahepatic ducts showed extensive dilatation. The CBD was 2.4 cm at the largest diameter with a tapered configuration of the distal portion (Figure 2B and C). A discrete mass, surgically proven to be jejunal adenoma, was detected in the vicinity of the duodenojejunal flexure without dilatation of the proximal gut, but with adhesion to the proximal jejunum (Figure 2B and C). The mass was enhanced heterogeneously on contrast-enhanced CT and MR images.

During subsequent operation, the CBD was found to be dilated and it extended along the duodenum and terminated at the horizontal duodenum.

DISCUSSION

In 75% of cases, the common bile duct enters the posteromedial aspect of the descending duodenum through an intramural common channel called the hepatopancreatic ampulla (ampulla of Vater), where the CBD is joined by the main pancreatic duct and the terminal pancreatic duct is inferior and anterior to the CBD^[4]. But the CBD can terminate at anomalous sites, including the third or fourth part of the duodenum, pyloric canal, duodenal bulb, or stomach^[5,6-9]. The union of the pancreatic and biliary ducts can also locate outside the duodenal wall forming a very long common channel (usually more than 15 mm), which is representative of the appearance of a PBM.

The cause of an anomalous pancreaticobiliary system has been ascribed to unidentified abnormalities during embryogenesis. The ventral diverticulum of the foregut forms the liver, gallbladder, bile ducts and ventral pancreas. Abnormalities of the pancreaticobiliary junctions occur where these are demarcated. Boyden produced a hypothesis that ectopic bile duct drainage occurs because of the disproportional elongation and early subdivision of the primitive hepatic diverticulum which divides into the pars hepatica and pars cystica^[10,11].

Multiple modalities permit depiction of the anatomy and lesions of the PDDU, including abdominal ultrasonography, ERCP, CT and MRI. Sonographic images often do not clearly display PBM and ectopic termination of the CBD, and ERCP is invasive and can be associated with significant complications, such as a 1% to 13.5% incidence of post-ERCP pancreatitis^[12]. In contrast, MDCT and MRI are modern and non-invasive techniques revealing more anatomical details with no risk of procedure-induced complications. With appropriate image post-processing, MDCT and MRI may provide prompt identification of anatomy and abnormalities of the biliary and pancreatic ducts and the surrounding structures, which would help endoscopists and surgeons to discern the anatomy requiring special attention during ERCP operation, choledochoscopic exploration, endoscopic and choledochoscopic papillotomy and local resection of PDDU carcinomas. CT and MRI examinations can also offer valuable information in adults with underlying abnormalities of the pancreatic duct or biliary duct when the symptoms and signs are nonspecific (intermittent abdominal pain, occasional jaundice and cholangitis).

Based on the density of bile, it is easy to differentiate the CBD from surrounding soft tissue and trace its course until its termination on CT images. In high-spatial-resolution CT, the MPD and pancreaticobiliary junction can be well observed. MR imaging combined with magnetic resonance cholangiopancreatography (MRCP) has a distinctive advantage in revealing the pancreaticobiliary system. In terms of the intensity of bile, pancreatic and intestinal juice, the configuration and courses of the CBD, MPD, and enteric gut can be directly observed. At the same time, transverse images can offer additional information about the surrounding tissue and show tiny structures at the termination. In

the present case, tracing the CBD from the level below the hepatic hilum until the third part of the duodenum in continuous planar, the termination was found at the distal aspect of the horizontal duodenum on CT and MR transverse images. This was clearer on coronal images than on transverse and MRCP images. Dilated CBD and pancreatic duct made it easy and definite to determine the area of termination. The union of the pancreatic and biliary ducts was seen to be located outside the duodenal wall.

Extensive dilatation of the pancreaticobiliary ducts accompanied by a mass located on the proximal jejunum was another characteristic finding in our case. Because the gut proximal to the adenoma showed no dilatation and the CBD revealed a tapered end, it could be concluded that dilatation of the pancreaticobiliary ducts was not the result of the space-occupied mass. Miyano *et al.*^[13] reported that the majority of patients with PBM in their study showed evidence of proximal biliary dilatation. Babbitt^[14] proposed that PBM might be the etiology of choledochal dilatation and cyst formation. The resultant injury to the choledochus from enzymatic bilio-pancreatic reflux may then cause choledochal dilatation, choledochal fibrosis without dilatation, and possibly biliary atresia^[15]. PBM may result in the frequent occurrence of biliary carcinoma and pancreatitis^[16,17]. In this case, a PBM was found which may have been the cause of choledochal dilatation associated with choledochal injury and fibrosis and bile stasis, but there was no choledochal cyst formation, biliary carcinoma or pancreatitis. With bilio-pancreatic reflux, hypertension of the pancreatic duct could also result in dilatation of the MPD.

In summary, MDCT and MR imaging, with appropriate image post-processing, could provide non-invasive and accurate information about anatomy and lesions of the PDDU, which may improve the feasibility of surgery and reduce postoperative complications.

Abstract

AIM: To analyze papers published in the *World Journal of Gastroenterology* (*WJG*) from 2006 to 2007. We investigated the highly cited papers for geographic distribution of the cited authors, as well as the distribution of the citing journals and year of citation.

METHODS: Papers published in *WJG* from 2006 to 2007 and their citations were retrieved from the Science Citation Index Expanded (SCIE). The papers and their citations were analyzed according to bibliometric methods, including the number of citations for a given paper, the distribution of the highly cited papers, the geographic distribution of the cited authors, and the years of citation.

RESULTS: Two thousand five hundred and six papers published in *WJG* from 2006 to 2007 were collected through SCIE, and 2335 of these were categorized as articles, reviews or proceedings. In 2006 and 2007, the average citation rate was 85.08% and 70.48%, respectively, and the average number of citations per paper was 4.33 and 2.51. Among the 2506 papers, 1963 were cited 8788 times by other articles. The mean number of citations per paper was 3.51. The papers with over three citations accounted for 54.72% of all those that were cited, and the total number of citations accounted for 85.38% of the total of 8788 citations. Thirteen papers were cited over 30 times and the highest number of citations for any one paper was 98. The cited authors came from 70 different

countries or regions, with China, Japan and the United States being the most frequent. The highest average citation rate and number of citations per paper were for authors from Canada (96.30%, 6.89), Hungary (92.31%, 5.62), Australia (88.46%, 5.46), Germany (87.04%, 5.33), and Spain (87.50%, 5.11). The impact factor was 2.081 and the self-citation rate was 9.41% in 2008. The papers published in *WJG* in 2006-2007 were cited by 1597 journals.

CONCLUSION: The papers in *WJG* have a high number of citations, and have been cited in numerous journals by authors from various countries. The results imply that *WJG* has an influential academic profile in gastroenterology around the world.

INTRODUCTION

In the natural sciences, especially in basic and life sciences, journals have never attracted more attention. The content and academic quality of journals is emphasized, and the academic profile of a journal can be evaluated through citation analysis of a given journal's papers, as well as the journal impact factor. The pertinent indexes for evaluating a scientific journal involve the publisher of the journal, its academic background, reputation of the authors, the number of times that papers are cited, and the journal impact factor^[1]. Some of these indexes may evaluate subjectively the journal impact in a qualitative manner, and some may measure quantitatively the general profile or average level of the

journal papers^[2]. The reputation of scientific journals, types of papers in a given journal, the number of papers in a given journal, the citation rate, and the number of times each paper is cited are all essential indicators of the quality of scientific journals.

The current study analyzed several features of papers published in *World Journal of Gastroenterology* (WJG), including the citation rate of the published papers, the average number of times a given paper was cited, the geographic distribution of the cited authors, the year of citation, and the distribution of the citing journals so that we can understand the character of WJG. The results will be of interest to the editors of WJG and its readers.

MATERIALS AND METHODS

The Science Citation Index Expanded (SCIE) is a sophisticated database established by the Institute for Scientific Information^[3], and is an essential tool for evaluating papers in renowned journals. The current study analyzed features of papers published in WJG with the aid of the search function of the SCIE.

The SCIE was accessed with the Web of Science. SCIE was searched using “World Journal of Gastroenterology” for the publication title and “2006-2007” for publication year. From the papers retrieved, we selected the following information: author(s), title, source, document type, address, cited times and ISSN. The retrieved data were downloaded, saved and managed with the Microsoft Excel.

There were some limitations to the data process:

- (1) we analyzed only the address of the corresponding author, and not that of all the authors in the paper; and
- (2) all the papers from WJG and their references were retrieved on May 4, 2009.

RESULTS

Outline of papers published in WJG 2006-2007

Two thousand five hundred and six papers were published in WJG in 2006-2007, including 1311 papers from the categories of article, review and proceedings in 2006 and 1024 from these categories in 2007. Among these papers, 1963 were cited 8788 times by SCIE. The mean number of citations was 3.51 per paper. The highest number of citations for any one paper was 98. The papers with one citation accounted for 25.11% of the total number of cited papers; those with two, 20.17%; those with three, 54.72%; and those with over three, 85.38% (Table 1). Thirteen papers were cited over 30 times (Table 2).

Citation analysis of papers published in WJG 2006-2007

Among the 2506 papers, nine belonged to the “other” category, which included author’s feedback, book reviews, commentaries, editorial announcements, memorials, and news. Within the other 15 categories in WJG, viral hepatitis, reviews and editorials had high citation rates of 92.73%, 92.86% and 92.31%,

Table 1 Citation frequency of papers published in WJG 2006-2007

Cited times	No. of cited articles		No. of cited times	
	Count	Percent (%)	Count	Percent (%)
1	493	25.11	493	5.61
2	396	20.17	792	9.01
3	270	13.75	810	9.22
4	175	8.91	700	7.97
5	160	8.15	800	9.10
6	107	5.45	642	7.31
7	77	3.92	539	6.13
8	56	2.85	448	5.10
9	41	2.09	369	4.20
10	42	2.14	420	4.78
11-20	111	5.65	1720	19.57
21-30	23	1.17	546	6.21
31-40	9	0.46	316	3.60
41-100	3	0.15	193	2.20
Total	1963	100.00	8788	100.00

respectively. The highest average number of citations for the top three columns was 8.89 for reviews, 6.43 for editorials, and 6.00 for topic highlights. The citation rates for case reports and letters to the editor were low, at 64.15% and 54.55%, respectively. Their average number of citations was 1.66 and 1.43, respectively, which were far lower than the total citation rate (78.33%) and average number of citations (3.51) (Table 3). In 2006 and 2007, the total citation rate (with the “other” category excluded) was 85.08% and 70.48%, and the total average number of citations was 4.33 and 2.51.

Geographic distribution of cited authors

The cited authors came from 70 countries. Twenty-nine countries or areas had over 10 cited papers, 11 countries between 5-9 papers, and 29 countries 1-4 papers. China, Japan and the United States were ranked as the top three countries according to the highest total number of citations. The countries with the highest citation rates and average number of citations per paper included Canada (96.30% and 6.89), Hungary (92.31% and 5.62), Australia (88.46% and 5.46), Germany (87.04% and 5.33), and Spain (87.50% and 5.11) (Table 4).

Year of citation for papers published in WJG 2006-2007

The year of citation is shown in Table 5. In 2008, papers published in 2006 and 2007 were cited 3079 and 1780 times, respectively. In 2009, the figures so far are 1101 and 931, respectively. From 2006 to 2009, the self citation rate was 22.16%, 11.33%, 9.41% and 5.01%, respectively.

Distribution of citing journals

The 8788 citations from WJG 2006-2007 were in 1597 journals (Table 6). The *American Journal of Gastroenterology*, *Alimentary Pharmacology & Therapeutics*, *Gastrointestinal Endoscopy* cited papers from WJG most often. Twelve journals each had 40-49 citations from WJG, nine journals had 30-39 citations, 27 journals had 20-29 citations, 115 journals had 10-19 citations, 245 journals

Table 2 List of papers published in *WJG* 2006-2007 with over 30 citations

had 5-9 citations, 115 journals had four citations, 172 journals had three citations, 285 journals had two citations; and 598 journals had only one citation. These citations were in a wide range of related journals, which implies that *WJG* has a widespread academic impact.

DISCUSSION

The frequency with which papers from a given journal are cited is a measure of the academic profile and quality of the journal^[4]. It is accepted widely that the academic quality of a journal is correlated positively with number of cited numbers in the journal. In citation analysis of papers published from 2006 to 2007 in *WJG*, 78.33% of all published papers were cited by a journal included in SCIE. Table 1 shows that 1074 papers were cited more than three times, with a total of 7503 citations. These accounted for 54.72% of all papers and 85.38%

of the total number of citations. The highest number of citations for one paper was 98, and papers that were cited more than four times accounted for 40.96%.

The use of subsections or categories is useful for reflecting the scope of a given journal. The editors need periodically to evaluate their choice of subsections to facilitate development of the journal, enable academic exchange and attract the attention of readers with different information needs. Among all the categories in *WJG*, reviews, editorials, topic highlights and esophageal cancer were of most interest to readers. Papers in these categories showed a high citation rate and high average number of citations. However, the categories of *H pylori*, rapid communications, case reports, letters to the editor and leading articles had fewer citations, which may have resulted from the types of papers and current research trends, and deserves further attention from the journal editors.

Table 4 Geographic distribution of cited authors

Rank	Area	Paper	No. of cited papers	Percent (%)	Cited times	Average citations per paper	Rank	Area	Paper	No. of cited papers	Percent (%)	Cited times	Average citations per paper

17	Pancreas	53	0.60
18	Revista Espanola de Enfermedades Digestivas	52	0.59
19	Journal of Gastroenterology	51	0.58
	Total	2125	24.18

The authors of articles published in *WJG* were from a wide range of countries. From 2006 to 2007, China, Japan, Germany, Italy, USA and Turkey were ranked the top six countries by the number of papers and total number of citations^[5]. The authors cited in *WJG*

were also from a large range of 70 countries or regions. The papers written by authors from Canada, Hungary, Australia, Germany and Spain also had a high number of citations.

The impact factor is a routine bibliometric index to evaluate the academic profile of journals. Similar to the number of cited papers, the impact factor is correlated positively with the academic impact. According the criteria for measuring the impact factor in the Journal Citation Report, only the paper types of article, review, and proceedings are taken into account for calculations. The impact factor of *WJG* in 2008 was 2.081 $[(3079 + 1780)/(1311 + 1024) = 2.081]$. Regarding publication year, the number of times a paper was cited was low in the year of publication. In the following 2 years, the number of citations increased rapidly, which is consistent with the finding that the peak number of citations is within 2 or 3 years for most publications^[6,7].

The number of journals that cite papers from a given journal reflects the academic profile of the journal, its influence, its impact on some specialties, and its attraction to readers from different fields. The papers published in *WJG* in 2006-2007 were cited 8788 times in 1597 journals. Given the wide range of citing papers and journals, as well as the large proportion of citations in the same field, it is clear that *WJG* has a widespread influence.

In conclusion, the setting of the subsections in *WJG* is appropriate. With a high self-citation rate, and citations in papers from different countries and different journals,

it appears that *WJG* is already on the right road and its academic impact and profile are expanding gradually.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (World J Gastroenterol ISSN 1007-9327, DOI: 10.3748) is a weekly, peer-reviewed, online, open-access (OA) journal supported by an editorial board of 1126 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in *WJG* will include the following. (1) Editorial: to introduce and comment on major advances in rapidly developing areas and their importance. (2) Frontier: to review recent developments and comment on current research status in important fields, and propose directions for future research. (3) Topic Highlight: this column consists of three formats, including: (a) 10 invited review articles on a hot topic; (b) a commentary on common issues associated with this hot topic; and (c) a commentary on the 10 individual articles. (4) Observation: to update the development of old and new questions, highlight unsolved problems, and provide strategies for their resolution. (5) Guidelines for Basic Research: as suggested by the title. (6) Guidelines for Clinical Practice: to provide guidelines for clinical diagnosis and treatment. (7) Review: to review systemically the most representative progress and unsolved problems, comment on current research status, and make suggestions for future work. (8) Original Article: to report original and innovative findings. (9) Brief Articles: to report briefly on novel and innovative findings. (10) Case Report: To report a rare or typical case. (11) Letters to the Editor: to discuss and reply to contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest. (12) Book Reviews: to introduce and comment on quality monographs. (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities on basic research and clinical practice

The WJG Press and Baishideng

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments,

References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS AND DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of *P* values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as 1F , 2F , 3F ; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at <http://www.wjgnet.com/wjg/help/14.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No.62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Telephone: +86-10-59080039

Fax: +86-10-85381893

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Language evaluation

The language of a manuscript will be graded before it is sent for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

World Journal of Gastroenterology®

Weekly Established in October 1995

Volume 15 Number 36
September 28, 2009

Contents

EDITORIAL

- 4481 Antioxidant therapy in the management of acute, chronic and post-ERCP pancreatitis: A systematic review
Mohseni Salehi Monfared SS, Vahidi H, Abdolghaffari AH, Nikfar S, Abdollahi M

REVIEW

- 4491 Adenosine: An immune modulator of inflammatory bowel diseases
Ye JH, Rajendran VM

ORIGINAL ARTICLES

- 4499 Iron increases HMOX1 and decreases hepatitis C viral expression in HCV-expressing cells
Hou WH, Rossi L, Shan Y, Zheng JY, Lambrecht RW, Bonkovsky HL
- 4511 EGFR and HER2 expression in advanced biliary tract cancer
Harder J, Waiz O, Otto F, Geissler M, Olschewski M, Weinhold B, Blum HE, Schmitt-Graeff A, Opitz OG
- 4518 Protein interaction network related to *Helicobacter pylori* infection response
Kim KK, Kim HB
- 4529 Attenuation of portal hypertension by natural taurine in rats with liver cirrhosis
Liang J, Deng X, Lin ZX, Zhao LC, Zhang XL
- 4538 Induction of apoptosis and cell cycle arrest in human HCC MHCC97H cells with *Chrysanthemum indicum* extract
Li ZF, Wang ZD, Ji YY, Zhang S, Huang C, Li J, Xia XM
- 4547 Effects of lysophosphatidic acid on human colon cancer cells and its mechanisms of action
Sun H, Ren J, Zhu Q, Kong FZ, Wu L, Pan BR

BRIEF ARTICLES

- 4556 Early graft dysfunction following adult-to-adult living-related liver transplantation: Predictive factors and outcomes
Gruttadauria S, di Francesco F, Vizzini GB, Luca A, Spada M, Cintonino D, Li Petri S, Pietrosi G, Pagano D, Gridelli B
- 4561 COX-2 polymorphisms -765G→C and -1195A→G and colorectal cancer risk
Hoff JH, te Morsche RHM, Roelofs HMJ, van der Logt EMJ, Nagengast FM, Peters WHM

Contents		<i>World Journal of Gastroenterology</i> Volume 15 Number 36 September 28, 2009
	<p>4566 Lack of correlation between <i>p53</i> codon 72 polymorphism and anal cancer risk <i>Contu SS, Agnes G, Damin AP, Contu PC, Rosito MA, Alexandre CO, Damin DC</i></p> <p>4571 Hemoperfusion with polymyxin B-immobilized fiber column improves liver function after ischemia-reperfusion injury <i>Sato H, Oshima K, Kobayashi K, Yamazaki H, Suto Y, Takeyoshi I</i></p> <p>4576 Epithelioid angiomyolipoma of the liver: Cross-sectional imaging findings of 10 immunohistochemically-verified cases <i>Xu PJ, Shan Y, Yan FH, Ji Y, Ding Y, Zhou ML</i></p> <p>4582 Effect of preoperative transcatheter arterial chemoembolization on angiogenesis of hepatocellular carcinoma cells <i>Xiao EH, Guo D, Bian DJ</i></p>	
CASE REPORT	<p>4587 Pseudolymphoma of the liver associated with primary biliary cirrhosis: A case report and review of literature <i>Okada T, Mibayashi H, Hasatani K, Hayashi Y, Tsuji S, Kaneko Y, Yoshimitsu M, Tani T, Zen Y, Yamagishi M</i></p> <p>4593 Repetitive response to gemcitabine that led to curative resection in cholangiocarcinoma <i>Kim SH, Kim IH, Kim SW, Lee SO</i></p> <p>4596 Post-gastrectomy acute pancreatitis in a patient with gastric carcinoma and pancreas divisum <i>Kuo IM, Wang F, Liu KH, Jan YY</i></p> <p>4601 Hemorrhagic hepatic cysts mimicking biliary cystadenoma <i>Zhang YL, Yuan L, Shen F, Wang Y</i></p>	
ACKNOWLEDGMENTS	4604 Acknowledgments to reviewers of <i>World Journal of Gastroenterology</i>	
APPENDIX	<p>4605 Meetings</p> <p>4606 Instructions to authors</p>

INSIDE BACK COVER	Online Submissions	
INSIDE FRONT COVER	Online Submissions	

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

EDITORS FOR THIS ISSUE

Responsible Assistant Editor: *Xiao-Fang Lin*
Responsible Electronic Editor: *Wen-Hua Ma*
Proofing Editor-in-Chief: *Lian-Sheng Ma*

Responsible Science Editor: *Lai-Fu Li*
Proofing Editorial Office Director: *Jian-Xia Cheng*

Furthermore, antioxidant therapy including allopurinol and N-acetylcysteine failed to prevent the onset of PEP in almost all trials. In conclusion, the present data do not support a benefit of antioxidant therapy alone or in combination with conventional therapy in the management of AP, CP or PEP. Further double blind, randomized, placebo-controlled clinical trials with large sample size need to be conducted.

Antioxidant therapy in the management of acute, chronic and post-ERCP pancreatitis: A systematic review. *World J Gastroenterol* 2009; 15(36): 4481-4490 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4481.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4481>

Abstract

We systematically reviewed the clinical trials which recruited antioxidants in the therapy of pancreatitis and evaluated whether antioxidants improve the outcome of patients with pancreatitis. Electronic bibliographic databases were searched for any studies which investigated the use of antioxidants in the management of acute pancreatitis (AP) or chronic pancreatitis (CP) and in the prevention of post-endoscopic retrograde cholangio-pancreatography (post-ERCP) pancreatitis (PEP) up to February 2009. Twenty-two randomized, placebo-controlled, clinical trials met our criteria and were included in the review. Except for a cocktail of antioxidants which showed improvement in outcomes in three different clinical trials, the results of the administration of other antioxidants in both AP and CP clinical trials were incongruent and heterogeneous.

INTRODUCTION

Pancreatitis, both chronic and acute, contributes to thousands of annual hospital admissions and consecutive complications^[1]. Acute pancreatitis (AP), an acute inflammatory condition, is thought to be due to activation of enzymes in the pancreatic acinar cells, with inflammation spreading into the surrounding tissues^[2]. Patients with AP were either treated with strict bowel rest or given parenteral nutrition to allow the pancreas to rest until the serum enzyme levels returned to normal^[3]. Chronic pancreatitis (CP) is a progressive inflammatory disorder that is characterized by recurrent episodes of severe abdominal pain. Affected patients typically suffer years of disabling pain, and conventional therapeutic interventions are often unable to offer satisfactory analgesia^[4].

Oxidative stress caused by short lived intracellular reactive oxygen and nitrogen species, can oxidize lipids in the cell membrane, proteins, depolarize the mitochondrial

membrane, and induce DNA fragmentation. Active free radicals in the body can be produced during diseases or exposure to xenobiotics^[5,6].

Basic and clinical evidence suggests that the pathogenesis of both AP and CP can be associated with oxidative stress seeming independent of the etiology of pancreatitis, because oxidative stress is observed in different experimental pancreatitis models^[7,8]. Findings show that free radical activity and oxidative stress indices such as lipid peroxide levels are higher in the blood and duodenal juice of patients with AP or CP^[9,10].

Based on the mentioned findings, the idea of using antioxidant regimens in the management of both AP and CP as a supplement and complementary in combination with its traditional therapy is rational and reasonable. As a result of this hypothesis, antioxidant therapy should improve the inflammatory process that is involved in pancreatitis and therefore ameliorate the recovery rate.

In addition, pancreatitis is the most common serious complication of endoscopic retrograde cholangiopancreatography (ERCP), occurring in 1%-7% of cases^[11]. Although, the exact mechanisms involved in the pathophysiology of post-ERCP pancreatitis (PEP) are not clear, the role of oxidative stress cannot be neglected. Therefore, the use of antioxidants before, during or after this intervention has already been studied in a few clinical trials^[12,13]. Although some clinical trials have proved the benefits of using various antioxidants in AP or CP, there are still controversies^[14].

To our knowledge, there is no definite consensus on the benefits of antioxidant therapy in the management of AP or CP. Our objective was to systematically review and summarize the literature on antioxidant therapies for AP and CP as well as PEP, to provide recommendations for future research.

METHODS

PubMed, Scopus, Google Scholar, Cochrane library database, and Evidence based medicine reviews were searched for any relevant studies that investigated the use of antioxidants in the management of AP or CP and in the prevention of PEP up to February 2009. We also hand-searched references in key articles. The search terms were: AP or CP, pancreatic inflammation, antioxidant, vitamin, superoxide dismutase, manganese, glutamine, butylated hydroxyanisole, taurine, glutathione, curcumin, catalase, peroxidase, lutein, xanthophylls, zeaxanthin, selenium, riboflavin, zinc, carotenoid, cobalamin, retinol, alpha-tocopherol, ascorbic acid, beta-carotene, carotene and all MeSH terms for pharmacologically active antioxidants. Studies were limited to clinical trials and those written in the English language.

To assess the quality of clinical trials, we employed the Jadad score, a previously validated instrument that assesses trials based on appropriate randomization, blinding, and description of study withdrawals or dropouts^[15]. The description of this score is as follows: (1) whether randomized (yes = 1 point, no = 0); (2) whether

randomization was described appropriately (yes = 1 point, no = 0); (3) double-blind (yes = 1 point, no = 0); (4) was the double-blinding described appropriately (yes = 1 point, no = 0); (5) whether withdrawals and dropouts were described (yes = 1 point, no = 0). The quality score ranges from 0 to 5 points; a low-quality report score is ≤ 2 and a high-quality report score is at least 3.

Data synthesis was conducted by three reviewers who read the title and abstract of the search results separately to eliminate duplicates, reviews, case studies, and uncontrolled trials. The inclusion criteria were that the studies should be clinical trials which used an antioxidant for the treatment or prevention of pancreatitis. Outcomes of the studies were not the point of selection and all studies that analyzed the effects of an antioxidant on pancreatitis, from pain reduction^[16] to changes in plasma cytokines, were included.

Data from selected studies were extracted in the form of 2×2 tables. All included studies were weighted and pooled. The data were analyzed using Statsdirect (2.7.3). Relative risk (RR) and 95% confidence intervals (95% CI) were calculated using the Mantel-Haenszel and DerSimonian-Laird methods. The Cochran Q test was used to test heterogeneity. The event rate in the experimental (intervention) group against the event rate in the control group was calculated using L'Abbe plot as an aid to explore the heterogeneity of effect estimates. Funnel plot analysis was used as a publication bias indicator.

RESULTS AND DISCUSSION

A total of 211 potentially relevant papers were identified, of which 22 papers were eligible^[4,16-36]. Amongst the 22 papers, 19 (86%) scored 3 and only three studies^[17,25,31] scored 2 or lower according to the Jadad score. Table 1 presents controlled clinical trials of antioxidants in patients with AP or CP. Trials that used antioxidants to prevent PEP are summarized in Table 2. To perform a meta-analysis we included only four studies in which allopurinol was used in PEP.

Antioxidants in AP and CP

Glutamine: Glutamine is the most abundant amino acid both in plasma and in the intracellular free amino acid pool. It is essential for a wide variety of physiologic processes, in particular, the growth and function of immune cells including lymphocytes and macrophages^[17]. Glutamine is normally synthesized *de novo* by a number of cells and therefore is not an essential amino acid. Although glutamine is an antioxidant, in conditions of excess glutamine utilization such as sepsis, trauma, major surgery or severe AP, endogenous glutamine production may not be adequate and glutamine depletion occurs^[23].

In four studies^[17,18,22,23] glutamine was supplemented to standard total parenteral nutrition (TPN) in AP patients. In one randomized controlled study ($n = 28$), glutamine was used in AP in combination with standard TPN and demonstrated a decrease in the duration of TPN therapy and hospitalization without a change in the total

¹Significant increase as compared with control; ²Significant decrease as compared with control; ³No significant difference between groups. PEP: Post endoscopic pancreatitis.

cost of parenteral feeding^[22]. Another similar study ($n = 44$) showed that even though TPN therapy containing glutamine reduces infectious morbidity, it has no significant effect on hospitalization and total mortality^[18]. However, both studies showed laboratory improvement in AP after administration of glutamine such as an increase in serum albumin or decrease in C-reaction protein (CRP).

Proinflammatory cytokine release was assessed in another study with a small patient number ($n = 14$). Glutamine supplementation did not significantly influence tumor necrosis factor- α or interleukin (IL)-6 release, but, in contrast, median IL-8 release was reduced by day 7 in the glutamine group while it was increased in the conventional group^[23]. Another non-blinded study examined the administration of glutamine in AP for 10 d starting either on the day of admission or 5 d after admission. Investigators reported an improvement in all clinical findings including hospitalization, infection, and mortality rate^[17]. No adverse effects were reported in these trials.

Allopurinol: Allopurinol, a xanthine oxidase inhibitor that historically has been effective in preventing attacks of acute gouty arthritis, is an effective anti-oxidant with anti-apoptotic effects. It has been shown that allopurinol is a hydroxyl radical scavenger^[37,38]. Two studies used allopurinol to reduce chronic pain in CP^[24,27]. In one clinical trial ($n = 78$), CP patients with chronic pain were admitted to hospital and received an analgesic regimen of pethidine with or without allopurinol. Their results showed that allopurinol could reduce pain and gastric tenderness. Hospitalization was also decreased in allopurinol-treated patients^[27]. Another clinical study ($n = 13$) showed that 4 wk of allopurinol administration did not reduce pain in CP when compared with placebo^[24]. Allergy, general malaise, and gastrointestinal disturbances were adverse events of allopurinol.

Vitamin C: Ascorbic acid or vitamin C is a monosaccharide antioxidant. This water-soluble vitamin is a reducing agent and can neutralize oxygen species. Vitamin C is an important antioxidant which protects the body from damage caused by inflammation, and high-dose vitamin C can improve immune function^[21]. Vitamin C alone was only investigated in one study and other studies used vitamin C in combination with other antioxidants which will be discussed later. In one randomized study ($n = 83$), 10 g/d of vitamin C was used intravenously compared to 1 g/d of vitamin C in the control group for 5 d in patients with AP. Their results indicated that 10 g vitamin C decreases hospitalization and duration of disease, and increases the cure rate. Proinflammatory cytokines and CRP were also diminished by vitamin C administration^[21].

Combined antioxidants (selenium, β -carotene, vitamin C, vitamin E and methionine): A combination of various antioxidants including selenium, β -carotene, vitamin C, vitamin E, and methionine was studied in three controlled clinical trials^[4,16,28]. In the first

clinical trial, the efficacy of antioxidant therapy in the management of pancreatitis was determined using the above combination in CP patients ($n = 28$). Their results showed that this cocktail can reduce the pain which is experienced by patients^[28]. Another study with a slightly larger sample size ($n = 36$) used the above combination at the same doses but with greater bioavailability in CP patients. In this trial, congruent with the previous trial, pain was reduced after 10 wk of the combined antioxidants. Indeed, quality of life, physical and social functioning, and health perception were also enhanced as a result of antioxidant therapy^[4]. The latest published controlled clinical trial in the field of antioxidants and pancreatitis has also used this combination at the same doses as the previous studies. In this larger clinical trial ($n = 147$), the antioxidants were administered for 6 mo, and showed that, similar to the two preceding trials, pain and hospitalization were reduced^[16]. All three studies showed that serum concentrations of the above-mentioned antioxidants were higher after a period of intake and laboratory indices of oxidative stress markers such as lipid peroxidation, free radical activity, and total antioxidant capacity improved after therapy. Another cohort study which is not presented in Table 1 examined this combination of antioxidants in 12 CP patients and showed that this combination reduces pain and hospitalization^[39]. Headache, nausea, vomiting, and constipation were some of the adverse effects of this combination. A clinical trial studied the effect of selenium, vitamin C and N-acetylcysteine (NAC) combination for 7 d in 43 AP patients. All primary endpoints including hospitalization, Acute Physiology and Chronic Health Evaluation II score, and organ dysfunction were statistically similar between the placebo and antioxidant-treated groups^[19].

Curcumin: Curcumin is a polyphenolic compound commonly found in the dietary spice turmeric^[40]. Curcumin is an inhibitor of nuclear factor- κ B and has various biological activities such as anti-inflammatory, antioxidant, antiseptic, and anticancer activity^[41]. In the one available pilot study ($n = 20$), patients with CP received 500 mg of curcumin with 5 mg of piperine or placebo for 6 wk. There was a significant reduction in erythrocyte malondialdehyde levels following curcumin therapy when compared with placebo. A significant increase in glutathione (GSH) levels was also observed. There was no corresponding improvement in pain and no adverse effects were reported^[20].

Glutathione precursors [S-adenosyl methionine (S-AdoMet)]: S-AdoMet, a highly bioactive metabolite of methionine is a precursor of glutathione, which is the key defense against reactive species. Of the two clinical trials that examined S-AdoMet in pancreatitis, in one, S-AdoMet was administered to AP patients^[25] and in the other, S-AdoMet was administered to CP patients^[26]. S-AdoMet did not enhance the clinical outcomes in either AP or CP patients. However, laboratory indices such as free radical activity were better after 10 wk of S-AdoMet administration

Figure 1 Individual and pooled relative risk (A), heterogeneity indicators (B), and publication bias indicators (C) for the outcome “prevention of all kinds of pancreatitis” in the studies considering allopurinol vs placebo therapy.

in CP patients. Methionine in combination with other antioxidants was discussed previously under the topic of combined antioxidants.

Antioxidants in PEP

NAC: NAC is a free radical scavenger capable of stimulating glutathione synthesis. NAC was used in two clinical trials. In one of these trial ($n = 106$), 600 mg NAC was given orally 24 h and 12 h before ERCP and 600 mg was given intravenously, twice a day for 2 d after ERCP. Their results showed that the rate of PEP was not significantly reduced. In addition, urine amylase activity, total bilirubin, alanine, aspartate aminotransferases and white blood cells showed no change^[31].

In the other double-blind, placebo-controlled trial ($n = 256$), patients received intravenous NAC at a loading dose of 70 mg/kg 2 h before and 35 mg/kg at 4-h intervals for a total of 24 h after the procedure. Similar to the previous study, there were no statistical differences in the incidence or severity of PEP grades between the groups. The mean duration of hospitalization for pancreatitis was not different in the NAC group as compared to the placebo group^[33]. The results of those studies showed the absence of any beneficial effect of NAC on the incidence and the severity of ERCP-induced pancreatitis.

Natural β -Carotene: β -carotene is a natural antioxidant which has been used as a supplement in various conditions. In a double-blind trial, 321 patients were given a single dose of natural β -carotene, 12 h prior to the procedure, and monitored for procedure complications, antioxidant levels, and plasma oxidation for 24 h post-procedure. The overall incidence of AP was not significantly different between the β -carotene and the placebo groups. The rate of severe pancreatitis was lower in the β -carotene-treated group. No reduction in the incidence of PEP was reported but there may be some protective effect of treatment with β -carotene regarding the severity of disease. Adverse events were not reported^[35].

Allopurinol: There were four randomized clinical trials which used allopurinol orally before ERCP to prevent

Table 3 Studies evaluating post-ERCP pancreatitis after allopurinol administration

Study	Allopurinol	Placebo
Romagnuolo <i>et al</i> ^[30] 2008	16/293	12/293
Katsinelos <i>et al</i> ^[32] 2005	4/121	21/118

Budzyńska <i>et al</i> ^[36] 2001	12/99	8/101

PEP (Table 3). These studies were meta-analyzed for their primary PEP outcome. The summary RR for “prevention of all kinds of pancreatitis” in the four trials^[30,32,34,36] was 0.86 with a 95% CI of 0.42-1.77 and a non-significant RR ($P = 0.6801$, Figure 1A). The Cochrane Q test for heterogeneity indicated that the studies were heterogenous ($P = 0.0062$, Figure 1B) and could not be combined. Thus the random effect for individual and the summary of RR was applied. Regression of normalized effect *vs* precision for all included studies for clinical response among allopurinol *vs* placebo therapy was -1.961983 (95% CI: -14.671469 to 10.747502, $P = 0.5749$), and Kendall’s test on standardized effect *vs* variance indicated tau = 0, $P = 0.75$ (Figure 1C). The summary RR for “prevention of mild pancreatitis” in three trials^[30,32,36] was 1.08 with a 95% CI of 0.7-1.67, a non-significant RR ($P = 0.7238$, Figure 2A). The Cochrane Q test for heterogeneity indicated that the studies were homogenous ($P = 0.2255$, Figure 2B) and could be combined. Thus the fixed effect for individual and the summary of RR was applied. Regression of normalized effect *vs* precision for all included studies for clinical response among allopurinol *vs* placebo therapy could not be calculated because of too few strata. The summary RR for “prevention of moderate pancreatitis” in the three trials^[30,32,36] was 0.655 with a 95% CI of 0.388-1.105 and a non-significant RR ($P = 0.113$, Figure 3A). The Cochrane Q test for heterogeneity indicated that the studies were homogenous ($P = 0.0614$, Figure 3B) and could be combined. Thus the random effect for individual and the summary of RR was applied. Regression of normalized effect *vs* precision for all included studies for clinical response among allopurinol *vs* placebo therapy could not be calculated because of too few strata.

Figure 2 Individual and pooled relative risk (A) and heterogeneity indicators (B) for the outcome “prevention of all kinds of pancreatitis” in the studies considering allopurinol vs placebo therapy.

Figure 3 Individual and pooled relative risk (A) and heterogeneity indicators (B) for the outcome “prevention of moderate pancreatitis” in the studies considering allopurinol vs placebo therapy.

Figure 4 Individual and pooled relative risk (A) and heterogeneity indicators (B) for the outcome “prevention of severe pancreatitis” in the studies considering allopurinol vs placebo therapy.

The summary RR for “prevention of severe pancreatitis” of allopurinol vs placebo therapy among the three trials^[30,32,36] was 0.68 with a 95% CI of 0.2-2.23,

indicating a non-significant RR for allopurinol administration ($P = 0.5206$, Figure 4A). The Cochrane Q test for heterogeneity indicated that the studies were not significantly heterogeneous ($P = 0.6154$, Figure 4B) and the fixed effects for individual and the summary of RR was applied. Regression of normalized effect vs precision for all included studies for any adverse events among allopurinol vs placebo therapy could not be calculated because of too few strata.

Oxygen radicals play an essential role in the development of inflammation in various conditions^[42-50]. The involvement of free radicals in the pathogenesis of pancreatitis has been shown in both animal and human studies^[51]. Oxidative stress expedites mechanisms which lead to cell damage. It can directly destruct the cell membrane, accelerate lipid peroxidation, deplete cell reserves of antioxidants, and change signaling pathways inside the cells^[52,53].

Although the pathophysiology of pancreatitis has been studied before, there is no specific therapy for this disastrous disease yet. Enteral or parenteral nutrition, antibiotic therapy, surgical procedures such as removal of abscess and necrosis, and cholecystectomy have been developed to treat AP^[14]. In CP, pain management and probably surgical resection of pseudocysts are the goals of treatment. Because these treatments do not target the main problem and are recommended for symptoms and complications, investigators are still looking for new effective approaches in combination with current treatment.

Clinical studies of the evaluation of typical antioxidants on AP and CP were performed firstly at Man-

chester Royal Infirmary by Braganza and her colleagues. Two placebo controlled clinical trials^[28,29] examining combined antioxidant therapy on recurrent CP showed a significant decrease in pain and an elevation in serum antioxidant biomarkers; however, in one study in which SAME was examined as an antioxidant, alone or in combination with selenium and β -carotene, the results showed that SAME was ineffective in patients with recurrent pancreatitis. Another two recently published clinical trials^[4,16], particularly the latter study with a larger number of subjects (147), which used the same cocktail of antioxidants also showed pain reduction after administration. Therefore, the results of these studies show that such a combination of antioxidants could have a positive effect in the treatment of CP. However, we were unable to meta-analyze these three studies for pain as the primary outcome because pain reduction was assessed in a different way in each study. Except for the mentioned antioxidant cocktail, results of the administration of other antioxidants in both AP and CP clinical trials were incongruent and heterogeneous; and we cannot draw a definite conclusion on the efficacy of such therapy in the management of pancreatitis. We also evaluated the effect of etiology of pancreatitis including alcoholic, gallstone or idiopathic on the results of pain reduction and other outcomes, however, there was no relation between the cause of pancreatitis and clinical outcomes.

Furthermore, antioxidant therapy failed to prevent the onset of PEP in almost all trials (Table 2). Only one clinical trial in which 600 mg of allopurinol was administered twice before ERCP showed a significant decrease in the rate of PEP. However, our meta-analysis revealed that the RR for “prevention of mild, moderate and severe pancreatitis” of allopurinol *vs* placebo therapy was non-significant for allopurinol administration.

However, the present review indicates that there is insufficient data to support using antioxidants alone or in combination with conventional therapy in the management of AP, CP or PEP. Further double blind, randomized, placebo-controlled clinical trials with a larger sample size need to be conducted.

Abstract

Inflammatory bowel disease (IBD) is a common and lifelong disabling gastrointestinal disease. Emerging treatments are being developed to target inflammatory cytokines which initiate and perpetuate the immune response. Adenosine is an important modulator of inflammation and its anti-inflammatory effects have been well established in humans as well as in animal models. High extracellular adenosine suppresses and resolves chronic inflammation in IBD models. High extracellular adenosine levels could be achieved by enhanced adenosine absorption and increased *de novo* synthesis. Increased adenosine concentration leads to activation of the A2a receptor on the cell surface of immune and epithelial cells that would be a potential therapeutic target for chronic intestinal inflammation. Adenosine is transported *via* concentrative nucleoside transporter and equilibrative nucleoside transporter transporters that are localized in apical and basolateral membranes of intestinal epithelial cells, respectively. Increased extracellular adenosine levels activate the A2a receptor, which would reduce cytokines responsible for chronic inflammation.

INTRODUCTION

Adenosine is a purine molecule necessary for normal cell metabolism and growth. Recently, adenosine has been recognized as a potential anti-inflammatory molecule. In general, cellular adenosine is produced by both *de novo* synthesis and by absorption from the diet into the body through transporters in the gastrointestinal tract. It is thought that activation of adenosine receptors deactivates the synthesis of critical components necessary for activation of chronic inflammatory diseases, including inflammatory bowel disease (IBD). Many reviews have focused on the general aspects of adenosine activation of its receptors in inflamed tissues. This review focuses on the identification of the role of intestinal epithelial cell adenosine transporters during IBD.

CURRENT UNDERSTANDING OF INFLAMMATORY BOWEL DISEASES

IBD, including Crohn's disease (CD) and ulcerative colitis (UC), is a common and lifelong disabling gastrointestinal disease^[1,2]. It has highest incidence and prevalence in the developed countries. The worldwide incidence varies greatly with that of UC ranging from 0.5-24.5/100 000 and that of CD ranging from 0.1-16/100 000 in different populations. There are more than 2 million IBD patients in the United States^[3]. The precise mechanism of IBD is still unknown. CD and UC differ in their histological presentation and cytokine profile. The accumulated data indicate that IBD results from a complex interplay of genetic, environmental, and immunologic factors. The presence of one or more genetically determined defects leads to an over-reaction of the host mucosal

immune system to normal constituents of the mucosal microflora. The genetically determined alterations of gut epithelial barrier function enhance exposure of the mucosal immune system to microflora components. The over-reaction causes either a Th1-type T cell-mediated inflammation (Crohn's disease) or a Th2-type T cell-mediated inflammation (ulcerative colitis). Multiple cytokines are released in the inflammatory process. The most important factors are tumor necrosis factor (TNF)- α , interleukin (IL)-1, interferon (INF)- γ , IL-6, 12, 13 and 17, monocyte chemotactic protein (MCP)-1 and IL-8^[4]. These cytokines attract and activate neutrophils, eosinophils, mast/plasma cells and macrophages. These inflammatory cells produce large amounts of unstable chemical species such as reactive oxygen species (ROS) or oxyradicals (i.e. superoxide anions, hydrogen peroxide, hydroxyl radicals, peroxynitrite), resulting in tissue injury^[5,6].

Since the cause of IBD is still unknown, currently available treatments for the disease are non-specific and may cause side effects such as osteoporosis and suppression of the immune system. Many patients respond and maintain remission with existing therapy. Thus, at present, there is no cure for IBD. But for some patients, the available therapeutic options for IBD are still inadequate. The conventional treatments use corticosteroids, mesalamine, and immunosuppressants. These either nonspecifically block downstream inflammatory events, such as the secretion of cytokines and activation of immunocytes and neutrophils, or increase tissue adenosine levels, regardless of the nature of the underlying T cell response that generated these events. These agents have been used for treatment of mild and moderate IBD with some success for many years despite shortcomings and toxicities. The newer therapies using biologics, such as antibodies against TNF- α and α -integrin molecules, eliminate a specific major inflammatory cytokine or act by disrupting accumulation of cells at areas of inflammation. Both strategies have been successful in subsets of IBD patients but have also been associated with significant complications including fatal infections^[7-12].

Emerging treatments are being developed to target the hierarchy of the inflammatory cytokine effect including IL-12/IL-23^[13], IFN- γ ^[14], IL-6^[15], and IL-10 levels^[16]. Several antibodies currently on clinic trial include: anti-IL-12p40, an antibody against IL-12 and IL-23, the master cytokines underlying the Th1 response, for Crohn's disease^[13]; anti-IL-23p19, a potentially useful treatment for patients with resistance to anti-TNF therapy which acts by targeting IL-23 and IL-17 rather than IL-12 and IFN- γ in experimental colitis. Other approaches to the treatment of IBD currently under investigation are leukocytapheresis to eliminate effector cells^[17,18], administration of probiotics, use of GM-CSF to enhance innate immune function^[19], administration of microbe-derived agents or intestinal parasites to activate the innate immune system by inducing counter-regulatory immune responses to quell established inflammation^[20], administration of anti-CD3 antibodies^[21], autologous

hematopoietic stem cell transplant^[22], extracorporeal photophoresis to restore immunoregulation^[23], and adipose stem cell infusion^[24].

ADENOSINE MODULATES CHRONIC INFLAMMATION IN IBD

Adenosine exerts broad biologic effects, including smooth muscle contraction, neurotransmission in the peripheral and central nervous systems, platelet aggregation, pain, exocrine and endocrine secretion, lipolysis, glycogenesis, immune system development and response (e.g. severe combined immunodeficiency is due to lack of adenosine-deaminase), cardiac conduction and contractility, and anti-inflammation^[25]. It has long been reported that adenosine, a purine nucleoside that is released at injured and inflamed sites, plays a central role in the regulation of inflammatory responses and in limiting inflammatory tissue destruction^[26]. Early after the injurious or infectious signal, high concentrations of extracellular adenosine favor a transition from neutrophil infiltration to macrophage recruitment, to facilitate a highly efficient specific immune response carried out by macrophages. At later stages of immune or inflammatory processes, adenosine contributes to the resolution of inflammation, both by down-regulating macrophage activation and by advancing Th2- *vs* Th1-cell response^[26]. Some anti-inflammatory and immunomodulating drugs, such as salicylates, methotrexate and purine analogs like 6-MP and cyclosporine, exert their therapeutic actions in inflammatory diseases, at least in part, by decreasing intracellular adenosine 5'-triphosphate (ATP) concentrations and increasing extracellular adenosine levels^[27].

There are numerous reports that have demonstrated the ability of adenosine to exert anti-inflammatory actions in a variety of animal models. The anti-inflammatory effects can be achieved by increasing intracellular or extracellular adenosine levels through the mechanism of either enhanced production or inhibition of adenosine catabolism. The majority of work has been focusing on inhibition of adenosine catabolism or direct activation of adenosine receptors. A recent article by Antonioli *et al*^[28] reported that inhibition of adenosine deaminase can attenuate mucosal inflammation in experimental colitis through the mechanism of reducing mucosal myeloperoxidase activity, production of malondialdehyde and TNF- α levels as well as plasma TNF- α and interleukin-6 levels. Other studies have demonstrated that adenosine acting on the A2a receptor of T-lymphocytes can selectively suppress the expression of pro-inflammatory cytokines while sparing anti-inflammatory activity mediated by IL-10 and TGF- β ^[29]. The tissue injury and inflammation in mice with enteritis induced by *Clostridium difficile* toxin A can be alleviated by a new A2a receptor agonist, ATL 313, through the mechanism of inhibiting neutrophil infiltration, TNF- α production and adenosine deaminase activity^[30]. Adenosine can down-regulate neutrophil functions by

decreasing their adhesion, degranulation, and oxidant activities^[25]. An increase in endogenous adenosine levels by inhibition of adenosine kinase ameliorates colitis by suppression of IFN- γ in colonic tissue and CD69 expression in splenocytes, as well as maintaining tissue integrity by reducing energy demand, increasing nutrient availability, and modulating the immune system^[31]. At a molecular level, adenosine has been demonstrated to be a negative regulator of NF- κ B and MAPK signaling in human intestinal epithelial cells^[32]. Based on these findings, the adenosine system can represent a very promising target for therapies of inflammatory bowel diseases.

PHYSIOLOGY OF ADENOSINE METABOLISM BY INTESTINAL EPITHELIUM CELLS

Intracellular adenosine level is maintained by constant synthesis and degradation, as well as by trans-membrane transport through nucleoside transporters. The intracellular adenosine is produced by *de novo* synthesis from amino acids, CO₂, carbon-1-tetrahydrofolate and ribose-5-phosphate, salvage of endogenous adenine, dephosphorylation of ATP, ADP and AMP, as well as by transportation of exogenous nucleobases and nucleosides through concentrative nucleoside transporters (CNTs) or equilibrative nucleoside transporters (ENTs). Adenosine is metabolized to inosine by adenosine-deaminase, to either an end product uric acid or phosphorylated to ATP by adenosine-kinase or diffused into the extracellular space *via* ENTs^[33,34].

Most tissues and cells have *de novo* synthesis capacity to produce adenine endogenously from amino acids, CO₂ and carbon-1-tetrahydrofolate for their own use. However, some tissues and cells either lack or have very limited *de novo* synthesis capacity. These tissues and cells rely largely on exogenous nucleoside supply and salvage of endogenous nucleobases and nucleosides. Bone marrow, lymphocytes, leukocytes and intestinal epithelial cells are among them^[35-39]. The liver is the major organ supplying the nucleobases to these tissue and cells. The dietary nucleobases and nucleosides are absorbed by intestinal villous epithelial cells and degraded to end products such as uric acid. The uric acid is brought to the liver by blood and is taken up by hepatocytes and transformed into nucleobases. The synthesized nucleobases are released into the blood stream and carried to the tissues.

The intestinal epithelial cells have a very limited capacity for *de novo* synthesis; the villous cells can directly use the absorbed dietary nucleosides but the cryptal cells depend on blood supply. The impact of lack or limitation of nucleoside supply to cryptal cells on epithelial repair and barrier function during IBD has not been fully investigated^[40,41]. It is reasonable to speculate that poor absorption in the intestine or suppression of synthesis in the liver will ultimately result in disruption of epithelial barrier function in chronic bowel inflammatory diseases

like IBD, which in turn will lead to over-exposure of the innate immune system to intraluminal bacterial antigens and cause persistent inflammation or exacerbation of the diseases.

In general, the extracellular adenosine is produced by dephosphorylation of ATP by an enzymatic cascade consisting of Ntpases and ecto-5'-nucleotidase (Ecto 5'NTase), and direct diffusion of intracellular adenosine through ENTs. It is removed by enzymatic degradation by adenosine deaminase to inosine or by adenosine kinase to AMP. It can also be transported back into cells by membranous transporters like CNTs/ENTs. The extracellular adenosine level is believed to be lower than 1 μ mol/L in normal tissue but can be as high as 100 μ mol/L in inflamed or ischemic tissues^[25]. Only a high adenosine level can exert immunomodulatory and immunosuppressive effects. Luminal adenosine level is estimated to be 5 mmol/L in normal intestine, while it is 6 mmol/L in inflamed intestine due to ATP and adenosine secretion in inflammatory and other cell types^[42].

It is not entirely clear which cell types are the most important producer of extracellular adenosine, but endothelial cells, neutrophils, nerve terminal and epithelial cells have been identified in the literature^[43,44]. Extracellular adenosine binds to adenosine receptors (AR) 1, 2a, 2b and 3, all of which are expressed on the surface of immune cells. Low level expression of A1R is demonstrated in small intestine. A2bR is the only receptor expressed in epithelial cells of cecum and colon. A3R can be detected in jejunum and proximal colon^[45,46]. Adenosine receptors are members of the G protein-coupled family of receptors^[47]. A1 and A3 receptors are usually coupled with Gi proteins that inhibit adenylate cyclase, whereas the A2aR and A2bR receptors are coupled with Gs proteins that activate adenylate cyclase. Several studies have demonstrated that adenosine attenuates intestinal inflammation predominantly through the effects of the A2aR receptor of neutrophils and T-lymphocytes^[29,30,48]. However, Yang *et al.*^[49] found that activation of the A2bR can also have anti-inflammatory effects, using a gene knock-out method to delete this gene in order to show a pro-inflammatory phenotype.

MOLECULAR MECHANISM OF ADENOSINE TRANSPORT

The significance of exogenous adenosine transport by intestinal epithelial cells in the treatment of IBD and its impact on epithelial cell barrier function has not been explored. Concentrative nucleoside transporters (CNTs) have been identified as the major transporters for absorption of exogenous nucleosides from the diet. Three distinct CNTs (CNT1, CNT2 and CNT3) that exhibit different substrate specificity have been cloned and characterized from humans, rats and mice^[34]. CNT1 predominantly transports pyrimidines. CNT2 transports purine and uridine, while CNT3 transports purines and

pyrimidines. The expression of CNTs and their substrate specificity vary among species. CNT3 was not found in intestinal epithelial cells of human and rat^[34,50,51]. CNTs belong to the solute carrier family 28 (SLC-28). CNTs are expressed in the apical membranes of intestinal epithelial cells, as well as in other cell types including hepatocytes, endothelial cells, neutrophils, lymphocytes and macrophages.

CNT2 has been cloned and characterized in humans, mice, rats and rabbits. The rat CNT2 cDNA is 2.9 Kb and encodes a 659 amino acid protein with molecular weight of 72 kDa^[52]. The apparent molecular weight on western blot is usually around 60 kDa due to high hydrophobicity of membrane protein. Fourteen putative transmembrane domains were identified by hydropathy analysis. The presence of several consensus sequences for protein kinase-C (PKC) and protein kinase-A (PKA) phosphorylation sites on both N- and C-termini, and an ATP/GTP binding motif in N-terminus, suggest that CNT2 may be regulated by protein kinases and intracellular ATP and GTP. CNT2 may be a glycoprotein as there are five possible N-linked glycosylation sites. Na⁺-adenosine cotransport in brush-border membranes from rabbit ileum was identified and partially characterized in one previous study^[53]. *In vitro* expressed CNT2 in *Xenopus laevis* oocytes exhibited Na⁺-dependent adenosine uptake with an apparent *K_m* for adenosine of 6 μmol/L, with substrate selectivity to purine and uridine^[54].

REGULATION OF ADENOSINE TRANSPORT AND CNT2 EXPRESSION IN GENERAL

The CNT2 expression and adenosine uptake are highly regulated processes and are species and tissue specific^[55]. Sub-cellular trafficking (i.e. internalization of membrane transporters to sub-cellular storage vesicles) has been shown to be a regulatory mechanism for CNT2 in several cell lines including adrenal chromaffin cells, reticulocytes and cholangiocytes^[56-58]. Although CNT1 has been shown to be up-regulated in intestine and down-regulated in hepatocytes of pyrimidine-free diet fed animals, the dietary effects of adenosine on CNT2 activity and molecular expressions are not known^[59,60]. Several studies have shown that nucleoside transport functions and expressions are regulated by hormones^[61-66]. Tyrosine and glucagon have been shown to stimulate adenosine transport and CNT2 expression in both *in vitro* and *in vivo* models^[61-63]. Studies with insulin and glucose have yielded different results regarding adenosine transport and molecular expression. Insulin regulates adenosine transport through different signaling pathways that involve PI3K, MAPK, NO synthase, PKC and MAP kinase^[64-66]. One study showed that adenosine transport is up-regulated by activation of the A1 adenosine receptor through ATP-sensitive K-channels in hepatocytes, suggesting some positive feedback regulation among adenosine receptors and the

adenosine transporter^[67].

The effects of proliferative (EGF and TGF-α) and differentiating (glucocorticoid) hormones were demonstrated in IEC-6 cells (a rat intestinal cryptal cell line). A four-fold increase of adenosine transport activity and CNT2 molecular expression after treatment with dexamethasone was observed while no significant impact was noted from treatment with proliferative hormones^[68]. However, a more recent paper by the same research group found that TGF-β can transcriptionally up-regulate CNT2 gene expression in rat hepatocytes^[69]. Adenosine transport and CNT2 expression are altered during cell growth cycle and differentiation. Hepatocarcinogenesis is accompanied by loss of CNT2 expression and increased expression of ENTs. CNT2 mRNA and protein levels were increased right before the peak of incorporation of thymidine into DNA and during liver regeneration after partial hepatectomy^[70,71].

CNT2 expression was up-regulated by lipopolysaccharide (LPS), NO, INF-α and TNF-α in macrophages and B-lymphocytes in several studies^[72-74]. The LPS-induced increase of adenosine transport and molecular expression is TNF-α-dependent but not iNOs-dependent. cNOs is required for maintaining the basal transport activities of adenosine in activated B-cells. The CNT2 is recognized as an important regulator of extracellular adenosine concentrations. CNT2 expression is suppressed in inflamed tissue as a mechanism to maintain high extracellular adenosine concentration. The CNT2 expression is suppressed in neutrophils and macrophages during inflammation^[75]. There is controversy between the *in vivo* and *in vitro* studies about the functional status of adenosine transport and CNT2 expression during inflammation and the effects of inflammatory mediators.

MECHANISM OF REGULATION OF ADENOSINE TRANSPORT AND CNT2 EXPRESSION IN INTESTINAL EPITHELIAL CELLS

A systematic study for the mechanism of regulation of adenosine transport and CNT2 expression in intestinal epithelial cells is not available. Adenosine functions as a nutrient for nucleic acid metabolism, an energy carrier molecule for cell energy metabolism, and a second messenger in autocrine and paracrine hormone regulation. Adenosine transport is regulated differently from other nutrient transporters such as glucose and amino acid transporters. Luminal adenosine and ATP have been reported to regulate glucose and bile acid transport in intestine, proximal renal tubule cells and cholangiocytes^[42,76,77]. The role of the activation of purinergic receptors on adenosine uptake was also studied in vascular endothelial cells and chromaffin cells. ATP has been shown to up-regulate adenosine transport and protein expression in vascular endothelial cells and chromaffin cells^[78-80]. However, the effect of ATP on

adenosine transport in normal and inflamed intestine remains to be elucidated.

MECHANISM OF REGULATION OF Na^+ -CO-TRANSPORT IN INTESTINAL EPITHELIAL CELLS DURING CHRONIC INTESTINAL INFLAMMATION

The regulation of intestinal epithelial transporters during chronic inflammation is a very complex process, involving many cell types and immune-inflammatory mediators. The cells involved in chronic enteritis include all inflammatory cells (neutrophils, basophils, eosinophils, macrophages, lymphocytes), fibroblasts, vascular endothelial cells, nerve cells and epithelial cells. These cells produce numerous cytokines and immune-inflammatory mediators such as prostaglandins, leukotrienes, reactive oxidative metabolites (ROMs) and nitric oxide^[1-6]. So far, there are no perfect animal models for IBD though several different models exist with chemically-induced and genetically-induced enteritis. It is very difficult to fully understand the regulation of nutrient and electrolyte transport in the chronically inflamed intestine.

The mast cell has been implicated as an important player in chronic intestinal inflammation. It releases multiple inflammatory mediators including histamine, serotonin, cytokines, prostaglandins, leukotrienes and ROMs. The released mediators are very important regulators of transporters in epithelial cells. It was consistently demonstrated that blocking mast cell degranulation prevented down-regulation of a number of transporters including Na^+ -glucose and Na^+ -amino acid cotransport as well as electrolyte transporters such as $\text{Cl}^-/\text{HCO}_3^-$ exchange^[81].

Nitric oxide has been identified as an important regulating factor in the intestinal tract. Constitutive nitric oxide synthase (cNOS) plays an important role in the regulation of transporters in normal intestine. It is essential for some transporters to function properly under physiologic conditions. Inducible nitric oxide synthase (iNOS) is activated during chronic inflammation, ischemia and tissue injury. iNOS produces large amounts of nitric oxide (NO) during chronic inflammation, which is generally considered as detrimental to tissue and cells because of formation of peroxynitrous acid, though controversy continues about its role in inflammation. The mechanism of cNOS and iNOS effects on nutrient co-transporters in epithelial cells is possibly through direct and indirect effects, by stimulating the production and/or release of other inflammatory mediators such as arachidonic acid metabolites (e.g. prostaglandins and leukotrienes)^[82-84].

Prostaglandins have been shown to be very important inflammatory mediators in chronic intestinal inflammation. A large amount of prostaglandins are produced in the intestinal tissue during IBD. Prostaglandins inhibit electrolyte absorption and Na^+

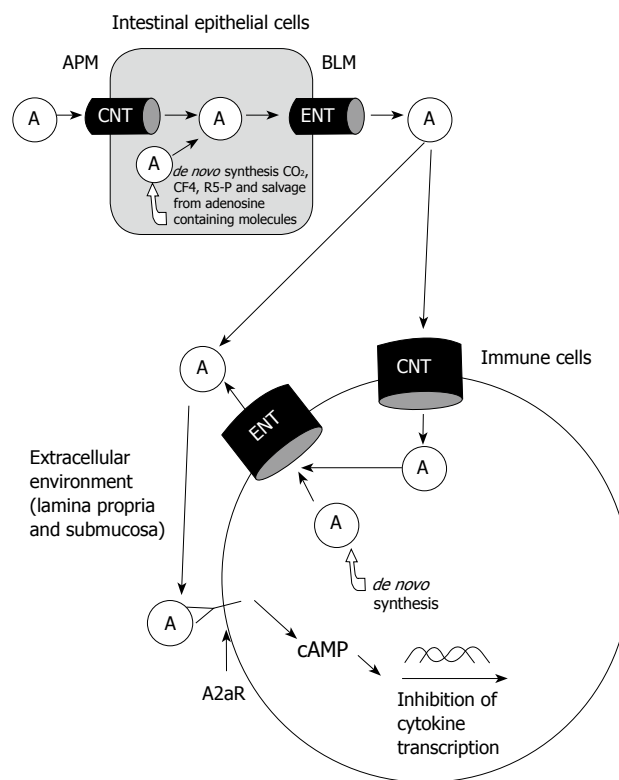

Figure 1 Pathways and roles of adenosine. Absorbed and *de novo* synthesized adenosine delivered to extracellular space. Adenosine binds to A2aR of immune cells and activates signaling pathways to inhibit the production of inflammatory mediators. A: Adenosine; APM: Apical membrane; BLM: Basolateral membrane; CNT: Concentrative nucleoside transporter; ENT: Equilibrative nucleoside transporter.

nutrient co-transporter functions^[85-89]. In addition, they also promote mucous secretion and cytoprotection in the gastrointestinal tract during IBD^[85,88]. Prostaglandin E2 (PGE2) was also reported to suppress glucose transport in the ovine intestine^[90]. Leukotrienes have been demonstrated to inhibit electrolyte transport in a similar pattern to prostaglandins^[91-98].

Corticosteroids are the most frequently used broad spectrum immunomodulators in IBD for blocking the production of most major inflammatory mediators. Corticosteroids prevent mast cell degranulation and block the phospholipase A2 (PLA2) enzyme pathway. They also down-regulate arachidonic acid release and production of prostaglandins and leukotrienes. In addition, corticosteroids suppress the production of iNOS and inducible cyclooxygenase (COX-2) during chronic inflammation^[99].

It is possible that mast cells, nitric oxide, arachidonic acid metabolites and steroids are all involved in the regulation of adenosine transport and CNT2 expression during chronic enteritis. It should be noted that adenosine itself is an inflammatory modulator. Extracellular adenosine can suppress all these above-mentioned inflammatory cells and mediators. The interplay among adenosine, inflammatory cells and mediators can be very complex and is also very interesting for further study.

CONCLUSION

The pathways of adenosine metabolism and transport are fully illustrated in Figure 1. Luminal adenosine is absorbed by intestinal epithelial cells through CNT and ENT transporters and can also be synthesized *de novo*. The increase in intracellular levels of adenosine leads to extracellular transport along with the release of adenosine from damaged cells during inflammation. Using various therapies during IBD, it may be possible to eventually increase the extracellular levels of adenosine so that the appropriate receptors can be activated to inhibit and reduce the effects of chronic inflammation on the gut. IBD is a common and lifelong disabling gastrointestinal disease. At present, there is no cure for IBD. Emerging treatments are being developed to target cytokines that perpetuate the chronic inflammatory response. Adenosine is an important modulator of inflammation and its anti-inflammatory effects have been well established in humans as well as in animal models. Therapeutic targeting of receptors such as the A2a receptor could reduce cytokine levels and thus reduce the effects of chronic inflammation during IBD.

increased oxidative stress and up-regulated *HMOX1* gene expression. Iron did not affect mRNA or protein levels of Bach1, a repressor of HMOX1. Silencing the up-regulation of HMOX1 nuclear factor-erythroid 2-related factor 2 (Nrf2) by Nrf2-siRNA decreased FeNTA-mediated up-regulation of HMOX1 mRNA levels. These iron effects were completely blocked by deferoxamine (DFO). Iron also significantly decreased levels of HCV core mRNA and protein by 80%-90%, nonstructural 5A mRNA by 90% and protein by about 50% in the Con1 full length HCV replicon cells, whereas DFO increased them.

CONCLUSION: Excess iron up-regulates HMOX1 and down-regulates HCV gene expression in hepatoma cells. This probably mitigates liver injury caused by combined iron overload and HCV infection.

Iron increases HMOX1 and decreases hepatitis C viral expression in HCV-expressing cells. *World J Gastroenterol* 2009; 15(36): 4499-4510 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4499.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4499>

Abstract

AIM: To investigate effects of iron on oxidative stress, heme oxygenase-1 (HMOX1) and hepatitis C viral (HCV) expression in human hepatoma cells stably expressing HCV proteins.

METHODS: Effects of iron on oxidative stress, HMOX1, and HCV expression were assessed in CON1 cells. Measurements included mRNA by quantitative reverse transcription-polymerase chain reaction, and protein levels by Western blots.

RESULTS: Iron, in the form of ferric nitrilotriacetate,

INTRODUCTION

Iron overload is known to be toxic to many organs, particularly to the liver. The liver is the major site of storage of excess iron. The most common form of iron overload is that related to classic hereditary hemochromatosis, in which, due to mutations in the *HFE* gene, there is excessive uptake of iron into enterocytes^[1-3]. In hemochromatosis, decreased hepatic production and secretion of hepcidin leads to increased ferroportin expression at the plasma membranes,

especially of enterocytes and macrophages. Ferroportin is the only known physiologic iron exporter from cells and its uncontrolled over expression leads to excess uptake of iron from the enterocytes into the portal blood and to increased release of iron from macrophages and other cells of the reticulo-endothelial system, including the Kupffer cells of the liver^[4-6]. The excess iron in the portal blood and/or released by Kupffer cells within the liver is taken up by hepatocytes where it is stored, chiefly in the form of holo-ferritin. Iron in ferritin is relatively non-reactive and non-toxic. However, release of tissue ferritin from damaged or dying cells leads to activation of hepatic stellate cells and a cascade of pro-inflammatory and pro-fibrogenic events. This may eventuate in the development of hepatic fibrosis, cirrhosis, and hepatocellular carcinoma, as well as all of the usual complications of advanced chronic liver disease^[7-9].

In recent years, it has become increasingly clear that only modest amounts of iron in the liver may play a role as a co-morbid factor in the development and progression of non-hemochromatotic liver diseases^[10-15]. The link between iron and non-hemochromatotic liver diseases is particularly strong for steatohepatitis, both non-alcoholic and alcoholic^[10,14,15] and viral hepatitis B and C^[16-18].

Porphyria cutanea tarda, the most common form of porphyria, is known to be triggered or exacerbated by iron and is often associated with *HFE* gene mutations, chronic hepatitis C, and alcohol use^[19-21]. The treatment of choice for porphyria cutanea tarda involves removal of iron, which leads to remission of the biochemical and clinical features of the disease. Blumberg and colleagues were among the first to stress the importance of iron status in influencing outcomes and progression of acute hepatitis B infection^[22,23]. In the case of hepatitis C infection, a number of investigators from throughout the world have noted high prevalences (35%-50%) of elevations of serum ferritin and high, albeit somewhat lower, frequencies of elevations of serum transferrin saturation in patients with chronic hepatitis C^[10,24-26]. Despite this, the occurrence of heavy iron overload in chronic hepatitis C is infrequent and is chiefly related to advanced liver disease. Increases in serum measures of iron and stainable iron in the liver have been directly correlated with more severe chronic hepatitis C and with lower likelihoods of response to currently available antiviral therapy, especially type 1 interferons^[24,27,28]. In addition, it has been shown repeatedly that reduction of body iron by therapeutic phlebotomy improves the responsiveness of chronic hepatitis C infection to interferon therapy^[29].

Heme oxygenase-1 (HMOX1) has emerged as a key cytoprotective gene and enzyme in numerous experimental and clinical contexts (For reviews, see^[30-33]). The *HMOX1* gene is under complex regulation and can be up-regulated markedly by heme, the physiologic substrate for the HMOX1 protein, by iron and other transition metallic ions, and by oxidative and heat stress and other stressful perturbations. Regulation of *HMOX1*

gene expression is related in part to alterations in levels of several transcription factors, including Bach1, and nuclear factor-erythroid 2-related factor 2 (Nrf2). Normally, Bach1 in nuclei represses *HMOX1* gene expression, whereas Nrf2, in concert with small Maf proteins, up-regulates its expression^[34-36].

The study of hepatitis C viral (HCV) infection has been difficult because of the lack of a readily available, inexpensive animal model of acute or chronic hepatitis C infection. The recent development of human hepatoma cell lines, which stably express HCV proteins, and support the replication of HCV RNA or the formation of complete infectious virions of HCV^[37,38], has facilitated studies on pathogenesis and the role of potential co-morbid factors, such as iron. We used such lines to investigate the effects of iron on oxidative stress, HMOX1 and HCV expression. Here we report that excess iron results in further increased oxidative stress and up-regulation of HMOX1 *via* Nrf2, and down-regulation of HCV protein expression in human hepatoma cells in culture (Huh-7) expressing HCV RNA and proteins. These effects are reversed by deferoxamine (DFO), the selective and potent iron chelator.

MATERIALS AND METHODS

Reagents and materials

Mouse anti-HCV nonstructural 5A (NS5A) protein was purchased from Virogen (Plantation, FL). Goat anti-human Bach1, goat anti-human GAPDH polyclonal antibodies, goat anti-mouse IgG, and donkey anti-goat IgG were purchased from Santa Cruz Biotechnology, Inc (Santa Cruz, CA). ECL-Plus was purchased from Amersham Biosciences Corp (Piscataway, NJ). Dimethyl sulfoxide was purchased from FisherBiotech (Fair Lawn, NJ). Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), zeocin, geneticin, trypsin and TRIzol were from Invitrogen Inc. (Carlsbad, CA). FeCl₃, Na₃NTA, H₂O₂, 2',7'-dichlorodihydrofluorescein diacetate (H₂DCF-DA) and its oxidation-insensitive analog 2',7'-dichlorofluorescein diacetate (DCF-DA) were purchased from Sigma-Aldrich (Allentown, PA). DFO mesylate was from Novartis (Cambridge, MA).

Cell cultures

The human hepatoma cell line, Huh-7, was purchased from the Japan Health Research Resources Bank (Osaka, Japan). 9-13 and CNS3 cell lines derived from Huh-7 cells, which stably express HCV proteins were gifts from Dr. R Bartenschlager (University of Heidelberg, Heidelberg, Germany). Human hepatoma Huh-7 cells were maintained in DMEM supplemented with 100 U/mL penicillin, 100 µg/mL streptomycin, and 10% (v/v) FBS. 9-13 and CNS3 replicon cells were cultured with additional antibiotics (1 mg/mL geneticin or 10 µg/mL zeocin), respectively. 9-13 replicon cells stably express HCV nonstructural proteins (NS3-5B), and CNS3 cells stably express subgenomic proteins from core to nonstructural protein 3 (core-NS3). The Con1 subgenomic genotype 1b HCV replicon cell line was

from Apath LLC (St, Louis, MO). The Con1 cell line is a Huh-7.5 cell population containing the full-length HCV genotype 1b replicon. The Con1 cells were maintained in DMEM supplemented with 10% (v/v) FBS and 0.1 mmol/L nonessential amino acids, 100 U/mL penicillin, 100 µg/mL streptomycin, and selection antibiotic 750 µg/mL geneticin. Cells were maintained in a humidified atmosphere of 95% room air and 5% CO₂ at 37°C.

siRNA transfection

A smart pool of siRNAs targeting four positions of the human Nrf2 mRNA, was purchased from Dharmacon (Lafayette, CO). Transfections of Nrf2-siRNA were performed with Lipofectamine 2000 from Invitrogen (Carlsbad, CA) as described previously^[35]. Cells were transfected for 48 h with 20–100 nmol/L Nrf2-siRNA, or an irrelevant control, and subsequently were exposed for 4 h to indicated concentrations of ferric nitrilotriacetate (FeNTA). Cells were harvested and total RNA and proteins were extracted for measurements of mRNA or protein levels by quantitative RT-PCR or Western blots.

Quantitative RT-PCR

Total RNA from treated cells was extracted and cDNA was synthesized and real time quantitative RT-PCR was performed using a MyiQ™ Single Color Real-Time PCR Detection System (BIO-RAD) and iQ™ SYBR Green Supermix Real-Time PCR kit (BIO-RAD, Hercules, CA) as described previously^[39,40]. Sequence-specific primers used for HMOX1, HCV core, NS5A and GAPDH were synthesized. We included samples without template and without reverse transcriptase as negative controls, which were expected to produce negligible signals (Ct values > 35). Standard curves of HMOX1, HCV core, NS5A and GAPDH were constructed with results of parallel PCR reactions performed on serial dilutions of a standard DNA (from one of the controls). Fold-change values were calculated by comparative Ct analysis after normalizing for the quantity of GAPDH in the same samples.

Western blotting

Protein preparations and Western blots were performed as described previously^[39,40]. In brief, total proteins (30–50 µg) were separated on 4%–15% gradient SDS-PAGE gels (Bio-Rad). After electrophoretic transfer onto immunoblot PVDF membrane (Bio-Rad), membranes were blocked for 1 h in PBS containing 5% nonfat dry milk and 0.1% Tween-20, and then incubated overnight with primary antibody at 4°C. The dilutions of the primary antibodies were as follows: 1:500 for anti-NS5A, 1:1000 for anti-Bach1, 1:2000 for anti-HCV core and anti-GAPDH antibodies. The membranes were then incubated for 1 h with horseradish peroxidase-conjugated secondary antibodies (dilution 1:10 000). Finally, the bound antibodies were visualized with the ECL-Plus chemiluminescence system according to the manufacturer's protocol (Amersham, Piscataway, NJ). A Kodak 1DV3.6

computer-based imaging system (Eastman-Kodak, Rochester, NY) was used to measure the relative optical density of each specific band obtained after western blotting. Data are expressed as percentages of the controls (corresponding to the value obtained with the vehicle-treated cells), which were assigned values of one.

Cellular reactive oxygen species (ROS) production assay

Levels of cellular oxidative stress were measured using DCF assay. Briefly, cells were seeded into 24-well plates. The following day, the media were removed, and the cells were washed with PBS (PBS supplemented with 1 mmol/L CaCl₂ and 0.5 mmol/L MgCl₂), and then incubated with 100 µmol/L 2',7'-dichlorodihydrofluorescein (H₂DCF-DA) or 2',7'-dichlorofluorescein diacetate (DCF-DA) in DMEM without phenol red for 30 min at 37°C in the dark. The cells were washed twice with PBS, and then treated with selected concentrations of FeNTA for 1 h. Intracellular ROS levels were measured as an increase in fluorescence of the oxidized product of DCF-DA on a Synergy HT Multi-Detection Microplate Reader (BioTek, Winooski, VT) at the excitation and emission wavelengths of 488 and 525 nm, respectively. The oxidation-insensitive analog of H₂DCF-DA served as a control to correct for possible changes in cellular uptake, ester cleavage, and efflux. It showed no changes in fluorescence in these studies.

Statistical analysis

Experiments were repeated at least three times with similar results. Except for Western blots, all experiments included at least triplicate samples for each treatment group. Representative results from single experiments are presented. Statistical analyses were performed with JMP 6.0.3 software (SAS Institute, Cary, NC). Initial interpretation of data showed that they were normally distributed. Therefore, appropriate parametric statistical procedures were used: Student's *t*-test for comparisons of two means and analysis-of-variance (*F* statistics) for comparisons of more than two, with pair-wise comparisons by the Kruskal-Wallis test. Values of *P* < 0.05 were considered significant.

RESULTS

Iron up-regulates HMOX1 mRNA levels in Huh-7 and cell lines expressing HCV proteins

As shown in Figure 1, *HMOX1* gene expression was significantly increased in CNS3 cells, which express HCV core to NS3, even without exposure to iron or hydrogen peroxide, compared to 9-13 cell lines, which express NS3 to NS5B, or parental Huh-7 cells. Iron, in the form of FeNTA and hydrogen peroxide (another known oxidative stressor), further up-regulated the *HMOX1* gene expression in CNS3 cells. Increase of *HMOX1* gene expression by iron in Huh-7 (6.7 fold) and 9-13 cells (5.2 fold) was greater than in CNS3 cells (1.9 fold).

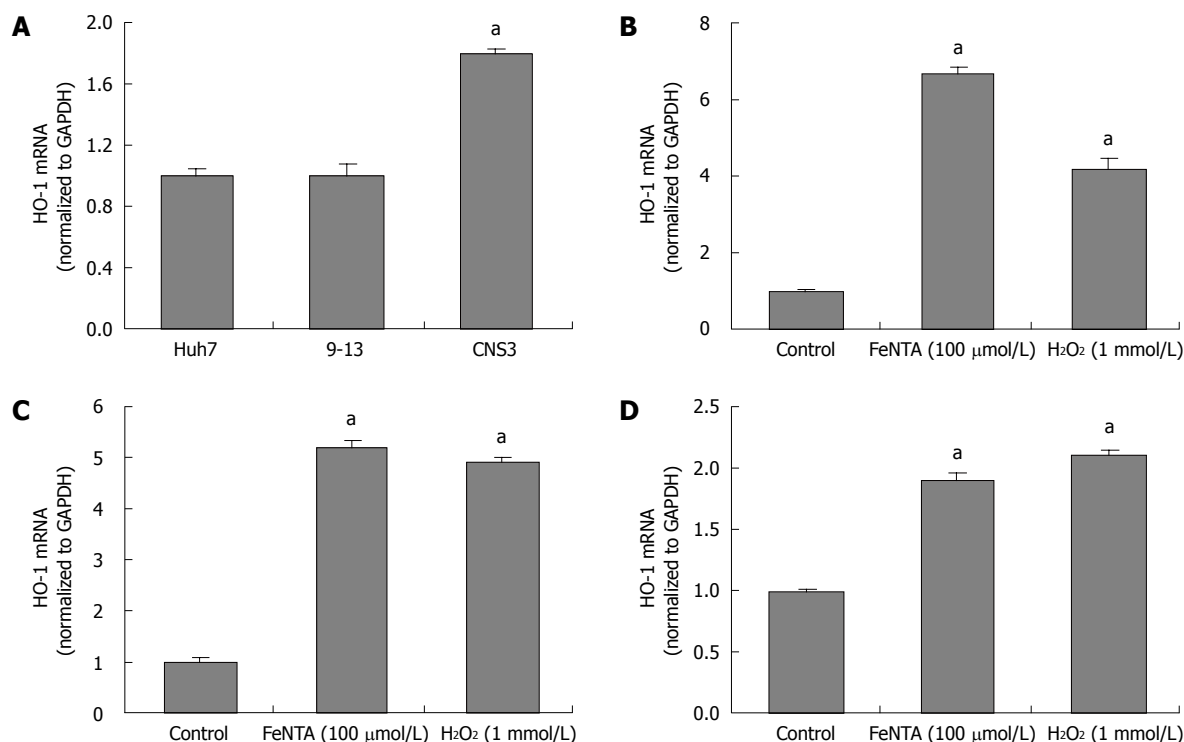

Figure 1 Iron up-regulates HMOX1 mRNA levels in Huh-7, 9-13 and CNS3 cells. A: HMOX1 mRNA levels in Huh-7, 9-13 and CNS3 cells; B: HMOX1 mRNA levels in Huh-7 cells treated with 100 μ mol/L FeNTA or 1 mmol/L H₂O₂ for 6 h; C: HMOX1 mRNA levels in 9-13 cells treated with 100 μ mol/L FeNTA or 1 mmol/L H₂O₂ for 6 h; D: HMOX1 mRNA levels in CNS3 cells treated with 100 μ mol/L FeNTA or 1 mmol/L H₂O₂ for 6 h. Values for cells without any treatment were set equal to 1. HMOX1 mRNA data are presented as means \pm SE from triplicate samples, all normalized to GAPDH in the same samples. ^a*P* < 0.05 vs control. Huh-7, 9-13 or CNS3 cells were cultured as described in Materials and Methods, and treated with 100 μ mol/L FeNTA or 1 mmol/L H₂O₂ for 6 h. Cells were harvested and total RNA was extracted. Levels of mRNA for HMOX1 and GAPDH were measured by quantitative RT-PCR.

Effects of Iron on Nrf2 and Bach1 protein levels in Huh-7 and cell lines expressing HCV proteins

Previous studies from our and other laboratories have demonstrated that Bach1 and Nrf2 act as transcriptional factors that regulate *HMOX1* gene expression in mammalian cells^[34-36], and that Huh-7 cells expressing HCV proteins show significant up-regulation of the *HMOX1* gene, and reciprocal down-regulation of the *Bach1* gene^[41]. To determine whether iron affected the *Nrf2* or *Bach1* gene expression, parental Huh-7 and cell lines (9-13 and CNS3) expressing HCV proteins were treated with FeNTA, and Nrf2 and Bach1 protein levels were measured by Western blots, as described in Materials and Methods. Cells exposed to 50 and 100 μ mol/L FeNTA showed significant accumulation of Nrf2 protein (Figure 2A-C), whereas 50 or 100 μ mol/L NaNTA did not affect Nrf2 protein levels (data not shown). In contrast, there were no detectable changes of Bach1 protein levels in either Huh-7 cells or cell lines expressing HCV proteins, suggesting that Bach1 is not involved in up-regulation of the *HMOX1* gene expression by iron (Figure 3A-C).

Nrf2-siRNA abrogates up-regulation of the HMOX1 gene expression by iron in 9-13 cells

To further establish the role of Nrf2 in up-regulation of the *HMOX1* gene expression by iron, we silenced *Nrf2* gene expression by Nrf2-siRNA as we did previously in Huh-7 cells^[35]. In comparison with control, 20 nmol/L

Nrf2-siRNA significantly reduced Nrf2 protein expression, and 100 nmol/L Nrf2-siRNA repressed Nrf2 protein expression by 92% (Figure 4A). We also successfully silenced the *Nrf2* gene expression in CNS3 cells (data not shown). HMOX1 mRNA levels were significantly induced by iron in cells without Nrf2-siRNA transfection, and this effect was blocked in cells transfected with 100 nmol/L Nrf2-siRNA, indicating that Nrf-2 siRNA plays a key role in up-regulation of the *HMOX1* gene expression by iron (Figure 4B).

Increased ROS, induced by iron, in the form of ferric nitrilotriacetate, in the cell lines expressing HCV proteins

Oxidative stress is one of the key stressors inducing the *HMOX1* gene expression^[30,31], occurring due to iron-catalyzed formation of reactive oxygen species (ROS)^[42]. We observed that the cells exposed to 50 μ mol/L FeNTA exhibited significant increases in the fluorescence intensity of H₂DCF-DA (by 1.4 fold in Huh-7, 1.7 fold in 9-13 and 1.6 fold in CNS3 cells), which are similar to the increases produced by hydrogen peroxide (1 mmol/L). 100 μ mol/L FeNTA further increased fluorescence intensity by 2.1 fold in 9-13 and 1.9 folds in CNS3 cells (Figure 5A-C), whereas 50 or 100 μ mol/L NaNTA did not affect fluorescence intensity (data not shown). The results of the same experiment done with the oxidation-insensitive analogue of the probe (DCF-DA) in CNS3 (Figure 5D), Huh-7 and 9-13 cells (data not shown) indicated no significant

Figure 2 Effects of FeNTA on Nrf2 protein levels in Huh-7, 9-13, and CNS3 cells. A: Nrf2 protein levels in Huh-7 cells; B: Nrf2 protein levels in 9-13 cells; C: Nrf2 protein levels in CNS3 cells. ^a $P < 0.05$ vs control. Huh-7, 9-13 or CNS3 cells were treated with different concentrations of FeNTA (0, 20, 50, 100 $\mu\text{mol/L}$) or 100 $\mu\text{mol/L}$ NaNTA for 6 h, after which cells were harvested and total protein was isolated, as described in Materials and Methods. Proteins were separated on 4%-15% SDS-polyacrylamide gel, transferred to a PVDF membrane, and probed with anti-human Nrf2 and GAPDH specific antibodies. The relative amounts of Nrf2 proteins were normalized to GAPDH.

difference between control cells and cells treated with FeNTA or H_2O_2 . Therefore, the increased fluorescence intensity seen with the oxidation sensitive probe $\text{H}_2\text{DCF-DA}$ (Figure 5A-C) can be directly ascribed to changes in the oxidation of the probe in the cells. We also changed the order of adding the $\text{H}_2\text{DCF-DA}$ and FeNTA or H_2O_2 and observed the same pattern of results (data not shown).

The iron chelator DFO blocks increased ROS induced by iron in the cell lines expressing HCV proteins

DFO and deferasirox (Exjade) are widely used iron chelators to remove excess iron from the body. They act by binding iron at 1:1 (deferoxamine:iron) and 2:1 (deferasirox:iron) ratios and enhancing its elimination. By removing excess iron, these agents reduce the damage

done by iron to various organs and tissues such as the liver. In this study, DFO was used to examine whether the effects of FeNTA were blocked by DFO chelation. In comparison with 100 $\mu\text{mol/L}$ FeNTA alone, 50 $\mu\text{mol/L}$ DFO (deferoxamine:iron 1:2) significantly decreased DCF fluorescence intensity in 9-13 and CNS3 cells (Figure 6A-C). Indeed, ROS induced by iron were completely blocked by DFO in all three cell lines treated with 50 $\mu\text{mol/L}$ FeNTA and increasing concentrations of DFO (50, 100 and 200 $\mu\text{mol/L}$) (Figure 6A-C). To confirm we were truly measuring changes in $\text{H}_2\text{DCF-DA}$ oxidation and not changes in its uptake, ester cleavage, or efflux, we repeated experiments shown in Figure 6A-C with the oxidation-insensitive analogue of the probe (DCF-DA). No significant differences between control

Figure 3 Effects of FeNTA on Bach1 protein levels in Huh-7, 9-13, and CNS3 cells. A: Bach1 protein levels in Huh-7 cells; B: Bach1 protein levels in 9-13 cells; C: Bach1 protein levels in CNS3 cells. Huh-7, 9-13 or CNS3 cells were treated with different concentrations of FeNTA (0, 50, 100 μmol/L) or 100 μmol/L NaNTA for 16 h, after which cells were harvested and total protein was isolated, as described in Material and Methods. Proteins were separated on 4%-15% SDS-polyacrylamide gel, transferred to a PVDF membrane, and probed with anti-human Bach1 and GAPDH specific antibodies. The relative amounts of Bach1 were normalized to GAPDH.

and treated cells were found in CNS3 (Figure 6D), Huh-7 or 9-13 cells (data not shown).

Iron decreases HCV protein expression in cell lines expressing HCV proteins

To evaluate the effect of iron in the form of FeNTA on HCV RNA and protein expression, Con1 full length HCV replicon cells were exposed to FeNTA and with or without DFO. Treatment with FeNTA resulted in a 80%-90% reduction in HCV core mRNA and protein levels (Figure 7A and B), and decreased expression of HCV NS5A mRNA by about 90% and protein by about 50% (Figure 7C and D), whereas no significant effects were produced by NaNTA, establishing that the effects are due to iron and not to the nitrilotriacetate anion

(data not shown). These down-regulatory effects were abrogated by DFO (200 μm).

DISCUSSION

The major findings of this work are as follows: (1) Iron, in the form of FeNTA, up-regulates *HMOX1* gene expression in human Huh-7, and cell lines (9-13 and CNS3) stably expressing HCV proteins (Figure 1); (2) Iron significantly increases Nrf2 protein levels in human hepatoma cells, and silencing the *Nrf2* gene with Nrf2-specific siRNA abrogates the up-regulation of *HMOX1* by iron (Figures 2 and 4); (3) Iron does not significantly change Bach1 protein levels in human hepatoma cells (Figure 3); (4) Iron increases ROS (Figures 5 and 6) but

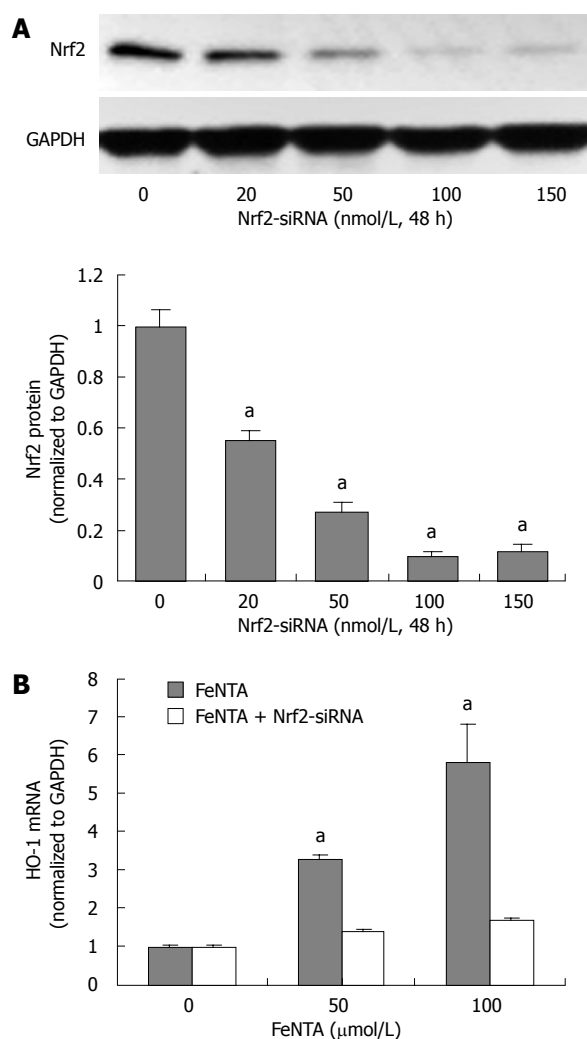

Figure 4 Silencing the Nrf2 gene abrogates up-regulation of the HMOX1 gene by iron. **A:** Dose-response effect of Nrf2-specific siRNA on Nrf2 protein levels; **B:** Effect of Nrf2-specific siRNA on FeNTA up-regulated levels of HMOX1 mRNA. ^a $P < 0.05$ vs control. 9-13 cells were transfected with selected concentrations of Nrf2-siRNA (0, 20, 50, 100, 150 nmol/L). After 48 h of transfection, cells were treated with different concentrations of FeNTA (0, 50, 100 μmol/L) for 6 h, after which cells were harvested and total RNA was isolated. The HMOX1 mRNA levels were measured by quantitative RT-PCR as described in Materials and Methods.

decreases HCV gene expression (Figure 7) in human hepatoma cells; and (5) These effects are blocked by the selective iron chelator DFO (Figures 5-7). However, none of the effects is produced by Na_3NTA , establishing that they are due to iron and not to the NTA anion. These results show clearly that iron is capable of acting directly on hepatoma cells and on HCV gene expression in hepatoma cells, without the need for mediation of effects by other tissues, organs, or cell types. Thus, it appears that iron exerts manifold effects on HCV-infected hepatocytes. On the one hand, it increases ROS and oxidative stress, acting in concert with HCV proteins, especially the core protein. On the other hand, it induces HMOX1 by increasing expression and activity of Nrf2 (Figures 1, 2 and 4), and it decreases levels of CNS3 or NS5A mRNA and protein expression (Figure 7). These latter effects are likely mediated by the recently described iron-dependent inactivation of the HCV RNA

polymerase NS5B^[43].

HMOX1 is a heat shock protein (also known as HSP 32), which can be induced to high levels, not only by heat shock, but also by a large number of physiological or pathological stressors^[30-33]. Nrf2 is a basic leucine zipper transcriptional activator^[44,45]. It protects cells against oxidative stress through antioxidant response element (ARE)-directed induction of several phase 2 detoxifying and antioxidant enzymes, including HMOX1^[35,46]. Nrf2^{-/-} mice displayed a dramatically increased mortality associated with liver failure when fed doses of ethanol that were tolerated by wild type mice, establishing a central role of Nrf2 in the natural defense against ethanol-induced liver injury^[47]. Cobalt protoporphyrin (CoPP)-mediated induction of HMOX1 involves increased Nrf2 protein stability in human hepatoma Huh-7 cells^[35]. In this study, silencing Nrf2 by Nrf2-siRNA markedly abrogated FeNTA-mediated up-regulation of HMOX1 mRNA levels. Therefore Nrf2 plays a central role in up-regulation of HMOX1 gene expression by FeNTA (Figure 4B).

Bach1, a member of the basic leucine zipper family of proteins, has been recently shown to be a transcriptional repressor of HMOX1, and to play a critical role in heme-, CoPP-, SnMP- and ZnMP-dependent up-regulation of the HMOX1 gene^[35,36,48-53]. Upon exposure to heme, heme binds to Bach1 and forms antagonizing heterodimers with proteins in the Maf-related oncogene family. These heterodimers bind to MAREs, also known as AREs, and suppress expression of genes that respond to Maf-containing heterodimers and other positive transcriptional factors. Surprisingly, ZnMP does not bind to Bach1, but it still produces profound post-transcriptional down-regulation of Bach1 protein levels by increasing proteasomal degradation and transcriptional up-regulation of HMOX1^[53]. In contrast, iron does not affect levels of Bach1 mRNA (data not shown) or protein (Figure 3), suggesting that Bach1 is not involved in up-regulation of the HMOX1 gene by iron.

Expression of HMOX1 was recently reported to be decreased in human livers from patients with chronic hepatitis C^[54,55] including some with only mild fibrosis. The reasons for this are not known currently. It is known that levels of expression of the HMOX1 gene depend in part upon genetic factors (lengths of GT repeats in the promoter^[56-59] and a functional polymorphism (A/T) at position -413 of the promoter^[60,61]). Higher expression and/or induction of HMOX1 are probably beneficial to mitigate liver cell injury in HCV infection, as well as in other liver diseases. This may be a therapeutic goal, achieved by treatment with heme or CoPP or with silymarin^[62] or other herbal products or compounds that combine anti-oxidant, iron-chelating and HMOX1-inducing effects.

Recently, we showed that HCV expression in CNS3 cells increases the levels of HMOX1 mRNA and protein^[41]. This induction is likely in response to oxidative stress. More recently, we showed that micro RNA-122, which is expressed at a high level in hepatocytes, causes down-regulation of Bach1, which, as already described,

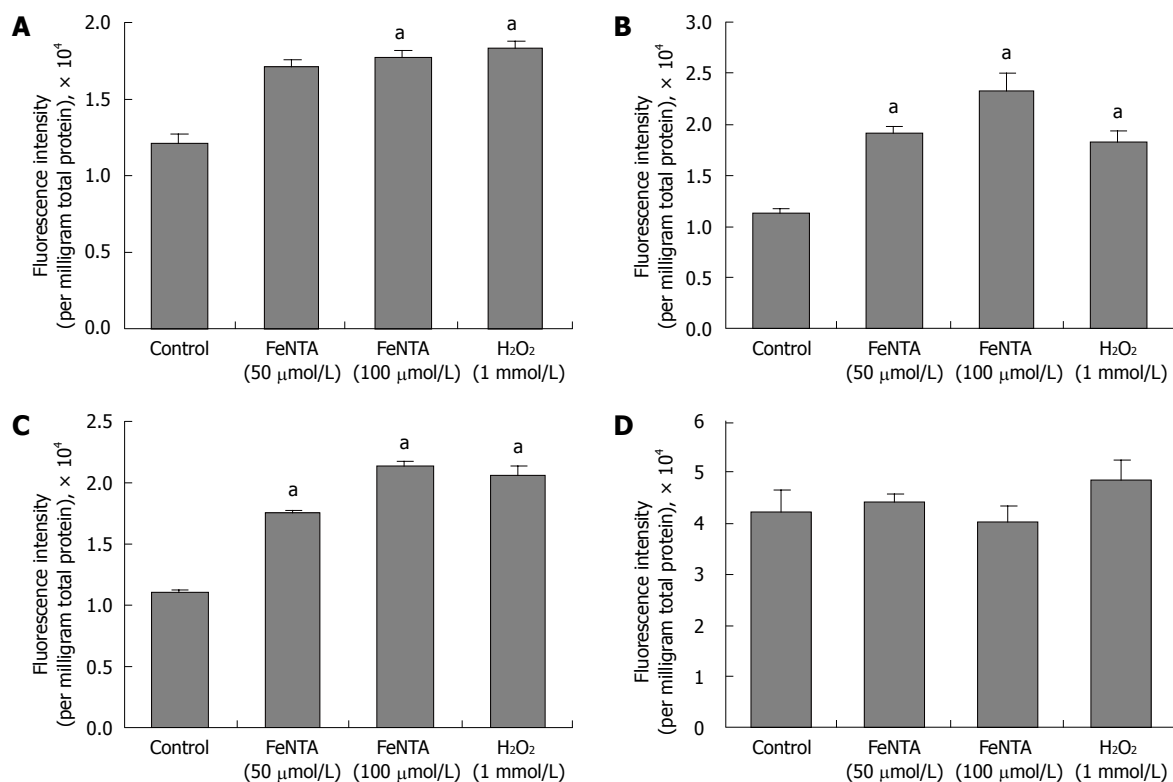

Figure 5 Effects of FeNTA on intracellular ROS in Huh-7, 9-13, and CNS3 cells. A: Fluorescence intensity with the H₂DCF-DA probe in Huh-7 cells; B: Fluorescence intensity with the H₂DCF-DA probe in 9-13 cells; C: Fluorescence intensity with the H₂DCF-DA probe in CNS3 cells; D: Fluorescence intensity with the (control) DCF-DA in CNS3 cells. Cells were preincubated with 100 μmol/L H₂DCF-DA or DCF-DA for 30 min, and then exposed to selected concentrations of FeNTA (0, 50, 100 μmol/L) for 1 h. Intracellular ROS production was measured as described in Materials and Methods. Data represent fluorescence intensity measured and expressed as relative fluorescence units per milligram total protein (mean ± SE, *n* = 3 experiments). ^a*P* < 0.05 vs control.

Figure 6 Effects of deferoxamine on intracellular ROS induced by FeNTA in Huh-7, 9-13, and CNS3 cells. A: Fluorescence intensity with the H₂DCF-DA probe in Huh-7 cells; B: Fluorescence intensity with the H₂DCF-DA probe in 9-13 cells; C: Fluorescence intensity with the H₂DCF-DA probe in CNS3 cells; D: Fluorescence intensity with the (control) DCF-DA in CNS3 cells. Cells were loaded with 100 μmol/L H₂DCF-DA for 30 min, treated with different concentrations of deferoxamine (50, 100, 200 μmol/L) for 30 min, and then exposed to different concentrations of FeNTA (50, 100 μmol/L) for 1 h. Intracellular ROS production was measured as described in Materials and Methods.

Figure 7 Effects of FeNTA on HCV core and NS5A mRNA and protein levels. A: Core mRNA levels in Con1 cells treated with FeNTA and with or without deferoxamine; B: Core protein levels in Con1 cells treated with FeNTA and with or without deferoxamine; C: NS5A mRNA levels in Con1 cells treated with FeNTA and with or without deferoxamine; D: NS5A protein levels in Con1 cells treated with FeNTA and with or without deferoxamine. Data are presented as mean \pm SE from triplicate samples, all normalized to GAPDH in the same samples. $^aP < 0.05$ vs control. The Con1 full length HCV replicon cells were treated with indicated concentrations of FeNTA and with or without deferoxamine. After 24 h, cells were harvested and total RNA and proteins were extracted. Levels of mRNA were measured by quantitative RT-PCR, and protein levels were determined by Western blots as described in Materials and Methods. Values for cells without any treatment were set equal to 1.

tonically down-regulates the *HMOX1* gene^[40]. In addition, we and others have shown that expression of micro RNA-122 is required for HCV replication in human hepatoma cells^[40,63,64]. Whether iron affects levels of micro RNA-122 has not yet been assessed, to our knowledge.

Others recently reported that iron binds to NS5B, the RNA dependent RNA polymerase of HCV, and inhibits its enzymatic activity^[43]. The HCV replicon system used in that study showed changes in the gene expression of certain genes involved in iron metabolism, including down-regulation of ceruloplasmin and transferrin receptor 1 but up-regulation of ferroportin thus producing an iron-deficient phenotype^[65]. The authors speculated that the HCV genes and proteins somehow produced these changes in order to diminish the effects of iron to inhibit NS5B RNA polymerase activity and to decrease HCV protein expression.

Regardless of these results in cell culture models, the preponderance of clinical evidence^[10-15,24-29] supports the view that iron acts as a co-morbid or synergistic factor in chronic hepatitis C infection. Because both iron and HCV infection increase oxidative stress within

hepatocytes, one attractive mechanistic explanation for the additive or synergistic affects of these two perturbations is that they act, at least in part, by increasing oxidative stress in the form of highly reactive oxygen species. These considerations provide additional rationale for the notion that reduction of iron and antioxidant therapy^[62] may be of benefit in the management of difficult to cure chronic hepatitis C^[10-15,24-29,66-68]. Iron reduction has usually been achieved with therapeutic phlebotomies. However, deferasirox (Exjade) recently has been approved in the USA and other countries as oral chelation therapy for iron overload states. Thus, studies of deferasirox for therapy of chronic hepatitis C are timely and important^[69], especially because the therapy of chronic hepatitis C currently is fraught with side effects, difficulties of adherence and rates of response that are not better than about 50%^[70-72].

In conclusion, iron can cause or exacerbate liver damage, including viral hepatitis. In the work reported in this paper we assessed effects of iron and iron chelators on liver cells, some of which also expressed genes and proteins of the HCV. Iron increased oxidative stress

and led to up-regulation of the *HMOX1* gene, a key cytoprotective gene. A mechanism for this action was to increase expression of the positive transcription factor Nrf-2. In contrast, iron did not affect expression of Bach1. Iron decreased expression of HCV genes and proteins. All the effects of iron were abrogated by DFO. The induction of HMOX1 helps to protect liver cells from the damaging effects of the HCV.

ACKNOWLEDGMENTS

We thank Ralf Bartenschlager (University of Heidelberg, Germany) for kindly supplying the HCV replicon cells used in this paper and Melanie McDermid for help in preparing the manuscript.

COMMENTS

Background

Iron overload is known to be toxic to many organs. The most common form of iron overload is hereditary hemochromatosis. In this disease, iron overload results in damage to many organs including the heart, pancreas and liver. In fact, the main site of iron deposition is in the liver. Recently it has been learned that iron plays a role in non-hemochromatotic liver disease. By insight into the mechanisms of how iron leads to this damage, novel ways to improve outcomes and success in treating these liver diseases may be achieved. One such liver disease is chronic hepatitis C.

Research frontiers

Currently chronic hepatitis C affects more than 170 million people worldwide. Standard therapy consists of a combination of pegylated alpha interferon and ribavirin. This is a difficult treatment regimen consisting of almost 1 year of therapy in many cases. Unfortunately, there is only a 50% success rate for treatment overall. There is much ongoing research seeking to improve this success rate. Until recently there were no tissue culture models for investigating hepatitis C, but cell lines have been developed which support hepatitis C viral (HCV) replication. These models allow for a unique and new way to investigate HCV replication and pathogenicity.

Innovations and breakthroughs

This article examines the role of iron in inducing heme-oxygenase 1 (HMOX1) in a tissue culture model of hepatitis C. HMOX1 is a heat shock protein that is induced by physiologic and pathologic stressors. Oxidative stress is one such stressor. The authors have shown that HMOX-1 is up regulated in cell lines that express HCV proteins. The addition of iron in the form of ferric nitrilotriacetate (FeNTA) to these cell lines further upregulates *HMOX-1* gene expression. This up regulation is independent of Bach1, a protein which functions to suppress HMOX-1. The addition of iron increased oxidative stress in these cell lines as measured by a fluorescence assay and they feel it is this oxidative stress that results in further up regulation of *HMOX1* gene expression. Conversely the expression of HCV proteins was down-regulated when HMOX1 was induced. The induction of HMOX1 likely helps to protect liver cells from the damaging effects of the HCV. The iron chelators deferoxamine (Desferal) and deferasirox (Exjade) blocked the effects of FeNTA in generating reactive oxidative stress as measured by fluorescence.

Applications

Clinical evidence supports the view that iron acts as a co-morbid factor in chronic hepatitis C infection. This may be a result of the increased oxidative stress caused by both iron and HCV infection. Therefore the use of anti-oxidant therapy and iron chelators could be of benefit in the treatment of chronic HCV infection. Recently, deferasirox (Exjade) has been approved in the USA and other countries to treat iron overload states. Studies using deferasirox as an adjunct to the treatment of hepatitis C may be an aid to advance the therapy for chronic hepatitis C.

Peer review

The manuscript is a very well written and well-designed study. In this study authors have shown the critical role of iron on HCV expression and potential use of anti-chelating agents to treat the HCV patients. The study is novel.

RESULTS: 34/124 patients (27.4%) had gallbladder cancer, 47 (37.9%) had intrahepatic BTC and 43 (34.7%) had extrahepatic or perihilar BTC. EGFR expression was examined in a subset of 56 samples. EGFR expression was absent in 22/56 tumors (39.3%). Of the remaining samples expression was scored as 1+ in 12 (21.5%), 2+ in 13 (23.2%) and 3+ in 9 (16%), respectively. HER2 expression was as follows: score 0 73/124 (58.8%), score 1+ 27/124 (21.8%), score 2+ 21/124 (17%) and score 3+ 4/124 (3.2%). *HER2* gene amplification was present in 6/124, resulting in an overall amplification rate of 5%.

CONCLUSION: Our data suggest that routine testing and therapeutic targeting of HER2 does not seem to be useful in patients with BTC, while targeting EGFR may be promising.

Abstract

AIM: To analyze the pathogenetic role and potential clinical usefulness of the epidermal growth factor receptor (EGFR) and the human epidermal growth factor receptor 2 (HER2) in patients with advanced biliary tract cancer (BTC).

METHODS: EGFR and HER2 expression was studied in biopsy samples from 124 patients (51% women; median age 64.8 years), with advanced BTC diagnosed between 1997 and 2004. Five micrometers sections of paraffin embedded tissue were examined by standard, FDA approved immunohistochemistry. Tumors with scores of 2+ or 3+ for *HER2* expression on immunohistochemistry were additionally tested for *HER2* gene amplification by fluorescence *in situ* hybridisation (FISH).

INTRODUCTION

Biliary tract cancer (BTC) is a heterogeneous tumor entity consisting of an intrahepatic mass forming type cholangiocarcinoma, perihilar Klatskin tumors, extrahepatic BTC, also termed intraductal growth type, and gallbladder cancer. More than 50% of tumors are diagnosed at an advanced stage with these patients having a dismal prognosis with a mean overall survival of 7-8 mo^[1,2]. Chemotherapy is widely used but of only little benefit. Therefore, new treatment options are urgently needed. Growth factor inhibitors or antibodies and small molecules such as erlotinib, gefitinib, cetuximab, panitumu-

mab, trastuzumab and lapatinib targeting the epidermal growth factor receptor (EGFR) or the human epidermal growth factor receptor 2 (HER2) have been successfully used for the treatment of colorectal, breast, lung and head and neck cancers among others^[3-7]. While there are some case reports and a phase II trial reporting promising results targeting EGFR in BTC there are no data regarding the use of trastuzumab or lapatinib also targeting HER2^[8-10]. For pancreatic carcinoma, a malignancy somewhat related to BTC, trastuzumab has been successfully used in one study and at least one further multicenter study is currently under way^[11,12].

EGFR and HER2 are receptor tyrosine kinases encoded by proto-oncogenes. Growth factors such as epidermal growth factor (EGF) or transforming growth factor (TGF) bind to these receptors at their extracellular ligand-binding domain and initiate intracellular signalling cascades, leading to tumor cell proliferation, migration, invasion, resistance to apoptosis and angiogenesis^[3,4]. In an experimental tumor model a high proportion of ErbB-2 (HER2) transgenic mice develop BTC, suggesting a role of ErbB-2 signalling in biliary carcinogenesis^[13].

Overall, overexpression of EGFR and HER2 in tumor cells has been associated with a poor prognosis, but also offers the therapeutic option of pharmacologically targeting these receptors. To date, EGFR and HER2 overexpression has been reported in up to about 80% of BTC, mostly in small patient cohorts^[14-19]. Nevertheless, there are no data regarding the correlation of immunohistochemical scores, determined by standardized methods, with clinical findings, including the overall survival of patients with advanced BTC treated by chemotherapy. The aim of this study, therefore, was to assess the clinical significance of the expression of EGFR and HER2 proteins and their potential as therapeutic targets in advanced BTC.

MATERIALS AND METHODS

Patients

Expression of EGFR and HER2 was analyzed in biopsy samples from 124 patients with advanced or relapsed, unresectable BTC (51% women, median age 64.8 years). The patients had been consecutively diagnosed at the Tumorzentrum Ludwig Heilmeyer-Comprehensive Cancer Center Freiburg between 1997 and 2004, and were followed for a median of 71 mo. All BTC cases were histologically proven adenocarcinoma. Written informed consent was obtained from all patients. Primary gastrointestinal cancers other than BTC were excluded by upper endoscopy, colonoscopy and a multislice computed tomography (CT) scan according to the consensus guidelines published in 2002^[20]. Sixty-one patients (49.2%) had been treated by chemotherapy and could be restaged for response. The chemotherapy regimens were based on 5-fluorouracil or gemcitabine, often in combination with cisplatin or oxaliplatin. The treatment response was measured by CT, magnetic resonance imaging or

ultrasound according to the standard World Health Organization (WHO) criteria (WHO, 1979). The patients subgroup analyzed for EGFR was randomly selected. The different tumor types were similar between the subgroup and the whole study population. The baseline characteristics of the study population are given in Table 1.

Immunohistochemistry

Biopsy samples were fixed in 10% formalin, embedded in paraffin, cut in 5 µm sections and stained with hematoxylin/eosin for histological typing and grading. Immunohistochemistry (IHC) was performed on adjacent freshly cut deparaffinized sections using the peroxidase-labelled streptavidin-biotin technique, EGFR pharmDx™ for EGFR and Dako REAL™ detection system for HER2 staining (both Dako Glostrup, Denmark). Immunostaining was performed according to the package insert of the two FDA-approved detection systems, using only the supplied reagents and procedures.

IHC results were scored independently by two pathologists (Waiz O and Schmitt-Graeff A) blind to all clinical data. As recommended by the manufacturer additional tissue controls were performed along with the cell line controls.

The EGFR pharmDx™ kit is based on the dextran technology. First sections were treated with proteinase K at 37°C for 5 min (epitope retrieval) prior to incubation with the EGFR antibody for 1 h at room temperature. Following incubation with the primary antibody, the visualization reagent consists of both labeled polymer and HRP (Horseradish peroxidase). Subsequently added chromogen DAB+ results in a visible reaction product (brown) at the antigen site. Staining was performed using the Dako Autostainer® (Dako Glostrup, Denmark) au-

Figure 1 Immunohistochemistry of biliary tract cancer specimens for expression of HER2 (A, C, E and G) and EGFR (B, D, F and H). A: HER2 neg.; B: EGFR neg.; C: HER2 1+; D: EGFR 1+; E: HER2 2+; F: EGFR 2+; G: HER2 3+; H: EGFR 3+.

tomated system. As recommended for the interpretation of EGFR pharmDx™, both the intensity and percentage of tumor cells exhibiting membranous and/or cytoplasmic staining were assessed. If specific membrane staining was observed in less than 1% of tumor cells, the specimen was reported to be EGFR negative. The

four categories negative, weak (1+), moderate (2+) and intense (3+) were used as recommended by the manufacturer and approved by the FDA (Figure 1).

The detection of HER2 was performed with heat induced epitope retrieval (HIER) in 10 mmol/L citrate buffer (Target Retrieval Solution, pH 6.1, Dako) in a

Figure 2 Dual color FISH analysis of HER2 in cholangiocarcinoma specimens. A: Nonamplified tumor with single *HER2* gene copy status. The red probe is specific for *HER2*. The green probe is specific for chromosome 17 centromere; B: Tumor with high amplification of the *HER2* gene. There are multiple red *HER2* specific signals in this tumor in relation to the green chromosome 17 signals.

water bath at 98°C for 45 min and anti-HER2 primary antibody (Polyclonal Rabbit Anti Human c-erbB-2 oncoprotein, Dako Glostrup, Denmark). Following incubation with the primary antibody, the visualization is based on the sequential application of biotinylated link antibody and streptavidin labeled with alkaline phosphatase antibody. Subsequently added chromogen Fast RED results in a visible reaction product (red) at the antigen site. HER staining was also performed using the Dako Autostainer® (Dako Glostrup, Denmark). Tumors were counted negative if less than 10% of carcinoma cells were stained, irrespective of membrane signal intensity. If 10% or more of carcinoma cells showed membrane staining, the staining intensity was classified as weak (1+), moderate (2+) or intense (3+) as recommended by the manufacturer and approved by the FDA (Figure 1). Cytoplasmic staining was discounted. Images provided by DAKO were used to define these staining categories.

Fluorescence in situ hybridization (FISH)

The PathVysion™ detection kit (Abbott, Illinois, USA) was used for FISH analysis in cases of IHC expression scores 2+ or 3+ for HER2. FISH staining was carried out according to the manufacturer's manual. The presence of gene amplification was determined using the supplied fluorescence-labelled DNA probe for chromosomal locus 17q11.2-q12 for the detection of *HER2*. FISH-stained sections were scanned at $\times 1000$ magnification and in each of three separate carcinoma areas. Twenty nuclei were analyzed. *HER2* and chromosome 17 copy number were counted for all cells and the ratio of *HER2* to chromosome 17 was calculated. A normal *HER2*:17 ratio was defined as ≤ 2 ; a ratio > 2 was interpreted as gene amplification. A normal *HER2* copy number was attested at < 4 signals per cell (Figure 2).

Statistical analysis

Data are presented as mean \pm SD or medians with range for continuous variables and as absolute and relative frequencies for categorical variables. Overall survival estimates and median survival times were calculated by the Kaplan-Meier method followed by Cox models estimating relative risks. All statistical tests were two-sided using a 5% significance level. SAS software was used for the calculations.

RESULTS

Expression of EGFR and HER2 protein

From the 124 patients examined 34 (27.4%) had gallbladder cancer, 47 (37.9%) had intrahepatic mass forming type BTC (IHCC) and 43 (34.7%) had extrahepatic or perihilar, intraductal growth type BTC (EHCC). Because EGFR expression was expected to be present two fold more frequently than HER2 expression in BTC only a subset of 56 samples was examined. EGFR expression was negative in 39.3% (22/56) of the patients. Weak (1+) positive EGFR staining was found in 21.5% (12/56), moderate (2+) in 23.2% (13/56) and intense (3+) in 16% (9/56) of the tumors. Overall 39.2% of the samples showed EGFR overexpression (scores 2+ and 3+), being significantly ($P = 0.028$) more frequent in EHCC (57.9%) than in IHCC (25%). HER2 expression was as follows: 72/124 (58%) were negative, 26 (21%) 1+, 22 (18%) 2+ and 4 (3%) 3+. Representative examples of EGFR and HER2 immunohistochemical staining and *in situ* hybridization are shown in Figures 1 and 2.

A close correlation between treatment response and gene amplification has been shown for HER2 in previous studies^[4]. However, unlike the case of trastuzumab and HER2 in breast cancer, *EGFR* gene amplification detected by FISH has not been approved as being as useful for deciding on an EGFR targeted therapy yet. Therefore, we did not study *EGFR* gene amplification in our patient cohort. Regarding HER2, based on published data and the manufacturer's recommendation, tumors with no or 1+ HER2 immunostaining were not further investigated for gene amplification. Of the 124 patients samples tested 25 were examined for *HER2* gene amplification. HER2 FISH was performed in 2+ and 3+ samples and was successfully performed in all but one tumor examined. All specimens exhibiting 3+ immunostaining (4/4) showed gene *HER2* amplification while amplification was present in 2/21 (10%) of 2+ samples. Taken together, *HER2* gene amplification could be detected in 6/124 (5%) tumors.

Correlation of EGFR and HER2 expression with clinicopathological factors

Among the 124 patients 80 (64.5%) had moderately differentiated tumors, 36 (29%) had poorly differentiated and

8 (6.5%) had well differentiated tumors. The majority of patients (64/124, 51.6%) had stage IV disease, 31 (25%) had stage III, 20 (16.1%) stage II and 9 stage I (7.3%). The patients had not undergone surgery because of unresectability, comorbidity or patients' wish. Half of the patients (62/124) had been treated with chemotherapy, resulting in tumor control in 59% (14.7% PR, 44.3% SD). Median overall survival was 13 mo with a median OS of 14 mo for patients treated with chemotherapy compared to 9 mo for patients not treated with chemotherapy. There was no statistical association between protein expression and grade, stage, overall survival and treatment response for EGFR and HER2, respectively. The frequencies of EGFR and HER2 overexpression and clinicopathological variables are summarized in Table 2. In univariate analysis EGFR and HER2 expression could not be shown to be of prognostic relevance for overall survival ($P = 0.06$ and $P = 0.49$).

DISCUSSION

Expression of the two ErbB family growth factor receptors EGFR and HER2 has been intensively studied in different tumor entities and led to the use of targeted therapy with specific inhibitors or antibodies of these receptors in colorectal, breast, lung as well as head and neck cancer^[4]. To date in other cancers monoclonal antibodies and small molecule tyrosine kinase inhibitors such as cetuximab, trastuzumab, erlotinib, gefitinib and lapatinib are under investigation. Expression of EGFR and HER2 as potential therapeutic targets has been reported in various tumors^[4,7,21,22]. For BTC, data for EGFR and HER2 overexpression have been presented in mostly small patient cohorts^[14,17,19,23]. Recently Yoshikawa *et al*^[24] described an unselected large cohort of 236 cases of resected BTC. In this study, we investigated EGFR and HER2 expression in a large cohort of patients with advanced, unresectable BTC.

In BTC the percentage of EGFR overexpressing tumors in previously reported series ranged from 8.1% to 81%. Yoshikawa *et al*^[24] showed EGFR overexpression in 26.4% of EHCC and 17.7% of IHCC. Similarly, in our study EGFR overexpression was more frequent in EHCC (57.9%) than in IHCC (25%, $P = 0.028$). In these reports by Ito *et al*^[23] and Yoshikawa *et al*^[24] EGFR overexpression was associated with biological aggressiveness of BTC. In addition, there is increasing evidence that EHCC and IHCC respond differently to chemotherapy suggesting different biological properties of these two tumor subtypes of "cholangiocarcinoma"^[25,26].

HER2 overexpression and amplification has been found in a range between 5% and 76% in BTC^[14-19,24,27]. This wide range may in part reflect the lack of standardized methodologies used within the different studies to assess HER2 status. In our cohort with advanced, unresectable BTC, HER2 overexpression was present in 20% and treatment relevant HER2 amplification in 5%. Some authors suggest that HER2 overexpression is due to gene deregulation rather than gene amplification because in some reports there is no strict correlation between protein expression and gene amplification^[19]. Overall, the highest concordance between HER2 expression and gene amplification was demonstrated for breast cancer^[7,28,29]. Our data suggest that in advanced BTC with high HER2 expression there is also a good correlation between overexpression and amplification, since all samples with a 3+ HER2 score showed gene amplification as compared to only 2/21 (10%) with a 2+ HER2 score. Similar correlations have been reported for other malignancies, including breast cancer with a tendency towards lower therapeutic relevant expression rates with improved, standardized detection methods. It has to be assumed that earlier reports overestimated HER2 expression in BTC, explaining the discrepancy between HER2 expression and gene amplification^[28,30,31]. Despite the fact that HER2 transgenic mice frequently develop BTC, HER2 does not seem to play a major role in human biliary tract malignancies. This animal tumor model may therefore be of limited value as a model for human BTC.

In recent reports in early stage, resected BTC overall HER2 amplification was about 5%-10%^[24,32]. In our cohort of patients with advanced BTC, HER2 amplification was merely 5%. Since targeted therapy with the anti-HER2 antibody trastuzumab in breast cancer is only effective when the HER2/neu receptor is overexpressed *via* gene amplification HER2 seems not to be a promising target in BTC. Therapeutic trials targeting HER2 should therefore not further be initiated.

Since EGFR expression does not predict its therapeutic usefulness, future clinical trials have to evaluate the advantage of Anti-EGFR therapy in comparison with standard treatment in patients with BTC.

In summary, our findings demonstrate that EGFR overexpression is frequent in BTC, especially in EHCC. In contrast, HER2 overexpression and gene amplification is a rare event. While therapeutic targeting

of HER2 seems to be not promising, future clinical trials in patients with BTC should focus on EGFR.

COMMENTS

Background

The epidermal growth factor receptor (EGFR) and the human epidermal growth factor receptor 2 (HER2) are involved in the carcinogenesis of many malignancies. Therapeutic molecules targeting EGFR and HER2 have been successfully used for the treatment of colorectal, breast, lung and head and neck cancers among others. It is unknown if EGFR and HER2 are overexpressed in advanced biliary tract cancer (BTC) and therefore may serve as therapeutic targets in these cancers.

Research frontiers

As the so called targeted therapies are most effective when the corresponding receptor or signalling pathway is activated, previous studies have focused on EGFR and HER2 in various tumors. There are conflicting data about overexpression of EGFR and HER2 in BTC and about the therapeutic importance of the two growth factor receptors in these tumors. Because of the low incidence, clinical trials on BTC are difficult and mostly performed in small patient cohorts. A possible selection bias might additionally explain these conflicting data.

Innovations and breakthroughs

While EGFR is significantly overexpressed in advanced BTC, HER2 overexpression and amplification is rare and therefore seems not to play a role in the carcinogenesis of BTCs.

Applications

Because of these expression data on EGFR and HER2 in BTC, and the correlation of expression and therapeutic effectiveness, especially with HER2 in other tumors, future clinical trials in BTC should focus on EGFR as a therapeutic target.

Terminology

EGFR and HER2 are receptor tyrosine kinases encoded by proto-oncogenes. Growth factors such as epidermal growth factor or transforming growth factor bind to these receptors and initiate tumor cell proliferation, migration, invasion, resistance to apoptosis and angiogenesis. BTC is a heterogeneous tumor entity with rising incidence, consisting of intrahepatic mass forming type cholangiocarcinoma, perihilar Klatskin tumors, extrahepatic bile duct tumors, also termed intraductal growth type cholangiocarcinoma, and gallbladder cancer.

Peer review

Harder *et al* describe low expression and gene amplification of HER2 in biopsy samples of advanced BTC, as assessed by immunohistochemistry and fluorescence *in situ* hybridisation, respectively. The authors suggest that deviating numbers of some earlier studies may be due to non-standardized techniques. It is convincing that in the present paper results for protein expression and gene amplification correlated well.

Abstract

AIM: To understand the complex reaction of gastric inflammation induced by *Helicobacter pylori* (*H. pylori*) in a systematic manner using a protein interaction network.

METHODS: The expression of genes significantly changed on microarray during *H. pylori* infection was scanned from the web literary database and translated into proteins. A network of protein interactions was constructed by searching the primary interactions of selected proteins. The constructed network was mathematically analyzed and its biological function was examined. In addition, the nodes on the network were checked to determine if they had any further functional importance or relation to other proteins by extending them.

RESULTS: The scale-free network showing the relationship between inflammation and carcinogenesis was constructed. Mathematical analysis showed hub and bottleneck proteins, and these proteins were mostly related to immune response. The network contained pathways and proteins related to *H. pylori* infection, such as the JAK-STAT pathway triggered by interleukins. Activation of nuclear factor (NF)- κ B, TLR4, and other proteins known to function as core proteins of immune response were also found. These immune-related proteins interacted on the network with pathways and proteins related to the cell cycle, cell maintenance and proliferation, and

transcription regulators such as BRCA1, FOS, REL, and zinc finger proteins. The extension of nodes showed interactions of the immune proteins with cancer-related proteins. One extended network, the core network, a summarized form of the extended network, and cell pathway model were constructed.

CONCLUSION: Immune-related proteins activated by *H. pylori* infection interact with proto-oncogene proteins. The hub and bottleneck proteins are potential drug targets for gastric inflammation and cancer.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a gram negative bacterium which infects about 50% of the world population^[1-3]. It is known to cause various gastroduodenal diseases such as chronic active gastritis in experimental animals and in humans. In human volunteers, *H. pylori* caused gastritis and hypochlorhydria^[4]. Mongolian gerbils infected by *H. pylori* also developed symptoms such as intestinal metaplasia and adenocarcinoma^[5-9]. Many scholars have demonstrated a relationship between *H. pylori* and gastric carcinoma^[3], and the World Health Organization (WHO) and the International Agency for Research on Cancer consensus group have classified *H. pylori* as a definite biological carcinogen^[10].

H. pylori colonization causes a strong systemic immune response^[11]. It induces the production of interleukins (ILs) (Korean Society for Medical Microbiology, 2004), tumor necrosis factor (TNF)^[12,13], and proinflammatory

cytokines^[14]. It also causes activation of nuclear factor κ B (NF- κ B)^[15], activator protein-1 (AP-1), c-Jun, NH₂-terminal kinase, mitogen-activated protein kinase/extracellular signal-regulated kinase, and other cell proliferation and survival factors^[16]. Bacterial toxins, high levels of superoxides, radicals, and singlet oxygen are known to induce carcinogenesis in gastric cells. Bacterial virulence factors such as CagA and VacA^[1,17,18] induce cell hyperproliferation and the expression of oncogenes. However, the exact mechanism between *H pylori* and gastric carcinoma is unclear^[19].

Various tools have been employed to identify the relationship between *H pylori* and gastric cancer, including c-DNA microarrays^[4,20]. However, most of these methods did not consider the systematic interaction of biological components. As an alternative, a network construction and analysis of protein-protein interactions^[21] were applied to examine the inflammatory response to *H pylori* infection in a systematic manner.

MATERIALS AND METHODS

The research method used in this study mainly consisted of three steps. Step one: extraction of the genes which changed significantly during *H pylori* infection from the database and by querying web databases to gather protein-protein interactions. Step two: construction of a network and summarizing the constructed network. Step three: analysis and extension search of the network. A flow chart showing the data flow is described in Figure 1.

Searching genes related to *H pylori* infection (Step 1)

Genes related to *H pylori* infection were collected by searching PubMed. The expression of genes significantly changed ($P < 0.05$) by *H pylori* infection in the microarray^[4,11,13,20] data was examined, and genes related to the immune response were identified and collected. A total of 39 filtered genes (Table 1) were obtained.

Scanning protein interactions and construction of protein interaction networks (Step 2)

The protein interaction networks were constructed based on statistical prediction through the analysis of microarray data. Selected genes were queried to the Uniprot database to convert into proteins. The proteins were scanned by a human Protein-protein Interaction Prediction (PIPs) database (<http://www.compbio.dundee.ac.uk/www-pips/>). Protein links were then extracted from the Human Protein Reference Database reference (HPRD, <http://www.hprd.org/index.html>). Without HPRD references, any further search of the protein links was stopped. An extended network was constructed by integrating all results extracted from the PIPs server (Figure 2). Pajek (<http://vlado.fmf.uni-lj.si/pub/networks/pajek/>) was used for the construction of extended networks. Then, a core network showing simplified main pathways, major proteins, and subcellular location information was extracted from the extended network using Cytoscape (<http://www.cytoscape.org/>).

Nodes with no HPRD reference were marked with x. HPRD: Human protein reference database.

Analysis of protein interaction network (Step 3)

The protein interactions of an extended network were examined whether or not the network contained known pathways related to *H pylori* infection, inflammation, and carcinogenesis. The core network was not analyzed because it was just the simplified form of the extended network.

Four factors: Shortest paths, degree (connectivity), betweenness centrality (BC), and closeness centrality (CC), were adopted to analyze general mathematical properties of the extended network and to search

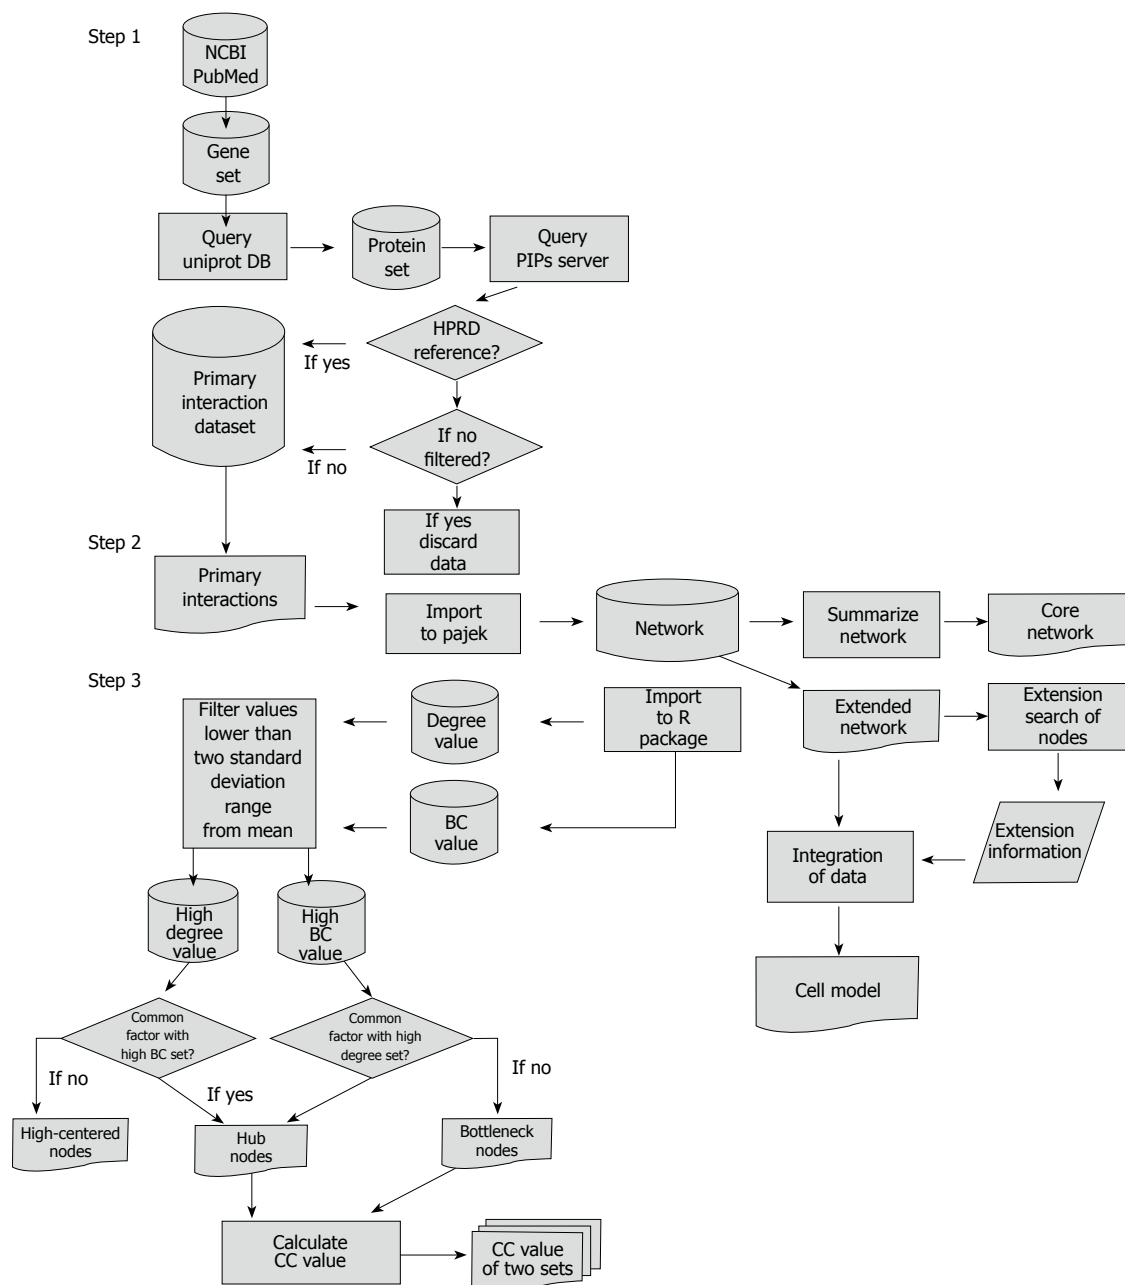

Figure 1 Flow chart showing overall methods and data flow used in this study.

topologically important proteins^[21].

Degree, the most basic characteristic of a node, is defined as the number of links the node has with other nodes. Degree distribution is obtained by counting the number of nodes with a fixed degree value, which is variable from minimum to maximum degree, and dividing it by the total number of nodes of a network^[22]. Highly concentrated nodes play a major role as a hub in a network. Degree was also used to check if an extended network was scale-free, which is frequently found in cellular networks^[22,23]. The scale-free network follows a power-law degree distribution^[22]. Power law is defined as: $P(x) = Cx^{-\alpha}$

$C = e^c$ and $P(x)$ is a probability that a selected node has exactly x links (degree value)^[23]. α is the degree exponent which determines some properties of the

network. Most of the networks found in nature are known to have degree exponent values between two and three^[22]. In this study, cumulative distribution function, a superior method of plotting data^[23], was used. The plot of log transformed probability distribution function $P(x)$ in which x has a degree value greater than or equal to x , was drawn. $P(x)$ is defined mathematically as^[23]:

$$P(x) = \int_x^{\infty} p(x') dx'$$

As the distribution follows power law,

$$P(x) = C \int_x^{\infty} x'^{-\alpha} dx' = \frac{C}{\alpha-1} x^{-(\alpha-1)}$$

A cumulative plot also follows power law, but the degree exponent of the plot is one less than the original distribution^[23]. The degree exponent was calculated by measuring the slope of the regression line and adding one to the exponent value. Other factors such as R

square, standard error, and *P*-value were also computed.

BC for node *k* is defined as:

$$b(k) = \sum_{i,j} b_{i \rightarrow j}(k) = \sum_{i,j} \frac{g_{i \rightarrow j}^k}{g_{i \rightarrow j}}$$

$g_{i \rightarrow j}$ is the number of shortest paths from node *i* to *j*, while $g_{i \rightarrow j}^k$ is the number of geodesics among $g_{i \rightarrow j}$ that passes through node *k*^[21,24]. The BC value of all nodes in the network was examined to check for bottlenecks in the network.

CC is defined as the inverse of the average length of the shortest paths to/from all the other vertices in the graph^[25]. It tells us the topological center of the network^[25]. CC was calculated by adopting the core algorithm of the R igraph package (<http://www.r-project.org/>). CC values of the protein set with either large BC value or degree were measured and compared to total CC values to check topological centrality of hubs and bottlenecks in the network.

The shortest path (geodesics) is calculated by measuring the length of all the geodesics from or to the vertices in the network. The average shortest path was measured to see how many average steps were required to link two randomly selected nodes in the network.

After computing BC and the degree of all the nodes, nodes under two standard deviation ranges from the mean were filtered out and CC values of nodes larger than two standard deviation ranges from the mean were measured. As a result, nodes with a large BC value, a large degree, both a large BC and degree, and CC value were obtained. The R package was used to calculate and analyze these values.

The network was constructed by scanning primary interactions of significantly and differentially expressed genes compared to control. Thus, it may not include hidden interactions of protein nodes between the two major nodes. For example, only the primary interaction between node A and B is available by ordinary network analysis, although the two proteins are linked *via* node C in reality. However, by extending the network, a pathway passing through node C between A and B can be found.

RESULTS

Protein interaction networks

By integrating scanned primary interactions of previously selected nodes from the PIPs server, the extended network was constructed. A core network was then derived from the extended network.

The extended network was composed of 604 nodes, connected *via* 808 edges (Figure 2). One giant network with 599 nodes and 805 edges, and two separate interactions were observed. Examining the shortest paths of the network showed that two randomly selected nodes on the network were connected *via* 4.89 links. This suggests that the nodes were very closely linked. In addition, a small world effect can be found^[26]. The distribution of the shortest paths was plotted using histograms (Figure 3A). The average value (4.89) was similar to other values of human protein networks^[21,26].

CC: Closeness centrality.

The cumulative distribution plot showed clear evidence that the extended network follows scale-free distribution (Figure 3B). By measuring the slope of the regression line of the plot drawn on the basis of log transformed cumulative data, the α value of 1.1968 in the power law distribution was determined. As the degree exponent of the cumulative plot is one less than original distribution^[23], the true degree exponent value should be 2.1968 (standard error = 0.04, coefficient of determination R square = 0.97, and *P*-value = nearly zero by the least square fit)^[27]. It is known that networks with a degree exponent larger than three do not have features that scale-free networks have^[22]. The degree exponent value of the extended network (2.1968) was lower than 3, which was similar to other networks following a scale-free distribution, rather than a random distribution.

Important nodes in the network

One of the properties of networks following scale-free distribution is the existence of a small number of highly connected nodes, called hubs which are more important than other less connected nodes^[22,28]. The hub nodes are more critical to the survival of cells (Tables 2 and 3). The scale-free networks are prone to breakdown into fragments when nodes are attacked^[29]. Other important nodes also have a large BC value. The node with a large BC functions as a bottleneck in the network, even when the node's degree is low. Nodes with a degree or BC value larger than the mean plus two standard deviations were selected. Sixteen nodes were determined to have a large degree (Table 2) and 19 nodes had a large BC (Table 4). Twelve nodes had both a large degree and a large BC (Table 3). Six nodes: NF-κB3 (Nuclear factor κB p65 subunit), MAPK8 (Mitogen-activated protein kinase 8), NFKBIA (NF-κB inhibitor α), HCK (Hemopoietic cell kinase), PTPRC (Leukocyte common antigen CD45), and ITGB2 (Integrin β-2) were the top six nodes on both degree and BC values.

Table 3 List of proteins with both a large BC and degree, and their functions

Protein name	Function
RELA/NF- κ B3	NF- κ B is a pleiotropic transcription factor which is present in almost all cell types and is involved in many biological processes such as inflammation, immunity, differentiation, cell growth, tumorigenesis and apoptosis
MAPK8	Responds to activation by environmental stress and pro-inflammatory cytokines by phosphorylating a number of transcription factors, primarily components of AP-1 such as JUN, JDP2 and ATF2 and thus regulates AP-1 transcriptional activity
NFKBIA	Inhibits the activity of dimeric NF- κ B/REL complexes by trapping REL dimers in the cytoplasm, masking their nuclear localization signals
HCK	May serve as part of a signaling pathway coupling the Fc receptor to activation of the respiratory burst. May also contribute to neutrophil migration and regulate the degranulation process of neutrophils
PTPRC	Required for T-cell activation through the antigen receptor
ITGB2	Receptor for ICAM1, ICAM2, ICAM3 and ICAM4
TLR4	Cooperates with LY96 and CD14 to mediate the innate immune response to bacterial lipopolysaccharide (LPS). Acts <i>via</i> MYD88, TIRAP and TRAF6, leading to NF- κ B activation, cytokine secretion and the inflammatory response
PLAT	Converts the abundant, but inactive, zymogen plasminogen to plasmin by hydrolyzing a single Arg-Val bond in plasminogen. By controlling plasmin-mediated proteolysis, it plays an important role in tissue remodeling and degradation, in cell migration and many other physiopathological events
TRAF4	Adapter protein and signal transducer that links members of the tumor necrosis factor receptor family to different signaling pathways by association with the receptor cytoplasmic domain and kinases
MAP2K1	Catalyzes the concomitant phosphorylation of a threonine and a tyrosine residue in a Thr-Glu-Tyr sequence located in MAP kinases. Activates ERK1 and ERK2 MAP kinases
TLR2	Cooperates with LY96 to mediate the innate immune response to bacterial lipoproteins and other microbial cell wall components
STAT6	Carries out a dual function: signal transduction and activation of transcription. Involved in interleukin-4 signaling

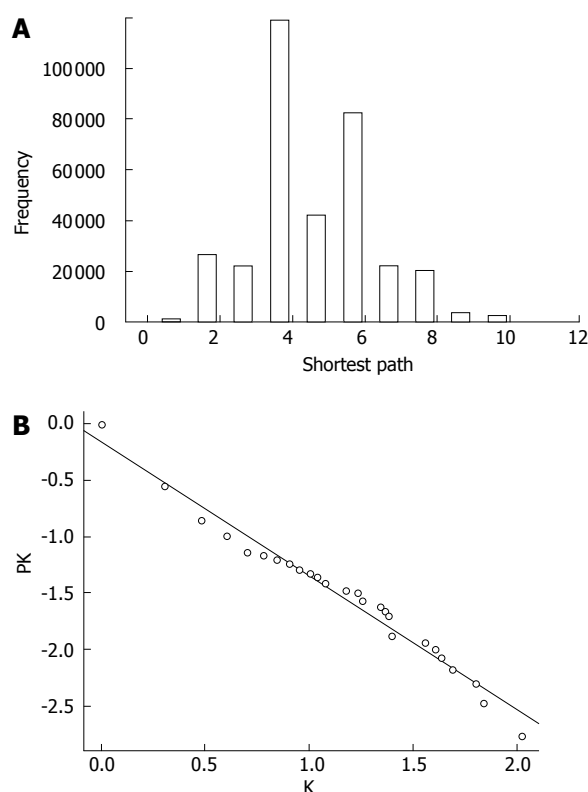

Figure 3 Properties of the extended network. A: Histogram showing distribution of the shortest path. Two randomly selected nodes were connected *via* 4.9 links; B: Cumulative degree distribution plot of the extended network showing that degree distribution follows the power law. Line indicates the degree exponent of 1.2, which is one lower than the true degree exponent of 2.2.

STAT6 (Signal transducer and activator of transcription 6), TLRs (Toll-like receptor), TRAF4 (TNF receptor-associated factor 4), and PLAT (TPA, Tissue-type plasminogen activator) also had both a large BC and degree (Table 3). NF- κ B3, NFKBIA, PTPRC, TLRs, and HLA-DRB5 are already well-known for having

BC: Betweenness centrality.

biological functions related to immune response^[2,3,21]. STAT6 is related to the JAK-STAT pathway which sends signals from ILs directly to the nucleus^[30]. MAPK8 of the MAPK signaling pathway can be found in the signaling of other inflammatory responses in asthma, and is related to cell proliferation^[31]. TRAF4 is involved in tumor necrosis and TPA (PLAT) in plasminogen activation, respectively. Most of these nodes are related to immune response and signal transduction, suggesting that these nodes perform major functions against *H. pylori* infection.

Not only nodes with both a large degree and BC, but also nodes with a large BC and a small degree were considered important in previous research^[21], since these nodes function as bottlenecks in the network,

Table 5 List of proteins with only a large BC and their functions

Protein name	Function
HMGB1	Binds to preferentially single-stranded DNA and unwinds double-stranded DNA
BTK	Plays a crucial role in B-cell ontogeny
CSNK2A1	Casein kinases are operationally defined by their preferential utilization of acidic proteins such as caseins as substrates
CXCR4	Transduces a signal by increasing the intracellular calcium ion level
CCL4	Monokine with inflammatory and chemokinetic properties
RAC2	Plasma membrane-associated small GTPase which cycles between an active GTP-bound and inactive GDP-bound state. In active state binds to a variety of effector proteins to regulate cellular responses, such as secretory processes, phagocytosis of apoptotic cells and epithelial cell polarization. Seems to be involved in the regulation of NADPH oxidase

even without the role of hubs. Six nodes: HMGB1 (High mobility group protein B), BTK (Bruton tyrosine kinase), CSNK2A1 (CSK2A1, Casein kinase II subunit alpha), RAC2 (Ras-related C3 botulinum toxin substrate 2), CCL4 (C-C motif chemokine 4), and CXCR4 (C-X-C chemokine receptor type 4) had a large BC but a low degree. Large BC nodes such as CXCR4, CCL4, BTK, CSNK2A1, and RAC2 with the exception of HMGB1 are related to immune response and signal transduction (Table 5). HMGB1 unwinds double-stranded DNA and binds preferentially to single-stranded DNA, which may be related to the gene regulation of immune response. As expected these large BC nodes were linked to important nodes, such as hubs. HMGB1 was linked to NF- κ B3, TLR4, TLR2, and PLAT, which have a large BC degree (Figure 2). BTK interacted with NFKBIA, TLR4, HCK, and IL10RA. NFKBIA, TLR4, and HCK had a large BC and degree, while IL10RA had a large degree only. CSNK2A1 was linked to NF- κ B3, NFKBIA, PTPRC, and HSPH1. RAC2 interacted with NFKBIA, HCK, and ALOX5. Lastly, CCL4 and CXCR4 were linked to PTPRC and PLAT. Thus, it was demonstrated that the nodes with large BC play important roles in the connection and communication of nodes including hubs.

The CC values of nodes with a large degree or BC were checked to see if these proteins were near to the topological center of the network. The larger the CC value is, the closer the node is to the center of the network^[21]. NF- κ B3 was closest to the topological center, and NFKBIA was the second closest in the network (Tables 2 and 4).

Biological functions of pathways and nodes in the network

Pathways related to immune response and other biological phenomena were observed in the network (Figures 4 and 5). The network contained previously known pathways which were involved in *H pylori* infection and inflammation.

The network (Figures 2 and 4) showed interactions of IL 1, 4, 8, 10, 13, 17, and 18 receptors with JAKs and STATs that send signals from cell-surface receptors to the nucleus^[30]. IL 8 increases significantly during *H pylori* infection, thus it was used as a standard to determine the pathogenicity of different *H pylori* strains^[19]. IL 1, 10, and 18 changed significantly, which was demonstrated by microarray analysis or Western blotting data^[11,13,32].

IL 4 and 13 are proinflammatory cytokines. While IL 4 induces eosinophilic inflammation and differentiation of Th2 cells, IL 13 produces immunoglobulin E (IgE)^[33].

Interactions of Toll-like receptors (TLRs), also known to be immune-related, were observed. The TLR4 signaling pathway is associated with an immune response by interacting with MYD88 and IRAK1^[34,35] in the network (Figure 4). They were linked to proteins in the nucleus through MAPKs.

Another pathway in the network was found among the MAPKs. Interactions among MAPK 1, 3, and 8 in the network were observed. In immune-related diseases such as asthma, the activation of MAPK due to infection has also been reported^[21,36,37].

Besides full pathways, the presence of single or a few interactions having biological functions were informative. NF- κ B and AP-1 are two key regulatory factors of inflammation^[38-40]. NF- κ B1-NF- κ B3 linkage and JAK-NFKBIA-STAT linkage were found (Figure 5). The regulation of NF- κ B by AP-1(JUN) and NFKBIA was also observed (Figure 4).

Although activation of TNF α ^[13] was not found in the network, TNFSF11 (Tumor necrosis factor ligand superfamily member 11) and TRAFs (TNF receptor associated factor), related to TNF, were found. Tumor necrosis factors induce cell proliferation by activating anti-apoptosis^[16]. Cell proliferation and carcinogenesis are one of the well-known characteristics of cells infected by *H pylori*^[19]. In addition, BRCA1 (Breast cancer type 1 susceptibility protein), FOS (*c-fos*, Proto-oncogene protein)^[41], REL (C-Rel proto-oncogene protein), and VAV1 (Proto-oncogene vav), which are oncogenes, were found. The presence of TNF and the oncogenes in the network suggests that *H pylori* infection may be related to carcinogenesis.

SRC (Proto-oncogene tyrosine-protein kinase) in the network is involved in cell maintenance and communication^[21]. CDK5 (Cyclin-dependent kinase 5), RASA1 (Ras GTPase-activating protein 1) and RASA3 are related to cell growth effect^[30].

Not only protein nodes related to inflammation and carcinogenesis, but also proteins related to stress resistance were found. Infection of *H pylori* increases levels of superoxide and singlet oxygen. The stress-resistance protein, HSPH1 (Heat shock protein 105 kDa), HSPA8 (Heat shock cognate 71 kDa protein), and HSPB1 (Heat shock protein β -1) were found.

Generally, stimulation and regulation of the immune

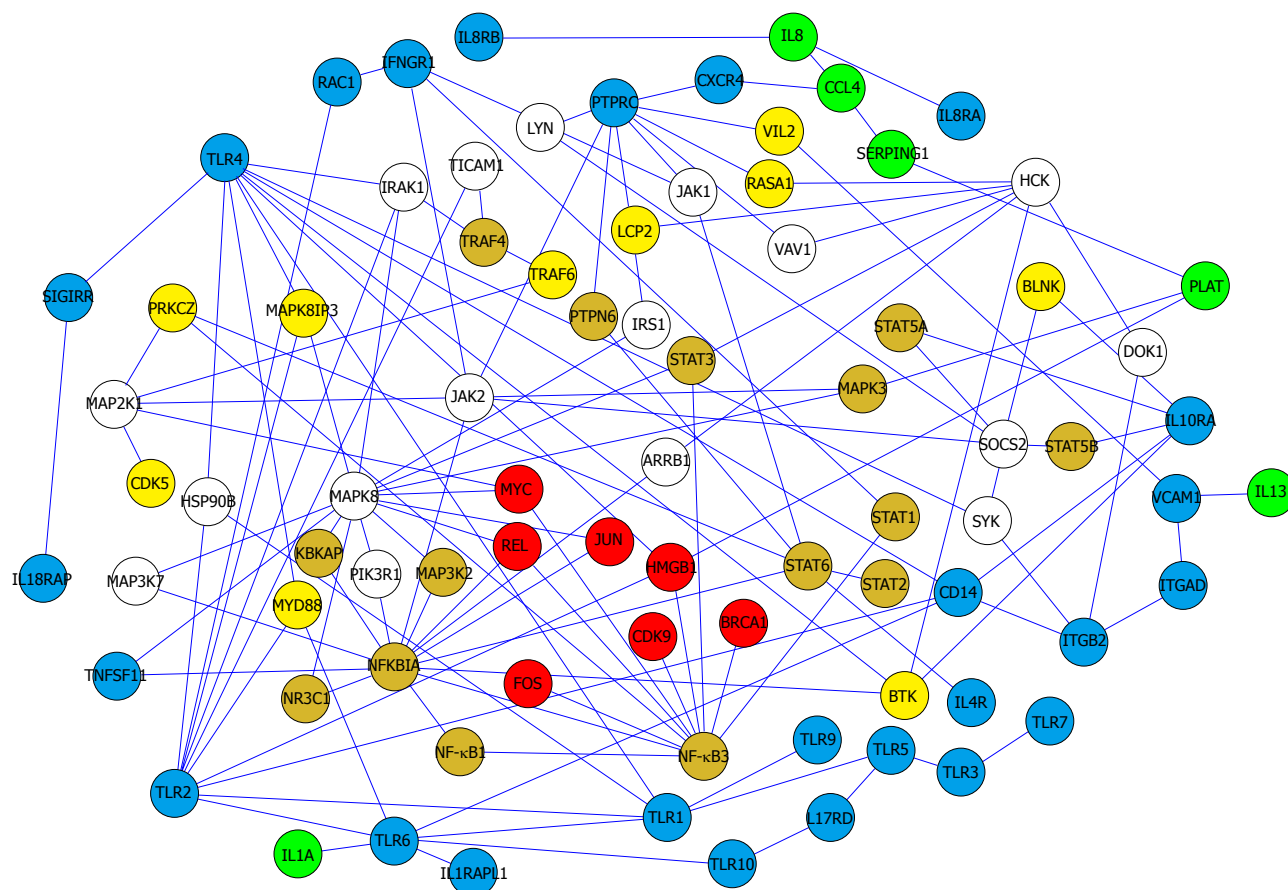

Figure 4 Core network showing simplified interactions and major pathways. Color of the nodes indicates subcellular location. Red (nucleus), orange (nucleus and cytoplasm), yellow (cytoplasm), blue (membrane), green (extracellular), and white (unknown).

Figure 5 Cell model showing major interactions after *H. pylori* infection.

system through their receptors were found in the network. Activation of cell signaling, cell proliferation, cell survival, proto-oncogenes, and stress resistance were observed. These functions are reminiscent of the observed response of cells infected by *H. pylori*. The virtual network analysis in this study reflects the real protein-interaction-network in the cell.

Extension search of the network

A biologically important protein can be missed, as the network is constructed by searching only the primary interactions of selected genes. To overcome this problem, further interactions of nodes regardless of their degree or BC were examined. The extension of SRC led to BCAR1 (Figure 5). Thus, the role of cell maintenance^[42]

was connected with that of carcinogenesis in BCAR1. ADRB2 (β -2 adrenergic receptor) extension was linked to PRKCE, PRKACA, MAPK1, and MAPK3 (Figure 2). This pathway has not previously been reported in *H. pylori* infection, but has been found in immune-related diseases such as asthma^[21]. BRCA1 was further linked to CDK2, 4, 7, and CDC2 (Cell division control protein 2 homolog) (Figure 5). CDKs are activated proceeding to the cell cycle. The extension of BRCA1 was linked to JUND (transcription factor jun D), which binds to an AP-1 site and stimulates its promoter activity. BRCA1 extension led to ZNF467 (Zinc finger protein 467), a transcription regulator which has a possible relationship with cancer (Figure 2). The extension of MAPK1 led to GNAQ (Guanine nucleotide-binding protein G(q) subunit α) *via* GNAS (Guanine nucleotide-binding protein G(s) subunit α isoforms short) and AVPR2 (Vasopressin V2 receptor)^[21] (Figure 5). The proteins in this pathway contribute to cell proliferation, a well-known characteristic of cells infected by *H. pylori*^[19]. STAT1-CREBBP (CREB-binding protein) linkage was related to G1 arrest of a cell^[21] (Figure 5).

DISCUSSION

The correlation between inflammation caused by *H. pylori* infection and gastric cancer has been studied and supported by many researchers. It is important to understand the relationship between inflammation and the carcinogenesis mechanism. Microarray data were used to determine the global gene expression of infected cells. Microarray data showed up/down regulation of gene expression related to immune response, cell cycle, cell growth, and signal transduction, which may support the hypothesis that *H. pylori* infection causes cancer development^[4,11,13,20]. However, the data did not present a clear mechanism of carcinogenesis in a systematic manner. In this study, network analysis methods were applied to integrate previous data and construct the network model which shows the relationship between inflammation and cancer development.

The extended network showing primary interactions of significantly expressed genes (proteins in the network) was constructed. The network contained many protein nodes related to immune response and signal transduction induced by extracellular signals such as cytokines. The important nodes selected based on large BC and degree values were mostly involved in immune response and signal transduction. For example, the p65 subunit of NF- κ B (NF- κ B3), one of the most important regulatory factors of inflammation, was the node with the largest degree and BC value. Large BC nodes, the bottlenecks in the network, were linked to important nodes with a large degree, a large BC, or both. Like large BC and degree nodes, a large BC node was mostly related to immune response and signal transduction, with the exception of HMGB1. The constructed network also contained many pathways related to immune response and signal transduction. TLR4, JAK-STAT, and MAPK8 pathways are major pathways found in the network. Not

only the pathways, but important nodes such as NF- κ B and AP-1 (JUN) were also found in the network.

The network also showed many nodes related to carcinogenesis. Tumor related proteins such as BRCA1, FOS, REL, VAV1, TNFSF11, and TRAFs were found. The extension search of nodes was also linked to pathways related to cell proliferation, cell survival, and the cell cycle. The extracellular signal from ILs and TLRs goes to NF- κ B, NFKBIA, and AP-1 in the nucleus *via* the JAK-STAT and MAPK signaling pathways. The signal then goes to proteins in the cytoplasm *via* the JAK-STAT pathway and BTK, promoting cell proliferation and proceeding to the cell cycle. These activated processes are one of the characteristics of cells infected by *H. pylori*. In addition, *H. pylori* infection is known to increase levels of radicals and oxides. Radicals and oxides are widely thought to be possible mutagens. Oxidative stress may be an additional mechanism of carcinogenesis.

Another important factor of hub and bottleneck protein nodes is that they are potential drug targets. By inhibiting the functions of hubs and bottlenecks by small molecules, the function of the network can be shut down, meaning that the inflammatory and carcinogenesis processes can be stopped, theoretically. Traditionally, antibiotics have been used to treat gastric inflammation caused by *H. pylori* infection^[14]. However, this treatment has the potential problem of antibiotic resistance in the bacteria. As a potential alternative, this study presented the hub and bottleneck nodes as a drug target of gastric inflammation, cancer, and other diseases caused by *H. pylori* infection.

The analysis of protein network interactions showed immune response and carcinogenesis-related cell responses in a bigger picture. The extension search of nodes also demonstrated key signal transductions linking inflammatory response and carcinogenesis. This study showed how a systematic approach such as the network construction produces meaningful information. It also offered a relatively easy and simple framework to understand the complexity of cellular interactions having functional importance. Therefore, the application of this tool may be an alternative to find important genes and drug targets in other diseases and in complex biological systems.

COMMENTS

Background

The correlation between inflammation caused by *Helicobacter pylori* (*H. pylori*) infection and gastric cancer has been studied and supported by many researchers.

Research frontiers

To explain the relationship between *H. pylori* infection and cancer development,

microarray analysis was used. Microarray data showed the regulatory patterns of gene expression related to immune response, cell cycle, cell growth, and signal transduction. However, the data obtained did not show the mechanism of carcinogenesis in a systematic manner.

Innovations and breakthroughs

In this study, protein network analysis, one of the bioinformatic tools, was applied to integrate previous microarray data, and a network model was constructed showing the relationship between inflammation and cancer development. The network contained many proteins related to immune response and signal transduction induced by extracellular cytokines. Some tumor-related proteins (BRCA1, FOS, REL, VAV1, TNFSF11, TRAF) were found.

Applications

This article offered a relatively easy and simple framework to understand the complexity of cellular interactions having functional importance. This tool may be used as an alternative to find important genes and drug targets in gastric inflammation and cancer and in complex biological systems.

Peer review

This study about protein interaction network in *H pylori* infection is potentially interesting and informative.

Abstract

AIM: To investigate the inhibitory effect of natural taurine (NTau) on portal hypertension (PHT) in rats with experimentally-induced liver cirrhosis (LC).

METHODS: Experimentally-induced LC Wistar rats (20 rats/group) were treated with either oral saline or oral NTau for 6 consecutive weeks. Evaluation parameters included portal venous pressure (PVP), portal venous resistance (PVR), portal venous flow (PVF), splanchnic vascular resistance (SVR) and mean arterial pressure (MAP). Vasoactive substance levels including nitric oxide (NO), nitric oxide synthase (NOS) and cyclic guanosine monophosphate (cGMP) were also measured. Histological investigation of type I and III collagen (COL I and III) and transforming growth factor- β 1 (TGF- β 1) was also performed.

RESULTS: Treatment with NTau (1) significantly decreased PVP, PVR and PVF, and increased MAP and SVP; (2) markedly increased the vascular compliance and reduced the zero-stress of the portal vein; (3) markedly decreased the amount of NO and cGMP and activity of NOS; and (4) improved the pathological sta-

INTRODUCTION

Liver cirrhosis (LC)-induced portal hypertension (PHT), also referred to as hepatocirrhotic portal hypertension, is highly susceptible to life-threatening complications such as esophageal and fundus ventriculi variceal bleeding, as well as ascites and hepatic encephalopathy (HE), resulting in high mortality among this group of patients. Currently, several treatment modalities are commonly employed for the management of LC-induced PHT, including systemic drug treatment, surgical intervention, endoscopic ligation, and liver transplantation. Although endoscopic ligation is useful in preventing initial hemorrhage in the upper digestive tract, it is less effective when dealing with recurring bleeding^[1]. Transjugular intrahepatic portosystemic stent shunt (TIPSS) can, to a certain extent, reduce various complications of PHT. It may, however, augment the incidence of HE. Therefore, TIPSS is not generally the first therapeutic option for patients with PHT owing to its inability to improve the survival rate^[2]. On the other hand, liver transplantation is regarded as the last option to combat advanced liver cirrhosis. However, the inherent risk

associated with this radical surgical procedure and the inevitable high costs of organ transplantation, together with the long-standing disturbance of the systemic hemodynamics after transplantation, practically prevents it from being a routinely used method. Presently, long-term pharmacological treatment is still the mainstay for LC-induced PHT. To date, to develop an effective therapeutic approach for the management of LC-induced PHT remains a formidable challenge to many researchers in the field.

Our previous study showed that natural taurine (NTau) markedly inhibited the contraction and collapse of hepatic stellate cells (HSCs)^[3]. It has been well established that contraction of HSCs significantly contributes to the initiation and progression of hepatocirrhotic portal hypertension^[4,5]. As a continuation of our previous efforts to evaluate the therapeutic potential of NTau for LC-induced PHT, the present study aims at investigating the inhibitory effects of NTau on PHT, specifically focusing on the perspectives of hepatic “forward” and “backward” flow theories as well as on portal venous biomechanics and hemodynamics.

MATERIALS AND METHODS

Animals and reagents

Male specific-pathogen-free (SPF) Wistar rats weighing 215 ± 18 g were provided by the Centre of Experimental Animals, Guangxi Medical University, Nanning, Guangxi Province, China. Immunohistochemical staining kits for type I collagen (COL I), type III collagen (COL III) and transforming growth factor- β 1 (TGF- β 1) were purchased from the Wuhan Boster Biological Technology Ltd (Wuhan, Hubei Province, China). Assay kits for nitric oxide (NO), nitric oxide synthase (NOS) and cyclic guanosine monophosphate (cGMP) were obtained from the Nanjing Jiangcheng Bioengineering Institute (Nanjing, Jiangsu Province, China). The instruments used in the current project included an electromagnetic flowmeter (MFV-3200; Nihon Kohden, Japan), an 8-channel physiology recorder (RM-6000; Nihon Kohden, Japan), an ultraviolet spectrophotometer (80-2106-20; Pharmacia, UK), a UV-spectrophotometer (9100; Beijing Rayleigh Analytical Instrument Corporation, Beijing, China), and a light microscope (BX51, Olympus, Japan).

Extraction of NTau

The natural taurine (2-aminoethyl-sulfonic acid) used in the present study was extracted from black clams (*Meretrix meretrix* L.). Briefly, after the clam meat was cleaned and weighed (500 g), it was then minced in an electrical blender (4000 r/min) ten times, with each process lasting for about 10 s. Distilled water (1 L) was then added into the mince and further homogenized for 30 min. The mixture was then boiled in a water bath at 100°C for 30 min, followed by filtering the mixture through four layers of gauze. The residue on the top of the gauze was discarded and the filtrate was then centrifuged to obtain the supernatant, which was then de-acidified with HCl

(HCl:H₂O = 3). After centrifugation, the proteins were adjusted to pH 10 with NaOH (20%) aqueous solution to yield the de-alkalined proteins. After the pH value was adjusted to 5, the supernatant was further condensed. The other unwanted amino acids and pigments were removed by column chromatography using strong acid cation exchange resin as the solid phase and eluting with distilled water. The resultant NTau was quantitatively measured by high performance liquid chromatography (HPLC) and the purity of the NTau was determined to be 98.8%.

Establishment of animal model and treatment protocol

An animal model of LC was established following a previously described protocol^[6]. In brief, rats were fed with animal chow consisting of 80% corn flour, 19.5% animal fat and 0.5% cholesterol. The animals were only allowed to drink 15% aqueous alcohol. After an initial subcutaneous injection of a 40% CCl₄-olive oil solution at a dose of 5 mL/kg, the subcutaneous injections were repeated once every 3 d at a dose of 3 mL/kg for a total duration of 42 d. All rats were kept at room temperature under 12-h dark/light cycles and received humane care in accordance with the Guidelines of the Guangxi University of Chinese Medicine for the Care of Laboratory Animals.

Forty Wistar rats were randomized into 2 groups, with 20 rats in each group: a model group without NTau treatment (LC - NTau), and a model group treated with NTau (LC + NTau). During establishment of the model, rats in the LC + NTau group were concomitantly administered with 600 mg/kg NTau by gavage once daily, while LC - NTau group received only saline. Another 20 Wistar rats which received only normal animal chow and no CCl₄-olive oil solution injection were also used as the normal healthy control (NML) in the experimental design.

Influence of NTau on the “forward flow” theory of LC

Measurement of hemodynamic parameters:

Measurement of the hemodynamic parameters was conducted according to the methods described previously^[7] and was performed by an experienced technician affiliated to the first author's research group. Briefly, the animals were fasted for 8 h prior to measurement. Pentobarbital sodium (30 mg/kg) was injected through an ear vein to induce anesthesia. Then, a median epigastric incision was made in each animal which was placed in a supine position. The main portal vein (about 2 cm in length) was dissociated and exposed by blunt dissection. An incision was made followed by placement of an electromagnetic probe with an appropriate caliber connected with the electromagnetic flowmeter into the portal vein to measure the portal venous flow (PVF). Similar catheterizations were made into the portal vein and carotid artery for the measurement of the portal venous pressure (PVP) and mean arterial pressure (MAP) with the aid of a physiology recorder. All data were recorded after the hemodynamic parameters were stabilized. Portal venous resistance

(PVR) and splanchnic vascular resistance (SVR) were also calculated separately using the following equations $PVR = PVP/PVF$ and $SVR = MAP/PVF$, respectively.

Determination of NO, NOS and cGMP in portal venous blood: Heparinized portal venous blood (5 mL) was obtained and centrifuged at 3000 r/min for 10 min. The serum was extracted for determination of the concentrations of NO, NOS and cGMP using the nitrate reductase method, chemical colorimetry and radioimmunoassay respectively according to the manufacturers' instructions.

Influence of NTau on the "backward flow" theory of LC

Histological investigation of the liver tissue: Twenty-four hours after the last dosing of the experiment, the rats were anesthetized with ethyl ether, and the livers were quickly removed from the etherized animals. Tissue mass of a size measuring about 1 cm × 1 cm × 1 cm was collected from a site about 0.5 cm distant from the hepatic margin of the left lobe and then placed in a 4% paraformaldehyde solution for fixation for 24 h. The tissue mass was dehydrated in increasing concentrations of ethanol. After hydration, wax-impregnation, embedding and sectioning, HE and Masson staining were sequentially performed. Morphological changes and the degree of fiber hyperplasia of the liver tissue in rats with LC were observed under a light microscope. The grading of LC was performed according to the Knodell HAI, Scheuer, METAVIR, modified Ishak HAI and Chevallier grading systems^[8,9].

Quantitative detection of COL I, COL III and TGF- β_1 in liver tissue: Liver tissue was fixed with 10% formalin and embedded in paraffin. Then, serial sections (4 μ m) were cut. Immunohistochemical staining was performed by the Streptavidin-biotin complex (SABC) method. Briefly, the paraffin sections were baked in an oven at 60°C for 1 h and then placed into a pure xylene solution for deparaffinization twice, with each lasting for 15 min. The sections were then placed into a 3% hydrogen peroxide solution at room temperature for 30 min to inactivate endogenous peroxidase, followed by boiling in a 0.01 mol/L citrate buffer under high temperature and pressure conditions for 2 min. After this, the tissues were covered with a normal goat serum blocking buffer and placed in an incubator at 37°C for 30 min. Subsequently, anti-COL I, COL III and TGF- β_1 primary antibodies were separately added at a dilution of 1:100 to the tissues. The sections were incubated at 37°C for 30 min. After being kept at 4°C overnight, the sections were washed thoroughly in PBS (5 min × 3 times), and then biotin secondary antibody was added before incubation at 37°C for 30 min. The sections were washed again in PBS (5 min × 3 times) and in distilled water (3 min × 3 times), followed by incubation with avidin-peroxidase at 37°C for 20 min. 3,3'-diaminobenzidine (DAB) was added after smearing. The color developing was monitored under a light microscope. The staining was stopped by washing the sections in distilled water. Following stain-

ing with hematoxylin for 1 min and washing in distilled water, the sections were sequentially dehydrated in 95% and 100% ethanol for 5 min each. After air drying, the sections were sealed by neutral gum and observed under a light microscope. Mias-2000 image analysis software (Institute of Image and Graphics, Sichuan, China) was used for quantitative measurement. The ratio of the positive area of COL I, COL III and TGF- β_1 to the overall visual field area was calculated.

Determination of biomechanics of the portal vein:

After sacrifice of the rats, the main portal vein was immediately removed and connected to a three-way baroreceptor. The pressure was amplified by a dynamic electric resistor which was linked to a computer. The biomechanics of the portal vein were evaluated by measuring the corresponding pressure when the relative volume of blood vessels was changed. The vascular compliance, denoted as C, was calculated using the following formula: $C = 2\pi R \cdot \Delta R / \Delta P$, where R represents the radius of the blood vessel, ΔR and ΔP are the change of the radius and portal vein pressure respectively.

To measure the zero-stress state of the blood vessels, cross-sections were made across the portal vein and arterial rings were obtained. A cut along the ventral margin of the arterial ring was made and the expanded angle of the arteriae aorta was observed under an anatomical microscope. The photographic recording was carried out, followed by printing out on paper. The included angle, i.e. the opening angle, which was formed from the midpoint of the inner lining of the arterial ring to the two broken ends of the inner lining, was measured and used to represent changes in the zero-stress state of the blood vessels. In each rat, 5 open angles of the arterial ring were measured and their mean value was calculated.

Statistical analysis

Data were expressed as mean \pm SE. Statistical comparisons among NTau-treated animals, non-treated model controls, and healthy controls were carried out using one-way analysis of variance (ANOVA), followed by *post-hoc* Dunnett's test using the appropriate group as the control. Comparison of degrees of LC between groups was conducted by rank sum test. The analysis was performed on the SPSS for Windows (version 14.0). Differences were considered significant at $P < 0.05$ or $P < 0.01$.

RESULTS

Effect of NTau on hemodynamic alterations

Table 1 summarizes the hemodynamic data of the normal healthy animals, those having undergone LC induction and LC animals treated with NTau for six consecutive weeks. Compared with the normal healthy control group, the LC rats had very significantly higher PVP ($P < 0.01$), and the PVF and PVR were also markedly elevated in the experimentally-induced LC animals, while the MAP and SVR were considerably lower in these model animals

Table 1 Comparison of the portal hemodynamics in different groups of animals

	MAP (mmHg)	PVP (mmHg)	PVF (mL/min per kg)	SVR (mmHg/mL per min/kg)	PVR (mmHg/mL per min/kg)
NML	105.12 ± 8.56	5.26 ± 0.72	43.15 ± 1.23	2.1 ± 0.23	0.07 ± 0.03
LC - NTau	90.23 ± 4.51 ^a	7.85 ± 0.91 ^a	59.65 ± 4.32 ^a	1.61 ± 0.26 ^b	0.10 ± 0.04 ^a
LC + NTau	93.42 ± 3.25 ^c	5.38 ± 0.65 ^d	48.21 ± 2.25 ^c	1.81 ± 0.35 ^c	0.07 ± 0.05 ^c

^a*P* < 0.05, ^b*P* < 0.01 *vs* the normal healthy control group; ^c*P* < 0.05, ^d*P* < 0.01 *vs* the non-treatment model group.

Table 2 Effects of NTau on the concentrations of NO, cGMP and activity of NOS in portal venous blood

	<i>n</i>	NO (μmol/L)	cGMP (nmol/L)	NOS (U/L)
NML	20	21.41 ± 2.32	0.21 ± 0.02	2.88 ± 1.35
LC - NTau	20	48.56 ± 3.61 ^a	0.34 ± 0.04 ^a	6.45 ± 0.42 ^a
LC + NTau	20	33.14 ± 5.33 ^b	0.26 ± 0.01 ^c	3.81 ± 1.21 ^c

^a*P* < 0.05 *vs* the control group; ^b*P* < 0.01, ^c*P* < 0.05 *vs* the non-treated model group.

(*P* < 0.05). The treatment with NTau significantly attenuated PVP (*P* < 0.01), PVF and PVR (*P* < 0.05) when compared with the non-treated model group. Accordingly, the NTau treatment enhanced the MAP and SVR (*P* < 0.05). These experimental data suggest that NTau was able to improve the hemodynamic conditions in animals with LC.

Effects of NTau on the concentrations of NO and cGMP and activity of NOS in the portal venous blood

The effects of NTau on the concentrations of NO and cGMP and NOS activity are summarized in Table 2. When compared with the healthy control group, the amount of NO and cGMP and the activity of NOS were significantly increased in animals with LC. Treatment with NTau caused a significant reduction in NO (*P* < 0.01) and cGMP (*P* < 0.05) content in the blood and in the activity of NOS (*P* < 0.05) when compared with that of the non-treated LC animals. The data derived from this experiment indicate that treatment with NTau significantly mitigates the release and activation of vasoactive substances such as NO, cGMP and NOS.

Histological investigation of the liver tissue

Histological observation of normal rat liver under HE staining was characterized by intact and distinct structure of liver tissue, normal structure of hepatic lobules, and radial distribution of a cord-like arrangement of hepatocytes around the central vein (Figure 1A). In experimentally-induced LC rats, abnormal histological features were observed such as the destruction of the normal structure of hepatic lobules; extensive fibroplasia of interstitial tissue of the liver, which divided the hepatic lobules into different sizes of hepatocellular mass (i.e. formation of pseudo-lobules); extensive fatty degeneration of hepatocytes with some necrosis; and infiltration of many inflammatory cells into the portal areas and hepatic lobules. In the NTau-treated

Table 3 Degrees of liver cirrhosis of rats in different experimental groups

	<i>n</i>	Grading of LC ¹

NML	20	0	0	0	0	0	0	0
LC - NTau ^b	20	0	0	0	0	5	12	3
LC + NTau ^d	20	0	0	2	6	7	5	0

¹ Grading criteria: S₀, normal structure of liver tissue, which is characterized by an absence of deposition of abnormal collagen fibers; S_I, occurrence of fibrous septa (FS) due to hyperplasia of collagen fibers in portal areas (P) or areas surrounding the central vein (C); extension of FS within 50% of the distance between two portal areas (P-P) or between portal and central vein areas (P-C); S_{II}, extension of fibrous septa beyond 50% of the P-P or P-C; connection of fibrous septa is either incomplete or complete; absence of completely enclosed or separated hepatic lobules; S_{III}, presence of completely enclosed hepatic lobules by FS; S_{IV}, separation of hepatic lobules by extensive hyperplasia of collagen fibers; destruction of the normal lobular structure; pseudo-lobules formed are mainly large-square-shaped (> 50%); S_V, concomitant presence of large-square- and small-round-shaped pseudo-lobules (both less than 50%); and S_{VI}, intrahepatic pseudo-lobules are mainly small-round-shaped (> 50%). ^b*P* < 0.01 *vs* the normal healthy control; ^d*P* < 0.01 *vs* the non-treated LC group.

group, the damage of the structure of hepatic lobules was still observed, but with milder fibroplasia, fewer infiltrations of inflammatory cells and only modest foamy degeneration of hepatocytes when compared with the non-treated LC rats. Under Masson staining, only a small amount of collagen was observed in the normal healthy group. In contrast, a large amount of collagen fibrils were found in the LC model rats; however, only thin collagen fibrils were observed in the NTau-treated animals.

The degree of LC in all three animal groups is presented in Table 3. It is evident that the experimental procedure involved in establishing the model, essentially the high fat diet and injection of CCl₄, succeeded in inducing LC in all rats, and the degree of LC ranged from S_{IV} to S_{VI}. The treatment with NTau succeeded in ameliorating the extent of LC.

COL I, COL III and TGF-β₁ changes in the liver tissue

Figure 2 is a bar chart presentation of the ratio of the positive area of COL I, COL III and TGF-β₁ in the different animal groups. It is evident that the induction of LC in the model rats significantly increased the amount of COL I, COL III and TGF-β₁, with COL I increasing from 9.41 ± 1.36 to 30.63 ± 8.25, COL III from 10.55 ± 2.46 to 33.65 ± 7.52, and TGF-β₁ from 15.37 ± 4.62 to 31.28 ± 7.85, respectively. The

Figure 1 Histological findings of liver tissue of the rats in different experimental groups. A: Normal healthy rats; B: LC rats; C: NTau-treated groups. (magnification, 10×20).

Figure 2 Bar chart presentation of the amount of COL I, COL III and TGF-β₁ in the liver tissue of rats in different experimental groups.

intervention with NTau was capable of reducing the amount of all these parameters in the LC rats, with COL I decreasing from 30.63 ± 8.25 to 17.58 ± 3.6 , COL III from 33.65 ± 7.52 to 20.34 ± 6.41 and TGF-β₁ from 31.28 ± 7.85 to 22.17 ± 5.43 , respectively. Figures 3-5 present the immunohistochemical analysis data of the expression of COL I, COL III and TGF-β₁ in the liver tissue of the different experimental groups.

COL I was only slightly expressed in the basement membrane of the central vein of the hepatic lobules in the normal healthy rats. Its expression was significantly elevated in the LC rats with thicker collagen fibrils clearly detectable in the connective tissue surrounding the hepatocytes. Compared with the non-treated model group, the rats in the NTau treatment group had conspicuously reduced expression of COL I and thinner collagen fibrils in the connective tissue surrounding the hepatocytes. There was mild expression of COL III in the interstitial connective tissue surrounding hepatocytes in the normal healthy rats. However, significantly increased and thickened COL III fibrils were observed in the interstitial connective tissue surrounding hepatocytes in the model group. Treatment with NTau was capable of markedly attenuating the expression of COL III, with thinner collagen fibrils being observed. Similarly, TGF-β₁ was only expressed mildly in the hepatocellular cytoplasm in normal rats, and there was a strongly positive expression of TGF-β₁

in hepatocellular cytoplasm in the LC rats. Similarly to expression of COL I and III, treatment with NTau showed a significant reduction in the expression of TGF-β₁ in hepatocellular cytoplasm.

Biomechanical and biodynamic changes in the portal vein

Experiments on portal vein biomechanics showed that, in general, the portal compliance decreased as the pressure in the portal vein increased (Figure 6). Among the different groups of rats, the portal compliance in the model group was significantly lower than that of the normal control group ($P < 0.05$), while the NTau treatment was able to markedly improve the portal compliance when compared with the non-treated model group ($P < 0.05$).

In addition, there was a substantial difference ($P < 0.01$) in the opening angle of the portal ring between the model group (89.23 ± 10.47 degree) and the healthy control group (76.25 ± 9.45 degree). The NTau treatment significantly reduced the opening angle of the portal ring (82.61 ± 6.31) when compared to the animals in the model group ($P < 0.05$). The direct proportion of zero-stress to opening angle indicated that the LC rats had a very significant increase in zero-stress level, and the NTau treatment was able to mitigate this abnormal elevation.

DISCUSSION

Taurine, a sulfur-containing β-amino acid [$\text{H}_2\text{N}-(\text{CH}_2)_2-\text{SO}_2\text{OH}$], is ubiquitously distributed in tissues of mammalian and marine organisms. Taurine was once thought to be a non-functional terminal metabolite of sulfur-containing amino acids in the body. However, recent studies have confirmed that taurine has a wide variety of biological functions including maintaining homeostasis and regulating physiological functions of different systems. Taurine also possesses a wide spectrum of pharmacological activities such as antipyretic, anticonvulsant, antiplatelet-aggregation, hypotensive, immunity-enhancing, liver-protecting and angiotensin-regulating effects^[10-17]. It is known that the liver is the main

Note the increased expression of TGF- β_1 ; C: NTau-treated rats. Note that the expression of TGF- β_1 was reduced. (magnification, 10×20).

organ for taurine biosynthesis and also an important target organ for taurine's many biological activities. Interestingly, the amount of taurine in the liver tissue of rats with chronic liver disease falls below the normal range^[18].

As a free amino acid, taurine can either be synthesized through chemical reactions or extracted from natural sources. Studies in China and other countries have demonstrated that synthesized taurine may inhibit hepatic fibrosis (HF) by inhibiting collagenation and proliferation of HSCs^[19,20]. However, the role of taurine in inhibiting PHT has hitherto not been systematically investigated. Our previous study found that NTau promoted apoptosis of HSCs in a more marked manner

than that of synthesized product^[21], and that NTau could lower PHT of LC through inhibiting contraction of HSCs^[22].

Two seemingly contradictory theories, i.e. the "backward flow" theory and the "forward flow" theory, have been put forward to explain the development of PHT in LC. In the "backward flow" theory, an increase in intrahepatic resistance is thought to be the main reason for the occurrence of PHT. The "forward flow" theory, on the other hand, considers systemic hyperdynamic circulation (SHC) as the primary cause for PHT. Recent studies have shown that both mechanisms are involved in the pathogenesis of PHT^[23]. In fact, patients with LC

Figure 6 Comparison of the portal ring compliance among rats in different experimental groups.

may present both disturbances of blood circulation (i.e. increased resistance of “backward flow” theory) in liver tissue and abnormality in vasoactive substances (i.e. hyperdynamic circulation of “forward flow” theory).

By combining the “backward flow” and the “forward flow” theory together, this would furnish a better understanding of the pathogenesis of PHT^[24,25]. In the “forward flow” theory, the pathogenesis of PHT may be primarily attributed to initiation factors, including dilation of peripheral vessels, decrease in peripheral vascular resistance and mean arterial pressure, increase in blood volume, splanchnic blood flow and cardiac output, and development of systemic hyperdynamic circulatory syndrome (HCS)^[23,26]. HCS plays an important role in the maintenance of PHT and is also a primary cause for the development of sodium-water retention, ascites, hepato-renal and hepato-pulmonary syndromes. Our experimental study showed that NTau was capable of decreasing portal blood flow and improving systemic HCS by reducing PVF and increasing SVR and MAP. All these experimental observations indicate that NTau is able to reduce portal pressure through acting on the “forward flow” mechanism.

An increase in endogenous vasodilators is regarded as the most significant factor for peripheral arterial vasodilatation. Consequently, an increase of vasodilators may elicit a wide spectrum of pathophysiological alterations including vasodilatation of peripheral and splanchnic tertiary arterioles, decreased resistance, deficiency of effective arterial blood volume, activation of neurohumoral systems for pressure and water-sodium retention, compensatory expansion of plasma volume, increase in returned blood volume and cardiac output, and splanchnic active hyperemia. All these alterations can lead to hyperdynamic systemic and splanchnic circulation. Among the common vasodilators, NO, glicentin, prostacyclin and calcitonin gene-related peptides are the most important ones. NO is produced by L-arginine in the presence of NOS and may exert biological effects by increasing cGMP *via* activation of guanylate cyclase. It is also an important signaling molecule involved in various physiological processes such as vasodilatation. NO has also been found to be involved in the development

of a hyperdynamic circulatory state in LC^[27,28]. In our experiments, decreased activity of NOS and reduced amounts of NO and cGMP were observed after the NTau treatment, suggesting that NTau attenuates PHT of LC most probably *via* regulating the NO system.

In the “backward flow” theory, the most critical initiating determinants of portal pressure include the progression of HF, passive structural disorder in the liver, formation of pseudo-lobules and interrupted supply of blood circulation to hepatocytes, which further contribute to hepatocellular necrosis, proliferation of collagen, and formation of regenerative nodules. Consequently, compression and traction of peripheral vessels and bile duct by regenerative nodules and proliferated collagen fibrils may lead to increased resistance to blood flow of portal and hepatic veins, and subsequently result in PHT^[25,29,30]. In our study, the treatment with NTau led to the improvement of the structure of liver tissue and significantly lowered the amounts of COLI and COL III, indicating that NTau can decrease portal pressure by acting on the “backward flow” mechanism, namely by improving the pathological structure of liver tissue and inhibiting HF.

TGF- β_1 is a multifunctional peptide with a wide range of potential influences on the growth and differentiation of cells, aggregation of extracellular matrix (ECM), and immune response. It is also one of the mediators that is most closely associated with the production of fibrils. In the occurrence and development of HF, TGF- β_1 has an ability to activate HSCs and promote the gene expression of collagen as well as the synthesis and deposition of ECM^[31,32]. In our experiments, the level of TGF- β_1 in the NTau treatment group was significantly lower than that of the LC model group, suggesting that NTau inhibits the development of HF, possibly through inhibiting the expression of TGF- β_1 .

Increased resistance to PVF may elicit biomechanical changes in the portal vein by causing vascular reconstruction characterized by thickening of vessel walls, narrowing of vessel lumen and proliferation of smooth muscle cells, resulting in further maintenance and exacerbation of PHT. Such alterations in biomechanics subsequently make treatment of LC-induced PHT ever more difficult^[33,34]. Therefore, to achieve a favorable therapeutic response in the treatment of PHT of LC, terminating this vicious circle becomes particularly important, and lowering the portal pressure should not be the sole target for intervention. Vessel wall is a viscoelastic tissue with unique biomechanical properties including creep, stress-relaxation and hysteresis. Compliance and zero-stress state are usually used to describe the biomechanical properties of vessels. Indeed, reduced portal compliance and enlarged opening angle were found in rats with LC. The NTau treatment, on the other hand, was able to improve the portal compliance and decrease the opening angle, indicating that NTau could inhibit the development of LC-induced PHT by improving the biomechanical properties of the portal vein.

The pathomechanism of LC-induced PHT is complex,

for it involves SHC, structural alterations in the liver, increased resistance to PVF and biomechanical changes in the portal vein. Our present experimental data derived from the LC rat model unequivocally demonstrate that NTau can inhibit PHT of LC by improving hyperdynamic circulation, structure of liver tissue, and the biomechanical properties of the portal vein by delaying the progression of HF. Given that taurine is an important nutrient in the body with a deficiency in chronic liver diseases, the supplementation of an adequate amount of taurine may improve the functional status of the body. In view of its pharmacological and nutritional values, we believe that treatment with taurine may provide an additional dimension for the management of portal hypertension associated with liver cirrhosis.

COMMENTS

Background

Portal hypertension which acts as the main manifestation of patients in the compensatory stage of cirrhosis of the liver is the material cause of death. Treatment of portal hypertension caused by liver cirrhosis can not only enhance the prognosis of the disease but also improve the patients' quality of life. Hence, the concept of implementing treatment of portal hypertension is gradually attracting more and more attention, changing the passive state of the past which practised symptomatic treatment when complications developed.

Research frontiers

Intensive literature review shows that taurine can suppress the course of liver cirrhosis. This project investigates the function of taurine in inhibiting the course of liver cirrhosis and portal hypertension caused by liver cirrhosis from different aspects.

Innovations and breakthroughs

This study proposes the concept of the integration of the three theories for the formation of liver cirrhosis: the backward flow theory, the forward flow theory and the biomechanics of portal vein theory, then systematically explores the inhibiting effect and possible mechanism of action of taurine on portal hypertension caused by liver cirrhosis.

Applications

The treatment of portal hypertension mainly embodies medication treatment, surgical treatment, interventional treatment, liver transplant etc. At present, long-term medication treatment takes the center stage. Though there are plenty of medicines available for portal hypertension caused by liver cirrhosis, there is still a lack of effective medication. As a result, there is sound justification for investigating the therapeutic functions of taurine in portal hypertension caused by liver cirrhosis. Pure natural taurine widely exists in marine fauna. The ocean, which occupies 70.8% of the total earth's surface, is a natural medicinal resource with huge potential. It makes great sense to explore new areas of marine life's application in the search for new medicinal resources.

Terminology

Forward flow theory is one of the theories of the formation of portal hypertension caused by liver cirrhosis. The pathogenesis of PHT may be primarily attributed to initiation factors, including dilation of peripheral vessels, decrease in peripheral vascular resistance and mean arterial pressure, increase in blood volume, splanchnic blood flow and cardiac output, and development of systemic hyperdynamic circulatory syndrome. For backward flow theory, the main cause of portal hypertension caused by liver cirrhosis is the formation of diffuse fibrous septa and regenerative nodules in liver which is followed by hepatic sinus narrowing. Then intra-liver vessels constrict and the resistance of blood flow in the portal system increases which results in passive congestion of the portal system. Finally, portal hypertension develops. As vasodilatation increases, the reactivity of vessels to endogenous vascular-constriction substances falls, then functional arteriovenous fistula and portal-systemic shunting develop and result in hyperdynamic circulation over the whole body while blood flow of the portal vein increases.

Peer review

This is a small but reasonably designed experimental study to examine the impact of natural taurine in a rat model of cirrhosis. The paper particularly

concentrates on the effects of this agent on the level of portal hypertension and clearly shows that this is attenuated following repeat dosage by gavage.

and cell cycle proteins, including P21 and CDK4, were measured by Western blotting.

RESULTS: CIE inhibited proliferation of MHCC97H cells in a time- and dose-dependent manner without cytotoxicity in rat hepatocytes and human endothelial cells. CIE induced apoptosis of MHCC97H cells in a concentration-dependent manner, as determined by flow cytometry. The apoptosis was accompanied by a decrease in mitochondrial membrane potential, release of cytochrome C and activation of caspase-9 and caspase-3. CIE arrested the cell cycle in the S phase by increasing P21 and decreasing CDK4 protein expression.

CONCLUSION: CIE exerted a significant apoptotic effect through a mitochondrial pathway and arrested the cell cycle by regulation of cell cycle-related proteins in MHCC97H cells without an effect on normal cells. The cancer-specific selectivity shown in this study suggests that the plant extract could be a promising novel treatment for human cancer.

Abstract

AIM: To investigate the effects of *Chrysanthemum indicum* extract (CIE) on inhibition of proliferation and on apoptosis, and the underlying mechanisms, in a human hepatocellular carcinoma (HCC) MHCC97H cell line.

METHODS: Viable rat hepatocytes and human endothelial ECV304 cells were examined by trypan blue exclusion and MTT assay, respectively, as normal controls. The proliferation of MHCC97H cells was determined by MTT assay. The cellular morphology of MHCC97H cells was observed by phase contrast microscopy. Flow cytometry was performed to analyze cell apoptosis with annexin V/propidium iodide (PI), mitochondrial membrane potential with rhodamine 123 and cell cycle with PI in MHCC97H cells. Apoptotic proteins such as cytochrome C, caspase-9, caspase-3

INTRODUCTION

Hepatocellular carcinoma (HCC) is known as a common and aggressive malignant tumor worldwide. In China, HCC accounts for 90% of primary liver cancer, which is the second most common cause of death^[1]. Chemotherapy plays an important role in the treatment of cancer, but it is limited to a significant extent by its toxicities, significant

resistance to available chemotherapeutic agents and side effects, including myelosuppression, neutropenia and thrombocytopenia^[2,3]. One possible way to increase the efficacy of anticancer drugs and to decrease toxicities or side effects is to develop traditional medicines, especially from medicinal plants^[4-7].

Natural products have become increasingly important for new pharmaceutical discoveries, and among all the uses for natural products in biomedical science, traditional Chinese herbology has been a pioneering specialty^[8]. This is particularly evident in the treatment of cancers, in which more than 60% of drugs are of natural origin^[9]. Hence a new medicinal plant with anticancer activities could be a valuable substance in cancer treatment. The flowers of *Chrysanthemum indicum* (*Chrysanthemi Indici* Flos), a *Compositae* plant, is a traditional Chinese medicine and medicinal plant distributed widely in China. Oriental *Chrysanthemum indicum* traditional medicine has been used to treat vertigo, hypertensive symptoms and several infectious diseases such as pneumonia, colitis, stomatitis and carbuncles^[10]. A series of studies have demonstrated that *Chrysanthemum indicum* possesses antimicrobial^[11], antiinflammatory^[11-13], immunomodulatory^[12], and neuroprotective effects^[14]. Recently, much attention has been devoted to the anticancer activity of *Chrysanthemum indicum* on human PC3, HL 60 and HeLa cancer cells in a dose- and time-dependent manner^[15-17]. However, its anticancer mechanism of action is still not clear and needs further investigation.

Apoptosis induced by herbs has become a principal mechanism by which anticancer therapy exerts its effect^[7,18]. Upstream initiator caspases including caspase-9 activate downstream effector caspases such as caspase-3, playing a pivotal role in the induction of apoptosis. Caspase-9, triggered by chemotherapeutic drugs, is the apical caspase in the mitochondria-initiated apoptosis pathway, which requires the release of cytochrome C from the mitochondria as well as interaction with Apaf-1^[19]. This pathway, associated with changes in the permeability of the outer mitochondrial membrane and the collapse of the membrane potential ($\Delta\psi_m$), results in release of cytotoxic proteins and caspase activation^[19].

Cell cycle regulation, a fundamental mechanism determining cell proliferation, is tightly mediated through a complex network of positive factors, such as cyclin-dependent kinases (CDKs) and cyclin, and negative factors, including CDK-inhibitor (CDKI) regulatory molecules. The activated CDK4-cyclin complexes are inactivated by binding to P21, a CDKI^[20]. Plant extracts which arrest the cell cycle in cancer cells *via* regulation of CDK and CDKI proteins also can be used for therapeutic intervention^[21-23].

The aim of the present study was to examine the anticancer activities of *Chrysanthemum indicum* and related mechanisms in MHCC97H cell lines, typical human HCC cell lines, which are commonly used in the study of antitumor cells^[24]. In order to compare the actions of *Chrysanthemum indicum* on normal hepatocytes and endothelial cells, the effects of the extract were examined in rat hepatocytes and a human umbilical

vein endothelial cell ECV304 cell line. Furthermore, we investigated the effect of the extract in human MHCC97H cells and the mechanisms underlying its effect on inhibition of proliferation.

MATERIALS AND METHODS

Plant material and extraction

Fresh, ripe fruits of high quality flowers of *Chrysanthemum indicum* were procured from Xi'an traditional medicine group (Shaanxi, China) in March 2006 and the characteristics were consistent with that described in the Pharmacopeia of the People's Republic of China. Moreover, *Chrysanthemum indicum* was also authenticated by Professor Wang Jun-Xian, a taxonomist in the Department of Pharmacy in Xi'an Jiongtong University. The plant materials were air dried at room temperature and then powdered. The dried and powdered fruit of *Chrysanthemum indicum* (500 g) were extracted with 95% ethanol (EtOH) twice under refluxed temperature. After evaporation of organic solvent under reduced pressure, the resultant *Chrysanthemum indicum* EtOH extract (CIE) was concentrated under reduced pressure to give 66.5 g (13.3%) EtOH extract. The dry extract was stored in a refrigerator at -20°C until use in the experiments. CIE was dissolved in phosphate buffered solution (PBS) and diluted in cultured medium before use, and the control group was made up of medium, PBS and the cells.

Reagents, antibodies, cells, and culture medium

A human MHCC97H HCC cell line was purchased from the Liver Cancer Institute of Fudan University (Shang Hai, China). A human ECV304 cell line was obtained from the Cell Bank of Academia Sinica (Shang Hai, China). MHCC97H cells and ECV304 cells were cultured in DMEM medium supplemented with 10% fetal bovine serum (FBS) in a humidified incubator containing 5% CO₂ in air at 37°C before use and subcultured with 0.25% trypsin-0.02% EDTA. 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), rhodamine 123 (Rh123), annexin V and propidium iodide (PI) were purchased from Sigma Corporation (Sigma, St.Louis, MO, USA). DMEM, FBS and trypsin were obtained from GibcoBRL, Grand Island, NY, USA. Anti-caspase-3, anti-caspase-9, anti-cytochrome C, and anti- β -actin were purchased from Santa Cruz Company. Anti-CDK4 and P21 were obtained from eBioscience Corporation.

Hepatocyte preparation, culture and viability assay

Hepatocytes were isolated by the collagenase perfusion method^[9] from 10-wk-old male Sprague-Dawley rats anesthetized with intraperitoneal administration of ketamine. The viability of the isolated hepatocytes was over 90% as determined by 0.2% trypan blue exclusion. The cells were plated in 35 mm plastic dishes at a density of 3×10^5 cells/mL in 2 mL of Williams' Medium E supplemented with 10% FBS, and were cultured in a humidified atmosphere of 5% CO₂ and 95% air at 37°C overnight. After overnight incubation, the culture medium was changed to fresh medium, and

cultures were incubated with varying concentrations of CIE 400, 800 and 1200 $\mu\text{g/mL}$ for 24 h. According to a previous report^[25], the cells were then trypan blue stained and a hemocytometer was used to determine the total cell count and viable cell number. Viability of cells were determined as follows: viability (%) = viable cell number/total cell count \times 100%.

Cell viability assay

ECV304 cells were seeded in a 96-well plate (5×10^4 cells/well). After 24 h seeding, cells were treated with CIE (400, 800 and 1200 $\mu\text{g/mL}$) for 24 h, in 3 parallel wells each, with untreated cells serving as a control, then the MTT assay as described by Xiao *et al*^[26] was performed. At 24 h, 20 μL MTT solution (5 mg/mL) was added to each well and incubated for a further 4 h. The medium was removed and 200 μL DMSO was added to each well. Absorbance (A) at 570 nm was measured using a microculture reader. The percentage of viable cells was calculated as follows: (A of experimental group/ A of control group) \times 100%.

MHCC97H cells were seeded into 96-well plates at a density of 5×10^4 /well and were then incubated with different concentrations of CIE (400, 800 and 1200 $\mu\text{g/mL}$) for 24, 48 and 72 h, then the MTT assay was performed. At 24, 48 and 72 h, 20 μL MTT solution (5 mg/mL) was added to each well, and the cells were further incubated at 37°C for 4 h. The MTT assay and calculation of the percentage of viable cells were the same as described above.

Apoptosis assays

In accordance with the study of Chen *et al*^[27], the apoptotic rates were analyzed by flow cytometry using an annexin V-FITC/PI kit. Staining was performed according to the manufacturer's instructions, and flow cytometry was conducted on a FACS Caliber (Becton Dickinson, Mountain View, NJ, USA). Cells that were annexin V (-) and PI (-) were considered viable cells. Cells that were annexin V (+) and PI (-) were considered early apoptotic cells. Cells that were annexin V (+) and PI (+) were considered late apoptotic cells.

Cell cycle assays

Cell cycle analyses were carried out by the method of Vinodhkumar *et al*^[28]. Briefly, cells were incubated in culture media alone or culture media containing 400-1200 $\mu\text{g/mL}$ of CIE, at 37°C for 48 h. Cells were harvested in cold PBS, fixed in 70% EtOH, and stored at 4°C. Fixed cells were washed with PBS once and suspended in 1 mL of PI staining reagent 50 mg/mL containing 100 $\mu\text{g/mL}$ Rnase, and were then incubated in the dark for 30 min. The distribution of the cell cycle was measured by a Becton Dickinson FACS analysis system and quantitation of cell cycle distribution was carried out using Multicycle Software.

Detection of mitochondrial membrane potential (MMP $\Delta\psi_m$)

Loss of MMP $\Delta\psi_m$ was assessed by flow cytometry,

using a fluorescent indicator Rh123, as described by Tang *et al*^[29] and Li *et al*^[30]. Briefly, cells were treated with different concentrations of CIE. Then, Rh123 working solution was added to the culture at a final concentration of 2 $\mu\text{g/mL}$ and then incubated in the dark at 37°C for 30 min. Cells were then washed with PBS, and fluorescence of Rh123 was detected immediately using a FACS Caliber, at an excitation wavelength of 488 nm and emission wavelength of 525 nm.

Western blotting

Cancer cells (2.5×10^7 /well) were treated with different concentrations of CIE for 24 or 48 h. To extract cytoplasmic protein as by the method of Li *et al*^[31], cells were collected by centrifugation at 200 r/min for 10 min at 4°C. The cells were washed twice with ice-cold PBS, followed by centrifugation at 200 r/min for 5 min. The cell pellet was then suspended in ice-cold cell extraction buffer for 30 min on ice. In addition, as described by Hsu *et al*^[32], cells were then lysed in a sample buffer, followed by sonication and denaturation. Protein concentrations were measured using DC Protein Assay (Bio-Rad, Hercules, CA) and equal amounts of protein (50 μg) were subjected to SDS-PAGE on 12% gel. The proteins were then electrophoretically transferred to nitrocellulose membranes and processed for immunoblotting. Membranes were first blocked with 5% non-fat dry milk overnight at 37°C and immunolabeled using primary antibodies. Goat anti-rabbit horseradish peroxidase-conjugated antibodies (Cell Signaling Technology, Beverly, MA) were used as secondary antibodies and detected with enhanced chemiluminescence (Amersham, USA). Equal loading of each lane was evaluated by immunoblotting using the same membranes with β -actin antibodies after detachment of previous primary antibodies. The band density for the target protein in each sample was measured with image analysis software (Gene Genus, Gene Company) and normalized to β -actin expression.

Statistical analysis

All data were expressed as mean \pm SE. Statistical analysis was performed with analysis of variance (ANOVA) using the statistical software SPSS 11.0. *P*-values < 0.05 were regarded as statistically significantly.

RESULTS

Effect of CIE on numbers of viable rat hepatocytes and ECV304 cells

In order to compare the effects of CIE on rat hepatocytes and human ECV304 cells, the numbers of viable cells were measured. As shown in Figure 1A, CIE did not decrease the number of viable rat hepatocytes, used as a normal cell model. To confirm the activity of CIE in human cells, we measured the number of viable cells treated with varying concentrations of CIE in human endothelial cells (ECV304). CIE did not reduce the number of viable ECV304 cells at any dose (Figure 1B). Therefore, the effect of CIE in inhibiting

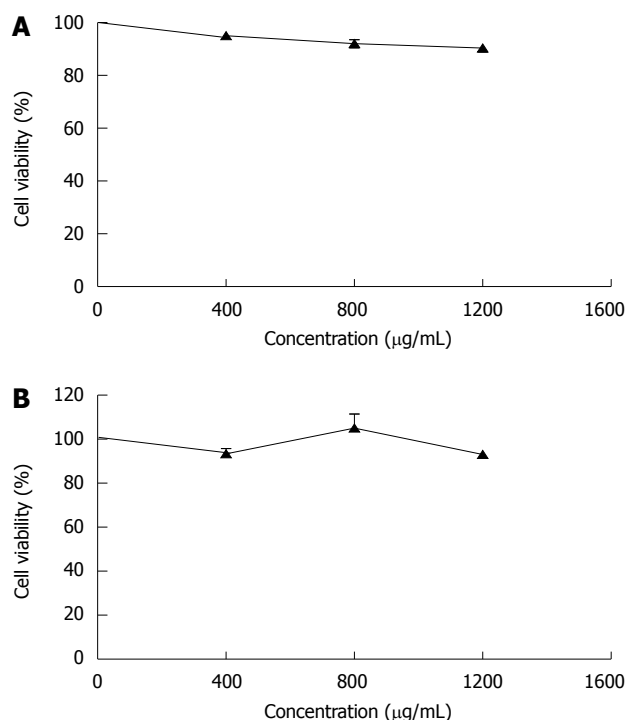

Figure 1 Effects of *Chrysanthemum indicum* extract (CIE) on cell viability of normal cells. A: Rat hepatocytes; B: Human umbilical vein endothelial cell line ECV304. Various concentrations of CIE were added, and the cells were incubated for 24 h. Cell viability was measured by 0.2% trypan blue exclusion (A) and MTT assay (B) respectively. Results presented are representative of 3 independent experiments.

Figure 2 Dose-response curves for CIE in MHCC97H cells, following 24 h, 48 h and 72 h incubation, as assessed by MTT assay. CIE produced a concentration- and time-dependent decrease in cellular proliferation. Results presented are representative of 3 independent experiments.

proliferation of MHCC97H cells and its mechanism were examined in subsequent experiments.

Cytotoxic activities of CIE against human HCC cells

When MHCC97H cells were incubated with 400-1200 $\mu\text{g/mL}$ CIE for 24, 48, 72 h, as shown in Figure 2, there was a significant dose-dependent reduction in cell viability. The IC_{50} value at 24 h was $1009 \pm 130 \mu\text{g}$. When 1200 $\mu\text{g/mL}$ CIE was incubated with cancer cells for 72 h, viable cells amounted to only 25% of control. These findings indicated that CIE significantly decreased

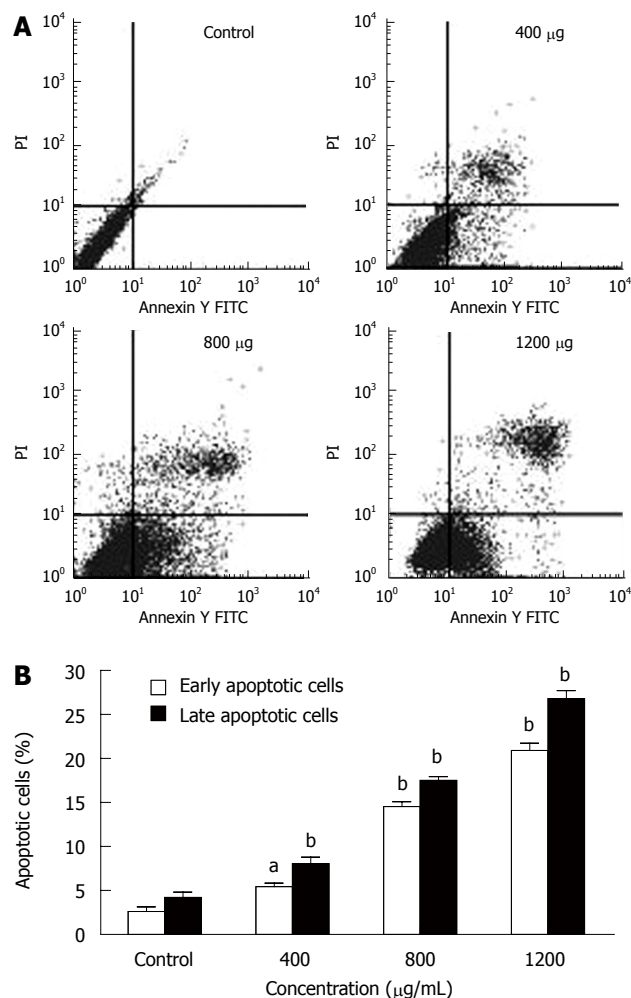

Figure 3 Effect of CIE on the induction of MHCC97H cell apoptosis. A: The apoptosis of MHCC97H cells induced by CIE were determined by flow cytometry at 24 h; B: CIE induced a concentration-dependent increase in early and late cellular apoptosis. Results presented are representative of 3 independent experiments. ^a $P < 0.05$, ^b $P < 0.01$ vs control group.

proliferation of MHCC97H cells in a dose- and time-dependent manner. Hence, the proliferation inhibitory effect of CIE on MHCC97H and its mechanisms were tested in the following experiments.

CIE induces MHCC97H cell apoptosis

MHCC97H cells were incubated with different CIE concentrations (400, 800 and 1200 $\mu\text{g/mL}$) for 24 h and were analyzed by flow cytometry. Pretreatment of MHCC97H cells with various concentrations of CIE induced significant apoptosis (Figure 3A). The numbers of early and late apoptotic cells were significantly increased compared with the control group (Figure 3B). The proportion of early and late apoptotic cells in the 1200 $\mu\text{g/mL}$ treatment group was more than 10 times higher than in the drug-free cells.

Effects of CIE on cell morphology

After incubation with CIE at different concentrations (400, 800, 1200 $\mu\text{g/mL}$), the cells were examined by phase contrast microscopy for evidence of morphological apoptosis induced by CIE (Figure 4). The control cells

Figure 4 Morphological changes in MHCC97H cells with CIE. Cells were observed by phase contrast microscopy in controls and after treatment with 400, 800, 1200 µg/mL CIE ($\times 200$).

showed a typical polygonal and intact appearance (control), whereas the CIE-treated cells displayed morphological changes with preapoptotic characteristics, such as cellular shrinkage (400, 800 µg/mL), rounding (800 µg/mL), and poor adherence (1200 µg/mL), as well as round floating shapes (1200 µg/mL).

CIE causes loss of $MMP\Delta\psi_m$

To explore whether CIE-induced apoptosis involved the $MMP\Delta\psi_m$, we used a fluorescent indicator, Rh123 to detect the $MMP\Delta\psi_m$ when MHCC97H cells were treated with 400-1200 µg/mL of CIE for 24 h. As shown in Figure 5A and B, after exposure to different CIE doses, cells exhibited much lower Rh123 staining (236.7 ± 9.3 , 170.7 ± 13.9 , 105 ± 10.5) than controls (275 ± 14.5 ; $P < 0.05$ or $P < 0.01$), indicating that CIE can significantly decrease $MMP\Delta\psi_m$ associated with cancer cell apoptosis.

CIE-induced apoptosis is caspase-dependent

To determine whether apoptosis induced by CIE was a mitochondrial-dependent caspase pathway, we further tested whether cytochrome C could be released from the mitochondria into the cytoplasm. As shown in Figure 6A, although there was no detectable cytochrome C in the cytosolic fraction of continuously growing MHCC97H cells, the level of cytochrome C released from the mitochondria increased dose-dependently in the presence of CIE concentrations ranging from 400 to 1200 µg/mL. In accordance with mitochondrial cytochrome C release into the cytoplasm, caspase-9 protein expression was increasingly detected. Accordingly, caspase-3 protein expression was also increased dose-dependently on exposure to CIE (Figure 6A and B). Taken together, these findings suggest that CIE exerted a significant apoptotic effect on MHCC97H cells in a concentration-dependent manner through the mitochondrial pathway, and was accompanied by a decrease in $MMP\Delta\psi_m$, release of cytochrome C, and activation of caspase-9 and caspase-3.

Cell cycle analysis

The cell cycle of cancer cells was also determined by flow cytometry. MHCC97H cells treated with CIE 400, 800, 1200 µg/mL for 48 h showed an accumulation of cells in the S phase of the cell cycle. In contrast, the population of cells in G0-G1 and G2/M phases was

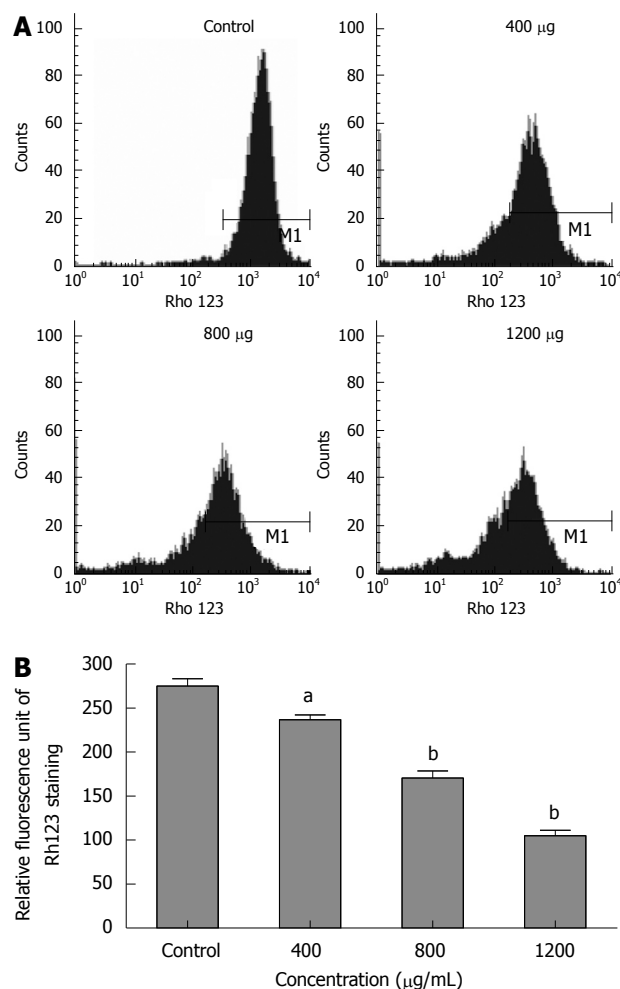

Figure 5 Effect of CIE on MHCC97H cellular mitochondrial membrane potential ($MMP\Delta\psi_m$). A: The $MMP\Delta\psi_m$ of MHCC97H cells were determined by flow cytometry at 24 h after CIE; B: Results presented are representative of 3 independent experiments. ^a $P < 0.05$, ^b $P < 0.01$ vs control group.

significantly decreased, especially at 400 µg/mL CIE (Figure 7A-C). In addition, as shown in Figure 7A, cancer cells incubated with higher doses of CIE for 48 h also showed a sub-G1 peak indicating apoptosis. These observations suggest that a small number of cancer cells escape from the S phase and undergo apoptosis, particularly at the 1200 µg/mL CIE concentration. Therefore, with the dose-dependent increase in cancer cell apoptosis, the proportion of cells arrested in the

Figure 6 Effect of CIE on apoptosis-related protein expression. A: The expressions of cytochrome C, caspase-9 and caspase-3 were assessed by Western blotting; B: Results presented are representative of 3 independent experiments. ^a $P < 0.05$, ^b $P < 0.01$ vs control group.

S phase by CIE decreased as the CIE concentration increased from 400 to 1200 μg/mL.

The mechanism of action of CIE on the cell cycle

To determine the mechanism by which CIE arrested the cell cycle in the S phase, Western blotting was used to determine the expression levels of cell cycle-regulating proteins including P21 and CDK4. P21 protein expression was markedly higher than that of the control group at all CIE doses tested. In contrast, CDK4 levels were significantly lower than that of the control group, as shown in Figure 8A and B. The results suggested that CIE could arrest the cell cycle *via* upregulation of P21 and downregulation of CDK4.

DISCUSSION

So far, the underlying mechanisms of the pharmacological effect of *Chrysanthemum indicum* in cancer therapy have been unclear, and this study examined the effect of CIE and its underlying mechanisms on inhibition of tumor cell proliferation. In the present study, we have demonstrated that CIE potently inhibits the proliferation of MHCC97H cells by inducing apoptosis (Figures 3 and 4) and arresting the cell cycle (Figure 7) but has no cytotoxicity in rat hepatocytes and human endothelial cells (ECV304) that were used as representatives of normal cells (Figure 1).

Morphological changes in apoptotic characteristics, such as cellular shrinkage, rounding, poor adherence, and round floating shapes in CIE-treated cells were also observed by phase-contrast microscopy (Figure 4). The

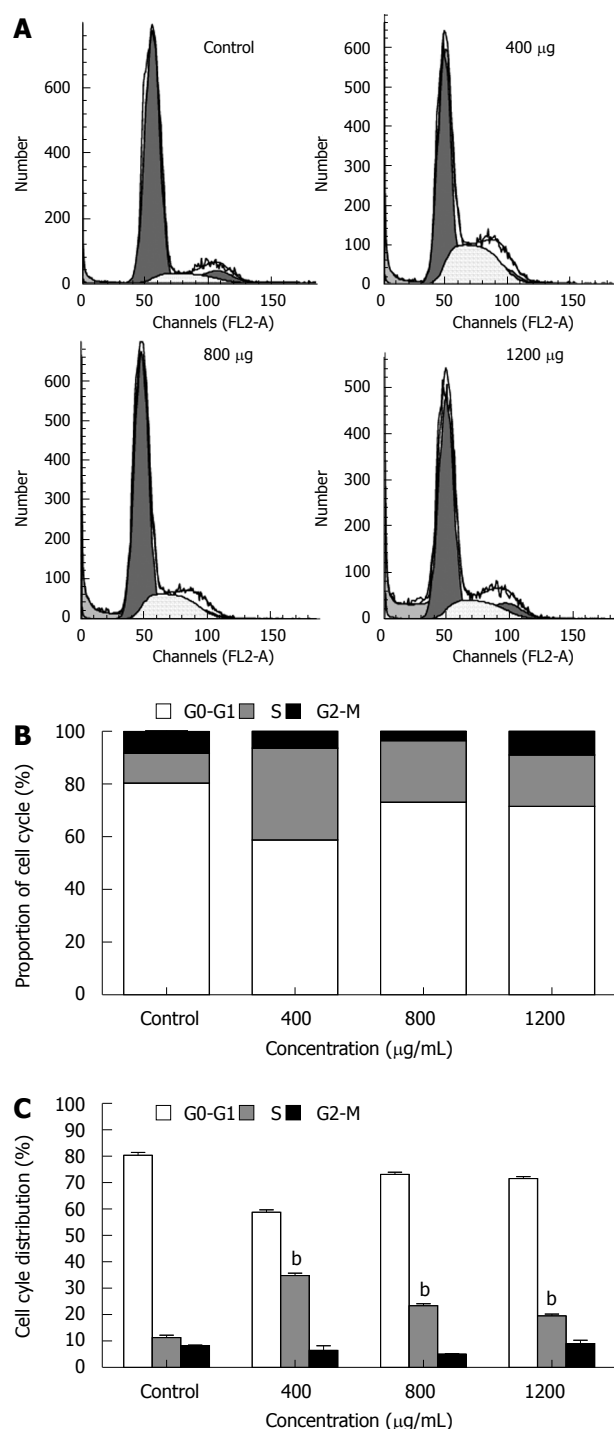

Figure 7 Effect of CIE on MHCC97H cell cycle. A: The cell cycle of MHCC97H cells in the presence of CIE was determined by flow cytometry at 48 h; B and C: Results presented are representative of 3 independent experiments. ^a $P < 0.05$, ^b $P < 0.01$ vs control group.

induction of cancer cell apoptosis without side effects is recognized as an important target in cancer therapy. Apoptosis triggered by activation of the mitochondrial-dependent caspase pathway represents the main programmed cell death mechanism^[19]. The mitochondrial-dependent apoptosis pathway is activated by various intracellular stresses that induce permeabilization of the mitochondrial membrane, leading to cytochrome C release^[33]. Flow cytometry with Rh123 staining showed

Figure 8 Effect of CIE on cell cycle-related protein expression. A: The expression of CDK4 and P21 was assessed by Western blotting; B: Results presented are representative of 3 independent experiments. ^b*P* < 0.01 vs control group.

disruption of $\text{MMP}\Delta\psi_m$ in the CIE-treated cells (Figure 5), indicating that the mitochondrial apoptotic pathway played a pivotal role in CIE-induced apoptosis of MHCC97H cells. Furthermore, cytosolic cytochrome C activates pro-caspase-9 by binding to Apaf-1 and in the presence of dATP, and contributes to activation of caspase-9 and caspase-3, thus triggering apoptosis^[34,35]. In this study, caspase-9 and caspase-3 levels reached a maximum at about 24 h in the cells after exposure to CIE 1200 μg/mL (Figure 6). These results indicated that CIE-induced apoptosis of MHCC97H cells was mediated by loss of $\text{MMP}\Delta\psi_m$, increased cytosolic translocation of cytochrome C, and activation of caspase-9 and caspase-3.

The inhibition of tumor cell growth without toxicity in normal cells has attracted attention as an important target in cancer therapy. Dysregulation of the cell cycle mechanism has also been shown to play an important role in various cancer cell growths, including HCC. In this study, CIE inhibited MHCC97H cell proliferation partly as a result of accumulation of cells in the S phase of the cell cycle. The present study, to the best of our knowledge, is also the first to demonstrate that CIE induced arrest of the cell cycle in the S phase in HCC cells (Figure 7). The S phase is associated with DNA synthesis and plays a crucial role in cell cycle progression. Recently, a series of S phase chemotherapeutic agents such as *Smilax glabra* Roxb^[36], baicalein from *Scutellariae radix* roots^[37] and others^[38] have been found to inhibit cancer cells, including HCC. Furthermore, in accordance with these results, CIE upregulated P21 and downregulated CDK4 (Figure 8), indicating that cell cycle-related proteins were involved in the CIE-induced cell cycle arrest in MHCC97H cells. One of the CDKI proteins, P21 can perform a key function in controlling cell cycle progression by negatively regulating

CDK4 activity^[38]. Inappropriate expression of cell cycle-related proteins, such as CDK4 and P21, could be one of the major factors contributing to HCC development^[39]. Moreover, CDK4 and P21 play important roles in regulation of the S phase of the cell cycle^[37,38,40,41]. These findings, taken together with the present study, suggest that upregulation of P21 and downregulation of CDK4 are likely to be involved in the S phase arrest induced by CIE in HCC cells.

Additionally, in clinical studies, *Chrysanthemum indicum* can be used in combination with other chemotherapeutic agents or traditional Chinese medicines in treatment of other cancers. Xiang *et al*^[42] found that patients with metastatic breast cancer postoperatively receiving *Chrysanthemum indicum* as one of the main components, in combination with other traditional Chinese medicines, had a 5-year overall survival rate of 70% and a complete response rate of 60%, and in combination with chemotherapeutic agents, had a 5-year overall survival rate of 77% and a complete remission rate of 80%, without adverse effects. Bi *et al*^[43] demonstrated that *Chrysanthemum indicum*, in combination with traditional Chinese medicines, achieved a response rate of 67% in advanced stage esophageal carcinoma patients, without myelosuppression or toxicities of the liver and kidney.

In conclusion, different effects of CIE treatment were observed in cancer and normal cells. CIE exerted a significant apoptotic effect on MHCC97H cells through the mitochondrial-dependent caspase-3 pathway. It arrested the cell cycle of cancer cells in the S phase by upregulation of P21 and downregulation of CDK4. In addition, the cancer-specific selectivity shown in this study suggests that the herb could be a promising novel plant with potential in the treatment of human cancer without side effects.

COMMENTS

Background

Ethnopharmacology used in folk medicine continues to be an important source of discovery and development of novel therapeutic agents in cancer. The flowers of *Chrysanthemum indicum*, a *Compositae* plant, is common in ethnopharmacology, and has long had wide spread use in the treatment of hypertension, colitis, pneumonia and carbuncles by traditional Chinese practitioners. Recently, much attention has been devoted to the anticancer activity of *Chrysanthemum indicum*, especially in hepatocellular carcinoma (HCC). However, the underlying mechanisms of the pharmacological effect of the plant extract in cancer therapy have been largely undetermined.

Research frontiers

Induction of apoptosis and arrest of the cell cycle by plant extracts has become a principal mechanism by which anticancer therapy is effective. Apoptosis triggered by the activation of the mitochondrial-dependent caspase pathway represents the main programmed cell death mechanism. Permeabilization of the outside mitochondrial membrane plays a vital role in cell apoptosis, during which loss of the mitochondrial membrane potential and release of cytochrome C into the cytosol, followed by caspase-9-dependent activation of caspase-3 occurs, resulting in apoptosis. Dysregulation of the cell cycle mechanism has also been shown to perform an important function in growth of various cancer cells, including HCC. The S phase is associated with DNA synthesis and plays a crucial role in cell cycle progression. One of the CDKs, P21, can influence key functions in the control of the cell cycle by negatively regulating CDK4 activity, and plays an important role in regulation of the S phase of the cell cycle.

Innovations and breakthroughs

So far, there has been no evidence found to show that the mitochondrial

pathway is involved in induction of apoptosis and cell cycle arrest by *Chrysanthemum indicum* extract (CIE) in human HCC cells. Therefore, the present study examined the anticancer activities of CIE and related mechanisms in MHCC97H cell lines. The data showed that CIE could induce apoptosis and arrest the cell cycle of MHCC97H cells. CIE exerted a significant apoptotic effect on MHCC97H cells through the mitochondrial-dependent caspase-3 pathway, and arrested the cell cycle in the S phase in cancer cells by upregulation of P21 and downregulation of CDK4.

Applications

This study suggests that *Chrysanthemum indicum* could be a promising plant with potential in the novel treatment of human cancer, particularly HCC.

Peer review

The manuscript written by Li ZF *et al* describes that *Chrysanthemum indicum* extract can induce apoptosis and cell cycle arrest in a hepatoma cell line. Many patients with HCC still die each year, and novel therapeutic strategies are needed. The data are encouraging and promising.

Abstract

AIM: To study the effects of lysophosphatidic acid (LPA) on proliferation, adhesion, migration, and apoptosis in the human colon cancer cell line, SW480, and its mechanisms of action.

METHODS: Methyl tetrazolium assay was used to assess cell proliferation. Flow cytometry was employed to detect cell apoptosis. Cell migration was measured by using a Boyden transwell migration chamber. Cell adhesion assay was performed in 96-well plates according to protocol.

RESULTS: LPA significantly stimulated SW480 cell proliferation in a dose-dependent and time-dependent manner compared with the control group ($P < 0.05$) while the mitogen-activated protein kinase (MAPK) inhibitor, PD98059, significantly blocked the LPA stimulation effect on proliferation. LPA also significantly stimulated adhesion and migration of SW480 cells in a dose-dependent manner ($P < 0.05$). Rho kinase inhibitor, Y-27632, significantly inhibited the up-regulatory effect of LPA on adhesion and migration ($P < 0.05$). LPA significantly protected cells from apoptosis induced by the chemotherapeutic drugs, cisplatin and 5-FU ($P < 0.05$), but the phosphoinositide 3-kinase (PI3K) inhibitor, LY294002, significantly blocked the protective effect of LPA on apoptosis.

CONCLUSION: LPA stimulated proliferation, adhesion,

INTRODUCTION

Colorectal cancer (CRC) is a common form of cancer and a major cause of cancer death. The incidence of CRC has been rapidly increasing in recent years. Although the incidence of CRC was substantially lower in Asia than in the USA in the mid-twentieth century, the incidence in Japan and China has been rapidly increasing^[1,2]. Thus, CRC is now a leading cancer killer worldwide.

Lysophosphatidic acid (LPA) was first found in the ascitic fluid from ovarian cancer patients. It is a bioactive glycerophospholipid generated and released by platelets, macrophages, epithelial cells, and some tumor cells. Studies have shown the presence of high levels of LPA in the ascitic fluid of patients with ovarian cancer^[3] and LPA is known to be an "ovarian cancer activating factor", which exerts growth factor-like effects through four specific G protein-coupled receptors (LPA₁₋₄).

LPA is a potent mediator with a broad range of cellular responses, including regulation of cell proliferation, protection from apoptosis, modulation of chemotaxis and transcellular migration^[4,5], which mediates survival of ovarian cancer cells, macrophages, fibroblasts, and neonatal cardiac myocytes. Some of these cellular responses indicate that LPA is a mediator of tumor progression.

In a recent study we found that plasma levels of several LPAs, including 18:1-LPA and 18:2-LPA, were significantly increased in CRC patients compared with controls^[6]. This is the first report of high levels of LPA in plasma of CRC patients. It implies that LPA may play roles in CRC development. In order to clarify these roles of LPA in CRC development, the LPA effect on the CRC cell line, SW480, was studied *in vitro*.

LPA was found firstly to be increased in the body fluids of ovarian cancer patients, so the roles of LPA in ovarian cancer have been widely studied. A few preliminary studies of LPA in CRC have been reported, but not in the cell line SW480. Our previous study revealed a high expression of LPA receptors on SW480 cells, especially LPA receptor 2^[7,8]. This study aimed to investigate the effect of LPA on proliferation, migration, adhesion, and apoptosis in the CRC cell line, SW480.

MATERIALS AND METHODS

1-Oleoyl LPA (18:1 LPA) was purchased from Avanti Polar Lipids (Birmingham, AL, USA). Inhibitor of phosphoinositide 3-kinase (PI3K), LY290042, and inhibitor of mitogen-activated protein kinase (MAPK), PD98059, are from Cell Signaling (Beverly, MA, USA). Rho kinase inhibitor, Y-27632, was from Biomol (Beverly, MA, USA). Boyden transwell migration chambers and 24-well plates were from Corning Costar Corporation (Cambridge, MA).

SW480 cells were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 100 mL/L fetal bovine serum, streptomycin (100 mg/L), and penicillin (100 kU/L) at 37°C in 50 mL/L CO₂ incubator. Cells were serum starved for 12 h before LPA treatment.

Cell proliferation assay

Methyl tetrazolium (MTT) colorimetry assay was employed to measure cell proliferation. SW480 cells (2×10^3 /well) were seeded in 96-well plates. After cells were starved for 12 h, DMEM containing LPA supplemented with 1 g/L bovine serum albumin was put into the wells. After 24, 48, 72 and 96 h of culture, 20 μ L of MTT solution (5 g/L) was added to each well. Four hours later, the medium was removed and 150 μ L of dimethyl sulfoxide was added to each well. Absorbance value was measured at 490 nm on a Microplate Reader (EXL800). Each assay was performed in quintuplicate.

Annexin V staining

After treating with cisplatin or 5-FU, LPA and/or inhibitors, the cells were resuspended in binding buffer (10 mmol/L HEPES/NaOH, pH 7.4, 140 mmol/L NaCl, 2.5 mmol/L CaCl₂). Then the cells were stained with 5 μ L of annexin-FITC and 5 mg/L propidium iodide (PI), and then analyzed by flow cytometry (FACSCalibur cytometer, BD Biosciences), and CellQuest (BD Biosciences) was used to quantify the apoptotic cells. Experiments were performed in triplicate.

Figure 1 Costar transwell cell culture chamber inserts.

Cell adhesion assay

Flat-bottom 96-well plates were coated with 2 μ g of collagen I (0.04 g/L) (Sigma Chemical Co.) in phosphate-buffered saline overnight at 4°C. Plates were blocked with 2 g/L BSA for 2 h at room temperature followed by washing three times with DMEM. SW480 cells (4×10^4 /well) were added to each well. Four hours later, unbound cells were removed, washing twice with DMEM. Bound cells were fixed by methanol and stained with crystal blue. Stained cells were counted with a phase contrast microscope. Experiments were performed in triplicate.

Cell migration assay

Migration assays were performed in Costar transwell cell culture chamber inserts (coated with collagen I; Corning Costar Corporation, Cambridge, MA) with an 8 μ m pore size as described as Figure 1. Briefly, SW480 cells (5×10^4 cells in 100 μ L of starvation medium) were used for cell migration, which was conducted for 4 h at 37°C. Migrated cells were fixed, stained and counted in five randomly ($\times 200$) selected fields with a phase contrast microscope, and the average numbers of cells per field were counted.

Administration of LPA and inhibitors

SW480 cells were starved in serum-free DMEM for 12 h and treated with LPA at different doses, and then reconstituted in DMEM containing 10 g/L BSA. All inhibitors including LY294002 (50 μ mol/L), PD98059 (10 μ mol/L), and Y-27632 (10 μ mol/L) were applied to cells 30 min before the action of LPA.

Statistical analysis

Statistical significance was assessed by one-way ANOVA using SPSS software. Data are presented as the mean \pm SE.

RESULTS

LPA stimulation of proliferation of SW480 cells

SW480 cells were starved in serum-free DMEM for 12 h and treated with LPA at different doses. After different time periods, MTT assay was performed to evaluate the

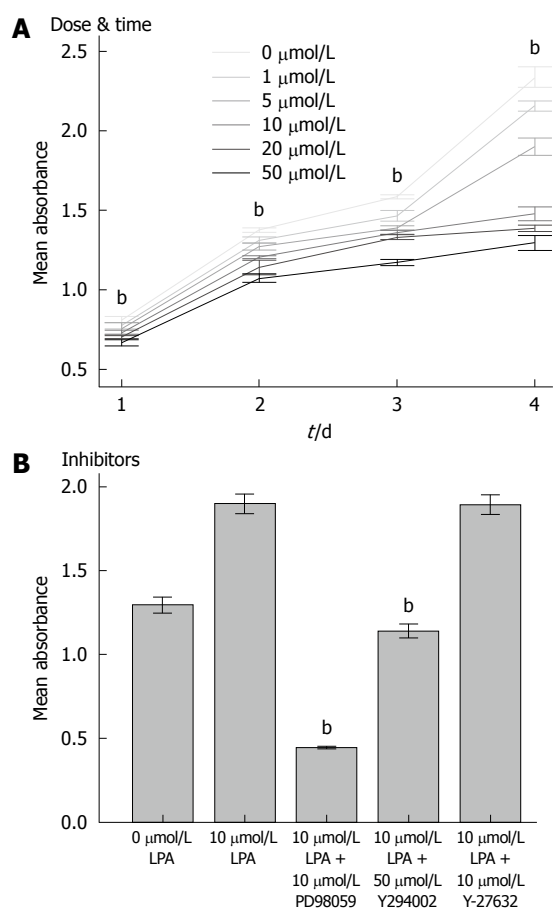

Figure 2 LPA effect on SW480 cell proliferation. Results presented as mean \pm SE, $n = 5$. A: Dose and time effect of LPA on the proliferation of SW480 cells. SW480 cells were starved in serum-free DMEM for 12 h and treated with LPA at different doses. At different time points, MTT assay was performed to evaluate cell numbers. $^bP < 0.001$ vs 0 $\mu\text{mol/L}$ LPA; B: Inhibitors blocked LPA-induced cell proliferation. SW480 cells were starved in serum-free DMEM for 12 h and treated with LPA (10 $\mu\text{mol/L}$). Inhibitors including LY294002 (50 $\mu\text{mol/L}$), PD98059 (10 $\mu\text{mol/L}$), and Y-27632 (10 $\mu\text{mol/L}$) were applied to cells 30 min before the action of LPA. ninety-six hours later, MTT assay was performed to evaluate cell growth. $^bP < 0.001$ vs 10 $\mu\text{mol/L}$ LPA.

activity of cell growth. It was found that LPA significantly stimulated the proliferation of SW480 cells in a dose- and time-dependent manner ($P < 0.001$, Figure 2A). LPA, especially when the concentration was ≥ 10 $\mu\text{mol/L}$, remarkably stimulated cell growth compared with the control group.

In order to investigate the signal pathways which mediated the stimulation effect of LPA on SW480 cells, inhibitors against key molecules of several signal transduction pathways were applied to the LPA-treated group. Three inhibitors were employed including PI3K inhibitor (LY290042), MAPK inhibitor (PD98059), and Rho kinase inhibitor (Y-27632). It was found that after applying the inhibitors, the stimulation effect of LPA on cell growth was significantly blocked by PD98059 and LY290042 ($P < 0.001$, Figure 2B); especially PD98059. This indicated that the Ras/Raf-MAPK signal pathway and the PI3K-AKT/PKB signal pathway may be involved in the LPA stimulation effect on proliferation of SW480 cells.

LPA induction of migration of SW480 cells

SW480 cells (1×10^5 cells in 100 μL of starvation medium) were seeded on the transwell inserts with an 8 μm pore size. Different doses of LPA in DMEM were added to the lower chamber of the transwell. Cells were then incubated at 37°C for 4 h. Cells migrated to the lower surface of inserts were fixed, stained, and quantified. It was found that LPA significantly enhanced SW480 cell migration toward the lower chamber of the transwell in a dose-dependent manner compared with the control ($P < 0.001$, Figure 3A and B). This indicates that LPA has a significant chemotactic effect on SW480 cells.

In order to investigate the signal pathways which mediated the chemotactic effect of LPA on SW480 cells, some inhibitors against key molecules of signal transduction pathways were employed. It was demonstrated that Rho kinase inhibitor (Y-27632 at 10 $\mu\text{mol/L}$) dramatically blocked the chemotactic effect of LPA on SW480 cells ($P < 0.001$, Figure 3C). This indicated that Rho kinase and G12/13-Rho-RhoA signal pathways may mediate the LPA effect on SW480 cell migration.

LPA induction of adhesion of SW480 cells

SW480 cells were seeded in 96-well plates. After the cells had undergone 12 h of starvation, LPA at different doses was added to the cells. SW480 cells were allowed to adhere to the plates for 4 h at 37°C in the incubator. Unbound cells were washed away twice. Adhered cells were fixed, stained, and quantified. Images of adhered cells under different doses of LPA were taken (Figure 4A). It was demonstrated that LPA significantly increased SW480 cell adhesion to extracellular matrix (ECM) in a dose-dependent manner compared with controls ($P < 0.001$, Figure 4B).

Some inhibitors were used to determine the mechanisms which mediated the LPA effect on adhesion. It was found that Rho kinase inhibitor (Y-27632) and LY294002 dramatically inhibited LPA upregulation of adhesion; especially Y-27632 ($P < 0.001$, Figure 4C and D). This indicated that the G12/13-Rho-RhoA signal pathway and the PI3K-AKT/PKB signal pathway may participate in the LPA effect on the adhesion of SW480 cells.

LPA protected SW480 cells from apoptosis

SW480 cells (1×10^5 /well) seeded in 24-well culture plates were starved for 24 h and then treated with cisplatin (10 mg/L) or 5-FU (8 mg/L) for 24 h in the absence or presence of LPA (20 $\mu\text{mol/L}$). Inhibitors including LY294002 (50 $\mu\text{mol/L}$) and PD98059 (10 $\mu\text{mol/L}$) were added to the LPA-treated group.

Apoptotic cells were detected by flow cytometry after Annexin V and PI staining. Apoptotic cells were defined as Annexin-positive, PI-negative (Figure 5). After cells were exposed to cisplatin and 5-FU, the apoptotic population was $20.2\% \pm 2.3\%$ and $14.2\% \pm 2.6\%$, respectively. However, after the action of LPA, the apoptotic population dropped to $14.6\% \pm 2.1\%$ in the cisplatin-treated group and $10\% \pm 2.8\%$ in the 5-FU-treated group. LPA protected 27.7% of cells from cisplatin-induced apoptosis and protected 29.6% of cells

Figure 3 LPA stimulated migration of SW480 cells. A: LPA stimulated migration of SW480 cells ($\times 200$). SW480 cells ($1 \times 10^5/100 \mu\text{L}$) were seeded into the inserts of transwell chambers after starvation for 8 h. Cells were incubated at 37°C for 4 h. Cells on the outside surface of inserts were fixed and stained. Typical images are presented; B: Migrated cells were quantified and relative migration rates (mean \pm SE) are presented. $^bP < 0.001$ vs $0 \mu\text{mol/L}$ LPA; C: Effect of inhibitors on LPA-induced cell migration. $50 \mu\text{mol/L}$ LPA in $600 \mu\text{L}$ medium was added to the lower chamber of transwell. Inhibitors including $10 \mu\text{mol/L}$ PD98059, $50 \mu\text{mol/L}$ LY294002 and $10 \mu\text{mol/L}$ Y-27632 were added to cells in the upper chamber. Cells on the outside surface of inserts were fixed, stained, and quantified. Data were analyzed using one-way ANOVA with post-hoc *t*-tests. $^bP < 0.001$ vs $50 \mu\text{mol/L}$ LPA.

from 5-FU-induced apoptosis. This suggests that LPA effectively protected SW480 cells from apoptotic death induced by the chemotherapeutic agents.

In order to elucidate the mechanisms of LPA protection from apoptosis, LY294002 and PD98059 were added to the LPA-treated group. Apoptotic population increased to $50.2\% \pm 3.2\%$ and $32.5\% \pm 3.6\%$ respectively after exposure to LY294002 (PI3K inhibitor) and PD98059 (MAPK inhibitor). This indicated that the PI3K, MAPK, PI3K-AKT/PKB signal pathways and the Ras/Raf-MAPK signal pathway may be involved in the LPA apoptotic-protection effect.

DISCUSSION

LPA, the simplest glycerophospholipid, was initially

found in the ascites of ovarian cancer patients at significant levels ($2\text{--}80 \mu\text{mol/L}$), and plays an important role in the development of ovarian cancer. LPA exerts growth factor-like effects through four specific G protein-coupled receptors (LPA₁₋₄). The effects include mitogenesis, secretion of proteolytic enzymes, and migration activity, which are accompanied by stress fiber formation and focal adhesion assembly in ovarian cancer cells.

We found recently that the level of LPA increases not only in the body fluid of ovarian cancer patients, but also in the plasma of patients with CRC. There are many studies focused on the LPA role in ovarian cancer cells. It has been found that LPA plays important roles in the progression of ovarian cancer and acts as an ovarian cancer promoter. Since LPA also increases in the plasma of CRC patients, what are the roles of LPA in CRC?

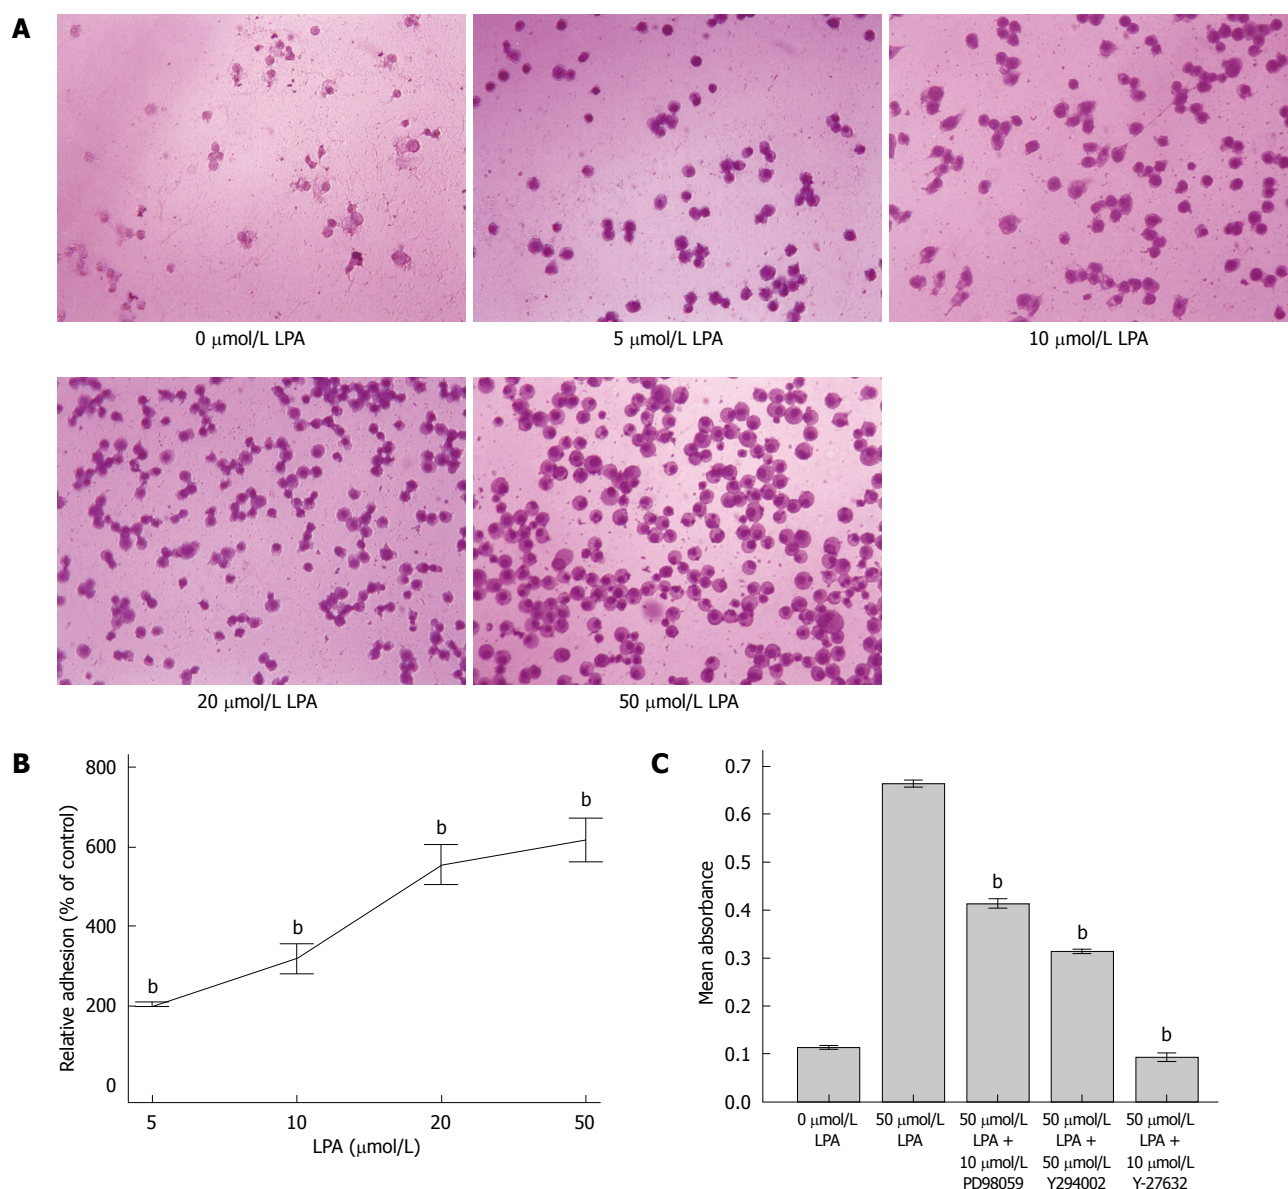

Figure 4 LPA stimulated adhesion of SW480 cells. A: Typical image of stained adhered cells ($\times 200$); B: Adhered cells were quantified and relative adhesion rates (mean \pm SE) are presented. ^b $P < 0.001$ vs 0 $\mu\text{mol/L}$ LPA; C: Effect of inhibitors on LPA induced adhesion. 50 $\mu\text{mol/L}$ LPA or LPA plus inhibitors (including 10 $\mu\text{mol/L}$ PD98059, 50 $\mu\text{mol/L}$ LY294002 and 10 $\mu\text{mol/L}$ Y-27632) were added to cells in 96 well plate. Adhered cells were quantified and presented. Results presented as mean \pm SE, $n = 5$. ^b $P < 0.001$ vs 50 $\mu\text{mol/L}$ LPA.

There are few studies regarding LPA effects on CRC. Furthermore, our previous study has shown that LPA receptors (LPA_{2,4}) are highly expressed in SW480 cells. In the present study, we preliminarily investigated the roles of LPA in the proliferation, migration, adhesion and apoptosis of SW480 cells and its mechanisms of action. We found that LPA significantly stimulated the proliferation of SW480 cells in a dose-dependent and time-dependent manner. This is consistent with the reports in ovarian cancer, in which LPA promotes growth of ovarian cancer similar to growth factor^[9].

We found that the MEK1 inhibitor, PD98059, significantly inhibited the LPA effect on the proliferation of SW480 cells. MEK1, a MAPK, is a key molecule of the Ras/Raf1/MEK/ERK signal pathway^[10]. We also found that the PI3K inhibitor, LY290042, partially inhibited the effect of LPA on the cell proliferation. This

indicated that LPA stimulates the proliferation of SW480 cells through the Ras/Raf1/MEK/ERK pathway, and that the PI3K-AKT/PKB signal pathway may also be partially involved in the LPA effect on proliferation.

MAPK transfers major cell proliferation signals from the cell surface to the nucleus. There are three major subfamilies of MAPK, including the extracellular-signal-regulated kinase (Ras/Raf1/MEK/ERK or ERK MAPK), the c-Jun N-terminal or stress-activated protein kinase (JNK or SAPK), and MAPK14^[11]. The Ras/Raf1/MEK/ERK pathway is one of the most important pathways for cell proliferation. Several lines of evidence suggest that, in CRC, the Ras/Raf1/MEK/ERK pathway, but not the JNK pathway or the p38 MAPK pathway, is the major regulator of cell proliferation. There is growing evidence that activation of the Ras/Raf1/MEK/ERK pathway is involved in the

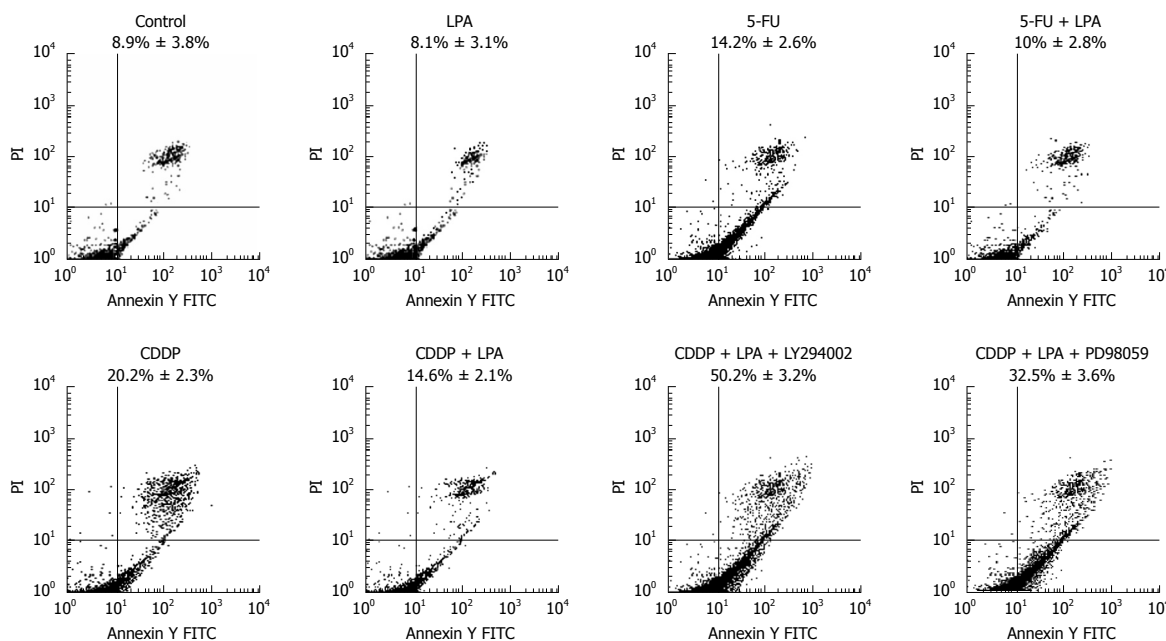

Figure 5 LPA protected cells from cisplatin- & 5-FU-induced apoptosis. SW480 cells were serum-starved for 24 h and treated for 24 h with 10 μ g/mL cisplatin (CDDP); 10 μ g/L cisplatin + 20 μ mol/L LPA; 8 μ g/mL 5-FU; 8 μ g/mL 5-FU + 20 μ mol/L LPA; 10 μ g/mL cisplatin + 20 μ mol/L LPA + 50 μ mol/L LY294002; 10 μ g/mL cisplatin + 20 μ mol/L LPA + 10 μ mol/L PD98059, respectively. Cells were harvested, stained with Annexin V/PI, and analyzed by FACS analysis. The Annexin V-positive and PI-negative population was defined as apoptotic cells. Representative results from three separate experiments are presented.

pathogenesis, progression, and oncogenic behavior of human CRC^[12]. This supports our observations that LPA stimulated growth of CRC cell line SW480 through the Ras/Raf1/MEK/ERK pathway.

There are several studies reporting LPA's effect on the proliferation of CRC cells. Zhang *et al*^[13] has found that LPA facilitates proliferation of colon cancer cells *via* induction of Krüppel-like Factor 5 (KLF5). KLF5 is a transcriptional factor highly expressed in the crypt compartment of the intestinal epithelium. LPA stimulated the KLF5 expression in colon cancer cells, SW480 and HCT116. Moreover, LPA-mediated KLF5 induction was partially blocked by inhibition of MAPK kinase and protein kinase C (PKC). This also indirectly indicated that the MAPK signaling pathway is involved in the proliferation of SW480 cells.

Yang *et al*^[14] reported that LPA-induced colon cancer cell proliferation requires the β -catenin signaling pathway. LPA activated the main signaling events in the β -catenin pathway, but inhibition of PKC blocked the effects, suggesting PKC involvement in LPA-induced activation of the β -catenin pathway. This also indirectly indicated that the PKC signaling pathway is involved in the proliferation of SW480 cells.

Balavenkatraman *et al*^[15] reported that DEP-1 protein tyrosine phosphatase inhibits proliferation and migration of colon carcinoma cells and is upregulated by protective nutrients. Upregulation of DEP-1 expression, and in turn inhibition of cell growth and migration, may present a previously unrecognized mechanism of chemoprevention by nutrients. This result contradicts other reports.

In our study, it was found that LPA significantly enhanced the migration and adhesion of SW480 cells

in a dose-dependent manner. The stimulation effect of LPA on cell adhesion, invasion and migration has been reported in other cancer types, including ovarian cancer^[16-19], pancreatic cancer^[18], and breast cancer^[20,21]. Enhanced migration activity and increased adherence to ECM are two major factors which contribute to tumor metastasis. Cell-ECM adhesions can alter the cell's capacity to attach and migrate through surrounding tissues. Changes of the expression and activities of the components of such adhesions could make an important contribution to preventing cancer invasion. Our study showed that LPA stimulated both migration and adhesion to ECM of colon cancer SW480 cells. This means that LPA significantly promotes the metastatic potential of SW480 cells. In our study, Rho kinase inhibitor, Y-27632, significantly inhibited cell migration and adhesion induced by LPA. LY294002 partially inhibited the LPA effect on adhesion. This indicated that the G12/13-Rho-GEFs-RhoA signal pathway may mediate the effect of LPA on both migration and adhesion, and that the PI3K-AKT/PKB pathway may partially mediate the LPA effect on adhesion.

Rho GTPase family proteins, including Rho, Rac1, and Cdc42, control a wide variety of cellular processes, such as cell adhesion, motility, proliferation, differentiation, and apoptosis^[22]. One of the best effectors of Rho is Rho-associated kinase (ROCK). ROCK is a target effect molecule downstream of RhoA. Rho activates ROCK by phosphorylation of Ser854 and Thr697, and induces a series of actions downstream to stimulate adhesion and migration. Y-27632 is a novel and specific inhibitor of ROCK, which is cell permeable and inhibits ROCK- I and ROCK- II by competing with ATP.

It has been reported in other tumors that LPA

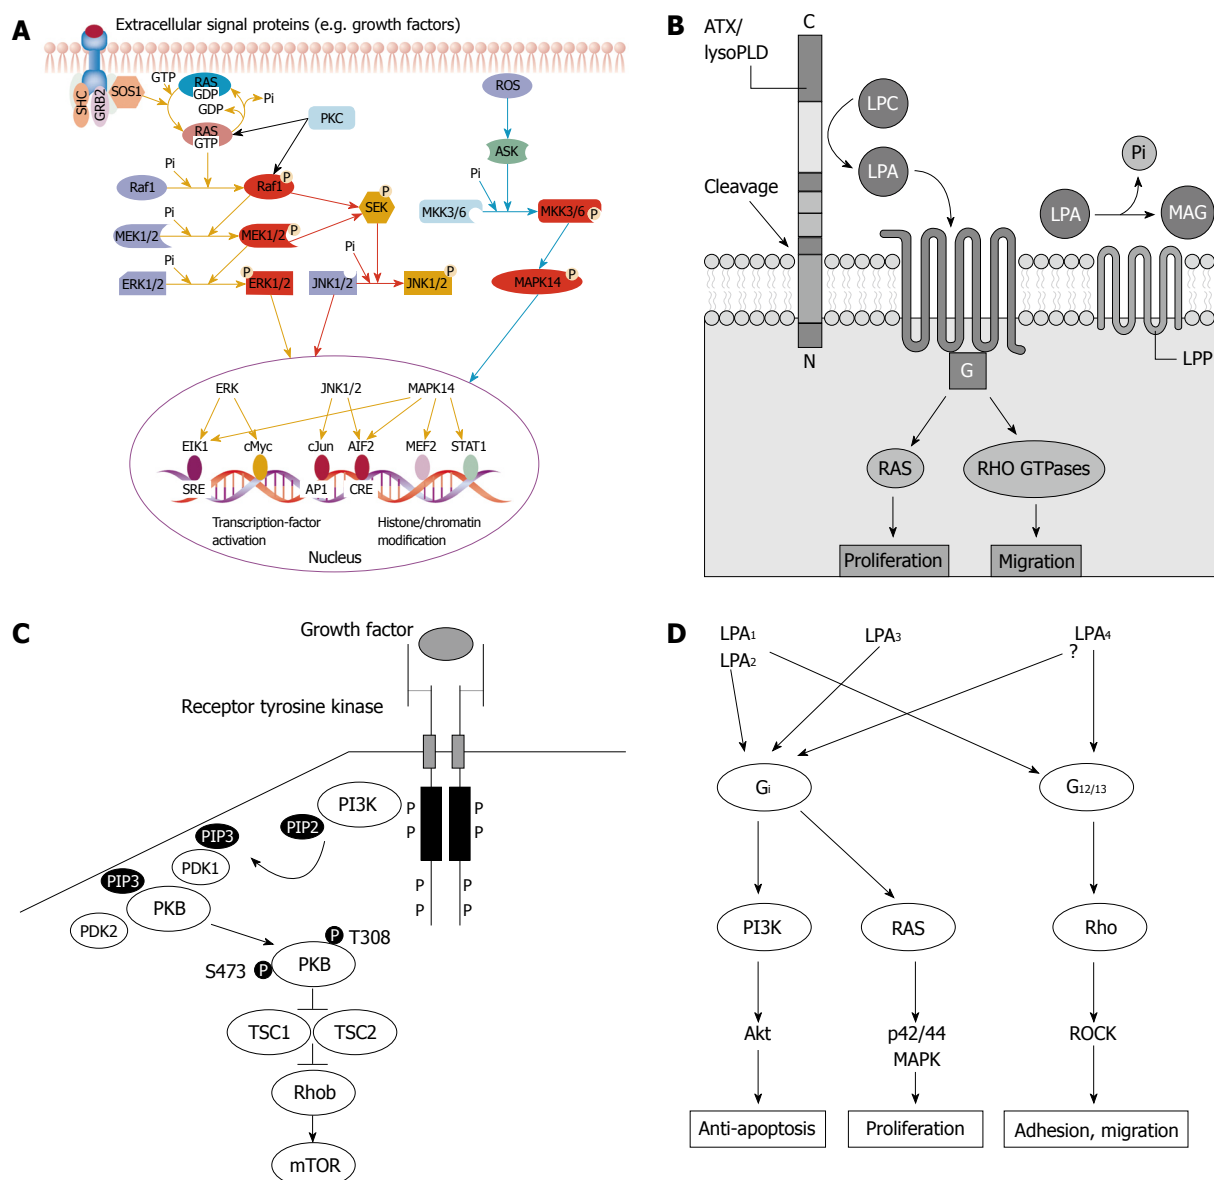

Figure 6 LPA effect and signal transduction pathway. A: Ras/Raf1/MEK/ERK signal pathway^[27]; B: G12/13-Rho-GEFs-RhoA signal pathway; C: PI3K-AKT/PKB signal pathway; D: Possible signal pathways mediated by LPA effect on SW480 cells.

drives the formation of focal adhesions, the tyrosine phosphorylation of focal adhesion proteins, and ROCK. Our results suggested that in colon cancer SW480 cells, the G12/13-Rho-GEFs-RhoA pathway may mediate migration and adhesion induced by LPA.

Several studies have also found that LPA promotes the metastatic potential of CRC.

Tatsuta *et al*^[23] found that LPA significantly increased the peritoneal and pleural metastases of intestinal adenocarcinomas induced by azoxymethane through RhoA activation. This is consistent with our study, in which the Rho signaling pathway was found to be involved in the LPA effect on metastasis. Other mechanisms have also been found.

Shiada *et al*^[24] found that cross-talk between LPA₁ and epidermal growth factor receptors mediates up-regulation of sphingosine kinase 1 to promote gastric cancer cell motility and invasion. Down-regulation of SphK1 attenuated LPA-stimulated migration and invasion of

MNK1 cells. Shiada *et al*^[25] also reported that LPA acts as a potent stimulator of colon cancer progression, although the binding to LPA₁ and LPA₂ induced slightly different responses. Komuro *et al*^[26] found that LPA₁ expression was increased in the early stage of adenoma.

We also found that LPA significantly protected SW480 cells from apoptosis induced by chemotherapeutic drugs, while LY294002 and PD98059 effectively blocked the LPA effect on apoptosis, indicating that the PI3K-AKT/PKB and the Ras/Raf-MAPK signal pathways may mediate the LPA effect on apoptosis; especially the PI3K-AKT/PKB pathway. The apoptosis protection roles of LPA have been reported in ovarian cancer cells.

PI3K can be divided into three classes. Class I PI3K is the most studied class of PI3K, consisting of an 110 kDa catalytic subunit and a regulatory subunit of 85 kDa. The activity of PI3K protein family is associated with cytoskeletal organization, cell division, inhibition of apoptosis and glucose uptake. The phospholipid

products of PI3K activate downstream targets, including PDK, Akt and PKC. LY294002 blocks PI3 kinase-dependent Akt phosphorylation and kinase activity. In SW480 cells we observed that the PI3K-AKT/PKB pathway may partially mediate the effect of LPA on proliferation.

In this study, it has been found that LPA significantly stimulated the proliferation, adhesion, and migration of human colon cells, SW480, and protected their apoptosis. The Ras/Raf-MAPK signal pathway may be involved in the LPA effect on proliferation. The G12/13-Rho-RhoA signal pathway may be associated with the LPA effect on adhesion and migration. The PI3K-AKT/PKB signal pathway may participate in the anti-apoptotic effect of LPA. This indicates that LPA probably acts as a promoter of the development of CRC. To decrease the LPA level in CRC patients and to block the LPA action (Figure 6) could be the aim of new strategies of treatment and prevention of CRC. The pathways involved in the LPA effects which we have discovered in this study could be new treatment targets of CRC.

COMMENTS

Background

Colorectal cancer (CRC) is a major cause of cancer death worldwide. The incidence has been rapidly increasing in recent years. Lysophosphatidic acid (LPA) was initially found in the ascites of ovarian cancer patients. Recently the authors group found that LPA levels increase not only in the body fluid of ovarian cancer patients, but also in the plasma of patients with CRC. There are many studies of LPA roles in ovarian cancer cells which have found that LPA stimulates the progression of ovarian cancer. Since LPA increases in the plasma of CRC patients as well, what are the roles of LPA in CRC? This study preliminarily investigated the roles of LPA in the proliferation, migration, adhesion and apoptosis of SW480 cells and its mechanisms of action.

Research frontiers

LPA was firstly found in the ascitic fluid from ovarian cancer patients. It is a bioactive glycerophospholipid generated and released by platelets, macrophages, epithelial cells, and some tumor cells. Studies have shown the presence of high levels of LPA in the ascitic fluid of patients with ovarian cancer and LPA is known to be an "ovarian cancer activating factor", which exerts growth factor-like effects through four specific G protein-coupled receptors (LPA₁₋₄). LPA is a potent mediator with a broad range of cellular responses, including regulation of cell proliferation, protection from apoptosis, modulation of chemotaxis and transcellular migration, which also mediates survival of ovarian cancer cells, macrophages, fibroblasts, and neonatal cardiac myocytes. Some of these cellular responses indicate that LPA is a mediator of tumor progression.

Innovations and breakthroughs

Since LPA was found in the ascites of ovarian cancer patients, there have been many studies on LPA, but most of the studies have focused on ovarian cancer. There are some studies of LPA in colon cancer, but this present study has some different findings from other studies. Firstly, because the expression level of LPA receptor varies in different colon cancer cell lines, and different LPA receptors mediate different responses to LPA, so LPA effects on SW480 cells are different from other colon cancer cell lines. Secondly, some mechanisms found in this study are not completely the same as findings in other studies. They found some pathways which mediate the LPA effect on proliferation, migration, and adhesion which are different from other studies.

Applications

In order to completely block the growth, metastasis and progression of CRC, the mechanisms for its development need to be clarified. The provided some information about the LPA effects on colon cancer cells and some mechanisms of action. These results will help to design targeted strategies to block LPA's stimulation effect on colon cancer.

Peer review

LPA is associated with inflammation and has been thought to be one of the

mediators of inflammation-induced promotion of cancer. LPA is one of the possible keys for inflammation-induced carcinogenesis in GI tract. Actually there are at least 511 papers on LPA and cell proliferation, among which there are nine papers on LPA and colon cancer. In this particular manuscript, the study was conducted carefully on many aspects including proliferation, apoptosis, cell adhesion, migration *etc.*, of colon cancer cells. Title, abstract, methods and results were carefully written.

Abstract

AIM: To describe a condition that we define as early graft dysfunction (EGD) which can be identified preoperatively.

METHODS: Small-for-size graft dysfunction following living-related liver transplantation (LRLT) is characterized by EGD when the graft-to-recipient body weight ratio (GRBWR) is below 0.8%. However, patients transplanted with GRBWR above 0.8% can develop dysfunction of the graft. In 73 recipients of LRLT (GRBWR > 0.8%), we identified 10 patients who developed EGD. The main measures of outcomes analyzed were overall mortality, number of re-transplants and length of stay in days (LOS). Furthermore we analyzed other clinical pre-transplant variables, intra-operative parameters and post transplant data.

RESULTS: A trend in favor of the non-EGD group (3-mo actuarial survival 98% vs 88%, $P = 0.09$; 3-mo graft mortality 4.7% vs 20%, $P = 0.07$) was observed as well as shorter LOS (13 d vs 41.5 d; $P = 0.001$) and smaller requirement of peri-operative Units of Plasma (4 vs 14; $P = 0.036$). Univariate analysis of pre-transplant variables identified platelet count, serum bilirubin, INR and Meld-Na score as predictors of EGD. In the multivariate analysis transplant Meld-Na score ($P = 0.025$, OR: 1.175) and pre-transplant platelet count ($P = 0.043$, OR: 0.956) were independently associated with EGD.

CONCLUSION: EGD can be identified preoperatively and is associated with increased morbidity after LRLT. A prompt recognition of EGD can trigger a timely treatment.

Early graft dysfunction following adult-to-adult living-related liver transplantation: Predictive factors and outcomes. *World J Gastroenterol* 2009; 15(36): 4556-4560 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4556.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4556>

INTRODUCTION

Small-for-size graft dysfunction (SFGSD) is one of the greatest limiting factors for the expansion of segmental liver transplantation from living donors^[1], and is characterized by: (1) onset within 2 wk after living-

related liver transplantation (LRLT); (2) a graft-to-recipient body weight ratio (GRBWR) below 0.8%; (3) total bilirubin higher than 5 mg/dL, and/or output of ascites through abdominal drainages of more than 1 L/d; and (4) exclusion of technical (e.g. arterial or portal occlusion, outflow congestion, bile leak), infective (e.g. sepsis) and immunological (e.g. acute cellular rejection) complications.

By definition, SFGSD can be diagnosed only in the presence of a GRBWR of less than 0.8%, or a ratio of graft volume (GV) relative to the standard liver volume (SLV) of the recipient (GV/SLV) of less than 30%^[1-4]. However, despite a GRBWR above 0.8%, some recipients of LRLT may have a worse clinical course.

The aim of this study was to analyze a group of LRLT recipients in order to identify those who developed a clinical picture of SFGSD in the absence of a GBWR of < 0.8% and with a GV/SLV ratio highest than 30%. Those patients were defined as affected by early graft dysfunction (EGD).

MATERIALS AND METHODS

We evaluated the rate of EGD in 73 consecutive recipients of adult-to-adult LRLT performed at our institute between July 2004 and September 2008, and whose GRBWR was > 0.8% and with a GV/SLV ratio higher than 30%. Follow-up in months was 27.34 ± 13.77 .

There were 43 males and 30 females, with a median age of 57 years (range 18-68 years). The etiology of the liver disease was related to hepatitis C virus infection in 47 cases, to hepatitis B virus infection in nine patients, to both B and C virus infection in three patients, and to non-viral causes in 14 patients. Twenty-two patients had hepatocellular carcinoma (HCC). Donor liver resection resulted in 73 right hepatectomies (liver segments 5-8). Graft implantation was performed with the piggy back technique and, in all cases, with the use of veno-venous bypass. Details of surgical procedures are reported elsewhere^[5,6]. Volumetric computed tomography (CT) scan was used to calculate liver and spleen volumes.

The main measures of outcomes analyzed were overall mortality, number of re-transplants and length of stay in days (LOS).

In order to identify predictors of EGD, epidemiologic pre-transplant variables such as age of the recipient and donor, sex of the recipient and donor, recently reported as markers of graft function^[7], were evaluated (Table 1).

Furthermore, we analyzed other clinical pre-transplant variables such as: serum bilirubin, serum albumin, serum sodium, INR, platelets count, WBC count, Child-Pugh score, MELD score, Meld-NA score, recently described^[8-10], percentage of donor liver steatosis, liver volume and spleen volume evaluated using CT, spleen/liver volume ratio (S/LVR), GBWR and GV/SLV (Table 2).

Then we observed the following intra-operative parameters: mean arterial pressure, systemic vascular resistance, cardiac output, cardiac index, units of

Table 1 Univariate analysis of epidemiologic data in the group with EGD *vs* the group without EGD, median (range)

	With EGD (10 pts)	Without EGD (63 pts)	P value
Age recipient	52.72 (38-61)	57.6 (18-68)	NS
Age donors	29.5 (26-54)	30 (18-53)	NS
Sex recipient (M/F)	5/5	38/25	NS
Sex donors (M/F)	5/5	39/24	NS

EGD: Early graft dysfunction.

transfused packed red blood cells, units of transfused platelets, and units of transfused fresh frozen plasma (Table 3).

Finally as post transplant data we looked at the LOS.

Statistical analysis

Survival analysis was performed using the Kaplan-Meier analysis with SPSS (SPSS Inc., Chicago, Ill, United States), and a descriptive analysis was used for the outcome. Normality was tested with the Wilk-Shapiro test. Differences between the two groups were tested using the unpaired Student's *t*-test, Mann-Whitney test, χ^2 test; $P < 0.05$ were considered significant. Multivariate analysis was performed to identify independent determinants for occurrence of EGD (logistic regression stepwise backward procedure).

RESULTS

Ten out of 73 patients (13.7%) fit our criteria for EGD. No statistically significant differences were found between EGD and non-EGD recipients in terms of 3-mo patient and graft mortality [one patient out of ten (10%) *vs* one patient out of 63 (1.6%), $P = 0.13$; two patients out of ten (20%) *vs* three patients out of 63 (4.7%), $P = 0.07$], number of re-transplants during the first 3 mo after LRLT [one patient out of ten (10%) *vs* two patients out of 63 (3.2%), $P = 0.33$] and 3-mo and 1-year actuarial patient survival (88% *vs* 98%; $P = 0.09$ by the log-rank test; 80% *vs* 94%, $P = 0.12$ by the log-rank test).

The 4-year actuarial patient survival was 77.78% *vs* 88.01%, ($P = 0.201$ by the log-rank test) (Figure 1). Although the statistical analysis doesn't indicate any statistical significance, probably due to the small size of the sample examined, the survival analysis points out a lower survival rate (77.78%) on the EGD patient *vs* non-EGD patient (88.01%); this is clinically relevant.

In the EGD patients, we observed two deaths: one because of sepsis and the second one due to multiorgan failure. In the non-EGD group, we observed six deaths: three because of neoplastic recurrence of HCC and three due to multiorgan failure. HCC recurrence could be explained by the advanced stage of the tumor at the pathologic examination, although the patients were classified within Milan criteria.

We did observe a significant difference between the two groups in terms of LOS, with the EGD group having

Table 2 Univariate analysis of pre-transplant clinical data in the two groups: EGD *vs* non-EGD

	EGD (10 pts)	Non-EGD (63 pts)	P value

Units plasma transfused	14 (0-47)	4 (0-34)	0.036

MAP: Mean arterial pressure; SVR: Systemic vascular resistance; C/O: Cardiac output; C/I: Cardiac index; PRBC: Units of transfused packed red blood cells. Data are expressed as mean (range), or mean ± SD.

a longer median LOS (13 d *vs* 41 d, $P = 0.001$) and greater median number of units of plasma transfused during surgery (4 *vs* 14, $P = 0.036$).

At univariate analysis of the variables collected, INR, platelet count, serum bilirubin and Meld-Na score, were identified as predictors of EGD (Table 3).

In the multivariate analysis (logistic regression, backward stepwise procedure), we analyzed INR, platelet count, serum bilirubin and Meld-Na score. Meld-Na score ($P = 0.025$, OR: 1.175) and pre-transplant platelet count ($P = 0.043$, OR: 0.956) were the variables independently associated with occurrence of EGD (Table 4).

In conclusion, the main clinical outcomes of the two groups were not statistically significant in terms of both early and late patient survival, probably because of the small size of the sample. In fact, as the survival rate was 77.78% *vs* 88.01% for EGD and non-EGD patients, we can hypothesize that survival rate acquires a statistically significant difference by enrolling a larger number of patients.

DISCUSSION

A GRBWR below 0.8% is considered mandatory for

Table 4 Multivariate analysis of pre-transplant epidemiologic and clinical data in the two groups: EGD *vs* non-EGD (logistic regression, backward stepwise procedure)

	P value	OR	95% CI per OR

**Figure 1** Survival analysis.

the diagnosis of SFSGD. Despite these findings in the literature, there are few patients who fully develop SFSGD by classic definition.

On the other hand, there are many patients who do not do well immediately after LRLT. We observed a clinical picture similar to that of SFSGD in patients who received partial livers that could not be described as small (GRBWR > 0.8).

In this study, the relevant clinical impact of EGD is suggested by the reduced 3-mo and 1-year patient survival and the increased graft-loss rate in the group of patients with this condition, even though there was no statistically significant difference, which is probably

due to an insufficient sample size (and a small number of events). The increased LOS in the EGD group reflects the increased time of recovery. Those patients who developed EGD were in fact those with worse INR, platelet count and total bilirubin. In addition, as previously reported by Yoshizumi *et al*^[11], we noted that patients with a higher MELD score, higher Child Pugh score and hyponatremia, tended to have a worse outcome.

In fact, in the EGD group (Table 3), these parameters were higher than in the non-EGD patient.

Our data, although not significant in accordance to others^[10], are clinically relevant especially at the time of selection of donors and recipient.

Our study was also aimed at finding objective criteria for identifying those patients who had a worse clinical course in the 2 wk after LRLT, and with a GRBWR above 0.8%. Our data support the hypothesis that SFGSD and EGD have a multi-factorial genesis in which the combination of the donor's factors (GV and quality of the graft) and the recipient's factors (portal hypertension and stage of liver disease) lead to allograft dysfunction after partial liver transplantation^[3,9,10,12].

The clinical variables identified at the univariate analysis as predictors of EGD confirmed the relevant roles of liver disease and portal hypertension in graft dysfunction.

Serum bilirubin, INR, and Meld-Na score are markers of liver function and platelet count is a marker of portal hypertension. However, at the multivariate analysis, the only variables independently associated with occurrence of EGD were Meld-Na score and pre-transplant platelet count.

The transplant community is now focused on the possibility of detecting predictive factors based on simple biochemical and imaging assessments which could allow physicians to treat those patients at risk of EGD immediately after surgery.

It has been demonstrated that in patients with cirrhosis and severe portal hypertension, the occlusion of the splenic artery causes a significant reduction in portal pressure, which is directly related to the spleen volume and indirectly related to the liver volume^[13]. This concept is at the center of our strategy for performing early splenic artery embolization for the treatment of SFGSD following LRLT^[14].

EGD can be identified preoperatively and is associated with increased morbidity after LRLT. Obviously, a prompt recognition of EGD can trigger a timely and appropriate treatment.

COMMENTS

Background

Small-for-size graft dysfunction (SFGSD) following living-related liver transplantation (LRLT) is characterized by early graft dysfunction (EGD) when the graft-to-recipient body weight ratio (GRBWR) is below 0.8%. However, patients transplanted with GRBWR above 0.8% can develop dysfunction of the graft.

Research frontiers

The study was aimed at finding objective criteria for identifying those patients who had a worse clinical course in the 2 wk after LRLT and had a GRBWR above 0.8%. They describe a condition that they define as EGD which can be identified preoperatively and seems to be associated with increased morbidity after LRLT.

Innovations and breakthroughs

A GRBWR below 0.8% is considered mandatory for the diagnosis of SFGSD. Despite the findings in the literature, there are few patients who fully develop SFGSD by classic definition. The authors observed a clinical picture similar to that of SFGSD in patients who received partial livers that could not be described as small (GRBWR > 0.8).

Applications

A prompt recognition of EGD can trigger a timely and appropriate treatment.

Terminology

The authors describe a condition that they define as EGD which can be identified preoperatively and seems to be associated with increased morbidity after LRLT.

Peer review

This is an important study which impacts on the field. Gruttadauria and colleagues report herein the parameters which allow preoperative identification of a condition defined as EGD i.e. the transplant Meld-Na score and pre-transplant platelet count. The study is original, well designed and performed.

COX-2 polymorphisms -765G→C and -1195A→G and colorectal cancer risk. *World J Gastroenterol* 2009; 15(36): 4561-4565 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4561.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4561>

Abstract

AIM: To determine the possible modulating effect of the COX-2 polymorphisms, -765G→C and -1195A→G, on the risk of colorectal cancer (CRC) in a Dutch population.

METHODS: This case-control study includes 326 patients with CRC and 369 age- and gender-matched controls. Genotypes of the COX-2 polymorphisms -765G→C and -1195A→G were determined by polymerase chain reaction-based restriction fragment length polymorphism. COX-2 genotypes and haplotypes were analyzed and odds ratios with 95% confidence intervals were estimated by logistic regression.

RESULTS: The -765GG genotype was associated with an increased risk of developing CRC (OR, 1.45; 95% CI, 1.03-2.04). No significant difference was observed in the genotype distribution of the -1195A→G polymorphism between patients and controls. The GG/AC haplotype was present significantly less often in patients than in controls (OR 0.44; 95% CI, 0.22-0.85). When the AC, AG and GG haplotypes were investigated separately, the AC haplotype showed a tendency to be less frequent in patients than in controls (OR_(AG/AC) 0.78; 95% CI, 0.57-1.06).

CONCLUSION: The -765GG genotype is associated

INTRODUCTION

Colorectal cancer (CRC) is a common disease in both men and women. CRC includes cancerous growths in the cecum, colon, sigmoid and rectum. In Western countries, 5% of the population ultimately develop CRC, thus this disease is an important public health issue^[1]. CRC is ranked the third most common form of cancer worldwide in terms of incidence^[2]. In the Netherlands, CRC is the second most common form of cancer affecting women and the third most common form of cancer affecting men. In 2003 in the Netherlands 9898 new cases of CRC were diagnosed^[3].

CRC is usually observed in one of three specific patterns: sporadic, inherited or familial. The sporadic form accounts for approximately 70% in the population and is most common in individuals older than 50 years of age, probably as a result of interactions between low penetrance genes and environmental factors. Fewer than 10% of the population has an inherited predisposition to colon cancer. Inherited colon cancer is usually the result of a single germ line mutation. The third pattern, familial colon cancer, includes those families in which CRC develops too frequently to be considered as sporadic colon

cancer and which are not in a pattern consistent with an inherited syndrome. Up to 25% of all cases of CRC are estimated to fall into this category^[1].

Cyclooxygenase (COX), also known as prostaglandin endoperoxidase H synthase, is a modifier gene and key enzyme in the conversion of arachidonic acid into prostaglandins.

The COX family consists of two isozymes: COX-1 and COX-2. COX-1 is constitutively expressed in most cell types and is involved in the homeostasis of various physiological functions. COX-1 is well known as the housekeeping gene. COX-2 is an inducible form and its expression can be induced by mitogenic and proinflammatory stimuli. Increased expression of COX-2 is observed in many types of cancers. COX-2 is also associated with many stages of cancer development, e.g. invasion, metastasis, hyperproliferation, transformation and tumor growth^[4,5].

Recent studies suggest that single nucleotide polymorphisms (SNPs) in the COX-2 promoter may alter the enzyme function of COX-2 by differential regulation of COX-2 expression. A differential COX-2 expression may influence the risk of the development of gastrointestinal adenocarcinomas, including CRC^[6-9].

In a study of African-Americans, an inverse association was found between the Val511Ala polymorphism and the risk of CRC^[8]. In two studies the promoter polymorphisms -765G→C and -1195A→G were associated with an increased risk of CRC^[9,10], whereas Ulrich *et al*^[11] reported a reduced risk of CRC associated with the -765G→C polymorphism. The inconsistent results may indicate that the COX-2 polymorphisms -765G→C and -1195A→G may play a role in carcinogenic processes in combination with specific life-style conditions or dependent on the racial composition of a particular population.

The purpose of our study was to determine the possible modulating effect of the COX-2 polymorphisms -765G→C and -1195A→G on the risk of sporadic CRC in a Dutch population. The results of this research will lead to a better understanding on the role of SNPs in the COX-2 promoter in colon cancer carcinogenesis. Such knowledge in future may eventually lead to better preventive measures for CRC.

MATERIALS AND METHODS

Patients and controls

This case-control study included 326 patients with CRC (59.8% men, 40.2% women) and 369 cancer-free controls (59.1% men, 40.9% women). In the patient group, 31.0% had a proximal tumor and 68.1% had a distal tumor, whereas in 0.9% of cases localization of the tumor was unknown (see legend of Table 1). All subjects were of Caucasian origin with a mean age of 63.7 years and were recruited at Radboud University Nijmegen Medical Center, the Netherlands. The patient and control groups were matched for gender and age. The characteristics of patients and controls are summarized in Table 1.

Table 1 Characteristics of patients with colorectal cancer (CRC) and controls (mean ± SD)

	Patients with CRC (n = 326)	Controls (n = 369)
Age (yr)	62.7 ± 11.7	64.5 ± 10.7
Male gender	195 (59.8%)	218 (59.1%)
Female gender	131 (40.2%)	151 (40.9%)
Localization of tumor ¹		
Proximal ²	101 (31.0%)	
Distal ³	222 (68.1%)	

¹Note that the localization of the tumor was unknown in 3 patients;

²Proximal tumor: cecum, ascending and transverse colon; ³Distal tumor: descending colon, sigmoid, rectosigmoid junction and rectum.

Genotyping

DNA from patients and controls was isolated from whole blood using the Pure Gene DNA isolation kit (Gentra Systems, Minneapolis, MN) and stored at 4°C. Genotypes of the COX-2 -765G→C and -1195A→G polymorphisms were determined by polymerase chain reaction (PCR)-based restriction fragment length polymorphism, according to the method of Zhang *et al*^[5].

First, PCR was used to amplify the COX-2 promoter region containing the polymorphism -765G→C and -1195A→G. The primers used to amplify the COX-2 promoter region were 765F5'-TATTATGAGGAGAATTTACCTTTCGC-3'/765R5'GCTAAGTTGCTTTCACAGAAGAAT-3', and 1195F5'CCCTGAGCACTACCCATGAT-3'/1195R5'GCCCTTCATAGGAGATACTGG-3'. PCR was performed using a 25 µL reaction mixture containing 100 ng of DNA, 10 mmol/L of Tris/HCl (pH 9.0), 50 mmol/L of KCl, 0.1% of Triton X-100, 2 mmol/L of MgCl₂, 200 nmol/L of each primer, 250 µmol/L of deoxyribonucleotide triphosphates and 2.5 U Taq DNA polymerase. The PCR profile for the -1195A→G polymorphism consisted of an initial melting step of 3 min at 95°C, followed by 40 cycles of 30 s at 95°C, 30 s at 58°C, 30 s at 72°C and a final elongation step of 7 min at 72°C. Cycle conditions for the -765G→C polymorphism were 4 min at 95°C, followed by 40 cycles of 30 s at 95°C, 30 s at 54°C, 30 s at 72°C and finally the same elongation step as for the -1195A→G PCR assay. The samples were then analyzed by agarose gel electrophoresis for control of the PCR products.

The PCR products (10 µL) were incubated with 10 U of restriction enzymes *Pvu*II and *Hba*I at 37°C for determination of the -1195A→G and -765G→C genotypes, respectively. Finally, the samples were analyzed by agarose gel electrophoresis. The -765G→C and -1195A→G genotypes that could be detected were: 765CC (100 bp fragment), 765GC (100 + 74 + 26 bp fragments), 765GG (74 + 26 bp fragments), 1195AA (273 bp fragment), 1195GA (273 + 220 + 53 bp fragments) and 1195GG (220 + 53 bp fragments), respectively.

Statistical analysis

The data analysis was performed using SPSS software

Table 2 Genotype distribution and OR of the *COX-2* -1195A→G and -765G→C polymorphisms in patients with CRC and controls

Genotype	Patients with CRC (n = 326)	Controls (n = 369)	OR (95% CI)
-1195AA	213 (65.3%)	232 (62.9%)	Reference

OR: Odds ratio; CI: Confidence interval.

(Version 14.0, SPSS, Chicago, IL, USA). Logistic regression was used to assess the association between the genotypes and the risk of CRC. The statistical significance of the -1195A→G and -765G→C genotype distributions between the patient and control groups was determined by Chi-square analysis. A *P*-value of < 0.05 was used as the criterion of statistical significance and all analyses were adjusted for age and sex. A test for deviation from the Hardy-Weinberg equilibrium, by comparing the expected to observed genotype frequencies, was used. Odds ratios (ORs) and 95% confidence intervals (CI) were calculated. Based on the two polymorphisms tested, a haplotype analysis was performed. In the two populations studied, seven different haplotypes could be distinguished: AC/AC, AG/AC, AG/AG, GC/AC, GG/AC, GG/AG and GG/GG. The localization of the tumor, distal or proximal, was also included in the database analyses.

RESULTS

Using cancer-free controls as a reference we tested for an association of the two *COX-2* polymorphisms with CRC. The genotype distributions in patients and controls of the two *COX-2* polymorphisms investigated are summarized in Table 2. The observed genotype distributions for the -765G→C and -1195A→G polymorphisms in patients with CRC and controls were in accordance with the Hardy-Weinberg equilibrium, with *P*-values of 0.19 and 0.99 for patients with CRC and 0.24 and 0.46 for controls, respectively. When both polymorphisms were investigated separately, there was no significant difference in the -765G→C or -1195A→G allele frequency between the patient and control group. However, the -765GG genotype was more frequent in patients than in controls (OR, 1.45; 95% CI, 1.03-2.04). There was no significant difference in the genotype distribution of the -1195A→G polymorphism among patients and controls.

Next, the potential association of genotype distribution of the two *COX-2* polymorphisms with tumor localization was investigated. We distinguished proximal and distal tumor localization. Proximal included the cecum, colon ascendens and colon transversum and distal included the rectum, sigmoid, colon descendens and flexura lienalis. No association between the -765G→C and -1195A→G polymorphisms and tumor

Table 3 *COX-2* haplotypes in patients with CRC and controls

Haplotype	Patients with CRC (n = 326)	Controls (n = 369)	OR (95% CI)
AC/AC	9 (2.8%)	8 (2.2%)	1.16 (0.40-3.42)
AG/AC	59 (18.1%)	74 (20.1%)	0.83 (0.54-1.27)
AG/AG	145 (44.5%)	150 (40.7%)	Reference
GC/AC	1 (0.3%)	-	-
GG/AC	16 (4.9%)	38 (10.3%)	0.44 (0.22-0.85)
GG/AG	84 (25.8%)	86 (23.3%)	1.01 (0.68-1.50)
GG/GG	12 (3.7%)	13 (3.5%)	0.92 (0.38-2.24)

localization was detected.

Also no association of the genotype distribution of the -765G→C and -1195A→G polymorphisms in the patient group was found with gender and age.

Based on the two polymorphisms tested, a haplotype analysis was performed in the two populations studied and seven haplotypes could be distinguished (Table 3). A significant difference between the *COX-2* haplotypes was observed. The GG/AC haplotype was less frequent in patients (OR, 0.44; 95% CI, 0.22-0.85). When the AC, AG and GG haplotypes were investigated separately; the AC haplotype tended to occur less frequently in patients than in controls (OR_(AG/AC) 0.78; 95% CI, 0.57-1.06).

DISCUSSION

The *COX-2* protein was detected in 70% of all colorectal cancer tissues. In adjacent normal colorectal tissue in the same slide the *COX-2* protein was not observed. These results suggest that increased expression of *COX-2* is associated with CRC^[12]. SNPs in the *COX-2* promoter may alter the enzyme activity of *COX-2* by differential regulation of *COX-2* expression, which may influence the risk of the development of CRC^[7-9]. It has been recently demonstrated that the polymorphisms -765G→C and -1195A→G may have a functional effect on *COX-2* expression and enzyme activity^[7-9]. Both the -765G→C and -1195A→G polymorphisms were shown to display a lower *COX-2* promoter activity, which may result in a lower expression of the *COX-2* enzyme^[5,13].

We investigated the potential association of the *COX-2* polymorphisms -765G→C and -1195A→G and the risk of developing CRC, and found that the -765GG genotype was present more often in patients than in controls. As demonstrated by Zhang *et al*^[5] the reporter gene expression driven by the -765G-containing *COX-2* promoter was higher as compared to the -765C-containing counterpart. This indeed could mean a higher *COX-2* expression in -765GG individuals.

A study in American Caucasians reported a reduced risk of colorectal adenomas in individuals bearing the -765GG genotype, but this lower risk was found only among users of non-steroidal antiinflammatory drugs (NSAIDs). In addition, a lower risk of adenoma among -765CC genotypes was found only in non-users of NSAIDs^[11]. Zhang *et al*^[5] and Tan *et al*^[9] reported that the -765GC genotype was associated with an increased

risk of esophageal squamous cell carcinoma (ESCC) and CRC, in Chinese populations. The findings of Tan *et al*^[9] and Zhang *et al*^[5] seem in contrast with our results, since we found a reduced risk of CRC with the -765G/C genotype. However, racial differences in the study populations may explain these apparent contradictory results, since the distribution of the COX-2 polymorphisms studied here differs considerably between the Chinese and Dutch study populations. The genotype frequencies found in our Dutch patients with CRC for the -765G → C and -1195A → G polymorphisms were: 73.9% GG, 23.0% GC, 3.1% CC and 65.3% AA, 31.0% GA, 3.7% GG, respectively. Zhang *et al*^[5] in a Chinese population reported genotype frequencies of 90.6% GG, 9.4% GC, 0% CC and 30.5% AA, 52.9% GA and 16.6% GG. Tan *et al*^[9] in Chinese patients with CRC recently reported approximately the same genotype frequencies as Zhang *et al*^[5]: 91.6% GG, 8.4% GC, 0% CC and 34.5% AA, 49.4% GA and 16.1% GG. These findings suggest that ethnic differences in genotype frequencies of COX-2 polymorphisms may have a significantly different modulating effect on disease phenotypes in different ethnic populations.

According to Zhang *et al*^[5] and Tan *et al*^[9] in a Chinese population, the -1195GA and -1195AA genotypes were associated with an increased risk of ESCC and CRC, respectively. This again is not in line with our findings, since we could not demonstrate a significant difference in the allele distribution of the -1195A → G polymorphism between our Dutch patients with CRC and controls.

We also investigated the potential association of the genotype distributions of the -1195A → G and -765G → C polymorphisms with tumor localization. No association between the two polymorphisms and tumor localization was found, which is in accordance with the results of Tan *et al*^[9] who found a very similar distribution of both COX-2 genotypes in patients with colon ($n = 403$) or rectal ($n = 597$) cancer.

The COX-2 GG/AC haplotype (-1195G-765G/-1195A-765C) was found to be present less frequently in patients. When the AC, AG and GG haplotypes were investigated separately, the AC haplotype tended to be less frequently present in patients with CRC than in controls (OR_(AG/AC) 0.78; 95% CI, 0.57-1.06). This is in line with the findings of Zhang *et al*^[5] who demonstrated that the luciferase expression of the AG constructs was higher than the expression of the AC constructs, suggesting that the AC haplotype was associated with a lower COX-2 expression and a decreased risk of CRC.

However, Zhang *et al*^[5], Tan *et al*^[9] and Moons *et al*^[14] found an association of the AC haplotype with an increased risk of ESCC, CRC and esophageal adenocarcinoma (EAC). These findings are in contrast with our results, as described above. In addition, the predicted expression levels of the COX-2 protein are higher in AG versus AC haplotype individuals, according to Zhang *et al*^[5], which is not in agreement with the hypothesis that high expression of COX-2 is a risk factor for colorectal or esophageal carcinoma. It should be noted however

that haplotype frequencies of AC are very low in the patient and control populations studied by Zhang *et al*^[5] and Tan *et al*^[9], being 4.5% *vs* 1.6% and 3.8% *vs* 1.8%, respectively, compared to 21.2% *vs* 32.6% in our study. In the study of Moons *et al*^[14] the AC haplotype occurred in 25.0% of the total study population, who were patients with esophageal adenocarcinoma, Barrett's esophagus and reflux esophagitis, a proportion which is very close to our data. In the study of Moons *et al*^[14] unfortunately no cancer-free controls were included, but patients with Barrett's esophagus or reflux esophagitis were used as controls, both of which would confer a risk of esophageal adenocarcinoma.

In summary, we found a significant difference in the -765G → C polymorphism distribution between the patients with CRC and the control group; the -765GG genotype was associated with an increased risk for CRC. The GG/AC haplotype was found less frequently in patients with CRC and may be associated with a reduced risk of CRC. These findings suggest a modulating role for the COX-2 polymorphisms -1195A → G and -765G → C in the development of CRC in a Dutch population.

COMMENTS

Background

Cyclooxygenase-2 (COX-2) is a key enzyme in the development and progression of neoplasms. COX-2 was found to be over-expressed in gastrointestinal tumors, including those of the colon/rectum. The corresponding COX-2 gene is polymorphic and two single nucleotide polymorphisms (SNPs; -1195A → G and -765G → C) were demonstrated to influence the expression of COX-2. Therefore, these polymorphisms may modulate the risk for gastrointestinal cancers, such as cancers of the colon/rectum.

Research frontiers

In this study, the -765GG genotype was associated with an increased risk of developing CRC and the GG/AC haplotype seemed to protect against CRC.

Innovations and breakthroughs

The COX-2 polymorphisms -765G → C and -1195A → G may modulate the development of CRC in a Dutch population.

Applications

Screening for the COX-2 -765GG genotype in a population at risk of colorectal cancer may be valuable in future in order to select the high risk patients. Information and prevention programs can then be focused on these patients.

Terminology

COX-2 is an enzyme that catalyzes the conversion of arachidonic acid in prostaglandin H₂, the precursor of other prostaglandins, prostacyclin and thromboxanes. These regulatory compounds play a role in many biological processes such as cell proliferation, angiogenesis, immune function and inflammation, which are all crucial in the development and progression of neoplasms.

Peer review

The manuscript, reported by Hoff *et al*, analyzes COX-2 polymorphisms -765G → C and -1195A → G and colorectal cancer (CRC) risk in a Dutch population. This manuscript contributes in the effort to characterize some molecular signatures as risk factors for colon cancer in different ethnic populations.

INTRODUCTION

Squamous cell carcinoma (SCC) of the anus is a relatively uncommon malignancy, affecting approximately 4600 patients per year in the United States^[1]. Globally, annual incidence rates of invasive anal cancer range from 0.1 to 2.8 cases per 100 000 among men and 0.0-2.2 cases per 100 000 among women^[2]. In particular, anal cancer rates among men who have sex with men are notably higher^[3]. Invasive anal cancer, like invasive cervical cancer, has been causally linked to high-risk human papillomavirus (HPV) infection^[4,5]. According to a recent review, HPV is detected in 71% of invasive anal cancers, with approximately 72% of the HPV-positive cases being associated with HPV 16 and/or 18 infection^[6]. This estimate of HPV 16 and 18 prevalence is similar to that found in invasive cervical cancer^[7].

Although many risk factors for the development of anal cancer have been identified, such as the practice of receptive anal intercourse and immunodeficiency, the molecular mechanisms related to anal carcinogenesis remain unclear. Mutations in the *p53* gene are the most common genetic alterations in human cancer and they can be found in up to 80% of anal carcinomas^[8]. In addition to gene mutations, some polymorphisms in the *p53* gene have been suggested to play a role in different malignancies^[9-11]. Recent studies have focused on a common single-base-pair polymorphism at codon

Abstract

AIM: To investigate the potential role of *p53* codon 72 polymorphism as a risk factor for development of anal cancer.

METHODS: Thirty-two patients with invasive anal carcinoma and 103 healthy blood donors were included in the study. *p53* codon 72 polymorphism was analyzed in blood samples through polymerase chain reaction-restriction fragment length polymorphism and DNA sequencing.

RESULTS: The relative frequency of each allele was 0.60 for Arg and 0.40 for Pro in patients with anal cancer, and 0.61 for Arg and 0.39 for Pro in normal controls. No significant differences in distribution of the codon 72 genotypes between patients and controls were found.

CONCLUSION: These results do not support a role for the *p53* codon 72 polymorphism in anal carcinogenesis.

72, which results in a Pro (CCC) or Arg (CGC) residue at this position. The two polymorphic variants have been shown to have not only structural differences, as reflected by distinct electrophoresis patterns of migration, but also different biological properties^[12-14]. The Arg variant has been demonstrated to be more susceptible to degradation by the HPV E6 protein than the Pro variant, with individuals who are homozygous for Arg having a higher risk of being affected by HPV-associated malignant tumors^[15].

In this article, we present the results of what is believed to be the first study to investigate the potential association of *p53* codon 72 polymorphism with invasive carcinoma of the anal canal.

MATERIALS AND METHODS

Cases and controls

Thirty-two patients with histologically confirmed primary SCC of the anal canal (mean age 60.3 years, range 30-81 years) were enrolled prospectively in the study. As a non-malignant control group, we studied 103 consecutive healthy blood donors with no previous history of cancer (mean age 47.7 years, range 40-72 years). Demographic characteristics of cases and controls are shown in Table 1. After pretreatment assessment, including a complete medical history and physical examination, colonoscopic examination, computed tomography of the abdomen and pelvis, and chest radiography, the patient's AJCC (American Joint Committee on Cancer) tumor stage was determined^[16]. The distribution was as follows: 6.2% stage I ($n = 2$), 53.1% stage II ($n = 17$), 34.3% stage III ($n = 11$) and 6.2% stage IV ($n = 2$).

The study was approved by the Ethics and Scientific Committee of the Santa Casa Hospital Complex and Hospital de Clínicas de Porto Alegre. Informed consent was obtained from all patients and controls before being enrolled in the study.

DNA extraction and genotyping

p53 codon 72 polymorphism was studied in blood samples collected by venous puncture. Genomic DNA was extracted from peripheral lymphocytes using Ultra Clean DNA Bloodstain Kit (MoBioLabs, Solana Beach, CA, USA) according to the manufacturer's instructions. Polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) analysis of codon 72, modified from the technique described by Ara *et al.*^[17], was used to identify *p53* genotypes. The forward primer used was 5'-TTGCCGTCCCAAAGCAATGGATGA-3', and the reverse primer was 5'-TCTGGGAAGGGACA GAAGATGAC-3'. Each PCR reaction mixture (50 mL) contained 10 pmol each primer, 1.5 mmol/L MgCl₂, 200 mmol/L each dNTP, 1 U Platinum®*Taq* DNA polymerase (Invitrogen, Sao Paulo, Brazil), and 100-300 ng genomic DNA. Reaction mixtures were preincubated for 5 min at 94°C. PCR conditions were 94°C for 1 min and 55°C for 1 min, followed by 72°C for 1 min for 35 cycles. The final extension was at 72°C for 10 min.

Table 1 Demographic characteristics of cancer patients and controls n (%)

Characteristics	Cases	Controls	P
Gender			
Male	7 (22)	22 (21)	NS
Female	25 (78)	81 (79)	
Race			
White	28 (87)	96 (93)	NS
Non-white	4 (13)	7 (7)	
Age (yr); mean (range)	60.3 (30-81)	47.7 (40-72)	< 0.001
Total	32 (100)	103 (100)	

NS: Not significant.

After confirmation of an amplified fragment of the expected size (199 bp) on an agarose gel, 10 µL PCR product was digested with 6 U restriction enzyme *Bst*UI (New England Biolabs, Ipswich, MA, USA) at 60°C for at least 4 h. DNA fragments were electrophoresed through a 2.5% agarose gel and stained with ethidium bromide. RFLP results were confirmed by sequencing the PCR fragments from nine randomly selected samples (three of each genotype) using an automated sequencing system (ABI Prism 310 Genetic Analyzer; Applied BioSystems, Foster City, CA, USA). Sequencing reactions were performed using the BigDye® Terminator V3.1 cycle sequencing reaction kit (Applied BioSystems) according to the manufacturer's instructions. Forward and reverse primers were utilized as sequencing primers.

Statistical analysis

Univariate statistics were used first to compare cases and controls for demographic variables and genotype prevalence. The χ^2 test was used to analyze categorical variables and ANOVA was used to compare the continuous variable age. The association between the *p53* polymorphism and anal cancer was determined using the logistic regression method to assess ORs and 95% CI. $P < 0.05$ was considered statistically significant.

RESULTS

Detection of *p53* codon 72 polymorphism by PCR-RFLP was performed in all cases and controls. The Arg allele was cleaved by *Bst*UI, which yielded two small fragments (113 and 86 bp). The Pro allele was not cleaved by *Bst*UI, which had a single 199-bp band. Heterozygotes contained three bands, which corresponded to 199, 113 and 86 bp. The PCR results were confirmed by DNA sequencing.

The distribution of the codon 72 genotypes in patients and controls did not deviate from the Hardy-Weinberg equilibrium. The genotype frequencies in cases and controls are presented in Table 2, with no association with anal cancer risk being observed. The relative frequency of each allele was 0.60 for Arg and 0.40 for Pro in patients with anal cancer, and 0.61 for Arg and 0.39 for Pro in normal controls.

We also analyzed the codon 72 polymorphism of the healthy controls according to their age. The genotype

Table 2 Distribution of *p53* codon 72 polymorphism in cancer patients and controls *n* (%)

	Total	Arg/Arg	Arg/Pro	Pro/Pro	OR ¹	CI	P
Anal cancer	32	10 (31.2)	19 (59.4)	3 (9.4)	1.6	0.6-4.9	0.325
Controls	103	31 (30.1)	62 (60.2)	10 (9.7)			

¹Adjusted for age. Arg/Arg vs Arg/Pro and Pro/Pro.

distribution in the 78 controls under 50 years old was as follows: 25 Arg/Arg (32.1%), 6 Pro/Pro (7.7%), and 47 Arg/Pro (60.3%). The distribution in the 25 controls over 50 years old was: 6 Arg/Arg (24.0%), 4 Pro/Pro (16.0%), and 15 Arg/Pro (60.0%). No significant difference in the genotype distribution was found between these two age groups ($P = 0.407$).

DISCUSSION

High-risk HPV infection has been implicated in the pathogenesis of different malignancies^[17-21]. Several biochemical and genetic studies have shown that HPV E6 and E7 proteins exert a cooperative effect on cellular transformation and immortality by interfering with the function of cellular tumor suppressor proteins^[22-24].

A common polymorphism has been known in codon 72 of the *p53* gene, with two alleles encoding either Arg (*p53*Arg) or Pro (*p53*Pro)^[13,14]. Storey *et al*^[15] have investigated the effect of this polymorphism on the susceptibility to E6-mediated degradation and found that individuals homozygous for Arg are seven times more susceptible to HPV-associated cervical carcinogenesis than heterozygotes are. Since then, the effect of codon-72 polymorphism of *p53* on cervical cancer has been studied, with contradictory results being reported. Overall, as demonstrated in a recent meta-analysis, compared with the heterozygous genotype (Pro/Arg), the homozygous genotype (Arg/Arg) of codon-72 of *p53* is associated with an approximately 20% increased risk of cervical cancer^[25].

Invasive anal cancer, like invasive cervical cancer, has well-documented precursors, known as anal intraepithelial neoplasia 2-3 (histology) or high-grade squamous intraepithelial lesions (cytology)^[6]. Anal cancer also has been causally linked to high-risk HPV infection, therefore, we decided to evaluate, perhaps for the first time, the potential role of codon 72 polymorphism as a risk factor for development of this type cancer.

In order to minimize sources of bias and avoid misinterpretation of the results, standard safeguards were adopted. Patients and controls were matched ethnically and derived from a population living in the same geographic region (Southern Brazil), and were enrolled consecutively in a single institution. All PCR results were confirmed by DNA sequencing.

We investigated the allele and genotype frequencies at *p53* codon 72 in 32 patients with anal cancer and 103 healthy individuals from southern Brazil. No significant differences in the relative allele frequency and in the distribution of genotypes were found between patients

and controls. These results are in line with several studies that failed to demonstrate a correlation of the *p53* codon 72 polymorphism with development of non-cervical HPV-associated epithelial malignant tumors, such as head and neck and oral SCCs^[26,27].

The association between codon 72 polymorphism and risk of cancer has been reported in different populations^[28]. Studies have been conducted to evaluate this polymorphism as a risk factor for different types of cancer, such as gastric^[29], lung^[9] and breast carcinomas^[11]. So far, the published data have been inconclusive. The conflicting results found in the literature might be attributed to variations in protocols among different laboratories, or to poor selection of control groups^[29]. They also might have been caused by the inherent characteristics of the population being analyzed, as there are considerable variations in the distribution of the codon 72 genotypes in various populations. This polymorphism seems to be maintained by natural selection influenced by environmental factors, such as the degree of exposure to the UV-B component of sunlight^[30]. The resulting North-South Arg/Pro gradient has been reported in different geographical regions. Population-based studies have indicated that the Arg allele is most prevalent in individuals with light complexion and least prevalent in those with darker complexion, with a clear and consistent decline in the prevalence of the Pro allele, with increasing northern latitude^[30-32].

The population from Southern Brazil, in contrast with other regions of the country, is composed mainly of Caucasian individuals who are descended from European immigrants^[33]. Although most of these immigrants came from Portugal, Germany and Italy^[34], the genotype distribution found in our healthy controls was notably different from the genotype distribution observed in those countries^[35-37]. This can be explained partially by the process of miscegenation among different ethnic groups (Caucasians, Amerindians and Afro-Brazilians) that took place during Brazilian colonization^[38]. Each specific population seems to have its own characteristic genotype distribution that can differ markedly from the polymorphic frequencies found in other populations, even when neighboring countries are compared.

We believe, however, that the lack of correlation between the codon 72 genotype distribution and anal cancer risk observed in our study cannot be interpreted solely as a result of population ethnicity. In a previous study of cancer patients and normal individuals from Southern Brazil, we were able to detect a significant

association of *p53* codon 72 polymorphism with breast cancer risk^[39]. We analyzed blood samples collected from 118 women with primary breast carcinoma and from 202 female blood donors (healthy controls) through PCR-RFLP and DNA sequencing. The Arg/Arg genotype was significantly associated with an increased risk for breast cancer (OR 2.9; 95% CI: 1.43-3.6; $P < 0.002$). The relative frequency of each allele was 0.75 for Arg and 0.25 for Pro in patients with cancer, and 0.62 for Arg and 0.38 for Pro in normal controls ($P < 0.001$). In the present study, the relative frequency of each allele observed within the control group (0.61 for Arg and 0.39 for Pro) was therefore very similar to our previous observation in normal controls derived from the same population.

In summary, we did not detect significant differences in the allele distribution at codon 72 of *p53* between patients with invasive anal cancer and healthy controls. Our results do not support the hypothesis that *p53* codon 72 polymorphism is associated with anal cancer susceptibility. The role of the genetic susceptibility to high-risk HPV infection and anal cancer, however, merits further investigation.

COMMENTS

Background

A common Arg/Pro polymorphism at codon 72 of the *p53* gene has been studied as a risk factor for human papilloma virus (HPV)-associated malignancies. Although anal cancer has been associated repeatedly with high-risk HPV infection, this polymorphism has not been investigated in this type of cancer up until now.

Research frontiers

Although several risk factors for the development of anal cancer have been determined, the molecular mechanisms involved in anal carcinogenesis remain unclear. In this context, the identification of new factors involved in progression of the anal carcinoma represents a critical step towards development of new anticancer strategies in this malignancy.

Innovations and breakthroughs

This is believed to be the first study to investigate *p53* codon 72 polymorphism in patients with anal cancer. The authors did not detect differences in the allele distribution at codon 72 of *p53* between patients with invasive anal cancer and healthy controls. In contrast to previous observations with cervical cancer, this polymorphism does not seem to be associated with anal cancer susceptibility. The results, however, are in line with several studies that failed to demonstrate a correlation of the *p53* codon 72 polymorphism with development of non-cervical HPV-associated epithelial malignant tumors, such as head and neck and oral squamous cell carcinomas.

Applications

In the process of identifying genetic causes of cancer, it is important to determine precisely which elements of a biological pathway are responsible for affecting tumor suppression or development. Then, treatments and preventive measures can be directed to those individuals who would benefit most. Previous studies have identified *p53* codon 72 polymorphism as a potential contributing factor in HPV-associated carcinogenesis. This study found that *p53* codon 72 polymorphism is not a likely risk factor for anal cancer, and future research should focus on other parts of the *p53* gene pathway to understand its role in development of this type of cancer.

Terminology

Mutations in the *p53* gene are the most common genetic alterations in human cancer. In addition to gene mutations, some polymorphisms in the *p53* gene have been suggested to play a role in different malignancies. A polymorphism is known in codon 72 of the *p53* gene, which results in a Pro or Arg residue at this position. These two polymorphic variants have been shown to have different biological properties, including differences in cancer susceptibility.

Peer review

Contu *et al* Have described the lack of a functional role of a specific *p53* polymorphism in the pathogenesis of anal cancer. The major point of this paper and the spectrum of methods used are rather confined, but the point is clear and the paper is well written. Although this paper presents negative data, I feel that the attempt to perform genetic analysis on a relatively uncommon malignancy (anal cancer) may be viewed favorably clinically.

Abstract

AIM: To investigate the usefulness of direct hemoperfusion with a polymyxin B-immobilized fiber column (DHP-PMX therapy) for warm hepatic ischemia-reperfusion (I/R) injury after total hepatic vascular exclusion (THVE) using a porcine model.

METHODS: Eleven Mexican hairless pigs weighing 22-38 kg were subjected to THVE for 120 min and then observed for 360 min. The animals were divided into two groups randomly: the DHP-PMX group ($n = 5$) underwent DHP-PMX at a flow rate of 80 mL/min for 120 min (beginning 10 min before reperfusion), while the control group did not ($n = 6$). The rate pressure product (RPP): heart rate \times end-systolic arterial blood pressure, hepatic tissue blood flow (HTBF), portal vein blood flow (PVBF), and serum aspartate aminotransferase (AST) levels were compared between the two groups.

RESULTS: RPP and HTBF were significantly ($P < 0.05$) higher in the DHP-PMX group than in the control group 240 and 360 min after reperfusion. PVBF in the DHP-PMX group was maintained at about 70% of the flow before ischemia and differed significantly ($P < 0.05$) compared to the control group 360 min after reperfusion. The serum AST increased gradually after

INTRODUCTION

In ischemia-reperfusion (I/R), the generation of reactive oxygen species on reoxygenation inflicts tissue damage and initiates a cascade of deleterious cellular responses leading to inflammation, cell death, and ultimately organ failure^[1]. Hepatic I/R injury occurs in various clinical settings, such as transplantation, trauma, liver or bowel resection, and hemorrhagic shock^[2]. Severe hepatic I/R injury can lead to liver or multiple organ failure and is associated with increased morbidity and mortality^[3]. Total hepatic vascular exclusion (THVE), which involves the total occlusion of the liver vasculature at the hepatoduodenal ligament (i.e. Pringle's maneuver) and the occlusion of the inferior vena cava below and above the liver, is used during the resection of large and posterior portions of the liver clinically^[4,5]. As this technique induces hepatic I/R injury, inhibition of this injury caused by THVE is necessary to obtain a better postoperative course.

The Toraymyxin polymyxin B-immobilized fiber column (PMX cartridge; Toray Industries, Tokyo, Japan) was developed in Japan in 1994 as an extracorporeal

hemoperfusion device that uses polymyxin-B fixed to α -chloroacetamide-methyl polystyrene-derived fibers packed in the cartridge. Direct hemoperfusion with PMX (DHP-PMX) therapy can remove circulating endotoxin and reduce various cytokines, even in patients with high plasma cytokine levels^[6]. This method has been used to treat endotoxemia^[7] and was reported to lower inflammatory cytokine and plasminogen activator inhibitor-1 (PAI-1) levels immediately^[8]. DHP-PMX therapy has also been found effective for severe sepsis secondary to intra-abdominal infection^[9] and acute lung injury or acute respiratory distress syndrome caused by sepsis^[10]. Recently, we reported the efficacy of DHP-PMX therapy in normothermic cardiopulmonary bypass^[11], a pulmonary warm I/R injury model^[12], and a small intestine warm I/R injury model^[13].

In this study, we evaluated the usefulness of DHP-PMX therapy in warm hepatic I/R injury with a porcine THVE model.

MATERIALS AND METHODS

Animals

All animals were cared for in accordance with the Principles of Laboratory Animal Care formulated by the National Society for Medical Research and the guidelines set forth in the Guide for the Care and Use of Laboratory Animals, published by the National Institutes of Health (NIH publication 85-23, revised 1985). The study was performed under the supervision of the Animal Care and Experimental Committee of Gunma University, Showa campus, Japan.

Operative procedure

Eleven Mexican hairless pigs (both sexes, weighing 22-38 kg) were used in this study. They were not allowed access to food for 24 h before the experiment. After administering ketamine hydrochloride (250 mg) and atropine (0.5 mg) intramuscularly, the pigs were intubated endotracheally and ventilated mechanically at a tidal volume of 25 mL/kg and a rate of 12 breaths/min. During the experiment, general anesthesia was maintained with a mixture of 1%-2% isoflurane and 100% oxygen. Lactated Ringer's solution (20 mL/kg per hour) was infused *via* a catheter inserted into the right subclavian vein. A laparotomy was performed *via* a midline incision. The liver was skeletonized completely by dividing all of the suspensory ligaments and dissecting the retrohepatic vena cava from the posterior abdominal wall. The portal vein, hepatic artery, and common bile duct were isolated and their collaterals were occluded separately. THVE was achieved by clamping the infrahepatic and suprahepatic vena cava after clamping the portal vein and hepatic artery. An active venovenous (v-v) bypass system was started as a portosystemic shunt just before THVE to prevent congestion of the portal vein and lower body. This system consisted of a centrifugal pump system (Lifestream; St. Jude Medical, Chelmsford, MA) and venous cannulas. The blood-contact surfaces of these

components were heparin-coated. The v-v bypass system was established with drains (12 Fr) inserted into the splenic and right external iliac veins for blood removal, with another drain inserted into the right external jugular vein (12 Fr) for blood return. Blood from the portal vein and infrahepatic vena cava was bypassed into the right external jugular vein *via* a Y-shaped shunt. The bypass blood flow was maintained at more than 20 mL/kg per minute with systemic heparinization (200 U/kg). Liver ischemia was induced by total exclusion of hepatic inflow for 120 min. After releasing the clamps to end the ischemia, the bypass system was removed. The splenic, right external iliac, and right external jugular veins were ligated after removing the cannulas. The parameters described below were measured and the animals were observed for 360 min after reperfusion.

Experimental groups

The experimental study involved two groups: the DHP-PMX ($n = 5$) and control ($n = 6$) groups. The animals were assigned randomly to either group. In the DHP-PMX group, a double-lumen catheter was positioned in the right atrium through the left subclavian vein and DHP-PMX was performed through the catheter at a flow rate of 80 mL/min for 120 min (beginning 10 min before reperfusion). Direct hemoperfusion was not performed in the control group.

Monitoring and sampling

The external iliac artery was cannulated for monitoring the arterial blood pressure and collecting blood samples. Arterial blood pressure and heart rate (HR) were monitored directly through a catheter connected to a transducer (Spectramed TA 1017; San-ei, Tokyo, Japan). The rate pressure product (RPP: $\text{HR} \times \text{end-systolic arterial blood pressure}$) was also calculated. Blood samples were collected from the same catheter before and after the procedure [before ischemia and immediately (0 min) and 30, 60, 120, 240 and 360 min after reperfusion]. All samples were centrifuged at $900 \times g$ for 15 min at 4°C, and the serum or plasma was frozen at -80°C for later measurement.

Hepatic tissue blood flow (HTBF)

HTBF was measured with a laser Doppler flowmeter (Laser Blood Flow Monitor MBF 3; Moor Instruments, Devon, UK) before ischemia and immediately (0 min) and 30, 60, 120, 240 and 360 min after reperfusion. The laser probe was always placed on the right median lobe of the liver. HTBF is expressed as a percentage of the flow before ischemia.

Portal vein blood flow (PVBF)

PVBF was measured before ischemia and 30, 60, 120, 240 and 360 min after reperfusion using an electromagnetic blood flowmeter (Model MFV-3100; Nihon Kohden, Tokyo, Japan). PVBF is expressed as a percentage of the flow before ischemia.

Figure 1 The rate pressure product (RPP: heart rate \times systolic arterial blood pressure) before ischemia (pre) and immediately (0 min) and 30, 60, 120, 240 and 360 min after reperfusion. Data are expressed as the mean \pm SE. ^a $P < 0.05$ vs the control group.

Figure 2 The hepatic tissue blood flow (HTBF) before ischemia (pre) and immediately (0 min) and 30, 60, 120, 240 and 360 min after reperfusion. The HTBF was evaluated as a percentage of the flow before ischemia. Data are expressed as the mean \pm SE. ^a $P < 0.05$ vs the control group.

Figure 3 The portal vein blood flow (PVBF) before ischemia (pre) and 30, 60, 120, 240 and 360 min after reperfusion. The PVBF was evaluated as a percentage of the flow before ischemia. Data are expressed as the mean \pm SE. ^a $P < 0.05$ vs the control group.

Serum aspartate aminotransferase (AST) assays

Serum AST levels were measured at 37°C using an ultraviolet rate assay on an autoanalyzer (Hitachi 736-60; Hitachi, Tokyo, Japan) with blood samples collected and preserved using the method described above.

Statistical analysis

The results are expressed as the mean \pm SE. StatView ver. 5.0 (Abacus, Berkeley, CA) was used for the statistical analyses. Statistical comparisons were made using repeated measure analysis of variance followed by Fisher's protected least significant difference. $P < 0.05$ were considered to be statistically significant.

RESULTS

All animals survived until the endpoint of the study (360 min after reperfusion).

The changes in RPP

The changes in RPP were similar in both groups until reperfusion. The RPP in the control group decreased gradually until 360 min after reperfusion, while that in

the DHP-PMX group was maintained at about 6000 bpm·mmHg and differed significantly ($P < 0.05$) from the RPP in the control group 240 and 360 min after reperfusion (Figure 1).

The changes in HTBF

The HTBF decreased to about 20% of the baseline immediately after reperfusion in both groups (Figure 2). After reperfusion, the HTBF in the DHP-PMX group was maintained above 60% of the baseline, while no improvement was seen in the control group; the HTBF in the control group was significantly ($P < 0.05$) lower than that in the DHP-PMX group 240 and 360 min after reperfusion (Figure 2).

The changes in PVBF

The PVBF decreased after reperfusion in both groups (Figure 3). The PVBF was similar in both groups 30 and 60 min after reperfusion. Subsequently, the PVBF in the DHP-PMX group was maintained at about 70% of the flow before ischemia, while that in the control group decreased gradually beginning 120 min after reperfusion; a significant ($P < 0.05$) difference was observed between the two groups 360 min after reperfusion (Figure 3).

The changes in serum AST

As shown in Figure 4, the serum AST before ischemia did not differ significantly between the two groups. The serum AST increased gradually after reperfusion in both groups, although the increment in the DHP-PMX group was smaller than in the control group and differed significantly 360 min after reperfusion (Figure 4).

DISCUSSION

Polymyxin B binds to endotoxin, which is an outer membrane component of Gram-negative bacteria and is thought to be an important pathogenic trigger for the production of inflammatory mediators. Several preclinical studies have demonstrated that hemoperfusion or plasmapheresis over immobilized polymyxin B removes

Figure 4 The serum AST before ischemia (pre) and immediately (0 min) and 30, 60, 120, 240 and 360 min after reperfusion. Data are expressed as the mean \pm SE. ^a $P < 0.05$ vs the control group.

endotoxin from blood^[14-16]. Recently, some studies have shown improved hemodynamic status^[17] and survival^[18] in patients with sepsis who were treated with PMX. Moreover, DHP-PMX therapy was found to be effective for patients with septic shock infected with either Gram-negative or Gram-positive bacteria, which do not release endotoxins^[19]. Therefore, DHP-PMX therapy is used in patients with severe sepsis or septic shock and its clinical effect has been described. In addition, studies have reported on the mechanism of DHP-PMX action. Kushi *et al*^[20] showed that the adsorption of pathogenic bacteria prevented the release of inflammatory cytokines and reduced the stimulation of vascular endothelial cells to lower the PAI-1 level, rather than direct inhibition of PAI-1 production by DHP-PMX therapy. Tani *et al*^[8] postulated that the reduction in plasma endotoxins by endotoxin adsorption contributed to the cessation of cytokine gene expression and the excretion of cytokines. In addition, DHP-PMX therapy improved the PaO₂/FiO₂ ratio in patients with acute lung injury or acute respiratory distress syndrome caused by sepsis, and this appeared to be related to decreases in the blood neutrophil elastase and IL-8 levels^[10]. We hypothesized that DHP-PMX therapy might be effective in various inflammatory situations and have evaluated the utility of DHP-PMX therapy in normothermic cardiopulmonary bypass in a pig model^[11], pulmonary warm I/R injury in a canine model^[12], and small intestine warm I/R injury in a canine model^[13] with satisfactory results. In this study, we evaluated whether DHP-PMX therapy could reduce hepatic I/R injury in a THVE model.

We found that RPP, PVBF, and HTBF in the DHP-PMX group were preserved significantly ($P < 0.05$) better than in the control group after reperfusion. In addition, the increase in serum AST was significantly ($P < 0.05$) lower in the DHP-PMX group. These results demonstrate that DHP-PMX therapy reduces the hepatic warm I/R injury caused by the THVE technique.

The natural ligands of cannabinoid receptors are lipid-like substances called endocannabinoids, and include arachidonoyl ethanolamine or anandamide and 2-arachidonoylglycerol. Cannabinoid-2 receptor agonists

have been reported to have a protective effect against I/R injury in the liver and other organs by reducing endothelial cell activation, the expression of adhesion molecules such as intercellular adhesion molecule and vascular cell adhesion molecule, the levels of tumor necrosis factor- α and chemokines, neutrophil infiltration, lipid peroxidation, and apoptosis^[21,22]. In addition, Wang *et al*^[23] demonstrated that the absorption of anandamide during DHP-PMX therapy eliminated the diverse negative effects of anandamide, such as hypotension, immunosuppression, and cytotoxicity. Considering these results, DHP-PMX treatment appears not only to remove endotoxins, but also to reduce the inflammatory reaction by inhibiting various inflammatory cascades and to have an effective role in I/R injury. Further studies are required, including the suitable timing and duration and the detailed mechanisms of DHP-PMX therapy in I/R injury.

In conclusion, DHP-PMX therapy reduced the hepatic warm I/R injury caused by the THVE method using a porcine model.

COMMENTS

Background

Total hepatic vascular exclusion (THVE) is used during the resection of large and posterior portions of the liver clinically. This technique induces hepatic ischemia-reperfusion (I/R) injury, and severe hepatic I/R injury is associated with increased morbidity and mortality. The inhibition of the hepatic I/R injury caused by THVE is necessary to obtain a better postoperative course.

Research frontiers

The Toraymyxin polymyxin B-immobilized fiber column (PMX cartridge) was developed as an extracorporeal hemoperfusion device. Direct hemoperfusion with PMX (DHP-PMX) therapy can remove circulating endotoxin. The authors had already demonstrated the efficacy of DHP-PMX therapy in a pulmonary warm I/R injury model and a small intestine warm I/R injury model. In this study, the authors investigated whether DHP-PMX therapy reduced the hepatic warm I/R injury caused by THVE in a porcine model.

Innovations and breakthroughs

The authors found that systemic hemodynamics, blood flow for liver and liver function were preserved significantly better in the group treated with DHP-PMX therapy than in the group with no treatment after reperfusion.

Applications

Their results demonstrate that DHP-PMX therapy reduces the hepatic warm I/R injury caused by the THVE technique.

Terminology

The PMX cartridge (Toray Industries, Tokyo, Japan) was developed in Japan in 1994 as an extracorporeal hemoperfusion device that uses polymyxin-B fixed to α -chloroacetamide-methyl polystyrene-derived fibers packed in the cartridge. DHP-PMX therapy can remove circulating endotoxin and reduce various cytokines, even in patients with high plasma cytokine levels. This method has been used to treat endotoxemia and was reported to lower inflammatory cytokine and plasminogen activator inhibitor-1 levels immediately. DHP-PMX therapy has also been found effective for severe sepsis secondary to intra-abdominal infection and acute lung injury or acute respiratory distress syndrome caused by sepsis.

Peer review

This is an interesting study that investigates the utility of direct hemoperfusion with a polymyxin B-immobilized fiber column (DHP-PMX therapy) on warm hepatic I/R injury with THVE using a porcine model. The title accurately reflects the major topic and contents of the study. The abstract gives a clear delineation of the research background, objectives, materials and methods, results and conclusions. Materials and Methods are very well described. The results are clearly presented and the conclusions are scientifically reliable and valuable.

Abstract

AIM: To retrospectively evaluate the computed tomography (CT)/magnetic resonance imaging (MRI) imaging features of epithelioid angiomylipoma of the liver (Epi-HAML), with pathology as a reference.

METHODS: The CT/MRI findings (number, diameter, lobar location, and appearance of lesions) in a series of 10 patients with 12 pathologically proven epithelioid angiomylipomas of the liver were retrospectively analyzed. The imaging features, including attenuation/signal intensity characteristics, presence of fat, hypervascular, outer rim, and vessels within lesion, were evaluated and compared with that of non-Epi-HAML in 11 patients (13 lesions). The Fisher exact test was used to compare difference in probability of imaging features between the two types.

RESULTS: For 21 patients, CT images of 15 patients and MR images of six patients were available. No patient underwent two examinations. For the 15 patients with a CT scan, all HAML lesions in the two groups (10 Epi-HAML and seven non-Epi-HAML) manifested as hypoattenuation. For the six patients with MRI, all lesions (two Epi-HAML and six non-Epi-HAML) were hypointense on T1WI (fat suppression) and hyperintense on T2WI. There were 10 non-Epi-HAML, but only two Epi-HAML lesions showed the presence of

fat, which significantly different between the two types ($P = 0.005$). On the dynamic contrast enhancement (DCE) imaging, eight Epi-HAML, and 13 non-Epi lesions manifested as hypervascular. Punctate or curved vessels were displayed in 10 Epi-HAML as well as in nine non-Epi lesions and outer rim enhancement could be found with eight Epi-HAML as well as six non-Epi lesions.

CONCLUSION: Little or no presence of adipose tissue was found to be an imaging feature of Epi-HAML, compared with the non-Epi type. In addition, hypervascularity with opacification of central punctiform or filiform vessels on DCE would be a characteristic enhancement pattern for Epi-HAML.

INTRODUCTION

Hepatic Angiomylipoma (HAML) is a rare benign tumor and the etiology is unclear. Some cases have been associated with the tuberous sclerosis complex (TSC). HAML belongs to a family of tumors that have collectively been called "PEComa"^[1-3]. Histologically, HAML is composed of a heterogeneous mixture of blood vessels, smooth muscle, and adipose cells, of varying proportions and distributions, not only among different tumors, but from area to area within the same tumor. Thus, according to the line of differentiation and the predominance of tissue components, HAML is usually subcategorized into mixed,

lipomatous ($\geq 70\%$ fat), myomatous ($\leq 10\%$ fat), and angiomatous types. The smooth muscle cell component is the most specific for the diagnosis. Depending on the dominant cell type, HAML can be subcategorized into epithelioid, spindle, and intermediate forms^[1]. Epithelioid AML (Epi-AML) was first described in the liver in 2000^[4], diagnosis can be difficult, for example the differentiation of Epi-AML from hepatocellular carcinoma and the metastatic sarcomatoid variant of renal cell carcinoma. Only one case report of Epi-AML has been mentioned or reviewed in the literature^[4-7]. In this paper, 10 immunohistochemically verified cases were retrospectively analyzed and the CT/MR imaging findings were summarized and compared with those of non-epi-HAML.

MATERIALS AND METHODS

Patients

The imaging examinations of 21 cases (10 Epi-HAML and 11 non-Epi-HAML) with pathologically proven HAML were included in this study. Proof of diagnosis was based on findings at liver resection and pathological manifestations, including immunohistochemical staining. Cases were collected from one university hospital over a seven-year period and were identified by reviewing pathology databases. In our patients, AML were incidentally detected on cross-sectional imaging performed for various reasons, such as abdominal pain ($n = 15$), suspected gallbladder stone ($n = 3$), or urinary ($n = 3$) diseases. Institutional review board approval and patient consent were not required for this retrospective study because patient privacy was maintained and patient care was not impacted.

Imaging protocols and methods

Helical multiphasic CT was performed in 15 patients using a Siemens Sensation 16 (Siemens Medical Solutions) or a PHILIPS Marconi MX8000 4 slice CT unit with 5 to 7 mm contiguous sections. After non-enhanced acquisitions of the liver, patients underwent helical multiphase CT that included both hepatic arterial phase and portal venous phase imaging (30-35 s and 80-85 s, respectively), after *i.v.* infusion of 90-100 mL nonionic contrast material (iopromide, Ultravist 300, Bayer Schering Pharma). Contrast material was injected at a rate of 3 mL/s with a power injector (Envision CT, MEDRAD).

MRI was performed in six patients using 1.5-T MR units (Magnetom avanto, Siemens Medical Solutions) with the combination of a phased-array body coil and spine array coil for signal reception. Baseline MR images, including a respiratory-navigated T2-weighted turbo spin-echo sequence [TR/TE, 2000/104 ms; slice thickness, 7 mm; flip angle, 150°; matrix, 207 (phase) \times 384 (read); FOV, 33-38 cm] and a breath-hold T1-weighted fast low angle shot (FLASH) sequence [TR/TE, 112/4.76 ms; slice thickness, 7 mm flip angle, 70°; matrix, 114 (phase) \times 256 (read); FOV, 33-38 cm]. Dynamic imaging, breath-hold T1-weighted FLASH sequence was performed using the following parameters: TR/TE, 230/2.47 ms; flip angle, 70°; matrix, 135 (phase) \times 256 (read); effective slice thickness, 7 mm; and FOV, 33-38 cm. Dynamic imaging was

performed before and after administration of gadopentate dimeglumine (Magnevist; Bayer Schering Pharma), consisting of late arterial (delay time 20-25 s), portal (70-90 s), and equilibrium (180 s) phases. The contrast-enhanced imaging was acquired after a bolus injection of 30-35 mL of contrast with a fixed delay. The contrast material was injected into the antecubital vein at a rate of 2.5 mL/s *via* a power injector (Spectris, Medrad, Indianola, PA, USA). Three dynamic phases were repeated for 18-21 s during a single breath-hold.

Imaging analysis

Imaging studies were evaluated on film by two abdominal radiologists (with experience ranging from 5 to 10 years) in consensus. Readers were not blinded to the pathology results.

The following imaging criteria were analyzed: number of lesions; lesion diameter; lesion location according to the hepatic segment numbering system of Couinaud; attenuation at non-enhanced CT, classified as hypoattenuating, isoattenuating, or hyperattenuating to the adjacent liver parenchyma; signal intensity characteristics of the lesions at non-enhanced T1-weighted (including T1WI and T1WI with fat suppression) and T2-weighted MRI; presence of fat tissue, hypoattenuating foci (-20 to -120 Hu) on non-enhanced CT images or hyperintense on T1WI but hypointense on T1WI with fat suppression; enhancement pattern at contrast-enhanced CT or MRI with regard to three-phase dynamic enhancement; presence of the central vessels in lesion at contrast-enhanced imaging; and presence of outer rim enhancement.

Pathology

All tissues were reviewed independently by one pathologist. Histopathological diagnosis was made according to the World Health Organization's classification of tumors of the liver and intrahepatic bile ducts^[8]. The most important diagnostic criterion was the presence of HMB-45-positive myoid cells. All tumor tissues had been fixed in neutral buffered formalin and were routinely embedded in paraffin. Hematoxylin-eosin stained sections were evaluated and immunohistochemical studies were performed on representative blocks by the EnVision Plus system (DAKO, Glostrup, Denmark) with a panel of antibodies (HMB-45, SMA, S-100, CD34, A103, MSA, Vimentin, CD68, CD117, HepPar-1, AFP, AE1/AE3, and CK8).

Statistical analysis

Statistical analysis was performed by using software (Intercooled Stata, version 9.0 for Windows, 2005; Stata Corp, College Station, TX, USA). We used the Fisher exact test to compare probability of these imaging features for Epi-HAML and non-Epi lesion. A *P* value less than 0.05 was considered statistically significant.

RESULTS

General data

The data are summarized in Tables 1 and 2. Age at diagnosis of hepatic angiomyolipoma varied between

Table 1 Synopsis of demographics and imaging findings in 10 patients with Epi-HAML

No.	Age (yr)/sex	Size (cm), segment	Unenhanced CT/MR	Fat	Vascularity	Outer rim	Vessels in lesion
1	51/F	6.5, 4.0 VI/VII, IV	Hypo	No	Hypovascular	Yes	Yes
2	42/F	4.2, I	Hypo	No	Hypovascular	No	No
3	35/F	7.5, VI	Hypo	No	Hypervascular	No	Yes

11	21/F	12.0, VI/VI	T1 hypo, T2 hyper	No	Hypervascular	Yes	Yes

Table 3 Comparison of imaging features between Epi-HAML and non-Epi-HAML¹

	Epi-HAML, <i>n</i> = 12 (10)	Non-Epi-HAML, <i>n</i> = 13 (11)	<i>P</i> value
Fat	2 (1)	10 (8)	0.005
Hypervascular	8 (8)	13 (11)	0.082
Vessels in lesions	10 (9)	9 (7)	0.645
Outer rim	8 (7)	6 (4)	0.428

¹Data without parentheses are the number of lesions and data in parentheses are the number of patients. The Fisher exact test was used to analyze difference in per-lesion probability of imaging features between two types.

17 and 55 years (mean 40.7 years). In the Epi-HAML group, there was history of TSC for one patient, and a combination of left kidney AML for another one. Among 10 patients, eight had solitary lesions and two had two lesions. Lesions had a mean diameter of 4.6 (range, 1.5-10.0). In the non-Epi-HAML group, there was right kidney AML in one patient, 10 had solitary lesions, and one had three lesions. Lesions had a mean diameter of 4.9 (range, 1.0-12.0).

Comparison of CT/MRI findings between Epi-HAML and non-Epi-HAML

The CT/or MR images of 21 patients (CT images for 15 patients and MR for six) were available for retrospective analysis. The results are shown in Tables 1-3.

At non-enhanced CT, 10 Epi-HAML and seven non-Epi HAML were hypoattenuating to the surrounding liver. Two Epi-HAML and six non-epi lesions were hypointense on T1WI (fat suppression) and hyperintense on T2WI. The presence of fat was detected in 10 non-Epi HAML but only two Epi type lesions (Figure 1) and there were significant differences between the two lesion types ($P < 0.01$, Table 3).

On arterial phase, eight Epi-HAML and 13 non-Epi-HAML showed obvious enhancement (Figures 1-3). Punctate or curved vessels could be seen within 10 Epi-HAML as well as nine non-Epi type lesions (Figures 1-4) on arterial or/and portal phase. Outer rim enhancement could be found in eight Epi-HAML as well as in six non-Epi-HAML on enhanced imaging (Figures 3 and 4).

Pathology

Immunohistochemical studies showed that tumor cells were positive for HMB-45 and A103, but negative for cytokeratin (HepPar-1, AFP, AE1/AE3, CK8.) in all cases. Smooth muscle actin (SMA) and desmin staining were weak to moderate in epithelioid cells. MSA staining was similar to desmin but was more weak when positive. The endothelial cells lining the blood vessels were positive for CD34. CD117 and S-100 were negative in all cases.

Follow-up

Imaging and clinical follow-up was available in 10 patients with Epi-HAML and ranged from one to six years.

Figure 1 33-year-old woman with epithelioid angiomyolipoma in left lobe of liver (patient 7). A: Non-enhanced CT scan shows hypoattenuating lesion with fat components (arrow, CT value mean-35 Hu) in segments II/III/IV; B: Contrast-enhanced CT scan shows inhomogeneous enhancement lesion with punctiform or filiform enhanced vessels (arrowheads, the window width and level was adjusted) on arterial phase; C: Contrast-enhanced CT scan at 1-year follow-up shows enhanced recurrent nodule (arrow) on arterial phase image after the left lobe surgery.

Recurrent hepatic lesions were found in one patient (Figure 1), pubic bone destruction and metastatic nodule in body soft tissue were proved with biopsy in another.

DISCUSSION

Previous literatures showed variable imaging appearances for HAML^[9-12]. The imaging characteristics of HAML are correlated with its histological components, and demonstration of blood vessels and mature adipose tissue are the most important radiographic features. Color Doppler sonography shows a punctiform or filiform vascular distribution pattern. Contrast-enhanced CT shows marked enhancement of the soft tissue components in the arterial phase. MRI is the most

Figure 2 55-year-old woman with epithelioid angiomyolipoma in left lobe of liver (patient 6). A: Non-enhanced CT scan shows hypoattenuating lesion in segment II; B: contrast-enhanced CT scan shows obviously enhanced lesion on arterial phase; C: the punctate enhanced vessels (arrowhead) within the lesion is show on an arterial phase image by adjusting the window width and level.

specific imaging entity for the detection of lipomatous components; however, because hepatic AML can have such variation in the amount of adipose tissue present, detection varies based on the percentage of the lesion that is composed of adipose tissue. MRI findings include hypointensity or hyperintensity on T1WI, slight hyperintensity on T2WI, dense enhancement in the arterial phase, and hypointensity in the delayed phase.

In our study, most of the Epi-AML tumors (10/12) were completely devoid of adipose tissue, which is the characteristic finding compared with that of non-Epi type. The result was consistent with a previous report^[1]. After *i.v.* contrast administration, there was obvious enhancement on the arterial phase for most of these lesions, suggesting that Epi-AML was a hypervascular tumor. Most lesions (seven) manifested as hypoattenuation or hypointensity on portal/equilibrium phase. By adjusting the window

Figure 3 17-year-old girl with epithelioid angiomyolipoma in right lobe of liver (the patient had a history of tuberous sclerosis complex, patient 5). A: Non-enhanced CT scan shows homogeneous hypoattenuating lesion in segment V/VII/VIII; B: Contrast-enhanced CT scan shows inhomogeneous enhanced lesion with opacification of central vessels (arrow) on the arterial phase; C: The slight enhanced outer rim (arrow) around the inhomogeneous enhancement lesions is shown on portal phase contrast-enhanced CT; D: Immunohistochemical staining for HMB-45 shows diffusely positive staining in tumor cells within the cytoplasm (EnVision, $\times 100$).

Figure 4 46-year-old woman with epithelioid angiomyolipoma in left lobe of liver (patient 9). A: Non-enhanced MRI T2WI shows hyperintense lesion in segment II/III; B: Contrast-enhanced MRI shows obvious enhanced lesions with outer rim enhancement (arrow) and opacification of punctate or curved vessels (arrowhead) on arterial phase.

width and level, punctate or curved vessels could be seen within 10 lesions on enhanced scanning. In addition, intact or discrete outer rim enhancement within 8 lesions was observed. According to the pathology specimens and literature report, it is not true capsular but a pseudocapsule, which is composed of the compressed liver parenchyma and sparse fibrosis tissues with small vessels, resulting in delayed enhancement on late phase^[13]. A similar manifestation can be found in other hypervascular lesion, such as hepatocellular carcinoma (HCC) and focal nodular hyperplasia (FNH). The distinction between these lesions can be difficult. However, the enhancement patterns were somewhat different among Epi-AML, HCC, and FNH. Most of the HCC enhanced markedly in the arterial phase

and decreased rapidly on the portal venous/equilibrium phase. Additionally, capsule could be found in most of the HCC, so the margins of HCC were more clear than those of AML in the portal venous phase, a suggestive finding for correct diagnosis^[14]. The enhancement pattern of FNH was similar to AML, in both of them prolonged enhancement could be shown in the portal venous phase. However, most of FNH enhanced homogeneously on the arterial phase except the central scar, which was characteristic of FNH and could be enhanced on the portal venous phase/delayed phase^[15].

Five cases of hepatic malignant angiomyolipoma have been reported^[5,16-19]. Strict histology criteria for defining hepatic angiomyolipoma as malignant have not been put

forward, but it should be suspected, especially in tumors with many mitoses. Those with necrosis and significant cellular pleomorphism might show aggressive behavior. There is clinical evidence of aggressive behavior such as recurrence and metastases beyond the liver, for two cases in these 10 Epi-AML cases. However, there are no characteristic findings for malignant HAML on cross-sectional imaging. Therefore, although most HAMLs are biologically benign, this tumor should be considered to have malignant potential, especially for Epi-AML. So resection and careful follow-up are recommended.

It is important to recognize the limitations of our study. Firstly, the study is retrospective; secondly, the numbers reported are limited and no one patient had both CT and MRI. A further limitation is that not every patient underwent regular imaging follow-up and documentation was incomplete.

In summary, little or no adipose tissue was found to be an imaging feature of Epi-HAML, *vs* non-Epi-HAML. In addition, hypervascularity with opacification of central punctiform or filiform vessels on DCE would be a characteristic enhancement pattern for Epi-HAML.

COMMENTS

Background

Hepatic Angiomyolipoma (HAML) is a rare benign tumor and belongs to a family of tumors that have collectively been called "PEComa". The immense variability of the morphological appearance is due to the different heterogeneous mixtures of vessels, epithelioid cells, and lipocytes. As a specific form, the epithelioid HAML (Epi-HAML) has characteristics in pathology and diagnosis that can be difficult, e.g. differentiation of Epi-AML from hepatocellular carcinoma and the metastatic sarcomatoid variant of renal cell carcinoma.

Research frontiers

Previous studies showed variable imaging appearances for HAML. The imaging characteristics of HAML are correlated with its histological components. Both CT and MRI, for the most part, do not allow the definitive differentiation of HAML from hepatocellular carcinoma, adenoma, liposarcoma, lipoma, hamartoma, and sometimes even from focal nodular hyperplasia, especially if the fat content is low. The Epi-HAML has morphological characteristics of tumor cells. In addition, the tumors are devoid of fat or only scattered fat cells distribution in pathology. However, the imaging features of Epi-HAML have not been unequivocally described and evaluated. In this study, the authors summarized CT/MRI imaging features of Epi-HAML and compared with those of non-Epi-HAML.

Innovations and breakthroughs

Previous reports have showed demonstration of mature adipose tissue is the most important radiographic features and highlighted the importance in the diagnosis of HAML, in particular for mixed, lipomatous types of HAML. This is the first study to report that blood vessels are also an imaging feature in Epi-HAML. Furthermore, the study would suggest that little or no adipose tissue might be imaging characteristics of Epi-HAML, *versus* non-Epi-HAML.

Applications

By understanding the imaging characteristics, this study could help radiologists familiarize themselves with the appearance of Epi-HAML, and improve the confidence in the diagnosis of incidental liver tumor, especially in cases where the fat content is low and the interpretation of histological findings is difficult.

Terminology

Immunohistochemistry is a method of analyzing and identifying cell types based on the binding of antibodies to specific components of the cell. The most important diagnostic criterion for HAML is the presence of HMB-45-positive myoid cells.

Peer review

The manuscript reported the imaging characteristics of Epi-HAML, only a few reports had been published about the lesion before. It will be helpful for radiologists to obtain knowledge of the lesion.

Abstract

AIM: To evaluate the effects of four types of preoperative transcatheter arterial chemoembolization (TACE) on angiogenesis of hepatocellular carcinoma (HCC) cells.

METHODS: A total of 136 patients with HCC underwent liver resection. One to five courses of TACE prior to liver resection were performed in 79 patients (TACE group), in which one to four courses of chemotherapy alone were performed in 11 patients (group A); one to five courses of chemotherapy combined with iodized oil were performed in 33 patients (group B); one to three courses of chemotherapy combined with iodized oil and gelatin sponge were performed in 23 patients (group C); one to three courses of chemotherapy combined with iodized oil, ethanol and gelatin sponge were performed in 12 patients (group D). The other 57 patients only received liver resection (non-TACE group). The microvessels were marked by CD31. The expression of CD31 and vascular endothelial growth factor (VEGF) protein were detected by immunohistochemical methods.

RESULTS: The mean microvessel density (MVD) in HCC cells was significantly higher in groups A, B, C and D than in the non-TACE group ($P < 0.05$). The expression of VEGF protein in HCC cells were significantly higher in groups A, B, C and D than in the non-TACE group ($P < 0.05$). MVD and the expression of VEGF

protein were positively correlated. Mean MVD and the expression of VEGF protein were closely related to the number of courses of TACE and the interval of TACE.

CONCLUSION: Four different types of preoperative TACE regimens enhanced angiogenesis in HCC cells by up-regulating the expression of VEGF protein. It is necessary to repress angiogenesis of liver cancer after TACE.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies in Asian countries. It is responsible for more than 250 000 deaths worldwide each year, 40% of which occur in China ranking HCC second after gastric carcinoma^[1-3]. Surgical resection is recognized as the most effective treatment method for patients with HCC^[4]. Although recent advances in treatment have helped prolong the survival of patients with HCC, they consequently increase the risk of intrahepatic recurrence and extrahepatic metastasis. Only a minority of patients currently diagnosed with HCC may benefit from this radical option^[5].

Transcatheter arterial chemoembolization (TACE) has become one of the most popular and effective palliative methods for patients with HCC^[6-11]. Various mixtures of anticancer drugs, lipiodol and gelatin sponge have been used as TACE agents. There have been few reports comparing the efficacy of different TACE regimens in patients with HCC^[12-14].

There is ample evidence that tumor angiogenesis is the pathological basis and a necessary condition for solid tumor growth and metastasis^[15]. Vascular endothelial growth factor (VEGF) is a strong angiogenesis factor in HCC^[16], and plays an important role in the development and prognosis of liver cancer. In the present study, we examined the effects of the four main types of TACE used clinically (pure intra-arterial chemotherapy, chemotherapy plus lipiodol, chemotherapy plus lipiodol plus gelatin sponge, and chemotherapy plus lipiodol plus alcohol plus gelatin sponge) on angiogenesis of HCC cells *in vivo*.

MATERIALS AND METHODS

Patients

From February 1992 to February 2001, a total of 136 patients with HCC were referred to our hospital for surgery, of which, 122 were men and 14 were women with a mean age of 45 years (range: 20 to 70 years). A diagnosis of HCC was obtained for all patients by preoperative ultrasound (US) and/or computed tomography (CT) and/or magnetic resonance imaging (MRI) and/or plasma AFP levels, and was then confirmed by biopsy.

Surgical procedure

The patients were randomly divided into two groups. In the TACE group, 79 patients underwent 1-5 courses of chemoembolization prior to liver resection, in which one to four courses of chemotherapy alone were performed in 11 patients (group A), one to five courses of chemotherapy combined with iodized oil were performed in 33 patients (group B), one to three courses of chemotherapy combined with iodized oil and gelatin sponge were performed in 23 patients (group C), and one to three courses of chemotherapy combined with iodized oil, ethanol and gelatin sponge were performed in 12 patients (group D). Fifty patients underwent one course of TACE, 19 patients underwent two courses of TACE and 10 patients underwent three or more courses of TACE during an interval of 52.8 ± 12.2 d (mean \pm SD). Twenty-five patients had an interval of one month or less, 29 patients had an interval of two months or less, 16 patients had an interval of three months or less and 9 patients had an interval of more than three months. In the non-TACE group, 57 patients received initial liver resection without preoperative TACE. The extent of liver resection carried out was based on the location of the tumor, the severity of concomitant liver cirrhosis and preoperative liver reserve function.

Immunohistochemical methods

The formalin-fixed, paraffin-embedded specimens were examined immunohistochemically using anti-CD31 antibody and anti-VEGF antibody (LSAB Kit, Dako). Breast cancers were used as positive controls. Negative controls were generated by substituting the primary antibody with phosphate-buffered saline (PBS). CD31 and VEGF immunostained cells showed a brownish-yellow color in the cytoplasm (Figure 1A and B). Microvessel

Figure 1 Expression of CD31 (A) and VEGF (B) protein detected by immunohistochemical methods after chemotherapy combined with ethanol, iodized oil and gelatin sponge (Dako Envision, peroxidase method $\times 400$).

density (MVD) counting followed the method of Weidner *et al*^[17], i.e. first, the regions with the highest density of CD31-positive cells were chosen and counted under a low-power microscope ($\times 40$). Then microvessel numbers were counted under a high-power microscope ($\times 400$). Each isolated brown vascular endothelial cell or cluster of endothelial cells was counted as a vascularization. VEGF counting followed the method of Park *et al*^[18], i.e. negative (-) was $< 5\%$ of positively stained cells, weakly positive (+) was 5% to 15% of positively stained cells, moderately positive (++) was 15% to 50% of positively stained cells and strongly positive (+++) was $> 50\%$ of positively stained cells. All slides were reviewed and scored in a blind test by two observers without knowledge of the corresponding clinical data. A few cases with discrepant scoring were jointly re-evaluated until agreement was reached.

Statistical analysis

MVD was expressed as mean \pm SD and analyzed using the two-sample *t*-test for the two groups, and by analysis of variance for multiple comparisons. VEGF was analyzed using table χ^2 test. The correlation between MVD and VEGF was analyzed using Pearson correlation analysis. *P*-value < 0.05 was considered statistically significant.

RESULTS

Correlation between methods of TACE and expression of CD31 and VEGF protein

The mean MVD was (47.71 ± 23.33), (56.05 ± 22.45),

Table 1 Expression of VEGF protein in groups A, B, C, D, and the non-TACE group

Group	Cases	Expression of VEGF (%)			
		-	+	++	+++
A	11	2 (18.2)	4 (36.4)	3 (27.3)	2 (18.2)
B	33	5 (15.2)	6 (18.2)	9 (27.3)	13 (39.4)
C	23	2 (8.7)	6 (26.1)	4 (17.4)	11 (47.8)
D	12	1 (8.3)	2 (16.7)	4 (33.3)	5 (41.7)
Non-TACE group	57	17 (29.8)	16 (28.1)	13 (22.8)	11 (19.3)

Table 2 Correlation between expression of CD31 and VEGF protein

Group	Cases	MVD
VEGF (-)	27	35.47 ± 17.35
VEGF (+)	34	44.12 ± 15.84
VEGF (++)	33	52.56 ± 17.29
VEGF (+++)	42	60.72 ± 23.46

(54.36 ± 24.46), (51.90 ± 19.41) and (44.36 ± 17.67) in groups A, B, C, D and the non-TACE group, respectively. The mean MVD was significantly higher in groups A, B, C and D than in the non-TACE group ($P < 0.05$). The expression of VEGF protein was significantly higher in groups B, C and D than in group A or the non-TACE group ($\chi^2 = 12.63$, $P < 0.05$) (Table 1). When the expression of VEGF protein was increased, MVD increased significantly, and both were positively correlated (Pearson correlation, $r = 0.445$, $P < 0.05$) (Table 2).

Correlation between courses of TACE and expression of CD31 and VEGF protein

The mean MVD was (44.36 ± 17.67), (54.01 ± 23.83), (53.38 ± 22.64) and (51.94 ± 22.64) in the non-TACE group, the one-course TACE group, the two-course TACE group and the three-, four- and five-course TACE group, respectively. The mean MVD was significantly higher in the one-course TACE group than in the non-TACE group ($P < 0.05$). The expression of VEGF protein was higher in the TACE groups than in the non-TACE group ($\chi^2 = 16.786$, $P > 0.05$) and decreased as the courses of TACE increased (Pearson correlation, $r = 0.331$) (Table 3).

Correlation between interval of TACE and expression of CD31 and VEGF protein

The mean MVD was (44.36 ± 17.67), (49.20 ± 19.84), (55.30 ± 23.31), (61.48 ± 26.63) and (44.25 ± 17.52) in the non-TACE group, the 1 mo-interval TACE group, the 1-2 mo interval TACE group, the 2-3 mo interval TACE group, and the > 3 mo interval TACE group, respectively. A comparison between the groups showed that the mean MVD was higher in the 1 mo-interval TACE group, the 1-2 mo interval TACE group and the 2-3 mo interval TACE group than in the non-TACE group ($P < 0.05$). The expression of VEGF protein was higher in the TACE interval groups than in the non-

Table 3 Correlation between courses of TACE and expression of VEGF protein

Group	Cases	Expression of VEGF (%)			
		-	+	++	+++
One-course	50	5 (10.0)	14 (28.0)	12 (24.0)	19 (38.0)
Two-course	19	3 (15.8)	4 (21.1)	3 (15.8)	9 (47.4)
Three-, four- or five-course	10	2 (20.0)	0 (0.0)	5 (50.0)	3 (30.0)
Non-TACE group	57	17 (29.8)	16 (28.1)	13 (22.8)	11 (19.3)

Table 4 Correlation between interval of TACE and expression of VEGF protein

Group	Cases	Expression of VEGF (%)			
		-	+	++	+++
1 mo interval	27	4 (14.8)	7 (25.9)	7 (25.9)	9 (33.3)
1-2 mo interval	28	2 (7.1)	7 (25.0)	6 (21.4)	13 (46.4)
2-3 mo interval	16	3 (18.8)	2 (12.5)	5 (31.3)	6 (37.5)
> 3 mo interval	8	1 (12.5)	2 (25.0)	2 (25.0)	3 (37.5)
Non-TACE group	57	17 (29.8)	16 (28.1)	13 (22.8)	11 (19.3)

TACE group ($\chi^2 = 12.488$, $P = 0.407$) and was highest in the 1-2 mo interval TACE group (Table 4).

DISCUSSION

TACE is one of the most common and effective palliative treatments. The prognosis of patients treated with TACE depends not only on the use of an effective TACE regimen but also on tumor factors^[12]. According to the literature, very limited data are currently available regarding the molecular mechanism of TACE treatment in patients with HCC^[13-15]. We believe that the current study is the first to detail the correlations between the expression of CD31 and VEGF protein and different TACE regimens, courses of TACE and interval of TACE.

There is ample evidence that tumor angiogenesis is the pathological basis and a necessary condition for the growth and metastasis of solid tumors^[15]. VEGF is a strong factor in the angiogenesis of HCC^[16], and plays an important role in the development and prognosis of liver cancer. It also has a biological effect by combining its specific VEGF receptor (vascular endothelial growth factor receptor, VEGFR), of which VEGFR-1 and VEGFR-2 are mainly distributed in vascular endothelial cells. Binding of VEGFR-1 and VEGF allows vascular endothelial cell migration, maintains tubular structure and regulates vascular permeability. Binding of VEGFR-2 and VEGF also promotes vascular endothelial cell proliferation and maturation^[19]. This study showed that MVD of HCC was positively correlated with the expression of VEGF protein.

Whether angiogenesis of liver cancer after TACE is enhanced is still controversial. Some reports have suggested that the mean MVD of HCC specimens before and after TACE were not statistically significantly

different^[20-23]. However, there are other reports which show that the mean MVD was significantly higher in the TACE group than in the non-TACE group^[24-26]. The current study showed that the mean MVD of HCC was significantly higher in the TACE groups than in the non-TACE group. The expression of VEGF protein was significantly higher in the TACE groups than in the non-TACE group. After chemoembolization, the expression of VEGF protein increased, and the change in expression and MVD showed a significant positive correlation. It has also been reported that serum VEGF in patients with liver cancers was significantly increased after TACE^[27,28]. Tumor tissue ischemia and hypoxia after TACE are important in promoting increased VEGF expression^[29]. Therefore, it is necessary to repress angiogenesis in liver cancer after TACE.

The study on the effects of the interval between surgical resection of the tumor and the end of embolization on MVD, revealed that MVD was not significantly different in the group with an interval of less than 30 d or in the group with an interval of more than 90 d, but was significantly increased in the group with an interval of 31-90 d compared with the control group. This showed that after chemoembolization, tumor hypoxia-ischemia results in a series of biochemical changes which cause increased angiogenesis and a gradual increase in MVD, reaching a peak in 1-3 mo. More than three months later, the blood supply to the residual tumor improves, the formation of tumor angiogenesis slows, the residual cancer cells grow, infiltration occurs and damage to generated tumor angiogenesis occurs.

The mean MVD and expression of VEGF protein in liver cancer has a tendency to decrease as the time from TACE therapy increases, although this difference was not significant. It was reported that survival after a number of pre-operative TACE treatments was significantly better than that after a single TACE treatment^[30]. Therefore, multiple pre-operative TACEs should be carried out in suitable patients.

In conclusion, the present study demonstrated that angiogenesis of residual HCC cells following treatment with four types of TACE is significantly increased and is positively correlated with the expression of VEGF protein. The effect of TACE on angiogenesis of HCC cells has a close correlation with the number of courses of TACE and the interval of TACE.

COMMENTS

Background

Transcatheter arterial chemoembolization (TACE) has become one of the most popular and effective palliative methods for patients with hepatocellular carcinoma (HCC). Various mixtures of anticancer drugs, lipiodol and gelatin sponge have been used as TACE agents. However, there have been few reports comparing the effects of different TACE regimens on angiogenesis of HCC cells.

Applications

According to the results of this study, it is necessary to repress angiogenesis of liver cancer after TACE.

Terminology

TACE indicates transcatheter arterial chemoembolization; MVD indicates

microvessel density.

Peer review

TACE stimulates angiogenesis. It would be very useful from a clinical standpoint to identify which type of TACE stimulates more angiogenesis and give appropriate "prophylactic" anti-angiogenic therapy. The authors have the merit of confirming that TACE is an angiogenesis stimulating procedure and also give new information on this process -- e.g. angiogenesis peaks about 1 mo after TACE and then seems to wane off. The number of observations and the histological specimen (surgical) are adequate.

Abstract

We report a case of two pseudolymphomas of the liver in a 63-year-old Japanese woman with primary biliary cirrhosis. One of the lesions was found incidentally during a medical examination, presenting as a 10 mm hypodense nodule that revealed hyperdensity in the early phase and hypodensity in the late phase in computed tomography (CT) after injection of contrast medium. Retrospectively, the 10 mm nodule had first been discovered as a 4 mm nodule during CT 4 years previously. Superparamagnetic iron oxide-enhanced MRI revealed another 4 mm hyperintense nodule in segment 6 in addition to the 10 mm hyperintense nodule in segment 7. CT during arterial portography revealed two hypointense nodules. Findings with other imaging modalities such as ultrasonography, magnetic resonance imaging, and hepatic angiography were consistent with hepatocellular carcinoma. A right posterior segmentectomy was performed, and the lesions were microscopically diagnosed as pseudolymphoma. To the best of our knowledge, only 31 other cases of this disease have ever been reported, with a highly asymmetrical male:female ratio of 1:9.7. Although we could find only one case of transformation of hepatic

INTRODUCTION

Pseudolymphoma in the liver is an extremely rare disease. Although the exact etiology remains unknown, it is speculated that the disorder is a reactive immunological response to a chronic infection or inflammation^[1]; hepatic pseudolymphoma can develop in patients with autoimmune diseases^[2,3], malignancy^[4], or hepatitis^[5] or who are administered interferon therapy^[6]. It has been reported that diagnosis of pseudolymphoma is difficult without histopathological examination, since image findings are quite similar to hepatocellular carcinoma (HCC)^[2]. Although pseudolymphoma is generally thought to be benign, the risk of malignant transformation into lymphoma remains controversial.

We report a case of hepatic pseudolymphoma in a female Japanese patient with primary biliary cirrhosis (PBC) and discuss the literature.

CASE REPORT

A 63-year-old female with a history of PBC and resection of the left adrenal gland for primary aldosteronism, was admitted to our hospital for further evaluation of

Figure 1 Computed tomography (CT) showing a 10 mm nodule in segment 7. A: A hypodense nodule in plane phase; B: A hyperdense nodule in the early phase after injection of contrast medium; C: A hypodense nodule in the late phase after injection of contrast medium.

Figure 2 Magnetic resonance imaging (MRI) showing a 10 mm nodule in segment 7. A: A hypointense nodule on T1-weighted images; B: A hyperintense nodule on T2-weighted images; C: A hyperintense nodule in the early phase after injection of contrast medium; D: A hypointense nodule in the late phase after injection of contrast medium.

a hepatic lesion incidentally discovered in abdominal computed tomography (CT). The patient had taken only ursodeoxycholic acid 300 mg/d for PBC for 10 years and had not taken immunosuppressive agents. The patient was asymptomatic on admission and her condition was generally good. She had a surgical scar on her abdomen. We noted no hepatosplenomegaly, lymphadenopathy, or peripheral edema. Laboratory tests showed a prothrombin time of 11.8 s (normal, 10.8-13.3), a total bilirubin level of 0.6 mg/dL (normal, 0.3-1.2), and an albumin level of 4.0 g/dL (normal, 4.0-5.0). Her serum alkaline phosphatase level was 350 IU/L (normal, 115-359), γ -glutamyltransferase 48 IU/L (normal, 10-47), aspartate aminotransferase 24 IU/L (normal, 13-33), and alanine aminotransferase 16 IU/L (normal, 6-27). Serology examinations for hepatitis B and C viruses were negative. Rheumatoid factor antibodies, Sjögren syndrome-A antibodies, and Sjögren syndrome-B antibodies were negative. Antinuclear antibodies and antimitochondrial

antibodies were positive. Immunoglobulin G, immunoglobulin M, and immunoglobulin A were within normal ranges. Alpha-fetoprotein, protein induced by vitamin K absence, and carcinoembryonic antigen were within normal ranges. A urea breath test was negative. Abdominal ultrasonography showed a hypoechoic lesion, 10 mm in diameter in segment 7 (data not shown). CT demonstrated a 10 mm hypodense nodule that revealed hyperdensity in the early phase and hypodensity in the late phase after injection of contrast medium (Figure 1). Retrospectively, this nodule had previously shown up as a 4 mm nodule in a CT performed for examination of an adrenal tumor 4 years previously (data not shown). Magnetic resonance imaging (MRI) showed a hypointense nodule on T1-weighted images and a hyperintense nodule on T2-weighted images in segment 7. Following injection of contrast MRI, a hyperintense nodule in the arterial phase and a hypointense nodule in the portal phase were revealed (Figure 2). Superparamagnetic iron oxide-

Figure 3 Superparamagnetic iron oxide-enhanced MRI showing hyperintense nodules. A: 10 mm nodule in segment 7; B: 4 mm nodule in segment 6.

Figure 4 CT during arterial portography showing hypointense nodules. A: 10 mm nodule in segment 7; B: 4 mm nodule in segment 6.

Figure 5 The pathological findings of the lesions. A: Macroscopically, the lesion was white and hard with a clear margin (a lesion in segment 7); B: Microscopically, the lesion consisted of a nodular lymphoid infiltrate with germinal centers (a lesion in segment 7), HE stain ($\times 40$); Lymphocytes in the lesions consisted of CD3-positive T-cells (C) and CD20-positive B-cells (D), Both $\times 100$; E: Stained for κ light chains with *in situ* hybridization ($\times 200$); F: Stained for λ light chains with *in situ* hybridization ($\times 200$).

enhanced MRI revealed another 4 mm hyperintense nodule in segment 6 in addition to the 10 mm hyperintense nodule in segment 7 (Figure 3). Although angiography *via* the common hepatic artery did not demonstrate tumor staining, CT during arterial portography revealed two hypointense nodules (Figure 4). Imaging findings suggested HCC, although no other hypervascular tumor could be excluded. The patient received an explanation of the results, including the possibility of a benign tumor, and expressed a desire for surgical extraction of the nodules. A right posterior segmentectomy was

performed. Macroscopically, the lesion in segment 7 was white and hard with clear margins (Figure 5A) and the lesion in segment 6 was not detected. Microscopically, two lesions showed similar histological features. The lesions exhibited a nodular infiltration of mature small lymphoid cells with many lymph follicles. No obvious atypical cells were identified in both lesions. Bile ducts were identified at the periphery of the lesions, although characteristic lymphoepithelial lesions could not be identified. No necrosis or granulomatous inflammation was identified (Figure 5B). Pseudolymphoma and extranodal marginal

zone B-cell lymphoma (MALToma) were differential diagnosis. Then, we performed immunohistochemical analysis and *in situ* hybridization. Immunostainings for CD3, CD20, and CD79 revealed regularly distributed T cells and B cells (Figure 5C and D). Plasma cells were not many in number in the lesions, but *in situ* hybridization for immunoglobulin light chains was performed because it is one of the useful tools to discriminate between reactive lymphoid lesions and MALToma. *In situ* hybridization revealed no significant difference between the numbers of cells positive for kappa-chain and lambda-chain (Figure 5E and F). Based on these histological features, the lesions were diagnosed as pseudolymphoma.

In the background liver, liver parenchyma showed bridging fibrosis with lymphoid infiltrate in portal tracts. Granulomas cholangitis and ductopenia were identified. Those histological features were consistent with Stage 2 PBC. The patient had an uneventful postoperative course and has shown no sign of recurrence for 11 mo.

DISCUSSION

In the liver, pseudolymphoma has also been variously termed as reactive lymphoid hyperplasia and nodular lymphoid lesion, and shows histological features of hyperplastic lymphoid follicles with polymorphic and polyclonal cell populations composed of small mature

lymphocytes, mature plasma cells, macrophages, stroma fibrosis and often numerous germinal centers. It is usually localized and well demarcated from surrounding tissue^[1]. Pseudolymphoma may occur at numerous sites including the stomach^[7], lung^[8], ocular adnexa^[9], hard palate and oral mucosa^[10], skin^[11], and breast^[12].

To the best of our knowledge, 32 cases (including ours) of hepatic pseudolymphoma have been reported in the English and Japanese literature (Table 1). There was a strongly asymmetric male-to-female ratio of 1:9.7 (3 M/29 F). While other sites of pseudolymphoma also tended to show asymmetry, only pseudolymphoma of the breast approached that of the liver in terms of asymmetry magnitude. All seven reported cases of breast pseudolymphoma were female^[12], but breast examination is limited almost exclusively to females, which could bias these findings. Reported male-female ratios of pseudolymphoma of the hard palate and oral mucosa^[10], lung^[8], and skin^[11] were 1:2.8, 1:1.2 and 1:1.8, respectively, while ocular adnexal lymphoid hyperplasia affects men and women about equally^[9]. Thus the extreme female asymmetry of hepatic pseudolymphoma is a unique characteristic.

Eight of 32 cases of hepatic lymphoma were associated with autoimmune disease and eight with malignant tumor (Table 1). In the lung, cases of pseudolymphoma associated with autoimmune disorders

such as Sjögren's disease were reported^[13], which is similar to the liver. In other organs, several factors are thought to be associated with pseudolymphoma, i.e. Epstein-Barr virus (hard palate and oral mucosa^[14]), mechanical stimulation (ear^[15]), anticonvulsant drugs (skin^[16]) and *Helicobacter pylori* (*H. pylori*) (stomach^[17,18]). Regarding the association of *H. pylori* with gastric pseudolymphoma, successful treatment of the pseudolymphoma by eradication of *H. pylori* has been reported^[19]. Ota *et al.*^[20] reported a case of hepatic pseudolymphoma in which the diameter decreased after *H. pylori* eradication. In the case reported here, the patient had no *H. pylori* infection.

Transformation of pseudolymphoma to lymphoma has been discussed. Malignant transformation of pseudolymphomas in the lung^[21] and stomach^[22] have been reported. These reports, however, either predated or did not include the use of immunofluorescent techniques. It is likely that these cases were in fact the early stage of primary lymphoma misinterpreted as benign^[8]. On the other hand, evidence of progression from histologically benign, immunohistochemically polyclonal lymphoid infiltrates to malignant lymphoma in cutaneous pseudolymphoma is well delineated in the literature^[23]. A potential association between lymphoma and PBC is suggested on the basis of individual reports in the literature^[24-29]. In a retrospective study by Panjala *et al.*^[30] based on an estimated 2,912 patients evaluated at their institution during a 22-year period, only 13 (an estimated 0.6%) patients were evaluated in referral visits for evidence of lymphoma. Although we could find one case of transformation of hepatic pseudolymphoma into lymphoma^[31], we were unable to deduce the long term natural course of hepatic pseudolymphoma since most reported cases of hepatic lymphoma underwent surgical resection.

In conclusion, we have reported a case of hepatic pseudolymphoma associated with PBC. Hepatic pseudolymphoma appears unique in its female preponderance and associated diseases. If hypervascular nodules in the liver of female patients with autoimmune disease are found, the possibility of pseudolymphoma should be considered. Cases of hepatic pseudolymphoma should be followed carefully as the exact nature of this disorder is still not fully understood.

Abstract

This study reports a case of unresectable intrahepatic mass-forming cholangiocarcinoma which showed a dramatic response to gemcitabine that led to curative resection and a long-term survival of more than five years. Six and five cycles of gemcitabine monotherapy were administered separately over a three-year period and a radical excision was performed at 4.5 years after diagnosis. This case indicates the role of gemcitabine as a neoadjuvant chemotherapeutic agent for cholangiocarcinoma and guarantees a randomized controlled prospective study.

INTRODUCTION

Cholangiocarcinoma is a devastating malignancy with a

poor prognosis. Early diagnosis and extensive surgery offers the only chance for cure although other treatment modalities have been applied. Response rates to chemotherapy are relatively low although several kinds of chemotherapeutic agents such as gemcitabine are known to be effective. Furthermore, the role of neoadjuvant chemotherapy for unresectable cholangiocarcinoma has not been established either. Here we report the case of a patient with huge intrahepatic mass-forming cholangiocarcinoma who showed repetitive responses to a gemcitabine single regimen, and eventually underwent curative resection that led to long-term survival of more than five years.

CASE REPORT

A 54-year-old female patient was admitted with mild epigastric discomfort and a liver mass was detected by ultrasonography in January 2004. She had a history of cholecystectomy due to gallstone disease 20 years ago. She denied any recent history of medication or herbal treatments. She had never consumed raw fresh-water fish. An abdominal computed tomography (CT) scan showed a 10 cm sized irregular hypovascular mass occupying the left hepatic lobe and growing inferiorly to compress the gastric antrum and the pancreas (Figure 1A). Invasion of the middle hepatic vein and left portal vein were strongly suggested. Multiple lymph node enlargements were noted at the liver hilum and lesser omentum. Laboratory data showed a white blood cell count of $9560/\text{mm}^3$ (normal $4800-10800/\text{mm}^3$), hemoglobin 15.8 g/dL (normal 13-18 g/dL), platelet count of $203000/\text{mm}^3$, AST 33 IU/L (normal 12-33 IU/L), ALT 20 IU/L (normal 5-35 IU/L), total bilirubin 0.9 mg/dL (normal 0.2-1.2 mg/dL), and albumin 4.6 g/dL (normal 3.5-5.3 g/dL). A tumor marker study revealed AFP 2.3 ng/mL (normal 0-8 ng/mL), CEA 2.2 ng/mL (normal 0-5 ng/mL), and CA19-9 17.6 U/mL (normal 0-36 U/mL). A serologic study showed HBs Ag (-), ANA (-), HCV Ab (+) and HCV RNA PCR (-). Esophagogastroduodenoscopy and colonoscopy were nonspecific except for mild chronic gastritis and a small hyperplastic rectal polyp. An abdominal magnetic resonance imaging (MRI) reported T1 low and T2 slightly high lobulated contour solid mass showing a similar invasion pattern with the CT scan. Biliary dilatation at the upper portion of the mass was seen (image not shown). Percutaneous needle biopsy from the mass reported well differentiated cholangiocarcinoma (image not shown). Histo-

Figure 1 Abdominal CT scan images at two different levels are shown serially. A: At left portal vein level (black arrowhead), a 10 cm sized irregular hypovascular mass (asterisk) occupying left hepatic lobe is shown; B: At lower, main portal vein level (black arrow), the inferiorly grown mass is shown. Invasion of middle hepatic vein and left portal vein were strongly suggested with multiple lymph node enlargements at the liver hilum and lesser omentum; C and D: On CT scan taken after the end of the first 6 cycles (18 times) of gemcitabine chemotherapy, the tumor mass decreased in size dramatically, smaller than half of the previous diameter; E and F: On CT scan on 3 years and 3 mo from diagnosis, mass does not show any significant change except for a little sclerotic change; G and H: On CT scan on 4 years from diagnosis, tumor mass shows re-increment of the size than previous study; I and J: On follow up CT scan after second 5 cycles of gemcitabine chemotherapy, partial response is shown again with slight decrease of the mass size; K and L: On CT scan taken 11 months after R0 resection, there is no any recurrence or new lesion growing.

chemical and immunohistochemical study showed tumor cells were positive for CK-7, and negative for CK-19, and CK-20. An extended surgery was recommended to the patient after explaining the degree of tumor invasion and low possibility of curative resection. However, the patient declined any kind of treatment including surgery and chemoradiotherapy. After 3 mo from diagnosis, the patient was persuaded to undertake chemotherapy. Gemcitabine monotherapy was provided as intravenous 2 h infusions of 1000 mg/m² body surface area weekly every three out of 4 wk. A total of six cycles of chemotherapy were treated tolerably.

The CT scan taken on October 2004 (10 mo after diagnosis) showed that the tumor mass dramatically decreased in size and was smaller (half of the diameter) than that of the previous CT (Figure 1B). Surgery was again recommended to the patient. However, the patient

declined surgery and further chemotherapy. After ending chemotherapy treatment the tumor mass did not show any significant change on a regular CT scan over 3 years and 3 mo except for a little sclerotic change (Figure 1C).

Unfortunately, an abdominal CT scan in January 2008 showed a slight increase of the mass with a symptomatic complaint of fatigue (Figure 1D). Gemcitabine treatment was restarted under the same protocol as the previous one. The patient barely finished five cycles of treatment due to various symptoms such as weakness or edema. On follow up CT scan in May 2008, a partial response was repeated with a slight decrease in the mass size (Figure 1E). Radical surgery was recommended and the patient agreed to it. A curative resection of atrophied left liver including the mid-hepatic vein and extrahepatic bile duct was performed. A hepatico-enterostomy was followed after the resection. Histological findings

Figure 2 Histological finding of resected specimen is shown. Well differentiated adenocarcinoma is seen with glandular structure and a dense fibrous stroma. Scattered lymphocytes are also present (40 × magnification). In higher magnification, tumor is composed of glands lined by cuboidal mucin-producing epithelium resemble biliary epithelium (Inset, 400 × magnification).

of the resected specimen showed well differentiated cholangiocarcinoma composed of a glandular structure lined by cuboidal mucin-producing epithelium resembling cholangiocytes and a dense fibrous stroma with desmotic reaction (Figure 2). All resection margins were negative for malignancy microscopically. One cycle of adjuvant gemcitabine chemotherapy was administered due to concern about remnant tumor cells. On a CT scan taken 11 mo after R0 resection, there was no recurrence or new growing lesion (Figure 1F). In July 2009, 5 years and 6 mo from diagnosis (1 year from the surgical resection) the patient is living well without any symptoms.

DISCUSSION

The establishment of an optimal chemotherapeutic regimen for cholangiocarcinoma is necessary because most of the patients are diagnosed in an advanced stage and curative resection would not be viable. Gemcitabine is known as one of the most effective agents for cholangiocarcinoma and response rates were reported as 20%-35%^[1] for a single regimen^[2] or in combination

with other agents such as 5-FU (or capecitabine)^[3], mitomycin-C^[4], or a platinum analog^[5]. This case study showed repetitive responses to a gemcitabine single agent regimen given separately over a long-term interval. Tumors were observed to be strongly repressed for more than three years after the first cycle of treatment.

Studies in neoadjuvant settings for unresectable cholangiocarcinoma are very few although there was a remarkable success of a neoadjuvant protocol with the use of radiotherapy and capecitabine prior to liver transplantation^[6]. There was no report about gemcitabine based chemotherapy as a neoadjuvant approach combined with surgical tumor excision. In our case, a very large unresectable intrahepatic mass-forming cholangiocarcinoma showed a definite response to gemcitabine alone that eventually led the patient to a curative resection and long-term survival. This result suggests that gemcitabine based chemotherapy should be tried more actively for unresectable cholangiocarcinoma.

Abstract

Gastrectomy is commonly performed for both benign and malignant lesions. Although the incidence of post-gastrectomy acute pancreatitis (PGAP) is low compared to other well-recognized post-operative complications, it has been reported to be associated with a high mortality rate. In this article, we describe a 70-year-old man with asymptomatic pancreatic divisum who underwent palliative subtotal gastrectomy for an advanced gastric cancer with liver metastasis. His post-operative course was complicated by acute pancreatitis and intra-abdominal sepsis. The patient eventually succumbed to multiple organ failure despite surgical debridement and drainage, together with aggressive antibiotic therapy and nutritional support. For patients with pancreas divisum or dominant duct of Santorini who fail to follow the normal post-operative course after gastrectomy, clinicians should be alert to the possibility of PGAP as one of the potential diagnoses. Early detection and aggressive treatment of PGAP might improve the prognosis.

INTRODUCTION

Although gastrectomies for lesions of the stomach and duodenum have been performed safely for more than one hundred years, major complications such as anastomosis leakage, duodenal stump leakage and post-operative bleeding cannot be completely avoided even by experienced surgeons. In the past, most gastrectomies were performed for benign gastric or duodenal ulcer. One of the complications associated with these procedures was post-gastrectomy acute pancreatitis (PGAP). The pathogenesis of this condition is hypothesized to be related to pancreatic parenchymal injury secondary to severe adhesion of peripancreatic tissue, compromised pancreatic micro-circulation, hyperpressure of the duodenum, and edema or spasm of the major papilla^[1,2]. The incidence of PGAP has decreased in recent years, coinciding with the dramatic reduction in the need for surgical intervention of complicated peptic ulcer disease in the advent of improved medical and endoscopic management. Gastrectomies nowadays are performed mainly for patients with gastric malignancy. The "pancreatitis-like" presentation is mostly seen in patients with afferent loop obstruction after gastrectomies, mostly following Billroth II reconstruction. The true PGAP might be related to the extended lymph node dissection and resection of adjacent organs (such as splenectomy and distal pancreatectomy) in radical gastrectomies for gastric cancer^[3-5]. However, the correlation between pancreatic anomalies and PGAP has not been well documented in the literature. This article, therefore, reports a patient with concurrent advanced gastric cancer and pancreas divisum (PD) who had PGAP and died from multiple organ failure post-operatively.

CASE REPORT

A 70-year-old gentleman with a medical background of hypertension and asthma, presented with a 3 mo history

of poor appetite, 10 kg weight loss, postprandial fullness and nausea. There was, however, no history of tarry stool, hematemesis, fever or abdominal pain. The physical examination did not reveal any palpable abdominal mass, lymphadenopathy, anemia, or jaundice. All laboratory data, including biochemistry examination and hemogram, were within normal ranges except for a low hemoglobin level (10.3 g/dL). Esophagogastroduodenoscopy (EGD) was performed and one ulcerative mass over the posterior wall of antrum was identified (Figure 1). The histopathological examination of the biopsy of the gastric lesion confirmed that it was an adenocarcinoma. Dynamic CT was arranged for pre-operative staging. It revealed several cystic lesions of the liver and possible deformity of the duodenal bulb without definite evidence of metastatic disease (Figure 2). In addition, the gallbladder was contracted with suspicious wall thickening and heterogeneous content. At laparotomy, one unsuspected nodule was seen in segment 3 of the liver. The lesion was confirmed to be a metastatic liver nodule by frozen section. At the time of the operation, severe adhesion between the head of the pancreas and the peripyloric tissue was noted. As a result, a palliative subtotal gastrectomy with Billroth II gastrojejunostomy was performed due to partial outlet obstruction.

Post operatively, the patient had low-grade fever and persistent epigastric pain without jaundice, tarry stools, or active upper gastrointestinal hemorrhage. The laboratory tests on the 3rd postoperative day demonstrated a raised white cell count with left shift (11 500/ μ L), a platelet count of 176 000/ μ L and a hemoglobin of 9.5 g/dL. Serum biochemistry revealed a normal liver function and renal function but a raised C-reactive protein (CRP) of 193.27 mg/L. Slightly elevated amylase (185 U/L) and normal lipase (39 U/L) level were also noted. Chest X ray and urinary analysis were obtained and disclosed no pneumonia or urinary tract infection. Although the drainage fluid was clear, there was some yellowish and cloudy discharge from the abdominal wound. We collected the fluid for microbial analysis only and culture, which grew a yeast-like organism. Fever persisted despite the administration of intravenous antibiotics. Abdominal CT arranged on the 8th postoperative day demonstrated irregular pancreatic contours with diffuse enlargement and fluid accumulation in the lesser sac with retroperitoneal extension (Figure 3), suggestive of either an acute pancreatitis or duodenal stump leakage. The laboratory tests on the 10th postoperative day demonstrated a white cell count with marked left shift (8400/ μ L, 86% in segment form and 10% in band form), a decreased platelet count of 58 000/ μ L, a raised CRP of 247.95 mg/L, and normal serum level of pancreatic enzymes (amylase level was 79 U/L and lipase level was 26 U/L). In view of continuing clinical deterioration associated with peritonitis and intra-abdominal sepsis from a possible anastomosis leak rather than acute pancreatitis (according to the normal amylase and lipase levels), the patient underwent an exploratory laparotomy instead of percutaneous drainage of the fluid 10 d after the first operation. At laparotomy, colorless turbid fluid accumulation was found at the same regions as reported on the abdominal CT scan. There was no

Figure 1 The esophagogastroduodenoscopy (EGD) showed an ulcerated, annular lesion over the gastric antrum.

evidence of bile leak, and the duodenal stump and anastomosis were intact. The necrotic tissues around the cavity of the loculated fluid collection had a similar appearance to fat necrosis in acute pancreatitis. Limited debridement was performed and a sump drain tube was placed for post-operative irrigation and drainage.

Bile-stained fluid was noted in the sump drain 2 d after the second operation, and the biochemistry study of the drainage fluid disclosed lower amylase and lipase levels (14 U/L and 9 U/L). Blood culture grew *Bacteroides fragilis* and hemogram showed progressive pancytopenia. A repeat CT scan suggested possible duodenal stump leakage with abscess formation (Figure 4). Despite total parenteral nutrition, hemodialysis for acute renal failure, and sump drain irrigation-drainage with intravenous antibiotics for septicemia and intra-abdominal infection, the patient eventually died of profound septic shock and multiple organ failure on day 30 after the first operation. A retrospective review of the patient's abdominal CT demonstrated a previously undiagnosed, asymptomatic PD (Figure 5).

DISCUSSION

Gastrectomy is a commonly practiced procedure for both benign and malignant lesions of the stomach. Major complications such as postoperative bleeding, anastomotic leak and delayed gastric emptying are well documented^[6]. In the past, most gastrectomies were performed for benign gastric or duodenal ulcer. The incidence of PGAP might be as high as 40.8% and the mortality rates in this group of patients ranged from 12.6% to 62.5%^[1,2]. Recently, gastrectomies have mostly been performed for gastric malignancies, and the complication and mortality rates are much less because of improved surgical technique and postoperative care. The incidence of PGAP nowadays, although difficult to accurately estimate, has been reported to be less than 5%^[7]. The mortality rate, however, can be up to 33.3%-50%^[8,9] and is higher than acute pancreatitis of other etiologies^[10]. Chen *et al.*^[3] reported a higher incidence of PGAP in patients having total gastrectomy compared with other types of gastrectomies (7.4% *vs* 0.8%), with a 33.3% mortality rate. Another study reported higher

Figure 2 Preoperative abdominal CT images in coronary and transverse sections. The white solid arrows indicate diffuse wall thickening at the gastric antrum. The white dotted arrow indicates a contracted gallbladder with eccentric wall thickening. The black solid arrows point to the apparent deformity of the duodenal bulb with adhesion to the head of the pancreas. There is no evidence of intra-abdominal metastasis in this study.

Figure 3 Abdominal CT 8 d after the first operation demonstrates massive fluid accumulation in the peripancreatic area and the lesser sac. The homogenous fluid extends to the retroperitoneal space. The status of the duodenal stump (black arrow) cannot be clearly assessed. The pancreas is well enhanced and enlarged, and the head shows an uneven and infiltrative margin (white arrow).

Figure 4 Follow-up abdominal CT after the second operation. Severe fat stranding is seen. An edematous duodenal stump is observed without a clear fat plane surrounding it. This is highly suspicious of a stump leak (black arrow). The loculated fluid with heterogeneous changes indicates the possibility of an abscess formation (white arrow).

PGAP rate in patients undergoing extended lymph node dissection^[4]. Despite the various advantages of laparoscopically assisted gastrectomy (LAG), the rates of acute pancreatitis after LAG have also been shown to range from 0.7% to 2.3%^[8,9,11]. The poorer prognosis of PGAP might be related to postoperative immunosuppression, increased pancreatitis-related hemorrhage because of extensive soft tissue/lymph node dissection, or anastomotic leak secondary to necrotizing pancreatitis

and intra-abdominal sepsis.

PGAP may be a result of several factors. The stomach/duodenum might adhere to the underlying pancreas because of severe peptic ulceration or desmoplastic change from malignancy. Sometimes, the pancreas might actually be the base of the ulcer. Injury to the pancreatic parenchyma by electrocauterization or traction, microcirculation compromise, and direct injury to the pancreatic duct might occur during gastrectomy^[7,11]. Other causes

Figure 5 The preoperative CT scan. The dominant dorsal duct (duct of Santorini) drains into the minor papilla (white arrow). The CBD is seen in the section (black arrow) but the ventral duct (duct of Wirsung) can not be traced. These features are consistent with pancreas divisum.

of PGAP such as duodenal hyperpressure^[1] and post-operative spasm of the major papilla^[2] have been hypothesized, but there is a general lack of evidence in the literature to substantiate these theories. Although some studies suggested insertion of a nasogastric tube or a duodenostomy tube after gastrectomy for decompression and releasing duodenal hyperpressure, Hsu *et al*^[12] reported no difference in PGAP in spite of NG tube insertion. On the contrary, the “pancreatitis-like” presentation (such as hyperamylasemia and epigastric pain) caused by afferent loop obstruction can be cured under careful management of operations or decompression procedures^[7,13]. The condition should be taken into consideration because the prognosis, timing of intervention and treatment options are far different from PGAP without A-loop obstruction.

The diagnosis of acute pancreatitis is mainly dependent on suggestive clinical features and laboratory studies. Physical examination may be variable and non-specific in postoperative patients because of pain and symptoms related to the operation. Elevated lipase levels 3-fold or more above the normal range appearing within 48 h is the most reliable test^[14]. However, normal serum pancreatic enzyme levels cannot exclude acute pancreatitis absolutely^[14]. Abdominal CT scan is particularly helpful in making a definitive diagnosis and excluding other differential diagnoses such as anastomotic leak, intra-abdominal abscess and hemorrhage^[15]. However, the anatomical distortion post-operatively often makes the interpretation of CT images difficult^[16]. This is exemplified by the present case report whereby a definitive diagnosis of PGAP was delayed because of equivocal pancreatic enzymes and non-specific CT findings of intra-abdominal fluid collection.

PD is a common congenital anomaly of the pancreas, with an incidence rate of 4% to 10%^[17-19]. Anatomically, the dorsal duct (duct of Santorini) becomes the dominant duct draining the majority of the pancreatic juice through the minor papilla. The ventral duct (duct of Wirsung) does not fuse with the dorsal duct and only drains a small portion of the pancreatic head through the major papilla. The diagnosis of PD is made with

endoscopic retrograde pancreatography (ERP) or magnetic resonance pancreatography (MRP). However, with the advent of multi-detector CT scans, high sensitivity and specificity for diagnosis of PD can be achieved by CT images in some particular conditions^[20-22]. The CT features consistent with PD include the presence of the dominant dorsal duct sign (the dorsal duct being larger than the ventral duct, or a missing ventral duct) and the miss-communication between the two pancreatic ducts^[20]. Both of these features were observed on the patient's CT images retrospectively (Figure 5). About 5% to 45.5% of patients with PD present with pancreatitis or chronic abdominal pain^[23,24]. The pathogenesis of this is attributable to the “relative stenosis” of the minor papilla as it drains the majority of the pancreatic juice through a small opening^[24], resulting in an increase in the intra-ductal pressure of the dorsal duct system (20-28 mmHg *vs* 8-14 mmHg in normal pressure of major papilla)^[25]. In addition, the unusual anatomical arrangement of the sphincter of the minor papilla could also contribute to the development of intra-ductal hypertension leading to pancreatitis^[26]. Kamisawa *et al*^[27] reported the high incidence of pancreatitis or pancreatic-type abdominal pain in patients with dominant duct of Santorini but without pancreas divisum.

According to these findings, it is reasonable to suppose that patients with PD might be more sensitive to minor injury of the pancreas and disturbance of its microcirculation. Once developed, it might progress precipitously to a more severe form and patients are slower to gain full recovery. Prophylactic administration of octreotide in the post-operative setting has been suggested in an attempt to prevent the development of PGAP^[7]. The roles of preoperatively prophylactic cannulation of minor papilla, stent placement, and sphincterotomy have not been reported yet. The potential benefits of these invasive procedures in patients with PD or dominant duct of Santorini undergoing gastrectomy warrant further investigation.

In conclusion, PGAP is a less frequent post-gastrectomy complication in the current era. However, diagnosis and intervention should be made as early as possible because of the relatively high mortality rate associated with PGAP. Theoretically, patients with pancreas divisum or dominant duct of Santorini might connect to PGAP but the absolute relationship should be explored. Although serum pancreatic enzymes play an important role in the diagnosis of acute pancreatitis, imaging study such as an abdominal CT scan is particularly helpful in patients at high risk for PGAP. The roles and benefits of prophylactic octreotide, preoperative cannulation/stenting of the minor papilla, and sphincterotomy of minor papilla have not been well documented and would therefore warrant further investigation.

Abstract

The hemorrhagic simple hepatic cyst is extremely rare and can sometimes be confused with biliary cystadenoma or cystadenocarcinoma. Here we present two cases of huge hemorrhagic simple hepatic cysts. Case 1 was a 43-year-old man with a cystic lesion measuring 13 cm × 12 cm in the right hepatic lobe. Ultrasound and computed tomography showed several mural nodules on the irregularly thickened wall and high-density straps inside the cyst. Case 2 was a 60-year-old woman with a huge cyst measuring 15 cm × 14 cm in the central liver. Ultrasound and magnetic resonance imaging showed the cystic wall was unevenly thickened and there were some flame-like prominences on the wall. The iconographic representations of the two cases mimicked biliary cystadenoma. Cystectomy and left hepatectomy were performed for the two patients, respectively. Both patients recovered quickly after their operations and showed no recurrence.

INTRODUCTION

Intrahepatic cysts are generally classified as congenital cyst, traumatic cyst, infectious cyst, parasitic cyst, or neoplastic cyst. Congenital hepatic cysts include simple hepatic cysts and adult polycystic liver disease. A few simple hepatic cysts can reach large sizes and occasional complications, such as rupture, infection, hemorrhage, obstructive jaundice, or portal hypertension may occur.

Intracystic hemorrhage is an extremely rare complication of simple hepatic cysts and few cases have been reported worldwide. The hemorrhage usually occurs in solitary huge hepatic cysts in older patients. Massive bleeding into the cysts can significantly enlarge the cysts in a short time, which might partly contribute to the huge size of the cysts. The clinical manifestations of the hemorrhagic hepatic cysts are usually lack of specificity and the iconographic representations often mimic biliary cystadenoma or cystadenocarcinoma. Therefore, it is sometimes very difficult to make a precise diagnosis and select the appropriate treatment for this disease in clinical practice.

Here we present two cases of huge hemorrhagic simple hepatic cysts mimicking biliary cystadenoma, and discuss the diagnosis and the treatment of the disease.

CASE REPORT

Case 1 was a 43-year-old man admitted to hospital complaining of right upper quadrant abdominal pain for seven days. No positive clinical signs were found upon physical examination. The patient's serum carbohydrate antigen 19-9 (CA 19-9) concentration was four times higher than normal. Abdominal ultrasound examination showed a liquid anechoic area measuring 13 cm × 12 cm in right hepatic lobe. The cyst had an irregularly thickened wall with several mamelons on it. There were flocculation echoes inside the cyst. A computed tomography (CT) scan showed a low density cystic lesion with high density straps inside. The thickened cyst wall and mural nodules were not enhanced on contrast CT (Figure 1).

Case 2 was a 60-year-old woman admitted to hospital with a huge cystic liver mass found by regular ultrasound examination without any symptoms. The mass could be partly palpated below the right costal margin. The patient's serum concentration of CA 19-9 was normal. Abdominal ultrasound examination showed

Figure 1 CT scan showing a huge low density cystic lesion in the right liver with high density straps (arrowhead) inside and mural nodules (arrow) on the cyst wall.

Figure 2 MRI (T2 weighted sequence) showing a huge cyst in the central liver with liquid content and flame-like prominences inside.

a huge echoless cyst measuring 15 cm × 14 cm in the central liver. The margin of the cyst was clear but its wall was unevenly thickened. There were some flame-like prominences on the wall. MRI showed the cyst content was liquid; the flame-like prominences were seen but not enhanced with contrast (Figure 2).

It was difficult to make a diagnosis in either case preoperatively. Biliary cystadenoma was highly suspected. Operations were performed for both cases. Case 1 received a cystectomy and case 2 received a left hepatectomy. The pathological diagnosis was hepatic simple cysts accompanied by intracystic hemorrhage. The mural nodules and prominences on the cyst wall were blood clots. Both patients recovered quickly after their operations and have been alive for six years and two years, respectively.

DISCUSSION

The clinical manifestation of this disease is lack of specificity. Generally the patients might have acute or chronic upper abdomen pain, but some patients have no symptoms^[1-4]. Extra attention should be paid to patients whose symptoms are relative to the severe complications caused by the intracystic hemorrhage. For example, Iguchi *et al*^[5] reported a 76-year-old man with severe edema of both lower extremities and a CT scan revealed an enlarged hemorrhagic hepatic cyst compressing inferior vena cava (IVC) in which massive thromboses formed. Buyse *et al*^[6] reported a patient with simple hepatic cyst developed acute dyspnoea. It was found that the intracystic bleeding led to the enlargement of the cyst and compression of the IVC, followed by pulmonary embolism and dyspnoea. The clinical signs of hemorrhagic simple hepatic cysts depend on the size, location, and complications of the cysts, in which abdominal mass is more common.

The iconographic representations of hemorrhagic hepatic cyst sometimes mimic biliary cystadenoma or cystadenocarcinoma. The common manifestation on ultrasound includes hepatic cystic mass, hyperechoic intracystic straps, and irregularly thickened cyst wall with flame-like prominences or convex palliates. The mural nodules can sometimes be seen to be mildly enhanced

on contrast enhanced CT and MRI^[2], which increases the difficulty in differential diagnosis with cystic neoplasms. In fact, as proved by surgery and histological examination, the mural nodules are usually blood clots or organized hematomas^[1,2]. In our cases, although the mural nodules and prominences on the cyst wall were not enhanced on contrast CT and MRI, the suspicion of biliary cystadenoma could not be precluded.

The distinction between hemorrhagic simple hepatic cysts and biliary cystic neoplasms can prove difficult to determine by clinical and iconographic features alone. For differential diagnosis, percutaneous transhepatic aspiration might be helpful if serosanguineous fluid is obtained^[4]. However, the puncture should be forbidden if malignancy is highly suspected. Naganuma *et al*^[7] reported that contrast-enhanced ultrasound clearly showed microbubbles oozing from the cyst wall into the cyst cavity in a case of hepatic cyst with intracystic bleeding, suggesting contrast-enhanced sonography might be a useful diagnostic tool for the disease. Akiyama *et al*^[8] also reported that Levovist ultrasonography imaging could play an important role in the correct diagnosis of a simple hemorrhagic cyst, by demonstrating the avascularity of the visualized intracystic structures. Horsmans *et al*^[9] found in a four-patient small group that both serum and cystic fluid CA 19-9 levels were elevated in the two patients with cystadenoma or cystadenocarcinoma, but remained normal in the other two patients with hemorrhagic simple cyst. This suggested that the determination of serum and cyst fluid CA 19-9 levels might be of help in distinguishing between hemorrhagic simple cyst and cystadenoma or cystadenocarcinoma. However, other studies revealed that the CA 19-9 levels in neither serum nor cyst fluid had a relationship to the benign or malignant property of hepatic cystic lesions^[10-12]. In the present two cases, the serum CA 19-9 level was high in one case but normal in the other case, which seems to agree with the latter standpoint. Except for biliary cystadenoma and cystadenocarcinoma, other hepatic lesions such as hemangioma^[13], abscess, and parasitic cyst should also be differentially diagnosed.

Treatment for the hemorrhagic simple hepatic cysts should be active because intracystic bleeding can enlarge

the cysts significantly and cause severe complications, such as rupture, infection, and compression of the IVC leading to venous return obstruction or thrombosis. For poorly conditioned patients, transcatheter arterial embolization, transhepatic cyst drainage, intracystic ethanol injection or noninvasive methods are indicated. These methods can obtain therapeutic effect in some patients, though the bleeding may recur afterwards^[3-5,14,15]. Surgery should be performed for most well conditioned patients, especially those whose diagnosis does not preclude malignancy. The operations can include partial hepatectomy, cystectomy, and fenestration. Partial hepatectomy and cystectomy can remove the whole cyst and reach curative effect^[1-4,8,9,11,13,16]. Occasionally, a fenestration operation is performed to simplify the procedure, which can also obtain a good therapeutic effect^[6].

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (World J Gastroenterol ISSN 1007-9327, DOI: 10.3748) is a weekly, peer-reviewed, online, open-access (OA) journal supported by an editorial board of 1126 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in *WJG* will include the following. (1) Editorial: to introduce and comment on major advances in rapidly developing areas and their importance. (2) Frontier: to review recent developments and comment on current research status in important fields, and propose directions for future research. (3) Topic Highlight: this column consists of three formats, including: (a) 10 invited review articles on a hot topic; (b) a commentary on common issues associated with this hot topic; and (c) a commentary on the 10 individual articles. (4) Observation: to update the development of old and new questions, highlight unsolved problems, and provide strategies for their resolution. (5) Guidelines for Basic Research: as suggested by the title. (6) Guidelines for Clinical Practice: to provide guidelines for clinical diagnosis and treatment. (7) Review: to review systemically the most representative progress and unsolved problems, comment on current research status, and make suggestions for future work. (8) Original Article: to report original and innovative findings. (9) Brief Articles: to report briefly on novel and innovative findings. (10) Case Report: To report a rare or typical case. (11) Letters to the Editor: to discuss and reply to contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest. (12) Book Reviews: to introduce and comment on quality monographs. (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities on basic research and clinical practice

The WJG Press and Baishideng

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments,

References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS AND DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of *P* values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as 1F , 2F , 3F ; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No.62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Telephone: +86-10-59080039

Fax: +86-10-85381893

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Language evaluation

The language of a manuscript will be graded before it is sent for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

World Journal of Gastroenterology®

Weekly Established in October 1995

Volume 15 Number 37
October 7, 2009

Contents

EDITORIAL

- 4609** Involvement of interleukin-15 and interleukin-21, two γ -chain-related cytokines, in celiac disease
De Nitto D, Monteleone I, Franzè E, Pallone F, Monteleone G
- 4615** Anemia and digestive diseases: An update for the clinician
Gomollón F, Gisbert JP

TOPIC HIGHLIGHT

- 4617** An update on iron physiology
Muñoz M, Villar I, García-Erce JA
- 4627** Classification of anemia for gastroenterologists
Moreno Chulilla JA, Romero Colás MS, Gutiérrez Martín M
- 4638** A guide to diagnosis of iron deficiency and iron deficiency anemia in digestive diseases
Bermejo F, García-López S
- 4644** A short review of malabsorption and anemia
Fernández-Bañares F, Monzón H, Forné M
- 4653** Spectrum of anemia associated with chronic liver disease
Gonzalez-Casas R, Jones EA, Moreno-Otero R
- 4659** Anemia and inflammatory bowel diseases
Gomollón F, Gisbert JP
- 4666** Intravenous iron in inflammatory bowel disease
Muñoz M, Gómez-Ramírez S, García-Erce JA
- 4675** Use of agents stimulating erythropoiesis in digestive diseases
Moreno López R, Sicilia Aladrén B, Gomollón García F

Contents		<i>World Journal of Gastroenterology</i> Volume 15 Number 37 October 7, 2009
	4686	Blood transfusion for the treatment of acute anaemia in inflammatory bowel disease and other digestive diseases <i>García-Erce JA, Gomollón F, Muñoz M</i>
ORIGINAL ARTICLES	4695	Clonality and allelotype analyses of focal nodular hyperplasia compared with hepatocellular adenoma and carcinoma <i>Cai YR, Gong L, Teng XY, Zhang HT, Wang CF, Wei GL, Guo L, Ding F, Liu ZH, Pan QJ, Su Q</i>
BRIEF ARTICLES	4709	Analysis of risk factors for central venous port failure in cancer patients <i>Hsieh CC, Weng HH, Huang WS, Wang WK, Kao CL, Lu MS, Wang CS</i>
	4715	A systematic review of treating <i>Helicobacter pylori</i> infection with Traditional Chinese Medicine <i>Lin J, Huang WW</i>
	4720	Correlation between anti-fibrotic effect of baicalin and serum cytokines in rat hepatic fibrosis <i>Peng XD, Dai LL, Huang CQ, He CM, Chen LJ</i>
CASE REPORT	4726	Tumor lysis syndrome after transarterial chemoembolization of hepatocellular carcinoma: Case reports and literature review <i>Hsieh PM, Hung KC, Chen YS</i>
	4729	A rare case of periampullary carcinoma with ectopic ending of Vater's ampulla <i>Jin SG, Chen ZY, Yan LN, Zeng Y, Huang W, Xu N</i>
ACKNOWLEDGMENTS	4732	Acknowledgments to reviewers of <i>World Journal of Gastroenterology</i>
APPENDIX	4733	Meetings
	4734	Instructions to authors
FLYLEAF	I-VII	Editorial Board

INSIDE FRONT COVER		Online Submissions

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

Celiac disease (CD), an enteropathy caused by dietary gluten in genetically susceptible individuals, is histologically characterized by villous atrophy, crypt cell hyperplasia, and increased number of intra-epithelial lymphocytes. The nature of CD pathogenesis remains unclear, but recent evidence indicates that both innate and adaptive immune responses are necessary for the phenotypic expression and pathologic changes characteristic of CD. Extensive studies of molecules produced by immune cells in the gut of CD patients have led to identification of two cytokines, namely interleukin (IL)-15 and IL-21, which are thought to play a major role in orchestrating the mucosal inflammatory response in CD. Here we review the current knowledge of the expression and function of IL-15 and IL-21 in CD.

INTRODUCTION

Celiac disease (CD) is a chronic gastrointestinal disorder caused, in genetically predisposed individuals, by ingestion of the gluten proteins of wheat, rye, and barley. The prevalence of CD is approximately 1% in the Western world^[1-3]. The disease is strongly associated with *HLA-DQ* genes. Most patients carry a variant of DQ2 (alleles DQA1*05/DQB1*02) and others carry a variant of DQ8 (alleles DQA1*03/DQB1*0302)^[4,5]. These haplotypes are relatively common in the healthy population, and only 1:20 individuals who express HLA-DQ2/DQ8 have CD^[4,5]. These observations and the fact that the concordance rate between HLA-identical siblings is much lower than between monozygotic twins suggest that most probably other non-HLA genes are involved in the pathogenesis of CD^[6-8].

In CD patients, ingestion of gluten triggers a mucosal inflammatory response, which leads to the tissue damage. The histological features of CD are villous atrophy, crypt cell hyperplasia, and increased number of intra-epithelial lymphocytes (IELs). The clinical manifestations can range from asymptomatic to severe malabsorption. Patients can also manifest symptoms of other immune-mediated diseases, which can associate with CD. The only treatment is a lifelong gluten-free diet, which results, in the vast majority of patients, in complete remission of symptoms and recovery of the normal mucosal histology^[9].

Although the pathogenesis of CD is not fully understood, it is known that gluten peptides are deamidated by tissue transglutaminase and presented by DQ2⁺ or DQ8⁺ antigen-presenting cells to lamina propria CD4⁺ T cells^[9,10]. Upon activation, CD4⁺ T cells polarize along the T helper (Th)1-type pathway, as substantiated by their ability to produce large amounts of interferon (IFN)- γ , the signature cytokine of Th1 responses^[11,12]. In CD patients on a gluten-free diet, IFN- γ production is as low as in healthy controls but it can be stimulated *in vitro* by gluten to reach levels of untreated CD patients. In these mucosal cultures, neutralization of IFN- γ prevents gliadin-mediated

morphological changes thus supporting the role of the adaptive immune response and IFN- γ in CD immunopathology^[11,12]. More recently it has become clear that some gluten peptides can induce mucosal damage by directly activating innate immune mechanisms^[13]. These observations collectively underline the complexity of the pathogenic mechanism in CD and suggest that the CD-associated mucosal damage relies on the activation of multiple rather than single cell pathways.

GLUTEN PEPTIDES STIMULATE INNATE IMMUNITY AND CAUSE EPITHELIAL DAMAGE VIA AN INTERLEUKIN (IL)-15-DEPENDENT MECHANISM

It has long been known that gluten peptides cause epithelial damage when added to *ex vivo* organ cultures of biopsies taken from CD patients on a gluten-free diet, but not from controls^[14]. As previously mentioned, this pathogenic response was initially thought to be secondary to the activation of lamina propria CD4⁺ T cells and production of inflammatory cytokines, such as IFN- γ ^[11]. However, more recently Maiuri *et al*^[13] showed that the gluten p31-43 peptide is able to induce mucosal damage by directly activating innate immune cells. In particular, it was shown that the p31-43 peptide elicits the production of IL-15 by lamina propria macrophages and dendritic cells in *ex vivo* organ cultures of CD biopsies, thus triggering a sequence of events that culminates in epithelial damage (Figure 1). These findings correlate well with the demonstration that IL-15 is over-expressed in both the lamina propria and intestinal epithelium of patients with active, untreated CD as compared with normal controls or inactive, gluten-free diet treated CD patients^[15,16].

The majority of intestinal IELs are T cell receptor (TcR) $\alpha\beta^+$ CD8⁺CD4⁻ and a significant proportion are TcR $\gamma\delta^+$ CD8⁺CD4⁻^[14]. IELs express a variety of natural killer (NK) lineage receptors, supporting their involvement in epithelial cell damage^[14]. Corroborating Maiuri's results, Hüc *et al*^[17] showed that treatment of biopsies taken from inactive CD patients with the gluten p31-49 peptide enhances the enterocyte expression of the non-conventional HLA molecules MICA/B. MIC molecules are known to be induced on enterocytes by stress and are up-regulated in active CD mucosa^[18]. MICA/B are ligands of the activating NKG2D receptor, which signals through the adaptor protein DAP10 and is expressed on most NK cells, CD8⁺ TcR $\alpha\beta^+$ and TcR $\gamma\delta^+$, but normally not on CD4⁺ T cells^[19,20]. Expression of NKG2D in IELs is increased in active CD mucosa, and IELs lyse epithelial cells *via* NKG2D^[17]. Up-regulation of MICA/B molecules also occurs in CD biopsies treated with exogenous IL-15, and a neutralizing IL-15 antibody blocks the gluten-mediated MIC-inducing effect in organ cultures of CD biopsies^[17,21]. Meresse *et al*^[22] showed that IL-15 also enhances the expression of both NKG2D and DAP10 in IELs, and that the cytolytic

attack of the epithelium by IELs may be perpetuated *via* NKG2D independently of TcR specificity (Figure 1). Taken together these findings emphasize the critical role of IL-15 in intestinal epithelial cell death induced by NKG2D-expressing IELs.

IL-15 AND COUNTER-REGULATORY MECHANISMS IN CD

In the gut, mucosal homeostasis arises from a highly dynamic balance between host protective immunity and regulatory mechanisms^[23]. One such counter-regulatory mechanism involves transforming growth factor- β 1 (TGF- β 1), a cytokine that is able to exert a number of negative effects on immune cells, including inhibition of T cell proliferation and differentiation, as well as down-regulation of macrophage activation and dendritic cell maturation^[24]. Consistently, mice with global TGF- β 1 defects, such as TGF- β 1-deficient mice or transgenic mice expressing a dominant-negative TGF- β RII chain that are unresponsive to TGF- β 1 signaling, develop intestinal mucosal inflammation^[25,26]. On the other hand, studies in mouse models of gut inflammation have shown that production of TGF- β 1 is consistently associated with greatly diminished severity of inflammation^[27]. Because TGF- β 1 regulates both lymphoid and myeloid cells^[24], several researchers have examined the expression and activity of TGF- β 1 in chronic gastrointestinal inflammatory diseases, including CD. Initial studies conducted by Lahat *et al*^[28] showed that in active CD mucosa there was enhanced expression of transcripts for TGF- β 1 as compared to controls. In contrast, Lionetti *et al*^[29] reported that the total RNA expression of TGF- β 1 did not differ between active CD and controls. However, in active CD, TGF- β 1 production was mostly confined to lamina propria T cells and macrophages, while in controls it was mostly produced by epithelial cells^[29].

TGF- β 1 initiates signaling through the ligand-dependent activation of a complex of heterodimeric transmembrane serine/threonine kinases, consisting of type I (TGF- β RI) and type II (TGF- β RII) receptors^[30]. Upon TGF- β 1 binding there is phosphorylation and activation of TGF- β RI by the constitutively active and auto-phosphorylating TGF- β RII. TGF- β RI in turn phosphorylates two proteins, termed Smad 2 and Smad3. Once phosphorylated, Smad2 and Smad3 associate with Smad4 and translocate to the nucleus where Smad protein complexes participate in transcriptional control of target genes^[30]. This pathway has been reported to be antagonized by inflammatory cytokines, which can impair the regulatory functions of TGF- β 1 and alter immune homeostasis^[31,32]. Therefore, it is conceivable that, during chronic inflammatory processes, there may be deficient TGF- β 1 activity despite this cytokine being highly produced. In line with this, Benahmed *et al*^[33] have recently shown that TGF- β 1 inhibited the proliferative response of normal intestinal IELs and lamina propria

Figure 1 Hypothetical view of the pathogenic effects of IL-15 and IL-21 in celiac disease. In active celiac disease mucosa, IL-15 is produced by epithelial cells and antigen presenting cells (APC) in response to gluten stimulation. APC also produce interferon (IFN)- α , which stimulates CD4⁺ T cells to polarize along the Th1 pathway. IL-21 is produced by activated CD4⁺ T cells, including Th1 cells. IL-15 activates various pathways, which lead to the lysis and death of epithelial cells. IL-15 augments the production of granzyme B by IELs and IFN- γ by IELs and Th1 cells; enhances the expression of the activating NKG2D receptor on IELs; induces the NKG2D ligand, MICA, on epithelial cells. IL-21 seems to contribute to the tissue-damaging immune response in CD, given that this cytokine is able to enhance the production of perforin by IELs and IFN- γ by T cells, and to stimulate stromal cells to make extracellular matrix-degrading metalloproteinases.

lymphocytes induced by IL-2 but not that triggered by IL-15. The inhibitory effect of IL-15 on TGF- β 1 activity was substantiated further by the demonstration that IL-15 impaired the formation of Smad3-DNA complexes in response to TGF- β 1 stimulation^[33]. In contrast, IL-15 enhanced the activation of the Janus kinase (JNK) pathway thus promoting the inhibitory effect of phospho-c-jun on the formation of Smad-DNA complexes. Further analysis revealed that the transcription levels of tristetraprolin, a TGF- β target gene under the control of the Smad3 pathway, were decreased in duodenal biopsies from patients with active CD compared with controls. This defect was associated with no significant change in the intracellular levels of phosphorylated Smad3 and Smad7, clearly indicating that initial steps of TGF- β signaling are preserved in patients with active CD^[33]. This is in contrast to the Smad7-dependent inhibition of TGF- β 1/Smad3 signaling described in patients with inflammatory bowel diseases^[34,35].

IELs, lamina propria lymphocytes, and epithelial cells of active CD contain high levels of phospho-c-jun, and inhibition of this protein in organ cultures of CD biopsies enhances tristetraprolin^[33]. Moreover, treatment of *ex vivo* organ cultures of CD biopsies with anti-IL-15 reduces phospho-c-jun and increases tristetraprolin, thus confirming the prominent role of IL-15 in the phospho-c-jun-mediated inhibition of TGF- β 1 signaling^[33].

While NKG2C and NKG2D are activating NK receptors, NKG2A is considered an inhibiting NK receptor. NKG2A can associate with CD94 and bind the non-classical MHC Ib molecule, HLA-E, which is expressed on epithelial cells of CD patients but not on epithelial cells of healthy individuals^[36,37]. Although NKG2A competes with NKG2C for its interaction

with HLA-E, the former has a higher binding affinity for HLA-E compared with NKG2C. Upon binding to this ligand, CD94/NKG2A delivers negative signals to cytotoxic cells^[38]. A higher percentage of small intestinal TcR $\gamma\delta$ IELs express CD94/NKG2A compared with TcR $\alpha\beta$ IELs, and TcR $\gamma\delta$ IELs exert negative effects on the IL-15-mediated induction of IFN- γ , granzyme B, and NKG2D in CD8⁺ TcR $\alpha\beta$ IELs^[39]. These observations suggest that TcR $\gamma\delta$ IELs have the ability to suppress the cytotoxic programming of TcR $\alpha\beta$ IELs. This inhibitory effect requires interaction of NKG2A with its ligand HLA-E, a phenomenon which is followed by enhanced secretion of TGF- β 1. Notably, blockade of TGF- β 1 activity with a neutralizing human TGF- β 1 antibody partially abrogates the suppressive capability of TcR $\gamma\delta$ IELs, and exogenous TGF- β 1 dose-dependently inhibits the IL-15-mediated induction of IFN- γ , granzyme B, and NKG2D in CD8⁺ TcR $\alpha\beta$ IELs^[39]. Therefore, in this cell context, IL-15 is not sufficient to abrogate the immunosuppressive action of TGF- β 1. These findings conflict with the aforementioned data published by Benahmed *et al.*^[33]. It is likely that this discrepancy may simply be due to differences in cell culture conditions used in these two studies. Another possibility is that the IL-15-mediated negative regulation of TGF- β 1 signaling occurs only in specific cell types. Since TGF- β 1 can trigger both Smad-dependent and -independent intracellular pathways^[39,40], it is also plausible that IL-15 can interfere with some and not all TGF- β 1-activated signals.

Expression of NKG2A is decreased on TcR $\alpha\beta$ IELs and TcR $\gamma\delta$ IELs from CD patients as compared to normal subjects^[39-41]. The mechanism that removes this negative regulator from CD IELs remains unknown. NKG2A possesses in its promoter a binding site for

Smad3, and there is evidence that TGF- β 1 cooperates with the TcR in enhancing the expression of NKG2A on CD8⁺ T cells^[18,42]. Therefore, molecules that disrupt TGF- β 1 signaling could, at least in theory, contribute to the down-regulation of NKG2A in CD. IL-15 is not able to directly regulate NKG2A expression^[43], even though it remains possible that it could inhibit the TGF- β 1-induced NKG2A expression.

IL-21 as a positive regulator of Th1 cell response in CD

The demonstration that CD lesions are associated with a marked infiltration of IFN- γ -secreting cells has boosted intensive research aimed at identifying the factors that promote the ongoing mucosal Th1 cell response. Paradoxically, IL-12, the major Th1-inducing factor in man, is not over-produced in CD mucosa^[12]. However, analysis of transcription factors that drive Th cell differentiation revealed that in active CD mucosa there is enhanced expression of T-bet, a member of the T-box family of transcription factors that directs Th1 lineage commitment and is essential for IFN- γ production in CD4⁺ T cells^[43]. In contrast, no increase in GATA3 and active STAT6, two transcription factors that specifically regulate Th2 differentiation, is seen in active CD samples as compared to controls^[43]. Interestingly, active CD biopsies do not exhibit enhanced activation of STAT4^[43], an IL-12-dependent Th1-inducing transcription factor, thus confirming the lack of IL-12 activity. These data strongly support the existence of a regulatory pathway for Th1 differentiation that starts from activation of T-bet and is independent of IL-12-driven STAT-4 signaling. So the critical question is: what induces and sustains T-bet in CD? We have recently shown that in the duodenal mucosa of patients with active but not inactive CD there is enhanced production of IL-21^[44]. Interestingly, neutralization of IL-21 activity in *ex vivo* organ cultures of CD biopsies reduces both T-bet expression and IFN- γ production^[44]. Since IFN- γ enhances T-bet *via* a STAT1-dependent mechanism^[43], it is tempting to speculate that IL-21 is part of a positive feedback loop that helps amplify and stabilize the committed Th1 cell phenotype in CD (Figure 1).

Recent genome-wide association studies have provided convincing evidence that the chromosomal 4q27 region harboring the *IL-2* and *IL-21* genes is associated with CD^[7]. A similar genetic association has been described in other immune-mediated diseases, such as psoriasis, type 1 diabetes, and inflammatory bowel diseases^[45,46]. However, it is not yet known if such polymorphisms can influence the tissue levels of IL-21.

Biopsies taken from CD patients on a gluten-free diet over-express IL-21 when challenged *in vitro* with gluten peptides^[44]; however, the basic mechanisms that control the expression of IL-21 in CD mucosa remain to be elucidated. Previously, we showed that IFN- α is up-regulated in the mucosa of active CD patients, where it most probably contributes to intensifying IFN- γ production^[47]. Indeed, neutralization of IFN- α activity drastically reduces the gliadin peptide-driven

IFN- γ expression in biopsies of inactive CD patients^[48]. Interestingly, IFN- α enhances the mRNA expression of IL-21 in activated human T cells^[49], thus suggesting a role for this cytokine in the positive control of IL-21 in CD (Figure 1).

Potential involvement of IL-21 in the activity of other mucosal cells types

The biological functions of IL-21 are mediated by a cell-surface class I cytokine receptor, formed by the common γ -chain subunit (shared with IL-2, IL-4, IL-7, IL-9, IL-13 and IL-15 receptors) and its own unique receptor (designated IL-21 receptor)^[50]. Since this receptor is expressed by both immune and non-immune cells, it is plausible that IL-21 maintains chronic inflammation and/or favors tissue damage in CD by targeting additional cell types other than Th1 lymphocytes. In fact, IL-21 has been shown to stimulate epithelial cells to secrete chemokines and facilitate recruitment of immune cells within the inflamed tissue, induce fibroblasts to make tissue-damaging proteases, and make effector CD4⁺ T cells resistant to regulatory T cell-mediated immunosuppression^[51-53]. In light of the role of IL-21 in the control of B cell and plasma cell function^[54], IL-21 may also contribute to the production of CD-associated autoantibodies. Since its discovery, it has become clear that IL-21 is also able to modulate the proliferation and/or effector function of CD8⁺ T cells and NK cells^[55]. Using IELs isolated from human jejunal mucosa, Ebert has recently shown that IL-21 increases perforin-mediated cytotoxicity and serine esterase release without affecting the growth and survival of these cells^[56]. The relevance of this finding for CD pathogenesis remains to be ascertained, although IL-21-mediated cytotoxic T cell activation could contribute to the intestinal epithelial cell death and villous atrophy in CD.

CONCLUSION

A growing body of evidence suggests that IL-15 and IL-21 may play important roles in the immune response associated with inflammation and tissue damage in CD, even though some intriguing questions remain to be resolved. For instance, it remains to be determined whether these two cytokines contribute qualitatively and quantitatively differently to the initiation and progress of the inflammatory cascade in CD. The fact that IL-15 and IL-21 share a receptor subunit and target the same cell types raises the possibility that these cytokines may cooperate in regulating specific cell immune responses. Indeed, both IL-15 and IL-21 are known to stimulate the growth of T cells, enhance the production of IFN- γ by Th1 cells, and promote the activation of cytotoxic cells^[21,44,50,57] (Figure 1). As outlined in this article, these two cytokines might also act in concert to disrupt local mechanisms of immune tolerance. This hypothesis is supported by the demonstration that IL-15 inhibits TGF- β 1 activity, and IL-21 renders effector CD4⁺ T cells resistant to the suppressive effects of CD4⁺CD25⁺ regulatory T cells^[33,53]. Nonetheless it is noteworthy that

IL-15 and IL-21 seem to differentially modulate some aspects of both innate and adaptive immunity, such as dendritic cell maturation and T cell apoptosis^[50,57]. Therefore, we cannot exclude the possibility that, at least in some stages of the inflammatory process, IL-15 and IL-21 can exert opposing effects on the gluten-driven immune response.

Abstract

Anemia and iron deficiency are so common in digestive diseases that often are underestimated and undertreated. Our goal is to review from classification to treatment of the diverse types of anemias in different digestive diseases to update our knowledge on diagnosis and treatment. With the goal of improving the prognosis and quality of life of digestive diseases patients, we will review current transfusion, intravenous iron, and erythropoietin roles in the treatment of anemia.

Gomollón F, Gisbert JP. Anemia and digestive diseases: An update for the clinician. *World J Gastroenterol* 2009; 15(37): 4615-4616 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4615.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4615>

The human mind is a marvellous albeit complex tool. It is not easy to understand how it works^[1] with no exception for the clinician^[2]. Inflammatory bowel diseases (IBD) are complex, often difficult to manage, and anemia is so common around the world^[3] that perhaps even the most astute clinician simply cannot always see that specific tree in the forest^[4]. However, anemia is really important for patients, and we should not forget this. Since publication of the landmark article by Gasche^[5], a study^[6]

has shown the importance of anemia that should be actively looked for and treated. Anemia in IBD is a good example^[6], and we will dedicate our specific attention to it, but anemia can also be a key point in many different clinical scenarios of gastroenterology and hepatology. Therefore, in this short article, we will attempt to review several aspects we consider interesting for the practicing clinician. There are many possible approaches and we will take a look at different perspectives. Hematologists, gastroenterologists, hepatologists and even nephrologists will contribute to our task.

Anemia is both a simple word and a complex one. There are many different diseases that could be included in the World Health Organization definition of anemia (a patient has anemia if his or her blood hemoglobin level is below standard for age and sex). However, the simple final result can be due to the consequence of many different causes and mechanisms that can even overlap in the same patient and at the same time. Our first goal is to furnish our readers with an up-to-date classification of anemia. To do this work, we have chosen the hematologists' point of view.

Iron is not only the most abundant chemical element on Earth, but also a key element for life from very ancient ancestors. Life beings often compete for iron, a key to the control of redox reactions in many living organisms^[7]. Perhaps, due to evolutionary reasons, iron regulation is important in inflammation. In many digestive diseases, iron is a principal player because absorption, loss and regulation of iron metabolism, can all be affected in different diseases. Most likely, the paradigm is Crohn's disease^[8], in which malabsorption, inflammation and blood loss, all contribute to iron deficiency and iron deficiency anemia in some cases. The regulation of iron metabolism has been a very interesting topic in the last few years, and some new molecules have been developed. Hepcidin is a rising star, but it is not alone^[9]. The clinician should know the basics of these mechanisms to understand the treatment modalities, and so we have asked the experts to summarize this topic.

It is a bit counterintuitive, but luminal contents are out of our body, in a bacterial world (in fact all the earth is a bacterial world). To get iron in, it has to be absorbed as many other elements or substances. The role of malabsorption in anemia is a very interesting topic for gastroenterologists.

Anemia is a rather common problem in liver units as well. Patients with severe liver disease often have anemia and need specific treatment. Blood transfusion is common

(perhaps too common) in these patients. Anemia in patients with liver disease has interesting particularities, such as the role of portal hypertension, renal failure or antiviral drugs. Thus, a specific article has been devoted to anemia in liver disease.

The story of intravenous iron is a complex one^[10]. Some old preparations are difficult to manage and cause significant risks in patients. So, when new safer preparations^[11] that are easier to use appear, clinicians are simply fearful of using intravenous iron. However, with increasing experience in nephrology, oncology, gastroenterology, and gynecology, IV iron is becoming a standard treatment for patients at all ages and conditions^[12]. If we want this to be a real life standard, clinicians need clear rules, namely “who”, “when”, and “how” are the classic questions that are addressed in a specific article on IV iron.

Intravenous iron is not always enough to treat anemia since erythropoietin can be very useful if used judiciously. For this topic, we prefer the nephrologists’ point of view because they have the most important experience with both sides: Dr. Jeckyll (the improvement in quality of life) and Mr. Hyde (mortality associated with a high hemoglobin level), who will tell us about their experience, which is very interesting with rather complex economic implications^[13].

Blood transfusion can be lifesaving in many clinical situations, and has been one of the greatest advances in medicine. However, blood transfusion is not a risk and/or cost-free, and may have been overused in many situations. Very important evidence from traumatology, surgical and intensive care units has been published in recent years^[14]. We should apply this update knowledge in our patients, following the most recent guidelines. The hematologists’ point of view can be important for the gastroenterologist and the hepatologist.

Anemia, intravenous iron, blood transfusion, iron metabolism, *etc*, have been a few of the changing topics over the last few years. To help our patients, we still need

to know many things about this very old tree with many roots and branches. We have selected to update our knowledge on some of them, with the aim of helping our patients. In Darwin’s year, it was always tempted to use the tree image, and so in a Freudian way to recognize him as the father of modern biology.

Abstract

Iron is an essential micronutrient, as it is required for adequate erythropoietic function, oxidative metabolism and cellular immune responses. Although the absorption of dietary iron (1-2 mg/d) is regulated tightly, it is just balanced with losses. Therefore, internal turnover of iron is essential to meet the requirements for erythropoiesis (20-30 mg/d). Increased iron requirements, limited external supply, and increased blood loss may lead to iron deficiency (ID) and iron-deficiency anemia. Hepcidin, which is made primarily in hepatocytes in response to liver iron levels, inflammation, hypoxia and anemia, is the main iron regulatory hormone. Once secreted into the circulation, hepcidin binds ferroportin on enterocytes and macrophages, which triggers its internalization and lysosomal degradation. Thus, in chronic inflammation, the excess of hepcidin decreases iron absorption and prevents iron recycling, which results in hypoferrremia and iron-restricted erythropoiesis, despite normal iron stores (functional ID), and anemia of chronic disease (ACD), which can evolve to ACD plus true ID (ACD + ID). In contrast, low hepcidin expression may lead to iron overload, and *vice versa*. Laboratory tests provide evidence of iron depletion in the body, or reflect iron-deficient red cell production. The appropriate combination of these laboratory tests help to establish a correct diagnosis of ID status and anemia.

INTRODUCTION

Erythropoiesis is a part of the larger process of hematopoiesis. In the normal adult human, the daily turnover of red blood cells (RBCs) exceeds 10^{11} cells. In periods of increased RBC loss caused by hemolysis or hemorrhage, the production of RBCs increases rapidly and markedly. However, an overproduction of RBCs (i.e. rebound polycythemia) does not occur even after the most severe loss of RBCs. Thus, erythropoiesis is a finely regulated yet rapidly responsive process that maintains the normal number of circulating RBCs within a narrow range^[1].

The major stages of differentiation in human erythropoiesis are depicted in Figure 1. The commitment of multipotent hemopoietic stem cells to erythroid progenitors is driven by several growth factors, such as stem cell factor, thrombopoietin, and interleukin (IL)-3^[2]. The most immature stage of committed erythroid progenitors is the burst-forming unit-erythroid, which differentiates into colony-forming unit-erythroid (CFU-E) in approximately 7 d, with declining proliferative potential as the progenitors approach CFU-Es. Each CFU-E develops a single cluster of 8-64 mature erythroblasts within 7 d, after several differentiation stages (proerythroblast, basophilic erythroblast, polychromatic erythroblast, and orthochromatic erythroblast). Orthochromatic erythroblasts do not divide but they enucleate, and form nascent RBCs, called reticulocytes, which are released into the bloodstream. After 1 d of circulation in the peripheral blood, reticulocytes mature into RBCs^[3]. The normal proliferation and differentiation of erythroid progenitor cells require several essential

nutrients, such as iron, folate, and vitamin B12, the interaction with the stromal cells in the bone marrow, and stimulation by erythropoietin (EPO)^[3].

IRON HOMEOSTASIS

For a 70-kg male individual, total body iron is about 3.5 g (50 mg/kg). Most of the iron in the body is distributed within RBC hemoglobin (65%; 2300). Approximately 10% is present in muscle fibers (in myoglobin) and other tissues (in enzymes and cytochromes) (350 mg). The remaining body iron is stored in the liver (200 mg), macrophages of the reticuloendothelial system (RES; 500 mg), and bone marrow (150 mg). In premenopausal women, total body iron (especially the stored fraction, 250-300 mg) is lower than in men. The normal diet contains 15-20 mg of iron, and the body absorbs 1-2 mg/d of dietary iron. This is balanced with losses *via* sloughed intestinal mucosal cells, menstruation and other blood losses. Therefore, internal turnover of iron is essential to meet the bone marrow requirements for erythropoiesis (20-30 mg/d)^[3-5].

On the other hand, the body has no effective means of excreting iron and thus the regulation of absorption of dietary iron from the duodenum plays a critical role in iron homeostasis in the body^[5]. This is extremely important as iron is essential for cellular metabolism and aerobic respiration, whilst cellular iron overload leads to toxicity and cell death *via* free radical formation and lipid peroxidation, thus, iron homeostasis requires tight regulation^[3,4,6]. A summary of proteins involved in iron homeostasis, as well as their most frequently used acronyms, is given in Table 1.

Iron absorption

Nearly all absorption of dietary iron occurs in the duodenum. Several steps are involved, including the reduction of iron to a ferrous state, apical uptake, intracellular storage or transcellular trafficking, and basolateral release (Figure 2). Dietary iron is found in heme (10%) and non-heme (ionic, 90%) forms and their absorption occurs at the apical surface of duodenal enterocytes *via* different mechanisms. Dietary non-heme iron primarily exists in an oxidized (Fe^{3+}) form that is not bioavailable, and must first be reduced to the Fe^{2+} form by a ferrereductase enzyme, before it is transported across the intestinal epithelium by a transporter called divalent metal transporter 1 (DMT-1), which also transports other metal ions such as zinc, copper and cobalt by a proton-coupled mechanism^[3,4]. There is also a siderophore-like iron uptake pathway mediated by lipocalin-2 (that seems to exert an innate immune response to bacterial infection by sequestering iron) but its physiological role is not fully worked out.

The absorption of non-heme can be diminished by co-administration of tetracyclines, proton pump inhibitors and antacid medication, phytates (high-fiber diets), calcium, and phenolic compounds (coffee and

tea). In addition, infection with *Helicobacter pylori* (*H. pylori*) produces gastric atrophy that, even in the absence of significant bleeding, can lead to profound iron-deficiency anemia (IDA). As expected, this anemia is poorly responsive to oral iron therapy, but can be corrected by eradication of *H. pylori* infection^[7].

Heme iron is absorbed into enterocytes by a putative, not totally identified heme carrier protein 1, which is a membrane protein found in the proximal intestine, where heme absorption is greatest^[8]. Once internalized in the enterocytes, it is likely that most dietary heme iron is released as ferrous iron by heme oxygenase to enter a common pathway with dietary non-heme iron before it leaves the enterocytes^[3,4] (Figure 2). However, it remains uncertain whether some heme might traverse the cells intact, leaving the enterocytes through the action of the recently characterized heme exporters, Bcrp/Abcg2 and feline leukemia virus C receptor (FLVCR)^[8]. If this does occur, the subsequent disposition of plasma heme

Table 1 Main proteins involved in iron homeostasis in mammals

Protein name (alternative name)	Acronyms	Function	Localization
Divalent metal transporter 1 (divalent cation transporter 1, NRAMP 1 and 2)	DMT1 DCT1 NRAMP1* NRAMP2	Traffics divalent metal ions such as iron, zinc, copper and cobalt across the membrane by a proton coupled mechanism	Enterocyte (apical membrane) Erythroblast (siderosome) Macrophage (plasma membrane, phagocytic vesicles*) Hepatocyte Kidney cells
Ferriredutase	Dcytb STEAP3*	Reduction of Fe ³⁺ to Fe ²⁺	Enterocyte (apical membrane) Erythroblast (siderosome*)
Heme carrier protein 1	HCP1	Putative transporter that traffics heme across the membrane by an unknown mechanism	Enterocyte (apical membrane) Hepatocyte Kidney cells
Heme oxygenase		An enzyme that disassembles heme to liberate iron	Enterocyte (microsomal fraction) Macrophages
Ferroportin 1 (Iron regulatory protein 1)	FPN 1 Ireg1 MTP1	Transmembrane Fe ²⁺ transporter (exporter)	Enterocyte (basolateral membrane) Macrophages
Hephaestin	Hp	Membrane-bound multicopper ferroxidase, similar to plasma ceruloplasmin, which oxidizes Fe ²⁺ to Fe ³⁺ to load it onto transferrin Maintenance of cell-surface localization of ferroportin	Hepatocytes Enterocyte (basolateral) Macrophage Hepatocyte?
Transferrin	Tf	Plasma Fe ³⁺ binding protein Ligand for transferrin receptors 1 and 2	Plasma
Transferrin receptor 1	TfR1	Cellular uptake of transferrin bound iron	Ubiquitously expressed
Transferrin receptor 2	TfR2	Sensor for diferric transferrin; regulates hepcidin expression; may participate in a signaling complex with HFE	Enterocyte Hepatocyte Erythroblast
Mitoferrin	SLC25A37	Mitochondrial iron importer that plays a critical role in supplying iron to ferrochelatase for insertion in protoporphyrin IX to form heme	Erythroblast (mitochondria)
Ferritin	Ft	Iron storage protein (H and L chains) Ferroxidase activity (H chain)	Enterocyte Erythroblast Macrophage Hepatocyte Myocytes and cardiomyocytes
Hemosiderin		Iron storage protein; breakdown product of ferritin that occurs when iron levels are high	Macrophage (lysosomes) Hepatocytes (lysosomes)
Heme exporters	LFLVCR* Bcrp/Abcg2** Abcb6***	ATP-independent heme export at the cell membrane* ATP-dependent heme export at the cell membrane** and mitochondrial membrane***	Erythroblast* Ubiquitously expressed***
HFE	HFE	Regulates hepcidin expression, mechanism uncertain; may participate in a signaling complex with TfR2; interacts with TfR1 & β -2-microglobulin	Enterocyte Macrophage Hepatocyte
Hemojuvelin Lipocalin 2	HFE2	Acts as a BMP co-receptor to stimulate hepcidin transcription Mediates a siderophore-like iron uptake pathway. Its an innate immune response to bacterial infection by sequestering iron, but its physiologic role in iron absorption is not fully worked out	Hepatocytes Enterocytes (apical membrane) Macrophages Adipocyte
Hepcidin	HEP HAMP LEAP1	Iron regulatory hormones, binds ferroportin to cause its internalization and degradation	Hepatocytes Adipocytes (low secretion) Enterocytes?
Erythropoietin	EPO	Upregulates the expression ferroportin in macrophages, TfR1 in erythroblasts, and DMT1 and hephaestin in enterocytes Downregulates hepcidin expression in hepatocytes and DMT1 expression in macrophages	Kidney (interstitial peritubular cells) Hepatocytes (low secretion)

BMP: Bone morphogenetic protein.

is unknown. In addition, it is not yet known whether heme carrier protein 1 has physiological roles in tissues other than the intestine. The protein is also expressed in the kidneys and liver, which suggests that it may act at those sites. It might, for example, scavenge free heme or mediate cellular uptake of heme from its circulating carrier protein, hemopexin^[9].

Once inside the intestinal epithelial cell, iron may

either remains in the cell for use or storage (this iron is never absorbed into the body; rather, it is lost when enterocytes senesce and are sloughed into the gut lumen) or exported across the basolateral membrane of the enterocyte into the circulation (absorbed iron). Ferroportin 1 is the only putative iron exporter identified to date. Ferrous iron once exported across the basal membrane by ferroportin 1, is then oxidized

by a multi-copper oxidase protein called hephaestin (an enzymatic protein similar to plasma ceruloplasmin) before being bound by plasma transferrin. Ferroportin 1 is also the putative iron exporter in macrophages and hepatocytes (Figure 2)^[3,4].

The absorption of iron is dependent on the body's iron stores, hypoxia and rate of erythropoiesis. Two models have been proposed to explain how the absorption of iron is regulated: the crypt programming model and the hepcidin model.

The crypt programming model: This model proposes that enterocytes in the crypts of the duodenum take up iron from the plasma. The intracellular iron level of the crypt cells corresponds to the body's iron stores, which in turn determines the amount of iron absorbed from the gut lumen, as these crypt cells migrate upwards to become absorptive cells at the brush border. The crypt cells express both transferrin receptor 1 (TfR1) and TfR2, which mediate the cellular uptake of transferrin-bound iron from plasma^[3,5].

TfR1 is expressed ubiquitously and transferrin mediated iron uptake is thought to occur in most cell types. HFE, an MHC-class 1-like molecule that interacts with $\beta 2$ -microglobulin and forms a complex with TfR1, is highly expressed in crypt cells. Its role in the regulation of TfR1-mediated transferrin-bound iron uptake remains unclear, but it seems to enhance transferrin-bound iron uptake from the plasma into crypt cells *via* TfR1, and may also inhibit the release of iron from the cell *via* ferroportin 1. In contrast, TfR2 is restricted to hepatocytes, duodenal crypt cells and erythroid cells, which suggests a more specialized role in iron metabolism. The intracellular iron concentration controls the interaction of cytosolic iron regulatory proteins (IRPs) 1 and 2 with iron regulatory elements (IREs; which act as iron sensors in mammalian cells and regulate translation or stability of mRNA-encoding proteins) in the 3' and 5' regions of different mRNA molecules. In the absence of iron, IRP1 binds to IREs of TfR1, DMT-1, and ferroportin 1 mRNA, the transcript is stabilized, translation proceeds, and the proteins are synthesized. Thus, a high IRP binding activity reflects low body iron stores and results in upregulation of these proteins in the duodenum and increased dietary iron absorption. When IRPs bind to IRE of ferritin mRNA, translation of the transcript is blocked and synthesis is halted. Thus, ferritin levels are regulated reciprocally - being increased in iron-replete states and decreased in iron-deplete states^[3].

The hepcidin model: Liver hepcidin is a 25-amino-acid cysteine-rich peptide with antimicrobial properties, which is regulated by a number of factors such as liver iron levels, inflammation, hypoxia and anemia. The hepcidin model proposes that hepcidin is secreted into the blood and interacts with villous enterocytes to regulate the rate of iron absorption, by controlling

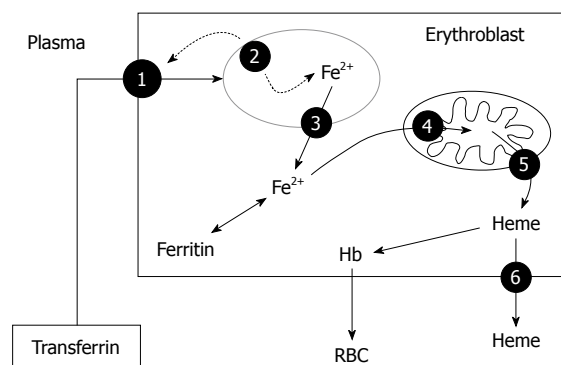

Figure 3 Main pathways of iron utilization by erythroblasts in mammals. 1: TfR1; 2: Diferric-transferrin-TfR1 complex; 3: Natural resistance macrophage protein (NRAMP-1); 4: Mitoferrin; 5: Mitochondrial heme exporter (Abcb6); 6: Heme exporter (FLVCR, Bcrp/Abcg2) (for details see Table 1).

the expression of ferroportin 1 at their basolateral membranes. The binding of hepcidin to ferroportin 1 results in internalization of ferroportin 1 and loss of its function. Ferroportin 1 molecules present in macrophages and liver are also targets for hepcidin. Thus, it is hypothesized that when hepcidin levels are increased in iron overload (by the uptake of transferrin bound iron *via* TfR1/HFE and TfR2) or inflammation (*via* IL-6), iron release from intestinal crypt cells, liver and macrophages is reduced. In contrast, when hepcidin levels are reduced, as in iron deficiency (ID), anemia or hypoxia, it is likely that ferroportin 1 expression and iron release from intestinal cells, liver and cells of reticuloendothelial system is increased^[10]. In contrast, a mutation in the *ferroportin 1* gene is responsible for type IV hemochromatosis.

There is evidence to support both models and it is possible that both control mechanisms may contribute to the regulation of iron absorption. In this regard, there is emerging evidence that hepcidin may act directly on mature villous enterocytes rather than crypt enterocytes. There are several situations (e.g. acute phase response) when iron absorption can be modulated more rapidly (within hours) than can be accounted for *via* the mechanism that involves the programming and maturation of crypt enterocytes (lag time of days)^[5].

Iron distribution

Iron released into the circulation binds to transferrin and is transported to sites of use and storage. Transferrin has two binding sites, binding one iron atom each (thus three forms can be found in plasma: apo-transferrin which contains no iron, monoferric-transferrin and diferric-transferrin). About 30%-40% of these sites are occupied under normal physiological conditions. Thus, transferrin-bound iron is about 4 mg, but this is the most important dynamic iron pool^[11]. Transferrin-bound iron enters target cells - mainly erythroid cells, but also immune and hepatic cells - through a process of receptor-mediated endocytosis (Figure 3). As diferric-

transferrin has a much higher affinity for TfR than does monoferric-transferrin, it binds to the TfR at the plasma membrane, and patches of cell-surface membrane that carry receptor-ligand complexes invaginate to form clathrin-coated endosomes (siderosomes)^[11]. After clathrin is removed, the siderosomes become acidified through an ATP-dependent proton influx, which leads to conformational changes in transferrin and TfR1, and promotes iron release of Fe^{3+} from transferrin. Fe^{3+} is then reduced to Fe^{2+} by a ferrireductase and transported to the cytoplasm through the DMT-1, whereas the TfR is recycled to the cell membrane and transferrin shed back to the circulation^[3,12] (Figure 3). Production of hemoglobin by the erythron accounts for most iron use. High-level expression of TfR1 in erythroid precursors ensures the uptake of iron into this compartment. To make heme, iron must again cross an ion-impermeable membrane to enter the mitochondria. The mitochondrial iron importer was recently identified as mitoferrin (also known as SLC25A37), a transmembrane protein that plays a crucial role in supplying iron to ferrochelatase for insertion into protoporphyrin IX to form heme^[12] (Figure 3). Recently, different human heme exporters have been identified in erythroblasts, and their activity seems to be essential for erythropoiesis, by transferring heme from the mitochondria to cytosol (Abcb6) and removing the excess of heme from the erythroid cells (FLVCR, Bcrp/Abcg2) (Figure 3).

In the erythroid precursors, the expression of TfR1, DMT-1 and ferritin are regulated reciprocally through IRP1 and IRP2, which act on the IRE present in their RNA. Thus, when increased iron uptake is needed, the expression of TfR1 and DMT-1 is increased, whereas the synthesis of ferritin is halted^[3]. In addition, there is evidence that EPO activates IRP-1, leading to upregulation of TfR1 expression in the erythroid precursors, which is maintained along with the differentiation process, and DMT-1 and hephaestin gene expression in the duodenum^[13]. To date, three patients have been reported with DMT-1 mutations that cause microcytic hypochromic anemia, as a result of decreased erythroid iron utilization, but lead to increased liver iron storage^[14].

A truncated form of the TfR can be detected in human serum. The serum concentration of this soluble form of TfR (sTfR; normal median concentration: 1.2-3.0 mg/L, depending on the assessment kit used) is proportional to the total amount of surface TfR. Increased sTfR concentrations indicate ID even during the anemia of chronic disease (ACD), as well as increased erythropoietic activity without ID, whereas lower sTfR concentrations may reflect decreased numbers of erythroid progenitors^[3,15].

Iron storage

Hemoglobin iron has substantial turnover, as senescent erythrocytes undergo phagocytosis by RES macrophages. Within the phagocytic vesicles, heme is metabolized by

Figure 4 Main pathways of iron storage and exportation by macrophages in mammals. 1: NRAMP-1; 2: TfR1; 3: DMT-1; 4: Others: others: bacteria, lactoferrin, hemoglobin-haptoglobin, heme-hemopexin; 5: Ferroportin (Ireg-1); 6: Hephaestin (for details see Table 1).

heme oxygenase and the released iron is exported to the cytoplasm through the action of natural resistance-associated macrophage protein-1, a transport protein similar to DMT-1 (Figure 4). Macrophages can also obtain iron from bacteria and apoptotic cells, from plasma through the action of DMT-1 and TfR1, and from other sources (Figure 4). Within the cell, iron can be stored in two forms: in the cytosol as ferritin and, after breakdown of ferritin within the lysosomes, as hemosiderin. Hemosiderin represents a very small fraction of normal body iron stores, mostly in macrophages, but increases dramatically in iron overload^[11]. Iron export from macrophages to transferrin is accomplished primarily by ferroportin 1, the same iron-export protein expressed in duodenal enterocytes, and hephaestin^[3] (Figure 4). The amount of iron required for daily production of 300 billion RBCs (20-30 mg) is provided mostly by recycling iron by macrophages^[4]. Importantly, iron storage at the macrophages is safe, as it does not lead to oxidative damage. EPO reduces iron retention in macrophages by decreasing DMT-1 and increasing ferroportin 1 expression^[16].

The liver is the other main storage organ for iron. In iron overload, free radical formation and generation of lipid peroxidation products may result in progressive tissue injury and eventually cirrhosis or hepatocellular carcinoma^[17]. Iron is sequestered in hepatocytes predominantly in the form of ferritin or hemosiderin. The uptake of transferrin-bound iron by the liver from plasma is mediated by TfR1 and TfR2 (Figure 5). In iron overload, TfR1 is downregulated in hepatocytes^[5]. TfR2 is expressed highly in human liver and is likely to play an important role in liver iron loading in iron overload states. Unlike TfR1, TfR2 lacks an IRE and thus is not regulated reciprocally in response to the level of plasma iron. Instead, TfR2 protein expression is regulated by transferrin saturation (TSAT), and is upregulated in iron overload. In normal and iron-loaded conditions, expression of TfR2 exceeds that of TfR1, which suggests that TfR2 plays an important role in hepatic iron loading in hemochromatosis^[5].

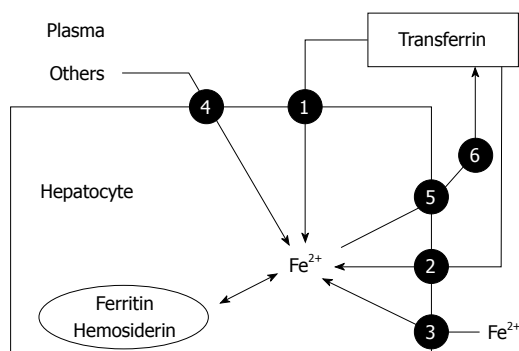

Figure 5 Main pathways of iron storage and exportation by hepatocytes in mammals. 1: TfR1; 2: TfR2; 3: DMT-1; 4: Others: hemoglobin, heme, ferritin; 5: Ferroportin (Ireg-1); 6: Ceruloplasmin (for details see Table 1).

In fact, a mutation in TfR2 is responsible for type 3 hemochromatosis^[14].

As transferrin becomes saturated in iron overload states, excess iron is also found as non-transferrin-bound iron is transported across the hepatocyte membrane *via* a carrier-mediated process consistent with DMT-1. The hepatocytes may also store iron from ferritin, hemoglobin-haptoglobin complexes, and heme-hemopexin complexes. In contrast, once again, ferroportin 1 is likely to be the only protein that mediates the transport of iron out of hepatocytes, which is then oxidized by ceruloplasmin and bound to transferrin^[3,4] (Figure 5).

Iron storage within cardiomyocytes is also of outstanding interest, as cardiac failure is the leading cause of death among patients with untreated hereditary hemochromatosis or transfusion-associated hemosiderosis^[3]. In cardiac cells, excess iron may result in oxidative stress and alteration of myocardial function because of DNA damage by hydrogen peroxide through the Fenton reaction^[3].

EFFECTS OF INFLAMMATION ON IRON HOMEOSTASIS AND ERYTHROPOIESIS

Anemia is a frequent complication of chronic inflammatory diseases (e.g. cancer, rheumatoid arthritis, inflammatory bowel diseases, and congestive heart failure), as well as sepsis and chronic renal failure. In addition to blood loss, hemolysis, hepatic or endocrine disorders, nutritional deficiencies, bone marrow infiltration (cancer cells), or vitamin consumption (bacteria), this anemia may be the result of activation of the immune system by the underlying process, and certain immune and inflammatory cytokines including tumor necrosis factor (TNF)- α , interferon (IFN)- γ , and IL-1, 6, 8 and 10^[18,19].

As for chronic inflammatory diseases (and sepsis), these inflammatory mediators lead to anemia through several of the following pathophysiological mechanisms^[19] (Figure 6): (1) decreased RBC half-life because of dyserythropoiesis, RBC damage and increased erythrophagocytosis (TNF- α); (2) EPO responses are inadequate for the degree of anemia in most, but not

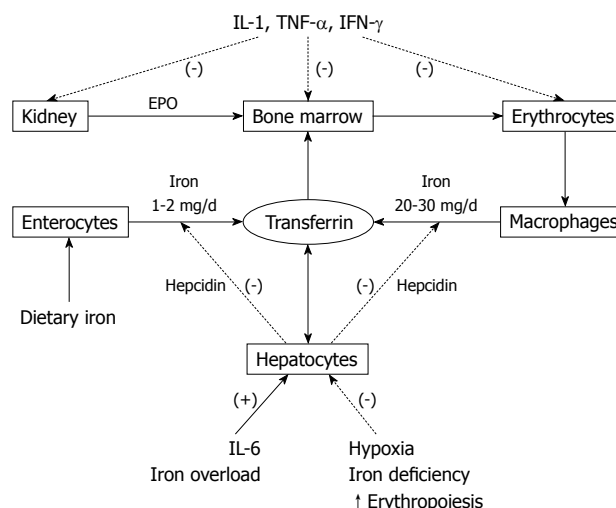

Figure 6 Effects of inflammation on erythropoiesis and iron homeostasis in mammals. (-): Negative effect; (+): Positive effect.

all (e.g. systemic-onset of juvenile chronic arthritis) (IL-1 and TNF- α)^[20]; (3) impaired responsiveness of erythroid cells to EPO (IFN- γ , IL-1, and TNF- α); (4) inhibited proliferation and differentiation of erythroid cells (IFN- γ , IL-1, TNF- α , and α -1-antitrypsin); and (5) pathological iron homeostasis caused by increased DMT-1 (IFN- γ) and TfR (IL-10) expression in macrophages, reduced ferroportin 1 expression (IFN- γ and IL-6-induced high hepcidin levels) in enterocytes (inhibition of iron absorption) and macrophages (inhibition of iron recirculation), and increased ferritin synthesis (TNF- α , IL-1, IL-6, IL-10) (increased iron storage). All these lead to hypoferremia through iron diversion to the RES [functional iron deficiency (FID) that is characterized by low serum iron and decreased TSAT], iron-restricted erythropoiesis, and mild-to-moderate anemia.

Thus, the immunological pathophysiology of ACD includes disturbances of iron homeostasis, impaired proliferation of erythroid progenitor cells, and a blunted EPO response to anemia^[19]. However, the pathophysiology of acute inflammation-related anemia (e.g. trauma or surgery) is somewhat different. In this setting, inflammatory responses are mediated mainly by IL-6 and IL-8 (with transient contribution of TNF- α and IL-1 in some visceral surgery, such as gastrointestinal or cardiac procedures), whereas IFN- γ plasma levels are undetectable or within the normal range^[21-23]. Therefore, in most of these conditions, the two major mechanisms that lead to anemia are perioperative or traumatic blood loss and blunted erythropoiesis caused by decreased iron availability (caused by IL-6-induced high hepcidin levels), whereas EPO levels are normal or near-to-normal^[24]. Finally, with persisting decreased iron absorption and/or chronic blood loss, ACD may evolve to ACD with true ID (ACD + ID).

On the other hand, it must be borne in mind that iron is not only required for erythropoiesis and oxidative metabolism. Cellular immune responses are also

dependent on the presence of iron, and specific defects in cell-mediated immunity have been described in detail, even in mild ID, including the impaired proliferation and function of lymphocytes and natural killer cells, and a depressed neutrophil respiratory burst^[25,26]. Thus, ID or FID may lead not only to a blunted erythropoiesis and chronic fatigue, but also to an inappropriate immune response. For this reason, systemic inflammatory response episodes last longer in critically ill patients with FID, and result in prolonged stay in the intensive care unit and increased morbidity^[27]. On the other hand, the effectiveness of the administration of iron sucrose, alone or in combination with EPO, has been assessed in a population of anemic, critically ill patients^[28]. Compared to those in the control group who only received folic acid, patients treated with iron sucrose experienced an amelioration of systemic inflammatory response [decreased C-reactive protein (CRP) levels]. These beneficial effects were not as evident in patients who received iron sucrose plus recombinant human EPO (rHuEPO), probably because of the persistence of FID caused by rHuEPO-enhanced erythropoietic activity.

LABORATORY ASSESMENT OF IRON STATUS

Under physiological conditions, there is a balance between iron absorption, iron transport and iron storage in the human body. However, ID and IDA are common conditions among medical, surgical and critically ill patients, and result from the interplay of three distinct risk factors: increased iron requirements [e.g. growth or use of erythropoiesis-stimulating agents (ESAs), pregnancy and post-bleeding recovery], limited external supply (e.g. malnutrition, malabsorption caused by inflammatory bowel disease, use of gastric antiacid agents, infection with *H. pylori*, even in the absence of significant bleeding), and increased blood loss (e.g. chronic gastrointestinal bleeding)^[28]. ID can be either absolute or functional. In absolute ID, iron stores are depleted; in FID, iron stores, although replete, cannot be mobilized as fast as necessary from the macrophages of the RES to the bone marrow. As stated above, FID occurs in anemia of inflammatory diseases because iron is trapped in the RES^[3,29].

Thus, laboratory tests for investigating ID fall into two categories: measurements providing evidence of iron depletion in the body, and measurements reflecting iron-deficient RBC production^[30] (Table 2). The appropriate combination of these laboratory tests will help to establish a correct diagnosis of anemia and ID status^[19].

ID without anemia

Normal hemoglobin level does not exclude ID, because individuals with normal body iron stores must lose a large amount of body iron before the hemoglobin falls

Table 2 Main laboratory tests for the diagnosis of anemia and iron deficiency

Laboratory test	Normal values, units	Conversion to SI units
Iron depletion in the body		
Serum iron	50-180 µg/dL	× 0.179 µmol/L
Transferrin	200-360 mg/dL	× 0.01 g/L
TSAT	20%-50%	
Ferritin	30-300 ng/mL	× 2.247 pmol/L
sTfR	0.76-1.76 mg/L	6.4-25.7 nmol/L
Ratio of sTfR to serum ferritin (sTfR/log ferritin)	< 1	
Iron deficient red cell production		
Hemoglobin	12-16 g/dL (female) 13-17 g/dL (male)	× 0.6206 mmol/L
MCV	80-100 fL	
RDW	11-15	
MCH	28-35 pg	
HYPO	< 5%	
CHr	28-35 pg	

TSAT: Transferrin saturation; sTfR: Soluble transferrin receptors; MCV: Mean corpuscular volume; RDW: Red cell distribution width; MCH: Mean corpuscular Hb; HYPO: Hypochromic red cells; CHr: Reticulocyte Hb content.

below the laboratory definition of anemia. According to WHO criteria, laboratory definition of anemia is Hb < 12 g/dL for female and < 13 g/dL for male. However, although we will refer to these values in the following paragraph, it is worth noting that WHO criteria have been challenged recently. Analysis of the large NHANES-III (the third US National Health and Nutrition Examination Survey) and Scripps-Kaiser databases has indicated that a hemoglobin concentration < 13.7 g/dL in a white man aged between 20 and 60 years would have only an approximately 5% chance of being a normal value. The corresponding value for female of all ages would be 12.2 g/dL^[31]. Should these new definitions of anemia be applied to our inflammatory bowel disease patient population, the prevalence of anemia would be higher than that reported in several previous studies.

In non-anemic patients, the most important clinical clue of ID is the symptom of chronic fatigue (iron is required for the enzymes involved in oxidative metabolism). However, it is of little screening value because clinicians rarely consider the presence of ID in patients who are not anemic, and therefore ID is invariably diagnosed in the laboratory^[30]. A normal hemoglobin level with a mean corpuscular hemoglobin (MCH) in the lower limit of normality (normal range: 28-35 pg), or an increased RBC distribution width (RDW, normal range: 11-15) point to mild ID without anemia, but the main laboratory finding is low ferritin level. Although ferritin is an intracellular iron storage protein, small amounts of ferritin are secreted into the circulation and can be measured in the laboratory, and 1 ng/mL serum ferritin corresponds to approximately 8 mg of stored iron. Thus, measurement of ferritin

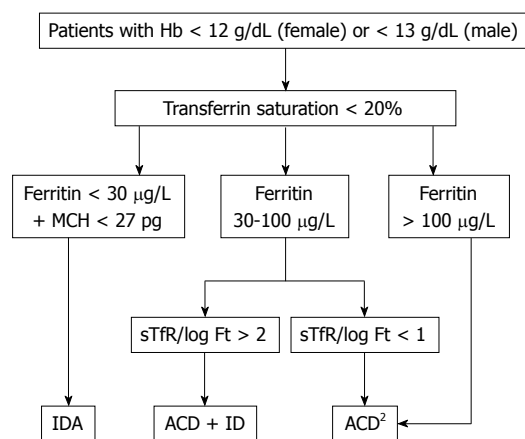

Figure 7 A simplified algorithm for the diagnosis of IDA (modified from Weiss *et al*^[19]).

provides the aID can be defined by a ferritin level < 30 ng/mL in the absence of inflammation (normal serum concentrations of CRP: < 0.5 mg/dL) (true ID). In the presence of inflammation, a normal ferritin level (acute phase reactant) does not exclude ID, and TSAT also should be measured. As transferrin is the only iron-binding protein involved in iron transport, TSAT reflects iron availability for the bone marrow. Thus, in the presence of inflammation, ID should be better defined by normal ferritin concentrations and low TSAT (FID). FID may also occur in response to the therapeutic use of ESAs, such as epoetin or darbopoetin, which place a significant demand on iron stores that may surpass the iron-release capacity of the RES^[32].

IDA

Patients should be considered to suffer from IDA when they presented with low Hb (male < 13 g/dL and female < 12 g/dL), TSAT (< 20%) and ferritin concentrations (< 30 ng/mL) but no signs of inflammation^[30]. The MCH rather than mean corpuscular volume (MCV) has become the most important RBC marker for detecting ID in circulating RBCs (Figure 7). MCV is a reliable and widely available measurement but is a relatively late indicator in patients who are not actively bleeding. In addition, patients may present with IDA and without microcytosis, with coexisting vitamin B12 or folate deficiency. sTfR levels are usually high or very high, but they are not usually required for the diagnosis of uncomplicated IDA.

ACD

Patients should be considered to suffer from ACD when they have: (1) evidence of chronic inflammation (high CRP level); (2) hemoglobin concentration < 13 g/dL for male and < 12 g/dL for female; and (3) low TSAT < 20%, but normal or increased serum ferritin concentration (> 100 ng/mL) or low serum ferritin concentration (30-100 ng/mL), and an sTfR/log ferritin ratio < 1^[19,33-35] (Figure 7). ACD, as well as FID, are frequent among

patients with inflammatory disease without apparent blood loss (e.g. rheumatoid arthritis, renal failure or chronic hepatitis).

On the other hand, although ACD is typically mild to moderate, and RBCs may not show any stigmata of ID (normochromic, normocytic anemia), the underlying iron etiology is evident: macrophages that normally recycle iron are found to sequester it, intestinal iron absorption is interrupted, and erythroid precursors respond very rapidly when iron-transferrin is made available, especially by the administration of iv iron preparations. Thus, it can be speculated that the normocytic RBCs result from the combination of iron insufficiency and an as-yet-unexplained tendency to macrocytosis (e.g. alterations in folate or B12 metabolism in response to inflammation)^[12].

ACD + ID

Patients should be considered to have ACD + ID when they have: (1) chronic inflammation (high CRP level); (2) hemoglobin concentration < 13 g/dL for male and < 12 g/dL for female; and (3) low TSAT < 20%, serum ferritin concentration > 30 and < 100 ng/mL, and an sTfR/log ferritin ratio > 2^[19,33-35] (Figure 7). This type of anemia is more frequent in patients with inflammatory diseases and chronic blood losses (e.g. inflammatory bowel disease). There are two important hematological indices that may also help in the diagnosis of ACD + ID: reticulocyte hemoglobin content (CHr) and hypochromic red blood cells (HYPO). In non-ferropenic patients, the 2.5 percentile values were 28 pg for CHr and 5% for HYPO^[15]. However, these hematological indices are only available in specific hematological analyzers. The Advia 120 hematology analyzer determines CHr and RBC hemoglobin content (≥ 27 pg), whereas the Sysmex XE-2100 hematology analyzer determines RET-Y, which can be considered as the reticulocyte hemoglobin equivalent, as well as RBC-Y, which can be considered as the RBC hemoglobin equivalent^[36,37]. These hematological indices (CHr and HYPO) are direct indicators of FID, in contrast to the majority of biochemical markers, which measure FID indirectly *via* iron-deficient erythropoiesis and demonstrate weaknesses in the diagnosis of FID as defined by hematological indices^[15]. New hematological indices are being developed for other hematological analyzers (e.g. Beckman-Coulter LH 750) and their clinical utility in the diagnosis of ID will be evaluated in the near future.

Although hepcidin affects iron traffic in ACD and ACD + ID, individuals suffering from ACD + ID have significantly lower hepcidin levels than ACD subjects, and ACD + ID individuals, in contrast to ACD subjects, are able to absorb some dietary iron from the gut and to mobilize some iron from macrophages. Thus, hepcidin determination may also aid differentiation between ACD and ACD + ID and in selecting appropriate therapy for these patients^[33].

CONCLUSION

Iron is an essential micronutrient, as it is required for an adequate erythropoietic function, oxidative metabolism and cellular immune response. Although the absorption of dietary iron (1-2 mg/d) is regulated tightly, it is just balanced with losses. Therefore, internal turnover of iron is essential to meet the requirements for erythropoiesis (20-30 mg/d). Hepcidin, which is primarily made in hepatocytes in response to liver iron levels, inflammation, hypoxia and anemia, is the main iron regulatory hormone for iron absorption and recirculation. Increased iron requirements, limited external supply, and increased blood loss may lead to ID and IDA. During inflammation, the excess of hepcidin decreases iron absorption and prevents iron recycling, which results in hypoferrremia and iron-restricted erythropoiesis, despite normal iron stores, and finally, in ACD, which can later evolve to ACD + ID. An appropriate combination of laboratory tests that provides evidence of iron depletion or reflects iron-deficient RBC production will help to establish a correct diagnosis of ID status and anemia^[38].

Abstract

Most anemia is related to the digestive system by dietary deficiency, malabsorption, or chronic bleeding. We review the World Health Organization definition of anemia, its morphological classification (microcytic, macrocytic and normocytic) and pathogenic classification (regenerative and hypo regenerative), and integration of these classifications. Interpretation of laboratory tests is included, from the simplest (blood count, routine biochemistry) to the more specific (iron metabolism, vitamin B12, folic acid, reticulocytes, erythropoietin, bone marrow examination and Schilling test). In the text and various algorithms, we propose a hierarchical and logical way to reach a diagnosis as quickly as possible, by properly managing the medical interview, physical examination, appropriate laboratory tests, bone marrow examination, and other complementary tests. The prevalence is emphasized in all sections so that the gastroenterologist can direct the diagnosis to the most common diseases, although the tables also include rare diseases. Digestive diseases potentially causing anemia have been studied in preference, but other causes of anemia have been included in the text and tables. Primitive hematological diseases that cause anemia are only listed, but are not discussed in depth. The last section is dedicated to simplifying all items discussed above, using practical rules to guide diagnosis and medical care with the greatest economy of resources and time.

INTRODUCTION

Erythrocytes and the digestive system are linked closely from the very beginning of life. The yolk sack is the origin of the first generation of erythrocyte precursors. Yolk-sac-derived progenitor cells may seed the developing liver *via* the circulation and produce mature red blood cells that are required to meet the metabolic needs of the fetus. By week 8, liver-derived red cells are evident and the liver is the only source of erythrocytes until the 18th week of gestation. Afterwards, the spleen and bone marrow take over, but a small percentage of hepatic erythropoiesis remains until the postnatal week 6.

In adult life, the esophagus, stomach, bowel and liver are involved in the pathogenesis of different types of anemia caused by nutritional deficiency, bleeding or chronic inflammation.

Several diseases of the esophagus may produce chronic or acute bleeding: varicose veins, diverticula, diaphragmatic hernia, tumors, ulcers, esophagitis and Mallory-Weiss syndrome. The stomach plays a decisive role in the protection of vitamin B12 until it is absorbed in the final portion of the ileum, and contributes to an optimum absorption of iron reducing Fe^{3+} to Fe^{2+} . The stomach also may be a source of bleeding in peptic ulcer, gastritis and tumors, and treatment with acetylsalicylic acid and nonsteroidal anti-inflammatory drugs. The absorption of iron is a sophisticated and specialized process located mostly in the duodenum. The integrity of the small-intestinal mucosa is essential for folate absorption. Vitamin B12 absorption takes place chiefly in the ileum. In consequence, several gastrointestinal diseases, hereditary or acquired, including surgical resection, may produce nutritional deficiency anemia. Small-bowel inflammatory disease is a widespread cause of chronic disease anemia. Chronic bleeding is a crucial

sign in the diagnosis of malignant and benign lesions (such as diverticula) in the colon and rectum.

Splenomegaly is a relatively common cause of chronic hemolysis, and Zieve's syndrome is an infrequent cause of acute hemolytic crisis. Last, but not least, the liver plays an essential role in the control of iron metabolism through the hepcidin pathway, and accounts for most vitamin B12, folate and iron stores.

The links between anemia and digestive system are strong and multiple. Because of this, hematologist and the specialist in digestive system should work together to acquire a profound know of common pathogenic processes.

CONCEPT OF ANEMIA

Anemia is defined as a lower than normal hemoglobin concentration. Low hematocrit is a subrogate value for anemia, but it is not measured directly by the hematological analyzer. Instead, it is calculated from hemoglobin and other parameters. The erythrocyte count may be misleading in the evaluation of anemia. In fact, in some cases of microcytic anemia, such as thalassemia, there is usually an elevated erythrocyte count (spurious polycythemia).

In order to make a generalized approach to the diagnosis of anemia, the World Health Organization (WHO) has established a reference range for normal blood hemoglobin concentration, depending on age and sex^[1]. According to this criterion, anemia is present if the blood concentration of hemoglobin falls below 130 g/L in men or 120 g/L in women. This rule does not apply to infants, children and pregnant women, who have their own tables of lower limits of hemoglobin concentration. The WHO criterion has been accepted widely for diagnosis and publication, but its universal application has been questioned mainly because of racial differences. Beutler has proposed a lower limit of hemoglobin (1-2 g less) in African Americans than in Caucasians. The reference range of hemoglobin concentration in blood may vary depending on the population analyzed, age, sex, environmental conditions and food habits^[2,3].

Anemia causes tissue hypoxia and triggers compensating mechanisms. Both processes together produce the signs and symptoms characteristics of anemic syndrome. Patients with anemia may present with fatigue, dizziness and dyspnea; however, mild anemia shows few clinical signs or symptoms. The signs of anemia include pallor of the conjunctivae, face, nail beds and palmar creases, although the absence of pallor does not rule out anemia^[4].

Anemia is one of the most frequent causes of medical visits because of the high incidence in children, young women and elderly people, especially if malnutrition is present. Moreover, anemia is one of the leading signs in many diseases or is the first evidence of disease observed in routine blood cell enumeration. Anemia is unusually prevalent in developing countries because of malnutrition, and genetic, parasitic or infectious

diseases^[5,6]. The prevalence of anemia varies greatly, from 2.9% to 61%, depending on population, age, sex, and normal limits of hemoglobin used by the author^[7].

The most frequent cause of chronic anemia is gastrointestinal pathology, and this explains why patients with anemia are often sent for consultation to a gastroenterological specialist^[8].

Anemia is a syndrome, not a disease, and therefore, the etiology must always be investigated and therapy must be directed mainly to the causal disease, and not only to restoring a normal hemoglobin concentration. In a patient with anemia, whose clinical and laboratory data are insufficient to find the cause, examination of the digestive system is a priority for two reasons. The first one is the high frequency of anemia in bowel disease, and the second is the opportunity to diagnose a malignant disease before it is too advanced^[9-11].

CLASSIFICATION

Anemia can be classified from three points of view: pathogenesis, red cell morphology, and clinical presentation. All are important to guide the diagnosis. Pathogenic mechanisms involved in the production of anemia are very simple: inadequate production and loss of erythrocytes as a result of bleeding or hemolysis. Based on these pathogenic mechanisms, anemia can be divided into two types. (1) Hypo-regenerative: when bone marrow production is decreased as a result of impaired function, decreased number of precursor cells, reduced bone marrow infiltration, or lack of nutrients; (2) Regenerative: when bone marrow responds appropriately to a low erythrocyte mass by increasing production of erythrocytes.

In practice, classification based on basic parameters of red cell morphology such as mean corpuscular volume (MCV), allows for a quicker diagnostic approach.

Anemia also can be classified according to the form of clinical presentation as acute (usually bleeding or hemolysis) or chronic.

Anemia can be classified as microcytic, normocytic or macrocytic, depending on MCV. As stated above, it can be hypo-regenerative or regenerative, which depends on the number of reticulocytes. Using both, the list of possible diagnoses in the individual patient is reduced considerably. Both parameters can be supplied routinely by most of the automatic hematological cell counters.

PATHOGENIC CLASSIFICATION

The reticulocyte count is useful to distinguish anemia in which there is an appropriate bone marrow response from that in which there is a decrease in the production of erythrocytes. The concentration of reticulocytes reports on the bone marrow response to anemia. This approach is especially useful when MCV is normal.

A decrease in hemoglobin stimulates erythropoiesis through an increase in circulating erythropoietin. Therefore, when the bone marrow shows a normal

regenerative capacity, there should be an inverse relationship between the decrease in hemoglobin and the increased number of reticulocytes (regenerative anemia). The expected reticulocyte count is much higher than normal to compensate for the anemia. However, when the hemoglobin decreases and the bone marrow does not have regenerative capacity, the expected increase in reticulocytes fails, despite the increase in erythropoietin plasma level (hypo-regenerative anemia)^[12].

The reticulocyte count is expressed as a proportion of the number of erythrocytes, which must be corrected for anemia, and for increased lifespan of reticulocytes in peripheral blood. Most hematological analyzers provide directly the number of reticulocytes per mm³, which is a better estimation of erythropoietic activity than a percentage. However, the absolute reticulocyte enumeration per mm³ overestimates the actual activity of erythropoiesis, since reticulocytes are released earlier and remain longer in the circulating blood. To avoid these confounding events, it is recommended to calculate the reticulocyte index.

The next step is the calculation of reticulocyte production index (RPI):

$$\text{RPI} = \frac{\text{corrected reticulocyte count (\%)} \times (\text{haematocrit observed/normal haematocrit})}{\text{F (reticulocyte maturation times in vivo)}}$$

RPI in a healthy person is 1. An RPI > 3 in a patient with anemia suggests an appropriate bone marrow response, and therefore, regenerative anemia^[13,14]. Nevertheless, the best estimate of the actual erythropoietic activity^[15], and easiest to calculate, is to divide by two the number of reticulocytes per mm³.

Regenerative anemia

This is characterized by increased generation of erythropoietin in response to decreased hemoglobin concentration, and generally reflects a loss of erythrocytes, due to bleeding or hemolysis (Table 1). In both cases, there is a typical increase in reticulocytes. The bleeding can be intense, with a sharp drop of hematocrit and obvious clinical signs; or of small intensity and chronic, with progressive decrease in hematocrit and MCV, which may go unnoticed. Over time, chronic hemorrhagic anemia becomes hypo-regenerative and microcytic because of depletion of iron stores.

Hemolysis, can be acute (usually intravascular) or chronic (usually extravascular). Acute hemolysis is characterized by sudden episodes with very obvious clinical signs (fever, chills, back pain, dark urine) and typical laboratory data (hemoglobinuria and reduced plasma haptoglobin)^[16].

Hypo-regenerative anemia

This is caused by alteration of bone marrow progenitor cells, which can be located at different stages of differentiation and maturation. The impairment of pluripotent stem cells usually produces pancytopenia (anemia, leukopenia and thrombocytopenia). Pancytopenia may be caused by intrinsic [bone marrow aplasia, leukemia,

Table 1 Etiopathogenic classification of anemia

Regenerative anemia
Acute or chronic bleeding
Hemolytic anemia
Hereditary (hemoglobinopathy, enzymopathy, membrane-cytoskeletal defects)
Acquired (autoimmune, mechanical destruction, toxic-metabolic, drugs, infectious, PNH, hypersplenism)
Hypo-regenerative anemia
Bone marrow failure caused by stem cell pathology
Quantitative disorder
Selective: erythroblastopenia (pure red cell aplasia)
Global: aplastic anemia
Qualitative disorder (dysmyelopoiesis)
Inherited: hereditary dyserythropoiesis
Acquired: myelodysplasia
Bone marrow infiltration
Leukemia, lymphoma, multiple myeloma
Solid tumors
Myelofibrosis
Thesaurismosis (Gaucher disease)
Inflammatory chronic diseases, microorganisms (Histoplasma, HIV)
Drugs, hypothyroidism, uremia
Erythropoietic factors deficiency
Iron
IDA
ACD
Cobalamin and folate
Megaloblastic anemia
Hormones: erythropoietin, thyroid hormones, androgens, steroids

PNH: Paroxysmal nocturnal hemoglobinuria; IDA: Iron-deficiency anemia; ACD: Anemia chronic disease.

myelodysplastic syndrome (MDS) or myelofibrosis] or extrinsic (metastasis, Gaucher disease and other thesaurismosis, tuberculosis, histoplasmosis, viral and parasitic infections). All of them are capable of displacing normal hematopoiesis or changing the microenvironment necessary for regeneration, differentiation and proliferation of stem cells^[16,17].

Less frequently, progenitor cells committed to the erythroid line (burst-forming unit-erythroid and colony-forming unit-erythroid) are affected selectively, and the result is pure red cell aplasia. When progenitor red cells are impaired selectively, bone marrow erythroblasts are much reduced or absent, while other hematological cellular lines remain normal. Pure red cell aplasia, hereditary or acquired, is very rare. However, a qualitative alteration of the red cell line (dyserythropoiesis) is often seen in clinical practice. In contrast to pure red cell aplasia, the bone marrow is rich in erythroblasts in patients with dyserythropoiesis. In these cases, the erythropoiesis is abnormal morphologically and functionally. Erythroblastopenia as dyserythropoiesis may have a hereditary or acquired origin. The former is extremely rare. Thymoma is the most common cause of acquired pure red cell aplasia. MDS is the most common cause of acquired dyserythropoiesis. In MDS patients, the lesion is located at the level of very primitive multipotent progenitors, and thus, the morphological and functional alterations can affect all blood cell lines (erythrocyte, granulocyte-monocyte and megakaryocyte)^[18-20].

Table 2 Morphological classification

Microcytic anemia (MCV < 82 fL)
IDA
Thalassemia
Non thalassemic conditions associated with microcytosis
ACD (e.g. rheumatoid arthritis, Hodgkin's lymphoma, chronic infection, neoplasia)
Sideroblastic anemia (e.g. hereditary, lead poisoning)
Normocytic anemia (MCV = 82-98 fL)
Nutritional anemia (iron deficiency, cobalamin y/o folate)
Anemia of renal insufficiency
Hemolytic anemia
Red cell intrinsic causes: membranopathy, enzymopathy, hemoglobinopathy
Red cell extrinsic causes: immune-mediated, microangiopathic, associated with infection, chemical agent (spider venoms), metabolic
ACD
Primary bone marrow disorder
Causes that are intrinsic to hematopoietic stem cells: bone marrow aplasia (idiopathic, PNH, Fanconi syndrome), pure red cell aplasia (acquired, congenital, Diamond-Blackfan syndrome), myelodysplastic syndrome
Extrinsic causes: drugs, toxins, radiation, viruses, immune-mediated, bone marrow infiltration (metastatic and lymphoma)
Macrocytic anemia (MCV > 98 fL)
Drugs (hydroxyurea, zidovudine, methotrexate)
Nutritional (vitamin B12 and folate deficiency)
Drug-induced hemolytic anemia
Dyserythropoiesis, myelodysplastic syndrome, clonal hematologic disorder
Hereditary hematologic disorders
Mild macrocytosis (MCV = 100-110 fL)
Reticulocytes
Excess alcohol intake, liver disease, smoking
Hypothyroidism, Waldenström's macroglobulinemia
Copper deficiency, bone marrow aplasia, erythroidopenic anemia
Down syndrome
Chronic obstructive pulmonary disease

MCV: Mean corpuscular volume.

Anemia caused by nutritional deficiencies or decreased production of erythropoietin is much more frequent than that caused by a primitive defect in bone marrow.

MORPHOLOGICAL CLASSIFICATION

Pathogenic classification is very important to understand the mechanisms involved in the genesis of anemia (Table 2). However, in daily clinical practice, it is more useful to start with the analytical parameters of the hemogram. MCV allows us to classify anemia as microcytic (MCV < 82 fL), normocytic (MCV = 82-98 fL) and macrocytic (MCV > 98 fL)^[21,22].

MCV has a relationship with mean corpuscular hemoglobin (MCH), which reports on the mean hemoglobin per erythrocyte expressed in picograms (normal range: 27-32 pg). Therefore, MCV and MCH decrease (microcytic, hypochromic anemia) or increase (macrocytic, hyperchromic anemia) jointly. The MCH concentration (MCHC) reports on the average concentration of hemoglobin in each erythrocyte expressed as a percentage (normal range: 32%-36%), and its variations are very small, even in the presence of hypochromia. MCHC increases only in a few rare

Table 3 Classification of anemia as RDW and MCV

	↓ MCV	Normal MCV	↑ MCV
Normal RDW	β-thalassemia	Normocytic	Bone marrow aplasia
Increased RDW	α-thalassemia Iron deficiency	Inflammatory anemia Hypothyroidism	Megaloblastic anemia

RDW: Red blood cell distribution width.

diseases such as hereditary spherocytosis, and therefore, its practical utility is scarce.

It should always be borne in mind that MCV is an average value and therefore does not provide information about the homogeneity of the erythrocyte population. To resolve this problem, hematological analyzers provide the erythrocyte distribution curve, with an index of dispersion: red blood cell distribution width (RDW) (normal range: 10%-14%). RDW is a rough indicator of anisocytosis and is an essential complement to MCV (Table 3).

Microcytic anemia

Faced with microcytic anemia, the three main diagnostic possibilities include iron deficiency anemia (IDA), thalassemia, and anemia of chronic disorders (ACD). A fourth possibility, sideroblastic anemia, is so rare that is not considered in the initial diagnosis, unless there is a history of contact with lead (Figure 1).

Iron deficiency is the most common cause of anemia, so the first step in diagnosis should be directed toward confirmation or exclusion of IDA. Serum ferritin allows us to confirm the diagnosis. Despite ferritin being an acute phase reactant, the diagnosis of IDA is unlikely with normal or elevated ferritin levels. Other parameters of iron metabolism (serum iron, total transport capacity of iron, and transferrin) are unable to distinguish with certainty IDA from ACD^[23].

IDA occurs in 2%-5% of adult men and postmenopausal women in the developed world^[24,25], and is a common cause of referral to a gastroenterology clinic 4%-13%^[26].

It is important to note that microcytosis without anemia is characteristic of thalassemia trait, but also of polycythemia associated with iron deficiency^[27].

The simple analysis of different parameters provided by the hematological analyzer gives a diagnosis of microcytic anemia. RDW helps to distinguish thalassemia from IDA. RDW is normal in thalassemia; on the contrary, microcytic anemia with RDW > 15 is probably IDA.

In recent years, the importance of serum soluble transferrin receptor has been recognized in differential diagnosis of IDA and ACD. Serum soluble transferrin receptor is increased in IDA, without interference in case ACD is present^[28,29]. Intra-erythrocytic ferritin and erythrocyte zinc-protoporphyrin also help to differentiate IDA from ACD. These parameters allow the diagnosis

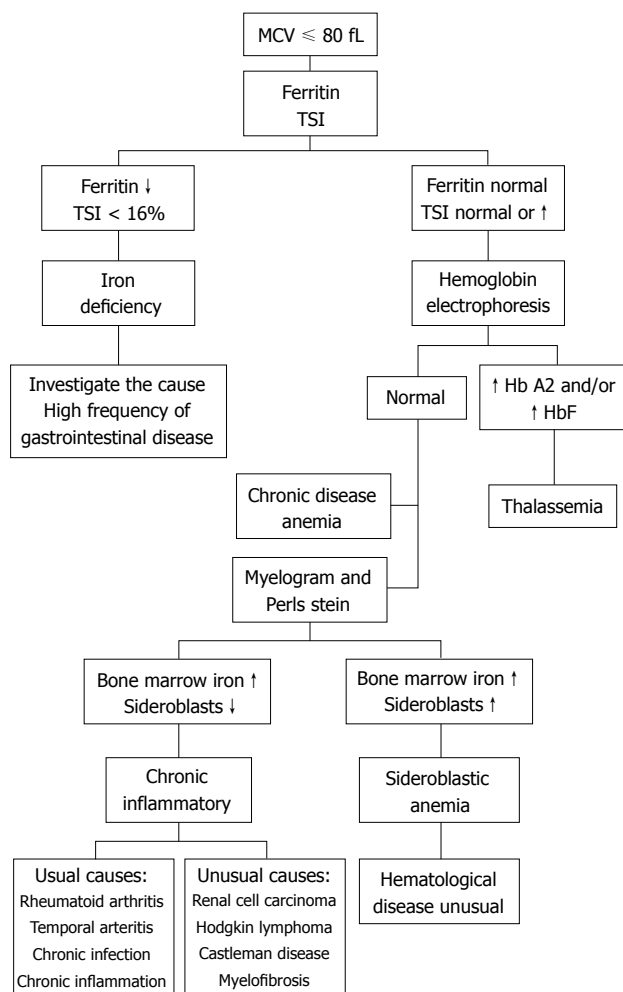

Figure 1 Evaluation of microcytic anemia. TSI: Transferrin saturation index; MCV: Mean corpuscular volume; Hb: Hemoglobin.

of borderline patients who, at another time, would have undergone unnecessary investigation of iron in the bone marrow^[30-32].

In men and postmenopausal women, the bigger concern should be to rule out the presence of occult bleeding. If positive, the first exploration should be a colonoscopy, mainly in men, because of the frequent association of occult blood with adenocarcinoma^[33,34]. If the colonoscopy does not reveal the cause of the anemia, gastroscopy should be performed. The study of the small bowel is more controversial, but it is convenient to keep in mind that celiac disease is a cause of IDA^[35].

In premenopausal women, genital bleeding is the most frequent cause of anemia. Therefore, gastrointestinal exploration is controversial. An anamnesis directed towards the characteristics of menstrual bleeding, although a subjective criterion, may be useful for distinguishing a subgroup of women without excessive genital bleeding, who require direct assessment of occult bleeding, followed by gastrointestinal exploration if positive. In cases in which occult bleeding is negative, the exploration should be directed to the genital system^[36-38].

Microcytosis associated with normal ferritin guides the

Figure 2 Evaluation of normocytic anemia. RPI: Reticulocytes production index.

diagnosis toward hereditary diseases, mainly thalassemia. If there are no family antecedents of microcytosis, it is necessary to investigate acquired causes of non-iron deficiency microcytosis, mainly ACD and sideroblastic anemia. Normal RDW guides the diagnosis toward the former and a high RDW toward the latter.

Normocytic anemia

The fundamental question in normocytic anemia is to recognize the causes and susceptibility to treatment as soon as possible. Among the causes are nutritional deficiency, renal failure and hemolytic anemia^[21]. Nutritional mixed anemia that combines deficiency of vitamin B12, folic acid and iron is frequent. In consequence, these three parameters should be requested in the initial phase of the diagnosis of normochromic anemia.

In order to differentiate among regenerative (hemolysis and bleeding) or hypo-regenerative anemia (bone marrow aplasia, chronic disease, nutrition deficiency and hemopathy), it is necessary to determine the corrected RPI (Figure 2). In anemia of renal failure, morphological alterations in the blood are scarce and serum erythropoietin may be normal, but inappropriately low for the degree of anemia. The severity of anemia is not evident until the disease is very advanced.

It will always be necessary to rule out hemolysis, by performing easily accessible laboratory tests [lactate dehydrogenase (LDH), indirect bilirubin, haptoglobin and reticulocytes]. These parameters do not inform us

Table 4 Serum levels that differentiate ACD, IDA and mixed anemia

	ACD	IDA	Mixed anemia

about the origin of hemolysis, and it is necessary to evaluate others, such as schistocytes in peripheral blood (intravascular hemolysis), the Coombs test (autoimmune hemolysis), tests of osmotic fragility (extravascular hemolysis), and tests to rule out hemolysis induced by drugs^[39]. A detailed anamnesis and Coombs test, with and without the suspected drugs, are very useful in the investigation of drug-induced hemolytic anemia.

When the cause of normocytic anemia is not any of the previously mentioned causes, it is necessary to guide the diagnosis toward a chronic disease or to primitive hematological disease^[21,22]. It is difficult to arrive at the definitive diagnosis. In this situation, it is fundamental that a careful clinical evaluation is carried out to rule out other causes of normocytic anemia: alcoholism (more frequently macrocytic), effects of drugs (chemotherapy, immunosuppression), radiotherapy, neoplasia (bone marrow infiltration), infections (mainly in hospitalized patients), surgery, or recent trauma (first phase of bleeding). The association with pathological concomitant processes, elevation of erythrocyte sedimentation rate (ESR) and the absence of morphological alterations in peripheral blood smears supports the suspicion of ACD^[40]. ACD is the most frequent cause of anemia after ferropenia^[41,42]. It is observed in patients that have immune hyperactivity. Activation of cytokines and the reticuloendothelial system induces changes in iron homeostasis, erythroid precursor proliferation, erythropoietin secretion, and erythrocyte life span^[43]. All of these contribute to the pathogenesis of anemia.

ACD can be complicated with chronic bleeding, and in this case, the diagnosis is more difficult because of the presence of microcytosis and ferropenia. The biochemical parameter that better differentiates ACD from IDA is serum ferritin^[44] (Table 4).

The hematologist must revise the blood smear if primitive disease of bone marrow is suspected. Depending on the result, a bone marrow study may be necessary to detect hematological diseases or metastasis. The biopsy, bone marrow smear, or both inform us of: the morphology of the hematopoietic cells, on their quantitative distribution, especially the myelo-erythroid ratio (normal 3:1); fibrosis; the presence of non-hematopoietic cell; or possible bone marrow aplasia. Perls' specific iron stain informs us of the state of iron stores, and it allows quantification of siderocytes

and sideroblasts. In a patient with anemia and fever of unknown origin, we must carry out careful microscopic examination of bone marrow, some selective staining, and bone marrow cultures to diagnose any underlying infectious diseases. Some infectious or parasitic diseases that are diagnosed with relative frequency are: tuberculosis, histoplasmosis, kala-azar and malaria^[45-47].

Macrocytic anemia

Macrocytosis is observed frequently using blood cell analyzers (Figure 3). Its prevalence is 1.7%-3.9%, but 60% of the patients with macrocytosis do not have anemia^[48]. On the other hand, macrocytosis can be physiological in some circumstances (infants, pregnancy, some families). Even keeping in mind the precedent data is convenient to make a careful evaluation of macrocytosis in every patient, to rule out any underlying pathology. In vitamin B12 and folic acid deficiency, as well as in other diseases, macrocytosis (blood) is accompanied by megaloblastosis (bone marrow). In such cases, both terms can be used interchangeably^[49].

The starting point in the diagnostic process for macrocytic anemia will be to rule out therapy with drugs that interfere with nucleic acid metabolism, such as hydroxyurea, methotrexate, trimethoprim, zidovudine or 5-fluorouracil, as well as habitual intake of alcohol^[49,50]. Hydroxyurea is the drug that increases most the MCV (> 110 fL); the other drugs and alcohol induce a moderate macrocytosis (100-110 fL).

In the absence of intake of any of the drugs mentioned above or alcohol, the most frequent cause of microcytic anemia is nutritional deficiency^[50]. Therefore, serum vitamin B12 and folic acid levels should be evaluated. The last can be modified by the previous day's folic acid intake. A better alternative is intra-erythrocyte folate, which remains stable during the lifetime of red blood cells and gives a better indication of possible chronic folic acid deficiency. The measurement of erythrocyte folate is a difficult technique that is not available in every laboratory. The determination of homocysteine is an accessible alternative to intra-erythrocyte folate. In the absence of folic acid, homocysteine levels increase rapidly because it cannot be converted into methionine. Normal serum levels of homocysteine are highly unlikely in folate deficiency^[21].

In the same way, vitamin B12 deficiency is correlated with low serum levels, although there are clinical situations in which low serum levels are not correlated with vitamin B12 deficiency (pregnancy, elderly patients, and those with low white blood cell counts). In these circumstances, normal serum methyl-malonic acid levels, in the absence of congenital errors of metabolism or renal failure, preclude a deficiency of vitamin B12^[51].

To complete the study of vitamin B12 deficiency, it is necessary to look for antibodies to intrinsic factor, which if positive, confirms the diagnosis of pernicious anemia. If not present, it is necessary to investigate malabsorption by performing the Schilling test^[52] (Table 5).

Figure 3 Evaluation of macrocytic anemia.

ANEMIA, A PRACTICAL APPROACH FOR THE GASTROENTEROLOGIST: STRATEGY TO DIAGNOSE PATIENTS WITH ANEMIA, AND PREVALENCE OF DIFFERENT TYPES OF ANEMIA

The strategy for establishing a diagnosis of anemia by gastroenterologists must follow a classic pattern that includes a clinical interview, a basic physical examination, and careful selection of complementary tests.

The clinical history should emphasize the causes of blood loss, including non-gastrointestinal diseases, recent history of gastrointestinal symptoms, gastrointestinal surgery, use of nonsteroidal anti-inflammatory drugs, acetylsalicylic acid and anticoagulant therapy, family history of hematologic diseases and colorectal neoplasia^[53-55]; all symptoms should be recorded, and not only the gastrointestinal ones.

A single blood sample can give information on the concentration of hemoglobin (essential for the diagnosis of anemia according to WHO criteria), the erythrocyte indices MCV and MCH (useful for the morphological classification of anemia), RDW (estimate of anisocytosis) and ESR, which reports on possible ACD.

The hematologist should examine a blood smear if any abnormal erythrocyte indices have been detected. A clotted blood sample (to obtain serum) allows the

determination of the rest of the analytical parameters that are useful in diagnosis, which are iron metabolism (mainly ferritin), urea, creatinine, bilirubin and total protein. In cases of suspected IDA, the concentration of soluble transferrin receptor should be included as a key parameter in differentiation between IDA and ACD^[56]. The most probable causes of microcytic anemia are IDA, thalassemia or thalassemia trait. RDW and iron metabolism are clues to differentiate between these processes in the initial step, as has been mentioned above. The most likely causes of normocytic anemia are ACD, renal failure and primitive hematological diseases (least frequently). Iron metabolism and routine biochemical tests may help to guide the diagnosis, but in some cases, erythropoietin serum levels and bone marrow examination are necessary.

In cases of macrocytic anemia, serum levels of vitamin B12 and serum and/or erythrocyte levels of folate will guide the diagnosis to deficiency of one of these. Most causes of folic acid deficiency are nutritional, although malabsorption should always be kept in mind. In contrast, vitamin B12 deficiency is almost always the result of malabsorption^[49,57]. The few exceptions are in strict vegetarians and hereditary transcobalamin II deficiency (a very infrequent disease). Among malabsorption causes of B12 vitamin deficiency, the most frequent is pernicious anemia. Therefore, the first step is to establish whether the serum levels of gastrin are highly elevated, because

Table 5 Causes of megaloblastic anemia

Cobalamin deficiency
Poor diet
Deficiency of intrinsic factor
Pernicious anemia
Total or partial Gastrectomy
Ingestion of caustic (lye)
Functional defect of intrinsic factor
Alteration of ileal (microenvironment)
Insufficient pancreatic protease activity
Inactivation enzyme (Sd. Zollinger-Ellison)
Competition for cobalamin
Alteration of ileal mucosa
Acquired
Surgical resection or by-pass
Regional enteritis (Crohn's disease)
Tropical sprue
Celiac disease, Tuberculosis
Lymphomatous infiltration
Induced by drugs
Congenital
Sd Immerslund-Gräsbeck
Congenital transcobalamin II deficiency or abnormality
Congenital methylmalonic acidemia and aciduria
Hemodialysis
Urinary losses (congestive heart failure)
Folate deficiency
Dietary
Old age, infancy, poverty, alcoholism, chronic invalids, psychiatrically disturbed, scurvy and kwashiorkor
Excess utilization or loss
Physiologic: pregnancy and lactation, prematurity
Pathologic: Hematologic diseases
Malignant diseases
Inflammatory disease
Metabolic disease
Excess urinary loss, congestive heart failure, active liver disease
Hemodialysis, peritoneal dialysis
Malabsorption
Congenital
Anti-folate drugs
Alcoholism
Tropical sprue, gluten-induced enteropathy
Extensive jejune resection, Crohn's disease, partial gastrectomy, systemic bacterial infection, Whipple's disease
Congenital abnormalities of folate metabolism
Cyclohydrolase, methionine synthetase
Combined deficit of folate and cobalamin
Celiac disease
Regional enteritis (Crohn's disease)
Congenital disorder of DNA synthesis
Disorders of DNA synthesis induced by drugs
Anti-folate
Purine antagonists
Pyrimidine antagonists
Alkylating
Eritroleucemia

Table 6 Differential diagnosis of anemia from a gastrointestinal point of view

Gastrointestinal causes of anemia
Microcytic anemia
Iron deficiency
Decreased iron absorption
Frequent: Celiac disease, gastrectomy, <i>H pylori</i> colonization
Infrequent: Bowel resection, bacterial overgrowth
Occult gastrointestinal blood loss
Frequent: aspirin and nonsteroidal anti-inflammatory drug use, colonic carcinoma, gastric ulceration, angiodysplasia, inflammatory bowel diseases
Infrequent: esophagitis, esophageal carcinoma, gastric antral vascular carcinoma, small bowel tumors, ampullary carcinoma, <i>Ancylomasta duodenale</i>
Non-gastrointestinal blood loss
Frequent: menstruation, blood donation, ACD
Infrequent: Hematuria, epistaxis
Sideroblastic anemia (alcohol, lead, drugs), vitamin B6
ACD
Normocytic anemia
Frequent: ACD (liver disease, renal insufficiency, malignancy, nutritional deficiency, drug effects, alcoholism, recent trauma or surgery, iron deficiency)
Infrequent: primary bone marrow disorder
Macrocytic anemia
Non-megaloblastic
Systemic disease:
Frequent: liver disease, alcoholism
Infrequent: primary bone marrow disease (myelodysplastic syndrome, aplastic anemia), metastatic infiltration, hemolytic anemia, hypothyroidism
Megaloblastic anemia
Vitamin B12 deficiency: pernicious anemia, gastrectomy, hereditary deficiency of intrinsic factor, inflammatory bowel disease, primary intestinal malabsorptive disorders, parasitic colonization, nutritional deficiencies
Folate deficiency: diet poor in folates, regional enteritis, Whipple's disease, scleroderma, amyloidosis, increase requirements (liver disease, hemolytic anemia)
Antifolate drugs: methotrexate

they are > 1000 pg/mL only in atrophic gastritis type A (pernicious anemia) and Zollinger-Ellison syndrome. In pernicious anemia, pepsinogen I levels are low, gastric pH is high and gastric acid secretion does not respond to stimulation with histamine or pentagastrin. Serum antibodies against intrinsic factor and parietal cells are not sensitive or specific enough to confirm the diagnosis. The exploration that leads directly to diagnosis is gastroscopy, with mucosal biopsy and study

of antiparietal cell antibodies. Gastric biopsy has the added advantage of giving information about possible metaplasia or precancerous lesions^[58]. In the absence of gastric disease, the most likely cause of malabsorption of vitamin B12 is Crohn's disease, with involvement of the terminal ileum^[59]. Hereditary causes of malabsorption (Immerslund syndrome) or transport (transcobalamin II deficiency) are extremely infrequent.

The list of causes of anemia is long and cumbersome, but most can fit into a very small number of diseases on which we must concentrate as a first diagnostic option (Table 6)^[60-66].

IDA is the most prevalent form of anemia worldwide, especially in women and children. Thirty-percent of the world's population, some 1300 million people, suffer from anemia. However, the prevalence of anemia worldwide is unequal (36% in underdeveloped and 8% in developed countries) About half of the patients with anemia have IDA, which is most prevalent in the general population and in outpatients. The most likely cause of IDA is malnutrition in children, bleeding in adult males (especially gastrointestinal), menstruation or lactation in fertile

women, and bleeding in the elderly. The distribution of nutrient-deficiency anemia in the elderly is: 48% iron alone, 19% folate alone, 17% vitamin B12 alone, and the rest have combined deficiencies. Therefore, in young male adults and in both sexes older than 65 years, the most likely cause of IDA is chronic bleeding, especially from gastrointestinal lesions^[67].

The hemogram, the concentration of iron, ferritin and transferrin in blood and investigation of fecal occult blood are sufficient to obtain a diagnosis in most cases.

ACD is the most prevalent form of anemia after IDA in the general population^[40,68], but is even more common in hospitalized patients, regardless of sex and age^[42,67,69,70].

The underlying causes of ACD vary greatly: acute and chronic infections, 18%-95%; cancer, 30%-77%; autoimmune diseases (including chronic inflammatory bowel disease), 8%-71%; rejection of solid organ transplantation, 8%-70%; and chronic renal disease, 23%-50%. ACD is found in 20% of elderly people with anemia (30% excluding nutritional deficiency), and a further 4.3% suffer from ACD and kidney failure. Therefore, we should keep in mind ACD as the most likely diagnosis in elderly and inpatients, and as the second most likely diagnosis in outpatients under 65 years of age^[68]. The laboratory tests needed to confirm the diagnosis include serum iron, transferrin, transferrin saturation, ferritin, urea and creatinine.

The gastroenterologist must rule out chronic inflammatory bowel disease, tumors of the digestive tract and liver disease. In some patients, the cause of anemia is complex (chronic disease and chronic hemorrhage). In these cases, it is difficult to confirm the diagnosis and additional testing is required: soluble transferrin receptor and microscopic examination of bone marrow with special stains for iron.

The most common type of anemia after IDA and ACD is megaloblastic anemia (vitamin B12 deficiency, folic acid or both). It is important in gastroenterology because intestinal malabsorption and pernicious anemia are common causes of this form of anemia. The diagnosis is suspected when MCV is elevated, and is confirmed by measuring serum vitamin B12 and serum and erythrocyte folate.

Hemolytic anemia follows next in order of frequency. Acute hemolysis presents a distinctive clinical picture, but chronic hemolysis may go unnoticed. If hemolytic anemia is suspected, the appropriate laboratory tests are antiglobulin test (direct and indirect), LDH, haptoglobin, total and conjugated bilirubin in serum, and salts and bile pigments in urine. These tests can give us the generic diagnosis of hemolytic anemia, immune or not immune, but the etiological diagnosis should be resolved in collaboration with the hematologist.

Anemia is common in hematological malignancies, but with limited gastrointestinal symptoms, except for gastric or intestinal bleeding caused by thrombocytopenia or lymphoma. It is rare, but it should be noted that gastric or intestinal lymphoma sometimes presents as

mild anemia with nonspecific gastrointestinal symptoms. Endoscopy usually provides the diagnosis.

Hereditary anemia is extremely rare, except for thalassemia and sickle cell disease in certain geographical areas. Sickle cell disease is restricted to blacks. When one suspects hereditary anemia, the cooperation of a hematologist should be sought, because the diagnosis is difficult and the laboratory tests should be carefully selected.

CONCLUSION

More than 100 diseases may cause anemia, but 90% belong to three groups: nutritional deficiencies (iron, vitamin B12 and folic acid), ACD (chronic inflammation, tumors), and bleeding (excluding chronic bleeding, which produces iron deficiency). Hemolytic anemia, although less frequent than the other, is the last option before considering the diagnosis of rare diseases.

A few laboratory tests, such as blood count, ESR, serum ferritin, and serum iron and transferrin, are sufficient to focus the diagnosis. According to initial results, additional laboratory tests should be ordered: serum vitamin B12 and serum and erythrocyte folate (in case of macrocytosis), tumor markers and acute phase reactants (if ACD is suspected), LDH, haptoglobin and antiglobulin test (if hemolytic anemia is suspected).

With these key data, the doctor can put in place more specific tests: imaging, endoscopy and additional laboratory tests. The next step should be to correct the cause of anemia when possible or correct anemia itself when the cause cannot be treated. The advantages are clear if the cause is a cancer that can be diagnosed at an early stage. On the other hand, we can improve the quality of life of patients by correcting the anemia with medical treatment or regular transfusions.

Abstract

Iron deficiency (ID), with or without anemia, is often caused by digestive diseases and should always be investigated, except in very specific situations, as its causes could be serious diseases, such as cancer. Diagnosis of ID is not always easy. Low serum levels of ferritin or transferrin saturation, imply a situation of absolute or functional ID. It is sometimes difficult to differentiate ID anemia from anemia of chronic diseases, which can coexist. In this case, other parameters, such as soluble transferrin receptor activity can be very useful. After an initial evaluation by clinical history, urine analysis, and serological tests for celiac disease, gastroscopy and colonoscopy are the key diagnostic tools for investigating the origin of ID, and will detect the most important and prevalent diseases. If both tests are normal and anemia is not severe, treatment with oral iron can be indicated, along with stopping any treatment with non-steroidal anti-inflammatory drugs. In the absence of response to oral iron, or if the anemia is severe or clinical suspicion of important disease persists, we must insist on diagnostic evaluation. Repeat endoscopic studies should be considered in many cases and if both still show normal results, investigating the small bowel must be considered. The main techniques in this case are capsule endoscopy, followed by enteroscopy.

Key words: Anemia; Iron-deficiency; Iron deficiency anemia

INTRODUCTION

Iron deficiency (ID) is defined as the decrease of the total content of iron in the body. Iron deficiency anemia (IDA) occurs when ID is sufficiently severe to reduce erythropoiesis. This type of anemia is the most frequent chronic anemia. ID may be the result of either excessive loss or, less frequently, decreased absorption. In general, the iron absorbed daily equals the amount needed to compensate its loss, so that the overall iron pool remains stable. This fine balance is easily broken, because the capability to absorb iron orally is limited. When the inputs are less than necessary or, more frequently, when the outputs increase and cannot be compensated for, ID and finally IDA, develops. In many cases, these alterations will be secondary to gastrointestinal disease. IDA occurs in 2%-5% of adult males and postmenopausal women in the developed world^[1,2]. ID, with or without anemia, is even more frequent. It is a common cause of consulting a gastroenterologist (4%-13% of all referred patients)^[3]; however, there is only one clinical guide published that deals with this clinical entity and the evidence level for most conclusions is medium-low, due to the paucity of reliable clinical data^[1]. In addition, for similar reasons, many of the patients treated by gastroenterologists will develop ID and IDA. This data underscores the importance of anemia in our clinical practice. Using a therapeutic iron course has been suggested as diagnostic test of ID. This is a reasonable approach only for people at high risk of physiological ID, such as adolescents and pregnant women^[4]. However, in daily clinical practice it is not unusual to find patients who have received several cycles of iron treatment before assessing the potential cause of anemia. This strategy leads to belated evaluation, especially in young females and in patients with a

prior history of anemia, resulting in significant delay in etiological diagnosis of anemia^[5]. In this sense, except in very specific situations, ID with or without anemia should always be investigated because it can be caused by potentially serious diseases^[1]. We will review the etiology and laboratory diagnosis of chronic ID and IDA to establish recommendations on the practical management of this clinical entity.

ETIOLOGY OF ID OR IDA

There are many potential causes of ID and IDA and some of them are very relevant. These causes are clearly different in developing and in developed countries. Deficient intake is the most frequent etiology in the former, whereas other important diseases are potentially implicated in the case of the latter.

In developed countries, the likeliest cause of anemia in each patient depends on age and sex. In women of childbearing age, excessive menstrual loss is the most frequent etiology, while in postmenopausal women and in males, digestive diseases are the main causes^[3,6]. Taking both these data and a detailed clinical history into account, we will plan diagnostic strategy in each case. However, these assumptions should not lead to errors in dealing with IDA or ID, such as not to investigate anemia in women assuming non-diagnosed gynaecological problems, because that attitude leads to a significant delay in detecting important diseases^[5].

In addition to digestive disorders, gynaecological diseases, urological diseases and other specific situations, such as intravascular hemolysis, the etiology of IDA (Table 1) includes aspects that exceed the purposes of this article. Focusing on digestive diseases, the etiology of ID and IDA of gastrointestinal origin can be divided into two groups: situations with increased loss of iron (the most common in developed countries), and those with decreased iron absorption. In the former, the blood loss can occur in the form of visible bleeding (melena, hematemesis, rectal bleeding) or hidden bleeding, which might be more difficult to diagnose. Among the diseases causing the blood loss we should emphasize, by frequency and importance, benign or malignant gastrointestinal tumors of the colon, stomach, esophagus and small intestine, peptic ulcer and reflux disease, use of non-steroidal anti-inflammatory drugs (NSAIDs), and inflammatory bowel disease. The possible existence of a malignancy as the source of anemia, which leads to early completion of endoscopic examinations in this clinical scenario, is of great concern. In the National Health and Nutrition Examination Survey and Epidemiologic Follow-up Study carried out in the USA on a cohort of 9024 individuals (aged between 25 to 74 years old without prior diagnosis of gastrointestinal malignancy), hemoglobin levels and iron saturation were determined. No case of ID in premenopausal women was determined to be due to malignancies. Among men and postmenopausal women with IDA [Relative Risk (RR) = 31, 95% confidence interval (CI): 9-107] or ID without anemia (RR = 5,

Table 1 Causes of iron deficiency anemia

Digestive disorders
Increased losses of iron
Cancer/polyp: colon, stomach, esophagus, small bowel
Peptic ulcer, esophagitis
NSAID use
Inflammatory bowel disease: ulcerative colitis, Crohn's disease
Intestinal parasites
Vascular lesions: angiodysplasia, watermelon stomach
Meckel's diverticulum
Reduced iron absorption
Celiac disease
Bacterial overgrowth
Whipple's disease
Lymphangiectasia
Gastrectomy (partial and total) and gastric atrophy
Gut resection or bypass
Urological and gynecological disorders
Intravascular hemolysis
Prosthetic valves and cardiac myxomas, paroxysmal nocturnal hemoglobinuria, marathon runners, multiple blood donations
Deficient iron intake

95% CI: 1-21) an increased risk of being diagnosed with cancer within the subsequent two years was observed^[7]. Therefore, gastrointestinal malignancies are uncommon in premenopausal women with ID or IDA, but in men and postmenopausal women with ID or IDA gastrointestinal malignancies are more common than in individuals with normal hemoglobin and iron levels.

Reduced iron absorption is the second category of ID causes of digestive origin, and can be caused by celiac disease, atrophic gastritis, and postsurgical status (gastrectomy, intestinal resection) among others. Celiac disease is very relevant and specific evaluation to exclude it must be performed. In a study on patients referred to a specialized gastroenterological consultation because of ID or IDA, celiac disease was finally the diagnosis in 10% of cases^[8]; other authors described that at least 2%-3% of patients with IDA are finally diagnosed as celiac disease^[3,6]. The prevalence of this disease worldwide is approximately 1%, and it is probably under diagnosed^[9]. Microscopic alterations in the duodenal mucosa in non-treated celiac disease patients will lead to them becoming refractory to oral iron treatment. This has also been described in patients with autoimmune atrophic gastritis and gastritis due to *Helicobacter pylori* (*H. pylori*)^[10-12]. Gastroscopy with biopsies, allowing us to detect the presence of atrophy with or without *H. pylori*, is essential. The positivity of autoantibodies (anti-intrinsic factor or anti-parietal cell) supports the diagnosis of autoimmune atrophic gastritis^[13]. Regarding the possible role of *H. pylori* in IDA, a recent meta-analysis indicated that the infection is associated with depleted iron deposits. The mechanism by which *H. pylori* induces this alteration is not clear, but it appears to involve gastrointestinal blood loss, diminished iron absorption from the diet, and increased consumption of iron by the bacteria. The authors suggest that the impact of eradication of *H. pylori* in the improvement of the iron deposits must be evaluated in large controlled trials^[14]. Finally, it must be pointed out that in our environment,

a deficit of dietary iron not associated with any other pathology will rarely be the cause of ID or IDA.

CLINICAL MANIFESTATIONS

The clinical picture varies greatly from one case to another, and it is produced both by the anemia itself and by the lack of iron, which is essential for cellular energy metabolism. Symptoms depend greatly on the speed of onset of anemia, its severity, and the characteristics of the patient. Thus, IDA or ID can be detected in an asymptomatic individual on a screening-analysis, or in a person with symptoms that include general weakness, fatigue, irritability, poor concentration, headache, and intolerance to exercise. These symptoms appear even in the figures for ID with normal hemoglobin levels. Patients often show relatively few symptoms spontaneously. Although the impact of ID on the quality of life of the subject is high, they often get used to their symptoms and these are assumed as normal. The patient becomes aware of an improvement only when the symptoms disappear. Some iron-deficient patients, with or without anemia, might have alopecia, atrophy of lingual papillae, or dry mouth due to loss of salivation. Other symptoms, such as weakness or digging fingernails (koilonychia), chlorosis, or the syndromes of Plummer-Vinson or Paterson-Kelly (dysphagia with esophageal membrane and atrophic glossitis) have virtually disappeared. These changes were caused by reduction of iron-containing enzymes in the epithelia and the gastrointestinal tract. Pica, the eating disorder in which there is an irresistible desire to lick or eat non-nutritive and unusual substances, such as soil, chalk, gypsum, ice (pagophagia) or paper, might appear in some cases. Pagophagia is considered quite specific to ID and it responds quickly to treatment. In a study on a group of patients referred to a gastroenterology consultation, more than half had pagophagia. It was especially frequent in women, and was not related to the cause of bleeding^[15].

Physical examination might be normal or show pallor of varying intensity, there may be a systolic murmur in cardiac auscultation, and abdominal and rectal exploration will allow us to rule out the existence of masses at those locations.

LABORATORY DIAGNOSIS: ID WITH OR WITHOUT ANEMIA

The diagnosis of anemia is simple and objective: the World Health Organization defines it as the decline in blood hemoglobin to a concentration below 13 g/dL in men and 12 g/dL in women. However, to confirm that ID is the origin of the anemia is not always easy. Sometimes the simple blood cell count strongly suggests this origin, the typical pattern being microcytosis, hypochromia (perhaps the most important, even more than the microcytosis), and elevation of red cells distribution width (RDW). However, up to 40% of

“pure” IDA cases are normocytic. Therefore, a normal mean corpuscular volume (MCV) does not exclude ID from being the cause of the anemia. Moreover, the presence of microcytosis does not necessarily imply ID and can be produced by other anemias (chronic process, sideroblastic anemia) and diseases (e.g. thalassemia). RDW measures the degree of anisocytosis (size difference) of the population of red cells and its elevation is neither sensitive nor specific for ID. The next step is to determine the so-called iron metabolism (in addition to all other necessary determinations, including levels of vitamin B12 and folic acid) and in many cases the level of C-reactive protein. A typical pattern is a decrease in sideremia, plasma ferritin, and transferrin saturation. However, this is not the usual case. The least reliable parameter for diagnosis of ID is probably the determination of sideremia, because it could be detected as an artefact of contamination of laboratory equipment, it has a nocturnal rhythm and it can normalize hours after ingestion. Serum ferritin, in the absence of inflammation (usually defined as a normal C-reactive protein level), reflects total body iron deposits. Thus, a low serum ferritin (< 30 ng/L) unequivocally means ID, whether accompanied by anemia or not. However, as serum ferritin is an acute phase reactant, a normal or even elevated ferritinemia does not exclude the presence of ID. Thus, in the presence of an inflammatory process (usually defined by an elevated C-reactive protein level), ID could exist even with levels of ferritin up to 100 ng/mL. Another parameter of the normal “iron metabolism”, especially useful when the determination of ferritin is equivocal, is the transferrin saturation index. This shows the percentage of transferrin that transports iron and thus a decrease (< 20%) implies ID, either absolute or functional.

In some cases, even taking into account all these determinations, ID can be difficult to diagnose. It generally occurs in situations where the anemia has a multifactorial origin. This is typical in cases of anemia of mixed origin, a chronic process that coexists with ID, which is a frequent scenario in gastrointestinal inflammatory disease or cancer. Even with all the determinations previously described, it can be difficult to estimate the role of each factor in the genesis of anemia in this setting. In these cases, other values can help us to assess the pathogenesis of anemia. These other factors include the determination of soluble transferrin receptor, reticulocyte hemoglobin concentration, the percentage of hypochromic red cells, the concentration of erythropoietin (and its relation to the expected values), and even the determination of hepcidin. The soluble transferrin receptor is one of the most useful as it is the least influenced by the presence of inflammation and it correlates well with concentration of transferrin receptor in the cell plasma membrane^[16]. If the levels are high, ID is likely to be a major component of anemia, while in those cases with normal or low levels; anemia is probably not associated with ID. In Table 2, the values of different determinations in different clinical scenarios are shown.

Table 2 Differences between the serum values of iron-deficiency anemia, anemia of chronic diseases, and anemia of mixed origin

	Iron-deficiency anemia	Anemia of chronic diseases	Anemia of mixed origin
Serum iron	Decreased	Decreased	Decreased
Transferrin	Increased	Decreased or normal	Decreased
Transferrin saturation	Decreased	Decreased	Decreased
Ferritin ¹	Decreased (< 30 ng/mL)	Increased (> 100 ng/mL)	Normal
Soluble transferrin receptor	Increased	Normal	Increased or normal
C-reactive protein	Normal	Increased	Increased
Erythropoietin	Increased	Normal or slightly increased for the degree of anemia	Increased or normal

¹Ferritin values between 30 and 100 ng/mL: Make other determinations to differentiate the two entities.

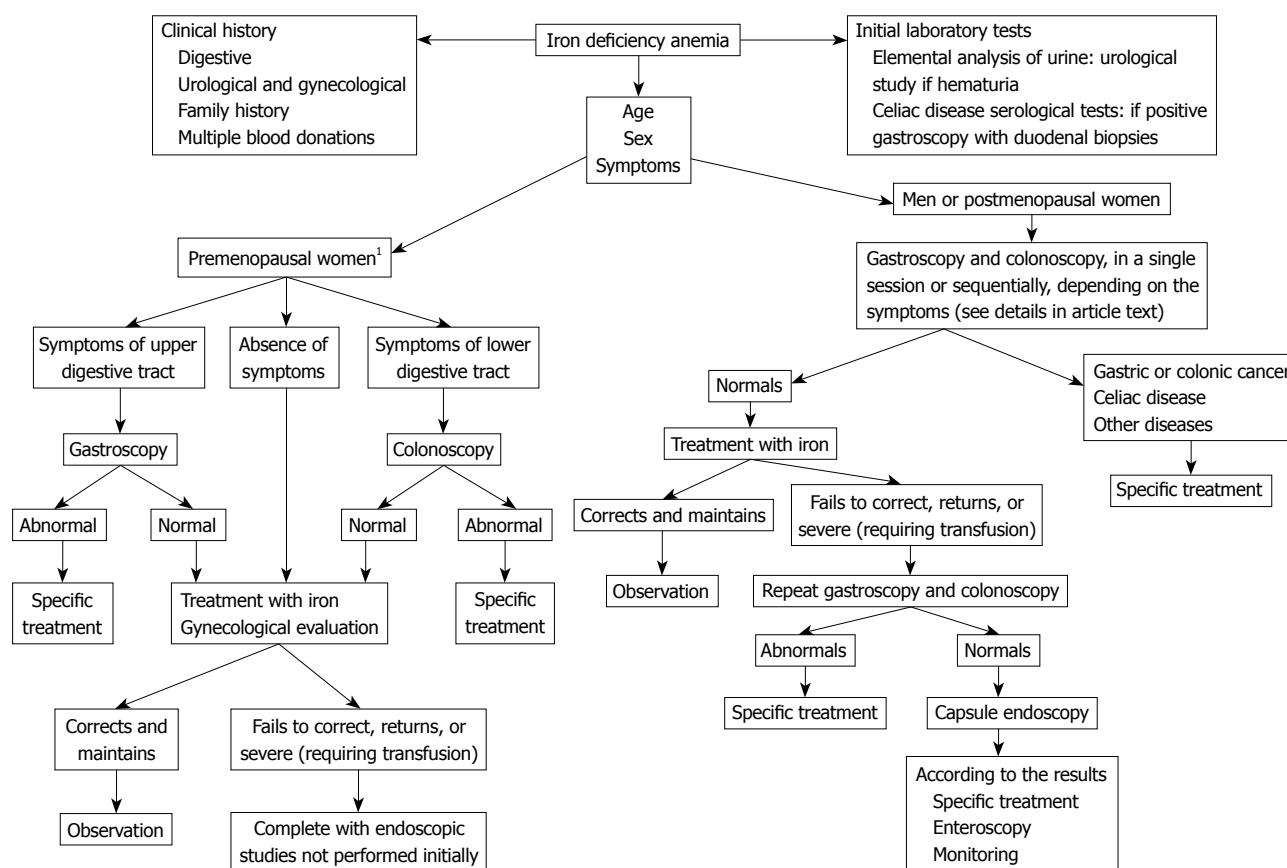

Figure 1 Etiologic diagnosis of iron deficiency anemia. ¹We must always consider gynecological cause.

ETIOLOGIC DIAGNOSIS OF ID ANEMIA

Once the diagnosis of IDA or ID without anemia has been established, it is necessary to investigate its origin (Figure 1), because it can be caused by very serious diseases. Taking into account the age and sex of the patient, and of course an adequate clinical history, we will plan a diagnostic strategy in every individual case.

In the clinical history, we should investigate any sign of digestive or urologic bleeding, and in the case of women, gynaecological history and symptoms should be included. Personal history of peptic ulcers and a family history of colon cancer or celiac disease should be investigated. The existence of suggestive symptoms in a location is a predictor of disease in that location. Therefore, the initial evaluation can be accompanied by the location of symptoms^[17].

The initial studies should include laboratory tests, with an elementary analysis of urine (up to one third of

the renal carcinomas have anemia). In the case of positive serological tests for celiac disease, it is also necessary to perform a gastroscopy with distal duodenum biopsies. In most patients, a dilemma will arise; is it necessary or mandatory to perform a gastroscopy, a colonoscopy or both? In patients over 50 years old, a colonoscopy is preferred to gastroscopy, and on the other hand, many of the patients under study for ID might have an indication of preventive colonoscopy screening, either because of family history or age (over 50 years)^[18]. It has been described that in the presence of a low ferritin value, the probability of finding any pathology at colonoscopy will be quadrupled^[19]. This supports the need for colonoscopy in the study of IDA and ID. It is important to underline that up to 15% of cases may have synchronous lesions in the upper and lower digestive tract, which means that it is necessary to perform both techniques, except in those cases in which celiac disease or a neoplasm is diagnosed

in the initial examination^[1]. Gastrointestinal endoscopies (gastroscopy and colonoscopy) might be performed in the same session or sequentially, according to clinical history (or serologic data). The combination of gastroscopy and colonoscopy is highly sensitive and specific for locating gastrointestinal lesions that produce anemia^[3,20,21]. However, the combination of both endoscopic techniques only determines the final cause of anemia in a little more than half of the patients. In a prospective study carried out on 100 consecutive patients with IDA, gastrointestinal endoscopies revealed at least one lesion potentially responsible for the loss of blood in 62 patients, 36% by gastroscopy, 25% by colonoscopy, and 1% by both^[17]. If examinations are normal, the anemia is not severe and symptoms do not suggest significant disease. The next step might be clinical follow-up, oral iron treatment (but iron supplementation may be harmful in some patients, e.g. in those with renal diseases) and cessation of any NSAIDs or aspirin consumption. Patients not responding to treatment with oral iron, those with severe anemia, or suspected serious illness, will require re-evaluation^[1,22]. Some authors describe that in the elderly, low MCV (≤ 60 fL) and a positive test for fecal occult blood are predictors of the presence of potentially bleeding lesions in endoscopy in patients with anemia without gastrointestinal symptoms^[23]. In premenopausal women, the most frequent endoscopic findings are gastritis by *H pylori* and celiac disease, and it has been suggested that in these patients initial diagnostic approach to IDA may include, in addition to the serologic celiac tests, a ¹³C-urea breath test, reserving endoscopic studies for cases where these tests are negative or anemia persists despite the eradication of *H pylori*^[24]. Finally, in the study of ID or IDA it must be pointed out that a barium enema is not a useful tool, being clearly inferior to colonoscopy^[25].

In those patients whose non-favourable clinical course after negative endoscopic studies advises further evaluation, repeating the endoscopic studies is justified because a proportion of lesions within the reach of conventional endoscopes might not be detected for several reasons. Repeating a gastroscopy might show erosions in a large hiatus hernia (Cameron lesions), peptic ulcer and vascular ectasy not detected in a previous exploration^[26]. Repeating a colonoscopy has a slightly lower yield, but it is a reasonable and necessary option if the previous colonoscopy was suboptimal because of incomplete or poor preparation. It has been shown that colonoscopy can fail in the diagnosis in 5% of colorectal tumors due to several reasons: an incomplete exploration, poor bowel preparation, misinterpretation of findings, inadequate biopsies of lesions^[27], or just not seeing the lesion.

In those cases in which repeated endoscopic examinations are all negative, we should investigate the small bowel as the source of anemia. In this scenario, the best initial approach is probably a capsule endoscopy^[28], reserving enteroscopy (single and double-balloon) for cases in which it is necessary to apply a treatment or to obtain biopsies of lesions localized by the capsule^[29,30]. This strategy significantly reduces the number of patients

requiring an alternative study after an initial investigation of the small intestine. Capsule endoscopy is a technique that explores the entire small intestine, something which is not always possible with enteroscopy. Capsule endoscopy has the disadvantage that it does not allow biopsies of detected lesions. The most common findings in patients with bleeding of obscure origin and/or IDA are angiodysplasia and Crohn's disease^[31]. According to the results of the meta-analysis of Triester *et al*^[32], diagnostic yield of capsule endoscopy (63%) in a study of patients with gastrointestinal bleeding of obscure origin was higher than that of push enteroscopy (26%), and of contrast studies with barium (8%). Enteroscopy should be considered as a second line technique in patients with a positive capsule endoscopy requiring sampling for histology or performing therapeutic endoscopy, and in patients in whom the suspicion of a small intestine lesion is high, despite the negativity of the capsule^[33].

Classical imaging studies of the small intestine (bowel through and enteroclysis) are much less sensitive for detecting lesions potentially causing anemia^[17] and have been reserved for those centres where the previous techniques are not available or are contraindicated. Radiological studies of the small bowel with computed tomography or magnetic resonance imaging techniques, which are very useful in the characterization of tumors from these locations and in the diagnosis of inflammatory bowel disease could, in experienced hands, increase the diagnostic yield^[34].

Finally, we should bear in mind that enteropathy by NSAIDs affects a significant number of people using these drugs, and that the amount of blood lost with the regular use of NSAIDs, such as ibuprofen, can be quite large^[35]. Injuries by the use of classic NSAIDs and selective inhibitors of COX-2 are very common (50%-70%) in the evaluation of the small intestine, i.e. by capsule endoscopy^[36,37]. We must remember that despite treatment with gastro-protective agents (proton pump inhibitors), aspirin and NSAIDs can cause gastrointestinal lesions of the lower bowel and thus cause bleeding and chronic ID.

CONCLUSION

IDA and ID are quite frequent in digestive pathology and they must always be taken into consideration for two reasons: (1) they have a clear impact on the patient's quality of life, and therefore they require adequate treatment and (2) they can be the consequence of significant or severe diseases, so it is essential to investigate their origin. Initial etiological evaluation must include celiac disease serological tests. In many patients, the usual endoscopic studies (gastroscopy and colonoscopy) will be prescribed, as they are necessary to rule out more severe diseases and they allow identification of the origin of anemia in more than half of the cases. In the rest of the patients, if anemia is severe or it does not respond to oral iron treatment, the first step will be to repeat those studies. If the results are still normal, it is necessary to investigate the existence of lesions in the small bowel by using capsule endoscopy. With all the diagnostic means

available nowadays, very few IDAs should be left without a diagnosis.

Abstract

Anemia is a frequent finding in most diseases which cause malabsorption. The most frequent etiology is the combination of iron and vitamin B12 deficiency. Celiac disease is frequently diagnosed in patients referred for evaluation of iron deficiency anemia (IDA), being reported in 1.8%-14.6% of patients. Therefore, duodenal biopsies should be taken during endoscopy if no obvious cause of iron deficiency (ID) can be found. Cobalamin deficiency occurs frequently among elderly patients, but it is often unrecognized because the clinical manifestations are subtle; it is caused primarily by food-cobalamin malabsorption and pernicious anemia. The classic treatment of cobalamin deficiency has been parenteral administration of the vitamin. Recent data suggest that alternative routes of cobalamin administration (oral and nasal) may be useful in some cases. Anemia is a frequent complication of gastrectomy, and has been often described after bariatric surgery. It has been shown that banding procedures which maintain digestive continuity with the antrum and duodenum are associated with low rates of ID. *Helicobacter pylori* (*H. pylori*) infection may be considered as a risk factor for IDA, mainly in groups with high demands for iron, such as some children and adolescents. Further controlled trials are needed before making solid recommendations about *H. pylori* eradication in these cases.

Key words: Anemia; Celiac disease; *Helicobacter pylori*; Cobalamin deficiency; Gastrectomy

INTRODUCTION

Anemia is a frequent finding in most digestive diseases which cause malabsorption. In this review we will focus on some frequent entities producing anemia and malabsorption, which are of current interest because of recent advances regarding each of them. Celiac disease (CD) may be considered as an archetypal malabsorption syndrome, and it is a frequent cause of anemia without associated intestinal symptoms. Anemia due to isolated cobalamin deficiency is a frequent finding in the elderly, and its etiology goes beyond the classical pernicious anemia concept. On the other hand, physicians should be aware that anemia often follows gastric surgery procedures, mainly after bariatric surgery, in order to implement prevention strategies. *Helicobacter pylori* (*H. pylori*) infection is being recognized as a frequent cause of iron deficiency (ID), both in developed and developing countries. In these cases eradication of the infection could be a successful therapy of the anemia.

ANEMIA IN CD

CD is an immunologically-mediated enteropathy, triggered in genetically susceptible subjects, by the intake of certain proteins of wheat, barley and rye, and resulting in small-bowel mucosal villous atrophy with crypt hyperplasia^[1].

Anemia has frequently been reported as the only manifestation or the most frequent extra-intestinal symptom of CD^[2-4]. Although folate and cobalamin deficiency are known complications of CD, the most common nutritional anemia associated with CD is ID. ID anemia (IDA) was reported in up to 46% of patients with subclinical CD in one study, and its prevalence was higher in adults than in children^[4]. In a recent case-control study, only anemia (OR: 26.3; 95% CI: 6-120) and diarrhea

Table 1 Prevalence of CD in patients presenting with IDA

Study, yr	n	Positive serology (%)	Positive biopsy (%)	Comments
Corazza <i>et al</i> ^[16] , 1995	200	8	5	IDA. 8.5% if only obscure IDA considered. All patients with positive serology were biopsied
Carroccio <i>et al</i> ^[17] , 1998	85	5.8	5.8	IDA. 20% if only refractory obscure IDA considered. All patients with positive serology were biopsied. 80% of CD cases were women
Unsworth <i>et al</i> ^[18] , 2000	483	6.6	4.6	Blood donors with anemia, most with IDA. Not all seropositive patients were biopsied. 95% of CD cases were women
Haslam <i>et al</i> ^[19] , 2001	216	2.3	n/a	Pregnant women with anemia. Four of five anemic women with positive serology have IDA. Only serology was performed
Annibale <i>et al</i> ^[20] , 2001	190	n/a	13.7	Obscure IDA. All patients were biopsied. 85% of CD cases were women
Howard <i>et al</i> ^[21] , 2002	258	10.9	4.7	Majority of patients with previously not studied IDA (4% folate deficiency). Not all seropositive patients were biopsied. 83% of CD cases were women
Ransford <i>et al</i> ^[22] , 2002	484	3.5	2.3	Previously not studied IDA. Not all seropositive patients were biopsied. 73% of CD cases were women
Grisolano <i>et al</i> ^[23] , 2004	103	n/a	8.7	Previously not studied IDA. All patients were biopsied. 100% of CD cases were women
Mandal <i>et al</i> ^[24] , 2004	504	n/a	1.8	IDA with normal upper gastroscopy. Not all patients were biopsied
Hershko <i>et al</i> ^[25] , 2005	150	5.3	5.3	Previously not studied IDA. All seropositive patients were biopsied
Kalayci <i>et al</i> ^[26] , 2005	135	4.4	4.4	Previously not studied children with IDA. All seropositive patients were biopsied
Zamani <i>et al</i> ^[27] , 2008	206	15	14.6	Obscure IDA. All patients were biopsied
Carter <i>et al</i> ^[28] , 2008	116	n/a	6.5	Previously not studied premenopausal women with IDA. All patients were biopsied

n/a: Not available data; IDA: Iron deficiency anemia; CD: Celiac disease.

(OR: 4.5; 95% CI: 2-10) were identified as independent predictors of an eventual diagnosis with CD among the different clinical presentations in general practice during the 5 years prior to the diagnosis of CD^[5]. Similarly, among patients identified by population screening, 50% were anemic as the primary presentation^[6].

Iron is absorbed in the proximal small intestine and the absorption is dependent upon several factors, including an intact mucosal surface and intestinal acidity^[7,8]. ID in CD primarily results from its impaired absorption as a result of the villous atrophy of the intestinal mucosa. Consequently, IDA develops. The concept of abnormal iron absorption is supported by the failure to increase serum iron following oral iron supplementation.

Occult gastrointestinal bleeding has been described in CD in correlation with the severity of villous atrophy^[9]. More recent studies have found, however, that the rate of positive occult blood tests in CD is low and does not exceed that of the general population^[10,11].

Anemia of chronic disease has also been described in CD^[12,13]. It is well known that pro-inflammatory cytokines play an essential role in the pathogenesis of CD^[14]. In this regard, both interferon- γ and interleukin-6 are powerful mediators of hypoferrremia in inflammation, leading to the abnormalities in iron homeostasis associated with the anemia of chronic disease^[15]. Accordingly, Harper *et al*^[12] described that in the majority of CD patients with anemia, low serum ferritin levels were an indicator of ID. However, in 13% of patients with anemia, serum ferritin levels were increased, such abnormalities reverting to normal after a gluten-free diet. In a recent study, refined precision laboratory methods to identify anemia of inflammation were used^[13]. Among 65 anemic CD patients, 45 had IDA, two had cobalamin or folate deficiency, and 11 had anemia of chronic disease alone or in combination with ID, which implies

a prevalence of 17%. After 12-mo on a gluten-free diet, the response was equally favorable in the patients with either IDA or anemia of chronic disease, indicating that the suppression of inflammatory intestinal changes by the diet improves anemia both by correcting iron absorption and by blunting the inflammatory response.

CD is frequently diagnosed in patients referred for evaluation of anemia, and subclinical CD appears to be a relatively common cause of IDA. Studies using serologic tests and small-bowel biopsies in patients referred for evaluation of IDA have reported CD in 1.8%-14.6% of patients (Table 1)^[16-28]. These studies are heterogeneous in design, as some included only patients with IDA whereas others included both folate and iron deficient patients, and used different methods for diagnosis of CD, often in selected referral populations. Highest frequencies of CD were observed in patients with obscure IDA, and frequency may be as high as 20% in patients with refractory obscure IDA^[17]. The frequency of CD in women with IDA is higher than in other risk groups of CD, with a female:male ratio of 2:1^[4,29], and several studies have reported that 73%-100% of IDA patients diagnosed with CD were adult pre-menopausal women^[17,18,20-23]. The higher iron demand in adult pre-menopausal women as a result of menstrual loss in a condition of chronic iron malabsorption attributable to CD probably explains this higher prevalence of CD in this group of patients.

Clinicians should consider CD as a possible cause of anemia in all subjects with IDA of unknown origin, even in menstruating women. Recent guidelines from the British Society of Gastroenterology recommend that duodenal biopsies should be taken during endoscopy if no obvious case of ID can be found^[30]. The treatment of IDA associated with CD is primarily a gluten-free diet with iron supplementation until the iron stores have been restored.

Table 2 Stages of cobalamin metabolism and corresponding causes of cobalamin deficiency

Stage of cobalamin metabolism	Causes of cobalamin deficiency
Intake solely through food	Strict vegetarianism without vitamin supplementation
Digestion brings into play haptocorrin, gastric secretions (hydrochloric acid and pepsin), pancreatic and biliary secretions, enterohepatic cycle	Gastrectomy; pernicious anemia (Biermer's disease); food-cobalamin malabsorption
Absorption brings into play intrinsic factor and cubilin	Ileal resection; malabsorption; pernicious anemia; Imerslund syndrome
Transport by transcobalamins	Congenital deficiency of transcobalamin II
Intracellular metabolism based on various intracellular enzymes	Congenital deficiency of various intracellular enzymes

Several studies have shown that many untreated patients with CD are folate deficient^[7]. Deficiency of vitamin B12 is also common in CD and frequently results in anemia^[7]. The main site of vitamin B12 absorption is the distal ileum; a small proportion is also absorbed passively along the entire small bowel. The causes of vitamin B12 deficiency in CD may include associated autoimmune gastritis, bacterial overgrowth, decreased gastric acid or decreased efficiency of mixing with transfer factors in the intestine.

ANEMIA AND COBALAMIN DEFICIENCY

Literature of the last 10 years has provided several definitions of cobalamin (vitamin B12) deficiency, depending mainly on the population studied and on the particular assay kits used. Cobalamin deficiency is defined in terms of the serum values of cobalamin and of homocysteine and methylmalonic acid, two components of the cobalamin metabolic pathway. High homocysteine levels (hyperhomocystinemia) may also be caused by folate or vitamin B6 deficiencies, and these should be excluded before a diagnosis of cobalamin deficiency is made^[31]. Accordingly, definitions of cobalamin deficiency are^[32]: (1) Serum cobalamin levels < 150 pmol/L (< 200 pg/mL) with clinical features and/or hematological anomalies related to cobalamin deficiency; (2) Serum cobalamin levels < 150 pmol/L on two separate occasions; (3) Serum cobalamin levels < 150 pmol/L and total serum homocysteine levels > 13 µmol/L or methylmalonic acid levels > 0.4 µmol/L (in the absence of renal failure and folate and vitamin B6 deficiencies); (4) Low serum holotranscobalamin levels < 35 pmol/L.

Epidemiological studies show that in the general population of industrialized countries, cobalamin deficiency has a prevalence of around 20%, ranging from 5% to 60% depending on the definition of cobalamin deficiency used^[31,32].

Cobalamin metabolism and corresponding causes of deficiency

The metabolic pathway starts when dietary cobalamin, obtained through animal foods, enters the stomach bound to animal proteins. A typical Western diet contributes 3-30 µg of cobalamin per day towards the recommended dietary allowance of 2.4 µg/d for adults^[33]. Pepsin and hydrochloric acid in the stomach split the animal protein, releasing free cobalamin. Most

of the free cobalamin is then bound to R-protein which is released from the parietal and salivary cells. Intrinsic factor is also secreted in the stomach, but its binding to cobalamin is weak in the presence of gastric and salivary R-protein. In the duodenum, dietary cobalamin bound to R-protein is joined by cobalamin-R-protein complexes that have been secreted in the bile. Pancreatic enzymes degrade both biliary and dietary cobalamin-R-protein complexes, releasing free cobalamin. The cobalamin then binds with intrinsic factor. The cobalamin-intrinsic factor complex remains undisturbed until the distal 80 cm of the ileum, where it attaches to mucosal cell receptors (cubilin) and the cobalamin is bound to transport proteins designated transcobalamin I, II and III. Transcobalamin II, although it represents only a small fraction (about 10%) of the transcobalamins, is the most important because it is able to deliver cobalamin to all cells in the body. The cobalamin is subsequently transported systemically *via* the portal system. Within each cell, the transcobalamin II-cobalamin complex is taken up by means of endocytosis and the cobalamin is liberated and then converted enzymatically into its two coenzyme forms, methylcobalamin and adenosylcobalamin. The causes of cobalamin deficiency according to the stage of cobalamin metabolism are described in Table 2^[31,32].

Cobalamin deficiency in the elderly: clinical entities

Vitamin B12 or cobalamin deficiency occurs frequently among elderly patients, but it is often unrecognized or not investigated because the clinical manifestations are subtle^[33]. However, the potential seriousness of the complications (particularly neuropsychiatric and hematological) requires investigation of all patients who present with vitamin or nutritional deficiency. In elderly patients, cobalamin deficiency is caused primarily by food-cobalamin malabsorption and pernicious anemia^[31]. Food-cobalamin malabsorption accounts for about 60%-70% of the cases among elderly patients, and pernicious anemia accounts for 15%-20% of the cases. Other causes included dietary deficiencies (< 5%), malabsorption (< 5%) and hereditary cobalamin metabolism diseases (< 1%).

Intrinsic factor, which is released by parietal cells in the stomach, binds to vitamin B12 in the duodenum. This vitamin B12-intrinsic factor complex subsequently plays a role in the absorption of vitamin B12 in the terminal ileum. This mechanism is responsible for 60% of the absorption of cobalamin. In addition, an alternate system exists that is independent of intrinsic factor or

even an intact terminal ileum: cobalamin is absorbed by simple diffusion or mass action independent of intrinsic factor if 300-1000 µg/d cobalamin is administered orally or intramuscularly to patients with pernicious anemia. Approximately 1%-5% of free cobalamin (or crystalline cobalamin) is absorbed along the entire intestine by passive diffusion^[33,34].

Food-cobalamin malabsorption: Food-cobalamin malabsorption syndrome is characterized by the inability to release cobalamin from food or from intestinal transport proteins, particularly in the presence of hypochlorhydria, where the absorption of “unbound” cobalamin remains normal. This syndrome is defined by cobalamin deficiency in the presence of sufficient food-cobalamin intake and a negative Schilling test, where the latter rules out malabsorption or pernicious anemia. Thus in this syndrome, patients can absorb “unbound” cobalamin through intrinsic factor or passive diffusion mechanisms. The recognition of the syndrome permits new developments of oral cobalamin therapy^[31-33,35]. Researchers have supported the existence of this syndrome by using a modified Schilling test, which employs radioactive cobalamin bound to animal proteins and reveals malabsorption when the results of a standard Schilling test are normal.

Food-cobalamin malabsorption is caused primarily by gastric atrophy. Over 40% of patients older than 80 years have gastric atrophy that may or may not be related to *H pylori* infection^[31]. Other factors that contribute to food-cobalamin malabsorption in elderly people include: intestinal microbial proliferation; long term ingestion of biguanides (metformin) and antacids, including H₂-receptor antagonists and proton pump inhibitors; chronic alcoholism; surgery or gastric reconstruction; partial pancreatic exocrine failure; and Sjögren's syndrome^[31,32].

The partial nature of this form of malabsorption may produce a more slowly progressive depletion of cobalamin than does the more complete malabsorption engendered by disruption of the intrinsic factor-mediated absorption. The slower progression of cobalamin depletion probably explains why mild, preclinical deficiency is more frequently associated with food-cobalamin malabsorption than with pernicious anemia^[32,33,35]. When associated with *H pylori* infection, eradication of the infection alone may correct cobalamin levels^[36].

Pernicious anemia: This is the classic cause of cobalamin deficiency and one of the most frequent among elderly patients. Pernicious anemia is an autoimmune disease characterized by the destruction of the gastric mucosa, especially fundal mucosa, by a primarily cell-mediated process^[31,37]. Gastric secretions are neutral to slightly acidic even in the presence of gastrin and contain little or no intrinsic factor. The disease is also characterized by the presence of two antibodies, particularly in plasma and gastric secretions: few people who do not have the disease have antibodies

(specificity 98%), but only about 50% of patients will have anti-intrinsic factor antibodies (IFA) (sensitivity 50%). Anti-gastric parietal cell (GPC) antibodies can also be measured in the serum (sensitivity > 90% but specificity 50%). Moderate hypergastrinemia, and sometimes major hypergastrinemia, have also been associated with pernicious anemia, but this is not a pathognomonic finding. A positive Schilling test with the addition of a test for IFA virtually confirms the diagnosis (specificity > 99%)^[31].

The optimal testing strategy remains unclear and considerable controversy still exists as to whether both indirect immunofluorescence testing for GPC and enzyme linked immunosorbent assay for IFA need to be performed as screening tests for pernicious anemia. It has been suggested that both autoantibodies do not need to be tested simultaneously, as the finding of IFA alone is very rare. GPC testing is therefore the most appropriate means of screening for pernicious anemia, with IFA testing as a more specific, but less sensitive test, being reserved for confirmatory testing^[38].

Treatment

The classic treatment of cobalamin deficiency has been parenteral administration, usually by intramuscular injection, of the vitamin (in the form of cyanocobalamin and, more rarely, hydroxocobalamin or methylcobalamin). The recommended practice involves administration of 1000 µg of cyanocobalamin per day for 1 wk, followed by 1000 µg/wk for 1 mo, and then the dose is reduced to 1000 µg/mo, normally for the rest of the patient's life^[31,33].

Alternative routes of cobalamin administration have been used: oral^[32-35] and nasal^[32,33]. These other routes of administration have been proposed as a way of avoiding the discomfort, inconvenience and cost of monthly injections. An evidence-based analysis supports the efficacy of oral cobalamin therapy^[32,33,35,39]. Sublingual therapy (2000 µg/d for 7-12 d) is another treatment modality for cobalamin deficiency, applicable in patients who refuse parenteral treatment and present either diarrhea or vomiting, and/or are unable to take oral medication^[34].

The procedure for oral cobalamin therapy has, however, not been completely validated yet in clinical practice, most notably the long-term efficacy. The current literature does not suggest a strategy in terms of the optimal form (hydroxy- or cyanocobalamin), frequency or duration of treatment. The therapeutic schema for use of oral cyanocobalamin would be^[33]: (1) Intensification treatment: cyanocobalamin 1000 µg/d for 1 mo; (2) Maintenance treatment: cyanocobalamin 125-500 µg/d for intake deficiency and food-cobalamin malabsorption, and cyanocobalamin 1000 µg/d for pernicious anemia.

ANEMIA AND GASTRIC SURGERY

Gastrectomy, previously used for peptic ulcer and its complications, is the preferred operation for palliation of gastric cancer either as total or partial gastrectomy.

Anemia is a frequent complication of gastrectomy. There are many reports addressing iron, vitamin B12 or folate deficiencies either alone or in combination after gastric surgery. The most frequent is the combination of iron and vitamin B12 deficiency^[40]. Impaired absorption of iron following gastrectomy is probably due to operative bypass of the duodenum and to rapid intestinal transit. Reduction in gastric acid (necessary for the absorption of food iron), a common consequence of subtotal gastrectomy, has also been incriminated. Vitamin B12 deficiency develops as a consequence of the decreased production of intrinsic factor which is essential for vitamin B12 absorption in the lower small bowel, and also because of a defect in the separation of vitamin B12 from its transporter protein. It is a frequent deficiency which will appear 2-4 years or even longer after gastrectomy, when the vitamin stores are exhausted. Thus, gastrectomized patients should be followed carefully to avoid iron and vitamin B12 deficiencies and anemia.

Over the last few decades, bariatric surgery has been suggested as an effective treatment for obesity. There are several different procedures, including gastric bypass, laparoscopic adjustable gastric banding, vertical banded gastroplasty, biliopancreatic diversion, and biliopancreatic diversion with duodenal switch^[41]. All of these procedures may be associated with long-term sequelae including iron, vitamin B12 and folate deficiencies^[41,42]. ID and anemia can have a strong impact on quality of life, especially in menstruating women who make up the majority of bariatric surgery patients. Most studies report ID, ranging from 6% to 50% within months to years of follow-up^[43-45]. Vitamin B12 deficiency may appear 1-9 years after gastric bypass, and its prevalence has been estimated to be 12%-33%^[42].

The main causes of ID after bariatric surgery are similar to those described after gastrectomy; diminished gastric acid secretion and exclusion of the duodenum. In gastric bypass, patients experience decreased gastric acid production in their proximal pouch and, in addition, the duodenum is excluded from digestive continuity. Thus, banding procedures which maintain digestive continuity with the antrum and duodenum are associated with low rates of ID and other nutritional deficiencies^[41]. Conversely, the biliopancreatic diversion with duodenal switch, a gastric bypass procedure that may preserve some function of the proximal duodenum, may offer protection from ID, as compared with biliopancreatic diversion (which excludes the duodenum)^[46,47].

Physicians should be aware that folate, vitamin B12, and iron deficiencies occur after gastric bypass, though the time to development is variable. In an attempt to prevent nutritional deficiencies, multivitamin preparations are in general prescribed to all patients. Systematic prescription of such supplements may prevent most nutritional deficits. However, vitamin B12 and iron deficits require specific supplementation. In spite of a multivitamin, ID still develops postoperatively in some patients. Adherence to oral iron supplements is often low because of digestive intolerance, and unresponsive IDA

can be an important problem in these patients. Parenteral iron treatment is recommended in those patients refractory to oral iron supplementation. Intramuscular vitamin B12 supplementation is recommended only when a deficiency becomes clinically apparent.

ANEMIA AND *H PYLORI* INFECTION

The current evidence regarding the association between *H pylori* infection and either ID or IDA is mainly based on case reports^[48-53], observational epidemiologic studies^[54], and a very limited number of intervention trials^[55-64]. The mechanisms of *H pylori*-related anemia have not been well defined and it is not known why only a small population develops IDA despite a significant worldwide *H pylori* infection rate^[65]. Individuals with increased demands of iron needed for growth and tissue building such as children, pregnant, postpartum or premenopausal women, or those with chronic inflammatory disorders such as CD, are thought to be more likely to develop IDA associated with *H pylori* infection.

H pylori infection has been shown to be associated with ID in asymptomatic *H pylori*-infected subjects in several cross-sectional studies. However, a great variability was found across the studies and most of these have been conducted in countries with high prevalence of *H pylori* infection. Recently, Muhsen *et al*^[54] performed two different meta-analyses of observational epidemiologic studies aimed at examining the association between *H pylori* infection and either ID or IDA. These analyses yielded a 2.8-fold increased risk for IDA (95% CI: 1.9-4.2), and an 1.38-fold increased risk for ID (95% CI: 1.16-1.65) in *H pylori*-infected subjects as compared with non-infected subjects.

In clinical and interventional trials, the participants were mostly children and adolescents, and only three trials were conducted among ill people (those presenting with symptoms for investigation in clinical settings)^[58,59,62]. Small sample sizes^[56-59,62], lack of control groups, and other methodological issues, including the use of validated tests to confirm active *H pylori* infection, are among factors that limit the interpretation and ability to generalize the relevance of the results of these studies^[54]. Several studies reported resolution of IDA with eradication of *H pylori* infection, regardless of the absence of iron supplementation. The study of Kurekci *et al*^[59], in which all participants received *H pylori* eradication therapy without a control group, emphasized that resolution of both ID and IDA associated with *H pylori* infection may be achieved by *H pylori* eradication treatment alone. The antagonistic effect of asymptomatic *H pylori* infection on the response to iron supplementation was investigated in India among participants of a randomized, controlled trial of iron supplementation ($n = 169$, age 1-10 years). It was found that asymptomatic *H pylori* infection was not associated with higher rates of anemia or ID, but had a significant adverse effect on response to iron supplementation among children^[53].

Sarker *et al*^[61] completed a population-based,

randomized, double-blind, and placebo-controlled trial to evaluate the response of iron *plus* anti-*H pylori* therapy in children with IDA ($n = 200$). This trial was performed in Bangladesh, an area highly endemic for ID and *H pylori* infection. Results failed to observe any additional impact of combined anti-*H pylori plus* iron therapy over the iron therapy alone. These findings support those obtained by an Alaskan trial^[60], in another highly prevalent *H pylori* infection area, where a large therapeutic, randomized, controlled, unblinded trial in children ($n = 219$) was performed. There were no significant differences between the intervention and the control groups in the rates of ID and anemia, during 14 mo follow-up period. The authors hypothesized that 14 mo was too early to resolve *H pylori*-induced gastric damage. Consequently, in a follow-up study performed at 40 mo, 176 children were reevaluated. Re-infection occurred among 52% of children who had initially cleared their infection. However, *H pylori*-negative children had lower prevalence of ID (RR: 0.62; 95% CI: 0.38-1.01) and IDA (RR: 0.22; 95% CI: 0.03-1.50), compared with *H pylori*-positive children. It was concluded that the resolution of *H pylori* infection for > 14 mo modestly reduced the prevalence of ID and substantially reduced the prevalence of ID and IDA^[64].

In the light of the above mentioned studies, *H pylori* infection may be considered as a risk factor for IDA, mainly in groups with high demands for iron, such as some children and adolescents. However, the relationship between *H pylori* and ID may be stronger than that described, since most of the above mentioned studies have been performed in geographical areas where both ID and *H pylori* infection are highly prevalent, and where the etiology of ID is possibly multifactorial (malnutrition, vitamin deficits, chronic parasitic infections, malaria)^[66]. In this setting, poor response to *H pylori* eradication should be viewed with caution. Thus, further large and well-controlled trials will be of value. Both the impact of anti-*H pylori* therapy on the improvement of iron stores and the role the infection plays in interfering with iron supplementation in patients with IDA require further evaluation before making solid recommendations.

The biologic mechanism

The relationship between refractory IDA and *H pylori* infection may be explained by several hypotheses. One of the possible explanations is the gastrointestinal blood loss that may range from chronic occult bleeding from discrete gastric erosions^[67] to massive bleeding from peptic ulcers^[68] and gastric carcinomas. However, most patients with *H pylori*-associated IDA have no evidence of gastrointestinal bleeding. Data obtained through case series and case reports mostly described patients with IDA after a comprehensive investigation including laboratory tests, imaging, and endoscopic studies, and *H pylori* gastritis was the only pathologic finding^[55,61-63].

Intragastric acidic pH plays an important role in the reduction of the ferric to the ferrous form. This reaction is enhanced by ascorbic acid. Gastric juice and mucosal ascorbic acid concentrations were significantly lowered

in *H pylori*-infected subjects as compared to those non-infected; the lower concentrations were associated with more severe gastritis^[69]. This negative influence of *H pylori* on gastric ascorbic acid was reversed after eradication of the infection^[70].

The results of some studies support the hypothesis that the infection by *H pylori* influences iron absorption directly, and that iron absorption improves significantly after clearance of the infection^[71,72]. It has been suggested that there is a competition for iron between the bacteria and the host. Iron is an essential nutrient for bacterial growth. Therefore, an efficient iron uptake system is an important factor for the maintenance of virulence^[73]. Many pathogens use the siderophore-mediated iron acquisition system that removes iron from lactoferrin or transferrin. The regulation of iron uptake systems in *H pylori* are different from other bacteria since they are constitutively expressed, most probably as a part of the germ adaptation to the conditions in the human stomach, where iron starvation and iron overload can be encountered frequently^[74]. The siderophore of *H pylori* has not yet been identified. Several studies support this hypothesis^[75-78].

Bacterial genetic factors related to *H pylori*-associated IDA pathogenesis have been studied. Non-IDA and IDA strains can be distinguished by their protein expression profiles, suggesting that polymorphisms in *H pylori* strains may be one of the factors determining the occurrence of *H pylori*-associated IDA^[79]. A mutation in the *H pylori pfr* gene causing overproduction of *H pylori* ferritin protein (Pfr) has been proposed as playing a role in the imbalance of body iron^[80]. However, an analysis of the complete coding region of the *pfr* gene revealed three sites of mutation with no differences in the mutation among *H pylori*-positive patients with or without IDA^[80]. On the other hand, three heme-binding iron-repressible outer membrane proteins that may be involved in the uptake of heme from the host by *H pylori* were described in the presence of poor iron environment^[81]. Recently, *feoB* gene product, which was regarded as a high-affinity ferrous iron transporter, was proposed as a possible pathway related to the bacterium itself; however, its relation to IDA remains unclear^[82]. Although *H pylori* CagA strains were proposed to be involved in alteration of the host's iron stores in some studies, more recent work does not support this hypothesis^[72,83,84]. However, seropositivity to *H pylori* CagA antibodies was inversely associated with gastric ascorbic acid concentrations^[84].

CONCLUSION

CD should be considered as a possible cause of anemia in all subjects with IDA of unknown origin, even in menstruating women. Duodenal biopsies should be taken during endoscopy if no obvious case of IDA can be found. Vitamin B12 or cobalamin deficiency occurs frequently among elderly patients, but it is often unrecognized or not investigated because the clinical manifestations are subtle. In this age group, cobalamin

deficiency is caused primarily by food-cobalamin malabsorption (60%-70% of cases) and pernicious anemia (15%-20% of cases). The classic treatment of cobalamin deficiency has been parenteral administration of the vitamin. However, recent data support the efficacy of oral cobalamin therapy. Folate, vitamin B12, and iron deficiencies occur after gastric bypass, with an incidence ranging from 6% to 50% within months to years of follow-up. *H pylori* infection may be considered as a risk factor for IDA, mainly in groups with high demands for iron, such as some children and adolescents. However, further large and well-controlled trials will be required before making solid recommendations about *H pylori* eradication in these cases.

INTRODUCTION

Chronic liver diseases frequently are associated with hematological abnormalities. Anemia of diverse etiology occurs in about 75% of patients with chronic liver disease^[1].

A major cause of anemia associated with chronic liver disease is hemorrhage, especially into the gastrointestinal tract. Patients with severe hepatocellular disease develop defects of blood coagulation as a consequence of endothelial dysfunction, thrombocytopenia, deficiencies of coagulation factors and various associated disorders^[2].

In severe hepatocellular disease, decreased synthesis of liver-produced plasma proteins leads to reduced serum levels of several blood clotting factors. Hemorrhage may occur as a complication of chronic liver disease because of a lack of one or more liver-produced blood clotting factors, thrombocytopenia, and/or defective platelet function. Hemorrhage in such patients may also occur from esophageal or gastric varices secondary to portal hypertension. The biosynthetic pathways of blood coagulation factors II, VII, IX and X are within the hepatocyte and are dependent on vitamin K^[3]. Low serum levels of these factors are associated with prolongation of the prothrombin time (PT). When attributable to hepatocellular disease, they are not improved by administration of vitamin K; correction of the associated impaired blood coagulation necessitates infusion of preparations of the deficient factors.

Splenomegaly, which is usually caused by portal hypertension in patients with chronic liver disease, may lead to secondary hemolysis, an increase in plasma volume, macrocytosis and megaloblastic anemia. Alcohol, a common etiologic factor of chronic liver disease, is toxic to the bone marrow. Alcoholics often develop secondary malnutrition, a manifestation of

Abstract

Anemia of diverse etiology is a common complication of chronic liver diseases. The causes of anemia include acute or chronic gastrointestinal hemorrhage, and hypersplenism secondary to portal hypertension. Severe hepatocellular disease predisposes to hemorrhage because of impaired blood coagulation caused by deficiency of blood coagulation factors synthesized by hepatocytes, and/or thrombocytopenia. Aplastic anemia, which is characterized by pancytopenia and hypocellular bone marrow, may follow the development of hepatitis. Its presentation includes progressive anemia and hemorrhagic manifestations. Hematological complications of combination therapy for chronic viral hepatitis include clinically significant anemia, secondary to treatment with ribavirin and/or interferon. Ribavirin-induced hemolysis can be reversed by reducing the dose of the drug or discontinuing it altogether. Interferons may contribute to anemia by inducing bone marrow suppression. Alcohol ingestion is implicated in the pathogenesis of chronic liver disease and may contribute to associated anemia. In patients with chronic liver disease, anemia may be exacerbated by deficiency of folic acid and/or vitamin B12 that can occur secondary to inadequate dietary intake or malabsorption.

Key words: Anemia; Liver disease; Liver failure; Aplastic anemia; Pegylated interferon; Ribavirin; Alcohol

which may be anemia caused by folic acid deficiency. In some patients, bone marrow failure and aplastic anemia develop after an episode of hepatitis. Finally, anemia is a recognized complication of treatment of chronic hepatitis C with a combination of interferon and ribavirin: anemia in this context is predominantly caused by ribavirin-induced hemolysis^[4].

The frequent association of anemia with chronic liver disease and/or hepatocellular failure provides a rationale for examining the role of the liver in the formation and destruction of erythrocytes. Indeed, the liver itself may be implicated in a variety of different mechanisms that contribute to the development of anemia in patients with chronic liver disease. This paper provides an overview of anemia that may complicate chronic liver diseases and the mechanisms responsible.

The frequent association of anemia with chronic liver disease and/or hepatocellular failure provides a rationale for examining the role of the liver in the formation and destruction of red blood cells. Indeed, a variety of different mechanisms may be implicated in the development of anemia in patients with liver disease.

PORTAL HYPERTENSION AND ANEMIA

Acute gastrointestinal hemorrhage is a common and potentially serious complication of portal hypertension^[5-8]. It is usually caused by rupture of an esophageal varix. Hemorrhage caused by this mechanism is the second most common cause of mortality in patients with cirrhosis. In such patients, a ruptured esophageal varix is the cause of approximately 70% of episodes of upper gastrointestinal hemorrhage^[6]. Acute hemorrhage may induce severe hypovolemia and subsequently secondary iron deficiency anemia. The initial aim of treatment is correction of hypovolemia and restoration of stable hemodynamic function; minimal values for mean arterial pressure and for hemoglobin of 80 mmHg and 8 g/100 mL, respectively, should be maintained. Initially, gelatin-based colloids or solutions of human albumin may be infused to correct hypovolemia. However, infusions of packed erythrocytes in plasma are ideal in this context since such infusions have the potential of correcting, not only hypovolemia, but also secondary anemia. First-line management involves institution of both medical and endoscopic treatments (Table 1)^[6]. Medical therapy includes administration of vasoactive drugs, such as somatostatin, octreotide or terlipressin. Optimal endoscopic treatment involves ligation of esophageal varices and obturation of gastric varices with tissue adhesives.

In some patients with cirrhosis, chronic hemorrhage into the gastrointestinal tract occurs. Esophageal and gastric varices and/or portal hypertensive gastropathy may be associated with slow chronic loss of blood into the gut and development of chronic iron deficiency anemia. The most important approach to management is prevention of variceal hemorrhage^[5,7,8]. The annual incidence of initial variceal hemorrhage in patients with cirrhosis is estimated to be about 4%, but for the group

Table 1 Management of acute gastrointestinal bleeding

Treatment of variceal bleeding

Pharmacological therapy
Somatostatin: initial bolus (24-48 h) and a perfusion (5 d)
Octreotide: initial bolus (24-48 h) and a perfusion (5 d)
Terlipressin: important side effects
Primary prophylaxis
β-blockers non-selective: propranolol, nadolol
Isosorbide 5-mononitrate
Secondary prophylaxis
β-blockers non-selective: propranolol, nadolol
Isosorbide 5-mononitrate
Endoscopy therapy: band ligation, sclerotherapy

with medium-sized or large varices, the incidence is about 15%^[6]. β-blockers or isosorbide 5-mononitrate may reduce the rate of transformation of small varices into large varices and decrease the incidence of variceal hemorrhage in patients with small varices^[5]. In patients who survive a first episode of variceal hemorrhage, the risk of recurrent hemorrhage is > 60%. Accordingly, all patients surviving variceal hemorrhage should receive active treatment aimed at preventing recurrence. Non-selective β-blockers or isosorbide 5-mononitrate and endoscopic therapy, including ligation of and/or sclerotherapy of varices, are the first-line treatments for preventing recurrence of variceal hemorrhage^[5,8]; a combination of both these approaches constitutes optimal management. Additional treatment with oral iron supplementation is indicated for iron deficiency anemia caused by chronic blood loss. In some cases of advanced chronic liver disease, intravenous iron formulations may be administered to increase plasma levels and tissue deposits of iron.

Hypersplenism secondary to portal hypertension is another mechanism of anemia in patients with chronic liver disease. Hypersplenism is associated with splenomegaly. In addition to chronic liver disease, thrombosis of the splenic vein may also be a cause of an increase in pressure within the portal venous system, which can lead to secondary hypersplenism. The main characteristics of hypersplenism are those attributable to pancytopenia. Hemolytic anemia occurs because of intrasplenic destruction of erythrocytes. Destruction of megakaryocytes and leukocyte precursors results in thrombocytopenia and leukopenia^[9]. Symptoms and signs of hypersplenism are influenced by the primary underlying disease; they include abdominal pain and/or discomfort, and, in advanced cases, gastrointestinal hemorrhage secondary to portal hypertension. There may be hyperplasia of the progenitor cells in the bone marrow. It is important to determine the cause of hypersplenism. The main therapeutic approach for this syndrome is management directed at the underlying primary disease, usually chronic liver disease. When chronic liver disease is advanced, additional therapeutic options may need to be adopted. After assessing the severity of impaired hepatocellular function in a patient with advanced chronic liver disease, splenectomy may

be considered if the splenic vein is thrombosed. An alternative approach is partial or total embolization of the splenic artery, which, in some recent studies, has been associated with good results, in particular, lower morbidity and mortality rates than those associated with surgery. Partial embolization preserves the immunological function of the spleen and is the preferred option for patients with cirrhosis^[10].

IMPAIRED BLOOD COAGULATION

The liver plays a central role in blood coagulation. Acute and chronic hepatocellular diseases are usually associated with defective blood coagulation due to a variety of different causes. These include: decreased hepatic synthesis of factors II, VII, IX and X; the presence of inhibitors of these factors; decreased clearance of activated coagulation factors; thrombocytopenia; impaired platelet function; hyperfibrinolysis; and disseminated intravascular coagulation^[11,12]. Coagulation defects complicating liver disease predispose to an increased bleeding tendency, which increases both morbidity and mortality^[11-13].

Defective blood coagulation associated with hepatocellular disease may be monitored using global screening tests, such as the PT and the activated partial thromboplastin time. In mild hepatocellular disease, PT usually is within the normal range or only modestly prolonged. In more advanced hepatocellular disease, prolongation of PT tends to reflect the severity of hepatocellular failure. Vitamin K routinely is administered parenterally (usually only once) to patients with liver disease and a prolonged PT, to exclude vitamin K deficiency as a cause of the prolonged PT^[11].

Thrombocytopenia (platelet count < 150 000/L) is common in patients with chronic liver disease; it has been reported in as many as 76% of patients with cirrhosis^[4,12]. The pathogenesis of the thrombocytopenia is complex; it includes splenic pooling, and increased destruction and impaired production of platelets (Figure 1). Impaired production of platelets is caused, at least in part, by low levels of thrombopoietin. Prolonged bleeding time, and impaired aggregation, reduced adhesiveness and abnormal ultrastructure of platelets reflect abnormal platelet function; these abnormalities have been attributed to an intrinsic platelet defect. Specific treatments to attempt to reverse the effects of this defect are not usually given, but platelet transfusions or platelet-stimulating agents have been administered in some cases.

An important coagulation defect associated with chronic liver disease is low levels of factor VIIa. In recent years, the hemostatic agent recombinant factor VIIa has become available as a potentially new therapeutic agent for use in the management of coagulopathy in patients with cirrhosis. This agent may enhance initial control of acute variceal bleeding^[14]. However, such therapy is associated with significant side effects, such as vascular injury and thrombosis.

Hyperfibrinolysis is another cause of impaired

hemostasis in patients with liver disease. In a non-randomized trial^[15], antifibrinolytic amino acids were administered to patients with acute or chronic liver disease, who had upper gastrointestinal bleeding and acquired defects of blood coagulation. However, administration of such amino acids does not have an established place in therapy.

Thrombotic events, although rare in patients with cirrhosis, may occur. They tend to involve particularly the portal and/or mesenteric veins.

A rational approach to managing disorders of blood coagulation in patients with liver disease is important because of the high risk of associated secondary hemorrhage.

APLASTIC ANEMIA

Aplastic anemia associated with liver disease is characterized by development of pancytopenia and hypocellular bone marrow in relation to the occurrence of hepatitis^[16]. The main feature of this syndrome is injury to or loss of pluripotent hematopoietic stem cells, in the absence of infiltrative disease of the bone marrow^[16-19].

Hepatitis-associated aplastic anemia (HAA) has been defined as a variant of aplastic anemia, which occurs concurrently with or within 6 mo of an increase in the serum level of alanine aminotransferase to at least five times the upper limit of the reference range. Severe marrow aplasia may be induced by hepatitis viruses, such as hepatitis B virus and hepatitis C virus (HCV), and also by other viruses, such as human immunodeficiency virus, Epstein-Barr virus, transfusion-transmitted virus and echovirus^[16,20]. Parvovirus B19 commonly infects pro-erythroblasts and may induce transient red-cell aplasia, particularly in patients with chronic hemolytic anemia. It has been postulated that viruses and/or antigens, through the mediation of γ interferon or the cytokine cascade, induce lymphocyte activation and ultimately apoptotic death of hematopoietic cells in the bone marrow^[17].

Clinical presentation includes symptoms and signs related to pancytopenia, such as pallor, fatigue, hemorrhagic manifestations, progressive anemia, and bacterial infections. The diagnosis of HAA is suggested by a complete blood count, which reveals pancytopenia (including anemia) together with absolute reticulocytopenia^[16]. A bone marrow biopsy typically reveals hypocellularity that affects red and white cell precursors and megakaryocytes; residual hematopoietic cells appear morphologically normal^[19].

The two major options for treating severe HAA are hematopoietic cell transplantation and immunosuppressive therapy. According to recent reviews, response rates to these approaches are 75%-88% and 75%-80%, respectively^[16,18]. Blood and platelet infusions are often necessary before instituting specific treatment; before administration blood products should be irradiated to avoid sensitization.

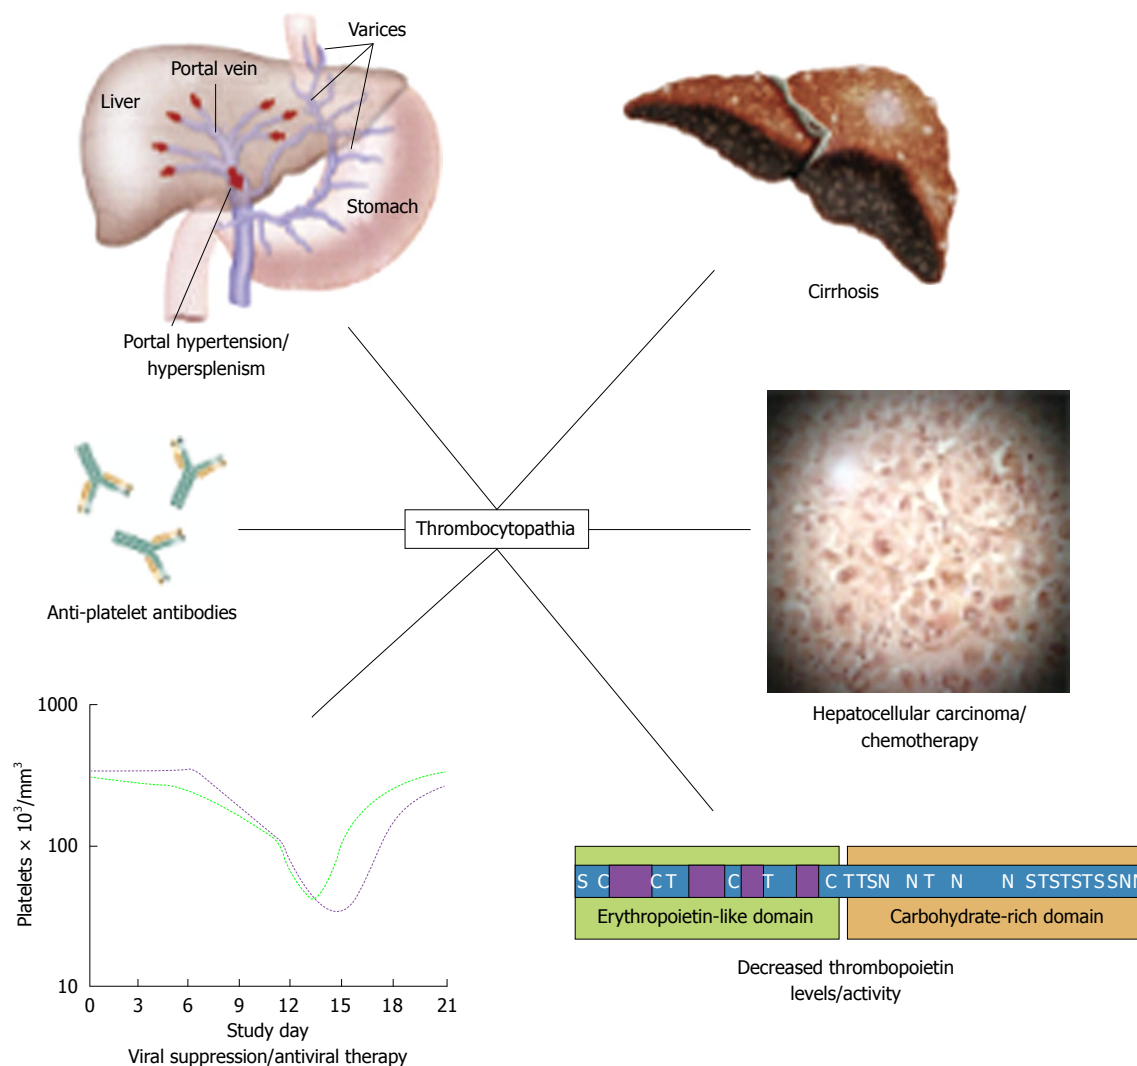

Figure 1 Development of thrombocytopenia in patients with chronic liver disease (adapted from Afdhal *et al*^[12]).

ANEMIA SECONDARY TO TREATMENT OF HEPATITIS

Currently, optimal treatment for chronic infection with HCV infection is a combination of therapy with pegylated interferon and ribavirin. Of hematological abnormalities that may be associated with such combination therapy, the most common is anemia^[21]. Significant anemia (hemoglobin < 10 g/dL) has been observed in 9%-13% of patients receiving interferon and ribavirin; moderate anemia (hemoglobin < 11 g/dL) occurs in about 30% of patients undergoing such treatment^[20-22]. There are several mechanisms by which anemia may occur during combination therapy for HCV infection, and ribavirin and/or interferons may contribute to anemia. In this context, hemoglobin concentrations decrease mainly as a result of ribavirin-induced hemolysis^[20].

Anemia caused to ribavirin leads to modifications of the dose in up to 25% of patients, and this type of anemia may be problematic in patients with HCV infection, especially those who also have renal or cardiovascular disorders. Adherence to ribavirin therapy is one factor that is critically important in the treatment

of HCV infection. Although ribavirin-associated anemia can be reversed by reducing the dose of ribavirin or by discontinuing the drug altogether, this approach compromises outcomes by significantly decreasing rates of sustained virological response. A recent study reviewed the predictors of anemia in patients undergoing treatment for HCV infection^[21]. Patients with impaired renal function may be at an increased risk of ribavirin-related anemia and, accordingly, should be monitored carefully. Furthermore, a decrease in hemoglobin concentration of ≥ 1.5 g/dL by week 2 of treatment has been found to be an excellent early predictor of subsequent substantial decreases in hemoglobin. This predictor might be applied to identify candidates for early intervention for management of anemia to facilitate maintenance of the dose of ribavirin. One of the specific approaches to manage ribavirin-associated anemia is administration of recombinant human erythropoietin^[21]. After 16 wk of ribavirin therapy, patients who had also been given erythropoietin alfa had significantly higher mean hemoglobin levels than patients in a control group. In patients with chronic hepatitis C, viremide, a prodrug of ribavirin that is

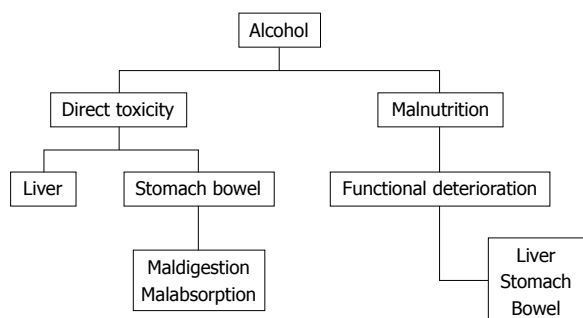

Figure 2 Scheme, in patients with alcoholic liver disease, depicting how different effects of alcohol may contribute to anemia (adapted from Moreno Otero *et al*^[23]).

selectively taken up by the liver, has the potential of maintaining the antiviral efficacy of ribavirin, while decreasing the risk of hemolytic anemia^[4].

Interferons may also contribute to anemia. Their main relevant action is induction of bone marrow suppression. This effect of interferon results in suppression of compensatory reticulocytosis associated with ribavirin-induced hemolytic anemia. Thus, the bone-marrow-suppressive effect of interferon may contribute to anemia, which complicates therapy with combination of interferon and ribavirin^[4].

ALCOHOL, LIVER DISEASE AND ANEMIA

Alcohol is implicated in the pathogenesis of chronic liver disease; it may contribute to anemia secondary to its direct effects on the liver and also to other diverse mechanisms (Figure 2)^[23].

Markers of iron overload tend to be higher among those who consume more than two alcoholic drinks per day than among non-drinkers, after adjusting for potential confounding factors^[24]. Consumption of alcohol appears to be associated with an approximately 40% reduction in the risk of development of iron deficiency anemia.

Folic acid and vitamin B12 deficiencies develop frequently in patients with cirrhosis. These deficiencies may be related to inadequate food intake or intestinal malabsorption. They are suspected when examination of a blood film reveals hypersegmented cells and oval macrocytes, in addition to round macrocytes characteristic of chronic liver disease. When anemia is caused by these deficiencies, the mean corpuscular volume is increased and bone marrow shows megaloblastic erythropoiesis.

Anemia due to folic acid deficiency may result, not only from a lack of folic acid in the diet, but also the weak antifolate action of ethanol. Folic acid deficiency is the most common cause of a low hematocrit in hospitalized patients who are alcoholics^[25,26]. Parenterally administered vitamin B12 not only corrects anemia caused by vitamin B12 deficiency, but may also induce improvement in the peripheral neuropathy that are associated with this deficiency^[23]. Supplements of vitamins A, B and C may be administered empirically to patients with advanced alcoholic disease.

Table 2 Etiologic factors that may contribute to anemia associated with alcoholism (adapted from Lewis *et al*^[26])

Cause of low hematocrit	Possible contributing factors
Hemorrhage and/or iron deficiency	Alcoholic gastritis Portal hypertension Peptic ulceration
Hemolysis	Chronic liver disease and/or cirrhosis Zieve syndrome Spur cell anemia of severe liver disease
Reduced erythropoiesis	Anemia of chronic disease Nutritional (e.g. folic acid deficiency) Sideroblastic anemia Alcohol toxicity
Hypersplenism	Portal hypertension
Hemodilution	Fluid retention of chronic liver disease Aggressive intravenous fluid therapy

Anemia in an alcoholic may also arise as a consequence of the direct toxic effects of alcohol on erythrocyte precursors in the bone marrow. Management of alcohol-induced suppression of erythropoiesis includes abstinence from alcohol and a nutritious diet with appropriate supplements.

Other factors that may contribute to anemia and a low hematocrit in alcoholic patients are given in Table 2.

CONCLUSION

Liver diseases are frequently associated with hematological abnormalities. Anemia of diverse etiology occurs in many of these patients. Bleeding is one of the most severe causes of anemia, with a high mortality, and defective blood coagulation contributes to the anemia. Other mechanisms of anemia include aplastic anemia secondary to previous hepatitis, or side effects of treatment of hepatitis with interferon and ribavirin. In patients with alcoholic liver disease, different effects of alcohol may contribute to anemia, such as malabsorption, malnutrition or direct toxic effect. The pathogenesis of the anemia in each case is different and it is important to begin the correct therapy.

Abstract

Too often anemia is considered a rare or unimportant manifestation in inflammatory bowel disease (IBD). However, over the last 10 years a number of studies have been conducted and the most relevant conclusions obtained are: (1) anemia is quite common in IBD; (2) although in many cases anemia parallels the clinical activity of the disease, many patients in remission have anemia, and iron, vitamin B12 and/or folic acid deficiency; (3) anemia, and also iron deficiency without anemia, have important consequences in the clinical status and quality of life of the patient; (4) oral iron can lead to gastrointestinal intolerance and failure of treatment; (5) intravenous iron is an effective and safe way to treat iron deficiency; (6) erythropoietin is needed in a significant number of cases to achieve normal hemoglobin levels. Thus, the clinician caring for IBD patients should have a comprehensive knowledge of anemia, and apply recently published guidelines in clinical practice.

INTRODUCTION

In addition to the intestinal signs and symptoms (such as abdominal pain or diarrhea), inflammatory bowel diseases (IBD), including Crohn's disease and ulcerative colitis, are associated with a number of extraintestinal manifestations (at joints, skin, eyes, etc). Furthermore, systemic manifestations of IBD may also include malnutrition and anemia^[1,2].

Compared with the average awareness of other extraintestinal disease complications such as arthritis or osteopathy, the topic of anemia in IBD has received little attention: perhaps it is so common that sometimes it is considered an unavoidable manifestation of the disease^[2,3]. Although efficient therapeutic options have been developed for the treatment of IBD-associated anemia, treating anemia often has had a low priority for gastroenterologists^[4]. However, anemia is a clinically relevant condition which may affect quality of life or the ability to work^[5,6], and it is a comorbid condition which is associated with other diseases (such as transfusion-associated hepatitis C) or even death^[1,7].

Anemia is a disease and should be approached as such. Anemia in IBD is not just a laboratory marker, it is a condition which needs a specific diagnostic and therapeutic approach. Moreover, it is a complex condition, because there are many factors which can cause anemia in IBD patients.

The aim of the present manuscript is to review the main clinically relevant aspects of the diagnosis and management of anemia in the patient with IBD.

PREVALENCE OF ANEMIA IN IBD

Often anemia is not even mentioned, perhaps because some authors think it is a rather uncommon problem in IBD^[2]. On the contrary, anemia is very common in IBD patients, although the reported prevalence of this condition has been markedly variable, depending both on the definition and on the patient population considered (hospitalized patients vs outpatients)^[1,8]. In a systematic review published in 2004, the prevalence of anemia in

patients with IBD ranged from 9% to 74%^[8]. In a more recent systematic review^[1], which included 19 studies (mainly on Crohn's disease) the figures ranged from 6% to 74%. Even more recently, we reviewed published studies evaluating the prevalence of anemia in IBD^[9-30], and calculated a mean prevalence of 17%^[2]. However, as the prevalence was 16% in outpatients, this figure increased up to 68% when only hospitalized patients were included. Therefore, it may be concluded that anemia could be the most common systemic complication of acute IBD^[2].

PREVALENCE OF IRON DEFICIENCY IN IBD

It is also common to consider that iron deficiency is an exceptional finding in IBD^[2]. On the contrary, this condition is even more common than anemia, but to demonstrate it requires active investigation. In fact, iron deficiency is the main cause of anemia in IBD patients, as a consequence of dietary restrictions, malabsorption (in part as a result of inflammation), intestinal bleeding, and/or undertreatment of anemia (achieving normal hemoglobin values does not mean normal iron stores). In a recent systematic review^[1], the prevalence of iron deficiency ranged from 36% to 90% (depending on the definition of iron deficiency and on the type of cohort included)^[16,21,26,31-33]. In the most recent systematic review^[2], mean prevalence of iron deficiency in IBD was 45%, which underlines the fact that this condition may be considered the rule rather than the exception in these patients, especially in severe cases.

THE MULTIFACTORIAL ORIGIN OF ANEMIA IN IBD

Anemia in patients with IBD results primarily from iron deficiency because of chronic intestinal blood loss from inflamed mucosa, although in active disease more complex mechanisms involving absorption are also important^[34]. However, the anemia in IBD is likely to be multifactorial in origin, frequently being the result of a combination of iron deficiency (the first cause) and anemia of chronic disease (the second major cause)^[35]. In some cases, anemia may also be induced by drugs (sulfasalazine, thiopurines), hemolysis, and myelodysplastic syndrome. Finally, in some patients with Crohn's disease, impaired absorption of vitamin B12 and/or folate because of small intestinal inflammation and/or extensive bowel resection, may contribute to anemia^[35], and all these conditions frequently overlap. Therefore, anemia in IBD is often complex and commonly represents a particular example of the combination of, at least, iron deficiency anemia and anemia of chronic disease, and may be a challenge even to the most astute clinician^[4,24].

IRON METABOLISM PARAMETERS FOR THE DIAGNOSIS OF IRON DEFICIENCY IN IBD

The diagnosis of iron deficiency is traditionally based on

a combination of parameters, including hematological and iron metabolism indices^[36]. Pure iron deficiency is recognized by low iron, ferritin and transferrin saturation but increased transferrin concentrations. However, diagnosing iron deficiency in the setting of IBD may be difficult, particularly when both iron deficiency and the anemia of chronic disease are present (as previously mentioned, both conditions frequently coexist). In these circumstances, many of the laboratory measures of iron status may be unreliable, as inflammation influences parameters of iron metabolism^[24,37]. For example, in the presence of chronic inflammation, the elevation in transferrin levels typical of iron deficiency may not be found, as patients with low albumin tend also to have low transferrin concentrations^[38]. Similarly, iron and total iron binding capacity levels are often difficult to interpret in the presence of inflammation^[35]. Finally, serum ferritin, the most accessible and well known measure of stored iron and the most powerful tests for iron deficiency^[39], can be normal or even increased - in response to inflammation, as it is an acute phase reactant - even in the presence of severe iron deficiency^[24]. Therefore, although at present ferritin is generally considered as the most efficient indicator of iron deficiency, this parameter may not provide adequate information about the storage compartment in the setting of inflammatory conditions such as IBD^[24]. Testing for increased soluble transferrin receptor concentration distinguishes reliably between iron deficiency and anemia of chronic disease, but it is not yet widely available^[40,41].

Accordingly, it has been suggested that diagnostic criteria for iron deficiency need to be adapted to the level of inflammation. Thus, in patients without biochemical (C-reactive protein, *etc*) or clinical (diarrhea, endoscopic findings, *etc*) evidence of inflammation, the cut-off point for defining a low level of serum ferritin is < 30 µg/L; however, in the presence of inflammation, the lower limit of this parameter consistent with normal iron stores should be increased up to 100 µg/L^[37,42]. Some authors do suggest considering the presence of ferroopenia if there are low iron values and < 16% transferrin saturation^[43].

DRUG-RELATED ANEMIA IN IBD

Some drugs commonly used in the treatment of IBD can have myelosuppressive effects, both indirect (for instance the "antifolate" effect of salazopyrine) or even direct (such as azathioprine or mercaptopurine)^[44]. In particular, sulfasalazine affects erythropoiesis by several mechanisms including folate absorption, hemolysis and aplasia^[45]. Isolated anemia in patients on azathioprine or mercaptopurine is unlikely to be caused by these drugs; in some cases, however, a mild and asymptomatic reduction in hemoglobin may be detected in patients treated with thiopurine drugs.

THE IMPACT OF ANEMIA ON THE QUALITY OF LIFE OF IBD PATIENTS

The repercussion of anemia on quality of life in

both general patients^[46,47] and specifically in patients with IBD^[3,4,6,8] is substantial. Moreover, anemia may impair quality of life even in the absence of specific symptoms^[5,6]. As has accurately been noted by Gasche *et al.*^[3,4], for a long time it was thought that the clinical symptoms of anemia (such as fatigue, headache, dizziness, shortness of breath, or tachycardia) occurred only when the hemoglobin level dropped abruptly. It had been argued that patients would adapt to low hemoglobin levels if anemia developed slowly. This has led to the concept of “asymptomatic” anemia. In truth, the term “asymptomatic” seems to reflect the fact that impairments in physical condition, quality of life, and cognitive function may be unrecognized by both patients and their doctors. Therefore, the process of adaptation to chronic anemia would, in fact, be adaptation to a lower quality of life^[3,4]. These concepts have been thoroughly developed in other pathologies, especially in patients on dialysis: intravenous iron can be a key point in management of these patients^[48].

Remarkably, the quality of life in IBD patients may be as low as in anemic patients with advanced cancer^[49]. Moreover, chronic fatigue caused by anemia can debilitate, affect and worry these patients as much as abdominal pain or diarrhea^[4]. Therefore the beneficial impact on quality of life derived from anemia correction in IBD patients can be similar to the control of diarrhea^[4,6,50].

THE ROLE OF TREATMENT OF THE UNDERLYING DISEASE (IBD) ON THE CORRECTION OF ANEMIA

A general correlation exists between disease activity and the depth of the anemia^[38]. Active disease can cause anemia because of multiple factors, the most recently demonstrated being anemia of chronic disease and impairment of iron absorption in active Crohn's disease. Therefore, the most important measure for IBD anemia treatment is the treatment of the underlying disease^[1,24]. Although apparently obvious, sometimes this step is missed in actual clinical practice. Moreover, the long term effect to alleviate anemia depends on whether the bowel inflammation itself can be adequately treated. Every effort to accomplish this has to be undertaken in order to preclude recurrent anemia^[37,51].

WHEN TO START IRON SUPPLEMENTATION IN IBD ANEMIC PATIENTS?

There may be a tendency to look upon anemia as an unavoidable accompaniment to IBD^[38]. Only in recent years has correction of anemia been highlighted as a specific therapeutic aim in these patients^[38]. It should not be assumed that some level of anemia is a normal finding in IBD patients and consequently need not be treated^[3]. On the contrary, iron supplementation should be started as soon as anemia (hemoglobin < 13 g/dL in

males, and < 12 g/dL in females^[52]) is detected. Thus, the World Health Organization definitions of anemia apply to patients with IBD. In fact, it is possible that patients without anemia but with iron deficiency should be considered for treatment because even without anemia, iron deficiency can have clinical relevance. In summary, anemia in IBD patients should be aggressively diagnosed, investigated, and treated^[2].

WHEN TO STOP IRON SUPPLEMENTATION IN IBD ANEMIC PATIENTS?

Apart from the correction of hemoglobin levels, the primary therapeutic goal is to improve quality of life. Therefore, the therapeutic objective of the treatment with oral iron should be to completely correct both the anemia and iron deficiency, and not only to partially increase the hemoglobin levels. Thus, our final aim should be to achieve the previously mentioned normal values (hemoglobin > 13 g/dL in males, and > 12 g/dL in females), in accord with that recommended in patients without IBD^[3,4,53]. In fact, it is important to remember that the highest improvement in the quality of life is observed precisely when the hemoglobin levels increase from 11 to 13 g/dL^[4,54]. Moreover, all patients should receive enough iron supplementation to correct anemia and replenish body stores^[39,55]. In other words, the goals of anemia treatment, both in patients with and without IBD, are to normalize not only the hemoglobin value but also the iron stores, usually defined by the serum ferritin level^[2].

DOSE OF IRON SUPPLEMENTATION IN IBD ANEMIC PATIENTS

Although conventional wisdom “says” that up to 200 mg of elemental iron (and even 400 mg in some textbooks) per day is required to correct iron deficiency anemia, this is probably incorrect^[56]. Since a maximum of 10-20 mg of oral iron can be absorbed per day, very high doses and even high doses are questionable. In fact, there is no rationale to use “high” doses of iron to treat iron deficiency anemia (in IBD or in any other associated disease). There is no evidence to support high doses of iron in comparative trials^[57-59]. This makes sense from a physiologic standpoint since it is well known that the iron absorptive process is very efficient yet can be saturated^[56]. In this respect, a single tablet of most of the ferrous salt preparations (for example sulphate) provides more iron than the intestine is able to absorb in one day^[57,58]. On the other hand, non-absorbed iron salts can be toxic to the intestinal mucosa^[60-67], and perhaps could activate the disease^[1,24]. In any case, high doses of iron may cause diarrhea, which in turn not only impair quality of life but also may make it difficult to differentiate from an IBD relapse^[65,68]. Finally, non-absorbed iron salts may inhibit (i.e. by feedback) the intestinal iron absorption and decrease tolerance and compliance, which is difficult especially in young patients requiring several complex oral treatments.

Therefore, since absorption and efficacy of oral iron are no greater when high doses are used, and because adverse effects of this preparation are dose-related, oral iron, if used, should be recommended in low doses (e.g. 50-100 mg of elemental iron daily)^[2].

RESPONSE OF ANEMIA TO ORAL IRON SUPPLEMENTATION IN IBD PATIENTS

The main factor in favor of oral iron is convenience. However, even when iron treatment is correctly prescribed, the oral route has relevant limitations, such as^[2]: (1) only part of the iron is absorbed and, as previously mentioned, experimental and clinical evidence suggests that the non-absorbed iron salts can be toxic and proinflammatory, and perhaps could activate the disease^[1,24]; (2) absorption of oral iron can be severely compromised because of disease activity^[34], and in some Crohn's disease cases because of previous intestinal resections or involvement of the duodenum; (3) oral iron is often not well tolerated by patients. From a recent systematic review on the management of anemia in IBD which included several studies prescribing oral iron^[27,35,65-67,69,70], the intolerance rate (mainly because of nausea, abdominal pain, or diarrhea) was a common finding leading to discontinuation in up to 21% of the cases^[1]. Moreover, IBD patients often do need to take several oral drugs and overall compliance could be compromised by oral iron side effects^[71]; (4) oral supplementation results in a slow response, and in some patients persistent blood loss exceeds the capacity of intestinal absorption of iron^[72].

INTRAVENOUS IRON FOR THE TREATMENT OF IRON DEFICIENCY ANEMIA IN IBD

The efficacy of intravenous iron for the treatment of iron deficiency anemia in the general population (without IBD) has been demonstrated in numerous studies^[73]. Although the experience with intravenous iron in IBD is more limited, it is similarly encouraging^[6,16,50,51,66,70,74-78]. Iron sucrose was prescribed in most cases, which was effective in 50%-91% of the patients (depending on the criteria used for efficacy definition)^[1]. More recently, a mean response of iron deficiency anemia to the treatment with this intravenous iron formulation was calculated to be 73%, which is a considerably high figure^[2]. In summary, intravenous iron sucrose is more effective (in terms of faster and prolonged response) than oral iron supplements, and has a better safety profile which might positively influence the compliance of IBD patients. Accordingly, the inconvenience of intravenous iron is offset by the advantages in achieving better therapeutic results.

Following a widely recommended algorithm, the initial therapeutic strategy of iron deficiency anemia in IBD patients would be based on the level of hemoglobin. Patients with hemoglobin > 10/10.5 g/dL would initiate

treatment with oral iron, while in those with levels < 10/10.5 g/dL, which are generally considered to denote severe anemia, the intravenous route would be of choice^[1,3,8]. Intravenous iron should also be prescribed to patients with hemoglobin > 10/10.5 g/dL when intolerance to the oral formulation is present. In summary, the established indications for the use of intravenous iron are: severe anemia (generally defined as hemoglobin < 10 g/dL^[1,8,37], although some authors set the cut-off point at 10.5 g/dL), need for quick recovery in mild anemia, intolerance to oral iron, and failure of oral iron.

Although in IBD iron sucrose is the most used intravenous formulation; there are other new intravenous iron preparations which theoretically could be used, with an extremely low incidence of adverse effects, and in particular severe adverse effects^[1,73,79,80], but data in the specific IBD population is lacking, as reviewed by Auerbach^[79]. The experience with low-molecular-weight iron dextran is rather more extensive and encouraging^[79] and also a new molecule, iron carboxymaltose, merits mention because its pharmacokinetic characteristics and preliminary clinical experience seems very promising, and in this case was obtained directly in an IBD population^[81].

ROLE OF ERYTHROPOIETIN IN THE TREATMENT OF ANEMIA IN IBD

As previously mentioned, anemia in IBD patients results primarily from iron deficiency because of chronic intestinal blood loss. However, intestinal inflammation is mediated by overproduction of cytokines, which may contribute to the generation of anemia in chronic disease, accompanied by inadequate erythropoietin production^[16]. Thus, IBD-associated anemia is a unique example of a combination of chronic iron deficiency and anemia of chronic diseases. Since it was first used in chronic renal failure, recombinant human erythropoietin has been shown to be effective for treating the anemia that accompanies several chronic diseases^[41]. During the last few years, several studies have evaluated the efficacy of erythropoietin in IBD patients, reporting encouraging results^[16,20,27,50,75,82-84]. Nevertheless, as the cost of erythropoietin is much higher than the cost of intravenous iron, the latter formulation should be considered first-line therapy in patients with severe anemia, and erythropoietin therapy should be considered only for patients with low erythropoietin levels or who are unresponsive to intravenous iron^[37,85]. One must not forget to exclude or correct other causes of anemia in IBD patients before administering erythropoietin^[86]. Finally, erythropoietin should be reserved for patients in which aggressive management of IBD (including immunosuppressive therapy) has not suppressed inflammation, which underlines the idea that erythropoietin is an adjunct, - and not an alternative, -to appropriate treatment of IBD^[38].

Erythropoietic agents should always be combined with intravenous iron supplementation, because functional iron deficiency, -defined as an inappropriate availability of iron for erythropoiesis despite normal

body iron stores, is likely to develop^[76]. In the particular case of Crohn's disease, folic acid and vitamin B12 status should also be frequently checked^[43] and deficiencies adequately corrected. Accordingly, erythropoietin therapy has been accompanied by iron supplementation in all trials published so far^[1]. In summary, the enhancement of erythropoiesis by erythropoietin makes it mandatory to administer iron supplementation during therapy to meet the increased demand^[86].

CONCLUSION

Anemia is rather common in IBD. Particularly in Crohn's disease, it can be a very difficult clinical problem because iron deficiency, vitamin B12 and/or folic acid defects, malabsorption, malnutrition, inflammation, intestinal resection, and drug effects all can be the cause or contribute to a multifactorial and complex problem. The control of inflammation is a key point, but often is not enough to treat anemia. As anemia has a considerable impact on the quality of life of patients, a thorough and complete diagnostic and therapeutic strategy should be followed to help our patients have as normal a life as possible. Very recent evidence raises a very important problem for the clinician: anemia can be a chronic or at least a recurrent problem in IBD; patients should be followed up after completing treatment, and anemia and iron deficiency actively assessed in the standard investigations^[48].

Abstract

The prevalence of anemia across studies on patients with inflammatory bowel disease (IBD) is high (30%). Both iron deficiency (ID) and anemia of chronic disease contribute most to the development of anemia in IBD. The prevalence of ID is even higher (45%). Anemia and ID negatively impact the patient's quality of life. Therefore, together with an adequate control of disease activity, iron replacement therapy should start as soon as anemia or ID is detected to attain a normal hemoglobin (Hb) and iron status. Many patients will respond to oral iron, but compliance may be poor, whereas intravenous (IV) compounds are safe, provide a faster Hb increase and iron store repletion, and presents a lower rate of treatment discontinuation. Absolute indications for IV iron treatment should include severe anemia, intolerance or inappropriate response to oral iron, severe intestinal disease activity, or use of an erythropoietic stimulating agent. Four different products are principally used in clinical practice, which differ in their pharmacokinetic properties and safety profiles: iron gluconate and iron sucrose (lower single doses), and iron dextran and ferric carboxymaltose (higher single doses). After the initial resolution of anemia and the repletion of iron stores, the patient's hematological and iron parameters should be carefully and periodically monitored, and maintenance iron treatment should be provided as required. New IV preparations that allow for giving 1000-1500 mg in a single session, thus facilitating patient management,

INTRODUCTION

When body iron stores are depleted, iron supplementation seems beneficial, although the optimal route of administration remains controversial. Oral iron supplementation is adequate in some clinical conditions. Administration of oral iron, in the absence of inflammation or significant ongoing blood loss, can correct the anemia, provided significant doses can be tolerated. However, although conventional wisdom “says” that up to 200 mg of elemental iron per day is required to correct iron deficiency anemia (IDA), this is probably incorrect^[1]. Early studies indicated that the co-administration of iron with ascorbic acid (vitamin C) might be of benefit in enhancing iron absorption, since, in theory, more ferrous iron is maintained in solution. However reports indicated that such co-administration can induce severe toxicity in the gastrointestinal tract^[2]. Moreover, classically, oral iron intake separately from meals is recommended for increasing its absorption but this enhances digestive intolerance and, therefore, decreases compliance. In addition, the absorption of iron salts can be diminished by co-administration of some antibiotics (mainly quinolones, doxycycline, tetracyclines, chloramphenicol or penicillamine); proton pump inhibitors and anti-acid medication (aluminum,

bicarbonate, zinc or magnesium salts), levodopa, levothyroxine, cholestyramine, phytates (high fiber diets), soy products, ibandronate, etidronate, tannates, calcium, and phenolic compounds (coffee, tea), whereas amino acids seem to act as enhancers of iron absorption^[3].

On the other hand, non-absorbed iron salts may produce a variety of highly reactive oxygen species including hypochlorous acid, superoxides and peroxides that may lead to digestive intolerance, causing nausea, flatulence, abdominal pain, diarrhea or constipation, and black or tarry stools, and perhaps could activate relapsed inflammatory bowel disease (IBD)^[2].

Although preoperative oral iron has shown to be efficacious in uncomplicated IDA, in anemia of chronic disease (ACD) [e.g. Crohn's disease (CD)], as well as in that associated with acute inflammation (e.g. postoperative period after gastrointestinal surgery), the effectiveness of oral iron administration is rather limited since absorption is down-regulated, and the small amount of iron absorbed is directed to the reticulo-endothelial system (RES), where it is sequestered^[4].

In these situations, intravenous (IV) iron has emerged as a safe and effective alternative for IBD anemia management. This takes into consideration factors such as intolerance of or contraindications to oral iron, severe anemia (especially if accompanied by significant ongoing bleeding), short time to surgery, need of a fast recovery or the use of erythropoiesis-stimulating agents (ESAs)^[5]. Because daily iron absorption is only 1-2 mg (up to 10 mg in deep ferroplenia), for patients presenting with moderate to severe anemia at least three to 4 mo of oral iron administration are needed to correct hemoglobin (Hb) levels and replenish iron stores. As IV iron can allow up to a five-fold erythropoietic response to significant blood-loss anemia in normal individuals^[6], Hb starts rising in a few days, the percentage of responding patients is higher and iron stores are replenished. Boosting iron stores is an advantage, particularly for patients receiving ESAs^[7].

INTRAVENOUS IRON AGENTS

All IV iron agents are colloids with spheroidal iron-carbohydrate nanoparticles. Each particle consists of an iron-oxyhydroxide core (Fe^{3+}) and a carbohydrate shell that stabilizes the iron-oxyhydroxide core. Differences in core size and carbohydrate chemistry determine pharmacological and biologic differences between the different iron complexes, including clearance after injection, iron release *in vitro*, early evidence of iron bioactivity *in vivo*, and maximum tolerated dose and rate of infusion^[8,9]. Complexes can generally be classified as labile or robust (kinetic variability), and as weak or strong (thermodynamic variability), with all possible intermediates. Four different products are mostly used in clinical practice: iron gluconate, iron sucrose, iron dextran, and iron carboxymaltose^[2,10,11] (Table 1).

Iron gluconate

Iron gluconate has a core tightly bound to gluconate

and weakly associated with sucrose (molecular weight 38 kDa), and is a type III iron complex (labile and weak) with fast degradation kinetics and direct release to plasma proteins (apotransferrin, apoferritin, and others). The potential for acute adverse reactions related to labile iron release after IV injection, which is caused by oversaturation of the transferrin binding capacity, is higher with iron gluconate compared to the other available IV iron preparations. Non-transferrin-bound labile iron may induce acute endothelial cell injury and a transient capillary leak syndrome. Clinical symptoms of iron acute toxicity include nausea, hypotension, tachycardia, chest pain, dyspnea (lung edema), and bilateral edema of the hands and feet, and should not be misread as anaphylaxis^[9]. To avoid these side effects, the maximum recommended dose is 125 mg; whereas the administration of total dose is not recommended. The use of iron gluconate for iron deficiency (ID) in patients on dialysis has been found to be efficacious and safe^[8,9].

Iron sucrose

Iron sucrose has a core tightly bound to sucrose (molecular weight 43 kDa), and is a partially stable type with medium degradation kinetics and partial uptake of released iron by plasma proteins such as (apo)-transferrin but also by the RES (Type II: semi-robust and moderately strong). Its half life is relatively short (5-6 h) and the amount of iron transported by transferrin, calculated using the Michaelis-Menten model for a single dose containing 100 mg of iron, is around 30 mg $\text{Fe}^{3+}/24 \text{ h}$ ^[12]. Following a single IV injection of 100 mg iron sucrose to anemic patients, up to 95% of the injected iron was utilized within 2-4 wk. During the last few years, experience of using iron sucrose in various forms of ID has evolved. In spite of its safety profile, nowadays a test dose is still required at most European countries. Single doses of 100-200 mg as an IV injection^[13] or up to 500 mg over an infusion time of 3.5 h seem to be safe^[14]. The maximal recommended dosage is 600 mg/wk (200 mg iron as iron sucrose injected or infused intravenously no more than three times a week) but this amount exceeds the physiological needs of the proliferating erythroblast. If the infusion speed is too fast (above 4 mg $\text{Fe}^{3+}/\text{min}$) or the single total iron dose too high (above 7 mg Fe^{3+}/kg , with a maximum of 500 mg), non-transferrin bound labile iron may cause transient hypotension, tachycardia, and dyspnea, as described for iron gluconate. Paradoxically diarrhea, epigastric pain or dummy aches could appear within minutes to hours after infusion. Cases of phlebitis have been described, but they are probably secondary to longer lasting administration (rather than larger doses), the need to keep a venous access, or the use of solutions that are too dilute (iron concentration must be at least 1 mg/mL). Overall, iron sucrose is currently considered as the safest IV iron preparation^[15].

Iron dextran

Iron dextran is a stable parenteral iron product with

Table 1 Some characteristics of the different intravenous iron formulations

	Iron gluconate	Iron sucrose	Iron dextran (LMWID)	Ferric carboxymaltose
Complex type	Type III	Type II	Type I	Type I
	Labile and weak	Semi-robust and moderately strong	Robust and strong	Robust and strong
Molecular weight (kDa)	38	43	73	150
Initial distribution volume (L)	6	3.4	3.5	3.5
Plasma half-life (h)	1	6	30	16
Labile iron release	+++	± ¹	-	-
Direct iron donation to transferrin (% injected dose)	5-6	4-5	1-2	1-2
Test dose required	No	Yes/No ³	Yes	No
Maximal single dose (mg)	125	300	TDI	1000
Premedication	No	No	TDI only	No
Life-threatening ADE ² (× 10 ⁶ doses)	0.9	0.6	11.3	??
Death rate (× 10 ⁶ doses) ²	0.25	0.11	0.78	??

¹If the infusion speed > 4 mg Fe³⁺/min or dose > 7 mg Fe³⁺/kg; ²Data from patients with chronic kidney disease; ³Not required at USA and UK. ADE: Adverse drug events; LMWID: Low molecular weight iron dextran; TDI: Total dose infusion.

a molecular weight of 73 kDa (Low molecular weight iron dextran, LMWID) or 156 kDa (High molecular weight iron dextran, HMWID). This type I iron complex (robust and strong) shows high structural homogeneity and only slow and competitive delivery to endogenous iron binding proteins. Complexes are actively phagocytosed by macrophages of the RES before they are released and become available for Hb synthesis. Although the plasma half life of LMWID is 30 h (3 d for HMWID), the full process of iron release from the dextran complex in the RES, storage in ferritin and delivery as TBI to the bone marrow or other tissues may take several months^[16]. Iron dextran can be administered as intramuscular (i.m.) or IV injections and as IV infusion, but a test dose is always required before the first administration. The stability of the dextran complex allows administration of high single doses (so called “total dose infusion” which may be given over 4-6 h). In contrast, the bioavailability of iron following i.m. administration has not been studied extensively. There seems to be a risk of incomplete and variable absorption of the iron from the injection site, and a considerable amount (30%-50%) of iron can remain at the i.m. injection site for many months. Therefore i.m. injections are no longer recommended^[17]. However, these iron complexes may cause well known dextran-induced anaphylactic reactions, especially in patients receiving HMWID (not commercially available in Europe and considered as an obsolete and dangerous IV iron agent). The exact mechanism of the anaphylactic reaction to iron dextran has not been clarified yet, but it seems to be related to the antibody-mediated release of mediators by mast cells^[15].

Ferric carboxymaltose (FCM)

FCM is another stable parenteral iron product with a molecular weight of 150 kDa very similar to iron dextran in terms of stability and structure (Type I, robust and strong). The pharmacokinetic characteristics of FCM are similar but not identical to iron dextran. The distribution volume of both preparations corresponds

nearly to that of plasma, but half life is approximately 16 h for FCM as compared to 30 h for LMWID. It seems that FCM is broken down quicker than iron dextran because α -amylase does not affect dextran, or acts at a very slow rate^[2]. A study using positron emission tomography has shown that iron from FCM accumulates in the liver, spleen and bone marrow and substantial amounts were found in these organs within minutes. In addition, FCM is able to exchange iron rapidly with transferrin^[18]. As a result, the utilization of iron for RBC increased rapidly up to days 6 to 9, after which the utilization increased at a much lower rate. Patients with IDA showed iron utilization over 90% after 24 d compared to 60%-80% utilization for patients with renal anemia^[18]. FCM is designed to mimic physiologically-occurring ferritin, providing high iron utilization, without the disadvantageous characteristics associated with iron dextran (anaphylaxis) and iron sucrose (high pH, high osmolarity, dosage limitations, and the long duration of administration). Up to 100-200 mg FCM can be administered as IV injection and up to 1000 mg iron can be infused in at least 15 min and no test dose is required (Table 1). In comparison, the European Union (EU) prescribing information for other IV iron preparations indicates they can be administered only in low doses (e.g. usual recommended dose of LMW iron dextran is 100-200 mg of iron and the maximum EU dose of iron sucrose is 200 mg of iron) over a period of greater than 30 min, which results in the need for frequent infusions to administer the total calculated iron replacement dose^[19]. No serious adverse effects, including deaths, were considered related or likely related to FCM by trial investigators; however, the US Food and Drugs Administration has raised concerns about a potential mortality safety signal based on an increased of deaths in comparison to other arms across clinical trials^[20]. In contrast, since 2007 the use of FCM corresponds to over 17 000 patient-years (one patient corresponds to 2000 mg iron), and up to September 2008 no anaphylactoid reactions or death have been reported, suggesting a good safety profile for FCM^[2]. Therefore, information regarding

FCM safety in the clinical setting is somehow conflictive and further post authorization trials to confirm its benefit and safety are needed.

EFFICACY OF PARENTERAL IRON AGENTS IN IBD

Experience with the use of IV iron therapy is extensive in different clinical settings over the last 60 years. In the late 1980s, the introduction of recombinant human erythropoietin (rHuEPO) led to a revitalized interest in the use of iron therapy, either in combination with rHuEPO therapy, or alone. Intravenous iron therapy can be used in a variety of clinical settings, as long as iron parameters are carefully monitored. In a number of studies, IV iron was shown to be useful for the treatment of anemia associated with a variety of medical [IBD, chronic kidney disease (CKD), chronic inflammatory arthritis, congestive cardiac failure, pregnancy and postpartum, or cancer] and surgical conditions (orthopedic, cardiac, colorectal cancer, and gynecological surgical procedures)^[21,22]. Interestingly, in the settings of CKD or cancer related anemia, the use of IV iron resulted not only in a more rapid and complete response to rHuEPO, but also in a reduction of rHuEPO dose, and probably in a reduction of rHuEPO side effects, such as thrombosis^[23,24].

Approximately, one third of IBD patients suffer from recurrent anemia across different studies (ranging from 6% to 73%, depending on Hb cut-off for the definition of anemia; patient selection, IBD phenotype and year of publication), and the prevalence of ID is even higher [mean prevalence: 45%, 95% confidence interval (CI): 40%-50%]. A retrospective study found that the prevalence of mild to moderate anemia significantly decreased in the IBD population between 1993 and 2003 (33.8% *vs* 16.7%, $P = 0.013$), although the prevalence of severe anemia was similar (6.3% *vs* 5.6%, $P = \text{NS}$), and the only difference detected between the two cohorts was the increased use of immunosuppressive drugs (mainly azathioprine)^[25]. Both ID (due to intestinal blood loss that cannot be matched by duodenal iron absorption, creating a negative iron balance) and ACD (due to the inflammatory nature of the disease) contribute most to the development of anemia in IBD, whereas cobalamin or folate deficiency and various other causes of anemia such as hemolysis occur infrequently. Whatever the underlying mechanism, anemia is universally accepted as a condition having a significant impact on the affected patient's quality of life^[1,26].

Anemia control and recovery in patients with IBD has a beneficial impact on quality of life indices. Our goal is to attain Hb levels above 13 g/dL in males and 12 g/dL in females by the administration of iron supplements, with or without erythropoietin. However, it is worth noting that without an appropriate control of disease activity, the management of anemia associated to IBD is much more difficult. Thus, it is desirable to initiate the pharmacological treatment after adequate inflammation control^[27].

According to the recommendations of the Guidelines on the Diagnosis and Management of Iron Deficiency and Anemia in Inflammatory Bowel Diseases (Statement 2B), iron supplementation should be initiated when IDA is present (Grade A). For ID without anemia, different approaches to iron replacement should be considered and discussed with the patient. If patients are likely to develop IDA the monitoring frequency should be increased (Grade D)^[26], although it is unknown how often monitoring should be performed.

When body iron stores are depleted, iron supplementation seems beneficial, although the optimal route of administration remains controversial. Total iron deficit (TID) can be calculated using the Ganzoni's formula: $\text{TID (mg)} = \text{Weight (kg)} \times (\text{Ideal Hb} - \text{Actual Hb}) \text{ (g/dL)} \times 0.24 + \text{depot iron (500 mg)}$.

According to this formula, a person weighing 70 kg with an Hb level of 9 g/dL would have a body iron deficit of about 1400 mg. Nevertheless, Ganzoni's formula may underestimate iron depot in males, as in them it has been consistently reported to be 700-900 mg^[28]. Thus, a TID of 1600-1800 mg may be a more realistic estimation for this subject.

Following the administration of oral iron to a patient with uncomplicated IDA, it takes 2-2.5 wk for the Hb to start rising, 2 mo for it to reach normal levels and 6 mo for iron stores to be replete^[7]. However, the efficacy of oral iron therapy in IBD patients may be hindered by some IBD specific factors, such as reduced absorption of iron due to inflammation and gastrointestinal side effects of oral ferrous iron (due to the release of activated hydroxyl radicals that may lead to digestive intolerance, causing nausea, flatulence, abdominal pain, diarrhea or constipation, and black or tarry stools)^[2]. In addition, oral iron compounds are not all alike, as they may vary in composition, elemental iron concentration, absorption profile, efficiency or tolerance. As a non-written rule, the best tolerated oral agent is usually the one that contains or delivers less iron.

In a crossover study of 19 IBD patients randomly assigned to start treatment with ferrous fumarate 120 mg orally once daily or iron sucrose 200 mg IV three times during a period of 14 d, oral ferrous fumarate, but not IV iron sucrose, increased clinical disease activity in IBD patients^[29]. In contrast, iron sucrose, but not ferrous fumarate, increased intravascular oxidative stress^[29]. However, a prospective study comparing usage, tolerance, and efficacy of 4 wk therapy with oral iron therapy in patients with ID and IBD and patients with ID of non-inflammatory cause, intolerance to iron was reported in 24% of the patients who had IBD (non-active) and 29% of the patients who did not ($P = \text{NS}$), and only a tiny minority of IBD patients relapse in association with use of oral iron therapy^[30]. This data suggest that patients with IBD are no more intolerant to oral iron than other patients and have similar rates of repletion, but the low number of evaluable patients ($n = 47$) precluded the drawing of definite conclusions. Nevertheless, to avoid the risk of poisoning,

Table 2 Characteristics of the clinical trials involving IBD patients that compared IV iron administration with oral iron or no intervention included in this review

Study (yr)	n	Study design	Compound	Baseline Hb (g/dL)	Total dose, mg (schedule)	Duration (wk)	Response (%)	DCT (%)

¹Also no response or intolerance to oral iron or clinical need of quick recovery of anemia. ΔHb ≥ 2 g/dL or normal Hb; DCT: Discontinuation due to serious adverse events; F: Female; M: Male.

other oral iron compounds (such as iron polymaltose which has very low toxicity and meets the requirements for a food supplement) might be used instead of ferrous salt preparations^[2] and lower doses (e.g. 50-100 mg of elemental iron) should be recommended^[1]. Additionally, the response and tolerance should be monitored and treatment changed to IV iron if necessary (Grade C)^[26].

Is this statement supported by the information reviewed above? Because of the limitations of oral iron therapy in IBD patients, parenteral routes of iron administration should be preferred, even though many patients will respond to oral iron. Intravenous iron is more effective, better tolerated, and improves quality of life to a greater extent than oral iron supplements (Grade A)^[26]. Absolute indications for IV iron include severe anemia (Hb < 10 g/dL), intolerance or inappropriate response to oral iron (once iron therapy has been initiated the response may be: “complete”, if Hb increases ≥ 2 g/dL; “partial”, if Hb increases 1-1.9 g/dL; or “no-response”, if Hb increases < 1 g/dL), severe intestinal disease activity, concomitant therapy with an erythropoiesis stimulating agent, or patient preference^[26]. In a prospective study of 103 patients with severe IBD-associated anemia who received IV iron sucrose for 4 wk (total dose 1200 mg), Gasche *et al*^[31] investigated the parameters that can predict effectiveness. Overall, a complete response at the end of the fourth week was observed in 67 (65%) patients, and the variables significantly associated with response were serum erythropoietin, soluble transferrin receptor, transferrin, and IL-6 levels. Once again, these data emphasized the need for an adequate inflammation control in IBD patients. We will review some studies assessing the efficacy of IV iron in anemic IBD patients (Table 2).

In this regard, a retrospective observational study in IBD patients with poor response or intolerance to oral iron, the administration of iron sucrose (200 mg once or twice per week to reach total ID) resulted in a “complete” response (Hb increment ≥ 2 g/dL or correction of anemia) in 60% of patients within 8 wk and in 90% of patients within 12 wk^[32]. However, a randomized, controlled, open-label, multicenter trial performed in 46 patients with anemia and transferrin saturation ≤ 20% and/or serum ferritin concentrations ≤ 20 µg/L found no differences in Hb increment within 6 wk between patients receiving IV iron sucrose and those receiving iron sulfate, but resulted in building up iron stores (about ferritin = 200 ng/mL, after 6 wk)^[14]. In addition, intractable gastrointestinal adverse events caused permanent study drug discontinuation in five patients (20.8%) receiving iron sulfate, whereas only one patient (4.5%) was withdrawn because of side effects due to IV iron sucrose^[14]. Thus, although being equal in short-term efficacy, these results suggest a better gastrointestinal tolerability for iron sucrose.

In a very recent study, 91 patients with IBD and anemia (Hb < 11.5 g/dL) were randomized to oral iron sulfate (*n* = 46) or IV iron sucrose (*n* = 45) treatment for 20 wk. More patients in the IV iron group completed the study (93% *vs* 78%, *P* = 0.001), increased their Hb ≥ 2 g/dL (66% *vs* 47%, *P* = 0.07), raised their ferritin levels to normal (74% *vs* 48%, *P* = 0.013), and recovered from anemia (84% *vs* 59%, *P* = 0.007) compared to patients in the oral iron group. In addition, treatment with IV iron sucrose improved iron stores faster and more effectively than oral iron (*P* = 0.002). Only 22 patients (48%) tolerated the prescribed oral dose, and 52% reduced the dose or withdrew from treatment because of poor tolerance^[33].

Finally, in a prospective multicenter study of 100 IBD patients with IDA [59 CD, 41 ulcerative colitis (UC)], those with Hb > 10 g/dL were prescribed oral ferrous sulphate ($n = 78$) and those with Hb < 10 g/dL received IV iron sucrose ($n = 22$). Hb normalization was achieved in 89% with oral and 77% with IV iron, and was associated with a relevant improvement in the patients' quality of life. IBD activity increase was not demonstrated in any patient. Four patients (5.1%) showed oral iron intolerance leading to discontinuation of treatment, whereas no adverse events were reported for IV iron^[34]. Thus, oral iron treatment was effective and well tolerated in most IBD patients, and did not exacerbate the symptoms of the underlying IBD, whereas IV iron was an effective and safe treatment in more severely anemic or intolerant patients.

At one author's centre, the safety and efficacy of IV iron sucrose therapy was evaluated in a preliminary study of 70 patients with digestive pathology (54 IBD: 27 CD, 18 UC, nine pouchitis)^[34]. IV iron sucrose in an "outpatient regimen" was used for patients with IDA due to digestive disorders with at least one of the following criteria: (1) no response or intolerance to oral iron; (2) IBD with severe anemia (Hb < 10.5 g/dL) and/or (3) clinical need of quick recovery of anemia. Average baseline Hb was 9.8 ± 1.7 g/dL, and 11.7 ± 1.5 g/dL at the end of treatment (mean increase 1.9 g/dL, range -2 to 5.5 g/dL), Hb increase exceeded 2 g/dL in 47% of treatments, and anemia was corrected in 67.8% of patients. No severe adverse events were witnessed. The authors concluded that IV iron sucrose should become the standard of care in IBD patients with ID^[35].

Therefore, treatment with IV iron sucrose is effective, safe, and well tolerated in correcting Hb and iron stores in patients with IBD, especially in those with severe anemia. The main disadvantage of IV iron sucrose is the need for multiple infusions as the maximum weekly dose should not exceed 600 mg. The availability of stable parenteral iron compounds allowing for TDI infusion may greatly facilitate iron replacement therapy in IBD patients.

As for children, the safety and efficacy of IV iron therapy was retrospectively evaluated in 70 pediatric patients with IBD (50 CD, 20 UC) who received a total of 119 TDI iron dextran infusions between February 1994 and February 2000. The average increase in Hb concentration was 2.9 g/dL. The authors concluded that TDI infusion of iron dextran, when appropriately used, is a safe and potentially efficacious treatment for children with IBD and IDA who are unresponsive to, or noncompliant with, oral iron therapy^[36]. However, as mentioned above, iron dextran, especially HMWID, has the disadvantage of potentially life-threatening dextran-associated anaphylactic reactions.

More recently, Kulnigg *et al.*^[37] randomized 200 anemic IBD patients (about Hb = 9 g/dL) to receive IV FCM (FCM, $n = 173$; maximum 1000 mg iron per infusion) at 1-wk intervals until the patients' calculated TID was reached or oral ferrous sulfate (100 mg *bid*)

for 12 wk. There were no differences between groups in Hb improvement at week 12 (3.8 ± 2.0 g/dL in both groups) or treatment-related adverse events, but response (defined as Hb increase of > 2.0 g/dL) was higher for FCM at week 2 ($P = 0.0051$) and week 4 ($P = 0.0346$), with a lower rate of discontinuation of study medication due to adverse events (1.5% and 7.9%, respectively), than for oral iron. Thus, FCM seems to be effective and safe in IBD-associated anemia.

Overall, from data depicted in Table 2, the mean response of IBD-associated anemia to treatment with IV iron (weighted mean) was (281/382) 73.6% and (140/215) 65.1% with oral iron, [odds ratio (OR): 1.49, 95% CI: 1.02-2.17, $P = 0.02$]. When the analysis was performed for data extracted from prospective randomized trials only, the response to IV iron was 72.5% (143/198) *vs* 58.2% (71/122) (OR: 1.87, 95% CI: 1.13-3.09, $P = 0.0097$). In addition, reviewed data strongly suggest that for patients with IBD, treatment with IV iron is effective, safe, well tolerated, provides a fast Hb increase and a sufficient refill of iron stores, and presents a lower rate of treatment discontinuation than oral iron. However, further research is needed to ascertain what is the appropriate timing to start treatment, which are the target Hb and ferritin levels to reach, and how IV iron may affect IBD clinical time course.

A TENTATIVE ALGORITHM FOR IRON REPLACEMENT IN IBD

Although further research is needed to ascertain what is the appropriate time to start treatment, which are the target Hb and ferritin levels to reach, or how IV iron may affect the IBD clinical time course, a tentative, easy to follow algorithm for iron replacement in IBD patients is depicted in Figure 1.

According to this algorithm, in which we assume that the severity of ID and anemia correlates with disease activity, the total iron dose and the route of administration rely upon baseline Hb, serum ferritin level and transferrin saturation. For male IBD patients (70-90 kg) with Hb > 13 g/dL and ferritin < 30 ng/mL, TID is estimated to be around 800-1000 mg. The corresponding value for TID in women (60-80 kg) with Hb > 12 g/dL would be 600-800 mg. If there are no contraindications, oral iron would be the simplest replacement therapy (50-100 mg/d, for 2-3 mo), and iron complexes are preferred to iron salts. If there is a contraindication for, or a non adequate response (ferritin < 100 ng/mL after 6-8 wk) to, oral iron, an IV iron preparation should be administered: iron sucrose (200 mg IV, 1-2 times/wk), LMWID (up to 1000 mg IV, single dose), or FCM (up to 1000 mg IV, single dose).

As for patients with Hb between 10 g/dL and 12/13 g/dL, ferritin < 100 ng/mL and transferrin saturation < 20%, TID is estimated to be 1300-1800 mg. Oral iron supplements could still be indicated (100 mg/d for 4-6 mo) but the IV route is preferred, as it will pro-

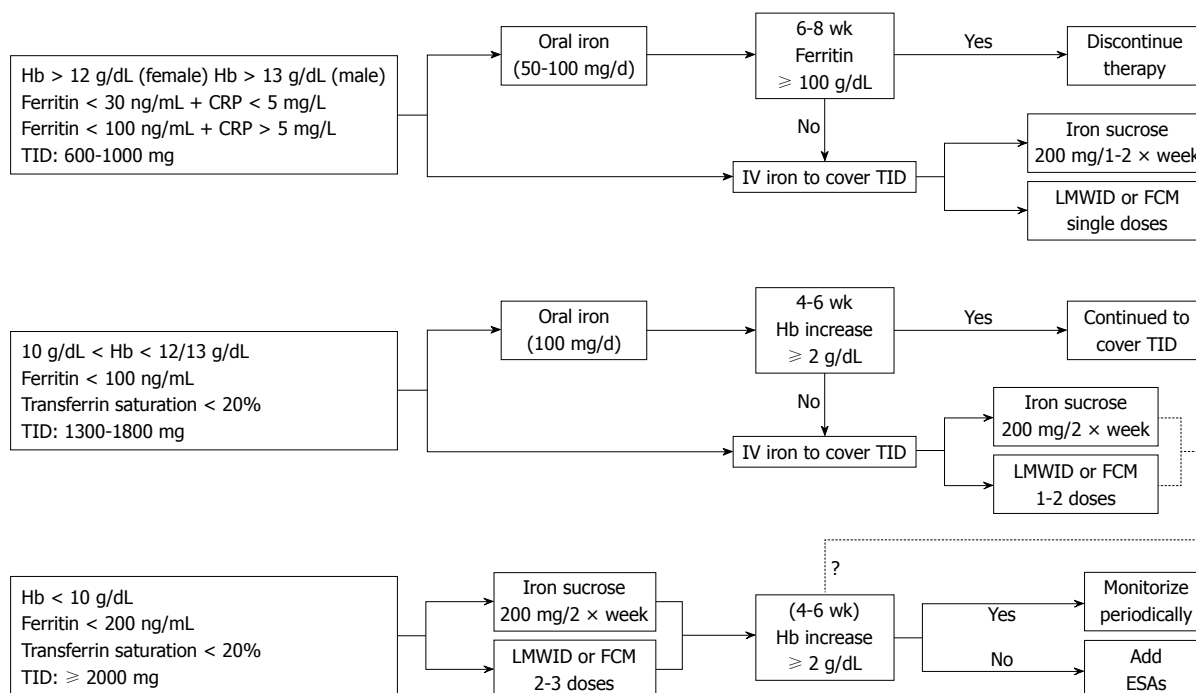

Figure 1 A tentative algorithm for iron replacement therapy in patients with inflammatory bowel disease. Hb: Hemoglobin; TID: Total iron deficit; CRP: C-reactive protein; LMWID: Low molecular weight iron dextran; FCM: Ferric carboxymaltose; ESA: Erythropoiesis stimulating agent.

vide a faster Hb recovery (iron sucrose 200 mg IV, twice a week; LMWID or FCM, two doses one week apart). Nevertheless, IV iron should be administered when there is intolerance to, or a non complete response to, oral iron, as defined by an Hb increase ≥ 2 g/dL or Hb normalization.

For patients with Hb < 10 g/dL and transferrin saturation < 20%, a higher ferritin trigger is selected (< 200 ng/mL), and a TID ≥ 2000 mg is estimated. These patients should receive IV iron (iron sucrose 200 mg IV, twice a week; LMWID or FCM, 2-3 doses). Patients should be re-evaluated after 4-6 wk; if there is not a complete Hb response, adjuvant treatment with erythropoiesis stimulating agents (e.g. epoetin, darbepoetin) should be considered.

SAFETY OF PARENTERAL IRON AGENTS

Nausea, abdominal pain, constipation, diarrhea, injection site reactions (pain, superficial phlebitis), metallic taste, headache, dizziness and rash may occur with all IV preparations, and were observed in clinical trials with an incidence of 1%-3%. However, the incidence of life-threatening adverse drug events (ADEs) associated with parenteral iron is much smaller.

Allergic and anaphylactic reactions

The numbers of non-CKD patients receiving IV iron are not large enough to draw definitive conclusions regarding the safety of IV iron agents in these clinical settings. Therefore, we will focus on ADEs associated with parenteral iron in CKD patients, as they are the largest collective receiving these drugs. According to data from the

United States Food and Drug Administration (FDA) on ADEs attributed to the provision of four formulations of IV iron (HMWID, LMWID, iron gluconate and iron sucrose) during 2001-2003, the total number of reported parenteral iron-related ADEs was 1141 amongst approximately 30 million doses administered (approx. 38 ADEs per million), with 11 deaths (seven iron dextran, three iron gluconate, one iron sucrose)^[15]. Relative to lower molecular weight iron dextran, total and life-threatening ADEs were significantly more frequent among recipients of higher molecular weight iron dextran and significantly less frequent among recipients of sodium ferric gluconate complex and iron sucrose. The absolute rates of life-threatening ADEs were 0.6, 0.9, 3.3 and 11.3 per million for iron sucrose, sodium ferric gluconate complex, lower molecular weight iron dextran and higher molecular weight iron dextran, respectively, whereas absolute rates of death were 0.11, 0.25, 0.75 and 0.78 per million, respectively (Table 1). However, there were no significant differences in mortality rates between LMWID and iron gluconate (OR: 0.3, 95% CI: 0.1-1.3) or iron sucrose (OR: 0.2, 95% CI: 0.1-1.0), and there are no conclusive data available regarding the safety of FCM. Therefore, the frequency of IV iron-related ADEs reported to the FDA has decreased, and overall, the rates are extremely low (Table 1). In addition, the rates of ADEs associated with IV iron, including iron-related deaths, are much lower than that of ABT-related severe side effects (10 per million) and ABT-related deaths (four per million)^[38].

IV iron and infection

Current information on the relationship between IV iron and infection, and between IV iron and oxidative

stress deserves special consideration. Elemental iron is an essential growth factor for bacteria with many species expressing iron transport proteins that compete with transferrin, and it has long been suggested that patients with iron overload are at increased risk of infection^[39]. In contrast, in the peritoneal dialysis population, no increased risk of peritonitis was found in patients receiving IV iron with respect to those not receiving IV iron^[40]. In addition, a meta-analysis of six observational studies (807 patients) revealed that the administration of IV iron to patients undergoing major orthopedic surgery led to a significant decrease in both transfusion rate [relative risk (RR): 0.60, 95% CI: 0.50-0.72, $P < 0.001$] and infection rate (RR: 0.45, 95% CI: 0.32-0.63, $P < 0.001$)^[41]. Nevertheless, despite this absence of definitive clinical data, it seems sensible to avoid IV iron administration in the setting of acute infection, and to withhold IV iron in patients with pre-treatment ferritin values > 500 ng/mL^[5].

IV iron and oxidant damage

Biologically active iron, which is released by all IV iron agents, also plays a role in inflammation, oxidative stress and the propensity for accelerated atherosclerosis. Persistent oxidative stress in CKD patients promotes inflammation and, in turn, atherogenesis, and increased cardiovascular morbidity and mortality. However, available evidence relating IV iron administration to atherogenesis is indirect, and there is little evidence that IV iron adversely affects survival in patients with dialysis-dependent CKD. Nevertheless, the evidence argues for caution, not complacency, in prescribing IV iron^[9].

IV iron and cancer development

The association between iron overload with cancer risk in humans has been under increased scrutiny in recent decades, although epidemiological studies on the association of iron with cancer remain inconclusive. The concerns are mostly focused on a possible risk associated with dietary iron in colorectal cancer, the increased risk of developing hepatocellular carcinoma in hereditary hemochromatosis and related hepatic iron overload and cirrhosis, and association between occupational exposure to iron and kidney, lung and stomach cancers. The risk of iron-induced sarcoma by repeated i.m. injections of iron dextran has also been raised. However, IV iron therapy has not been associated with an increase in tumor incidence^[42].

CONCLUSION

The prevalence of anemia across the studies on patients with IBD is high (30%) and that of ID is even higher (45%). However, the prevalence of anemia is decreasing, and this seems to be related with the availability and use of IV iron^[43].

Iron replacement therapy should start as soon as anemia or ID is detected (Grade D), and its goal is to attain a normal level of Hb, ferritin and transferrin saturation (Grade D)^[26]. Importantly, our efforts to correct anemia

should rely on adequate inflammation control, in the absence of which no proper approach to this condition is feasible^[27].

Although many IBD patients will respond to oral iron, IV iron is more effective, better tolerated, and improves the quality of life to a greater extent than oral iron supplements (Grade A)^[26]. Absolute indications for IV iron include severe anemia, intolerance or inappropriate response to oral iron, severe intestinal disease activity, use of ESAs, or patient preference^[26].

The use of ESAs should be restricted to those patients presenting with Hb < 10 g/dL and who do not appropriately respond to IV iron replacement for 4 wk (Grade B)^[26].

After the initial resolution of anemia and the repletion of iron stores, patients should be closely monitored, and maintenance iron treatment should be provided as required. New IV preparations that allows for giving up to 1000-1500 mg in a single session, provide an excellent tool to avoid or treat anemia and ID in the IBD patient population.

Abstract

Anemia is the most common complication of inflammatory bowel disease (IBD). Control and inadequate treatment leads to a worse quality of life and increased morbidity and hospitalization. Blood loss, and to a lesser extent, malabsorption of iron are the main causes of iron deficiency in IBD. There is also a variable component of anemia related to chronic inflammation. The anemia of chronic renal failure has been treated for many years with recombinant human erythropoietin (rHuEPO), which significantly improves quality of life and survival. Subsequently, rHuEPO has been used progressively in other conditions that occur with anemia of chronic processes such as cancer, rheumatoid arthritis or IBD, and anemia associated with the treatment of hepatitis C virus. Erythropoietic agents complete the range of available therapeutic options for treatment of anemia associated with IBD, which begins by treating the basis of the inflammatory disease, along with intravenous iron therapy as first choice. In cases of resistance to treatment with iron, combined therapy with erythropoietic agents aims to achieve near-normal levels of hemoglobin/hematocrit (11-12 g/dL). New formulations of intravenous iron (iron carboxymaltose) and the new generation of erythropoietic agents (darbepoetin

INTRODUCTION

Anemia is a frequent complication in patients with digestive diseases, especially chronic processes such as inflammatory bowel disease (IBD)^[1,2], and is associated with a higher rate of hospitalization and worse quality of life^[3,4]. The main cause of anemia associated with IBD is iron deficiency, but there is also a component of anemia that is associated with chronic diseases. Therefore, when there is no good response to intravenous iron therapy, combination with erythropoietic agents, erythropoietin (EPO) or darbepoetin, may assist in the management of anemia^[3,5-7]. The other subgroup of patients with digestive diseases in whom we can use erythropoiesis-stimulating agents (ESAs) are those being treated for chronic hepatitis C, whose anemia is caused by the use of rivabirin^[8,9].

Human EPO is a glycoprotein hormone of 30.4 kDa, which is composed of 165 amino acids, and is the main regulator of erythropoiesis. It inhibits the apoptosis of erythroid progenitors and induces the clonal proliferation of normoblasts^[10-12]. In adults, it is synthesized mainly in the kidney, which produces 90%-95% of the total circulating EPO; the remainder, about 10%, is synthesized by liver^[13,14]. In addition to kidney and liver, it has been shown that other organs can secrete EPO, including peripheral endothelial cells, vascular smooth

muscle cells, neurons, astrocytes, cardiomyocytes and microglia^[15].

The basal production maintains a relatively constant level of EPO in plasma, within a range between 5 and 29 U/L, which can increase up to 100 times in the presence of serious anemia^[16]. Tissue hypoxia is the most important trigger for increased synthesis of EPO^[10,17].

In 1977, Miyake *et al*^[18] purified EPO molecule, which enabled cloning of the gene in 1983, and the subsequent development of recombinant EPO in mammalian cell lines^[19]. The clinical use of EPO was started in 1986^[20] for the treatment of anemia of chronic kidney disease (CKD)^[21]. Treatment with EPO was able to eliminate almost completely transfusion dependence in hemodialysis patients, who in turn achieved a significant improvement in quality of life^[22-24]. Treatment of anemia with EPO has helped to reduce the need for transfusions and the associated risks: transmission of infection, allogeneic iron overload and immunological damage^[25].

There is a general consensus, as stated by the recommendations of panels of international experts (The National Kidney Foundation Dialysis Outcomes Quality Initiative^[26], the Canadian Society of Nephrology^[27], the European Renal Association/European Dialysis and Transplantation Association^[28,29], Kidney Disease: Improving Global Outcomes^[30] and the Japanese Society for Dialysis Therapy^[31,32]), that the partial correction of anemia in patients with CKD improves clinical parameters and quality of life compared with the lowest levels of hemoglobin^[26-32]. At present, for instance, in the United States, > 90% of patients on chronic dialysis and 30% on pre-dialysis are treated with EPO, with an average hemoglobin level of 12.0 g/dL^[33-35]. Subsequently, its use has been extended to the treatment of anemia associated with other diseases such as cancer^[36-38], IBD^[3,5-7], heart failure^[39,40] and the anemia associated with hepatitis C virus treatment^[8]. In addition to its role as an erythropoietic agent, EPO has other potential therapeutic uses currently under extensive investigation^[41,42], for use as a cytoprotective agent in the central nervous system^[43,44] and intestinal mucosa^[45-47]. Other possible applications include are cytoprotection in peripheral neuropathy, retinopathy and myocardial ischemia^[48,49].

TYPES OF EPO

In clinical practice there are several forms of EPO available for the treatment of anemia (Table 1). The first generation are two forms of recombinant human EPO (rHuEPO): epoetin α (Epogen, Amgen and Procrit/Eprex; Johnson & Johnson/Janssen-Cilag) and EPO β (NeoRecormon; Roche), which are administered three times a week^[50]. The development during the last decade of ESAs with a higher degree of glycosylation and prolonged half-life has allowed less frequent administration. A preparation called long-acting darbepoetin α (Aranesp; Amgen) produces a similar physiological response compared with rHuEPO^[51]. It has more chains of carbohydrates and sialic acid residues, which gives it a different

pharmacokinetic profile from that of rHuEPO, with a half-life approximately three times higher (25.3 h *vs* 8.5 h by iv administration), and a plasma clearance four times slower. This allows a frequency of administration of once weekly, or even every 2-4 wk^[52,53]. The equivalence relationship between rHuEPO and darbepoetin α from the molecular weight of both proteins is 1:200^[54]. In clinical practice, the multiplication factor is not so simple, as the required dose of rHuEPO can be higher, which probably is related to an increase in resistance to EPO^[55]. A pegylated derivative, the continuous EPO receptor activator (CERA) (epoetin β -methoxy polyethylene glycol, CERA; Roche) is another erythropoietic agent that activates repeatedly the EPO receptor. It has an elimination half-life in humans of about 130 h, and so can be administered every 3-4 wk^[56-59]. Several studies have shown an effect similar to EPO in maintaining hemoglobin levels^[60-65]. CERA is not available in United States, but is currently used in Europe. An additional advantage is that CERA can be kept out of the fridge and used for up to 1 mo (at < 25°C).

There is a new generation of erythropoietic analogues: synthetic erythropoiesis protein and peptide mimetics of EPO. These new agents stimulate erythropoiesis through activation of EPO receptors^[66-69]. Hematide (developed by Affymax) is a synthetic peptide agonist of the EPO receptor, and although it has no structural homology with EPO, it is able to activate the EPO receptor and stimulate erythropoiesis over a 1-mo period, with good tolerance and stability at room temperature^[66].

SIDE EFFECTS OF ESAs

The use of ESAs is related to several common side effects that should be well known by clinicians. Hypertension is the most common side effect, with an overall incidence of 5%-24%^[70]. Vascular access thrombosis occurs with higher incidence^[71,72], although it is not found in other small studies^[73,74]. The risk of serious cardiovascular events, such as thromboembolism and death, increases when hemoglobin levels increase rapidly (> 1 g/dL every 2 wk)^[75]. The development of anti-EPO antibodies is a very rare but serious complication of treatment with erythropoietic agents. From 1998 to 2004, it was apparent that there was a significant increase in the number of patients who developed pure red-cell aplasia (PRCA) secondary to the appearance of neutralizing anti-EPO antibodies^[76,77]. PRCA is characterized by severe anemia, high transfusion requirement and a total lack of response to increasing doses of rHuEPO. Most of the reported cases have been patients with chronic renal failure who received rHuEpo α (Eprex) subcutaneously. PRCA was related to a change of formulation of Eprex (replacement of human serum albumin by polysorbate 80, because of the risk of bovine spongiform encephalopathy) and formation of immunogenic micelles. Alternatively, it has been suggested that leachates released by the uncoated rubber stoppers of the pre-filled syringes may interact with polysorbate 80 and

Table 1 Erythropoietic agents available

	Half-life (h)		Periodicity	Initial dose	Target levels
	iv	sc			
Epoetin β	9	24	1-3 times per week	100-150 IU/kg per week, (max 300 IU /kg)	Hemoglobin: 11-12 g/dL, Hematocrit: 33%-36%, ↑ hemoglobin every 2 wk: 0.5-1 g/dL
Epoetin α	7	20	1-3 times per week	100-150 IU/kg per week, (max 300 IU /kg)	
Darbepoetin α	25	48	Every 1-2 wk	0.45 μ g/kg every 2 wk	
CERA	133	137	Every 2-4 wk	0.6 μ g/kg every 2 wk	

act as an adjuvant to the immune response. Failure in the cold chain is also a potential factor involved^[78-80]. The number of cases reported has dropped significantly from 2003, with none in 2007. This may have resulted from a change in the route of administration (at present the iv route is used in most patients on dialysis), maintenance of the cold chain, or elimination of uncoated rubber syringe stoppers^[75]. Should this complication occur, clinical guidelines for diagnosis and treatment are readily available^[81-84]. It has been suggested that the use of the new analogue hematide in these cases may be effective^[85].

Other possible side-effects are edema, fever, dizziness, insomnia, headache, pruritus, constipation, among other.

USEFULNESS OF ESAs IN DIGESTIVE DISEASES

IBD

Anemia is the most common complication of IBD^[86,87]. Inadequate monitoring and treatment leads to a worse quality of life^[88,89] and increased morbidity and hospitalization^[90-92]. Repeated loss of blood, and to a lesser extent malabsorption of iron are the main causes of iron deficiency in IBD^[86]. There is also a variable component of anemia that is related to chronic inflammation^[3,4,7,87,93]. This involves failure of iron transport that is mediated by inflammatory cytokines, such as hepcidin, which is the main negative regulator of iron absorption in the small intestine and of iron sequestration by macrophages^[94-101], and an inappropriately low production of EPO for the degree of anemia^[16,90,101-103]. The management of anemia in IBD should focus on proper control of the inflammatory process, as well as iron supplementation, and in cases of resistance, to assess iron therapy in combination with erythropoietic agents^[3,87,91,104]. Up to 25%-30% of patients with anemia associated with IBD combination therapy may require iron and erythropoietic agents to correct anemia^[3,105,106]. In other diseases (cancer, rheumatoid arthritis, AIDS), EPO levels < 500 mU/mL (some authors suggest < 100 mU/mL) may respond to administration of rHuEPO^[107-112].

In patients with anemia associated with IBD, high levels of transferrin (iron deficit indicators) as well as high levels of serum EPO (an indicator of a correct response to anemia) may predict a good response to treatment with iv iron. In contrast, low levels of serum EPO indicate the need to associate agents erythropoietic in addition to iron treatment^[3].

Since the increased production of hepcidin in anemia

of chronic diseases may limit the oral absorption of iron, it should be given by the iv route. The iv administration of iron has proven its efficacy, safety and tolerability, with iron sucrose^[7,89] as the new formulation iron carboxymaltose, that allows the administration of 1 g of iron in 15 min^[112,113]. The use of erythropoietic agents in the treatment of anemia associated with IBD is useful for patients who do not respond to treatment with iv iron, and in whom the aggressive treatment of IBD (including immunosuppressive therapy) has not abolished the mucosal inflammation, and who require additional blood transfusions^[5,7,114-116].

Hemoglobin target

Previous studies on the use of EPO in patients with CKD have found different results concerning the desirable target level of hemoglobin and its effect on cardiovascular prognosis. In 1997, the KDOQI guidelines^[117] recommended target levels for hemoglobin/hematocrit between 33% (11 g/dL) and 36% (12 g/dL). A similar recommendation was made in the 2006 update of the KDOQI guidelines^[26] although on that occasion, an upper limit for hemoglobin was set, because there was no evidence to maintain a target \geq 13 g/dL. The European Best Practice Guidelines Working Group did not recommend the complete correction of hemoglobin levels in patients with diabetes or cardiovascular disease^[29].

The clinical benefits and adverse effects associated with normal or near normal hemoglobin values were evaluated in multiple randomized studies that assessed mortality and morbidity from cardiovascular or cerebrovascular events, good control of blood pressure, quality of life, functional status and vascular access thrombosis^[71,118-126]. The results of these studies have not suggested any improvements after correction of anemia, except in quality of life. Despite differences in their populations, two large randomized studies published in November 2006, the CHOIR^[127] and CREATE^[128] studies have shown that attempts to correct anemia completely did not reduce mortality or cardiovascular disease in CKD patients, compared with partial correction. A meta-analysis that included these two studies concluded that patients with a higher target hemoglobin have a significantly higher risk of all-cause mortality and vascular access thrombosis^[129].

In light of these data, the KDOQI guidelines were reviewed and updated in 2007, with a recommended hemoglobin level of 11-12 g/dL, and not exceeding 13 g/dL^[130]. Also the European Best Practice Guidelines Working Group^[75] has concluded that hemoglobin

> 13 g/dL may be associated with cardiovascular events in these patients.

Factors that influence the increase in mortality with higher hemoglobin targets may include the impossibility of achieving the target hemoglobin, a too high hemoglobin target, the toxic effects of high doses of ESAs, the presence of comorbidity and other features^[131-135]. These factors were evaluated in a second analysis of the CHOIR study^[136] that found no clinical factor associated with risk, after adjustment and multivariate analysis, except for high dose of epoetin (> 20 000 U/wk), which was an independent risk factor for death, myocardial infarction, heart failure, or stroke. This increased risk was observed in the high and low hemoglobin groups, particularly among those who did not reach the target hemoglobin. These results suggest that increased mortality is due to high doses of ESAs rather than higher hemoglobin targets^[137]. Epoetin α dose should not exceed 20 000 U/wk in patients with CKD, and probably in other diseases. These patients should be assessed for other causes of poor response to treatment with EPO. Some studies have suggested the possible relationship between the variability of the hemoglobin level and the patient^[138,139]. Although there is variability in the results of different studies^[120,131,140-143], the most consistent observation is that there are better results in terms of quality of life, with no increase in adverse reactions of hemoglobin in the range of 11-12 g/dL (hematocrit 33%) compared with lower levels^[139-144]. There is a large study under way in relation to the normalization of hemoglobin. The Trial to Reduce Cardiovascular Events with Aranesp Therapy study is a randomized, placebo-controlled trial in pre-dialysis CKD patients with type 2 diabetes mellitus^[145,146], which is due to end in 2011.

In clinical practice, given the difficulty of maintaining standards within the narrow target range of 11-12 g/dL^[147-149], it's accepted the range 10-12 g/dL, particularly in patients with good tolerance.

The target haemoglobin level in patients with IBD is still to be determined. Data from recent studies in CKD patients indicate increased morbidity and mortality in relation to high levels of hemoglobin (normal)^[130-133], as in patients with cancer^[103,104]. It seems appropriate to establish a target hemoglobin level of 11-12 g/dL, which demonstrates greater benefit in quality of life and cost-effectiveness in renal patients^[120,133,139-145].

Dosage, monitoring and control

To maintain adequate levels of hemoglobin with erythropoietic agents iron stores must be normalized. Iron should be administered in sufficient quantity to achieve a transferrin saturation $\geq 20\%$ and a ferritin level ≥ 100 ng/mL^[7,87,150]. The response to EPO is dose dependent, but varies from patient to patient, depending on the frequency and route of administration (iv or sc), although to a lesser extent with darbepoetin^[151,152]. The hypertension may complicate treatment, particularly if hemoglobin level rises quickly (> 1 g/dL every 2 wk)^[153]. With the present preparations, sc and iv administration are indistinguishable; however, sc administration presents some advantages

over iv, such as a lower incidence of hypertension, and a 25%-50% reduction in dose compared with iv administration^[154-157]. Another important advantage of iv administration is a longer half-life (24 h vs 9 h)^[158,159]. Daily sc EPO is more effective than administration 2-3 times weekly^[160], although administration less frequently than every 2 wk is also effective^[161-163]. Discomfort at the injection site is minimal. It is important to remember to maintain the cold chain at 4°C to preserve a high effectiveness^[164].

EPO can be started at a dose of 100-150 U/kg per week sc with iron supplements. The dose can be increased by 25% every 2-4 wk to reach 300 U/kg per week. It is not worthwhile to continue increasing the dose in patients who do not respond after 12 wk, and in these patients, the dose should be kept to the minimum effective dose to avoid transfusion^[97,131]. The appropriate response should increase the hemoglobin level at least 0.5 g/dL at 2-4 wk. It is recommended analytical control in this period of time and if the hemoglobin increase is over target (> 10-12 g/dL) or > 1 g/dL in 2 wk, we must reduce dose by 25%. In contrast, if the hemoglobin level is < 10 g/dL (with adequate iron deposits) or hemoglobin increase < 1 g/dL in 4 wk, then we must increase dose by 25%^[101,104,165]. Children usually require higher doses than adults to achieve a similar response^[29,166]. In practice, most patients are dosed per unit dose (syringe) rather than kg. There are wide range of doses in pre-filled syringes.

Darbepoetin α can be administered iv and sc, with the main advantage of the half-life three times longer than epoetin. Effectiveness of Darbepoetin has been proved with administration weekly, every 2 wk^[167] and monthly^[117,168,169]. The initial dose of darbepoetin is 0.45 μ g/kg every 2 wk and that of CERA is 0.6 μ g/kg every 2 wk. Once the patient has been stabilized, the monthly dose may be doubled. Several well-designed prospective studies in renal patients have demonstrated the safety and effectiveness of weekly or even monthly treatment with epoetin α ^[170-174] in a similar way to new formulations of ESAs with long half-life^[175].

Resistance

Evidence of EPO resistance stems from studies with an inadequate response EPO in 5%-10% of patients^[176] or in patients who develop EPO resistance after a good initial response. There is a resistance to EPO when a sufficient dose of it, equal to or greater than 300 U/kg per week is not reached the desired concentration of hemoglobin^[28].

It has been shown that the most frequent and important cause of resistance to EPO is iron deficiency, but there are other less frequent factors^[28,177].

Blood loss is the most frequent cause of absolute iron deficiency, which is defined by ferritin levels < 100 ng/mL, transferrin saturation < 20%, and/or hypochromic red cells increased by 10%. Relative or functional iron deficiency results from difficulty in transferring stored iron to red blood cells and is defined by the existence of transferrin saturation < 20% while

maintaining high levels of ferritin > 100 ng/mL. The main causes of relative iron deficiency are acute and chronic inflammatory processes and chronic liver diseases^[178]. Elevated levels of parathyroid hormone in CKD patients are another cause of non-negligible resistance to EPO^[179]. The presence of an inflammatory disorder increases the resistance to treatment with erythropoietic agents, including the production of inflammatory cytokines that interfere with iron metabolism, reducing their availability in the bone marrow and causing functional iron deficiency. The process of dialysis may be associated with an increase in the induction of cytokines and the appearance of an inflammatory response syndrome^[180].

In patients undergoing hemodialysis, carnitine metabolism is altered and carnitine deficiency is more likely in patients with a protein-deficient diet and high dialysis dose^[181]. Carnitine may improve anemia in hemodialysis patients with EPO resistance^[182] by mechanisms not yet known^[183], or stabilizing the membrane as an antioxidant agent, or by stimulating erythropoiesis, by the increase in the number of reticulocytes demonstrated in some patients on hemodialysis treated with L-carnitine^[184]. The dose used in patients with EPO resistance is 1 g iv post-hemodialysis^[185].

Folic acid is involved in the process of regeneration and maturation of hematopoietic precursors. Folic acid deficiency is associated with ineffective erythropoiesis, and a megaloblastic anemia. Malnutrition, malabsorption, alcoholism, and various drugs that lower intestinal absorption, such as diphenylhydantoin, contraceptives and barbiturates, can cause folic acid deficiency. In dialysis patients with resistance to EPO, with normal ferritin levels, adjuvant treatment with folic acid may be attempted. It has been shown that the use of folic acid (10 mg/d) in hemodialysis patients improves the response to EPO, especially when presented with high mean corpuscular volume, even with normal levels of folic acid^[186].

The effectiveness of erythropoietic response to stimulation can be assessed by resistance index of ESAs. This expresses the relationship between the dose of erythropoietic agents and hemoglobin concentrations maintained (IU/kg per week divided by hemoglobin). Resistance index of ESAs varies from one patient to another and also in the same patient over time. These values range from 0 in patients able to maintain adequate hemoglobin level through the endogenous production of EPO, to > 50 IU/kg per week and per g/dL of hemoglobin in patients who cannot maintain adequate hemoglobin, even after high-dose EPO therapy (> 300 IU/kg per week)^[187-189].

Anemia following treatment with ribavirin in HCV patients

Hemolytic anemia is a frequent side effect of early use of ribavirin in the treatment of hepatitis C. It has a negative impact on quality of life, and it can, in extreme cases, cause deterioration in brain function and even death. Furthermore it is a common reason for reduction or discontinuation of antiviral therapy, which compromises the effectiveness and reduces the sustained viral response. The administration of EPO can

improve anemia, without the need to reduce the dose of ribavirin^[190-194].

FUTURE EXPECTATIONS WITH THE USE OF EPO

It has been discovered in recent years that the EPO is also synthesized locally by many tissues, especially in response to metabolic stress. EPO functions as a protective molecule that inhibits apoptosis in a wide variety of cell types, and reduces inflammation and local edema, as well as improving tissue regeneration^[195]. The mechanisms of tissue protection are mediated by a receptor. This receptor is different from that which mediates the effects of erythropoiesis of EPO^[196]. The future of EPO therapy in ischemic diseases, and as protective cytotoxic therapies appears promising. Of course clinical trials comparing its efficacy with other conventional therapies are needed^[197]. Also being evaluated is the effect of EPO on intestinal endothelial cells^[45], and in the maintenance and repair of the mucosa^[46].

SUMMARY AND PROSPECTS

For nearly 25 years, the anemia of chronic renal failure has been treated with rHuEPO, which has resulted in a significant improvement in quality of life and survival and avoidance of dependence on repeated transfusions^[22-24]. Subsequently, rHuEPO has been used in other conditions that occur with anemia of chronic diseases such as cancer, rheumatoid arthritis^[109] or IBD^[3,5,114-116], and anemia associated with the treatment of hepatitis C^[190-194]. It has also been investigated for its protective effects in other acute diseases such as myocardial ischemia and brain and kidney diseases^[198]. The classical dosing schedule of three times weekly has been simplified with the advent of new generations of erythropoietic agents such as darbepoetin α , which allows administration every 2 wk, and CERA, which has a longer half-life that allows prolonged administration monthly. Research continues to develop new biologically similar molecules such as agonists of the EPO receptor as hematein, which allows the treatment of patients with PRCA and monthly administration^[85]. As well as searching for orally active formulations that will simplify the management of anemia^[199-202]. There have also been negative aspects of treatment with EPO, as the cases of pure red cell aplasia^[64,80], or poor outcomes in relation to death and cardiovascular events in study of normalization of hemoglobin (in connection especially with high doses of EPO in patients with poor response)^[127-129,137] and worse survival in patients with cancer^[103,104]. However, EPO has been shown to be effective and safe in the treatment of anemia of chronic renal failure and has improved significantly quality of life of patients with chronic anemia^[22-25].

Similarly, the development of iv iron therapy was a major breakthrough in the management of chronic anemia. Iron sucrose has demonstrated its safety, efficacy and tolerance^[7,86,87]. Other new formulations of iron

that allow rapid iv administration of large doses with good efficacy and tolerance will make administration easier^[5,110,202].

CONCLUSION

To summarize we can say that erythropoietic agents come to complete the range available therapeutic for treatment of anemia associated with IBD that begins by treating the inflammatory disease basis, as well as intravenous ferroterapia first choice. In cases of resistance to treatment with iron may raise a combined therapy with erythropoietic agents to try to achieve near-normal levels of hemoglobin/hematocrit (11-12 g/dL). The new formulations of iv iron (iron carboxymaltose) and the new generation of erythropoietic agents (darbepoetin and CERA) will allow a more comfortable and spaced dosage schedule, with the same efficacy and safety.

Abstract

Allogeneic blood transfusion (ABT) is frequently used as the first therapeutic option for the treatment of acute anaemia in patients with inflammatory bowel disease (IBD), especially when it developed due to gastrointestinal or perioperative blood loss, but is not risk-free. Adverse effects of ABT include, but are not limited to, acute hemolytic reaction (wrong blood or wrong patient), febrile non-hemolytic transfusional reaction, bacterial contamination, transfusion-related acute lung injury, transfusion associated circulatory overload, transfusion-related immuno-modulation, and transmission of almost all infectious diseases (bacteria, virus, protozoa and prion), which might result in increased risk of morbidity and mortality. Unfortunately, the main physiological goal of ABT, i.e. to increase oxygen consumption by the hypoxic tissues, has not been well documented. In contrast, the ABT is usually misused only to increase the haemoglobin level within a fixed protocol [mostly two by two packed red blood cell (PRC) units] independently of the patient's tolerance to normovolemic anaemia or his clinical response to the transfusion of PRC units according to a "one-by-one" administration schedule. Evidence-based clinical guidelines may promote best transfusion practices by implementing restrictive transfusion

protocols, thus reducing variability and minimizing the avoidable risks of transfusion, and the use of autologous blood and pharmacologic alternatives. In this regard, preoperative autologous blood donation (PABD) consistently diminished the frequency of ABT, although its contribution to ABT avoidance is reduced when performed under a transfusion protocol. In addition, interpretation of utility of PABD in surgical IBD patients is hampered by scarcity of published data. However, the role of autologous red blood cells as drug carriers is promising. Finally, it must be stressed that a combination of methods used within well-constructed protocols will offer better prospects for blood conservation in selected IBD patients undergoing elective surgery.

Blood transfusion for the treatment of acute anaemia in inflammatory bowel disease and other digestive diseases. *World J Gastroenterol* 2009; 15(37): 4686-4694 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4686.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4686>

INTRODUCTION

In surgical, medical and critically ill patients, allogeneic blood transfusion (ABT) is frequently used as the first therapeutic option for the treatment of acute anaemia, especially when it developed due to traumatic or acute blood loss or when the patient's compensatory mechanisms have a limited capacity of response^[1-4]. As a result, a high proportion of patients receive at least one ABT unit during their hospital stays.

However, many reports show variation in transfusion practice for comparable groups of patients between hospitals, and even between different departments

within a hospital. Variations in rates of transfusion may be due to many factors, but still differing opinions on the threshold level of haemoglobin (Hb) and the implementation of transfusion alternatives are the most important ones. The first may reflect uncertainty about the benefits and risks of ABT, and the second different perceptions of the value of stimulation of erythropoiesis and minimising blood loss and subsequent transfusion^[5].

Of note, the main physiological goal of ABT, i.e. to increase oxygen consumption by the hypoxic tissues, has not been well documented^[6-8]. In contrast, the ABT is usually misused only to increase the Hb level within a fixed protocol [mostly two by two packed red blood cell (PRC) units] independently of the patient's tolerance to normovolemic anaemia or his clinical response to the transfusion of each PRC unit according to a "one-by-one" administration schedule.

Unfortunately, good clinical studies and outcome data establishing the benefits and risks of ABT for a patient in different clinical settings are not available^[9]. To the best of our knowledge, there are very few situations or pathological entities where ABT and/or liberal transfusion criteria have shown to benefit our patients (drepanocytosis, thalassemic or low-weight premature infants)^[10,11]. Thus, to promote best transfusion practices and reduce variability, minimizing the avoidable risks of transfusion, and to help clinicians in choosing the appropriate treatment options, a number of clinical guidelines have been issued by different medical societies^[12-17]. In this article, we review the indications, benefits and risks of blood transfusion of the different blood components available, both allogeneic and autologous, with special emphasis on patients suffering from inflammatory bowel disease (IBD), either ulcerative colitis (UC) or Crohn's disease (CD).

INDICATIONS FOR ABT

Transfusion of PRC is indicated in order to achieve a fast increase in the supply of oxygen to the tissues, when the concentration of Hb is low and/or the oxygen carrying capacity is reduced, in the presence of inadequate physiological mechanisms of compensation. Tissue oxygenation depends on various factors: (1) the concentration of Hb; (2) the saturation of Hb, which, in turn, depends on the O₂ tension and the affinity of the Hb for O₂; (3) the O₂ requirements, that is, the volume of oxygen needed by the tissues to carry out their aerobic function. But, there are a number of clinical factors that affect the physiological mechanisms of adaptation to anaemia: (1) a reduced increase in cardiac output: hypovolaemia, coronary artery disease, disorders of heart valves, congestive heart disease, negative inotropic drugs; (2) decreased capacity to increase the extraction of O₂: acute respiratory distress syndrome (ARDS), sepsis, systemic inflammatory response syndrome (SIRS), traumatic ischemia-reperfusion syndrome; three, altered gas exchange: chronic obstructive pulmonary disease (COPD), ARDS; and

four, increased consumption of O₂: fever, pain, stress, sepsis, SIRS or hyperventilation syndromes^[17].

When there is an indication to correct anaemia, but the situation is not urgent, strategies other than transfusion are preferred, such as the use of haematopoietic drugs (iron, vitamin B12, folic acid, recombinant erythropoietin) (see another chapter).

Non-surgical IBD patients

Nowadays the administration of oral or IV iron supplements, with or without erythropoiesis-stimulating agents, but not ABT, is the standard therapy for the anaemia of the medical IBD patient (see corresponding article in this issue). According to the recommendations of the Guidelines on the Diagnosis and Management of Iron Deficiency and Anemia in Inflammatory Bowel Diseases (Statement 3A), the goals of anaemia treatment are to increase Hb, and iron studies above the lower threshold of normal, to prevent a further fall in Hb, to avoid the use of ABT, to relieve symptoms related to anaemia, and to improve the quality of life (Grade D)^[18]. Nevertheless, some IBD patients are still being transfused, mostly because of acute gastrointestinal haemorrhage, although the Guidelines do not provided any recommendations in this regard. In our modest opinion, these ABT are some times administered without strict criteria, just to raise a low Hb figure ("cosmetic" transfusion) or to treat a hypovolemic situation, but not to correct transitorily hypoxic symptoms or signs.

Fortunately, severe acute gastrointestinal haemorrhage is uncommon in IBD, although among children 0-5 years of age patients presented with more rectal bleeding than patients aged 6-17 years, despite the later having a more complicated disease course^[19].

Belaiche *et al*^[20] reviewed 34 cases of acute gastrointestinal haemorrhage in CD patients (defined as acute rectal bleeding originating in diseased bowel and requiring an ABT of at least 2 U of PCR within 24 h). When the bleeding source was identified, the bleeding lesion was an ulcer in 95% of cases, most often in the left colon. The treatment was surgical (20.6%), endoscopic (20.6%), or medical (58.8%), and there were no deaths. The authors concluded that given the potential efficacy of endoscopic or medical treatment, as well as the absence of mortality, a conservative approach may be suggested as first-line therapy in the majority of patients.

Similarly, Pardi *et al*^[21] characterized the clinical features and course of such haemorrhage in patients at their institution from 1989 to 1996. Thirty-one patients had acute lower gastrointestinal bleeding from IBD (three UC, 28 CD), representing approximately 1% of admissions for IBD. Again, the bleeding lesion presented with an ileocolonic or colonic localization in most cases (68%), and surgery was required in less than half of cases. However, in both patient series, recurrent haemorrhage was not rare, and for these cases surgery may be the most appropriate treatment.

More recently, Kostka *et al*^[22] characterized the clinical features and course of 11 separate episodes of severe haemorrhage in six of 156 patients with CD (3.8%),

treated between 1985 and 2003 at their institution. Emergency surgery was necessary to stop the primary or recurrent haemorrhage in four patients. The authors concluded that, although a conservative approach may be first-line therapy, surgery is inevitable in patients suffering from massive bleeding and in patients with recurrent bleeding. Similar conclusions were reached by Veroux *et al*^[23] in a previous series of five CD patients with severe gastrointestinal bleeding.

In a recent review of five years, Campos *et al*^[24] reported 301 episodes of massive transfusion occurred at a university hospital, and found that 51 out of these 301 episodes were due to upper gastrointestinal haemorrhage (17%), with a mortality rate of 52%. It is recommended that the Transfusion Services have a special protocol to manage severe bleeding emergency, however the blood component administration schedules are neither clear nor uniform. In the last few years, there has been a general review of the blood component schedule during massive transfusion^[25]. Nowadays, data from several large observational studies show that early beginning of plasma and platelet administration, including the use of the so-called “transfusion packs”, could improve mortality of patients with severe bleeding^[26].

Surgical IBD patients

As for acute gastrointestinal haemorrhage, other emergency complications of IBD are rare, but may be life-threatening, require surgery, and result in permanent end organ damage. The most common non-bleeding complications associated with UC are fulminant colitis and toxic megacolon, and often result in a total proctocolectomy. The most common non-bleeding complications associated with CD are abscesses and intestinal obstruction, and usually also require surgical intervention and intestinal resection^[27].

Despite pharmacological advancements, the management of IBD has become increasingly complicated. In a study of 2892 adults with CD and 5895 with UC who received care between 1998 and 2005, Herrinton *et al*^[28] found: a shift in gastroenterology-related visits from the gastroenterology division to primary care; an increased use of IBD-related drugs; a 36% decline in the prevalence of prolonged steroid exposure for CD patients, with a 27% increase for UC patients; a 30% decline in the hospitalization rates for CD and UC patients; and a 50% decline in the surgery rate for UC, but no significant change for CD. In this regard, it is worth noting that in UC patients, surgery remains an important part of the overall treatment plan, especially for prophylactic total colectomy in certain patients at high risk for colorectal cancer^[29].

As for other patients undergoing major surgery, in the surgical IBD patient, intraoperative and postoperative management of potential or actual blood loss should include (ASA)^[16].

Monitoring the amount of blood loss: A periodic visual assessment of the surgical field and communication with

the surgical team should be done to assess the presence of excessive microvascular bleeding (i.e. coagulopathy).

Monitoring for the presence of inadequate perfusion and oxygenation of vital organs: By using conventional (e.g. blood pressure, heart rate, oxygen saturation, urine output, electrocardiography) and/or special monitoring systems (e.g. echocardiography, mixed venous oxygen saturation, blood gasses, National Institute of Radiological Sciences).

Monitoring for transfusion indications: Measure Hb or haematocrit when there is substantial blood loss or there is any indication of organ ischemia. However, as the haematocrit value is subjected to a variety of bias, especially in hypovolemic anaemic patients, Hb concentration should be preferred^[30]. In this regard, it's worth noting that in most of the available hematological analyzers the “haematocrit” is an indirectly calculated parameter.

Transfusion of allogeneic red blood cells (RBCs): Maintain adequate intravascular volume and blood pressure with crystalloids or colloids until the criteria for ABT are met (see below). Adequate quantities of RBCs should be transfused to maintain organ perfusion (PCR units should be transfused one-by-one, and anaemia symptoms reassessed after each transfusion). When appropriate, pre-deposited autologous blood donation and other means to decrease blood loss (e.g. deliberate hypotension, antifibrinolytics) may be beneficial (see below).

Hb transfusion triggers

The only indication for the transfusion of PRC is to correct or prevent tissue hypoxia; thus, the parameter “of choice” for making decisions should be intracellular pO₂. However, this parameter is not useful for clinical purposes and it is, therefore, necessary to rely on “surrogate” parameters, such as Hb and the haematocrit. The indication for and the degree of urgency of PRC transfusions cannot, however, be defined only on the basis of the values of Hb or the Htc, but must be based on a complete evaluation of the patient's clinical condition and the possible presence of mechanisms compensating for the anaemia (see above)^[17].

According to ASA guideline on blood transfusion^[16], PRC should usually be administered when the Hb level is less than 6 g/dL, whereas they are usually unnecessary when the level is more than 10 g/dL. These conclusions may be altered in the presence of anticipated blood loss. The determination of whether intermediate Hb concentrations (i.e. 6-10 g/dL) justify or require PRC transfusion should be individualised. This indication should be based on any ongoing indication of organ ischaemia, potential or actual ongoing bleeding (rate and magnitude), the patient's intravascular volume status, and the patient's risk factors for complications of inadequate oxygenation. These risk factors include a low cardiopulmonary reserve and high oxygen consumption^[16,17].

Table 1 Transfusion haemoglobin threshold according to patient's age and characteristics and type of anaemia

Haemoglobin threshold (g/dL)	Patients characteristics and type of anaemia
< 5	Patients with chronic anaemia and without risk factors ¹
< 6	Patients with symptomatic ² chronic anaemia and without risk factors
< 7	Acute anaemia in younger patients Asymptomatic chronic anaemia in patients with risk factors
< 8	Acute anaemia in surgical and critically ill patients
< 9	Acute anaemia in surgical patients older than 65 yr
< 10	Acute anaemia in patients with organ dysfunction ³
< 10	Patients with massive transfusion
> 10	Do not transfuse

¹Risk factors; ²Symptomatic anaemia; ³Organ dysfunction.

These indications are in agreement with those proposed by most international clinical guidelines and documents issued by several medical societies, such as the American Consensus Conference on perioperative red blood cell transfusion (Hb < 8 g/dL)^[12], British Haematological Society (Hb < 8 g/dL)^[13], the Scottish Guideline on Perioperative Blood Transfusion (Hb < 7 g/dL)^[4], or the Spanish Society for Blood Transfusion (Hb < 7 g/dL and Hb < 5 g/dL in chronic anemia)^[15]. Recently, the Italian Transfusion Society^[17] proposed the same recommendations as ASA^[16], but giving a Grade of recommendation 1A. A tentative table of Hb transfusion thresholds as a function patient's age and characteristics and type of anaemia is given in Table 1.

Transfusion yield

As a rough guide, in adults one unit of PRC increases the Hb concentration by 1 g/dL and the haematocrit by about 3%. In children, the transfusion of 5 mL/kg increases the Hb concentration by about 1 g/dL. In the case of a lower than expected transfusion yield, conditions causing the loss, sequestration or destruction of RBCs should be looked for. Such conditions include: occult bleeding, repeated blood sampling (particularly in children), fever, hypersplenism, primary and secondary immunological causes, mechanical or other type of hemolysis^[17].

BENEFITS OF ABT

The experience with Jehovah's Witness patients suggests that, overall, postoperative anaemia is well tolerated if Hb > 7 g/dL, but it increases the risk of mortality when Hb falls below 5 g/dL, this effect being magnified by blood loss and cardiac disease (Hb < 10 g/dL), and indirectly suggests that ABT is life-saving in this context^[9]. Also, ABT may be life-saving in children with severe anaemia and signs of respiratory distress and, possibly, in very low birth weight infants^[9]. In contrast, for critically ill patients, severe anaemia (Hb < 8 g/dL) increases the risk of mortality by 1.54, whereas the transfusion of 1-2, 3-4, or more than 4 U increases this risk by 1.48, 2.68, and

Table 2 Theoretical reasons supporting the restrictive or the liberal use of allogeneic red cells in normovolemic patients

Rationale supporting the liberal use of red cells
Augmenting O ₂ delivery may improve patient survival and functional recovery
Increased risk of coronary ischaemia due to increased demand
Reduces respiratory work
Age, disease severity and drugs may interfere adaptation to anaemia
Improved safety margin if further blood loss
Increased safety of donor blood products
Rationale supporting the restrictive use of red cells
Moderate anaemia has not proved to increased mortality
Red cell transfusions impair microcirculatory flow
Progressive loss of red cell functionality during storage
Pathologic supply dependency is rare
Risk of pathogen transmission
Immunodepression causing increased infections and tumor relapse following transfusion
Risk of TRALI and TACO
Blood products are increasingly scarce and expensive

TRALI: Transfusion-related acute lung injury; TACO: Transfusion associated circulatory overload.

4.01, respectively^[31]. However, ABT may be life-saving in extremely ill patients with cardiovascular disease^[11]. Theoretical reasons for using a "liberal" or "restrictive" transfusion protocol are given in Table 2.

On reviewing the literature, it can not be concluded that ABT is beneficial for less sick patients and those without cardiovascular disease when Hb is above 7 g/dL^[11,32]. On the other hand, the effects of anaemia below 7 g/dL and the subsequent beneficial effects of ABT, if any, can also not be determined from published studies since patients either refuse to receive ABT for religious reasons or are transfused systematically, except in the case of chronically anaemic patients like those with thalassemia or drepanocytosis^[10].

As for patients with cardiovascular diseases, there appears to be some evidence that ABT, in small amounts, can reverse ischaemic changes and restore normal myocardial function. However, the randomized controlled trials conducted so far have offered contradictory results regarding the safety of restrictive transfusion triggers in older patients. Whilst four of them reported that a restrictive transfusion protocol resulted in the transfusion of appreciably fewer units of RBC, with no differences between groups regarding postoperative morbidity or mortality^[11,32-34], the last one which was designed to find differences in postoperative quality of life, found that in elderly patients undergoing surgery for hip fracture repair a restrictive transfusion threshold (Hb < 8 g/dL) may result in a higher incidence of postoperative cardiovascular complications (10% *vs* 2%, *P* = 0.05) and 30 d mortality (8% *vs* 0%, *P* = 0.02) when compared with a liberal transfusion threshold (Hb < 10 g/dL)^[35]. The Transfusion Trigger Trial for Functional Outcome in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair^[36], which has been planned to be a 2600 patient, multicentre clinical trial, will most probably address the question of whether patients with cardiovascular disease

or cardiovascular risk factors undergoing surgical repair of hip fracture benefit from a higher or lower transfusion trigger^[15]. While data from randomized trials are available, patients with suspected or proven myocardial ischaemia must be closely monitored and ABT should be given unit-by-unit until cardiac function is normalized, rather than to adopt a fixed transfusion trigger for all such patients^[15].

Packed red cell transfusion to a predetermined Hb in view of optimizing oxygen transport is definitely not supported by a large trial in critically ill patients [Transfusion Requirements In Critical Care (TRICC) trial]^[11]. In fact, in the study by Hébert *et al*^[11], patients submitted to a restrictive transfusion strategy seem to have better outcomes than those submitted to a liberal transfusion strategy, especially those who are younger (< 55 years old) or less ill (APACHE score < 20). However, the analysis by Deans *et al*^[37] suggests that the results of the TRICC trial were strongly influenced by non-comparable subgroups with different practice misalignments in each arm of the study. The excess risk incurred by each of these subgroups makes the comparison of mortality rates between the two treatment arms in the overall study difficult to interpret. Furthermore, as publications before this trial indicated that clinicians used higher transfusion thresholds in patients with ischaemic heart disease compared with younger, healthier patients, neither arm fully represented or was compared with current practices, and it remains unclear if the use of an absolute transfusion threshold is superior to adjusting therapy based on individual patient characteristics or implementing consensus guidelines for transfusion practices^[37].

The rationale behind ABT is to restore oxygen delivery and provide a reserve should further blood loss occurs. After PRC transfusion, an increase in Hb levels is readily observed, but controversial results were found when evaluating the influence of stored PRCs on tissue oxygenation, assessed by surrogate markers of oxygenation, such as gastric pH and CO₂^[7,8]. Very recently, Leal-Noval *et al*^[6] and Smith *et al*^[38] studied the effect of ABT on cerebral oxygenation in patients with severe traumatic brain injury and found erythrocyte transfusion to be associated with a variable and prolonged increment of cerebral tissue oxygenation. However, no relationship was observed between brain tissue partial pressure of oxygen (PtiO₂), cerebral perfusion pressure and Hb concentration. In addition, 3 h after transfusion, all patients with basal PtiO₂ < 15 mmHg showed an increment in PtiO₂, *vs* 74.5% of patients with PtiO₂ ≥ 15 mmHg, *P* < 0.01^[6]. Moreover, in a subsequent study, this group demonstrated that an increment in PtiO₂ was only observed in patients receiving blood stored for less than 19 d^[39]. Thus, low baseline PtiO₂ levels could define those patients who benefit the most from ABT.

However, ABT providing Hb of 10-11 g/dL might be required for patients with COPD, as it may reduce minute ventilation and the work of breathing, for patients bleeding to improve haemostasis in massive transfusion^[25,26], and for surgical patients with sickle cell disease, reducing HbS levels by direct transfusion

or by RBC exchange (partial or total) to avoid sickling crisis^[10,14].

In conclusion, while ABTs save lives, they save far fewer lives than we have been taught to believe. As ABT will never be a risk free therapy (see below), each and every unit transfused unnecessarily is, potentially, a noxious unit. In other words, each ABT which is not strictly indicated is severely contraindicated!

RISKS OF ABT

Nowadays, due to a careful donor selection and the introduction of highly sophisticated tests for pathogen detection, ABT is safer but more scarce and expensive than ever, and is still not risk-free. Transfusion therapy with PRCs can cause adverse reactions, which are classified on the basis of their etiopathogenesis and the time of occurrence with respect to the transfusion. Adverse effects of ABT (Table 3) include a broad panoply including, but not limited to, incorrect blood transfusion (“wrong blood”), acute or delayed haemolytic transfusion reaction, allergic reaction (from urticaria to anaphylactic reaction), bacterial contamination, transfusion-related acute lung injury (TRALI), transfusion associated circulatory overload (TACO), transfusion-related immuno-modulation (TRIM), and transmission of infectious diseases (viruses, protozoas and prions)^[40], which result in increased risk of morbidity and mortality. As the risks of ABT-transmitted viruses were reduced to exceedingly low levels in the US and Europe, TRALI, haemolytic transfusion reactions (HTRs), and transfusion-associated sepsis (bacterial contamination) emerged as the leading causes of ABT-related deaths^[41]. Since 2004, preventive measures for TRALI and bacterial contamination have been implemented, but their implementation remains incomplete^[41]. Infectious causes of ABT-related deaths currently account for less than 15% of all transfusion-related mortality, but the possibility remains that a new transfusion-transmitted agent causing a fatal infectious disease may emerge in the future^[40,41]. These, together with the possible advantages of implementing restrictive transfusion protocols, strongly indicate that transfusion practice in surgery and intensive care should be (and must be) modified, especially in terms of the level of pretransfusion Hb (“restrictive” *vs* “liberal” use of ABT; “acceptable Hb” *vs* “optimal Hb”) (Table 2). Briefly, we will describe several of the most important adverse reaction to transfusion.

Transfusion reaction: According to Serious Hazards of Transfusion report 1994-2004, 1832 out of 2628 reported incidents corresponded to episodes of incorrect blood component transfused (IBCT) (wrong blood product or wrong patient)^[42]. Thus, the incidence of reported IBCT is about 1:20 000-25 000 and the consequences can be disastrous. In Spain^[43], 246 “near-miss administration errors” and 134 of IBCT were reported during 2007. Of those, 49 led to HTRs (33 due to ABO incompatibility), with at least three deaths reported and confirmed^[4]. In a Spanish region (Catalunya) the incidences were estimated as 1:11 000 of IBCT, 1:77 000 of “ABO-mistakes” and 1:310 950 of death secondary to transfusion^[44]. As for

Table 3 Risks or hazards of allogeneic blood transfusion

Acute transfusion reactions
Immunologic reactions
Acute haemolytic reaction (or THRs)
Febrile non-haemolytic reaction
Allergic reactions: Urticaria and anaphylaxis
Acute non-cardiogenic pulmonary edema: TRALI
Alloimmunization with acute platelet destruction
Non-immunologic reactions
Bacterial contamination
TACO
Hypotensive reaction
Non-immunologic haemolysis
Others: Hypocalcemia, hyperkalemia (cardiac arrest), hypothermia, hyperglycemia, <i>etc</i>
Delayed transfusion reactions
Immunologic reactions
Delayed haemolytic reaction
Alloimmunization against blood cell antigens (also platelets and leukocytes)
Graft <i>vs</i> host disease
Transfusion-related immunomodulation
Post-transfusion purpura
Non-immunologic reaction
Transfusion-transmitted infection: viruses (Hepatitis A, B, C, E, VIH 1-2, West Nile virus, HTLV I - II, Citomegalovirus, Virus Herpes viridae, TTV, SEN-1, SARS, <i>etc</i>), protozoa (malaria, babe biosis, Chagas disease, <i>etc</i>), prion (new variant Creutzfeldt Jacob disease)
Post-transfusion hemosiderosis (iron overload)

TRALI: Transfusion-related acute lung injury; TACO: Transfusion associated circulatory overload.

the surgical patient, general anaesthesia may mask the symptoms of both HTRs and non-HTRs. Signs of HTRs include hypotension, tachycardia, haemoglobinuria and microvascular bleeding, but these may be erroneously attributed to other causes in the anaesthetized patient. The most common signs of a non-haemolytic transfusion reaction in awake patients include fever, chills, or urticaria. However, these signs may not be detectable during anaesthesia. Thus, checking for signs and symptoms of a THR should periodically be done in the anaesthetized patient, including urine output and colour and peak airway pressure^[16].

Bacterial contamination: Bacterial contamination of blood products, most frequently platelets, is one of the leading causes of death from ABT^[40,41] (seven deaths in UK from 1996 to 2004)^[42]. The increased risk of bacterial overgrowth is related to a storage temperature of > 20-24°C. Many blood banks are now culturing their platelet concentrates, or inactivating them, although this leads to a decreased functionality. If a patient develops a fever within 6 h of receiving platelets, sepsis from contaminated platelets may be a possibility. Between 2001 and 2003, an average of 11.7 years in the United States were reported to the Food and Drug Administration, whereas 7.5 per year were reported in 2004 and 2005 - a decrease attributable in part to the mandating of bacterial screening of platelets beginning in 2004^[40]. In Spain, during 2007 at least 17 cases, with one death, have been reported and confirmed^[43].

TRALI: TRALI is a well-characterized and serious adverse consequence of blood product transfusion; its overall occurrence is almost certainly more common than the quoted estimate of one case in 4000 U of blood transfused (as TRALI is generally unrecognized or misdiagnosed, its actual incidence is unknown)^[45]. TRALI is non-cardiogenic pulmonary edema resulting from immune reactivity of certain leukocyte antibodies a few hours after transfusion. Signs and symptoms will appear 1-2 h after transfusion and are in maximum force within 6 h. Hypoxia, fever, dyspnea, and even fluid in the endotracheal tube may occur. There is no specific therapy other than stopping transfusion and instituting critical care supportive measures. Most patients recover in 96 h, although TRALI is one of the top three most common causes of transfusion related deaths^[45]. In Spain, 32 cases have been reported and confirmed during 2007, with at least two deaths^[43]. The estimated rate was 1/32 000 (at Catalunya), but the authors suspected a great underreporting^[44]. For example, during preparation of this manuscript one of the authors diagnosed one highly probable case of TRALI during a plasma exchange, but no physician at the intensive care unit knew what TRALI meant.

TACO: TACO is a cause of hydrostatic pulmonary oedema with clinical and radiologic manifestations similar to those of TRALI. In fact, the distinction between TRALI and TACO after transfusion is difficult, in part because the two conditions may coexist^[44,46]. During 2007, in Spain at least 39 cases had been reported and confirmed, with at least one death confirmed^[43].

TRIM: TRIM is associated with increased risk of postoperative infection^[2,3,47-49]. The combined data from three studies including over 1700 patients undergoing elective cardiac surgery with cardiopulmonary bypass showed that (1) transfusion of RBC concentrates was independently associated with increased rates of postoperative pneumonia, mediastinitis and sepsis; (2) these effects were dose-dependent and storage-time-dependent; and (3) other blood components might be also involved^[50-52]. As for patients undergoing elective surgery for gastrointestinal cancer resection or urgent surgery for hip fracture repair, similar data have been reported^[4,49,53].

Infectious diseases: Another major adverse effect of transfusion therapy is the transmission of infectious agents^[40,41]. For the past 20 years, transfusion induced hepatitis and acquired immunodeficiency syndrome (AIDS) have been dominant concerns regarding ABT. These infectious risks are now very rare. One of the major reasons for the decrease in blood borne infections has been the use of nucleic acid technology (NAT). The human immunodeficiency virus (HIV), C hepatitis virus (CHV), and West Nile virus can now be detected by this technology. To date, malaria, Chagas disease, severe acute respiratory syndrome (SARS), and variant Creutzfeldt-Jakob disease (vCJD) cannot be detected^[16]. The possible safety intervention that might further

reduce the risk of transfusion-transmitted infection is not static, as new agents continue to emerge, old ones change their properties and epidemiologic patterns, and new information and technology become available to change our understanding of that risk^[40,41]. During 2007 in Spain, twenty five cases of possible hepatitis B or C were reported, but none of them were confirmed^[43]. Between 2005-2007 five cases of Chagas disease were diagnosed, although four of them retrospectively after a “look back”^[43].

PREOPERATIVE AUTOLOGOUS BLOOD DONATION (PABD)

PABD consists of obtaining the patient's own blood prior to surgery in order to administer it if necessary afterwards^[1,54]. Extraction frequency, type of blood component or bag for conservation, and volume of blood extracted are established by each Local Blood Bank on an individual basis^[1,54-56]. In the elective surgical setting, PABD is a convenient, predictable, safe and widely practised form of transfusion support^[4]. However, PABD cannot be made available to all patients (minimal Hb ≥ 11 g/dL), and it is contraindicated in the presence of several infectious, cardiac, oncologic or neurologic pathologies. Hospital admission and operative dates must be guaranteed, as donated blood has a limited storage life of 35 d (up to 42 d in additive SAG-mannitol solution). In addition, it used to carry some of the risks of ABT, especially IBCT, although in the European Union there are regulations aimed to reduce these risks (e.g. personalized unit identification, separate conservation and transport, de-referral for allogeneic use, *etc*), and these can often present logistical difficulties^[1,54,55]. Nonetheless, PABD avoids immunological and viral hazards of ABT. In spite these benefits, PABD use is decreasing worldwide^[56].

In accordance with the conclusion of the Spanish Consensus Statement on Alternatives to Allogeneic Blood Transfusion (Seville's Document)^[55]: PABD would be indicated in elective surgery if the risk of ABT > 20%-30%, and in patients with difficulties receiving ABT; PABD can be used safely in children and elderly populations^[54,57]; the administration of rHuEPO in patients with moderate anaemia, facilitates PABD^[57]; PABD contribution to ABT reduction is decreased when a transfusion protocol is adopted; PABD may have problems of over-collection and over-transfusion (in fact, PABD increases the total number of transfusion episodes). It is not without infectious risks; PABD erythrocytes undergo “storage lesion”. PABD has been classically associated with higher rates of “clerical errors”, and ABT may still be required (break-through transfusion).

In this regard, it is well known that surgery in IBD is frequently associated with a need for perioperative blood transfusions, but PABD is often limited by IBD-associated anaemia, although it is reversible by intravenous iron and rHuEPO. Consequently there is a paucity of studies on the use of PABD in surgical IBD patients

(and none in the use of perioperative cell salvage or acute normovolemic haemodilution). Mittermaier *et al*^[58] tested the feasibility of PABD (2-4 U; 350-450 mL blood per unit; 1 U/wk) in six patients (five CD, one UC) with indications for elective bowel resection IBD. Patients received 200 mg of iron sucrose IV after each donation, plus concomitant rHuEPO if there was preexisting anaemia or C-reactive protein > 2 mg/dL. Four patients received PABD transfusions intra- or postoperatively, and no patient needed ABT. No serious adverse events were observed during blood donations, perioperatively, and during the one year follow-up period. Thus, when appropriately indicated and supplemented with IV iron and rHuEPO, PABD seems to be safe and useful for surgical IBD patients. Since 2003, we have treated 2668 PABD patients in our hospital, only three of them with IBD (two CU and one EC) scheduled to prostatectomy, coxarthrosis and avascular femoral necrosis surgeries, donating two units each patient. The first patient required two doses of β -epoetin 30 000 IU plus iron sucrose iv 400 mg, and the second was transfused with two PABD units plus two ABT units.

Recently, PABD has been used, not as an alternative to ABT, but as a carrier of drugs, owing to the ability of the RBC membrane to be opened and resealed under appropriate conditions. In an uncontrolled pilot study, Annese *et al*^[59] investigated efficacy and safety of dexamethasone-encapsulated erythrocytes in 10 steroid-dependent adults IBD patients (five UC, five CD). Fifty milliliters of blood were drawn from each subject; dexamethasone 21-phosphate (Dex 21-P) was encapsulated into erythrocytes by means of specially designed equipment, and drug-loaded erythrocytes were infused into the original donors (5.5 ± 2.4 mg Dex 21-P). The procedure was repeated after 4 and 8 wk, and patients were instructed to withdraw corticosteroids. After the third infusion, all patients were in clinical remission. After a mean follow-up of 12 ± 3 mo, six patients relapsed, and the remaining four patients remained in remission. Pre-existing steroid-related adverse effects disappeared during the follow-up. The authors concluded that Dex 21-P loaded autologous RBC is a feasible technique, which is safe, maintains patients in clinical remission and allows steroid withdrawal.

More recently, infusions of autologous RBCs loaded with Dex 21-P, performed every 4 wk for 24 mo, to 18 consecutive paediatric patients with steroid-dependent CD resulted in a reduction of the CD activity index, 78% of patients discontinued steroids and endoscopic findings showed remission in 44% of patients, whereas none of the patients experienced serious side effects^[60]. Therefore, infusions of autologous RBCs loaded with Dex 21-P seem to be safe and useful for maintaining long-term remission in paediatric patients with moderately active CD. However, large randomized controlled trials are needed to confirm these promising results.

CONCLUSION

ABT used to be the first therapeutic option for the treatment of acute anaemia in IBD patients, especially

when it developed due to gastrointestinal or perioperative blood loss, but was not risk-free. Adverse effects of ABT include, but are not limited to, IBCT (wrong blood), THRs, bacterial contamination, TRALI, TACO, TRIM and transmission of infectious diseases, which might result in increased risk of morbidity and mortality. Evidence-based clinical guidelines may promote best transfusion practices and reduce variability, minimizing the avoidable risks of transfusion, and help clinicians in choosing the most appropriate treatment for the patient-ABT, PABD or pharmacologic alternatives. The acceptance of normovolemic anaemia is indeed one of the most effective measures to reduce ABT requirements. Thus, the adoption of restrictive transfusion criteria (lower threshold level of Hb) must be the first measure to implement in order to reduce both the number of transfused units and transfused patients. Obviously, the second measure must be the pharmacological treatment of anaemia. PABD consistently reduces the frequency of ABT, with a small incidence of adverse effects, although its contribution to ABT avoidance is reduced when performed under a transfusion protocol. In addition, interpretation of utility of PABD in surgical IBD patients is hampered by scarcity of published data. However, the role of autologous RBCs as drug carriers is promising. Finally, for selected patients, a combination of methods used within well-constructed protocols will offer better prospects for blood conservation in IBD patients undergoing elective surgery.

RESULTS: Nodules of altered hepatocytes (NAH), the putative precursors of HCA and HCC, were found in all the FNH lesions. Polyclonality was revealed in 10 FNH lesions from female patients, and LOH was not detected in any of the six FNH lesions examined, the results apparently showing their polyclonal nature. In contrast, monoclonality was demonstrated in all the eight HCAs and in four of the HCCs from females, and allelic imbalances were found in the HCAs (9/9) and HCCs (15/18), with chromosomal arms 11p, 13q and 17p affected in the former, and 6q, 8p, 11p, 16q and 17p affected in the latter lesions in high frequencies ($\geq 30\%$). Monoclonality was revealed in 21 (40%) of the 52 microdissected NAH, but was not found in any of the five ordinary nodules. LOH was found in all of the 13 NAH tested, being highly frequent at six loci on 8p, 11p, 13q and 17p.

CONCLUSION: FNH, as a whole, is polyclonal, but some of the NAH lesions derived from it are already neoplastic and harbor similar allelic imbalances as HCAs.

Abstract

AIM: To identify clonality and genetic alterations in focal nodular hyperplasia (FNH) and the nodules derived from it.

METHODS: Twelve FNH lesions were examined. Twelve hepatocellular adenomas (HCAs) and 22 hepatocellular carcinomas (HCCs) were used as references. Nodules of different types were identified and isolated from FNH by microdissection. An X-chromosome inactivation assay was employed to describe their clonality status. Loss of heterozygosity (LOH) was detected, using 57 markers, for genetic alterations.

INTRODUCTION

Focal nodular hyperplasia (FNH) is defined as a lesion composed of hyperplastic hepatic parenchyma, subdivided into nodules by fibrous septa that may form stellate scars^[1,2]. As dystrophic vessels are observed in

the fibrous septa and an arteriole is present within most of the nodules, it is considered parenchyma overgrowth responsive to increased blood flow secondary to vascular malformations^[3]. Morphologically, FNH is classified into two categories, classical and nonclassical lesions^[4]. The latter includes telangiectatic, mixed hyperplastic/adenomatous types and lesions with cytologic atypia. The non-neoplastic nature appears to be supported by data from X-chromosome inactivation (XCI) analyses, which demonstrated polyclonality in all FNH lesions in most of the series^[5,6]. However, monoclonality was also observed in some of the lesions^[7], including telangiectatic FNH^[8,9]. FNH, as a descriptive term when proposed^[10], may represent a group of focal lesions with different morphologic phenotypes and genetic alterations, and may develop in different pathways. Chromosomal gains and losses have been observed in several lesions by comparative genomic hybridization, allelotyping or karyotyping^[9,11], but the molecular mechanism of FNH development remains unclear.

Hepatocellular adenoma (HCA) is a benign hepatic neoplasm, and its development is associated with the long-term use of steroids, mainly oral contraceptives^[2,12]. While HCA was proven to develop from foci of altered hepatocytes (FAH) in the liver of rodents^[13], the neoplastic features of human HCA have been confirmed by clonality analyses^[5,6,9]. Some HCA lesions tend to progress to hepatocellular carcinoma (HCC)^[2,13], and the malignant transformation has been linked to β -catenin activation^[14]. In contrast to HCA, FNH is a stable lesion in clinical phenotypes with a very low risk of malignant transformation, although FAH can be detected in FNH^[15] and HCC was identified in the liver harboring FNH as described in several case reports^[16-18].

The majority of FNH lesions are distinguishable from HCA by their morphologic features. However, the differential diagnosis is difficult for some lesions. A central scar is regarded as the most characteristic change, but it is detectable in less than half of FNH lesions. Even for classical FNH, its incidence was shown to be 62% (153/245)^[4,19]. More reliable procedures remain to be established for its distinction from HCA.

In the present study, we examined the clonality status of FNH, and compared its clonality with that of HCAs and HCCs, using assays based on XCI and polymorphism at the androgen receptor (AR) and phosphoglycerate kinase (PGK) loci. Secondly, these lesions were examined for loss of heterozygosity (LOH). In addition, 57 nodules were microdissected from FNH in female patients and used for the clonality analysis. Twenty-five nodules were also isolated from an FNH lesion and were used for LOH analysis.

MATERIALS AND METHODS

Tissue samples and histological examination

A total of 46 hepatic lesions were used, including 12 FNH lesions from 10 patients (Table 1), 12 HCAs from 11 patients and 22 well-differentiated HCCs (Table 2).

These patients were admitted to the Cancer Hospital, Chinese Academy of Medical Sciences in Beijing and Tangdu Hospital, the Fourth Military Medical University in Xi'an during the period from 1998 to 2007. All the lesions were resected by an operation. Representative formalin-fixed, paraffin-embedded tissue samples were retrieved from the archives for both tumors and the surrounding liver parenchyma. Sections of 4 μ m in thickness were prepared and stained by hematoxylin and eosin (HE).

All slides were reexamined independently by three pathologists (Su Q, Cai YR and Gong L), and their histologic features were reevaluated. FNH of the classical form was considered when the lesions showed characteristic features as proposed by other authors^[3,4,10]. All the HCA lesions were identified from livers without evidence of cirrhosis or diffuse fibrosis by their macroscopical and histological features using well-established criteria^[2]. FAH and nodules of altered hepatocytes (NAH) were identified on HE-stained sections^[20], and the lesions were further highlighted by a marked reduction or even absence of CK18-immunoreactivity in glycogenotic clear cells as described previously^[21]. Dysplasia, also designated as "small-cell change (SCC)"^[20,22] and "small-cell dysplasia"^[23], was recognized and graded into low-grade and high-grade lesions. The histological grades of HCCs were assessed as described by Hamilton and Aaltonen^[1], with the well-differentiated HCCs corresponding to all of the grade I and some of the grade II lesions by the criteria of Edmondson and Steiner^[24].

Immunohistochemical staining was performed using a streptavidin-labeled peroxidase (S-P) kit as in our previous study^[20]. The primary antibodies used in this study included those against cytokeratin (CK) 18, CK19, CD34, hepatitis B virus (HBV) surface antigen (HBsAg; Clone 3E7), p53 protein (DO-7) and Ki-67 antigen. All reagents were purchased from Dako (Glostrup, Denmark). Levels of Ki-67 antigen expression were expressed as Ki-67-labeling indices (Ki-67-LI). The nuclear accumulation of p53 protein was evaluated as many (3+, > 30%), moderate (2+, 5%-30%), few (+, < 5%) and absent (-, 0%), as described previously^[25].

Extraction of genomic DNA

Sections of 8 μ m in thickness were prepared. After staining with HE, the lesions of FNH, HCA and HCC were identified by microscopic examination. Then the lesional tissues, each covering an area of at least 1 cm \times 1 cm, were collected by a rubber policeman, and pooled into 1.5-mL tubes. The surrounding liver parenchyma and fibrous tissue were collected and used as controls. Previous XCI tests have demonstrated that monoclonality can be determined provided a given cell population contains at least 75% monoclonal cells^[26]. To guarantee reliability of the following assays, mesenchymal tissue areas containing inflammatory cell clusters were eliminated to enhance purity of target cells to at least 80%. Genomic DNA was then isolated with

an extraction kit (QIAGEN, Chatsworth, CA, USA) following the manufacturer's instructions. The DNA samples of 50 µL each were stored at -20°C until use.

Microdissection of preneoplastic nodules from FNH

Selected FNH specimens with well demarcated NAH were subjected to microdissection as described previously^[27].

Figure 1 Premeoplastic lesions in classical FNH. A and B: FNH04 from Case 03, showing a nodule largely occupied by an expanding NAH (arrowheads), before (A) and after microdissection (B); C: Portion of FNH06, showing an FAH (arrowheads), in which the altered hepatocytes integrate well with the surrounding hepatic plate; D: Portion of an NAH composed mainly of clear hepatocytes (arrowheads), showing compression to surrounding liver parenchyma. HE, A and B, $\times 40$; C and D, $\times 100$.

Ten consecutive sections were deparaffinized with xylene, rehydrated by rinsing through graded alcohol, stained with HE and immersed in glycerol. Larger nodules, 2.5-5.0 mm in diameter, from these sections were identified and correlated. Target tissues were outlined and collected with a clean $4\frac{1}{2}$ needle under a microscope (Figure 1A and B). The tissues of the same nodules from the consecutive sections were pooled together and stored in 1.5-mL tubes. Using the same procedure, tissues of the same size were also collected from the surrounding liver parenchyma and were used as controls. Genomic DNA was isolated as described above.

Clonality assays based on XCI mosaicism in somatic tissues in female patients

The principles of XCI assays have been described previously^[28]. Briefly, there are two X chromosomes within each somatic cell in females, one from the father and the other from the mother. Both PGK and AR genes are located on X chromosomes, showing readily demonstrable polymorphism in different frequencies. The former carries a *Bst*XI restriction-polymorphic site, reflecting the G/A single-nucleotide polymorphism at exon 1, while the latter is polymorphic at the CAG short tandem repeat (STR). These allelic differences and the XCI mosaicism enable us to identify monoclonal, neoplastic lesions from normal or regenerating tissues composed of polyclonal cell populations^[28,29].

The DNA templates extracted from tumors and the non-neoplastic tissues were incubated with 5 U of *Hpa*II (Promega, Madison, WI, USA) at 37°C for 12 h in a volume

of 20 μ L containing 0.2 μ L of 10 mg/mL bovine serum albumin and 2 μ L of 10 \times reaction buffer, and heated at 95°C for 5 min to inactivate the enzyme. The digested DNA samples, 5 μ L each, were then subjected to nested PCR for amplification of exon 1 of PGK and AR genes, as described previously^[28]. The PGK products, 10 μ L each, were incubated with 5 U of *Bst*XI (Promega) at 47°C for 8-10 h. The digested products were then resolved in 2% (g/mL) agarose gel containing ethidium bromide (0.2 μ g/mL), and visualized under ultraviolet light. The fluorescence intensities of the products of these two alleles, at the positions of 530 and 433 bp separately, were assessed using LabWork 3.0 (UVP). Efficacy of the reaction was demonstrated by including a sample from a male patient with FNH (Case 03) who had been demonstrated to harbor a *Bst*XI restriction site.

The amplification products of AR exon 1, 3 μ L each, were mixed with the same volume of sample buffer (99% formamide, 1 mg/mL bromophenol blue, 1 mg/mL xylene cyanol), resolved on 10% polyacrylamide gel containing urea (8.0 mol/L), and visualized by silver staining. Sizes of the products were determined using 100-bp and 10-bp DNA ladders (Gibco BRL).

LOH assays by conventional and multiplex PCR

A total of 57 loci, whose allelic loss has been frequently observed in HCC samples from various regions^[30-38], were chosen for the LOH assay. Amplification of the DNA samples from the whole FNH lesions, HCAs and HCCs was performed by conventional PCR. Sequences of the primer pairs (Table 3) were obtained from Genbank

¹Nucleotide sequences were written in a 5' to 3' direction, with the forward and reverse primers for each reaction presented at the upper and lower lines, respectively; ²Amplified as an internal control with a product of 406 bp.

(<http://www.ncbi.nlm.nih.gov> and www.gdb.org). The reaction mixture was 50 μL in volume, containing 50 ng of DNA templates, 4 μL of dNTP (2.5 mmol/L each; Gibco BRL), 1 μL of 20 μmol/L primers each, 5 μL of 10 × buffer (100 mmol/L Tris-HCl, pH 8.3, containing 500 mmol/L KCl and 25 mmol/L MgCl₂) and 1.25 U of *Taq* DNA polymerase (Gibco BRL). Amplification was conducted for 35 cycles (94°C, 40 s; 46°C, 50 s; 72°C, 1 min) following the initial denaturation at 94°C for 5 min. The final elongation was at 72°C for 15 min. The efficacy and reliability of the reactions were ensured by amplification of the β-actin gene in a parallel reaction.

For microdissected samples, the amounts of DNA extracted from the minute tissues were too small to complete all the reactions, and a highly efficient amplification system was needed. Nested PCR was employed for this purpose. A multiplex PCR was performed, according to

the principle of Henegariu *et al*^[39], followed by a second-round reaction in separate tubes. For the first-round PCR, 57 external primer pairs, as listed in Table 3, were designed based on the genomic sequences (Genbank). They were classified into 11 groups according to calculated annealing temperatures and compatibility with the assistance of Beacon Designer (Version 5.0) software, allowing amplification of four to seven STR sequences in the same mixture. The reaction mixture was 50 μL in volume as described above, but it contained 20 ng of DNA templates. The amplification was performed for 35 cycles, and the annealing temperatures varied according to the primer groups. The second-round amplification was followed using the internal primer pairs (Table 3), with the 57 reactions in separate tubes. After initial denaturation at 94°C for 5 min, amplification was conducted for 15 cycles (94°C, 40 s; 50°C, 50 s; 72°C, 1 min) at first,

followed by 25 cycles with the annealing temperature adjusted to 46°C. The amplification products, 3 µL each, were mixed with the same volume of sample buffer, and then electrophoresed on a 15% polyacrylamide gel containing urea (8 mol/L). Gels were fixed in 10% acetic acid for 30 min, and the resolved products were visualized by silver staining.

Evaluation of data and statistical analyses

The images of the gels were subjected to analysis with a densitometer (Applied Syngene, Cambridge, UK). For clonality analysis based on polymorphism at the PGK and AR loci, a reduction of $\geq 50\%$ in their signal intensities for the products of either allele, as compared to the samples not treated with *Hpa*II or *Hba*I, is regarded as loss of XCI mosaicism^[28]. Each reaction was repeated at least once to guarantee reproducibility. Moreover, parallel assays were carried out using the surrounding liver parenchyma or fibrous tissue as controls. For the tests on microdissected lesions, special attention was paid to avoid interference from the XCI skewing patches^[28]. For each FNH lesion, four tissue samples of similar sizes as microdissected nodules were taken from the surrounding liver parenchyma and examined as controls.

For the heterozygosity test, normal tissue samples showing signals from two alleles migrating at expected locations and with similar intensities were considered informative, and those showing only one signal, were considered noninformative. Allelic imbalance was determined by comparing the intensity ratio between the signals for the two alleles. For a given informative marker, LOH was identified when one of two signals was absent or the allelic ratio was greater than 3 or less than 0.33. Reliability of the assays was guaranteed by including control tissue samples for all FNH lesions and microdissected nodules in a parallel way. Interpretation of LOH results of the lesions was considered reasonable when all of the control reactions from the same case gave rise to consistent allelic ratios.

Statistical computation was carried out using SPSS 13.0 software (SPSS, Inc, Chicago, IL, USA). Student and Kruskal-Wallis tests were employed to assess cell kinetic features of different lesion types reflected by Ki-67-LI, and the χ^2 test was used to compare LOH frequencies in HCA, FNH and HCC groups. $P < 0.05$ was regarded as statistically significant.

RESULTS

Clinical and pathological features

Twelve FNH lesions (FNH 01-12) were identified from 10 patients (Cases 01-10), eight patients had solitary lesions and separate lesions were identified in two liver specimens (Table 1). The patients included eight females and two males, aged 22-53 years (mean, 37.6 years). Grossly, the resected FNH lesions were 1.2-7.0 cm in diameter (mean, 3.8 cm), and were invariably described as circumscribed and solid lesions. On cut surfaces, a

multinodular appearance was observed, and a fibrous stellate scar was not recorded in any of the lesions. Histologically, all the lesions were classified as the classical form^[4], being well demarcated from the surrounding liver parenchyma but free of a fibrotic capsule. The lesions were subdivided incompletely into nodules with fibrous septa that contained malformed blood vessels, proliferating ductules, and scattered lymphocytes.

Most of the hepatocyte nodules appeared similar, about 1-5 mm in diameter, and histologically resembling regenerative nodules from cirrhotic livers. FAH, frequently of the clear cell type and clear/amphophilic mixed cell type, were identified in some of the nodules from all the lesions. The altered hepatocytes were arranged in plates frequently of two cells in thickness, with the sinusoids appearing crowded, but were integrated well with the surrounding hepatocytes in the majority of the lesions (Figure 1C). In some nodules, nearly all the parenchymal cells were replaced by the altered hepatocytes. These lesions became larger than other nodules, 2.5-5 mm in diameter, showing marked compression to the surrounding tissue (Figure 1D) and fulfilling the criteria for NAH^[20,22]. In all the FNH lesions, including the FAH and NAH areas, the thickness of hepatic plates did not exceed two cells and no SCC was detected. All the lesions were negative for p53 protein. Ki-67-LI ranged from 0.3% to 1.6%, with a mean of 0.8%. While this value was shown to be lower than those of HCAs ($P < 0.01$) and the well-differentiated HCCs ($P < 0.01$), these three lesion types showed overlap in their Ki-67-LI, with 6 (50%) of the 12 HCAs and 6 (27%) of the 22 HCCs within the range of FNH (Tables 1 and 2). FAH, mainly small-sized, and clear-cell lesions, were also identified in the surrounding liver parenchyma in six of the 10 livers (Table 1).

As listed in Table 2, 12 HCAs (HCAs 01-12) were resected from 11 patients (Cases 11-21), including nine females and two males. The ages of the patients ranged from 28 to 57 years (mean, 36.6 years), and none had a history of using oral contraceptives or other steroid hormones. Among the 12 lesions, 10 were solitary, and two were resected from the same liver (Case 16). The lesions ranged in size from 1 to 12 cm in diameter (mean, 4.8 cm). Histologically, the lesions were well demarcated from the surrounding liver parenchyma, but an intact fibrotic capsule was absent in all the lesions. The tumor was composed of hepatocytes arranged in plates usually of two cells in thickness. Low-grade SCC was identified in HCAs 03 and 08. The portal tract was not visible within the lesions. All these lesions were negative for p53 protein. Ki-67-LI ranged from 0.9% to 3.1%, with a mean of 1.8%. Phenotypic change of the sinusoid cells, as highlighted by emergence of CD34-immunoreactivity, was observed in all the HCA lesions, being diffuse in four and patchy in eight of the lesions. FAH, mainly of the clear cell type, were also identified in the surrounding liver parenchyma in six of the 11 livers.

A total of 22 well-differentiated HCCs were collected from 12 males and 10 females (Table 2). The age of the patients ranged from 27 to 77 years, with a mean of

Table 4 Nonrandom X-chromosomal inactivation revealed in NAH microdissected from 3 FNH and their inactivation patterns

Origin of lesions	No. of NAH tested	No. with signals	No. with MC (%)	No. of lesions with	
				Upper band	Lower band
FNH09	38	34	14 (41.2)	12	2
FNH10	6	6	2 (33.3)	0	2
FNH11	12	12	5 (41.7)	0	5
Total	56	52	21 (40.4)	12	9

46.6 years. All the patients were shown to be seropositive for HBsAg. Of the 22 HCC cases, 20 appeared solitary and well demarcated and two were multifocal. The lesions ranged in size from 2.0 to 9.5 cm, with a mean of 4.6 cm. Histologically, nine of them were classified into grade 1, and 13 into grade 2. Ki-67-LI ranged from 0.9% to 65%, with the mean and median being 13.1% and 5.4%, respectively. This value was shown to be higher than that of HCAs ($P < 0.05$), while the Ki-67-LI in 10 (45%) of the 22 HCCs were within the range of HCAs. Immunoreactivity for AFP was demonstrated in four of the HCC samples (HCC 01, 11, 21 and 22). Overexpression of p53 protein was observed only in three HCC lesions, with the percentages of positive tumor cells as high as 10% in Case 21 and 80% in Cases 25 and 34. HBV infection was confirmed by immunohistochemical demonstration of HBsAg in all of the cases. Cirrhotic changes were evident in surrounding liver tissues in all the cases, where numerous NAH were identified.

Nonrandom XCI revealed in HCCs and HCAs, but not in the FNH lesions

XCI analysis was performed using tissues from 4 of the female patients with HCC (Cases 29, 30, 42 and 43) and all the nine females with HCA (Table 2). The G/A polymorphism at the PGK locus was demonstrated in three of the HCC patients (Cases 30, 42 and 43) and in three of the nine HCA patients (Cases 17, 19 and 21), showing two bands at positions 530 and 433 bp. Pretreatment with *Hpa*II resulted in loss, or marked intensity reduction, of one band in all the tumor samples, while the allelic ratio was retained in the samples from surrounding liver parenchyma (Figure 2A). One HCC (Case 29) and the remaining HCA patients were not polymorphic at the PGK locus, but the AR locus showed CAG STR length-polymorphism. Pretreatment with *Hha*I resulted in loss, or marked intensity reduction, of one band in these two tumor samples, while the allelic ratios were not changed in the corresponding peritumorous liver parenchyma (Figure 2B and C). These results demonstrated monoclonality and confirmed neoplastic nature in all the HCC and HCA lesions.

Of the eight female patients with FNH, 5 (Cases 1, 2, 5, 6 and 8) showed G/A polymorphism at the PGK locus, and the remaining three (Cases 7, 9 and 10) were shown to be AR-polymorphic at the CAG STR. Pretreatment with *Hpa*II (for PGK locus) or *Hha*I (for AR locus) did not cause a remarkable allelic ratio change in any of the 10 FNH samples (Figure 3A). These results demonstrated polyclonality of classical FNH lesions.

Figure 2 Representative data of X-chromosome inactivation (XCI) assays at PGK (A) and AR loci (B and C). Nonrandom XCI are present in HCAs (08 in A, 20 in B) and HCCs (09, 21 and 22 in A, 08 in C), revealing their monoclonality. A: The G/A single-nucleotide polymorphism at PGK exon 1 was demonstrated by *Bst*XI-digestion and electrophoresis on an agarose gel. The intact and cleaved amplification products migrate at positions of 530 (upper band) and 433 bp (lower band), respectively. Pretreatment with *Hpa*II (-: Before; +: After) resulted in marked reduction of the lower band in single tumor samples (T) and separate tumor areas (TA), but not in the surrounding liver parenchyma (N). M: DNA markers, with five bands at locations of 700, 600, 500, 400 and 300 bp; B and C: The length polymorphism of AR gene was resolved on a 10% polyacrylamide gel containing urea (8 mol/L) and visualized by silver staining, with one product migrating faster than the other. Pretreatment with *Hha*I (-: Before; +: After) resulted in loss or marked reduction of one band in tumor samples, but not in the non-neoplastic tissue. M: DNA marker at the location of 200 bp.

It appears that FNH is different in clonal composition from hepatocellular neoplasms including HCC and HCA.

Nonrandom XCI revealed in some NAH lesions microdissected from FNH

Three FNH lesions (FNH 09-11) with well-demarcated NAH from three women were chosen for microdissection. A total of 56 NAH lesions (NAH 01-56), ranging from 2.5 to 5 mm in diameter, and 5 ordinary regenerative nodules, of similar sizes and without involvement of FAH, were isolated from the FNH lesions for clonality analysis. Genomic DNA samples from 52 of the 56 dissected NAH were amplified successfully and subjected to AR (FNH 09 and 10) and PGK gene analysis (FNH11). Twenty-one (40%) of the 52 NAH showed monoclonality, including 14 (41%) of the 34 lesions in FNH09 (Figure 3B), 2 (33%) of the six in FNH10 and 5 (42%) of the 12 from FNH11 (Table 4). On average, the cross sectional areas of the 21 monoclonal

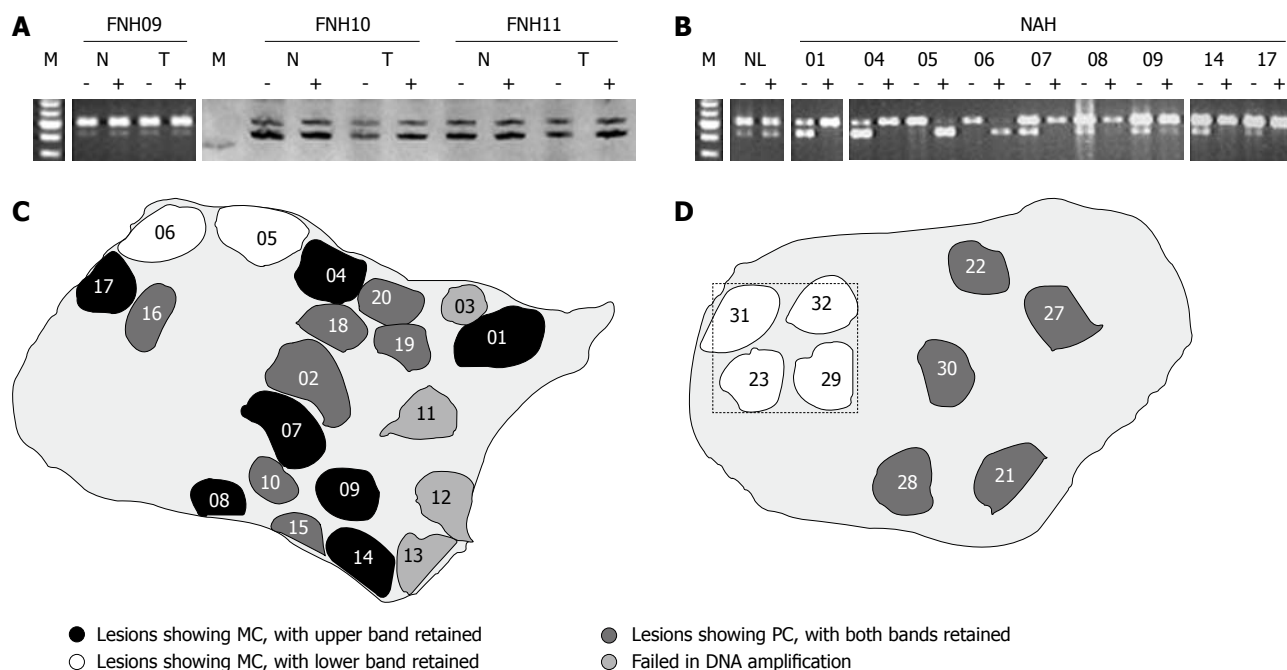

Figure 3 Clonality status of FNH lesions (A) and NAH (B), with XCI patterns revealed in different NAH (C and D). A: Polyclonality (PC) revealed in 3 FNH lesions, with FNH09 assayed at PGK locus and 10 and 11 at AR locus. *Hpa* II or *Hha* I pretreatment (-: Before; +: After) did not significantly change intensity ratios between the two bands of lesional tissues (T) compared to those of the surrounding liver parenchyma (N). M: DNA markers, with five bands at locations of 700, 600, 500, 400 and 300 bp for PGK assay, and a single band at the location of 200 bp for AR reaction; B: The PGK assay shows monoclonality (MC) in all of the nine NAH from FNH09, with the isolated reference tissue sample (NL), of a similar size to NAH, revealing polyclonality. XCI patterns of the NAH are different, with the upper band retained in NAH 01, 04, 07-09, 14 and 17, and the lower band retained in NAH 05 and 06; C: Sketch of a tissue section from FNH09, as illustrated in B, showing occurrence of monoclonal NAH with different XCI patterns and polyclonal lesions in the same section; D: Sketch of a tissue section from FNH11, showing four monoclonal and five polyclonal NAH. The clustered monoclonal lesions show the same XCI pattern, the XCI assays with small samples, as framed by hatch lines, may result in misinterpretation as monoclonality for the whole FNH lesion.

and 31 polyclonal lesions were 9.8 ± 7.0 and 9.5 ± 6.7 mm², respectively, the difference being insignificant ($P > 0.05$). Different alleles were retained among the 14 monoclonal NAH from FNH09 (Figure 3B and C), while identical inactivation patterns were observed in those NAH from FNH 10 and 11 (Figure 3D). All of the five ordinary nodules, four dissected from FNH09 and one from FNH11, were shown to be polyclonal in cell composition.

LOH detected in NAH, HCAs and HCCs, but not in whole FNH lesions

A total of 57 loci were examined in this study, located at 1p, 4q, 6q, 8p, 8q, 11p, 13q, 16q and 17p (Table 3). As shown in Table 2, the assay showed LOH, at least at one of the loci, in 15 (83%) of the 18 well-differentiated HCCs (01-07 and 10-20) and in all of the 9 HCAs examined (01-05 and 07-10, Figure 4A). Six of the FNH lesions (01-06), covering areas of at least 1.0 cm × 1.0 cm, were also examined, and no LOH was detected in any of them (Figure 4B).

Demonstration of clonal growth in some of the NAH from FNH, as described above, indicated that some genomic alterations may have occurred in these minute lesions. Twenty-five NAH were microdissected from an FNH lesion (FNH04) for LOH analysis. Genomic DNA samples from 13 of the microdissected lesions (NAH 57-69) were amplified successfully for the majority of the reactions, but for other samples

Figure 4 Representative data of amplification products at three length-polymorphic loci in HCAs 07-09 (A), FNH04 and NAH microdissected from the FNH lesion (B), with loss or marked reduction of the product from one allele (black dot) defined as LOH. A: Gels show the allelic imbalance at D11S2008, D13S164 and D13S164 in HCA07, at D13S126 in HCA08, at D13S164, but not in D11S2008, in HCA09 (T: Tumor; N: Peritumorous normal liver); B: The microdissected lesions NAH58 and NAH60, but not NAH57 and NAH59, show LOH at D11S2008. The lesions NAH62, NAH63, NAH67 and NAH69, but not NAH68, show LOH at D8S298. Both alleles are preserved in FNH04 as tested as a whole (FNH) and compared to those of the surrounding normal liver parenchyma (NL).

(NAH 70-81), the amounts of the extracted DNA were too small to complete all the reactions and the data obtained were not included. Allelic imbalance, at least at one of the loci, was demonstrated in all of the 13 NAH (Figure 4B, Table 5). The reliability of the assay was confirmed by full consistence between the results

obtained by the multiplex reactions and those obtained through conventional PCR.

Of the 57 loci examined, 39 (68.4%) showed LOH in at least one of the lesions tested. At the remaining loci, allelic imbalance was not detected in any of the samples examined. LOH was demonstrated in NAH, HCAs and HCCs at 21 (37%), 16 (28%) and 33 loci (58%), respectively. The allelic imbalance was more extensive among the locations tested in HCCs than in HCAs and NAH ($P < 0.01$), with their average numbers of LOH being 4.5 (0-12), 3.1 (1-5) and 4.1 (1-6), respectively. As shown in Figure 5, the most frequent LOH in NAH, HCA and HCC were at D8S298 (70%), D11S1301 (75%) and D6S1008 (50%), respectively. Several markers showed frequent LOH in the HCC samples but not in HCAs, including D6S1008, D8S1754, D8S261, D8S277, D16S3029, D16S303 and D17S796.

While LOH was demonstrated in NAH, HCAs and HCCs, its frequencies were found to vary with locations in the genome and lesion types (Figure 5), with those up to 20% and 30% considered frequent and highly frequent events, respectively. Of the 39 loci showing LOH, eight were found to be highly frequent in HCAs, clustering at 11p, 13q and 17p, six in the HCCs, located at 6q, 8p, 11p, 16q and 17p, and six in NAH, located at 8p, 11p, 13q and 17p.

Differences between these types of lesions were further demonstrated by their LOH frequencies at different locations at 8p, 11p and 17p (Figure 5). Among the four loci affected at 8p, D8S298 was the only one showing LOH in a high frequency (70%) in NAH. Its frequencies were lower in other clinically detectable hepatocellular neoplasms, being 20% in HCAs and 12% in the HCC samples. The difference between NAH and HCC was significant ($P < 0.01$), and that between NAH and HCAs did not reach statistical significance ($P > 0.05$). Among the three loci at 11p, D11S1301 and D11S2008 were affected more frequently in NAH, HCA and HCC.

As shown in Figure 5, allelic imbalances were found to affect more chromosomal locations in HCC specimens, with LOH demonstrated preferentially at D8S261 (3/8, 38%), D8S1754 (4/13, 31%), D8S277 (3/15, 20%) and

D17S796 (38%). Among the loci, D17S796 did not show allelic imbalance in any of the six NAH and 10 HCAs examined. The region 17p13.3, as shown using nine markers, was affected in 7 (39%) of the 18 HCCs, 6 (67%) of the nine HCAs and 6 (46%) of the 13 NAH examined, with the locus D17S926 involved frequently in all of the three lesions. The region 16q21-24, as tested using seven markers, was affected in 6 (33%) of the 18 HCCs, 1 (11%) of the nine HCAs and 5 (38%) of the 13 NAH examined, with D16S3029 and D16S3040 affected frequently in HCC and NAH, but not in HCA specimens.

DISCUSSION

FNH occurs within an otherwise normal liver, and is detected more frequently between the ages of 20 and 50 years. A careful survey of 168 patients in France revealed a marked female predominance, with the male to female ratio being 1/8 (18/150)^[4]. However, a male predilection was observed in a report from China involving 86 FNH cases, with the male to female ratio being 1.7:1 (54:32)^[19]. This may reflect the differences in lifestyle and eco-environmental factors between these two countries, as a similar tendency has also been noticed for HCA^[6]. The role of oral contraceptive use in its development remains a matter of debate^[40,41], while its progression was observed in women using oral contraceptives^[42-44]. The lesion is frequently solitary. A minority of cases ranging from 7% (6/86)^[19] to 24% (40/168)^[4] have been shown to have multiple (2 to 30) lesions.

The distinction between FNH and HCA may be difficult in some cases during pathological practice. A central stellate scar, when present, is helpful in establishing the diagnosis of FNH. However, this feature is undetectable in about half of FNH lesions^[4,19]. Moreover, a similar change was also observed in some well-differentiated HCCs^[45]. In our study, this hallmark feature was not recorded in any of the 12 lesions examined. Clearly, more reliable approaches are needed for the differential diagnosis.

The pathogenesis of FNH remains to be established. Wanless and collaborators proposed that FNH is a

Figure 5 Frequencies of LOH as demonstrated using 57 microsatellite markers in NAH ($n = 13$), HCAs ($n = 9$) and well-differentiated HCCs ($n = 18$). ^a $P < 0.05$, ^b $P < 0.01$ vs HCCs.

proliferative response to an arterial malformation^[3]. Analysis of angiopoietin (ANGPT) 1 and ANGPT2 mRNA expression revealed an increase in the ANGPT1/ANGPT2 ratio in classical FNH, but not in HCA and telangiectatic FNH^[8,9,46]. This may provide a possible mechanism for alterations in proliferation and remodeling of vascular elements within these lesions. However, the nodular hyperplasia of the involved parenchyma needs to be explained. An observation by Paradis *et al*^[5], using the XCI analysis, revealed polyclonality in all of the 12 FNH lesions examined. However, data from other laboratories, obtained by similar assays, demonstrated monoclonality in FNH lesions at frequencies ranging from 39%^[9] to 75%^[7]. The reason for this discrepancy is currently unknown. Insufficient sampling may result in the occurrence of skewed XCI patterns during a test with

normal tissues^[28,47], which may lead to misinterpretation of the data. The phenomenon was associated with clonal cell clusters (patching) as described in other tissues^[28,47-49]. It may also be true that clonal proliferation occurs focally within some of the classical lesions.

In this study, the neoplastic nature of HCC and HCA was confirmed, however, a random XCI inactivation pattern was demonstrated in all of the eight FNH lesions examined. In order to avoid interference from clonal patches, large samples were analyzed for all the lesions. Our results demonstrate that classical FNH, when examined as a whole, is polyclonal in cell composition. The assay is useful for the differential diagnosis between FNH and neoplastic hepatocellular lesions including HCA and HCC.

Human hepatocarcinogenesis is a multi-step process,

including the occurrence of FAH and NAH, neoplastic formation and malignant transformation through high-grade SCC to a fully developed HCC^[20,22]. The sequential changes may involve inactivation of multiple tumor suppressors^[38]. LOH is one of the main mechanisms for inactivation of tumor suppressor genes. Its occurrence has been localized frequently at 1p, 6q, 8p, 11p and 16q in early-stage, small HCC, while the losses at 4q, 13q and 17p were linked to progression of the lesion^[30-38]. As some well-differentiated HCCs and HCAs with high-grade SCC share many morphologic features, it may be difficult to make the differential diagnosis between these disorders with full certainty. This is particularly true when the lesion occurs in a liver without chronic viral hepatitis and cirrhosis. Activation of β -catenin and Wnt-1 signaling pathway has been linked to HCA lesions showing various degrees of phenotypes indicative of malignant transformation^[11,14], however, these changes were also found in some HCCs^[50,51]. In this study, we examined the allelic integrity of these chromosomal arms using 57 microsatellite markers in nine HCAs and 18 well-differentiated HCCs. Frequent LOH was observed in these well-differentiated HCCs at loci on 6q, 8p, 11p, 16q and 17p. In HCAs, the alterations were observed on similar chromosomal arms, but at different loci (Figure 5). Among the eight loci selected for 8p, four showed LOH, located at D8S261, D8S1754, D8S277 and D8S298, in HCC, and only one in HCA, at D8S298. Among the seven loci for 16q, four showed LOH in HCC, located at D16S3029, D16S303, D16S3040 and D16S402, and only one, at D16S303, in HCA. It seems that the demonstration of 8p losses at D8S261, D8S1754 and D8S277, 16q losses at D16S3029 and D16S3040, and 17p loss at 17S796 is helpful for the identification of HCC from HCA.

In contrast to HCA, FNH did not show TCF1/HNF-1 α or CTNNB1 gene mutations and rarely showed DNA losses^[14,52,53]. Allelic imbalances are also present in the majority of HCAs, as shown in this study, but results of LOH detection in FNH are confusing. A genome-wide assay by Bioulac-Sage and colleagues demonstrated LOH in 5 (26%) of the 19 classical FNH samples^[9], but another group, using a similar approach, did not find any LOH among the 212 informative loci^[54]. In the present study, we did not find LOH at any of the 57 loci in the six FNH lesions, as tested using samples as large as 1 cm \times 1 cm. This is consistent to the polyclonal nature of FNH as revealed in most of the lesions.

Results from our previous studies on human liver has enabled us to identify FAH and NAH in both explanted and resected liver specimens, and these lesions were associated with SCC and a markedly increased risk of HCC development^[20,22]. In a recent study, various kinds of nodules from livers with HBV-associated cirrhosis were microdissected. XCI assay revealed monoclonality in all of the NAH with SCC, 35% of the NAH without SCC, but not in any of the ordinary regenerative nodules examined^[27]. These NAH with clonal expansion were considered neoplastic, designated microadenomas and

representing hepatic intraepithelial neoplasia (HIN). In this study, multiple FAH and NAH were also identified in FNH lesions, all of these lesions were composed mainly of clear hepatocytes with none showing SCC. A total of 56 NAH were isolated from four FNH lesions, and monoclonality was revealed in 21 (40%) of the 52 informative NAH by XCI analysis, demonstrating multifocal microadenoma formation within FNH. In contrast, all of the five ordinary nodules were proven to be polyclonal.

The occurrence of NAH with different inactivation patterns, as shown in FNH09 (Figure 3B and C), proves that microadenomas develop independently, as described for multiple leiomyomas of the uterus^[28]. It is conceivable that FNH is composed of numerous NAH and NAH-forming lesions. The synchronous relationship between different NAH may provide an explanation for the stable behavior of most FNH lesions, in contrast to HCA. In addition, the presence of multiple microadenomas (HIN) with similar XCI patterns in an FNH lesion, as shown in FNH11 (Figure 3D), may result in misinterpretation of the data if the sample examined is small. For this reason, we proposed that sample areas for clonality assessment should be as large as 1 cm \times 1 cm for larger FNH or cover the largest cross section for smaller lesions.

While some NAH were shown to be monoclonal, their pathogenesis is unknown. Our assay demonstrated allelic imbalance in all of the 13 lesions, providing additional evidence for their neoplastic nature. The alterations were highly frequent in six loci, involving similar chromosomal arms, as in HCA, including 8p, 11p, 13q and 17p. However, chromosomal arms 8p and 16q were affected in different frequencies in these two types of lesions. D8S298 was affected frequently in both NAH and HCAs, but LOH at this locus was revealed in only a minority of the HCC lesions. Allelic imbalance at D8S298 has been observed in oral and laryngeal squamous cell carcinoma and its precursor lesions. The change was proposed to be an early event in development of the cancer^[55]. This change was also observed in HCC specimens, with its frequencies ranging from 15%^[56] to 32%^[57]. It remains to be determined whether there is a tumor suppressor gene near D8S298 preferentially responsible for HCC development in HBsAg-negative patients.

In summary, classical FNH lesions were shown to be polyclonal by XCI and LOH assays and distinguishable from HCA and HCC. Secondly, multifocal HIN formation, in the form of NAH, was demonstrated within the FNH lesions. In addition, allelic imbalances were also identified in the microdissected NAH, with similar chromosomal arms affected as in HCAs. Therefore, classical FNH is considered a cluster of NAH. Elucidation of the process will be helpful for further understanding of early human hepatocarcinogenesis.

discussions, Dr. Su-Sheng Shi for providing valuable tissue samples, Xiu-Yun Liu, Xin-Hua Xue and Yong-Qiang Xie for their technical assistance.

COMMENTS

Background

Focal nodular hyperplasia (FNH) is a lesion found in an otherwise normal liver, and is considered parenchyma overgrowth responsive to increased blood flow secondary to vascular malformations. While its clinical outcomes are believed to be different from hepatocellular adenoma (HCA) and carcinoma, its pathogenesis is largely unclear and its distinction from HCA is sometimes difficult.

Research frontiers

While FNH was proposed to be a hyperplastic lesion, its clonality status has not been elucidated and the development of hepatocyte nodules within the involved parenchyma needs to be explained. In this study, the authors demonstrate that classical FNH, when examined as a whole, is polyclonal in cell composition. However, the formation of multiple nodules of altered hepatocytes (NAH), showing monoclonality and genetic alterations, was found within all the FNH lesions.

Innovations and breakthroughs

Clonality status of FNH has not been clarified and the mechanism for development of multiple hepatocyte nodules within FNH is unknown. In this study, classical FNH lesions were shown to be polyclonal and distinguishable from HCA and carcinoma. Secondly, the multifocal formation of NAH, representing early-stage hepatic intraepithelial neoplasia (HIN), was demonstrated within the FNH lesions. In addition, allelic imbalances were also identified in microdissected NAH. Classical FNH is considered a cluster of NAH.

Applications

The results of clonality analyses demonstrated polyclonality in all the classical FNH lesions, the approach being useful for the differential diagnosis of FNH from HCA and well-differentiated carcinoma. In addition, elucidation of the pathogenesis of the NAH lesions, representing hepatocytic microadenoma and early-stage HIN, may lead to further understanding of early human hepatocarcinogenesis.

Terminology

Most, if not all, of HCAs and carcinomas develop from a single focus of altered hepatocytes through nodular transformation (formation of NAH) and appearance of cellular and architectural atypia (small-cell change). Monoclonality and nonrandom genetic alterations similar to HCA, as demonstrated in NAH lesions in this study, enable us to consider these lesions hepatocytic microadenoma that represent early-stage HIN.

Peer review

This is an interesting report of clonality and genetic alternations in FNH. The article is well written and deserves publishing.

Abstract

AIM: To analyze the risk factors for central port failure in cancer patients administered chemotherapy, using univariate and multivariate analyses.

METHODS: A total of 1348 totally implantable venous access devices (TIVADs) were implanted into 1280 cancer patients in this cohort study. A Cox proportional hazard model was applied to analyze risk factors for failure of TIVADs. Log-rank test was used to compare actuarial survival rates. Infection, thrombosis, and surgical complication rates (χ^2 test or Fisher's exact test) were compared in relation to the risk factors.

RESULTS: Increasing age, male gender and open-ended catheter use were significant risk factors reducing survival of TIVADs as determined by univariate and multivariate analyses. Hematogenous malignancy

decreased the survival time of TIVADs; this reduction was not statistically significant by univariate analysis [hazard ratio (HR) = 1.336, 95% CI: 0.966-1.849, P = 0.080]. However, it became a significant risk factor by multivariate analysis (HR = 1.499, 95% CI: 1.079-2.083, P = 0.016) when correlated with variables of age, sex and catheter type. Close-ended (Groshong) catheters had a lower thrombosis rate than open-ended catheters (2.5% vs 5%, P = 0.015). Hematogenous malignancy had higher infection rates than solid malignancy (10.5% vs 2.5%, P < 0.001).

CONCLUSION: Increasing age, male gender, open-ended catheters and hematogenous malignancy were risk factors for TIVAD failure. Close-ended catheters had lower thrombosis rates and hematogenous malignancy had higher infection rates.

INTRODUCTION

Central venous access is necessary for patients who require long-term intravenous chemotherapy, parenteral nutrition, transfusion of blood components and repetitive blood sampling. Techniques for external cannulation of the subclavian and internal jugular veins were described by Broviac *et al*^[1] and Hickman *et al*^[2] in the 1970s. In 1982, Niederhuber *et al*^[3] introduced the

totally implantable access port. The principal advantages of these access ports are; no external dressing, lower infection rates than non-totally implantable devices and allowance of patients to perform normal physical activities. It is common practice to insert totally implantable venous access devices (TIVADs) in cancer patients beginning a course of chemotherapy to eliminate potential peripheral venous access problems^[4,5]; however, risk factors impacting the survival of TIVADs remain unclear. Accordingly, this retrospective cohort study analyzed the risk factors for failure of the TIVADs and compared adverse events among risk factors.

MATERIALS AND METHODS

Patient population

Between January 1, 2003 and December 31, 2006, this retrospective study enrolled 1280 cancer patients who underwent an operation for placement of TIVAD at Chang Gung Memorial Hospital, Chiayi, Taiwan. All devices were indicated for administering prolonged antineoplastic chemotherapy. Medical records for 1280 cancer patients provided data for age, sex, disease, catheter type, surgical procedure, origin of patients, reason of catheter failure, surgical complications and length of implantation. All patients were followed through December 31, 2006, until death or catheter removal due to complications.

Surgical procedure and device care

All procedures were conducted in an operating room by surgeons under fluoroscopic control for correct positioning of the catheter tip in the superior vena cava. The implantation of TIVAD required only local anesthesia (usually 10 mL of 2% mepivacaine hydrochloride) in almost all patients; general anesthesia was used in combination with major surgical procedures for 10 devices. Perioperative antibiotic prophylaxis consisted of a single dose of cephalosporin during the surgical procedure.

Surgical approaches were cephalic cut-down or subclavian vein puncture on either side depending on the surgeon's preference. The right side was usually selected for the TIVAD implantation due to shorter access route to superior vena cava than left side. Implantation from the jugular vein or femoral vein system was considered when there was failure of the cephalic vein and subclavian vein system. The TIVAD system was fixed to the underlying pectoral muscle fascia with one non-absorbable suture. Filling the port system with diluted heparin saline was performed routinely at the end of each procedure.

The TIVAD system was routinely flushed with diluted heparin saline by trained oncologic nurses, following each administration of chemotherapy agents. The device was maintained by flushing with a heparinized solution every 4 wk. Non-coring Huber needles were utilized for all injections into the TIVAD system.

Two catheter tips for port systems are used at our institution: the Groshong valved close-ended catheter

(Bard, Salk Lake City, UT, USA), and the open-ended catheter. Port systems were assigned to patients depending on surgeon's preference during the review period.

Study outcomes

The primary endpoint was failure of the TIVAD and the analysis of risk factors affecting device failure among the variables of age, gender, origin of patients, type of catheter, insertion site and type of malignancy using univariate and multivariate methods. The secondary endpoint was to compare the adverse events in relation to the risk factors.

The number of catheter-indwelling-days of TIVAD was calculated from day of insertion to one of the following observation end points: December 31, 2006; date of death; date of catheter removal due to adverse events.

Adverse events of the TIVAD system were divided into three categories: infection events (local erythematous skin change or catheter-related systemic febrile); thrombosis events (intraluminal thrombosis); and surgical complications (pneumothorax, hemothorax, distortion of port system, catheter fracture or malposition). The incidence rate of adverse event was defined as number of events per 1000 catheter-days.

Statistical analysis

The numeric variables were presented as mean \pm SD. The number of catheter-indwelling-days was presented as median with inner quartile range (IQR). Log-rank test was conducted for time of death, device removal due to adverse events. For other analyses, independent proportions were compared by using the chi-square test or Fisher's exact test. Using catheter-indwelling-days of TIVAD as a dependent variable and age, sex, catheter type, tumor type, origin of patients and insertion site as independent variables, Cox proportional hazards modeling with forward selection was performed using a two-step technique. First, univariate analysis was performed and included any potential prognostic factor. Thereafter, only variables with a value of $P < 0.10$ by univariate analysis were introduced in the Cox model. $P < 0.05$ indicated a significant statistical difference. All statistical analyses were performed using Stata Statistical Software version 9.2. (StataCorp. 2005. Stata Statistical Software: Release 9.2. College Station, TX, USA).

RESULTS

Distribution of device and device life

From January 1, 2003 and December 31, 2006, 1348 TIVADs were implanted into 1280 consecutive patients. Of the study population, 796 (62%) (842 TIVADs) were male and 484 (38%) (506 TIVADs) were female. The mean age of the subjects was 60.13 ± 13.06 years (range, 13-91 years). Patient origins for insertion of TIVADs were 967 (72%) inpatients and 381 (28%) outpatients. The devices were inserted into 1272 (94%) patients for treatment of solid tumors and 76 (6%) patients for

hematogenous tumors. The catheters used were 830 (61%) Groshong catheters and 518 (39%) open-ended catheters (Table 1). Table 2 lists the distribution of primary malignancies and TIVADs.

Table 3 lists the insertion sites, surgical procedures and catheter type used. Of the 1280 consecutive patients who required 1348 TIVADs, 1100 (81.6%) were suited to a cephalic vein cut-down approach and 196 (14.6%) to a subclavian vein puncture procedure. Of the remaining 52 devices, 23 (1.7%) were placed *via* the jugular vein system due to difficulty approaching the subclavian vein system. The final 29 (2.1%) devices utilized femoral vein placement with or without a saphenous vein approach due to previous neck/thorax radiotherapy or superior vena cava syndrome.

The median (IQR) number of catheter-indwelling-days was 178 (70399) d and total number of catheter-indwelling-days was 368373 d. There were 563 device expires in this study, including 461 deaths (331 males and 130 females) and catheters removed due to 102 adverse events.

Comparisons of risk factors and adverse events

Univariate analysis demonstrated that the following were

Figure 1 Kaplan-Meier survival curve showing that the Groshong catheter of the TIVAD had better survival time than open-ended catheters by log-rank test ($P < 0.001$).

significant risk factors for TIVAD failure: increasing age; male gender; and use of an open-ended catheter (Table 4). The remaining variables, such as patient origin, insertion site and malignancy type were not statistically significant. Increasing age, male gender, open-ended catheter and hematogenous malignancy [hazard ratio (HR) = 1.499, 95% CI: 1.079-2.083, $P = 0.016$] were significant risk factors by multivariate analysis for reduced TIVAD survival, although hematogenous malignancy (HR = 1.336, 95% CI: 0.966-1.849, $P = 0.080$) was not statistically significant by univariate analysis. The median numbers of catheter-indwelling-days for patients inserted with a Groshong or open-ended tube were 218 and 143 d, respectively. The log-rank test showed highly significant statistical differences between these survival curves ($P < 0.0001$) (Figure 1). Clearly, the patients inserted with open-ended catheter type had much lower survival rates than those with Groshong catheters.

The overall complications were 102 events (7.5%): 40 infection events; 47 thrombosis events; and 15 surgical complications. The overall infection rate was 0.108 events per 1000 catheter-days (40 cases, 2.96%), the thrombosis rate was 0.127 events per 1000 catheter-days

Table 4 Univariate and multivariate analyses of risk factors for TIVAD failure

(47 cases, 3.48%), and the surgical complication rate was 0.04 events per 1000 catheter-days (15 cases, 1.1%).

Table 5 presents comparisons of adverse events for open-ended *vs* Groshong catheters and solid *vs* hematogenous malignancies. Open-ended catheter devices had a higher thrombosis rate than Groshong catheter devices (5% *vs* 2.5%, $P = 0.015$). Hematogenous malignancies had a higher infection rate (10.5% *vs* 2.5%, $P < 0.001$) and surgical complication rate (3.9% *vs* 0.9%, $P = 0.048$) than solid malignancies.

DISCUSSION

Notably, the TIVAD is designed to be a reliable, safe and dependable means of long-term venous access for administering chemotherapy or hyperalimentation nutrition. Several studies have documented the relative superiority of TIVADs over non-totally implanted devices^[3-6]. Nevertheless, factors affecting device survival remain a major concern. This study analyzed several risk factors including age, sex, patient origin, catheter type, insertion site and malignancy type to assess whether these factors influence the failure of TIVADs.

According to the literature, the average indwelling duration of the implanted devices varies from 61 to 512 d^[7-11]. In this series, the total number of catheter-indwelling-days was 368373 d and the median duration was 178 d.

The variable of age was a significant risk factor for TIVAD failure by univariate and multivariate analyses

(HR = 1.009, 95% CI: 1.003-1.016, $P = 0.003$), signifying that risk of TIVAD failure will increase 1.009 times for each additional year of age. Puig-la Calle *et al*^[11] reported an average of 512 catheter-indwelling-days for 123 patients with a mean age of 37 years. Hou *et al*^[10] identified an average of 395 catheter-indwelling-days for 298 patients with a mean age of 55 years. In this series, the median of catheter-indwelling-days was 178 d and mean age of 1280 patient was 60 years. Taken together, these three studies indicate that age affects TIVAD survival.

Male gender was another risk factor for TIVAD failure by univariate and multivariate analyses (HR = 1.566, 95% CI: 1.318-1.861, $P < 0.001$). Average number of catheter-indwelling-day for females (228 d) was longer than that for males (151 d). This finding may be due to a higher TIVAD failure rate for males (69%, 417/607 catheter) than females (31%, 190/607) in this series. The causes of TIVAD failure for males were 331 deaths and catheter removal due to 68 adverse events. Advanced stage of cancer with reduced life expectancy for male patients is the major reason for the decreased survival of the devices (data not shown).

The third significant risk factor was catheter type. Open-ended catheters (HR = 1.689, 95% CI: 1.435-1.989, $P < 0.001$) had shorter TIVAD survival time than closed-ended catheters (Groshong catheter). We utilized the log-rank test to compare the survival distributions of open-ended and closed-ended catheters. The results, depicted in Figure 1, show that the survival time for close-

ended catheters (Groshong catheter) is significantly better than open-ended catheters using log-rank test ($P < 0.001$). Hou *et al*^[10] reported these two catheter types had similar actuarial survival rates in their study. The Groshong catheter^[12] has a unique three-way, pressure-sensitive valve that allows infusion and blood aspiration while reducing risk of an air embolism, blood reflux, and clotting. This special design is supposed to increase TIVAD survival, which is confirmed in our study.

Hematogenous malignancy was the last risk factor analysed here. By univariate analysis, hematogenous malignancy decreased TIVAD survival, but was not statistically significant (HR = 1.336, 95% CI: 0.966-1.849, $P = 0.080$). Hematogenous malignancy became a significant risk factor by multivariate analysis (HR = 1.499, 95% CI: 1.079-2.083, $P = 0.016$) when correlated with age, sex and catheter type variables. Hematogenous malignancy has a hypercoagulable status when compared to solid tumors that is considered to be an etiology for shorter device life.

The reported total adverse event rate was 5.1% (13/296 catheters) in the study by Dillon *et al*^[13], 11% (33/298 catheters) in the study by Hou *et al*^[10], 12.8% (192/1500 catheters) in the study by Kock *et al*^[14] and 21% (14/66 catheters) in the study by Grannan *et al*^[15]. There was a 7.5% (102/1348 catheters) total adverse event rate in the present series. Groshong catheters (6.3%, 53/830 catheters) had a lower total adverse rate than the open-ended group (9.4%, 49/518 catheters), especially for thrombotic events (2.5% *vs* 5%, $P = 0.015$). This result supports the proposition that the valved tip of Groshong catheters prevents thrombotic events and prolongs catheter survival. Hematogenous malignancies had higher infection and surgical complication rates than solid malignancies ($P < 0.001$, $P = 0.048$, respectively). Vescia *et al*^[16] mentioned that sterile precautions are essential when implanting and accessing port systems; infections must be treated with adequate antimicrobial therapy and catheter-related thromboembolic complications constitute a major problem during the device life, but routine anticoagulation cannot be recommended based on the results of four clinical trials^[17-20].

Patients from an outpatient background for insertion of TIVAD had a lower risk for device failure than inpatients; however, the difference between the two groups was not statistically significant (HR = 0.926, 95% CI: 0.779-1.100, $P = 0.385$). The insertion site, i.e. right cephalic vein site or other sites, was not a significant risk factor.

In conclusion, increasing age, male gender, open-ended catheter use and hematogenous malignancy were all risk factors for reduced actuarial device survival time in this study by univariate and multivariate analyses. Close-ended (Groshong) catheters had a lower thrombotic rate than open-ended catheters. Hematogenous malignancies had higher infection and surgical complication rates than solid malignancies.

The authors thank Mrs. Peggy Liu for data collection and management.

COMMENTS

Background

Central venous access is crucial for patients who have need of long-term intravenous chemotherapy, parenteral nutrition, transfusion of blood components and repetitive blood sampling. The main advantages of the totally implantable venous access device (TIVAD) are no external dressing, lower infection rates than non-totally implantable devices and allowance of patients to achieve normal physical activities.

Research frontiers

It is common practice to insert the TIVAD in cancer patients beginning a course of chemotherapy to eliminate potential peripheral venous access problems; however, risk factors impacting the survival of TIVADs remain unclear. Accordingly, the research hotspot is to investigate the risk factors for failure of the TIVAD and correlate adverse events with risk factors.

Innovations and breakthroughs

Recent reports have highlighted the relative superiority of TIVADs over non-totally implantable devices. Nevertheless, factors influencing device survival are a major concern. In this study, the authors found that increasing age, male gender, open-ended catheter use and hematogenous malignancy were significant risk factors reducing survival of TIVAD by multivariate analysis. Close-ended catheters (Groshong) had a lower thrombosis rate than open-ended catheters; hematogenous malignancies had higher infection rates than solid malignancies.

Applications

By understanding the risk factors that affect the survival of TIVADs and adverse events relating to the risk factors, this study may represent a future strategy for prolonging the survival time of TIVADs and help prevent the occurrence of adverse events when cancer patients need central venous ports for long-term chemotherapy.

Terminology

TIVAD is a port with a central venous line that does not have an external connector, instead, it has a small reservoir that is covered with silicone rubber and is implanted under the skin. Medication is administered intermittently by placing a small needle through the skin, piercing the silicone and into the reservoir.

Peer review

This is a large-scale analytic study in which authors investigated risk factors and their impact on failure of TIVADs in cancer patients receiving long-term chemotherapy. The findings suggest that increasing age, male gender, open-ended catheter and hematogenous malignancy are the factors that reduce the survival of devices. Additionally, the authors depict that close-ended catheters had lower thrombosis rates and hematogenous malignancies had higher infection rates. The results are interesting and informative, adding to existing literature.

Abstract

AIM: To evaluate the efficacy and safety of Traditional Chinese Medicine (TCM) in the treatment of *Helicobacter pylori* (*H. pylori*) infection.

METHODS: We electronically and manually searched electronic databases, references lists and conferences compilations, and included all randomized clinical trials comparing the treatment of *H. pylori* using TCM with proton pump inhibitor or colloidal bismuth subcitrate-based triple therapy as controls. The Jadad score was used to assess trial quality, *H. pylori* eradication rate and the incidence of side effects were taken as outcome measurements, and heterogeneity analysis, meta-analysis and funnel plot analysis were conducted.

RESULTS: Sixteen trials were included. The Jadad scores of all the trials were not more than 2. Clinical heterogeneity and substantial statistical heterogeneity existed among the trials ($P = 0.001$, $I^2 = 59\%$) and meta-analysis was not conducted. The average eradication rates following TCM and triple therapy were 72% and 78% and the incidence of side effects were 2% and 29%, respectively. The funnel plot was obviously asymmetric.

CONCLUSION: Available evidence is not convincing enough to show that TCM has the same efficacy as triple therapy in *H. pylori* treatment. TCM may be safer than triple therapy. TCM should not be recommended as monotherapy in *H. pylori* infection.

INTRODUCTION

Helicobacter pylori (*H. pylori*) plays a crucial role in the pathogenesis of chronic gastritis, peptic ulcer, gastric mucosa associated lymphoid tissue (MALT) lymphoma and gastric carcinoma. Clinical trials have shown that *H. pylori* eradication can relieve mucosa inflammation, accelerate ulcer healing, reduce complications and recurrence, alleviate MALT and decrease post-operative relapse of early stage gastric carcinoma. The eradication rates of *H. pylori* with proton pump inhibitor (PPI) or colloidal bismuth subcitrate (CBS)-based triple therapy, recommended in the Maastricht consensus report, are around 85%-90%. However, antibiotic resistance in *H. pylori* has increased over the past few years. The incidence of primary resistance to metronidazole is over 50%^[1] and to clarithromycin is about 18%^[2]. Antibiotic resistance decreases the eradication rates of triple therapies significantly. The eradication rate dropped by 38% for *H. pylori* resistance to metronidazole and by 55% for the strain resistant to clarithromycin^[3]. Additionally, the high dosages of antibiotics applied in triple therapies readily induce a high incidence of adverse effects in about 16%-29% of patients, and poor patient compliance decreases the efficacy indirectly^[4]. Researchers are exploring more effective and safer treatment regimens.

Since Warren and Marshall isolated *H. pylori* in 1982, many *in vitro* and *in vivo* studies on the treatment of *H. pylori* with Traditional Chinese Medicine (TCM) have been carried out. The *in vitro* studies showed that some

herbs such as *Radix scutellariae*, *Lonicera*, *Radix Isatidis Sen Baphicacanthi*, *Coptis chinensis Franch* and *Fructus Aurantii Immaturus* have obvious inhibitory effects on *H pylori*^[5,6]. The results of clinical studies are, however, variable. There have been no systematic reviews on the efficacy and safety of TCM in the treatment of *H pylori* infection. Therefore, we reviewed the clinical trials treating *H pylori* with TCM published between 1982 and 2008 which compared the efficacy and safety of TCM with those of triple therapies, in order to define the status of TCM in *H pylori* treatment.

MATERIALS AND METHODS

Inclusion criteria

Inclusion criteria were as follows: (1) Randomized, positive-controlled and parallel trials, irrespective of whether blinding was adopted; (2) Subjects with chronic gastritis, peptic ulcers, remnant gastritis or gastro-esophageal reflux disease who were *H pylori* positive. Subjects with bleeding ulcer or gastric cancer were excluded. (3) Determination of *H pylori* positive status was in accordance with the criteria of the 2007 3rd National Consensus Report on *H pylori* Infection (Consensus Report)^[7]; (4) The treatment groups received TCM including single herb, formulae or Chinese medicine products; (5) The control groups received the first line therapy regimens recommended in the Consensus Report; (6) Outcome measurements included *H pylori* eradication rate and the incidence of adverse effects. The definition of *H pylori* eradication must meet the requirements of the Consensus Report.

Literature searching strategy

The electronic databases of MEDLINE (1982-2008), Cochrane Controlled Trials Register (1982-2008), Wei-Pu database (1989-2008) and Wan-Fang database (1998-2008) were searched by using a combination of MESH subject headings of “*H pylori*”, “Medicine”, “Traditional Chinese” and “clinical trial” without language limitation. Reference lists from trials selected by electronic searching and conference compilations were hand searched.

Data collection and assessment

Two independent reviewers screened all retrieved trials according to the inclusion criteria. If the two reviewers disagreed, the difference was discussed. If a consensus could not be reached, a third reviewer was consulted. The quality of all the eligible trials was scored using the Jadad criteria^[8]. Allocation concealment was assessed. Central randomization, pharmacy controlled randomization or random numbers sealed in envelopes were regarded as appropriate concealment. If the method of allocation concealment was not mentioned or the subjects were allocated by the sequence produced by an open random number table, it was regarded as inappropriate concealment^[9].

Statistical analysis

H pylori eradication rate and the incidence of adverse

effects were used to evaluate the efficacy and safety of the regimens. The relative risk of *H pylori* eradication rate and the incidence of adverse effects were calculated using the original data and presented with 95% confidence interval. If there was no heterogeneity among the trials, a fixed effects model was applied in the meta-analysis. If there was heterogeneity among the trials and $I^2 < 50\%$, a random effects model was used instead in the meta-analysis. If $I^2 > 50\%$, the meta-analysis was aborted. Potential publication bias was analyzed by the funnel plot. All statistics were conducted using RevMan4.2 software.

RESULTS

Trials characteristics and quality

Three hundred and nine papers were obtained after initial searching. 293 papers were excluded after reading titles, abstracts or texts due to the non-clinical nature of the studies, repetitious publication or failure to meet the inclusion criteria. Sixteen papers^[10-25] were finally included with a total number of 1983 subjects (124/per trial). All the clinical trials were conducted in China and published in Chinese language. The characteristics of the included trials are presented in Table 1.

The Jadad scores of all the included trials were not more than two. One trial presented details of the randomization methods (random number table)^[22] while the rest did not present any such detail. All the trials were single-centered and non-blinded without reporting allocation concealment and sample size calculation. Three trials^[10,17,23] reported dropout cases and one of these trials^[23] conducted intention-to-treatment analysis.

Clinical efficacy assessment

Due to the wide variety of TCM treatment applied in each trial and the statistical heterogeneity of the trials ($\chi^2 = 36.97$, $P = 0.001$, $I^2 = 59.4\%$), the data could not be pooled to conduct a meta-analysis. The *H pylori* eradication rates of the TCM treatment in each trial are presented in Table 2. The average *H pylori* eradication rates following TCM treatment and triple therapy were 72% (36%-90%) and 78% (44%-93%), respectively. The eradication rates following *Chang Wei Qing* oral liquid and *Jian Pi Qing Hua* formula were lower than those of CBS-based triple therapies. The eradication rates following *Jian Wei Yu Yang* granule and *Wei Kang* formula were lower than those of PPI-based triple therapies. There were no differences in the eradication rates between the remaining TCM treatments and triple therapy. Worst-case scenario was performed in two trials^[10,17] which reported dropout cases and did not conduct intention-to-treat analysis. There was no significant difference between the new result and the original result.

Clinical safety assessment

Eleven trials^[10,11,14,16-20,23-25] reported adverse effects without presenting the methods of acquiring the information on adverse effects. Eight of 11 reported that TCM treatment had adverse effects with an average incidence of 2%

RR: Relative risk; CI: Confidence interval.

(21/903), while 10 of 11 reported that triple therapy resulted in adverse effects with an average incidence of 29% (204/697). The adverse effects associated with TCM included dizziness, loss of taste, nausea/vomiting, poor appetite, belching and loose stool/diarrhea. There were no abnormalities in routine blood tests, liver or kidney function tests in the TCM groups. Twenty subjects withdrew from the trials due to adverse effects and all were in the triple therapy groups^[10,11,17,23].

Funnel plot analysis

Funnel plot analysis was conducted using the eradication rate as the index. The figure was obviously asymmetrical (Figure 1).

DISCUSSION

Although the statistical data in this review showed that there were no differences in eradication rate between

TCM treatment and triple therapy in the majority of the trials (12/16), there is no powerful evidence to conclude that TCM treatment has the same efficacy as triple therapy in the treatment of *H pylori* infection due to the following reasons:

Poor quality of the clinical trials

All 16 trials were of poor quality and did not meet the requirements of the CONSORT statement^[26]. Although these trials claimed to adopt randomization, only one trial presented details of the randomization method and the remaining trials did not give any details of the randomization method. None of the trials described the methods of allocation concealment. Thus, whether the randomization was truly or effectively conducted in these trials is doubtful. Inappropriate randomization or allocation concealment can lead to selection bias. All trials were single-centered and non-blinded, and the treatment courses of the study groups were longer

Figure 1 Funnel plot analysis of clinical trials treating *H pylori* with TCM. RR: Relative risk.

than those of the control groups in some trials, which may have resulted in performance bias. Dropout cases were reported in only three of 16 trials and were not mentioned in the other trials. It is not clear whether these trials had any dropout cases or whether they were simply not reported. Having dropout cases without reporting can result in attrition bias. Selection bias, performance bias and attrition bias may overestimate the efficacy of treatment groups. Additionally, none of the trials showed the calculation of sample size, thus, whether the sample size met the statistical requirement or the reliability of the statistical results cannot be judged. Therefore, confidence in the results obtained from these poor quality trials is questionable.

Asymmetrical funnel plot

The asymmetry of the funnel plot may have been caused by the poor quality of the trials and publication bias. All 16 trials were conducted in China and published in Chinese language. Fourteen trials were published in TCM journals, one in a journal of integrated Chinese and Western medicine and one in a college journal. TCM journals are inclined to publish only positive results showing efficacy of TCM treatment. Therefore, when we searched the literature, most of the papers we found reported positive results, with only a few presenting negative results.

Heterogeneity

The TCM formulae used in the 16 trials were composed of various herbs which can clear heat, strengthen the spleen, regulate *Qi* or promote blood circulation. The composition of the formula and the dosage of each herb were different in each trial. The treatment courses also varied in each trial, from 1 wk to 2 mo. This resulted in clinical heterogeneity. Heterogeneity analysis also showed that there was substantial statistical heterogeneity. Due to the limited number of trials and the variety of composition and treatment courses, these trials could not be classified into subgroups for meta-analysis. An overall comparison between TCM and triple therapy could not be conducted.

Eight of 11 trials showed that the incidence of adverse effects following TCM treatment was lower than those following triple therapy, while three trials showed that there was no difference between them. Although non-blinded and lacking in detail on how the information on adverse effects was obtained, due to the obvious difference in the incidence of adverse effects between the two groups (2% *vs* 29%), we speculate that TCM treatment might be safer than triple therapy.

On the basis of the above, we cannot conclude that TCM treatment has the same efficacy as triple therapy in the treatment of *H pylori* infection. TCM should not be recommended as monotherapy in the treatment of *H pylori* infection until stronger positive evidence is obtained. However, neither can we completely ignore the efficacy of TCM in the treatment of *H pylori* infection because of the poor quality of the trials. We suggest that a scientific proposal should be designed and clinical trials performed strictly in accordance with the requirements of evidence-based medicine, in order to truly show and objectively assess the efficacy of TCM in *H pylori* treatment. Additionally, based on the tenet that medical study originates from clinical practice and serves clinical practice, studies on TCM in the treatment of *H pylori* infection should focus on the problems faced in western medicine, such as antibiotic resistance, the high incidence of adverse effects and high cost of the treatment, in addition to comparing the efficacy between TCM and Western medical treatment.

COMMENTS

Background

As antibiotic resistance to *Helicobacter pylori* (*H pylori*) has increased over the past few years, the eradication rates following triple therapies have decreased. New approaches to eradicate *H pylori* are under development.

Research frontiers

Some herbs show obvious inhibitory effects on *H pylori* *in vitro*. Traditional Chinese Medicine (TCM) alone or integrated with western medicine have been used to treat *H pylori* infection in many clinical trials. However, the results of these trials are controversial and the efficacy of TCM in *H pylori* treatment is indefinite.

Innovations and breakthroughs

This is the first systematic review to assess the efficacy of TCM in the treatment of *H pylori* infection. It truly presents the quality of the clinical trials using TCM in *H pylori* treatment. The authors objectively concluded that the validity of TCM in the treatment of *H pylori* infection could not be determined due to the poor quality of the trials.

Applications

This study suggested that TCM should not be recommended as monotherapy to treat *H pylori* infection and the quality of TCM clinical trials need to be improved in the future.

Terminology

A systematic review is a summary of research that uses explicit methods to perform a thorough literature search and critical appraisal of individual studies to identify valid and applicable evidence.

Peer review

This is a good paper.

Abstract

AIM: To investigate the correlation between the antifibrotic effect of baicalin and serum cytokine production in rat hepatic fibrosis.

METHODS: Forty male Sprague-Dawley rats were divided randomly into four groups: normal control group, model group, baicalin-treated group, and colchicine-treated group. Except for the normal control group, all rats in the other groups were administered with carbon tetrachloride to induce hepatic fibrosis. At the same time, the last two groups were also treated with baicalin or colchicine. At the end of the 8 wk, all animals were sacrificed. Serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), transforming growth factor (TGF)- β 1, tumor necrosis factor (TNF)- α , interleukin (IL)-6 and IL-10 were measured. Liver index, hepatic hydroxyproline content and the degree of liver fibrosis were also evaluated.

RESULTS: The levels of ALT, AST and liver index in the baicalin-treated group were markedly lower than

those in the model group (ALT: 143.88 ± 14.55 U/L vs 193.58 ± 24.35 U/L; AST: 263.66 ± 44.23 U/L vs 404.37 ± 68.29 U/L; liver index: 0.033 ± 0.005 vs 0.049 ± 0.009 , $P < 0.01$). Baicalin therapy also significantly attenuated the degree of hepatic fibrosis, collagen area and collagen area percentage in liver tissue ($P < 0.01$). Furthermore, the levels of serum TGF β 1, TNF- α and IL-6 were strikingly reduced in the baicalin-treated group compared with the model group, while the production of IL-10 was up-regulated: (TGF- β 1: 260.21 ± 31.01 pg/mL vs 375.49 ± 57.47 pg/mL; TNF- α : 193.40 ± 15.18 pg/mL vs 260.04 ± 37.70 pg/mL; IL-6: 339.87 ± 72.95 pg/mL vs 606.47 ± 130.73 pg/mL; IL-10: 506.22 ± 112.07 pg/mL vs 316.95 ± 62.74 pg/mL, $P < 0.01$).

CONCLUSION: Baicalin shows certain therapeutic effects on hepatic fibrosis, probably by immunoregulating the imbalance between profibrotic and antifibrotic cytokines.

INTRODUCTION

Hepatic fibrosis is a common pathological process of chronic liver injury, regardless of etiology, and its progression leads to cirrhosis and liver cancer^[1]. Despite extensive efforts, its etiology and pathogenesis remain unclear, and effective therapy with limited side effects is still lacking^[2]. Baicalin is a major bioactive flavonoid contained in dried roots of *Scutellaria baicalensis*

Georgi (common name: *Huangqin* in China, a traditional Chinese herbal medicine) and it possesses a multitude of pharmacological activities. For instance, Baicalin exerts the inhibitory effects against several virus including influenza virus, human T cell leukemia virus and acquired human immunodeficiency virus type I [3-5]. It can act as potent anti-inflammatory, anti-allergic and anti-bacterial agent in a variety of inflammatory diseases [6-8]. It may also be potentially useful in the treatment of prostate and bladder cancers as well as hepatoma *via* multiple cellular mechanisms [9-11]. Most importantly, previous studies show that baicalin has significant scavenging effects on oxygen free radicals and protective effects on liver injury induced by iron overload and CCl₄, suggesting that it is a potent free radical scavenger and hepatoprotective drug [12,13]. However, the exact mechanisms of anti-fibrotic effect of baicalin remain unclear. Therefore, it is necessary to be further elucidated.

CCl₄-induced hepatic fibrosis is a well-established animal model to study the pathogenesis and therapy of chronic liver injury. Zhang *et al.* [14] have reported that several profibrotic cytokines, including transforming growth factor (TGF)-β1, tumor necrosis factor (TNF)-α and interleukin (IL)-6, play an important role in the initiation and perpetuation of CCl₄-induced liver fibrosis, whereas IL-10 plays an antifibrogenic role by counterbalancing the former effects. This study aimed to further investigate the effect of baicalin on hepatic fibrosis induced by CCl₄ and its relationship with the expression of TGF-β1, TNF-α, IL-6 and IL-10.

MATERIALS AND METHODS

Reagents and rats

Baicalin (7-glucuronic acid, 5,6-dihydroxyflavone, CAS No.: 21967-41-9) was provided by Sichuan Guanghan Bencao Plant Chemical Co., Ltd (Sichuan, China), and purity was assessed by HPLC (> 98%). Colchicine was purchased from Xiamen Sanland Chemical Co., Ltd (Fujian, China). CCl₄ was obtained from Chongqing Chemical Reagent Co., Ltd (Chongqing, China). Male Sprague-Dawley (SD) rats weighing 150-180 g were purchased from the Experimental Animal Center of Third Military Medical University. All studies involving rats were approved by the Institutional Animal Care and Use Committee.

Induction of liver fibrosis and baicalin treatment

Forty male SD rats were divided randomly into four groups: normal (*n* = 9); model (*n* = 11); baicalin-treated (*n* = 10); and colchicine-treated (*n* = 10). Except for the normal control group, all rats in the other groups were treated with subcutaneous injection of 40% CCl₄ (initial dose of 0.5 mL/kg, followed by 0.3 mL/kg), mixed with vegetable oil, twice weekly for 8 wk. The latter two groups were also treated with baicalin (70 mg/kg, dissolved in sterile saline water, intraperitoneal injection, once daily), or colchicine (50 μg/kg, dissolved in sterile saline water, intraperitoneal injection, once daily) on the same day as CCl₄ administration and continued for the

Baicalin	9	0.033 ± 0.005 ^{b,d}	143.88 ± 14.55 ^{b,d}	263.66 ± 44.23 ^{b,d}
Colchicine	9	0.031 ± 0.004 ^{a,d}	167.60 ± 21.66 ^{b,c}	325.61 ± 52.83 ^{b,c}

^a*P* < 0.05, ^b*P* < 0.01 *vs* normal control group; ^c*P* < 0.05, ^d*P* < 0.01 *vs* model group. AST: Aspartate aminotransferase; ALT: Alanine aminotransferase.

8-wk experimental period. The two drug doses were selected based on a previous study [13]. Simultaneously, normal control and model groups were intraperitoneally administered with the same volume of vehicle (sterile saline water) once daily. At the end of the 8-wk experimental period, all animals were anesthetized with 3% chloral hydrate and dissected. Blood and liver were obtained for further analysis.

Measurement of serum aspartate aminotransferase (AST)

Serum AST and alanine aminotransferase (ALT) levels were measured using an automated analyzer of biochemistry (Hitachi 7170, Tokyo, Japan) according to the manufacturer's instructions.

Liver index calculation

Liver index was measured according to the formula: (rat liver weight/rat weight) × 100% [15].

Histopathology

Samples were obtained from the same liver lobe in all animals and fixed in 10% buffered formalin, embedded in paraffin, sectioned, and stained with hematoxylin-eosin (HE) or van gieson (VG) stain.

The degree of liver fibrosis was evaluated on HE-stained sections as described previously [16,17]. The collagen content of the sections was also determined on VG-stained sections by a computer image analysis system (CM2000B, Beijing University of Aeronautics & Astronautics, China). Five random fields were chosen in each section and the amount of total collagen was detected in the area stained by VG, and expressed as percentage relative to the total area [18].

ELISA for serum TGF-β1, TNF-α, IL-6 and IL-10

Cytokine levels in the serum samples were measured by a commercially available ELISA kit (Biosources, San Jose, CA, USA) according to the manufacturer's instructions.

Statistical analysis

Statistical analysis was performed with SPSS for Windows, version 13.0 (Chicago, IL, USA). Parametric data were analyzed statistically by one-way ANOVA followed by post-hoc tests when appropriate. Degree of hepatic fibrosis was analyzed by Kruskal-Wallis nonparametric test. Data were expressed as the means ± SD. A significant difference was defined as *P* < 0.05.

RESULTS

Animals

Irritability, aggression and weight loss were present predominantly in the model group. At the end of the 8-wk experimental period, no death was found in the normal control group. There were four deaths in the model group, one in the colchicine-treated group, and one in the baicalin-treated group.

Liver index and serum aminotransferases

Liver index in the normal control group was 0.026 ± 0.004. However, 8 wk after CCl₄ injection, the liver index increased markedly. The increase was significantly attenuated by baicalin or colchicine treatment (*P* < 0.01, Table 1).

We then measured serum aminotransferase activity in different experimental groups. The levels of serum AST and ALT were significantly increased in the model group compared with those in the normal control group. In contrast, baicalin or colchicine treatment significantly suppressed upregulation of these parameters induced by CCl₄ (*P* < 0.05 or *P* < 0.01, Table 1).

Histopathology

Using HE staining, we observed that the liver tissue in normal control rats showed normal lobular architecture with central veins and radiating hepatic cords. However, liver sections taken from rats in the model group exhibited more inflammatory infiltration, steatosis, hepatocyte coagulative necrosis and fibrous septa compared with the normal control rats after 8 wk of CCl₄ treatment. In contrast, baicalin or colchicine treatment markedly ameliorated these histopathological changes (Figure 1A-D). The results were further supported by a significantly decreased staging score of hepatic fibrosis after baicalin or colchicine therapy (*P* < 0.01, Table 2).

We evaluated by VG staining the collagen level in the liver tissue from different treatment groups. Compared with the normal control group, both collagen area and collagen area percentage were significantly increased in the model group. The increases were reduced by baicalin or colchicine treatment, similar to the changes in hepatic histological examination (*P* < 0.01; Figure 1E-H, Table 3). Therefore, the above findings show that baicalin can prevent CCl₄-induced hepatic fibrosis in rats.

Effect of baicalin on serum TGF-β1, TNF-α, IL-6, IL-10 production

As shown in Table 4, the levels of serum TGF-β1, TNF-α and IL-6 in the model group were significantly higher than those in the normal control group (*P* < 0.01). Upregulation was markedly inhibited by treatment with 70 mg/kg baicalin (*P* < 0.01). On the other hand, IL-10 production in the model group was sharply decreased compared with that in the normal control group (55% reduction, *P* < 0.01). However, baicalin therapy significantly recovered the decrease induced by CCl₄ (*P* < 0.01).

DISCUSSION

In the present study, baicalin significantly lowered the levels of serum ALT, AST and liver index, reduced histological changes of liver fibrosis, suppressed the expression of cytokines, including TGF-β1, TNF-α and IL-6, and improved significantly the serum level of IL-10. Furthermore, our previous study showed that the increases of several fibrosis indices including serum hyaluronic acid, type IV collagen and hepatic hydroxyproline content after the CCl₄ injection can be notably inhibited by baicalin treatment^[13]. The above findings demonstrated that baicalin can effectively prevent CCl₄-induced hepatic fibrosis in rats and regulate the production of cytokines correlated with fibrosis.

Carbon tetrachloride (CCl_4), is a known hepatotoxin that can cause liver necrosis, fibrosis and cirrhosis when administered repeatedly. Hepatotoxicity is thought to involve two phases^[19,20]. The initial phase involves bioactivation by a microsomal cytochrome-P450-dependent monooxygenase system, which results in the formation of free radicals and oxidative

stress/lipid peroxidation which exhibits the increase of malondialdehyde (MDA) amounts and decrease of superoxide dismutase (SOD) levels^[19,21]. The second step involves the activation of Kupffer cells, which is accompanied by the production of profibrotic mediators such as TGF- β 1, TNF- α and IL-6^[22]. Hepatic stellate cells (HSC), activated by pro-fibrotic factors, lose

vitamin A and transform into myofibroblasts (MFB), expressing α -smooth muscle actin (α -SMA) and thus gaining the function of contractility, proliferation and fibrogenesis^[23,24]. In this study, we observed that baicalin significantly reduced the increase in profibrotic cytokines such as TGF- β 1, TNF- α and IL-6 induced by CCl₄. The reduction in profibrotic cytokines may be correlated closely with previous results that baicalin has good radical scavenging action (lessening the MDA level and activating the SOD activity) and can thus reduce the production of activated Kupffer cells^[12,13]. The down-regulation of pro-fibrotic cytokines induced by baicalin treatment then significantly inhibits the activation and proliferation of HSC and enhances HSC apoptosis *in vitro* or *vivo* studies^[13], which results in the extenuation of hepatic fibrosis. Thus, the reduction of pro-fibrotic cytokines such as TGF- β 1, TNF- α and IL-6 levels is one important mechanism associated with anti-fibrotic effect of baicalin.

IL-10 is a pluripotent cytokine produced by many activated immune cell types, including T-helper cells, B cells, macrophages, monocytes and keratinocytes^[25]. Recent studies have indicated that IL-10 might play an important role in antifibrogenesis during CCl₄-induced hepatic fibrogenesis^[26-28]. Our study showed that the level of circulating IL-10 in the model group was lower than that in the normal control group, which was consistent with a previous study^[14]. In contrast, baicalin significantly restored the decrease in IL-10 content induced by CCl₄, probably contributing to the antifibrotic effect of baicalin.

In conclusion, baicalin has significant antifibrogenic effects on CCl₄-induced liver fibrosis in rats. In addition to the inhibition of HSC activation and lipid peroxidation, as previously reported, immunoregulation of the imbalance between profibrotic and antifibrotic cytokines is one of the most important factors involved in the preventive effect of baicalin on CCl₄-induced liver fibrosis. The exact molecular mechanisms remain to be explored.

COMMENTS

Background

Hepatic fibrosis is a common pathological process of chronic liver injuries, regardless of etiology, and its progression leads to cirrhosis and liver cancer. Despite extensive efforts, its etiology and pathogenesis remain unclear and effective therapies with limited side effects are still deficient. Baicalin is a flavonoid purified from the medicinal plant *Scutellaria baicalensis* Georgi, a well known Traditional Chinese Medicine. The previous studies show that baicalin has significant scavenging effects on oxygen free radicals and protective effects on liver injuries induced by iron overload and CCl₄, however, its exact mechanisms remain unclear.

Research frontiers

Baicalin is a flavonoid purified from the medicinal plant *Scutellaria baicalensis* Georgi, a well known Traditional Chinese Medicine. In the area of prevention of hepatic fibrosis with baicalin, one of research hotspots is that how is the actual mechanism of anti-fibrotic effect of baicalin.

Innovations and breakthroughs

The previous studies have shown that baicalin has significant scavenging effects on oxygen free radicals and protective effects on liver injuries induced by CCl₄. In this study, the effect of baicalin on hepatic fibrosis induced by CCl₄

and its relationship with the expression of pro-fibrotic and anti-fibrotic cytokines were first investigated. The levels of liver index and serum aminotransferases in baicalin-treated group were markedly lower than those in model group. Baicalin therapy also significantly attenuated the degree of hepatic fibrosis, collagen area and collagen area percent in liver tissue. Furthermore, the levels of serum transforming growth factor- β 1, tumor necrosis factor- α and interleukin (IL)-6 were strikingly reduced in baicalin-treated group compared with model group while the production of IL-10 was up-regulated. The above results show that baicalin has certain therapeutic effects on hepatic fibrosis probably by immunoregulating the imbalance between pro-fibrotic and anti-fibrotic cytokines.

Applications

The study demonstrates that baicalin is a good hepatoprotective drug for preventing and treating human liver fibrosis probably by immunoregulating the imbalance between pro-fibrotic and anti-fibrotic cytokines.

Terminology

Hepatic fibrosis is characterized by elevated deposition and altered composition of extracellular matrix, which is a common stage in most chronic liver injuries. Baicalin is a bioactive anti-inflammatory flavone purified from the medicinal plant *Scutellaria baicalensis* Georgi, a well known Traditional Chinese Medicine.

Peer review

The authors analyzed the preventative effects and mechanism of baicalin in the treatment of liver fibrosis in rats. The results are interesting and suggest that baicalin may be a clinical useful agent for preventing and treating human liver fibrosis.

Abstract

Tumor lysis syndrome (TLS) is a potentially lethal complication in cancer therapy. It may occur in highly sensitive tumors, especially in childhood cancer and leukemia, whereas, it is rare in the treatment of solid tumors in adults. TLS results from a sudden and rapid release of nuclear and cytoplasmic degradation products of malignant cells. The release of these can lead to severe alterations in the metabolic profile. Here, we present two cases of large hepatocellular carcinoma (HCC) treated by transarterial chemoembolization (TACE) that resulted in TLS. Although TLS rarely happens in the treatment of adult hepatic tumor, only a few cases have been reported. We should keep in mind that all patients with HCC, particularly those with large and rapidly growing tumors, must be closely watched for evidence of TLS after TACE.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common neoplasm worldwide, and the third most common cause of cancer-related death. Despite the development of several methods for unresectable HCC, transarterial embolization (TAE) is the most widely used^[1]. Although TAE is an effective modality, there are several potential side effects such as hepatic failure, internal bleeding, liver abscess, biliary tract injury, and renal failure^[2]. Among these varied complications, tumor lysis syndrome (TLS) is easily neglected and may be fatal.

TLS was first reported in 1929, and is defined by the release of intracellular components into the bloodstream as a result of massive lysis of malignant cells after effective therapy. The release of these components can cause severe metabolic alterations, characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia^[3-5]. Hyperuricemia is caused by purine degradation and can lead to precipitation of uric acid crystals in the kidney collecting tubules, which results in obstructive nephropathy^[6]. Hyperkalemia, following potassium effusion from the cytoplasm, may lead to cardiac arrhythmia and arrest. Therefore, TLS can lead to acute renal failure and can be life-threatening, if it is not recognized early and treated. It is most commonly observed following chemotherapy for high-grade lymphoproliferative malignancy, such as acute lymphocytic leukemia and Burkitt lymphoma^[7,8]. Although TLS also has been reported in many different types of solid tumors, including lung and breast carcinoma^[9-11], it is still very rare in the treatment of HCC with transarterial chemoembolization (TACE). As far as we know, only a few cases have been reported in the English-language literature^[12,13].

Here, we report two cases of acute TLS in patients with HCC following TACE, and review the literature.

CASE REPORT

Case 1

A previously well 76-year-old woman suffered from epigastric fullness and dull pain for about 1 mo. Abdominal sonography revealed a large liver tumor that occupied the majority of the right lobe (Figure 1A), and biopsy of the tumor showed HCC. TACE with 20 mg adriamycin (Figure 1B) was performed during admission.

Figure 1 Computed tomography scan obtained before TACE showed a large HCC over the right lobe (A), and TACE revealed hypervascularization of the tumor (B).

The patient developed acute renal insufficiency on the next day. Contrast-induced acute renal failure was suspected in the beginning, but the symptom did not improved after adequate resuscitation. On the third day post-TACE, the acute renal failure worsened. In addition, hyperuricemia (16.6 mg/dL), hyperkalemia (5.7 mEq/L) and hypocalcemia (6.8 mg/dL) were noted later. Under suspicion of TLS, oral allopurinol and urine alkalization, combined with hemodialysis, were given immediately. The patient's renal function stabilized and the urine output increased progressively after treatment. Unfortunately, severe aspiration pneumonia developed during this period, and the patient expired because of sepsis on day 17 after TACE.

Case 2

A 56-year-old male patient was a hepatitis B virus carrier. Regular surveillance revealed a large hepatic tumor over segment 6 and a high α -fetoprotein level (247 ng/dL). Under suspicion of HCC, he was admitted for further treatment. After discussion with the hepatobiliary team, TACE (10 mg lipiodol + 20 mg adriamycin) was suggested as the treatment of choice. Oliguria occurred on the same night. The previous experience reminded us about the possibility of TLS in such a situation. We checked the laboratory profile for TLS immediately. Hyperuricemia (15.1 mg/dL), hyperphosphatemia (4.7 mg/dL) and hypocalcemia (6.6 mg/dL) were noted, and TLS was diagnosed. After standard treatment including oral allopurinol and urine alkalization, this patient's symptoms improved dramatically. Finally, he was discharged on day 6 post-TACE without any other complication.

DISCUSSION

HCC is the fifth most common neoplasm in worldwide, and the third most common cause of cancer-related

death. Only a minority of HCCs are diagnosed at an early stage for potentially curative therapy such as surgical resection or local ablation^[1]. Several methods have been developed for unresectable HCC, including radiotherapy, chemotherapy and TACE. Among the various treatments, TACE has shown evidence of a beneficial survival effect compared with other methods^[1,2]. As the most widely used treatment for advanced HCC, TACE still has some complications. Common adverse effects of TACE include liver dysfunction, post-embolization syndrome, hepatic infarction, and liver abscess. Besides these, TLS is a very rare and easily neglected complication.

The first two cases of TACE-induced TLS were reported by Burney in 1998, and both had large HCCs (> 5 cm in size)^[12]. As in our situation, the first case was diagnosed too late and the patient died. The second patient's syndrome was detected early and treated appropriately. Another case report was published by Sakamoto *et al*^[13]. This patient had a large HCC > 20 cm in size. After treatment with TACE, the patient also died of acute TLS. Both authors concluded that TLS is a possible and lethal complication of TACE for large HCC.

TLS is a known consequence of treatment of hematological malignancies such as leukemia and lymphoma^[7,8]. In general, TLS is less likely to occur in adult patients with solid tumors. However, some solid malignancies in adults, such as breast cancer, small cell lung cancer, seminoma, metastatic Meckel's cell tumor, medulloblastoma, and even hepatoma have been reported to be the cause of TLS^[9-11]. TLS may occur after various treatments of HCC, including radiofrequency ablation^[14], oral thalidomide^[15] and TACE^[12,13].

TLS arises from spontaneous cell death or within the first few days after cytotoxic therapy, and results from rapid tumor destruction. It leads to hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, or often, acute renal failure^[3-6]. Early identification of patients at risk and prevention of TLS development is critical. Acute renal failure may occur from intravascular volume depletion or from deposition of uric acid and calcium phosphate crystals in the renal tubules. Without prompt and proper management, derangements of TLS can result in death, as in case 1. Early recognition and treatment will reduce the risk of this fatal complication. For early recognition, it is essential to monitor patients at high risk, especially during the early course of treatment. Traditionally, patients with large tumor burdens and/or rapidly dividing tumors are at greatest risk for TLS. Other risk factors include chemosensitive tumors, large area of tumor necrosis, and pretreatment renal dysfunction. Serum potassium, uric acid, calcium, phosphate and lactate dehydrogenase level, and renal function should be monitored intensively in these high-risk patients after cancer therapy^[3-5].

According to the Cairo-Bishop classification, TLS is defined as a 25% change or a level above or below normal for any two or more serum values of uric acid, potassium, phosphate, and calcium within 7 d after cancer therapy^[5] (Table 1). The principles of treatment of TLS

Table 1 Cairo-Bishop definition of TLS

Uric acid	≥ 8.0 mg/dL or 25% increase from baseline
Potassium	≥ 6.0 mEq/L or 25% increase from baseline
Phosphorus	≥ 4.5 mg/dL or 25% increase from baseline
Calcium	≥ 7.0 mg/dL or 25% decrease from baseline

should address three critical areas: hydration, correction of metabolic abnormalities, and aggressive treatment of renal failure. Aggressive fluid administration has been recommended in all high-risk patients. Volume expansion with isotonic saline can reduce serum concentrations of uric acid, phosphate and potassium. As renal blood flow, glomerular filtration rate, and urine output are all increased, the concentration of solutes in the renal tubules is decreased, which makes precipitation less likely^[16]. Prevention and treatment of abnormal metabolites are the next step, especially hyperuricemia. Uric acid crystals can precipitate in renal tubules and cause obstructive nephropathy and renal failure. Oral or intravenous allopurinol (100 mg/m² every 8 h) is recommended for the treatment of hyperuricemia. Recently, another urate oxidase (rasburicase; 0.05-0.2 mg/kg) was demonstrated to be more effective than allopurinol for the treatment of hyperuricemia^[3-6]. If obstructive nephropathy persists and progresses to acute renal failure, aggressive hemodialysis should not be delayed^[16].

Oliguria is not a rare occurrence post-TACE. The most common cause is radiocontrast-induced renal insufficiency. However, oliguria also can be one of the early clinical signs of TLS^[5]. The incidence of acute renal insufficiency caused by TACE *per se* has been shown to be 3%-8% for each treatment session^[17]. It is much more common than that induced by TLS. Adequate hydration is sufficient to overcome this complication. Therefore, many physicians may misdiagnose oliguria as a sign of contrast-induced renal insufficiency and delay proper treatment. Hydration alone is not sufficient for the treatment of TLS. Correction of abnormal metabolites, such as reduction of uric acid level, is another essential feature. If we overlook the potential risk of TLS, the results can be tragic.

In conclusion, although rare, TLS can occur after TACE of HCC in adults. Pretreatment evaluation of risk factors, including large tumor size, rapid tumor growth, and renal insufficiency should be completed. Close monitoring after TACE in these high-risk patients is warranted. When TLS develops, effective treatment, including adequate hydration, oral medication (allopurinol

and/or urate oxidase) or hemodialysis, should be undertaken immediately.

Abstract

A 71-year-old woman was referred to our department complaining of painless progressive jaundice for the last 3 mo. Magnetic resonance imaging and magnetic resonance cholangiopancreatography (MRCP) showed the ectopic hepatopancreatic ampulla draining into the fourth part of the duodenum adjacent to the duodenojejunal flexure; the irregular morphology of the duodenojejunal flexure likely due to a soft tissue mass. Laparotomy confirmed the presence of the abnormal ampulla of Vater located at the fourth part of the duodenum and a soft tissue tumor about 6 cm × 5 cm × 5 cm with a peduncle adjoining the ampulla. Resection of the tumor, including some peripheral tissue, and a Roux-Y loop anastomosis choledochojejunostomy were performed. Pathological examination indicated an intestinal villous adenoma accompanied by severe dysplasia and focal canceration. Periampullary carcinoma with ectopic ending of the Vater's ampulla into the fourth part of the duodenum is rather rare. The embryonic genetic background of this anomaly has not yet been fully explained. It is worth mentioning that MRCP is useful for demonstrating anomalies and anatomic variants of the biliary tract system and pancreatic duct.

INTRODUCTION

The usual location of the major papilla of Vater is in the mid-portion of the descending duodenum, closer to the posterior wall than the anterior wall. On rare occasions it may be found in other sites, along a line extending from the stomach to the fourth part of the duodenum^[1-5]. Here we present a case of periampullary carcinoma combined with ectopic opening of the Vater's ampulla into the fourth part of the duodenum and a low confluence of the cystic duct into the common bile duct. To our knowledge, such a case has never been described previously, so the pathogenesis, diagnosis and treatment will be discussed in this report.

CASE REPORT

A 71-year-old woman was referred to our department complaining of painless progressive jaundice for the last 3 mo. Hypertension and diabetes mellitus were diagnosed 10 years previously, and a cholecystectomy was performed 18 years before admission. Physical examination did not show any abnormalities except jaundice. Laboratory data (Table 1) showed the levels of the serum total bilirubin, direct bilirubin, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, and glutamyl transpeptidase were 138.5 μmol/L, 120.0 μmol/L, 78 IU/L, 184 IU/L, 1031 IU/L, and 944 IU/L, respectively (significantly higher than normal); tumor markers including serum α-fetoprotein, carcinoembryonic antigen, carbohydrate antigen 199 (CA199), and carbohydrate antigen 125 (CA125) were 1.44 ng/mL, 3.27 ng/mL, 34.54 U/mL, and 89.87 U/mL, respectively (the latter two were a little higher than normal); the hepatitis B & C markers were negative; blood routine test (BRT) was normal. Sonography of the upper abdomen revealed only hepatic biliary and main pancreatic duct dilation. Subsequently magnetic resonance imaging and magnetic resonance cholangiopancreatography

Table 1 Some lab tests of patient

Lab items	Values		Normal values
TBIL ($\mu\text{mol/L}$)	138.5	↑	1.7-17
DBIL ($\mu\text{mol/L}$)	120.0	↑	0-6.8
ALT (IU/L)	78	↑	10-40
AST (IU/L)	184	↑	10-40
ALP (IU/L)	1031	↑	40-110
GT (IU/L)	944	↑	< 50
AFP (ng/mL)	1.44		< 20
CEA (ng/mL)	3.27		< 15
CA199 (U/mL)	34.54	↑	< 33
CA125 (U/mL)	89.87	↑	0-35

TBIL: Total bilirubin; DBIL: Direct bilirubin; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; ALP: Alkaline phosphatase; GT: Glutamyl transpeptidase; AFP: α -fetoprotein; CEA: Carcinoembryonic antigen.

Figure 1 Magnetic resonance imaging showed the expansion of hepatic biliary duct and the ectopic hepatopancreatic ampulla (arrow) draining into the fourth part of the duodenum.

(MRCP) were performed (Figure 1) which showed the expansion of the extrahepatic and intrahepatic biliary ducts and the main pancreatic duct, the ectopic hepatopancreatic ampulla draining into the fourth part of the duodenum adjacent to the duodenojejunal flexure, a low confluence of the cystic duct into the common bile duct with a distance of approx 4 cm to the Vater's ampulla, and the irregular morphology of the duodenojejunal flexure; likely due to a soft tissue mass, which did not rule out the possibility of periampullary tumor resulting in the common bile duct stricture. Gastroscopy revealed chronic superficial antral inflammation without orifice or mucosal ulceration in the stomach and without any duodenal papilla in the descending duodenum.

Laparotomy confirmed the presence of an abnormal ampulla of Vater located at the fourth part of the duodenum and a soft tissue tumor about 6 cm \times 5 cm \times 5 cm with a peduncle joined to the ampulla (Figure 2). Intraoperative choledochoscopic examination displayed no mass in the common bile duct. Consequently, complete resection of the tumor including some peripheral tissue was performed from an incision of the jejunum, close to the duodenojejunal flexure. Frozen pathological examination indicated an intestinal villous adenoma accompanied by severe dysplasia and highly suspect focal canceration, however, no incisional tumor cells were seen. A Roux-Y loop anastomosis

Figure 2 A soft texture tumor about 6 cm \times 5 cm \times 5 cm with a peduncle conjunct to the ampulla.

Figure 3 Microscopic examination (HE, \times 400) showed severe dysplasia and focal carcinomatous change.

at side-to-side choledochojejunostomy and end-to-side jejunojunctionostomy was carried out in order to prevent stricture at the end of the common bile duct. Pancreatoduodenectomy was not done. Paraffin block histopathologic examination confirmed a diagnosis of intestinal villous adenoma accompanied by severe dysplasia and focal carcinomatous change without incisional margin infiltration (Figure 3). After operation, the patient recovered without incident and liver function tests gradually reverted to normal levels.

DISCUSSION

The ectopic drainage of the biliary tract is a rare congenital anomaly, which consists of abnormal communication of the common bile duct, the cystic duct, or an intrahepatic duct with the gastrointestinal tract. As noted by previous authors, ectopic drainage of the common bile duct may be located along a line extending from the stomach to the fourth part of the duodenum^[1-5]. The frequency of this anomaly fluctuates between 0% and 13%^[1,6]. However, there only four cases with ectopic ampulla draining into the fourth part of duodenum were reported^[5,7]. Periampullary carcinoma combined with this anomaly has never described previously.

The embryogenetic background of this anomaly has not yet been fully explained. As is known, the extrahepatic biliary duct and the ventral pancreas arise

from the hepatic diverticulum of the end of foregut during the 4th to 6th week of embryo life^[8,9]. The dorsal pancreatic bud appears opposite the hepatic diverticulum. During development, as the duodenum rotates to the right and becomes C-shaped, the ventral pancreatic bud is carried dorsally with the bile duct. The ventral pancreatic duct joins the distal portion of the dorsal pancreatic duct to form the main pancreatic duct, which merges with the common bile duct, inserting into the duodenum *via* the papilla of Vater^[10]. Then, the proximal portion of the dorsal pancreatic duct gradually regresses and becomes obliterated at the junction with the ventral pancreatic duct. By the end of the 7th week, the proximal portion of the dorsal pancreatic duct may disappear or persist as the accessory pancreatic duct^[11,12]. Thus, we can make the hypothesis that the ampulla of Vater may be found in the sites along a line extending from the stomach to the fourth part of the duodenum, or in another words, along the end of the foregut. However, other factors may play a role in this process.

It is worth mentioning that MRCP is useful for demonstrating anomalies and anatomic variants of the biliary tract system and pancreatic duct^[13,14]. In our case, MRCP was of great value not only for depicting the ectopic common bile duct and pancreatic duct draining into the fourth part of duodenum but also for depicting the abnormal junction of the cystic duct and intraluminal small bowel lesion. According to Ruge's^[15] categorization, this variation of lower confluence of the cystic duct belongs to type II - the double-barreled type in which the cystic duct follows the hepatic duct for some distance before entering it. In addition to MRCP, gastroscopy should be used to assess the gastric mucosa and other malformations which could possibly exist.

Periampullary carcinoma includes cancer of the terminal end of the common bile duct, the ampulla of Vater and its adjacent duodenum. These lesions are similar to each other in many aspects, such as their clinical manifestations, changes noted by laboratory determinations and approach and technique of surgical excision. The prognosis is much better than for carcinoma of the head of pancreas. Endoscopic ampullectomy may be considered as a viable procedure in patients with small ampullary tumors who are unfit for surgery or who prefer a nonsurgical approach^[16-18]. But in our case, on the account of the ectopic hepatopancreatic ampulla and a likely major periampullary tumor located in the duodenojejunal flexure, endoscopic ampullectomy was unfit. So local excision, combined with frozen section, is a low morbidity and a valid alternative to pancreaticoduodenectomy^[19]. However, a choledochojejunostomy was carried out in order to prevent stricture of the lower end of the common bile duct after operation.

In conclusion, periampullary carcinoma with ectopic ending of the Vater's ampulla in the fourth part of the duodenum is rather rare. Although pathogenesis is not quite clear, accurate diagnosis and appropriate investigations are necessary for surgeons before operation. Use of MRCP is recommended for the diagnosis and

exclusion of associated anomalies of the biliary and pancreatic ducts.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (World J Gastroenterol ISSN 1007-9327, DOI: 10.3748) is a weekly, peer-reviewed, online, open-access (OA) journal supported by an editorial board of 1126 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in *WJG* will include the following. (1) Editorial: to introduce and comment on major advances in rapidly developing areas and their importance. (2) Frontier: to review recent developments and comment on current research status in important fields, and propose directions for future research. (3) Topic Highlight: this column consists of three formats, including: (a) 10 invited review articles on a hot topic; (b) a commentary on common issues associated with this hot topic; and (c) a commentary on the 10 individual articles. (4) Observation: to update the development of old and new questions, highlight unsolved problems, and provide strategies for their resolution. (5) Guidelines for Basic Research: as suggested by the title. (6) Guidelines for Clinical Practice: to provide guidelines for clinical diagnosis and treatment. (7) Review: to review systemically the most representative progress and unsolved problems, comment on current research status, and make suggestions for future work. (8) Original Article: to report original and innovative findings. (9) Brief Articles: to report briefly on novel and innovative findings. (10) Case Report: To report a rare or typical case. (11) Letters to the Editor: to discuss and reply to contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest. (12) Book Reviews: to introduce and comment on quality monographs. (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities on basic research and clinical practice

ISI, Thomson Reuters, 2008 Impact Factor: 2.081 (32/55 Gastroenterology and Hepatology).

Published by

The WJG Press and Baishideng

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments,

References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS AND DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P* < 0.05, ^b*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, ^c*P* < 0.05 and ^d*P* < 0.01 are used. A third series of *P* values can be expressed as ^e*P* < 0.05 and ^f*P* < 0.01. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No.62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Telephone: +86-10-59080039

Fax: +86-10-85381893

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Language evaluation

The language of a manuscript will be graded before it is sent for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

The evidence from recent surveys on chronic pancreatitis carried out around the world shows that alcohol remains the main factor associated with chronic pancreatitis, even if at a frequency lower than that reported previously. It has further confirmed that heavy alcohol consumption and smoking are independent risk factors for chronic pancreatitis. Autoimmune pancreatitis accounts for 2%-4% of all forms of chronic pancreatitis, but this frequency will probably increase over the next few years. The rise in idiopathic chronic pancreatitis, especially in India, represents a black hole in recently published surveys. Despite the progress made so far regarding the possibility of establishing the hereditary forms of chronic pancreatitis and the recognition of autoimmune pancreatitis, it is possible that we are more inaccurate today than in the past in identifying the factors associated with chronic pancreatitis in our patients.

INTRODUCTION

Augusto Murri, Chair of Clinical Medicine at Bologna in 1875 was regarded as one of the most famous Italian physicians and clinical researchers of his time, wrote that "...to know a disease is different from recognizing it; we can recognize a disease only when we know its natural history"^[1]. This concept implies that it is important to know also the etiology of the disease and this is particularly true for chronic pancreatitis.

More than ten years ago, in 1998, Lankisch and Banks^[2] reported that the prevalence of chronic pancreatitis appeared to be in the range of 3-10 per 100000 people in many parts of the world, and underlined that the most important medical problems associated with the disease included abdominal pain, steatorrhea, diabetes mellitus and the possibility that chronic pancreatitis may be considered a premalignant condition^[3,4]. In 2002, Banks^[5] further pointed out that the two most important etiological forms of chronic pancreatitis were alcoholic and tropical.

There is no doubt that, in Western countries, alcohol is the most frequent factor associated with chronic pancreatitis, that alcoholic chronic pancreatitis presents clinically in young adults of 30-40 years of age, with a higher prevalence in males, that the histological lesions are chronic "*ab initio*" and that, from a clinical point of view, the disease is characterized by recurrent attacks of abdominal pain. In Western countries, in the period from 1940 to 2003, the frequency of alcohol as an etiological factor of chronic pancreatitis increased from 19%^[6] to 50%^[7] and even up to 80%^[8,9]. The results of the latter study regarding the etiology of chronic pancreatitis were subsequently confirmed by others in Europe^[10-17] as well as in Brazil^[18], Australia^[19] and South Africa^[20]. On the other hand, four consecutive surveys carried out in Japan (from 1970 to 1977, from 1978 to 1984, in 1994, and in 1999, respectively)^[21] showed that alcohol as an etiological factor accounted for fewer than 60% of chronic pancreatitis cases in this country. The study by Sarles *et al*^[9] reported that India is the most characteristic country in which patients with chronic pancreatitis were mainly malnourished in childhood, had a low fat and low protein diet and were not alcoholics. Thus, this particular form of the disease was named "tropical pancreatitis". Subsequent studies from India and Africa confirmed this finding as was reported in the review article published by Mohan *et al*^[22] in 2003.

THE IMPORTANCE OF THE ETIOLOGY

From a practical point of view, understanding the pathogenesis of chronic pancreatitis may lead to the identification of novel molecular targets and the development of new potential therapeutic agents. Thus, the role of alcohol is the cornerstone of the pathogenesis of chronic pancreatitis, at least in Western countries. Durbec *et al*^[8] clearly demonstrated that alcohol is a risk factor for chronic pancreatitis; in fact, they showed that the relative risk would be multiplied by approximately a factor of 1.4 when passing from one 20-gram intake to the next. Furthermore, the increase appears to be more rapid when passing from the class of non-drinkers to that of 20-g of alcohol intake per day. The mechanism which determines the main manifestation of chronic pancreatitis, i.e. fibrosis of the pancreatic gland, has been well-summarized by Talukdar *et al*^[23]: the oxidation of ethanol to acetaldehyde determines the activation of the pancreatic stellate cells in the quiescent state without any pre-activation; this process generates a state of oxidant stress within the pancreatic stellate cells which subsequently activates the downstream pathways of fibrogenesis. This finding implies that, in the human pancreas, pancreatic stellate cells may be stimulated early during chronic alcohol intake even in the absence of necroinflammation. The importance of oxidative stress in chronic pancreatitis patients has also been reported using breath analysis^[24]. Using a mass spectrometer on breath samples from 31 patients with chronic pancreatitis (mainly alcoholics) and without pancreatic pain as compared to 11 healthy subjects, we found that the volatile compounds H₂S, NO and malononitrile were significantly higher in chronic pancreatitis patients than in healthy subjects^[25]. These substances are the final products of ethanol and oxidative stress and they are able to initiate fibrogenesis of the pancreas. Regarding tropical pancreatitis, several hypotheses have been proposed, in particular, the malnutrition theory, the cassava hypothesis and the oxidant stress hypothesis^[26]. Thus, in this particular form of the disease, it is also possible that there is activation by certain substances in the pancreatic stellate cells.

However, according to this postulated pathogenesis, alcohol seems to induce pancreatic fibrosis as has frequently been found in autopsic series of alcoholics without clinical history of chronic pancreatitis^[25-27].

Furthermore, animal models of alcoholic chronic pancreatitis have not been able to induce pancreatic damage similar to that observed in human chronic pancreatitis; alcohol requires prior sensitization with other agents (viruses, obstruction) in order to produce damage similar to that found in humans.

In summary, alcohol represents a defined risk factor for chronic pancreatitis; it is capable of inducing pancreatic fibrosis by its action on pancreatic stellate cells, but its role in the etiopathogenesis of the disease is still being debated.

NEW ETIOLOGICAL FORMS OF PANCREATITIS

Genetic factors

The possibility of evaluating mutations of the cystic fibrosis transmembrane conductance regulator-gene (*CFTR*-gene)^[28], as well as the identification of mutations of the cationic trypsinogen gene (*protease-serine-1* gene, *PRSS-1*)^[29], the serine protease inhibitor and *Kazal type 1* gene (*SPINK-1*)^[30], has led to a better evaluation of the familial/hereditary forms as well as idiopathic forms of chronic pancreatitis in Western countries. In tropical pancreatitis it has also been noted that this disease has been highly associated with the SPINK-1 N34S mutation^[31,32], whereas the frequency of CFTR mutations was lower than in white subjects^[33]. The PRSS1 mutations appear capable of inducing chronic pancreatitis whereas CFTR and SPINK-1 seem to be “gene modifiers” capable of inducing the disease in the presence of a risk factor such as alcohol^[32,34].

Autoimmune diseases

In 1961, Sarles *et al*^[35] reported the case of a non-drinker suffering from pancreatitis associated with hypergammaglobulinemia. The authors hypothesized that the disease in this patient was an autonomous pancreatic disease of autoimmune origin. After this report, other authors around the world described similar cases. In 1995, Yoshida *et al*^[36] suggested the term “autoimmune pancreatitis” for this disease and, therefore, this term has become largely accepted for pancreatic disease of an autoimmune origin. In the past 10 years, an increasing number of cases have been reported in all countries^[37], and the frequency of autoimmune pancreatitis will probably increase in the next few years.

Changing lifestyle

The impact of changing lifestyle, especially in developing countries, may contribute to modifying the etiology of chronic pancreatitis. For example, alcohol consumption in developing countries may increase^[38] and this could change the etiology of chronic pancreatitis in these countries. On the contrary, in Europe, there was a progressive reduction in alcohol consumption from 1961 to 1991^[39]. Furthermore, taking into account the lifestyle of chronic pancreatitis patients, it has been reported that the pancreatic functional changes caused by alcoholic pancreatitis progress even after cessation of alcohol use, but the progression is slower and less severe when alcohol intake is stopped^[40].

THE FREQUENCY OF CHANGE IN ETIOLOGY

All these new factors and changing lifestyle may contribute to the changing frequencies of the various etiologies of chronic pancreatitis. This is the reason why,

from 2004 to the present, the etiological features of chronic pancreatitis have been reported to be different compared to those in the past. Four studies show examples of this. In Korea^[41], the main etiological factor remains alcohol (64.3%) followed by an unknown etiology (20.8%), obstruction (8.6%) and autoimmune pancreatitis (2.0%). In a recent survey on chronic pancreatitis in the Asian-Pacific region^[42], there was a great variability in the frequency of alcoholic pancreatitis, accounting for about 19% of chronic pancreatitis cases in China to 95% in Australia, whereas tropical pancreatitis was 46.4% in China and, obviously, was not present in Australia. In a recent survey of chronic pancreatitis in Italy^[43], chronic pancreatitis associated with alcohol abuse accounted for less than 50% of cases and this figure is lower than that reported by Gullo *et al*^[10] in 1977. However, some regional differences regarding the frequency of alcoholic chronic pancreatitis exist in Italy. In fact, in Bologna (located in Northern Italy), alcohol as an etiological factor remains high (80.4%)^[44], whereas in Sicily (located in Southern Italy), the percentage of alcoholic chronic pancreatitis is about 60%^[45]. In a survey of chronic pancreatitis in Italy^[43], alcohol as an etiological factor of chronic pancreatitis is followed by obstruction (27%), pancreatitis of unknown origin (17%), autoimmunity (4%) and hereditary/genetic factors (4%). The most surprising results come from India. In a prospective nationwide study in India^[46], the authors found that the majority of patients had pancreatitis of unknown origin (60% of the cases); alcoholic chronic pancreatitis accounted for a third of the cases, whereas tropical pancreatitis was present in only 3.8% of the cases. It seems that alcohol tends to be increasing in frequency in India, as is chronic pancreatitis of unknown etiology. However, the data reported by the Indian researchers (60% were idiopathic forms of chronic pancreatitis) need to be re-evaluated. In this regard, it is worth noting that the frequency of chronic pancreatitis of unknown origin was 17% in the Italian survey^[43] ranging from about 12% in Bologna to 38% in Sicily^[44,45].

CONCLUSION

The evidence from recent surveys on chronic pancreatitis carried out around the world shows that alcohol remains the main factor associated with chronic pancreatitis, even if at a frequency lower than that reported previously. However, it has further confirmed that heavy alcohol consumption and smoking are independent risk factors for chronic pancreatitis^[47].

Autoimmune pancreatitis accounts for 2%-4% of all forms of chronic pancreatitis, but this frequency will probably increase over the next few years. The rise in idiopathic chronic pancreatitis, especially in India, represents a black hole in recently published surveys. Despite the progress made so far regarding the possibility of establishing the hereditary forms of chronic pancreatitis and the recognition of autoimmune pancreatitis, it is possible that we are more inaccurate today than in the past in identifying the factors associated with chronic pancreatitis in our patients.

Abstract

Celiac disease has been associated with some autoimmune disorders. A 40-year-old competitive strongman with celiac disease responded to a gluten-free diet, but developed profound and generalized motor weakness with acetylcholine receptor antibody positive myasthenia gravis, a disorder reported to occur in about 1 in 5000. This possible relationship between myasthenia gravis and celiac disease was further explored in serological studies. Frozen stored serum samples from 23 acetylcholine receptor antibody positive myasthenia gravis patients with no intestinal symptoms were used to screen for celiac disease. Both endomysial and tissue transglutaminase antibodies were examined. One of 23 (or, about 4.3%) was positive for both IgA-endomysial and IgA tissue transglutaminase antibodies. Endoscopic studies subsequently showed duodenal mucosal scalloping and biopsies confirmed the histopathological changes of celiac disease. Celiac disease and myasthenia gravis may occur together more often than is currently appreciated. The presence of motor weakness in celiac disease may be a clue to occult myasthenia gravis, even in the absence of intestinal symptoms.

INTRODUCTION

A range of neurological disorders have been identified in patients suffering from celiac disease^[1]. Occasionally, neurological changes first occur and celiac disease is only recognized later^[2]. Celiac disease is considered an immune-mediated disorder that affects the proximal small intestine and leads to reduced nutrient absorption, diarrhea and weight loss. Treatment with a gluten-free diet is usually sufficient. Marked fatigue and weakness may also occur in many chronic disorders, including celiac disease. However, here, concomitant myasthenia gravis was also discovered^[3].

Serological screening for celiac disease antibodies using stored frozen samples from a serum bank of 23 additional patients with acetylcholine receptor positive myasthenia gravis was also completed. From these banked serum samples, one was discovered with both positive IgA endomysial (EMA) and IgA tissue transglutaminase (tTG) antibodies. Subsequent clinical evaluation, including endoscopic biopsy studies, confirmed the findings of celiac disease.

Although rare and estimated to occur in only about 1 in 5000, myasthenia gravis may occur more frequently than is currently appreciated if celiac disease is also present. Ongoing fatigue and profound muscle weakness in celiac disease may be a clinical clue that this unusual immune-mediated neurological disorder, myasthenia gravis, is present.

CLINICAL CASE STUDY

A 40-year-old male orchidist was initially investigated in 2001 for diarrhea and weight loss of 10 kg with intermittent generalized fatigue. His IgA tTG antibody assay was increased to 89 units (normal, < 20 units). Gastroscopy and colonoscopy were visually normal, but small bowel biopsies showed changes of celiac disease with crypt hyperplastic villus atrophy (i.e. severe "flat" lesion, Marsh 3 lesion). Treatment with a gluten-free diet led to rapid resolution of diarrhea and weight loss. His IgA tTG antibody assay also subsequently normalized completely to 10.2 units.

By July 2003, however, his fatigue was persistent and his weakness became progressive and generalized. Although his physical attributes were well known locally, having previously been placed 6th in an international strongman competition, he stumbled and fell easily with weakness notably exacerbated by exertion. Marked leg fatigue developed, especially while standing on a ladder picking peaches. Once fatigue occurred, he was unable to step up to the next rung on the ladder, holding on with both arms.

While picking peaches, he also noted that he could only lift his arms above shoulder level for 15 min before he could no longer lift his arms. During the previous year, fatigue with chewing also developed along with right eyelid ptosis and diplopia.

Detailed neurological examination showed rapid muscle fatigue on repetitive exercise. Bilateral ptosis with a flattened facial expression, but normal speech function, was noted. Extra-ocular movements were abnormal with progressive eye elevation weakness after 20 to 30 s of sustained upward gaze along with worsening ptosis. Diplopia was also evident. After a minute of voluntary upward gaze, he was unable to elevate his eyes beyond the primary position. Facial muscles were strong. Examination of his upper extremities revealed deltoid fatigue after 10 to 15 repetitive movements, and examination of his lower extremities revealed that 9 stand-ups from a sitting position produced complete fatigue and an inability to stand upright. Reflexes and sensory studies were normal. His Quantitative Myasthenia Gravis (QMG) examination was at 18 (normal, 0; maximum deficit, 39)^[4]. A Mestinon test produced an evident response with return to normal strength. Repeated stimulation confirmed the existence of decrement. Computerized tomography of his chest revealed no evidence of a thymoma. Acetylcholine receptor antibodies were 22.0 nm/L (normal, < 0.1 nm/L). The final diagnosis was acetylcholine-receptor-antibody-positive, generalized myasthenia gravis class IIIb (Osserman classification)^[5].

Subsequent prednisone and Mestinon treatment provided partial improvement in motor weakness. Thymectomy was performed and the resected thymus was noted to be large (10 cm × 9 cm × 2 cm). Microscopic evaluation noted normal thymic tissue with no hyperplasia or evidence of thymoma. Post-operatively, his weakness on exertion persisted and his acetylcholine receptor antibodies increased by November

2004 to 38.4 nmol/L. Over the next 3 years, his symptoms improved with infusions of immunoglobulin along with the addition of mycophenolate mofetil and cyclosporin. His QMG score normalized to 3 with some persistent diplopia and minor facial weakness. This clinical improvement was accompanied by serological improvement with reduced levels of acetylcholine-receptor antibodies to 23 nmol/L.

SPECIAL SEROLOGICAL STUDIES

A total of 23 patients with acetylcholine receptor antibody positive myasthenia gravis were identified through the Neuroimmunology Laboratories in the UBC Brain Research Center (Dr. Joel Oger). Acetylcholine receptor antibodies were measured using a modified radioimmunoprecipitation assay^[6]. Approval to test samples for endomysial antibodies and IgA tissue transglutaminase antibody concentrations was obtained through the Clinical Research Ethics Board at UBC as previously noted^[7,8].

Residual frozen and stored serum samples from this myasthenia serum bank were quantitatively evaluated for IgA EMA and IgA tTG antibodies. IgA EMA was detected using indirect immunofluorescence against human umbilical cord using the method described by Ladinser *et al*^[9], measuring the serum at an initial dilution of 1:5. With this method, positive sera were repeated at increasing dilutions until they became negative. Titers of IgA tTG antibody were measured using an ELISA method based on that reported by Dieterich *et al*^[10] but modified to account for local differences in scientific supplies. During the initial evaluation of this assay, a reference range of up to 140 U/mL (3 SDs above the mean, 99% confidence limits) was calculated from titers on adult intestinal disease controls with normal small intestinal biopsies, and on sera from adults with biopsy-defined celiac disease as previously noted by Gillett and Freeman^[11]. During validation, all IgA-deficient patients were found to have tTG titers of 5 U/mL or lower. For this study, therefore, samples with titers of 5 U/mL or lower were tested for IgA deficiency using NOR-Partigen Total IgA kit (Behring Diagnostics Inc, USA).

RESULTS OF SCREENING

All 23 samples were examined for both IgA EMA and IgA tTG. One sample was EmA positive and tTG quantitation measured 1160 U/mL. All other serum samples were negative for EmA. For tTG quantitation using this assay method, all other serum samples were less than 95 U/mL. The single positive patient, a 16-year-old female, had endoscopic evaluation that revealed mucosal scalloping in the duodenum, consistent with celiac disease. Findings were confirmed on histologic evaluation of small intestinal biopsies and a gluten-free diet was initiated.

DISCUSSION

These studies suggest that myasthenia gravis, an

autoimmune neuromuscular disorder, may occur more often in adult celiac disease than is currently appreciated. In most patients with myasthenia gravis, circulating antibodies are thought to block acetylcholine receptors at the post-synaptic neuromuscular junction, inhibiting stimulatory effects of the neurotransmitter, acetylcholine, causing muscle weakness. Both generalized or localized muscle weakness with fatigue occur, particularly with exertion, but these might conceivably be ascribed to various chronic medical disorders, including celiac disease. In adults with celiac disease, weakness and fatigue could also result from changes in nerves (e.g. peripheral nerve lesion)^[12], or alternatively, skeletal muscle (e.g. rhabdomyolysis, myositis)^[13,14]. Alternatively, nutritional depletion associated with electrolyte alterations such as hypokalemia^[15] or a protein deficiency state such as hypoalbuminemia might be responsible. The present report further emphasizes that myasthenia gravis should also be considered as a specific association with both symptomatic or classical celiac disease as well as subclinical disease initially defined with screening measures.

Myasthenia gravis is uncommon, with estimates of about 1 in 5000 in the United States, while celiac disease has been estimated to occur in about 1 in 200. Although the appearance of these two disorders together could be coincidental, there is now other evidence available to suggest that these two distinct immune-mediated disorders occur together more frequently than is currently appreciated. First, early case reports from Europe recorded myasthenia gravis in celiac disease^[16-18]. Second, similar human leukocyte antigen (HLA) types (B8 and DR3) appear to independently predispose to both myasthenia gravis and celiac disease. Third, other historical serological survey studies with different, but less specific antibodies have been positive. For example, anti-reticulín antibodies (present in celiac disease) were previously recorded in myasthenia gravis^[19]. Finally, acetylcholine receptor antibodies have been recently detected by others in celiac disease^[20]. In the present study, both IgA EMA and IgA tTG antibodies in celiac disease were found in myasthenia gravis patients, while antibodies to acetylcholine receptors were defined in celiac disease before and after gluten-free diet treatment. In this case, seropositive patients were confirmed to have positive intestinal biopsies.

Celiac disease will have to be added to the increasing list of other autoimmune disorders that have been associated with myasthenia gravis, including diabetes mellitus, rheumatoid arthritis, thyroid disease, neuromyelitis optica (post-thymectomy myasthenia gravis)^[21] and multiple sclerosis^[22]. The suspicion of a common mechanism between these diseases is well supported by common HLA haplotypes, co-occurrence in the same families and confirmed by their occurrence in the same patients.

CONCLUSION

In conclusion, these studies suggest that celiac disease and myasthenia gravis may occur together

more frequently than is currently appreciated, in part because clinical changes may be subtle and difficult to recognize. The precise frequency of celiac disease in this local myasthenia population is unknown as serum was collected during the previous decade and additional celiac disease cases may have been subsequently detected. Future antibody screening studies exploring the frequency of celiac disease in myasthenia gravis, and *vice versa*, as well as their relatives remains to be elucidated.

Abstract

AIM: To establish the roles of lipopolysaccharide (LPS)/CD14/toll-like receptor 4 (TLR4)-mediated inflammation in a rat model of human necrotizing enterocolitis (NEC).

METHODS: Six pairs of intestinal samples from human NEC were collected before and after recovery for histological and molecular analysis of inflammatory cytokines and signaling components. In the rat NEC model, we isolated 10-cm jejunum segments and divided them into six groups ($n = 6$) for sham operation, treatment with LPS, bowel distension, combined bowel distension and LPS stimulation, and two therapeutic groups. The potential efficacy of a recombinant CD18 peptide and a monoclonal CD14 antibody was evaluated in the latter two groups. The serum and tissue levels of several inflammatory mediators were quantified by real-time polymerase chain reaction, ELISA and immunoblotting.

RESULTS: Human acute phase NEC tissues displayed significant increases ($P < 0.05$) in levels of TLR4, CD14, myeloid differentiation protein (MD)-2, tumor necrosis factor (TNF)- α and nuclear factor- κ B when

compared to those after recovery. The histological and inflammatory picture of human NEC was reproduced in rats that were treated with combined bowel distension and LPS, but not in the sham-operated and other control rats. Serum levels of interleukin-6 and TNF- α were also elevated. The NEC pathology was attenuated by treating the NEC rats with a monoclonal CD14 antibody or an LPS-neutralizing peptide.

CONCLUSION: LPS and distension are required to produce the histological and inflammatory features of NEC. A potential treatment option is blocking LPS activation and leukocyte infiltration.

INTRODUCTION

Necrotizing enterocolitis (NEC) is a common gastrointestinal disorder in newborn and premature infants with a relatively high mortality rate (approximately 30%), and requires emergency medical treatment^[1]. While the molecular pathogenesis of neonatal NEC is multifactorial and remains to be elucidated fully, its known risk factors include prematurity and low birth weight^[1,2]. Ballance *et al*^[3] have reviewed pathology specimens from a cohort of 84 neonatal NEC patients, and have reported that the most consistent features of

the disease are ischemic necrosis, inflammation, and bacterial overgrowth. Since neonatal NEC does not develop *in utero* in the sterile gut, bacterial contamination and/or microbial involvement have been implicated in its pathogenesis^[4]. Furthermore, > 90% of preterm infants who develop NEC have received enteral feeds^[5], and there is an increased risk of NEC when these infants are overfed frequently^[6-9]. This could result in intestinal injury because of impaired digestion of nutrients, delayed transit time and bacterial overgrowth^[10].

Based on these recent findings, we believe that there is a connection between host immunity and pathogenesis of NEC, and the toll-like receptor (TLR)-mediated immunity apparently plays an important role. TLRs are evolutionarily conserved transmembrane molecules that help the immune system to recognize pathogen-associated molecular patterns, and TLR4 sensitizes immune cells to bacterial lipopolysaccharide (LPS). When stimulated by bacterial LPS, many intracellular signaling pathways are activated, and lead to the generation of nuclear factor (NF)- κ B, which in turn promotes pro-inflammatory cytokine production and release^[11]. Caplan *et al*^[12] have reported upregulation of MD-2, one of the bacterial LPS co-receptors, in patients with NEC.

In overfed or food-intolerant neonates, bowel loops can become distended and filled with milk, and this creates a good nutritive medium for bacterial growth and colonization. We hypothesized that bacterial LPS or endotoxin from cultured bacteria can trigger inflammation in NEC. In order to validate this hypothesis, we studied the TLR4-mediated signaling in the jejunal tissue from a rat model of human NEC, and then used the findings to design novel therapeutic agents for use in neonatal patients with NEC. In this model, we ligated the jejunum, and distended the ligated jejunum with bacterial LPS in order to induce the inflammatory reaction of NEC.

MATERIALS AND METHODS

Human tissues

Necrotic NEC intestinal tissues were collected from six human infants (two girls and four boys) with stage 3 NEC, who underwent curative surgery at Queen Mary Hospital, Hong Kong. The mean gestational age of these NEC patients was 30 wk (range: 25-32 wk), and their mean birth weight was 1.51 kg (range: 0.57-2.51 kg). NEC was diagnosed between 2 and 32 d after birth (mean: 17 d). For comparison, intestinal tissues were collected during the recovery phase at the time of ileostomy closure. After surgical resection, each intestinal tissue sample was divided into two: one was snap-frozen in liquid nitrogen for determination of mRNA/protein levels, and the other was fixed in 10% buffered formalin for histological examination.

Reagents

Bacterial LPS from *Salmonella typhimurium* was purchased from Sigma (St. Louis, MO, USA), and was used to prepare a 5 μ g/mL LPS solution with endotoxin-free

saline^[13]. A polyclonal antibody for use as an antagonist against the CD14 antigen (M-20) was purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). The LPS-neutralizing peptide was prepared using our established procedures^[14,15]. The protein content in each solution was determined using Lowry's method^[16].

Animals

One-month old Sprague-Dawley rats were obtained from the Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC)-accredited Laboratory Animal Unit of the University of Hong Kong (Pokfulam, Hong Kong). The rats were maintained in a pathogen-free facility with a 12-h light/dark cycle at ambient temperature and in a controlled humidity environment. The rats had *ad libitum* access to sterilized animal chow and water. All experimental procedures were reviewed, approved, and conducted in accordance with the ethical guidelines set forth by the University's Committee on Using Live Animals for Teaching and Research.

Experimental NEC model

The rat model of human NEC was modified from our published model^[17]. Before surgery, rats were fasted overnight, and anesthetized by intraperitoneal injection of sodium pentobarbital (40 mg/kg body weight). Once anesthetized, the abdomen was opened by a midline incision, and a 10-cm segment of the most proximal jejunum was isolated with its vascular pedicle intact. One end of the segment was closed by ligation. An 18-G angiocatheter was inserted and fixed to the other end. The angiocatheter was connected to an infusion set whose height was 100 cm above the operating table.

Each control and experimental group comprised six animals. For the sham-operated control rats, the angiocatheters were closed for 3 h using a plug. For the rats treated with LPS alone, 2 mL of 5 μ g/mL LPS solution was injected directly into the jejunal segment. To increase intraluminal bowel pressure, the jejunal segment was distended with sterile saline at a pressure of 100 cm H₂O for 3 h in four groups of rats. In two groups, the bowel was distended with sterile saline alone or combined with 5 μ g/mL LPS. In the remaining two groups, the bowel was distended in an identical manner, and contained 5 μ g/mL bacterial LPS and 0.8 μ g/mL CD14 antibody or 0.8 μ g/mL CD18 peptide, which has LPS-neutralizing capacity. After 3 h bowel distension, the animals were killed humanely by an overdose of sodium pentobarbital (100 mg/kg). Formalin-fixed and snap-frozen jejunal tissues were prepared for histological examination and determination of mRNA/protein levels, respectively. Blood was also collected from the inferior vena cava of all rats for serum/plasma preparation, and stored at -70°C until use.

Assessment of NEC severity

Sections (4 μ m thick) of the harvested jejunal tissues were prepared for hematoxylin and eosin (HE) staining and immunohistochemistry^[18,19]. The severity of NEC

was scored histologically on the appearance of the intestine, using a modification of the method that was described by Caplan *et al.*^[20]: 0, normal intestine; 1, mild hemorrhage; 2, moderate hemorrhage and necrosis; 3, severe hemorrhagic necrotic lesions with or without pneumatosis. The degree of macrophage infiltration was determined following overnight incubation at 4°C with a macrophage staining reagent (Dako, Glostrup, Denmark). The resulting images were reviewed with a Nikon epifluorescent upright microscope E600 (Nikon, Tokyo, Japan), and captured with 3-CCD color camera DC-330 (DAGE-MTI, Michigan City, IN, USA).

Real-time polymerase chain reaction (PCR)

Real-time PCR was employed to determine the relative expression levels of CD14, TLR4 and MD-2 mRNA in human and rat jejunal tissues. First-strand cDNA was synthesized from extracted RNA from jejunal tissue^[20], and amplifications were done using the Power SYBR Green PCR Master Mix (Invitrogen, Carlsbad, CA, USA) in an ABI PRISM 7700 sequence detector system (Applied Biosystems, Foster City, CA, USA)^[21]. Normalization and comparison of mRNA transcript levels between the groups were then performed, as described previously^[22].

Immunoblotting of NF- κ B p65 and tumor necrosis factor (TNF)- α in the intestine of NEC patients

The nuclear levels of NF- κ B p65 and TNF- α in the jejunal tissue of NEC patients were detected by antibody against NF- κ B p65 (Invitrogen) and TNF- α (Santa Cruz Biotechnology), as described previously^[15].

Determination of serum pro-inflammatory cytokine levels

Serum TNF- α and interleukin (IL)-6 levels in the control, sham-operated, and treated rats were determined using commercially available ELISA kits that were purchased from Dakewe (Shenzhen, China) and eBioscience (San Diego, CA, USA), respectively, in accordance with the manufacturer's instructions.

Statistical analysis

Statistical analyses of the experimental data were performed using GraphPad Prism (version 4.0, GraphPad Software Inc, San Diego, CA, USA). Statistical significance was set at 5%, and data are presented as mean \pm SD.

RESULTS

Human NEC intestinal histology and inflammatory pathology

Serial samples of intestinal tissue from the acute and recovery phases of NEC were collected, prepared, and scored. Intestinal tissue from the acute-phase in which severe coagulative necrosis was observed histologically was given a score of 3 (Figure 1A). The appearance of the intestinal tissues from the recovery phase was normal, and given a score of 0. The extent of

macrophage infiltration in acute-phase intestinal tissues was greater than that in the recovery-phase tissues. To determine the potential causal immunological factors, we studied the expression of key signaling components that are mediated by LPS activation. The protein levels of NF- κ B p65 and TNF- α (Figure 1B) in acute-phase intestinal tissues were significantly higher than those in recovery-phase tissues. Furthermore, the gene transcript levels of CD14 and MD-2 (Figure 1C) were significantly increased in the acute-phase tissues, when compared to those in recovery-phase tissues. The TLR4 mRNA level was also higher in the acute-phase tissues than in the recovery-phase tissues, but this increase was not significant statistically.

Molecular pathogenesis of experimental NEC

Rat jejunal histology: Compared to the sham-operated control specimens (Figure 2A), there was no apparent histological damage (score 0) in jejunal loops that were treated with LPS alone (Figure 2B) or distended with normal saline (Figure 2C). We observed histological changes (Figure 2D) (score 2), such as sloughing of the villi and vascular congestion in jejunal specimens from rats that were treated with a combination of saline distension and bacterial LPS. Although the changes were less severe, they did resemble those that were observed in acute-phase intestinal specimens from NEC patients, and were associated with substantial macrophage infiltration (Figure 3A-D).

Jejunal distension requires bacterial LPS to trigger inflammatory reactions: To determine whether the inflammatory responses could be induced in the experimental NEC model, we assessed the key LPS-mediated signaling components or reporters (CD14, TLR4, MD-2, TNF- α and IL-6) at the transcript or protein level in the jejunal segments and plasma from each experimental group. The results were consistent with the histological findings. Combination treatment of intestinal distension and bacterial LPS jejunal injection significantly raised the level of CD14, TLR4 and MD-2 mRNA ($P < 0.05$) when compared to those in saline-distended jejunal tissues, those following jejunal distension alone and LPS jejunal injection alone, or those from the sham-operated controls (Figure 4). We then measured the systemic cytokine responses in the experimental NEC animals by ELISA. The serum TNF- α and IL-6 levels in the combined distension + LPS group were 3-4 times higher than those of the other single treatment groups (distension or LPS jejunal injection alone) and the sham-operated control rats (Figure 5A and B).

Therapeutic potential of CD14/CD18 blockage in NEC inflammatory response

We tested the therapeutic efficacy of CD14 or CD18 blockade in the established rat NEC model by using a CD14-neutralizing monoclonal antibody (M-20) as an antagonist, and a novel LPS-neutralizing peptide, CD18 β A peptide, which have been shown to neutralize the biological activity of endotoxin. Treatment with M-20

Figure 1 Pathological features of human necrotizing enterocolitis (NEC). A: Representative micrographs that show the microarchitecture of (upper panel), and the extent of macrophage infiltration (as marked by arrow) (lower panel) in jejunal tissues from NEC patients, which were collected in the acute phase and during recovery. Magnification $\times 200$; B: Immunoblotting showed overexpression of TNF- α and upregulated nuclear content of the p65 subunit of NF- κ B in jejunal tissues from NEC patients in the acute phase. Nuclear histone level was used as the loading control; C: Real-time PCR detected the mRNA transcript levels of CD14, TLR4 and MD-2 in jejunal tissues from NEC patients in the acute phase and during recovery. Statistical significance was determined by Student's *t* test, and all data are presented as the mean \pm SD of triplicate samples from two independent experiments.

(Figure 2E) or LPS-neutralizing peptide (Figure 2F) restored the jejunal microarchitecture to near normal (score 0), and attenuated the increased extent of macrophage infiltration in those loops that was distended with LPS-containing saline, and contained either an antibody against CD 14 (Figure 3E) or LPS-neutralizing peptide (Figure 3F). This was a sharp contrast to the jejunal distension that was caused by LPS-containing saline (Figures 2D and 3D), which caused marked histological changes such as villous sloughing and destruction. These histological changes were accompanied by concomitant changes in the expression levels of CD14, MD-2 and TLR4 mRNA (Figure 4), and the serum levels of TNF- α and IL-6 (Figure 5).

DISCUSSION

We investigated the role of innate immunity in the

pathogenesis of NEC by examining the LPS/CD14/TLR4-mediated inflammatory response in jejunal tissues from premature neonates with NEC. Using our recently established rat NEC model, we demonstrated that disease development requires intestinal bowel distension and bacterial LPS stimulation. In the human NEC tissues, increases in NF- κ B p65 and TNF- α and mRNA for CD14, TLR4 and MD-2 were found. All these signaling-cascade increases were also noted in the intestine of the rat NEC model, with a parallel increase in serum TNF α and IL-6. Histologically, changes in the LPS-distended rat bowel and human NEC tissue were similar. Furthermore, we showed in this model that the consequent pro-inflammatory reactions could be suppressed or modulated by blocking endotoxin activity using a monoclonal CD14 antibody, and a CD18 β A peptide that neutralizes LPS binding and inhibits leukocyte infiltration into inflamed tissues. From these

Figure 2 Histological features of rat jejunum. The severity of damage in the jejunum of rats from the different treatment groups was assessed histologically after HE staining. A: Sham-operated controls; B: LPS jejunal injection; C: Saline jejunal distension; D: Saline jejunal distension and LPS jejunal injection; E: Saline jejunal distension and LPS jejunal injection, and CD14 antibody treatment; F: Saline jejunal distension and LPS jejunal injection, and LPS-neutralizing peptide treatment. Only in (D) did the jejunal tissue show histological changes with a score of 2 for NEC (sloughing of villi and vascular congestion). Magnification $\times 200$.

Figure 3 Macrophage infiltration into the rat jejunum. The extent of macrophage infiltration into the jejunum of rats from the different treatment groups was evaluated by immunohistochemistry using a macrophage staining reagent. Stained macrophages are marked by arrows. A: Sham-operated control; B: LPS jejunal injection; C: Saline jejunal distension; D: Saline jejunal distension and LPS jejunal injection; E: Saline jejunal distension and LPS jejunal injection, and CD14 antibody treatment; F: Saline jejunal distension and LPS jejunal injection, and LPS-neutralizing peptide treatment. Magnification $\times 200$.

results, we concluded that each molecule may have therapeutic potential for treating infants with NEC.

The essential role of the innate TLR4 immunity has been reported in a recent study in which TLR4-

Figure 4 CD14, TLR4 and MD-2 mRNA expression in rat jejunum. Real-time PCR detected mRNA transcript levels for CD14, TLR4 and MD-2 in the jejunum of rats from the different treatment groups. Distension of jejunum with LPS-containing saline upregulated the expression of all studied transcripts, and these upregulated levels were attenuated by CD14 antibody and LPS-neutralizing peptide treatments. There were six rats in each experimental group. Data are displayed as the mean \pm SD, and analyzed statistically by one-way ANOVA. $^aP = 0.00126$; $^bP = 0.00498$; $^cP = 0.00838$; $^dP = 0.0127$; $^eP = 0.0151$; $^fP = 0.0187$.

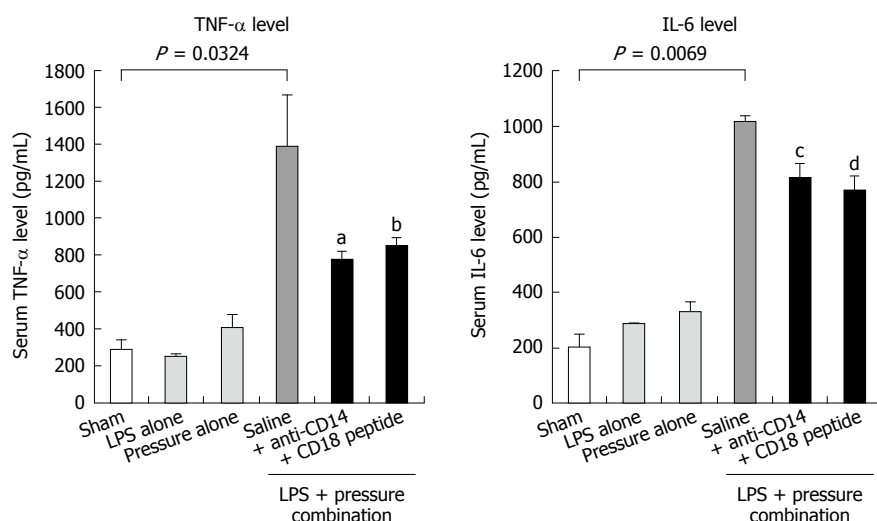

Figure 5 Serum TNF- α and IL-6 levels in NEC rats. Serum TNF- α and IL-6 levels in all NEC rats were measured by commercial ELISA kits. Distension of jejunum with LPS-containing saline significantly increased serum TNF- α and IL-6 levels, and these increases were suppressed when CD14 antibody and LPS-neutralizing peptide were added to the saline. There were six rats in each experimental group. Data are displayed as the mean \pm SD, and analyzed statistically by one-way ANOVA. $^aP = 0.0237$; $^bP = 0.0259$; $^cP = 0.0819$; $^dP = 0.0477$.

mutant C3H/HeJ mice were protected from developing NEC^[23]. The findings in our study support this essential role. We demonstrated that the activity of the TLR4 signaling pathway was upregulated in intestinal tissues from premature neonates with NEC. Given that TLR4 is the major receptor for bacterial LPS on immune and some epithelial cells, as well as endothelial cells, we examined whether activation of the TLR4 signaling pathway occurred in the intestine of rats with experimentally induced NEC. In this model, we injected or infused bacterial LPS into a jejunal segment because the jejunum, unlike the ileum and colon, is less likely to be contaminated by resident bacteria. By choosing this segment, we assumed that we would have better control over the bacterial LPS concentration in our investigation. We studied also the effect of bowel distension on the pathogenesis of NEC, because intestinal distension as a result of overfeeding is one of the many risk factors for NEC.

One-month-old rats were chosen for the study because, in our previous study^[17], the typical NEC histological pictures in the intestine could be seen when the correct distension pressure and bacterial

concentration were used. Further, these rats are more stable and can avoid changes caused by operative risks such as hypotension and hypothermia. NEC also occurs in full-term and older infants, and these infants have been found to have higher congenital heart diseases that also can cause hypoxia^[24].

Our data showed that bowel distension with saline or LPS injection alone could not induce significant inflammatory responses in rat jejunal segments. In contrast, bowel distension with saline that contained bacterial LPS induced substantial release of TNF- α and IL-6 into the serum, and increased the expressions of the LPS receptor and co-receptor mRNAs, and the extent of leukocyte infiltration into the jejunal mucosa. These findings suggest that bowel distension in overfed premature neonates is capable of potentiating LPS action on innate TLR4 immunity. The underlying mechanism by which bowel distension potentiates the action of LPS was not studied here. However, we believe that bowel distension injures the intestinal mucosa, and exposes the enterocytes to bacterial LPS. The hypoxic environment that is induced by bowel distension might also participate in this process by upregulating TNF- α

production from inflammatory macrophages^[24].

Perhaps more importantly, our results identified a monoclonal CD14 neutralizing antibody and an LPS-neutralizing peptide as potential therapeutic agents for use in NEC. We showed that both molecules could suppress the inflammatory response that was induced by bowel distension and bacterial LPS. This provides additional evidence for the critical role of innate TLR4 immunity in the pathogenesis of NEC. Moreover, our findings suggest that antagonism against members of the LPS signaling pathway could be beneficial therapeutically in the treatment of NEC. Given that the current management of premature neonates with NEC is still challenging, our novel molecules for treating NEC are of potential therapeutic importance.

In conclusion, our results suggest that bowel distension from overfeeding in premature neonates damages the intestinal mucosa. This resultant injury potentiates the action of bacterial LPS on enterocytes and resident immune cells, and triggers an immunological cascade that results in the development of NEC. In addition, we have shown that antagonistic molecules that target key members of this cascade can be used as potential therapeutic agents for treating infants with NEC.

COMMENTS

Background

Neonatal necrotizing enterocolitis (NEC) is a disease that affects mainly premature babies and its mortality and morbidity remain high. The pathogenesis of the disease is still not known and preventive measures have not been agreed upon. Its treatment is still difficult.

Research frontiers

Bacteria are required for the development of NEC. Since there are no bacteria *in utero*, there is no NEC in fetuses. At present, there is no single bacterium that has been identified to cause NEC. Many clinical studies have shown that premature babies with overfeeding or feed intolerance have a higher incidence of NEC. However, the mechanism by which feeding problems cause NEC is still unknown.

Innovations and breakthroughs

In many other studies, it has been shown that, in NEC tissue and patient serum, there is a marked increase in the pro-inflammatory cytokine profile, although again, the cause is unknown. In the present study, human NEC tissue showed increased levels of nuclear factor (NF)- κ B p65, tumor necrosis factor (TNF)- α , and CD14, toll-like receptor 4 (TLR4) and myeloid differentiation protein (MD)-2 mRNA. Bowel distension is common in overfed and feed-intolerant babies. In the present rat model used to mimic this condition, the intestine distended with lipopolysaccharide (LPS) showed increased mRNA for CD14, TLR4 and MD-2. Also, the rat serum showed raised TNF- α and IL6. Furthermore, the intestinal tissue in the rat after distension with LPS showed the typical features of NEC with villous sloughing and vascular congestion. These changes could be suppressed by blocking the endotoxin activity using a monoclonal CD14 antibody or a CD18 peptide that neutralized LPS binding and thus inhibited leukocyte infiltration into the inflamed tissue.

Applications

This study provides evidence that NEC can be caused by bowel distension with bacterial LPS, which is common in overfeeding and feed intolerance. The

process can be prevented by applying a carefully controlled feeding regimen to premature babies. Early detection and stoppage of feeding in the feed-intolerant babies can prevent the activation of the cytokine cascade pathway of the LPS and TLR4. In babies who have developed NEC, anti-CD14 antibody and CD18 neutralizing peptide can be a potential strategy to block the LPS activation pathway and prevention of leukocyte infiltration.

Terminology

TLRs are transmembrane molecules that help the immune system to recognize pathogens, and TLR4 is among the one that sensitizes immune cells to bacterial LPS. When stimulated by bacterial LPS, many intracellular signaling pathways are activated and lead to the generation of a cascade of pro-inflammatory cytokine production and release.

Peer review

It should be emphasized that this rat model of NEC resembles the phenotype of human NEC. Therefore, further studies may be needed to prove whether there is a correlation between the pathogenesis and possible treatment in the rat and human models.

Abstract

AIM: To investigate the role of emodin in protecting the liver against fibrogenesis caused by carbon tetrachloride (CCl₄) in rats and to further explore the underlying mechanisms.

METHODS: Rat models of experimental hepatic fibrosis were established by injection with CCl₄; the treated rats received emodin *via* oral administration at a dosage of 20 mg/kg twice a week at the same time. Rats injected with olive oil served as a normal group. Histopathological changes were observed by hematoxylin and eosin staining. The activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) in serum and hepatic hydroxyproline content were assayed by biochemical analyses. The mRNA and protein relevant to hepatic stellate cell (HSC) activation in the liver were assessed using real-time reverse transcription-polymerase chain reaction (RT-PCR), immunohistochemistry, western blotting and enzyme-linked immunosorbent assay.

RESULTS: The degree of hepatic fibrosis increased markedly in the CCl₄ group compared to the normal group ($P < 0.01$), and decreased markedly in the emodin group compared to the CCl₄ group according to METAVIR scale ($P < 0.01$) compared with those in the normal control group (51.02 ± 10.64 IU/L and 132.28 ± 18.14 IU/L). The activities of serum ALT and AST were significantly higher in rats injected with CCl₄ (289.25 ± 68.84 IU/L and 423.89 ± 35.67 IU/L, both $P < 0.05$). The activities of serum ALT and AST were significantly reduced by administration of emodin (176.34 ± 47.29 IU/L and 226.1 ± 44.52 IU/L, both $P < 0.05$). Compared with the normal controls (54.53 ± 13.46 mg/g), hepatic hydroxyproline content was significantly higher in rats injected with CCl₄ (120.27 ± 28.47 mg/g, $P < 0.05$). Hepatic hydroxyproline content was significantly reduced in the rats treated with emodin at 20 mg/kg (71.25 ± 17.02 mg/g, $P < 0.05$). Emodin significantly protected the liver from injury by reducing serum AST and ALT activities and reducing hepatic hydroxyproline content. The mRNA levels of transforming growth factor- β 1 (TGF- β 1), Smad4 and α -SMA in liver tissues were significantly down-regulated in SD rats that received emodin treatment. Furthermore, significant down-regulation of serum TGF- β 1 protein levels and protein expression of Smad4 and α -SMA in liver tissues was also observed in the rats. Emodin inhibited HSC activation by reducing the abundance of TGF- β 1 and Smad4.

CONCLUSION: Emodin protects the rat liver from CCl₄-induced fibrogenesis by inhibiting HSC activation. Emodin might be a therapeutic antifibrotic agent for the treatment of hepatic fibrosis.

INTRODUCTION

Hepatic fibrosis occurs in advanced liver disease, where normal hepatic tissue is replaced with collagen-rich extracellular matrix (ECM) and, if left untreated, results in cirrhosis. Several studies have shown that hepatic fibrosis is a reversible disease, therefore an effective treatment would probably prevent or reverse the fibrotic process in the liver^[1,2]. Transforming growth factor β 1 (TGF- β 1) is one of the strongest profibrotic cytokines^[3,4], and TGF- β 1/Smad signaling is the cardinal signal transduction pathway involved in fibrosis which has been verified by several related studies^[5]. The down regulation of TGF- β 1 expression and modulation of TGF- β /Smad signaling may be effective in preventing liver fibrosis^[6].

In the last decade, advances in the understanding of genes promoting hepatic stellate cell (HSC) activation are impressive^[7]. However, there are few breakthroughs in therapeutic intervention of hepatic fibrogenesis. Efficient and well-tolerated antifibrotic drugs are lacking and current treatment of hepatic fibrosis is limited to withdrawal of the noxious agent^[8]. Therefore, research identifying innocuous antifibrotic agents is of high priority and urgently needed.

Emodin (1,3,8-trihydroxy-6-methylantraquinone), isolated from the rhizome of the Giant Knotweed Rhizome, has been used for centuries in Asia as a treatment for inflammation, gastrointestinal, pulmonary, and liver disorders. Emodin is regarded as the most active constituent in Giant Knotweed Rhizome and exerts many potent biological effects^[9,10], such as anticancer^[11], antimicrobial^[12], and anti-inflammatory effects^[13]. Several studies have revealed that emodin is efficacious in the management of hepatic fibrosis^[14,15]. However, the mechanisms underlying remain to be elucidated.

The current study evaluates the *in vivo* role of emodin in the protection of the liver from fibrogenesis caused by carbon tetrachloride (CCl₄) in a rat model and further explores the underlying mechanisms. We hypothesize that emodin might protect the liver from CCl₄-induced fibrogenesis by inhibiting activation of HSC *via* modulating TGF- β 1/Smad signaling pathways. Results in this study support our hypothesis and provide novel insight into the mechanisms of emodin in the protection of the liver.

MATERIALS AND METHODS

Animals

This study was approved by the Animal Care and Use Committee of Qiqihar Medical University. A total of 50 pathogen-free male Sprague-Dawley (SD) rats (weight range: 200-240 g) were employed in the study. The animals were obtained from the Beijing Vital River

Experimental Animals Technology (Beijing, China), and were housed in sterile cages under laminar airflow hoods in a specific pathogen-free room with a 12 h light and 12 h dark schedule and fed autoclaved chow and water *ad libitum*. The animals were weighed every 7 d for the adjustment of the CCl₄ and emodin doses. Emodin were purchased from Xi'an Sino-Herb Bio-Technology CO., LTD (Purity: 98% by HPLC).

Establishment of a rat model with hepatic fibrogenesis caused by CCl₄

The rat model was established using the method originally described by Proctor *et al*^[16] and since used by many others^[17], with minor modifications. Fifty male SD rats were randomly divided into three groups: the normal control ($n = 10$) in which rats were not administered CCl₄ or emodin, but they were injected with olive oil and orally given sodium carboxymethylcellulose (CMC); the CCl₄ group ($n = 20$) in which rats were subcutaneously injected with CCl₄, without emodin treatment; the emodin group in which rats were injected with CCl₄ and treated with emodin at 20 mg/kg. Rats from the emodin group and the CCl₄ group were subcutaneously injected with a mixture of 40% CCl₄ (a mixture of pure CCl₄ and sterile olive oil) at 200 μ L/100 g body weight twice weekly for 12 wk. Emodin was dissolved in 0.5% sodium CMC and given once daily by gavage at 20 mg/kg. The rats in the normal group were similarly handled, including subcutaneous injections with the same volume of olive oil and oral administration of the same volume of CMC without emodin. At the end of the experiment, the survivors in the normal group, CCl₄ group and emodin group were 10/10, 9/20 and 11/20, respectively.

Forty-eight hours after the last CCl₄ injection, rats were sacrificed after being anesthetized by i.p. pentobarbital (50 mg/kg). A small portion of the liver was removed for hematoxylin and eosin (HE) staining and immunohistochemistry (IHC) studies by fixation with 10% formalin. The remaining liver was cut in pieces and rapidly frozen with liquid nitrogen for extraction of total RNA and protein. Blood was collected directly from the rats when they were sacrificed. Serum was separated by centrifugation within 1 h of blood collection and stored at -20°C until analyzed.

Light microscopy

Midsections of the liver lobe a few mm thick were taken from each rat and processed for observation by light microscopy. The process involved fixing the tissue specimen in 10% neutral buffered formalin solution, preparing the block in paraffin, cutting into 5-6 μ m thick sections, and staining the sections with HE. The sections were scanned and analyzed by a pathologist who was blinded to the different treatments in the experiment.

The histological changes were measured on HE stained sections. Lobular inflammatory activity and severity of liver steatosis were determined according to the criteria of the Chinese Medical Association Committee of Fatty Liver Disease in 2006 and Nouchi *et al*^[18,19]. Steatosis was

graded on the basis of the extent of parenchyma involved as Grade 0, no hepatocytes were involved; Grade 1, < 30% of hepatocytes were involved; Grade 2, 30% to 50% of hepatocytes were involved; Grade 3, 51% to 75% of hepatocytes were involved; Grade 4, > 75% of hepatocytes were involved. Inflammation was graded as Grade 1, focal collections of mononuclear inflammatory cells; Grade 2, diffuse infiltrates of mononuclear inflammatory cells; Grade 3, focal collections of polymorphonuclear cells in addition to mononuclear cell infiltrates; and Grade 4, diffuse infiltrates of polymorphonuclear cells in the parenchymal area or lobular area. The stage of liver fibrosis was graded with the METAVIR scale^[20], which grades fibrosis on a five-point scale: Grade 0, no fibrosis; Grade 1, portal fibrosis without septa; Grade 2, portal fibrosis with a few septa; Grade 3, numerous septa without cirrhosis; and Grade 4, cirrhosis.

Biochemical parameters

Activities of alanine transaminase (ALT) and aspartate aminotransferase (AST) in serum were measured by routine laboratory methods using a 7170-automatic biochemistry analyzer (Tokyo, Japan).

Determination of the hepatic hydroxyproline content

The hydroxyproline kit was purchased from Nanjing Jiancheng Bioengineering Research Institute (Nanjing, China). The content of hepatic hydroxyproline was determined by using the hydroxyproline kit following the protocol provided by the manufacturer. Results were expressed as micrograms of hydroxyproline per gram of hepatic tissue.

Enzyme-linked immunosorbent assay (ELISA)

The TGF- β 1 ELISA kit was obtained from Boster Biotechnology Co. Ltd. (Wuhan, China). The levels of TGF- β 1 in serum were determined by using the TGF- β 1 ELISA kit according to the manufacturer's protocol. In brief, 100 μ L of a serum sample was added to each well of the plate, followed by incubation for 2 h at 37°C. A Working Detector (100 μ L; Boster Biotechnology Co. Ltd) was loaded into each well, and the plate was incubated for an additional 1 h at room temperature (RT) before the addition of substrate solution (100 μ L; Boster Biotechnology Co. Ltd). The reaction was stopped by adding stop solution (1 drop; Boster Biotechnology Co. Ltd). The absorbance was read at 492 nm using a Microplate reader (LabSystems Multiskan Ascent 354, Finland). Calculation of the concentrations of TGF- β 1 was performed in a log-log linear regression according to the instructions in the protocol.

IHC analysis

Liver tissues were fixed in 10% neutral buffered formalin solution, embedded in paraffin, and stained for routine histology. The sections were incubated at 4°C overnight with primary antibody (Boster Biotechnology, Wuhan, China) in concentrations of 1:100 (Smad4) and 1:200 (α -SMA). As a secondary antibody, horseradish peroxidase-conjugated immunoglobulin G (Boster

Biotechnology), was used for 30 min at 37°C. After further washing with Tris-buffered saline, sections were incubated with complex/horseradish peroxidase (1:200 dilution) for 30 min at 37°C. Immunolocalization was performed by immersion in 0.05% 3,3'-diaminobenzidine tetrahydrochloride as chromagen. Slides were counter-stained with hematoxylin before dehydration and mounting. Incubation without the primary antibody was performed as a control for the background staining. Histological evaluation was performed by a pathologist who was blind to the pharmacological characteristics of the drugs.

RNA isolation and real-time reverse transcription polymerase chain reaction (RT-PCR)

Total RNA was extracted from 100 mg of frozen liver tissues using RNAiso Reagent kit (Takara Biotechnology, Dalian, China) according to the protocol provided by the manufacturer. cDNA was synthesized with SYBR ExScript™ RT-PCR kit (Takara Biotechnology, Dalian, China) according to the protocol provided by the manufacturer. Reverse transcription was carried out as follows: 42°C for 15 min, 95°C for 2 min (one cycle). cDNA was stored at -20°C for PCR. Real-time PCR was performed in 50 μ L of reaction solution containing 2 \times SYBR Premix Ex Taq polymerase, deoxynucleoside triphosphates, ROX Reverence Dye and the corresponding primers. The cycles for PCR were as follows: 1 cycle of 95°C for 10 s, 40 cycles of 5 s at 95°C, 5 s at 60°C, 31 s at 60°C and a final 7 min at 72°C. Melting curve analysis was always included to validate the specificity of the PCR products. Serial cDNA dilution curves were produced to calculate the amplification efficiency for all genes. A graph of threshold cycle (Ct) versus log 10 relative copy number of the sample from a dilution series was produced. The slope of the curve was used to determine the amplification efficiency. Reactions were performed in an ABI7300 Real-time PCR system (Applied Biosystems, CA) and threshold cycle (Ct) data were collected using the Sequence Detection Software version 1.2.3 (Applied Biosystems, CA). GAPDH was used as an internal control. mRNA -fold change relative to GAPDH was calculated with the comparative Ct method of $2^{-\Delta\Delta C_t}$ ^[21]. The following primers were used. 5'-GACAACTTTGGCATCGTGGA-3' (sense) and 5'-ATGCAGGGATGATGTTCTGG-3' (antisense) for the GAPDH gene; 5'-CCTGATGCTTCACTGTTCTGCAA-3' (sense) and 5'-CAACTGCACGGTTTCCGTTATTC-3' (antisense) for the Smad4 gene; 5'-TATAGCAACAATTCCTGGCG-3' (sense) and 5'-TGCTGTACAGGAGCAGTG-3' (antisense) for the TGF- β 1 gene; 5'-CCGAGATCTCACCGACTACC-3' (sense) and 5'-TCCAGAGCGACATAGCACAG-3' (antisense) for the α -SMA gene. mRNA levels were expressed as -fold changes after normalization with GAPDH. All tests were done in triplicate to ensure reproducibility.

Western blotting

Cytoplasm proteins were isolated from 120 mg of frozen liver tissues using a Cytoplasmic Protein

Extraction kit (Beyotime Biotechnology, Haimen, China) according to the protocol provided by the manufacturer. Protein concentrations were determined using the BCA Protein Assay kit according to the protocol provided by the manufacturer (Beyotime Biotechnology, Haimen, China). 100 μ L of supernatant was added to an equal volume of $2 \times$ SDS sample buffer and boiled for 5 min at 100°C. The samples were then stored at -80°C until analyzed. The electrophoretic mobility of the proteins analyzed in this study was determined by SDS-polyacrylamide gel electrophoresis using 15% acrylamide concentrations. After electrophoresis, the proteins were transferred electrophoretically to a nitrocellulose filter membrane that was then blocked for 4 h in a solution of 8% nonfat dry milk in Tris-buffered saline containing 0.1% tween (pH 7.6) at RT. The membrane was then incubated overnight at 4°C with Smad4 antibody and GAPDH antibody which are represented on Western blotting by two distinct bands at 65 and 36 kDa. Bands were washed four times, after which they were incubated with Horseradish Peroxidase Labeled Anti-Mouse IgG (Medical Biological Laboratory, Nagoya, Japan) for 2 h and again washed four times. The blots were developed using an ECL Western blotting kit as recommended by the manufacturer. GAPDH was probed as an internal control. GAPDH was used to confirm that an equal amount of protein was loaded in each lane. Band intensities were determined using an AlphaImager™ 2200 using the SpotDenso function of AlphaEaseFC™ Software version 3.1.2 (Witec, Littau, Switzerland).

Statistical analysis

All determinations were repeated three times, and results are expressed as the mean \pm SD. ANOVA was used to evaluate the difference among multiple groups followed by a post hoc test (Student-Newman-Keuls) for quantitative data, and RIDIT test was used for statistical analysis of qualitative data. The data were analyzed using SPSS 13.0 software (SPSS Inc., Chicago, IL, USA), and $P < 0.05$ was considered statistically significant.

RESULTS

Emodin protected the liver against CCl₄-induced injury and suppressed hepatic fibrogenesis in the rat model

The effects of emodin on the protection of the liver from injury and fibrogenesis were initially evaluated by histological analyses. Representative views of liver sections are shown in Figure 1A. As shown in tissue sections stained with HE, compared with sections from livers in the vehicle controls (normal group), CCl₄ caused prominent hepatic steatosis, necrosis, and formation of regenerative nodules and fibrotic septa between the nodules (CCl₄ group). Oral administration of emodin daily for 12 wk improved the state of steatosis with a significant reduction in the number of macro- and microvesicular steatosis lesions, and it apparently suppressed hepatic fibrogenesis by reducing the thickness of bridging fibrotic septa (emodin group).

Table 1 Pathological score of CCl₄-induced liver fibrosis in rats

Group	n	Degree of pathological					U
		0	1	2	3	4	
Steatosis							
Normal control	10	10	0	0	0	0	3.89 ^b
CCl ₄	9	0	0	1	1	7	
CCl ₄ + emodin	11	0	1	4	5	1	2.77 ^b
Inflammation							
Normal control	10	10	0	0	0	-	4.21 ^b
CCl ₄	9	1	1	3	4	-	
CCl ₄ + emodin	11	3	7	1	0	-	2.03 ^a
Fibrosis							
Normal control	10	10	0	0	0	0	3.89 ^b
CCl ₄	9	0	0	0	5	4	
CCl ₄ + emodin	11	0	3	4	3	1	2.81 ^b

A piece of liver tissue from rats in each group was fixed with formalin, and then it was embedded in paraffin. Thin sections were cut and stained with HE. U represents the RIDIT value of the two groups, $P < 0.05$ indicates $U > 1.96$, $P < 0.01$ indicates $U > 2.58$. ^a $P < 0.05$ vs CCl₄ group; ^b $P < 0.01$ vs CCl₄ group.

According to METAVIR scale, the degree of hepatic fibrosis increased markedly in the CCl₄ group compared to the normal group, and decreased markedly in the emodin group compared to the CCl₄ group ($P < 0.01$, Table 1). Taken together, emodin reduced hepatic fibrogenesis caused by chronic CCl₄ intoxication.

Emodin reduced the content of hepatic hydroxyproline in the CCl₄ rat model

The efficacy of treatment with emodin on protection of the liver from fibrogenesis was further evaluated by using a quantitative method to determine the content of hepatic hydroxyproline in the rat model. Compared with the normal controls (54.53 ± 13.46 mg/g), the hepatic hydroxyproline content was significantly higher in rats injected with CCl₄ (120.27 ± 28.47 mg/g, $P < 0.05$). The hepatic hydroxyproline content was significantly reduced in rats treated with emodin at 20 mg/kg (71.25 ± 17.02 mg/g, $P < 0.05$).

Emodin suppresses serum activities of ALT and AST in the CCl₄ rat model

Biochemical analyses of serum enzymes were performed to verify the role of emodin in the protection of the liver from injury. As shown in Figure 2, compared with those in the normal controls (51.02 ± 10.64 IU/L and 132.28 ± 18.14 IU/L), the activities of serum ALT and AST were significantly higher in rats injected with CCl₄ (289.25 ± 68.84 IU/L and 423.89 ± 35.67 IU/L). The activities of serum ALT and AST were significantly reduced by administration of emodin (176.34 ± 47.29 IU/L and 226.1 ± 44.52 IU/L). These results demonstrated that emodin protected the liver against CCl₄-induced injury.

Emodin reduces HSC activation in the liver in the CCl₄ rat model

IHC and real-time PCR experiments were performed to further evaluate the impact of emodin on regulating

Figure 1 Emodin protects the liver from CCl₄-induced fibrogenesis in rats via inhibition of hepatic stellate cell activation. A piece of liver tissue from each treated rat ($n = 6$ per group) was fixed with formalin, and then it was embedded in paraffin. A: Thin sections were cut and stained with HE; B: α -SMA proteins were stained by immunohistochemistry in liver tissue. Representative views from each group ($n = 6$ per group) are presented (original magnification, $\times 400$). Arrows indicated an area positively labeled with α -SMA; C: Semi-quantification of α -SMA staining. Values are expressed as mean \pm SD, $n = 6$ per group. $^aP < 0.05$ vs CCl₄ group. Total RNA extracted from rat liver tissues was used to synthesize cDNA; D: The α -SMA mRNA was detected by real-time PCR, and mRNA levels are expressed as -fold differences relative to normal rat after normalization to the housekeeping gene's GAPDH mRNA. Values are expressed as mean \pm SD, $n = 5$ per group. $^aP < 0.05$ vs CCl₄ group.

the expression of α -SMA, the marker of activated HSC. Liver sections from each group were immunolabeled with antibodies against α -SMA. As shown in Figure 1B, as expected, few cells in the liver sections from the normal group were recognized by antibodies against α -SMA, suggesting few activated HSC in the normal livers in the vehicle control rats. Administration of CCl₄ caused a significant increase in the number of cells recognized by antibodies against α -SMA. Emodin treatment significantly reduced the number of cells labeled with α -SMA antibodies, suggesting that emodin might suppress HSC activation in the rat model. The comparative Ct method of $2^{-\Delta\Delta C_t}$ and IHC evaluation result showed that protein and mRNA levels of α -SMA in liver tissues from normal control rats were 8.88 ± 1.26 and 1.01 ± 0.19 , respectively while those in the CCl₄ group were 21.97 ± 1.68 and 3.52 ± 0.60 , respectively. Treatment of rats with emodin during CCl₄ exposure largely increased expression of α -SMA and

resulted in protein and mRNA levels of 14.61 ± 1.67 and 2.46 ± 0.91 , respectively (Figure 1C and D).

Emodin reduces the concentration of TGF- β 1 in serum and mRNA levels in liver tissues

TGF- β 1 is the major profibrogenic factor during hepatic fibrogenesis. We examined the effect of emodin on the concentration of TGF- β 1 in serum and mRNA levels in liver tissues of the rat model by ELISA and real-time PCR. As shown in Figure 3, compared with those in the normal group (84.89 ± 27.14 pg/mL and 1.01 ± 0.16 , respectively), the levels of TGF- β 1 in serum (Figure 3A) and mRNA levels of TGF- β 1 in liver tissues (Figure 3B) were dramatically increased in the CCl₄ group (313.40 ± 57.75 pg/mL and 3.89 ± 1.00 , respectively, both $P < 0.05$ vs normal group). The levels of TGF- β 1 in serum and mRNA levels of TGF- β 1 in liver tissues were significantly reduced in the emodin group (151 ± 47.64 pg/mL and

Figure 2 Emodin decreases the levels of serum aspartate amino-transferase (AST) and alanine aminotransferase (ALT) activities. Serum samples were obtained from each treated rat through heart puncture when sacrificed. After coagulation, serum AST and ALT activities were determined by routine laboratory methods. Values are expressed as mean \pm SD, $n = 6$ per group. AST: ^a $P < 0.05$ vs CCl₄ group; ALT: ^c $P < 0.05$ vs CCl₄ group.

2.16 \pm 0.73, respectively, both $P < 0.05$ vs CCl₄ group). Although these were still higher than those of the normal group, these data indicated that emodin significantly reduced the levels of TGF- β 1 in serum and mRNA levels in liver tissues in the rat model, which might result in the inhibition of HSC activation stimulated by CCl₄.

Emodin down-regulates the protein and mRNA levels of Smad4 in liver tissues of the CCl₄ rat model

Because TGF- β 1 signals within the cell through Smad is involved in fibrosis, the effects of emodin on mRNA and protein levels of Smad4 in liver tissues were demonstrated by real-time PCR (Figure 4C), Western blotting (Figure 4D and E), and IHC analyses (Figure 4A and B). Experiments revealed that exposure of rats to CCl₄ significantly increased mRNA and protein levels of Smad4 in liver tissues from 1.00 \pm 0.13, 0.54 \pm 0.04 and 5.78 \pm 1.05, respectively, in the normal group to 4.63 \pm 0.86, 13.44 \pm 0.64 and 23.95 \pm 3.23, respectively, in the CCl₄ group. In contrast, protein and mRNA levels of Smad4 in liver tissues from rats treated with emodin during CCl₄ exposure were attenuated and were 2.94 \pm 0.74, 9.25 \pm 0.84 and 17.00 \pm 1.88, respectively. Treatment of rats with emodin during CCl₄ exposure blunted the increase in protein and mRNA levels of Smad4 significantly.

DISCUSSION

In the present study, we confirmed that emodin protects the rat liver from CCl₄-induced injury and fibrogenesis. The mechanism for this protective effect may relate to the fact that emodin efficiently inhibits HSC activation *in vivo*.

Hepatic fibrosis, which may lead to cirrhosis, is associated with most chronic liver diseases^[22]. Hepatic fibrosis is thought to be a reversible disease, however, there is no satisfactory method in clinical practice to reverse the pathological process yet^[23]. Several drugs, including antisense TGF- β 1 receptors, cytokines^[24], antioxidants, chemical drugs^[25], soluble type II receptor of TGF- β 1, and TGF- β 1 antibodies^[26] have been used in research work to block experimental hepatic fibrosis, but

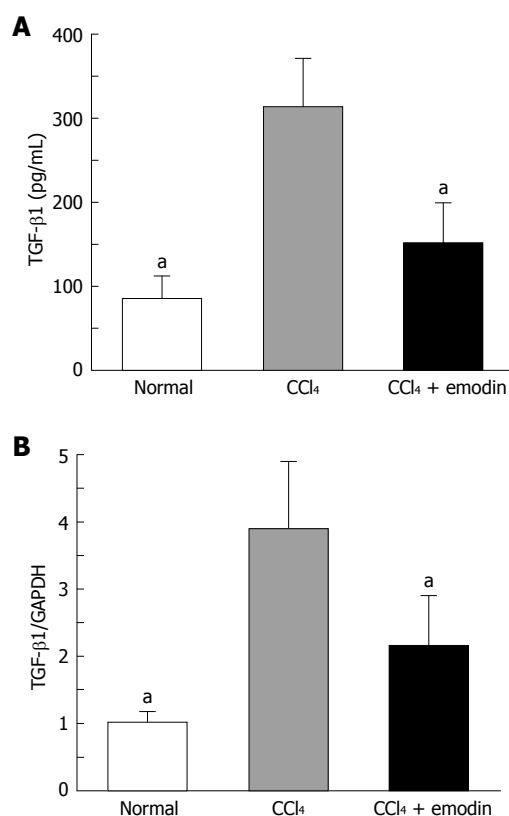

Figure 3 Emodin decreases the levels of serum transforming growth factor- β 1 (TGF- β 1) and mRNA levels in liver tissues in the rat model. Serum and liver tissue were obtained from each treated rat. A: Levels of serum TGF- β 1 were determined by ELISA; B: Total RNA extracted from rat liver tissues was used to synthesize cDNA. The mRNA level of TGF- β 1 in liver tissues was detected by real-time PCR, and mRNA levels were expressed as -fold differences relative to normal rat after normalization to the housekeeping gene's GAPDH mRNA. Values are expressed as mean \pm SD, $n = 5$ per group. ^a $P < 0.05$ vs CCl₄ group.

their effects were not as prosperous as we had expected. Some traditional Chinese drugs have been found effective in preventing fibrogenesis and other causes of chronic liver injury^[27,28], and this helps to develop a more hopeful future in controlling liver fibrosis and cirrhosis. Emodin is a main active monomer isolated from Giant Knotweed Rhizome, which is widely used in traditional Chinese herb treatment of liver cirrhosis^[29]. It is easy to extract, isolate and identify emodin, so it shows excellent prospects in the development of some new drugs for treating hepatic fibrosis.

CCl₄, a highly toxic chemical agent, causes hepatic injury including hepatocytic necrosis, steatosis, and inflammation. Research for establishing a model of liver fibrosis with CCl₄ began in 1936. Since then many methods to establish a model of liver fibrosis have been tried^[30]. Among them, hepatic fibrosis caused by CCl₄ has been extensively used in experimental models in rats because hepatic responses in rats to chronic CCl₄ stimulation are shown to be superficially similar to human cirrhosis^[31]. Hepatocyte damage is the initial factor of hepatic fibrogenesis and activities of ALT and AST in serum are the most commonly used biochemical markers of liver injuries^[32]. Hydroxyproline is an amino acid found

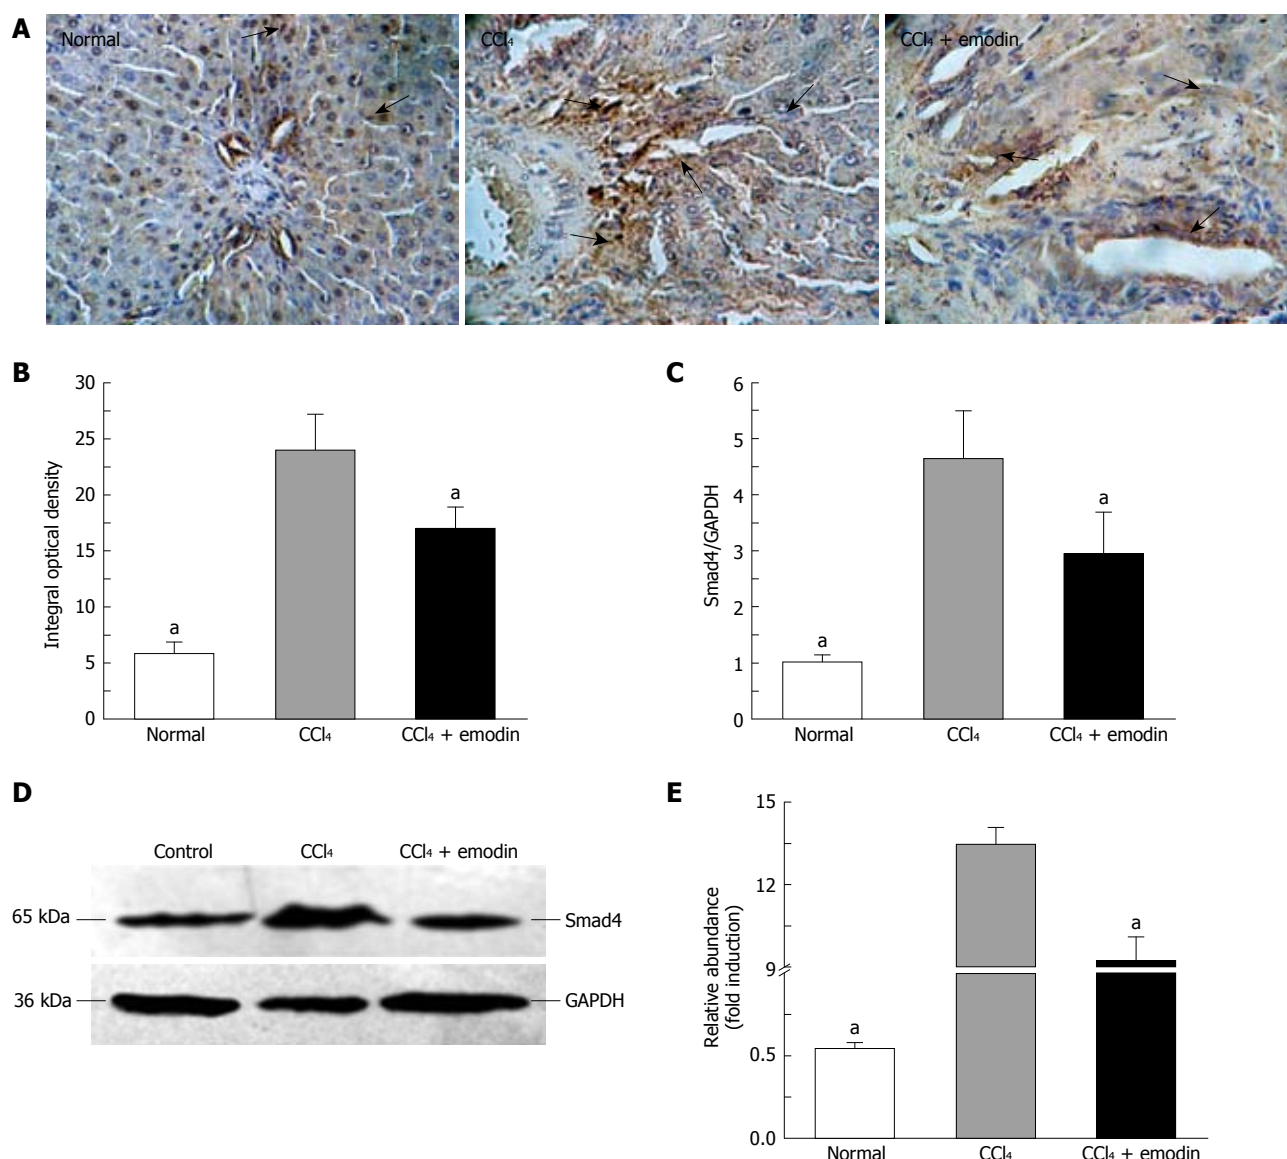

Figure 4 Emodin inhibits expression of protein and mRNA levels of Smad4 in liver tissues in the rat model. A piece of liver tissue was collected from each treated rat. A: Smad4 proteins in liver tissue were stained by IHC. Representative views from each group ($n = 6$ per group) are presented (original magnification, $\times 400$). Arrows indicate an area positively labeled with Smad4; B: Semi-quantification of Smad4 staining. Values are expressed as mean \pm SD, $n = 6$ per group. $^aP < 0.05$ vs CCl₄ group; C: Real-time PCR analyses of the mRNA levels of Smad4. Values are presented as means \pm SD, $n = 5$ per group. GAPDH was used as an invariant internal control for calculating mRNA-fold changes; D, E: Western blotting analyses of the protein abundance of Smad4. GAPDH was used as an invariant control for equal loading. $^aP < 0.05$ vs CCl₄ group.

almost exclusively in collagens. Determination of the content of hydroxyproline in liver tissue is regarded as a good method to quantify fibrosis and to evaluate the effectiveness of new potentially antifibrotic agents. In this study, the method of subcutaneously injecting CCl₄ was used to establish the model of liver fibrosis. Histological analysis showed CCl₄ caused prominent hepatic steatosis, necrosis, and formation of regenerative nodules and fibrotic septa between the nodules. Biochemical assay showed serum ALT activities, serum AST activities, and content of hepatic hydroxyproline were markedly increased in rats injected with CCl₄ for 12 wk, which are consistent with the histological observations.

Our results suggest that oral administration of emodin daily for 12 wk improved the state of steatosis with a significant reduction in the number of macro- and

microvesicular steatosis, and it also apparently suppressed hepatic fibrogenesis by reducing the thickness of bridging fibrotic septa. Emodin could decrease the scores of hepatic fibrosis grading, inhibit the ALT and AST activities in serum and reduced the content of hepatic hydroxyproline. All results confirm that emodin protected the liver from injury and fibrogenesis caused by CCl₄ in the rat model.

Chronic liver injury may lead to development of fibrosis, a process in which HSC play a major role. As a result of liver injury, HSC, which in the healthy organ store vitamin A, undergo a process of activation that is mediated by the concerted action of resident hepatic cell types such as Kupffer cells, liver endothelial cells, and hepatocytes. The phenotype of activated HSC is characterized by α -smooth muscle actin (α -SMA)

expression^[33]. α -SMA expression in the liver tissues is an indicator of hepatic stellate cell activation, which is recognized as being critical in liver fibrogenesis. Thus inhibition of the accumulation of activated HSCs is an important therapeutic strategy^[34]. Our results showed the levels of α -SMA in rat liver tissues increased significantly after CCl₄ administration for 12 wk. Emodin reduced α -SMA expression at mRNA and protein levels.

Inflammation is commonly associated with hepatic fibrogenesis during chronic liver diseases^[35]. CCl₄ is metabolized in the liver by cytochrome P450 into the free radical CCl₃^[36]. The free radical attacks hepatocytes and causes necrosis of parenchymal cells, which promotes inflammatory responses in the liver^[37]. Results in this study indicated that emodin suppressed inflammation caused by CCl₄, which might lead to the protection of the liver from injury. It is now widely accepted that the pro-inflammatory cytokine TGF- β 1 is a major cytokine in the regulation of the production, degradation, and accumulation of ECM^[38], and it has been suggested that overexpression of TGF- β 1 for a prolonged period of time after tissue damage may induce a fibroproliferative response and deposition of ECM, resulting in fibrosis in vital organs^[39]. Many studies have detected the presence of TGF- β 1, in the form of either protein or message, in the fibrotic tissues of animal models or human samples^[40]. Partial inhibition of the accumulation of ECM using either anti-TGF- β 1 serum or a TGF- β 1-binding protein has been reported in fibrosis models^[41]. Our results showed that TGF- β 1 mRNA levels and serum TGF- β 1 protein levels in normal rat were low. After injection of CCl₄ for 12 wk, mRNA and protein levels of TGF- β 1 increased significantly. Emodin down-regulated mRNA levels of TGF- β 1 expression in liver tissue. Furthermore, serum TGF- β 1 levels in the model rats were also significantly down-regulated by emodin treatment in a manner similar to hepatic fibrosis attenuation. These findings imply that emodin might attenuate hepatic fibrosis through down-regulation of TGF- β 1 expression *in vivo*.

Smad4 is well known to function as one of the downstream effectors of TGF- β 1, and it mediates TGF- β 1-induced collagen synthesis^[42]. Smads are intracellular signal transductive molecules of the TGF- β super family. According to differences in structure and function, nine Smads have been reported and classified into three groups. Smads 2 and 3 are named R-Smads in the pathway and Smad4 Co-Smads for all these pathways. Smads 6, 7, 8 are inhibitory factors of these Smads. When TGF- β 1 binds to its receptor, Smad 2/3 is phosphorylated and binds with Smad4 and together they move into the nucleus for translation and expression of the target gene^[43,44]. Smad signal transduction pathways are thought to play a crucial role in the process of liver damage and recovery, as well as liver fibrosis. These transcriptional responses appear to be mediated predominantly through Smad4. The widely held conclusion that Smad4 occupies a central role in transduction of TGF- β 1 signals comes from multiple lines of biochemical and genetic evidence^[45]. In reconstitution experiments, cell lines that lack Smad4

fail to respond to TGF- β 1 signals, transfection of wild-type Smad4 restores the signaling capabilities of these cells^[46]. Our study showed that both mRNA and protein expressions of Smad4 were remarkably up-regulated in fibrotic rats. We also observed down-regulation of Smad4 expression in emodin-treated fibrotic rats, suggesting that emodin attenuate hepatic fibrosis by regulating TGF- β 1/smud signaling.

In conclusion, the data presented herein provide evidence that emodin is active as an antifibrogenic drug able to reduce the biological effects of TGF- β 1 in ongoing fibrogenesis. Giant Knotweed Rhizome, a traditional Chinese herbal medicine, is widely used in clinical practice for treating cirrhosis. Emodin, the main active monomer isolated from Giant Knotweed Rhizome, may be an attractive therapeutic agent for the treatment of fibrotic liver diseases.

COMMENTS

Background

In the last decade, advances in the understanding of genes promoting hepatic stellate cell (HSC) activation are impressive. However, there are few breakthroughs in therapeutic intervention of hepatic fibrogenesis. Efficient and well-tolerated antifibrotic drugs are lacking and current treatment of hepatic fibrosis is limited to withdrawal of the noxious agent. Research identifying innocuous antifibrotic agents is of high priority and urgently needed.

Research frontiers

Emodin is efficacious in the management of hepatic fibrosis. However, the mechanisms underlying its effects remain to be elucidated. The current study evaluates the *in vivo* role of emodin in the protection of the liver from fibrogenesis caused by carbon tetrachloride (CCl₄) in a rat model and further explores the underlying mechanisms.

Innovations and breakthroughs

To the best of the authors' knowledge, this is the first study to report that emodin protects the liver from CCl₄-induced fibrogenesis by inhibiting activation of HSC *via* modulating transforming growth factor- β 1 (TGF- β 1)/Smad signaling pathways. Results in this study provide novel insight into the mechanisms of emodin in the protection of the liver.

Applications

By evaluating the role of emodin in protecting the liver against fibrogenesis caused by carbon tetrachloride (CCl₄) in rats *via* inhibition of hepatic stellate cells activation, emodin might be a therapeutic antifibrotic agent for the treatment of hepatic fibrosis.

Terminology

Smad4 is a protein which in humans is encoded by the *SMAD4* gene. SMAD4 is a 552 amino acid protein involved in cell signaling. It is the only known mammalian coSmad. It is a homolog of the *Drosophila* protein: "Mothers against decapentaplegic".

Peer review

This study examines the effects of emodin on CCl₄-induced liver fibrosis. The authors show reduced fibrosis, decreased stellate cell smooth muscle actin expression and decreased TGF- β expression. The study has been suitably designed and clearly reported.

Abstract

AIM: To analyze the accuracy of short-term bio-impedance as a means of measuring gastric motility.

METHODS: We evaluated differences in the short-term electrical bio-impedance signal from the gastric region in the following conditions: (1) fasting state, (2) after the administration of metoclopramide (a drug that induces an increase in gastric motility) and (3) after food ingestion in 23 healthy volunteers. We record-

ed the real component of the electrical impedance signal from the gastric region for 1000 s. We performed a Fast Fourier Transform (FFT) on this data and then compared the signal among the fasting, medicated, and postprandial conditions using the median of the area under the curve, the relative area under the curve and the main peak activity.

RESULTS: The median of the area under the curve of the frequency range in the region between 2-8 cycles per minute (cpm) decreased from 4.7 cpm in the fasting condition to 4.0 cpm in the medicated state ($t = 3.32$, $P = 0.004$). This concurred with the decrease seen in the relative area under the FFT curve in the region from 4 to 8 cpm from 38.3% to 26.6% ($t = 2.81$, $P = 0.012$) and the increase in area in the region from 2 to 4 cpm from 22.4% to 27.7%, respectively ($t = -2.5$, $P = 0.022$). Finally the main peak position also decreased in the region from 2 to 8 cpm. Main peak activity in the fasting state was 4.72 cpm and declined to 3.45 cpm in the medicated state ($t = 2.47$, $P = 0.025$). There was a decrease from the fasting state to the postprandial state at 3.02 cpm ($t = 4.0$, $P = 0.0013$).

CONCLUSION: Short-term electrical bio-impedance can assess gastric motility changes in individuals experiencing gastric stress by analyzing the area medians and relative areas under the FFT curve.

Effects of metoclopramide on gastric motility measured by short-term bio-impedance. *World J Gastroenterol* 2009; 15(38): 4763-4769 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4763.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4763>

INTRODUCTION

Numerous studies have demonstrated that gastric motility occurs at a rate of three cycles, or peristaltic waves, per minute. This consistent rate is due to myoelectrical activity, which produces ring contractions through the distal gastric wall. These peristaltic waves facilitate food digestion and gastric emptying^[1-3]. In various studies, gastric emptying has been used to assess many diseases using several different measurement techniques and methods of data analysis^[4-8].

Scintigraphy has become the gold standard technique for the evaluation of gastric activity despite the fact that it measures gastric emptying as the main consequence of gastric motility^[3,4,9]. Also for the evaluation of the gastric motility, there are invasive methods such as manometry, which uses a pressure probe device in a specific region of the gastric tract to directly measure the amplitude and frequency of the gastric movements^[10-12]. Electrogastrography could be another invasive method, if electrodes are introduced into the gastro-intestinal tract in order to record the myoelectrical activity in a specific area of the tract^[13]. The bio-impedance technique can also be invasive, for example, when used to measure intraluminal impedance in esophageal function studies^[14,15]. Non-invasive options include electrogastrography if recordings are performed through the skin using cutaneous electrodes^[16-23], and electrical bio-impedance in the gastric region when measured using cutaneous electrodes^[24-26]. As opposed to gastric electrical stimulation^[27,28], the bio-impedance technique uses a low current and voltage to obtain passive gastric impedance characteristics. In these two cases, uncertainties arise in the interpretation of the signal because cutaneous recording leads to the simultaneous acquisition of signals at multiple frequencies within the gastrointestinal (GI) system. The main challenge of this technique is the decomposition of the data to isolate the frequencies originating in the gastric tract^[16,25,29,30].

In looking for a balance between accuracy, reproducibility and patient comfort, electrogastrography and electrical bio-impedance are the most suitable techniques for the evaluation of gastric motility^[31], despite the fact that occasionally electrical activity does not correlate directly with mechanical movements^[11]. In the context of selecting one of these two techniques for gastric motility assessment, electrical bio-impedance has the advantage of being directly sensitive to movements and therefore a better option than electrogastrography for gastric motility evaluation.

In the evaluation of gastric motility, bio-impedance techniques have been shown to be sensitive to material changes, including internal conformational changes (bowel movements)^[26,32] and conduction properties (stomach acidity or properties of ingested food)^[33]. This method has been used in gastric emptying studies for long-term measurements. Measurements are evaluated by looking for global impedance changes, which are changes over long time periods and ignoring impedance oscillations, short-term faster oscillating changes, of the gastric region^[24].

Recently, this long-term assessment method has been proposed for the evaluation of gastric secretions because it is highly sensitive to the conductive properties of ingested food and internal fluid secretions, and therefore may be a useful method for such evaluations^[34].

For gastric motility, bio-impedance evaluation produces results consistent with those of other gastric motility methods, mainly the position of the main peak activity around three cycles per minute (cpm)^[24,25]. However, the sensitivity to other gastrointestinal regions and the overlapping of movements from those regions produce signals in other frequency ranges that are neither due to bradygastria or tachygastria but are associated with characteristic intestinal or colon frequencies^[1].

There are several benefits to the bio-impedance technique: it directly measures motility, it is non-invasive, and its use for interval measurements (short term bio-impedance) can accurately reconstruct a long period of measurement. The first benefit emphasizes accuracy while the latter two maximize patient comfort. Additionally, this approach is less expensive than other techniques and so the development of this method for clinical purposes can benefit a wider range of people worldwide.

In a previous study, we evaluated normal subjects in both the fasting and postprandial states using short-term electrical bio-impedance^[32]. We compared our data with those obtained from the concurrent use of long-term bio-impedance, and found consistent results. Thus, we concluded that short-term electrical bio-impedance is an accurate evaluation method in healthy volunteers. In particular, the position of the main activity around 3 cpm was strong support for the usefulness of this method in healthy volunteers because of its unequivocal agreement with several other methods of gastric motility assessment. However, for this technique to attain clinical relevance, bio-impedance must be shown to be equivalent to validated methods in subjects experiencing gastric stress, which manifests itself through small changes in peristaltic wave frequency. Thus, we must evaluate if short-term electrical bio-impedance (5-15 min) has sufficient sensitivity to record these changes.

In this study, we use the drug metoclopramide to induce gastric stress in healthy volunteers, mimicking a state of gastric stress that would warrant clinical evaluation. By comparing the data from the area under the Fast Fourier Transform (FFT) spectra curves to those obtained from the main peak of the spectra, we assessed the potential of electrical bio-impedance as a method for the evaluation of gastric motility in systems experiencing gastric stress.

MATERIALS AND METHODS

Subjects

For this study we recruited twenty three volunteers. Each met the following criteria: 18-30 years of age, no prior gastrointestinal disease, no prior disease that may affect the GI system function (including diabetes, Parkinson's disease, amyloidosis, myotonic dystrophy, polymyositis,

HIV infection or cytomegalovirus infection), and they must not have been taking medicine that could interfere with gastric activity. Additionally, participants must not have had significant weight loss within the 3 mo prior to the study, and must not have been overweight ($\text{BMI} \geq 25 \text{ kg/m}^2$). In addition to these physical criteria, subjects must have been free from psychological problems such as anxiety, stress, depression and mental disease, because these conditions could potentially affect gastric activity through endocrine and central nervous system modulation. Also, subjects were free from any other endocrine disorders and had no food allergies that interfered with the food administered in this trial.

All women who participated in this study underwent evaluation within the first 10 d (the early follicular phase) of their menstrual cycle. All subjects who participated in this study signed a consent form approved by the Human Ethics Committee of the University of Guanajuato. The study was conducted according to the Declaration of Helsinki^[35].

Metoclopramide administered orally

Metoclopramide [IUPAC name: 4-amino-5-chloro-N-(2-diethylamino ethyl)-2-methoxybenzamide] is a dopamine receptor antagonist with both antiemetic and prokinetic properties. The antiemetic property treats nausea and vomiting while the prokinetic properties enhance the peristaltic waves of the stomach and intestine, increasing the rate of absorption and thus the rate of passage through the stomach. Therefore, the administration of metoclopramide in healthy volunteers speeds gastric motility and subsequently the rate of gastric emptying in a measurable way. In healthy patients, metoclopramide is absorbed rapidly and almost completely from the GI tract following oral administration. The pharmacological action of orally administered metoclopramide begins 30–60 min after the subject takes the drug and persists for 1–2 h^[36]. Therefore, after performing our baseline recordings in the fasting individual, metoclopramide was administered and we took bio-impedance measurements after a 60 min resting period. This ensured that the subjects were experiencing the maximal pharmacological effects of metoclopramide while the bio-impedance measurements were taken.

Clinical evaluation

Before beginning the experiment, a clinical history was taken from each of the subjects. This evaluation included the following sections: (1) General Information: name, age, gender, occupation; (2) Pathological Antecedents: clinical history of disease related to the GI tract; (3) Physiological Information: anthropometrical measurements and body mass index; (4) Life-style variables: exercise, sleep habits, substance use (smoking, alcohol, medication); (5) Observations: additional information gained from the physical examination; (6) Gynecologic-Obstetric Characteristics: for all women, we collected data regarding the onset of menarche, last menstrual period, and history of gynecological problems.

Experiment

Before participation, each subject fasted for 8 h immediately prior to the experiment. In addition, they abstained from smoking, alcohol consumption, strenuous exercise, and substances containing caffeine for 24 h before testing.

A basal bio-impedance measurement of each individual in the fasting state was acquired during 16.7 min (1000 s) and served as a baseline for comparison with the experimental condition (metoclopramide). Patients subsequently ingested a 20 mg dose of metoclopramide with 150 mL of water. We waited 1 h before taking the second bio-impedance measurement so that patients would experience the peak pharmacological effects of metoclopramide during the test period. After this, another 1000 s bio-impedance measurement was recorded. We performed a third bio-impedance recording after the administration of a test meal that consisted of one cereal bar containing 124 calories (cal): 6.8 cal (1.7 g) of protein, 44.1 cal (4.9 g) of fat, and 73.1 cal (18.3 g) of carbohydrates and a fat free Yoghurt Drink containing 83 cal: 32 cal (7.8 g) of protein, zero cal (0 g) of fat, and 51 cal (12.5 g) of carbohydrates. In total, the subjects consumed 207 cal, of which 38.8 cal (9.5 g) were protein, 44.1 cal (4.9 g) were fat, and 124 cal (30.8 g) were carbohydrates.

To control the consistency of the ingested food, we divided the bars into four equal pieces and instructed the subjects to chew each piece 10 times and then immediately swallow. They were to repeat this with all four pieces of the cereal bar and when finished, immediately drink the yoghurt.

Approximately 5 min after food ingestion, subjects were measured again using the bio-impedance technique to assess gastric motility. There are two factors that affect the bio-impedance signal: the first is the dielectric properties of the food ingested, where fats lead to deadening of the signal. In our experiment, we controlled for this by administering a test meal low in fats. The second factor affecting the signal is noise produced by involuntary movements of the subjects, such as yawning, coughing and heavy breathing. Here, the use of short-term bio-impedance mitigated these effects by reducing the consecutive testing time for subjects.

For this experiment, we used a configuration of three electrodes as shown in Figure 1. This configuration consisted of two electrodes placed on the abdomen and a ground electrode placed on the back. The first (excitation) electrode was placed using the midline as a marker, and then by following the ribcage to the level just above and to the left of the umbilicus. The second electrode was placed approximately five centimeters from the first at a 45 degree angle up and to the left of this (recording) electrode. For the ground electrode, the vertebral column was used as a reference and the electrode was placed at approximately the average height of the corresponding abdominal electrodes.

All measurements were obtained with a SOLARTRON 1260 impedance analyzer in conjunction with a SOLARTRON 1294 biological sample interface. Disposable

Figure 1 The figure shows the three electrode configuration, with the ground electrode placed on the back.

3M “Red Dot” monitoring electrodes were used in each patient. A BI stimulus frequency of 1 V AC was applied at 50 kHz. During the experiment, data were recorded four times per second for 1000 consecutive seconds.

Statistical analysis

Before conducting the data analysis, we preliminarily assessed the results of the anthropometrical, lifestyle, and clinical variables to ensure that our group was homogeneous in terms of these variables and that there were no unusual fluctuations in our sample.

To analyze the information from each individual over time, we used a Butterworth filter in the framework of a FFT analysis for the frequency range of 1-12/min (or cpm) (0.017-0.2 Hz). We particularly noted the data in the region between 2-4 cpm (0.033-0.066 Hz) and between 4 and 8 cpm (0.066-0.132 Hz). These analyses were carried out using MatLab 6.5 and Origin 6.0.

The data recordings were cleaned of noisy periods, sudden fluctuations and data drifting, thus the remaining data periods for analysis were in the range of 5-10 min; we discarded recordings of less than 5 min.

The frequency range was divided in four regions: the first region (R1) spans 1-2 cpm, and is defined as a very low frequency range and was therefore not considered to be an important region in this work. The second region (R2), spans the frequencies from 2 to 4 cpm and has generally been recognized as the main frequency range in the literature regarding gastric studies^[1,24,25,32]. The third region (R3) spans 4-8 cpm, and contains the frequencies where movements from the intestines are important^[1]. The fourth region (R4) spans 8-12 cpm and corresponded with the respiration frequency range of the subjects. This region may contain important data regarding the gastrointestinal system, but because respiration generates significant signal noise, we were not able to use it. Other, more expansive regions were defined as region R5, spanning 2-8 cpm and region R6, spanning 2-12 cpm (Figure 2).

For the statistical analysis, we divided the FFT signal from 1-12 cpm into the regions described above and we used both the area under the FFT curve and the median of this area (the frequency which divides the area of the frequency region into two equal parts) and the position

Figure 2 The figure demonstrates the definition of the regions (R1 to R6) considered in this study.

of the main peak. Together, these measures described the characteristics of the entire frequency range from 2-8 cpm. This range was used to compare the relative activities within the high and low frequency ranges. We disregarded the activity due to respiratory movements, which contributed data at approximately 8-12 cpm.

To test the accuracy of our results, we also analyzed the position of the highest activity in the range of 2-4 cpm, which is the frequency range typically used in the assessment of gastric activity.

For data analysis, we used a MatLab platform to analyze the spectra. *T*-tests for dependent samples were performed to assess differences between fasting, medicated and post-prandial states using the parameters mentioned. Previously, the use of bio-impedance has been limited because of the complexity of the signal acquired from the impedance measurements. Therefore, the only parameter used was the average magnitude of resistance of the raw signal and its change over time. Our technique refines this previous method by parsing more parameters that can be independently evaluated and statistically analyzed. All statistical analyses were performed using Statistica (Stat-Soft, Inc, Tulsa OK, USA), and the threshold for significance was standardized at $P = 0.05$.

RESULTS

As mentioned above, three parameters were considered in this study: (1) The median of the area under the FFT curve for each region, (2) The ratio of the area of each region to the total area under the curve of the range from 1 to 12 cpm; and (3) the position of the highest peak in each region. The three parameters for each region were obtained from smoothed versions of the FFT curves. We took the average of all individuals evaluated in this study and used these data for further comparison.

Based on the three parameters used, we found the following.

Medians

In R2, the median changed from 2.8 cpm in the fasting state to 2.75 cpm in the medicated state. However, this change was not statistically significant ($P = 0.46$). In R3,

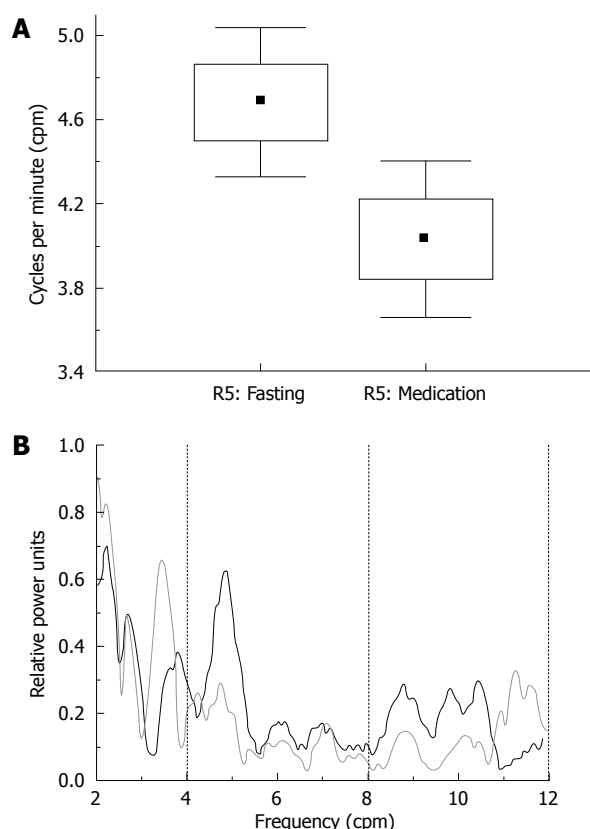

Figure 3 Changes in the median of the area under the region R5, from 2 to 8 cpm. A: Median change for the average of all individuals between the fasting and medicated states for R5 (from 2 to 8 cpm) $t = 3.32$, $P = 0.004$; B: This graph is an example of the change of R5 in an individual recording: fasting in black and medication in grey.

this parameter changed from 5.75 cpm in the fasting state to 5.9 cpm in the medicated state, however, this change was also not statistically significant ($P = 0.2$). As shown in Figure 3, R5 (R2 + R3) displayed a significant decrease in the median from 4.7 cpm in the fasting condition to 4.0 cpm in the medicated state ($t = 3.32$, $P = 0.004$). We did not find a statistically significant change in the median value in any region between the medicated and post-prandial states in the regions analyzed in this study. However, in the instances where the changes were not statistically significant, these changes showed a similar trend to those indicated in previous studies^[32].

Areas

The change observed in the median of R5 may be understood as the combination of the changes seen in the area under the FFT curve of R2 and R3. For R2, when we compare the ratios of the regional area to the total area between the fasting and medicated states, we observed an increase from 22.4% to 27.7%, respectively ($t = -2.5$, $P = 0.022$). The change was in the opposite direction for R3, with a decrease from 38.3% to 26.6% ($t = 2.81$, $P = 0.012$) for the fasting and medicated states, respectively. Figure 4A and B show these changes for R2 and R3, respectively.

In contrast to our findings regarding the changes in the median of the area under the FFT curve for R5, there were no significant differences in the area of R5

Figure 4 Average change in the median for R2 (A: $t = -2.5$, $P = 0.022$) and R3 (B: $t = 2.81$, $P = 0.012$) between the fasting and medication conditions.

between the post-prandial state and either the fasting or medicated state.

Peaks

Previously, the main parameter considered in the evaluation of gastric motility was the main peak in R2 (from 2 to 4 cpm) of the frequency domain and its shift across states. As discussed above as well as in previous works, the large overlap of activity in the abdominal cavity makes determination of the main peak difficult in certain frequency regions. When the main peak activity of R5 was analyzed, we found differences in the position of the highest peak which were statistically significant. Main peak activity in the fasting state was 4.72 cpm and declined to 3.45 cpm in the medicated state ($t = 2.47$, $P = 0.025$), as shown in Figure 5. There was also a decrease from the fasting state to the post-prandial state at 3.02 cpm ($t = 4.0$, $P = 0.0013$) but this change was not statistically significant with respect to the medicated state ($P = 0.28$).

DISCUSSION

These results demonstrate that global changes in the gastrointestinal tract can be measured using short-term electrical bio-impedance, giving useful information on gastric motility.

The typical parameter for gastric motility evaluation is the position of the main peak in the frequency region between 2-4 cpm and should be reconsidered in the context of global behavior of the combined frequency

Figure 5 Change in average main peak position between the fasting and medicated state in R5. *T* test for dependent samples, $t = 2.47$, $P = 0.025$.

ranges. The results described in our previous work were confirmed with the accurate measurement of gastric motility in the fasting state^[32]. In addition, this study demonstrated that the bio-impedance technique is also valid for systems experiencing gastric stress, as induced by metoclopramide. In this study, we demonstrated that there was a decrease in the median of the area under the FFT curve over time in the region from 2 to 8 cpm, which was a consequence of the change in the relative areas under the curves in the regions from 2 to 4 cpm (increase) and from 4 to 8 cpm (decrease). The position of the main peak can also be used as a parameter for gastric motility assessment, and in this case the main peak would be representative of the entire 2-8 cpm region.

When analyzing the lack of significant change in the main peak position in R5 between the medicated and post-prandial states, we can understand this physiologically as a result of the continued effects of metoclopramide during the post-prandial state. Peak effects of metoclopramide occur at 60 min after administration, but can persist for up to 2.2 h^[36]. Food administration and subsequent testing were well within this period, likely accounting for the lack of significant differences between the two states. The increased smooth muscle activity induced by metoclopramide administration persisted throughout the post-prandial state, causing similar bio-impedance activity in both states; this resulted in a lack of significant changes in gastric motility.

This study should be followed up with comparative studies between electrical bio-impedance and electrogastrigraphy and other standard techniques to ensure the equivalence of this technique to other proven methods and the overall validity of electrical bio-impedance for gastric motility assessment so that it can be used in a clinical context. Frequent and easy monitoring of gastric motility in subjects with problems that involve gastric motility may be an important clinical application of this technique, for example in the clinical diagnosis, and evaluation of gastroparesis. Other applications may include pediatrics, because this technique allows easy clinical evaluation. Extended monitoring of patients experiencing gastric distress may lead to more accurate assessment of the pathological antecedents of the chief complaint. This technique could also be used in the evaluation of the

effects of diverse drugs which act in the gastric motility.

The results of this study demonstrate that electrical bio-impedance can be used as an accurate and valuable clinical technique for gastric motility evaluation in individuals experiencing gastric stress.

COMMENTS

Background

Gastric motility assessment is an important diagnostic technique for a variety of diseases of the gastrointestinal tract. For the evaluation of gastric motility, there are invasive methods such as scintigraphy and manometry. Electrogastrography is an invasive method, if electrodes are introduced into the gastro-intestinal tract. Non-invasive options include electrogastrigraphy, when recordings are performed through the skin using cutaneous electrodes, and electrical bio-impedance in the gastric region when cutaneous electrodes are applied. In these latter two cases, uncertainties arise in the interpretation of the signal because the cutaneous recording leads to the simultaneous acquisition of signals at multiple frequencies within the gastrointestinal system. The main challenge of this technique is the decomposition of the data to isolate the frequencies originating in the gastric tract. Presently, research is underway to develop accurate gastric motility assessment tools which optimize patient comfort and cost.

Research frontiers

Electrical bio-impedance is a non-invasive technique that can measure gastric motility. Previously, assessment has been over long time intervals in gastric emptying studies that required immobilization of the patient for the duration of the test. Movement compromises results and the overlap of internal movements from the gastric region produce signals in other frequency ranges. Other alternatives to analyze bio-impedance data from the gastric region have been proposed in the literature, for example, discrete wavelet transform.

Innovations and breakthroughs

Here, the authors demonstrate that short-term bio-impedance can be used to assess gastric motility in healthy volunteers with gastric systems under stress. The areas and the median of the areas of specific regions under the Fast Fourier Transform (FFT) spectra were analyzed, as an alternative, to accurately depict gastric motility. Stress induced by metoclopramide mirrors a disease state by enhancing the peristaltic waves of the stomach and intestines. Thus, this work supports the clinical application of the bio-impedance technique.

Applications

In future studies, the authors hope to test short-term bio-impedance in parallel with other, previously validated methods for gastric motility assessment. If studies prove these methods to be equivalent, short-term bio-impedance could be used clinically to optimize gastric motility assessment with regard to both cost and patient comfort.

Terminology

Bio-impedance is a term used to describe the response or resistance of a living organism to an externally applied electric current. It can be described by the resistance or the conductivity. Short-term bio-impedance is a term used for short time recordings of bio-impedance signal. FFT is a mathematical technique to transform data from time domain to frequency domain. It gives information about the main variation frequencies for the data. Metoclopramide, is a dopamine receptor antagonist with both antiemetic and prokinetic properties. The antiemetic property treats nausea and vomiting while the prokinetic properties enhance the peristaltic waves of the stomach and intestine, increasing the rate of absorption and thus the rate of passage through the stomach.

Peer review

The manuscript entitled "Effects of metoclopramide on gastric motility measured by short-term bio-impedance" is an interesting report. They found that electrical bio-impedance can assess changes in gastric motility in individuals experiencing gastric stress. The manuscript add important information to the current knowledge.

Abstract

AIM: To ascertain whether carotid lesions are more prevalent in outpatients with incidental findings of nonalcoholic fatty liver disease (NAFLD) at abdominal ultrasound (US).

METHODS: One hundred and fifty-four consecutive outpatients (age range 24-90 years, both sexes) referred by general practitioners for abdominal US, and drinking less than 20 g alcohol/day, underwent carotid US for an assessment of carotid intima-media thickness (c-IMT) and carotid plaque prevalence. Hepatic steatosis, visceral fat thickness and subcutaneous fat thickness were also assessed at ultrasonography.

RESULTS: Higher c-IMT values were found in the presence of NAFLD (90 patients), even after adjustment for indices of general and abdominal obesity and for the principal cardiovascular risk factors (0.84 ± 0.10 mm *vs* 0.71 ± 0.10 mm, $P < 0.001$). The prevalence of carotid plaques was 57.8% in the patients with NAFLD *vs* 37.5% in the patients without this condition ($P = 0.02$). The adjusted relative risk of having carotid plaques for patients with NAFLD was 1.85 (95% CI: 1.33-2.57, $P < 0.001$).

INTRODUCTION

Hepatic steatosis is a feature of the metabolic syndrome^[1,2], a condition associated with a high cardiovascular risk and, in particular, an increased prevalence of carotid lesions^[3]. In the last few years several studies have assessed the association between hepatic steatosis and carotid atherosclerosis. Some case-controlled and cross-sectional studies^[4-8] showed a relationship between nonalcoholic fatty liver disease (NAFLD) and carotid intima-media thickness (c-IMT), an early independent predictor of cardiovascular events^[9-11]. In addition, other studies also showed a relationship with the presence of more advanced atherosclerotic lesions in the carotid arteries^[12-14]. However, the only study performed so far in the general population (4222 subjects) did not find any independent association between hepatic steatosis and c-IMT, showing an association with plaque prevalence only^[15]. The lack of concordance of these results may be related to non-standardized measurement methods and to the use of low frequency linear ultrasound (US) probes.

A possible relationship between hepatic steatosis and carotid lesions might have important practical consequences, considering the frequent incidental finding of hepatic steatosis in subjects undergoing abdominal US for any reason. In these subjects, an US

assessment of carotid arteries might also be advisable.

Thus, we have prospectively examined a random group of consecutive outpatients undergoing abdominal US to establish whether those with NAFLD had an increased prevalence of early or advanced carotid lesions. The study was performed following the Mannheim Consensus^[16], which proposed a standardized method for c-IMT measurement.

MATERIALS AND METHODS

Patients

From December 2006 to February 2007, we performed a cross-sectional study on 186 consecutive Caucasian outpatients, referred to our centre by general practitioners to perform an abdominal US assessment.

Body weight was measured in light clothing, without shoes, to the nearest 0.5 kg. Height was measured at the nearest 0.5 cm. Body mass index (BMI) was calculated as kilograms divided by square meters. Hypertension was diagnosed for values > 140/90 mmHg in non-diabetics and > 130/80 mmHg in diabetics, or when subjects were taking anti-hypertensive drugs^[17].

The design of the study did not allow any biochemical measurements, since many US assessments were performed in the late morning and some patients were not fasting. However, demographic characteristics (sex and age), some cardiovascular risk factors (smoking, history of diabetes and/or dyslipidemia) and possible causes of steatosis [alcohol consumption, anti-retroviral drugs, tamoxifen, amiodarone, corticosteroids, jejunal-ileal bypass, inflammatory bowel diseases, hepatitis C virus (HCV), and Human Immunodeficiency virus (HIV)] were collected in a structured questionnaire. The presence of dyslipidemia or diabetes was assumed if subjects were taking lipid-lowering/antidiabetic drugs, or positively answered the questions: “do you know you have high cholesterol or triglyceride values?” and “do you know you have diabetes?”. To quantify the number of cigarettes smoked, the total pack-years^[18,19] was calculated: (number of cigarettes smoked daily/20) x years of smoking. Smoking was categorized into the 3 following levels: never smoked, up to 20 pack-years and more than 20 pack-years. The cut-off value of 20 corresponded to the 75th percentile of pack-years distribution excluding non-smokers.

Thirty-two patients (17%) were excluded due to significant alcohol consumption (> 20 g/d, average weekly consumption). No other exclusion criteria were utilized. Thus, our study group consisted of 154 patients (75 male, mean age 59.6 ± 14.2 years, range 24-90 years) who underwent an abdominal US assessment for the following reasons: abdominal pain (44.2%), biliary/kidney stones (5.2%), follow-up of benign cysts of the liver (24.7%), kidney (15.6%) and ovary (3.2%), and for colorectal cancer (5.8%) and hepatocellular carcinoma (1.3%) surveillance.

Ultrasound evaluation

All subjects underwent abdominal and carotid US in

order to assess hepatic steatosis, visceral fat thickness (VFT), subcutaneous fat thickness (SFT) and c-IMT, and to ascertain the presence of carotid plaques. We used a Technos MP (Esaote, Italy), with convex probes (2.5-5 MHz) to scan the liver, and high frequency linear probes (7.5-13 MHz) to scan carotid arteries. All investigations were performed by two experienced operators (for abdominal and carotid US), blinded to each other regarding the respective US measurements and unaware of patients' clinical data.

Following the AGA classification of NAFLD^[20], steatosis was defined as the presence of diffuse hyperechoic echotexture, bright liver^[21], increased liver echotexture compared with the kidneys, vascular blurring and deep attenuation of the ultrasonic beam.

VFT and SFT were measured with the probe located 1 cm above the umbilicus, and defined as the distance between the linea alba and the anterior wall of the aorta, and as the distance between the skin and the linea alba, respectively^[22,23]. VFT and SFT US measurements correlate with visceral and subcutaneous fat areas as measured by CT scan^[24].

All measurements concerning c-IMT and plaques were performed according to the Mannheim Consensus^[16]. Longitudinal images of both the left and right side at the level of the common carotid artery, bulb and internal carotid were obtained in each patient. The arterial wall was assessed with a high frequency linear probe with appropriate focus, frame rate and gain setting to obtain a symmetrical brightness on the near and far wall.

c-IMT was measured in the far wall of the common carotid artery, along a 15 mm section free of plaque from the bifurcation, as the distance between the leading edges of the lumen-intima and media-adventitia interfaces. Maximum rather than mean values of c-IMT were considered, and edge detection was performed manually. c-IMT measurements from the left and right side were averaged. Previous studies have shown that “normal IMT values” vary according to age and atherosclerosis-related risk factors, ranging from 0.60-0.75 mm (30-49 years) to 0.79-0.86 mm (70-79 years)^[16]. Thus, values > 0.90 mm should be considered as increased in all cases.

A plaque was defined as a focal structure encroaching into the arterial lumen by at least 0.5 mm or 50% of the surrounding IMT value, or having a thickness > 1.5 mm as measured from the media-adventitia interface to the intima-lumen interface. The presence of plaques was evaluated in a 30 mm-long segment both in the left and right common carotid, internal carotid and bulb. Quality controls (phantom scans and proper US calibration) were performed monthly.

Statistical analysis

Analyses were performed using SPSS (14.0, Chicago, IL, USA) and Stata (8.0, StataCorp LP, Tx, USA) software. Quantitative characteristics were expressed as mean ± SD, or *n* (%). The study sample was divided into two groups according to the presence or absence of hepatic steatosis. Comparisons between groups were made by analysis of variance (ANOVA) and Kruskal Wallis' test for continuous

data, and using the χ^2 test with Yates correction for nominal data. ANOVA and Spearman's test were used to investigate the associations between c-IMT and demographic, clinical, anthropometrical and US characteristics. Multivariable analysis was performed with respect to c-IMT by means of analysis of covariance (ANCOVA). The mean scores of c-IMT, adjusted for the main risk factors (age, sex, BMI, diabetes, dyslipidemia, hypertension and smoking) were estimated in subjects with and without steatosis. To determine whether the adjusted mean scores of the two groups were significantly different, we tested the hypothesis that the steatosis coefficient was null using a multiple-partial F test. The assumption of parallelism was assessed by comparing a fitted model and expanded model with interaction terms with a multiple-partial F test. Adjusted R^2 was used to estimate the percentage of c-IMT variability explained by the model.

The adjusted relative risk of the presence of plaques associated with hepatic steatosis was assessed as prevalence ratio by the Cox regression model with equal time of follow-up assigned to all individuals and robust variance estimates, so that the calculated hazard ratio equaled the correct prevalence ratio^[25]. This method is preferred in cross-sectional studies with frequent outcomes, such as in this case, to avoid the overestimation of prevalence ratios obtained by odds ratios^[25]. Two-tailed tests were performed throughout and a P value < 0.05 was considered statistically significant.

RESULTS

Table 1 reports the clinical, anthropometrical and US characteristics of the population sample. No patients had chronic liver disease (except for two HCV-positive subjects), HIV-positivity, inflammatory bowel disease, abdominal surgery or received parenteral nutrition. None had taken drugs that could lead to hepatic steatosis.

Significantly higher BMI, VFT and SFT values were found in the subjects with NAFLD, who also reported a higher prevalence of dyslipidemia. Age, sex and smoking did not differ between the two groups (Table 2).

c-IMT was significantly associated with all cardiovascular risk factors, except for sex and SFT (Table 3). In univariate analysis c-IMT was also associated with NAFLD (Table 4).

In multivariable analysis, after adjustment for age, sex, BMI, smoking, hypertension, dyslipidemia and diabetes, c-IMT was still greater in the NAFLD group. The full regression model explained 46.4% of the variability of c-IMT.

The prevalence of plaques in the subjects with NAFLD was 52/90 (57.8%) *vs* 24/64 (37.5%) in those without ($P = 0.02$), which corresponded to a relative risk of 1.54; this risk even increased (1.85, $P < 0.001$) after adjustment for confounding factors (Table 4).

DISCUSSION

This study has shown that an incidental finding of NAFLD is associated with c-IMT and predicts the

presence of carotid plaques in outpatients undergoing abdominal US assessment.

An association between hepatic steatosis and c-IMT has already been reported in some previous studies^[4-8,12-15], and even in children^[26]. In 85 healthy, non-obese, male volunteers, Targher *et al*^[4] found a significant increase in c-IMT in the presence of non-alcoholic hepatic steatosis, and both conditions seemed to be due to visceral fat accumulation. In our sample, hepatic steatosis was independently associated with c-IMT, while VFT was associated with c-IMT in univariate analysis, but not in multivariable analysis. This may be explained by differences in sample composition and statistical analysis. Other studies that found an association between visceral obesity and c-IMT did not assess hepatic steatosis^[24,27,28]. One study reported that the association between NAFLD and c-IMT concerned only the patients with metabolic syndrome^[8]. On the other hand, two studies showed that the same relationship is absent,

or present but largely explained by insulin resistance, in type 2 diabetic patients^[29,30]. Finally, in the only large cross-sectional study to date, Volzke *et al.*^[15] described an independent association of hepatic steatosis with carotid plaques, but not with c-IMT. The discordance with our results might be due to the fact that these authors used low frequency (5 MHz) US probes, which are known to provide less accurate c-IMT measurements^[16].

In the present study, with high frequency probes and a standardized protocol to measure c-IMT, we found that NAFLD was independently associated with both c-IMT and the presence of carotid plaques. Defining the role played by NAFLD in the formation of initial or advanced carotid lesions is beyond the scope of this study, which was only designed to ascertain whether an incidental finding of NAFLD in outpatients may suggest the search for carotid lesions. The cross-sectional design, together with the impossibility of measuring metabolic variables such as serum lipids, glucose and insulin, and to exclude with certainty the presence of HCV or HIV infection, are the main limitations of this study, and impede any assessment of causality. The lack of metabolic measurements, together with the low frequencies, may also explain why the associations of NAFLD with diabetes and dyslipidemia were borderline or not significant.

In agreement with Targher *et al.*^[4] it seems likely that abdominal obesity may be the common antecedent of both NAFLD and carotid atherosclerosis, with the metabolic syndrome as an intermediate. However, we previously showed that endothelial dysfunction was more prevalent in patients with NAFLD than in controls matched for age and sex and with similar features of the

Table 4 Unadjusted and adjusted associations of NAFLD with c-IMT and presence of plaque

Variable	No NAFLD (n = 64)	NAFLD (n = 90)	P value ¹

metabolic syndrome^[31]. Moreover, in the present study the association between NAFLD and carotid lesions was independent from indicators of general and abdominal obesity, such as BMI, SFT and VFT. It thus seems possible that NAFLD may identify a subgroup of metabolic syndrome patients at higher cardiovascular risk.

In conclusion, hepatic steatosis is a marker of increased c-IMT and of the presence of carotid plaques in outpatients undergoing abdominal US. Any incidental US finding of hepatic steatosis should prompt medical practitioners not only to assess the metabolic risk, but also to consider the search for silent carotid lesions.

COMMENTS

Background

Nonalcoholic fatty liver disease (NAFLD) is often caused by abdominal obesity, which is also one of the main causes of insulin resistance and metabolic syndrome. The latter, in turn, is an important cardiovascular risk factor, and has been found to be associated with the presence of carotid atherosclerotic lesions. It is therefore understandable that an association may exist between NAFLD and carotid lesions.

Research frontiers

Although the association between NAFLD and carotid lesions is plausible and demonstrated, its practical implications have not been fully understood. This study highlights the possible relevance of these implications.

Innovations and breakthroughs

The association between NAFLD and early or advanced carotid lesions is not new, but in this study this association has been demonstrated for the first time in a random group of outpatients undergoing abdominal ultrasound. It is indeed in this type of patients that, not infrequently, a previously unknown hepatic steatosis is found. In the same patients an ultrasound assessment of the carotid arteries might prove particularly useful.

Applications

This study suggests that an incidental finding of hepatic steatosis may represent a new indication for performing an ultrasound assessment of the supra-aortic branches to search for silent arterial lesions.

Terminology

NAFLD is a general term including all cases of hepatic steatosis, with or without inflammation (steatohepatitis), which are not caused by alcohol abuse. It is often found associated with abdominal obesity and metabolic syndrome. Intima-media thickness (IMT) is the thickness of the two internal layers of the arterial wall, and is usually measured by ultrasound at the level of the common/internal carotid arteries. Its increase corresponds to the initial phase of the atherosclerotic process, and is associated with an increased cardiovascular risk.

Peer review

Although not novel, this is a well-conducted study that is reported quite concisely. The strengths over prior similar studies are the thorough design and the measurement of carotid intima-media thickness using the new Mannheim

consensus criteria. Moreover patients were enrolled consecutively, and pertinent demographic and clinical data were collected at the time of imaging, which was performed in a blinded fashion by experienced operators using high quality equipment.

Abstract

AIM: To evaluate the predictive value of tissue transglutaminase (tTG) antibodies for villous atrophy in adult and pediatric populations to determine if duodenal biopsy can be avoided.

METHODS: A total of 324 patients with celiac disease (CD; 97 children and 227 adults) were recruited prospectively at two tertiary centers. Human IgA class anti-tTG antibody measurement and upper

gastrointestinal endoscopy were performed at diagnosis. A second biopsy was performed in 40 asymptomatic adults on a gluten-free diet (GFD) and with normal tTG levels.

RESULTS: Adults showed less severe histopathology (26% vs 63%, $P < 0.0001$) and lower tTG antibody titers than children. Levels of tTG antibody correlated with Marsh type in both populations ($r = 0.661$, $P < 0.0001$). Multiple logistic regression revealed that only tTG antibody was an independent predictor for Marsh type 3 lesions, but clinical presentation type and age were not. A cut-off point of 30 U tTG antibody yielded the highest area under the receiver operating characteristic curve (0.854). Based on the predictive value of this cut-off point, up to 95% of children and 53% of adults would be correctly diagnosed without biopsy. Despite GFDs and decreased tTG antibody levels, 25% of the adults did not recover from villous atrophy during the second year after diagnosis.

CONCLUSION: Strongly positive tTG antibody titers might be sufficient for CD diagnosis in children. However, duodenal biopsy cannot be avoided in adults because disease presentation and monitoring are different.

INTRODUCTION

Serological assessment is the first step in celiac disease (CD)

diagnosis, and wide availability of serological antibodies allows for easy CD testing^[1]. IgA anti-endomysial antibodies (EMAs) are used as the “gold standard” for CD screening because of their high sensitivity and specificity. A high correlation between EMA titer and duodenal histopathology has also been reported^[2-4]. More recently, human anti-tissue transglutaminase (tTG) antibodies have also shown to be correlated with mucosal damage and are used widely in CD screening. However, neither antibody is detected in patients with minor mucosal changes (Marsh types I - II and IIIa) and IgA deficiency may be ruled out when using IgA type antibodies.

In the clinical setting, a patient with positive serological results requires duodenal biopsy to confirm CD diagnosis. However, a definitive diagnosis is only made when a response to gluten-free diet (GFD) is present^[5]. Furthermore, duodenal biopsy has several pitfalls: (1) at least four forced biopsies are needed to achieve good readability; (2) poorly oriented or inadequate biopsies may not be useful for diagnosis; and (3) it is an invasive procedure, both in children and adults. In the last few years, a more prominent role for a definitive diagnosis based solely on serological assays has been proposed. In pediatric populations, strongly positive tTG antibody results (≥ 100 U) showed a high specificity for Marsh type 3a or greater changes^[6,7]. This predictive value of high tTG antibody titers has also been reported in a retrospective cohort of adult and pediatric CD patients^[8]. Based on these studies, some authors have proposed to start a GFD for those patients with high tTG antibody levels and to perform a duodenal biopsy only when the patient's symptoms do not improve after a GFD.

The primary objective of the present work was to analyze the predictive value of a finding of high tTG antibody titers for the presence of duodenal atrophy at the time of diagnosis in adult and pediatric CD patients. In addition, the possibility that avoiding duodenal biopsy in these 2 groups of CD patients was explored.

MATERIALS AND METHODS

Ethical considerations

The study was approved by the Research and Ethical Committees of the participating hospitals.

Patients

Adult and pediatric CD patients were recorded prospectively from 2000 to 2008 at two tertiary centers in the North of Spain: Hospital Universitario Central de Asturias and Hospital de León. Pediatric and adult gastroenterology units at both centers have specialty CD clinics. Patients were referred from primary care settings or from other medical specialties for diagnosis and follow-up. Subjects were referred for evaluation of clinical complaints suggestive of CD, had positive family history or belonged to some high-risk group for CD.

None of the patients included had a previous diagnosis of CD before they attended at our clinic and were on a free diet (gluten containing diet). They were informed regarding the suspicion of illness and gave

informed consent to perform the complementary studies. The pediatric population included children ≤ 14 years and adults were ≥ 15 years old. A life time of 14 years was selected to discriminate children from adults because pediatric patients were below this age in our hospitals. The elapsed time between serological assay and duodenal biopsy was always < 8 wk.

The clinical spectrum was divided into two categories according to the main symptoms that led to diagnosis: (1) typical or classical, clinical malabsorption, chronic diarrhea or failure to thrive (children ≤ 2 years); and (2) atypical or oligosymptomatic, abdominal pain, iron deficiency anemia, chronic hypertransaminasemia, growth failure (children ≥ 3 years) or screening of risk groups or familial study.

Serology and human leukocyte antigen (HLA) genotype

Quantitative detection of human IgA class tTG antibody used the same commercial kits (Phadia Diagnostics, Uppsala, Sweden) in both centers. The manufacturer reference ranges for positive results were values > 10 U. From our experience, a cut-off value of 4 U showed a diagnostic value similar to IgA anti-endomysial antibodies^[9,10]. A cut-off level > 30 U tTG antibody was considered strongly positive for additional evaluations. IgA level was determined together with tTG antibodies and IgA deficiency patients were not included.

Adult CD patients were typed for HLA-DQ2 (DQA1*0501 and DQB1*0201 alleles) and DQ8 (DQA1*03 and DQB1*0302 alleles) by polymerase chain reaction. HLA genotype was performed only when duodenal biopsy showed inflammatory lesions (Marsh 1 and 2), in order to confirm CD diagnosis.

Histopathology

Biopsies from the distal duodenum (minimum of four forceps biopsies) were obtained by upper gastrointestinal endoscopy. Two pathologists experienced with CD diagnosis reviewed the histopathological specimens in each center and classified them according to Marsh's criteria as modified by Oberhuber *et al*^[11]. Type 3 specimens (any degree of villous atrophy) were considered characteristic of CD. Marsh 1 and 2 lesions were considered nonspecific, but consistent with CD diagnosis if serology was positive. When serology was negative, HLA-DQ was typed and symptoms evaluated with a GFD. Only those cases that were positive for HLA-DQ2 and DQ8, together with the disappearance of symptoms were included as definitive CD cases. Those cases with Marsh 3 lesions and negative serology were evaluated for an alternative diagnosis that could explain the histological abnormalities.

Follow-up

A second biopsy was performed in a selected cohort of 40 patients at Hospital de Leon to evaluate duodenal atrophy recovery. All of them showed, at the beginning, Marsh 3 lesions, and the second biopsy was performed during the second year after diagnosis, in patients taking a GFD, who were asymptomatic and with normal tTG antibody level.

Statistical analysis

Data were analyzed using SPSS version 13.0. Categorical

Figure 1 Serum tTG antibody level vs patient age. An inverse relationship was observed for the levels of serum tTG antibody with increasing patient age.

variables were expressed as numbers and percentages and quantitative variables as mean \pm SD. Categorical variables were analyzed by cross-tabulations using a χ^2 test with a continuity correction test when necessary. Differences between groups for quantitative variables were assessed by Student's *t* test or ANOVA. A non-parametric Mann-Whitney *U* test was used when the groups values deviated from a normal curve. Associations between quantitative variables were assessed by Pearson correlation test or Spearman rank correlation test. $P < 0.05$ was selected to reject the null hypothesis by two-tailed tests. Multivariate logistic regression was used to determine independent associations between histopathological and serological or clinical data. Analysis of receiver operating characteristics (ROC) curve was used to evaluate cut-off points for tTG antibodies as a predictor of Marsh scores.

RESULTS

Patient characteristics

A total of 324 patients who fulfilled the established CD diagnostic criteria comprised the study population. The pediatric population included 97 children (mean age: 4.5 years; range: 1-14 years) and 227 adult CD subjects (mean age: 39 years; range: 15-80 years). Female/male ratio was 1.7 for children and 2.6 for adults ($P = 0.06$).

A typical CD presentation was observed for 64/97 (66%) children *vs* 82/227 (36%) adults ($P < 0.0001$). Age-related differences in tTG antibody titers and histopathology were found. An inverse relationship of tTG antibody titers at diagnosis with increasing patient age was found (Figure 1). Higher levels were seen in children aged ≤ 2 years and lower titers in adults > 35 years. A trend towards less severe histopathology with increasing age at diagnosis was observed (Figure 2). Marked villous atrophy (Marsh 3b and 3c) was present in 63% of children *vs* 26% of adults ($P < 0.0001$).

Human recombinant IgA tTG antibodies and Marsh type

The levels of tTG antibody were correlated significantly with Marsh types in the entire population (Figure 3) ($r = 0.661$, $P < 0.0001$), and separately for the pediatric ($r = 0.633$, $P < 0.001$) and adult ($r = 0.574$, $P < 0.0001$) groups.

Figure 2 Histopathological differences between children and adults according to Marsh classification.

Figure 3 Serum tTG antibody levels vs Marsh classification. tTG IgA was significantly correlated with Marsh type.

Mean tTG antibody levels showed a progressive increase that was associated with higher Marsh types. Seventy-three patients showed Marsh types 1 and 2 (three were children and the remaining 70 were adults). In the pediatric group, only one Marsh type 2 patient showed tTG antibody titer < 30 U. Negative tTG antibody results were found for 46/73 (63%) Marsh types 1 and 2 CD subjects (all were adults). Twelve of 132 (9%) Marsh 3a CD patients had negative tTG antibody results (all were also adults). In contrast, none of the Marsh 3b and 3c patients had negative serology results. A definitive CD diagnosis was confirmed in this subgroup with minor mucosal changes and normal tTG antibody levels on the basis of clinical response to GFD, follow-up, and HLA-DQ2 or DQ8 compatibility.

Strongly positive tTG antibody titers (> 30 U) were present in 102 of 132 (77%) Marsh 3a patients, 79/95 (83%) Marsh 3b patients, and 24/24 (100%) Marsh 3c patients. Multiple logistic regression analysis showed that only the tTG antibody titer was an independent predictor for Marsh 3 lesions, but the clinical presentation type and patient age were not. As shown in Figure 4, at the cut-off point of ≥ 30 U tTG antibody, ROC curve analysis provided the highest area under the curve. Increasing this limit may increase the specificity and positive predictive value, but may decrease the area under the curve and sensitivity.

Duodenal biopsies can be avoided when strongly positive tTG antibody titer is found

If we had considered a cut-off point of 30 U tTG

Figure 4 ROC showing the maximum area under the curve for Marsh type 3 histology at cut-off point of 30 U tTG antibody.

Table 1 Biopsies that would be avoided by considering a cut-off point of 30 U tTG antibody in each Marsh type and age group (%)

	≤ 2 yr	3-14 yr	15-35 yr	> 35 yr
Marsh 1	0	0/2	0/9 (0)	0/27 (0)
Marsh 2	0	1/1 (100)	0/19 (0)	0/15 (0)
Marsh 3a	9/10 (90)	22/24 (92)	29/43 (67)	41/57 (72)
Marsh 3b	28/28 (100)	20/21 (95)	22/24 (92)	15/20 (75)
Marsh 3c	10/10 (100)	1/1 (100)	7/7 (100)	6/6 (100)
No. of biopsies avoided	47/48 (98)	44/49 (90)	58/102 (57)	62/125 (50)

antibody to predict atrophy (Marsh 3), we would have avoided 212/324 (65%) biopsies. However, if we had considered children and adults separately, 95% of children, but only 53% adults with true atrophy, would have avoided biopsy (Table 1). Furthermore, in 40 adults with CD with an initial biopsy of Marsh 3 type, a second biopsy was performed during the second year after diagnosis. Ten (25%) showed persistence of villous atrophy despite a correct GFD, being symptom free, and normalization of tTG antibody levels (Figure 5). One patient developed refractory type II CD after an initial biopsy compatible with Marsh type 3c^[12].

DISCUSSION

A positive correlation between tTG antibody serum level and duodenal histopathology has been described previously for pediatric and adult CD populations^[6,8,13]. Although some of these early studies employed guinea pig rather than human tTG as an antigen^[13,14], the higher sensitivity and specificity have rendered the latter as the worldwide standard.

The pathogenesis of gluten-induced small-intestinal changes and atrophy is not understood fully^[15]. It is considered to be T-cell mediated. However, recent *in vitro* studies^[16,17], and a study that reported anti-tTG2 IgA deposits in a morphologically normal jejunum before systemic detection of tTG antibody predicted overt CD with atrophy^[18], suggest a pathogenic role for antibodies.

The study population in the present study was selected on the basis of a prospective clinical CD diagnosis. However, previous similarly designed studies have used retrospective laboratory results to select positive tTG

Figure 5 Follow-up of adult patients with an initial Marsh type 3 biopsy. Repeated biopsy showed persistent atrophy in 25% of the cases.

levels^[6,8]. It is more likely that the results presented in our study are more easily generalized to other populations than those based on retrospective laboratory results. Furthermore, we also describe differences between adult and pediatric populations that were not analyzed in previous studies. These differences confirm our previously reported results in a single center CD population^[19]. The higher tTG antibody titers and the more severe Marsh grades that were observed consistently in the pediatric population are two important points to consider when looking for correlations and predictions. Although tTG antibody levels were correlated with duodenal histopathology in the adult and pediatric populations, the higher percentage of Marsh type 3 lesions observed in children makes a high antibody titer especially interesting for CD prediction in children.

The choice of an upper cut-off limit of tTG antibody to predict accurately CD or Marsh type 3 lesions may depend on the commercial kit used for tTG IgA ELISA. On the basis of previous experience^[9,10], we considered 30 U as the cut-off that resulted in the highest predictive value. The same cut-off value has also been adopted by other authors who have used the same commercial kit^[20]. This value showed the highest area under the ROC curve for Marsh type 3 histology in the entire CD population. Other series have considered a cut-off value > 100 U tTG antibody for a better Marsh type 3 prediction^[6-8]. The cut-off should probably be standardized in each laboratory based on experience with different kits.

Our series established CD diagnosis based on clinical judgment and expertise. This accounts for the high percentage of Marsh type 1 and 2 adult patients that were included, most of whom showed negative serology or low tTG antibody levels. North American Society for Pediatric Gastroenterology, Hepatology and Nutrition and European Society for Pediatric Gastroenterology, Hepatology and Nutrition guidelines indicate that Marsh type 1 or 2 changes are less specific or, perhaps, unlikely to be included in CD^[21]. However, in adult CD populations, atypical presentations with milder symptomatology and minor histopathology changes are described more frequently^[19,22]. There is evidence that CD patients who show only increased intraepithelial lymphocyte numbers, without mucosal atrophy, may show clinical features similar to those with Marsh type 3 lesions, and can also develop nutritional deficiencies and malabsorption^[23,24].

Any effort aimed at recognizing the presence of latent or occult minimally symptomatic CD would be the key reason to look for subtle abnormalities behind the symptoms^[25-27].

The primary reason to continue using biopsy as the definitive step in CD diagnosis is the possibility of false-positive serological results. All the cases in our series were diagnosed finally with CD, therefore, this possibility could not be explored. For some other series, a high positive tTG antibody result has not always been associated with a final CD diagnosis^[28]. However, these reports may be of questionable value to us for several reasons: (1) they were small series that lacked a prospective follow-up of tTG positive patients; (2) false-negative duodenal biopsies may be observed in CD (biopsy is not correctly performed, pathologist does not have experience with CD, or patchy histopathology lesions may be present); and (3) guinea pig tTG antibody, which lacks specificity, was used in some of the studies. Although tTG antibody positivity may appear in other gastrointestinal and liver inflammatory disorders, to date, strong positive results have not been described for such conditions^[29-32]. In addition, many of these patients may have coexisting CD^[33-35].

Based on the observed high predictive value of high tTG antibody titers in our series, 65% of the biopsies may not have been necessary. An important clinical difference was observed between adult and pediatric populations, in that only 53% of adults *vs* 95% of children would have properly avoided biopsy. The results for the adult population are concordant with a similar recent study^[20]. In 25% of our adult patients, mucosal recovery was not achieved in the second year after diagnosis on a GFD, despite normalization of serology and symptomatology. In fact, a slow mucosal recovery and persistent villous atrophy on a strict GFD in adult CD have been reported previously^[36-38]. Although asymptomatic, these patients without mucosal recovery may be at risk for subsequent severe complications^[36,39]. We believe that a follow-up biopsy may be important for detecting these individuals, and thus, should be mandatory. From our experience, this follow-up can be important for the correct identification of refractory CD.

Although we did not perform follow-up biopsies in children, the available results coincide with the idea that most pediatric CD patients recover from villous atrophy shortly after starting a GFD^[38,39]. Thus, for children it would be less important to perform an initial biopsy, as histological follow-up appears not to be necessary.

Overall, our results confirm the high diagnostic accuracy and predictive value of serological tests. We suggest that because of the high predictive value of tTG antibody for mucosal atrophy, duodenal biopsy may not always be necessary. In children, CD diagnosis may only require clinical and serological features, thus avoiding an invasive procedure, and starting an earlier GFD. In contrast, for adults, CD presentation and monitoring are different, thus rendering necessary a histopathological confirmation in all the cases at diagnosis, and in some selected cases at follow-up on a GFD. Future CD guidelines may take into account these age-related differences.

COMMENTS

Background

Duodenal biopsy remains the gold standard for celiac disease (CD) diagnosis. However, it has several pitfalls and requires an invasive procedure in children. In the past few years, a more prominent role for a definitive diagnosis based solely on serology has been proposed. The predictive value of high levels of anti-tissue transglutaminase (tTG) antibodies has also been reported in retrospective CD cohorts. Based on these studies, some authors have proposed to start a gluten-free diet (GFD) for those patients with high tTG antibody levels, without duodenal biopsy.

Research frontiers

There is no agreement to start a GFD without biopsy to confirm mucosal atrophy. There are age-related differences in CD diagnosis that may be taken into account to evaluate the predictive value of tTG antibody for mucosal atrophy.

Innovations and breakthroughs

This study revealed that tTG antibody is correlated with Marsh types, and is an independent predictor for Marsh type 3 lesions in children and adults. However, adults with CD showed less severe atrophy and lower tTG antibody titers than children. Moreover, a significant proportion of adult patients did not recover from atrophy during follow-up. These age-related differences have not been defined clearly in previous studies, and they are associated with the predictive value of tTG antibody for duodenal atrophy.

Applications

These results suggest that high tTG antibody titers may be sufficient for CD diagnosis in children, but a biopsy may be necessary to diagnose and monitor adults patients. Starting a GFD without a confirmatory biopsy may be possible in selected cases.

Terminology

CD is characterized by intolerance to ingested gluten in susceptible individuals. Immunologically mediated inflammation of the small intestine mucosa and the consequent atrophy is now the main point for diagnosis. Serological testing is the first step for diagnosis and tTG antibody is available widely as a screening method.

Peer review

In this interesting study, the authors investigated the predictive value of tTG antibody (cut-off value 30 U) for establishment of villous atrophy in children and adults suffering from CD. The serum parameter was correlated with histopathological findings in duodenal biopsies. The authors demonstrated that disease presentation and monitoring are different between children and adults. The increase in tTG antibody has a better predictive value in children. In conclusion, the authors recommend histopathological confirmation of tTG antibody serum levels in all adults, whereas in children with > 30 U tTG antibody, histopathological confirmation can be omitted.

Abstract

AIM: To assess the prevalence of portal hypertension (PH) related colorectal lesions in liver transplant candidates, and to evaluate its association with the severity of PH.

METHODS: Between October 2004 and December 2005, colonoscopy was performed in 92 cirrhotic liver transplant candidates. We described the lesions resulting from colorectal PH and their association with the grade of PH in 77 patients who underwent measurement of hepatic venous pressure gradient (HVPG).

RESULTS: Mean age was 55 years and 80.7% of patients were men. The main etiology of cirrhosis was

alcoholism (45.5%). Portal hypertensive colopathy (PHC) was found in 23.9%, colonic varices in 7.6% and polyps in 38% of patients (adenomatous type 65.2%). One asymptomatic patient had a well-differentiated adenocarcinoma. The manifestations of colorectal PH were not associated with the etiology of liver disease or with the Child-Pugh grade. Ninety percent of patients with colopathy presented with gastroesophageal varices (GEV), and 27.5% of patients with GEV presented with colopathy ($P = 0.12$). A relationship between higher values of HVPG and presence of colopathy was observed (19.9 ± 6.2 mmHg vs 16.8 ± 5.4 mmHg, $P = 0.045$), but not with the grade of colopathy ($P = 0.13$). Preneoplastic polyps and neoplasm ($P = 0.02$) and spontaneous bacterial peritonitis ($P = 0.006$) were more prevalent in patients with colopathy. We did not observe any association between previous β -blocker therapy and the presence of colorectal portal hypertensive vasculopathy.

CONCLUSION: PHC is common in cirrhotic liver transplant candidates and is associated with higher portal pressure.

Portal hypertensive colopathy is associated with portal hypertension severity in cirrhotic patients. *World J Gastroenterol* 2009; 15(38): 4781-4787 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4781.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4781>

INTRODUCTION

Orthotopic liver transplantation (OLT) is an effective therapeutic approach to chronic end-stage and acute liver

diseases^[1]. Portal hypertension (PH)-related lesions in the gastrointestinal tract of cirrhotic patients are frequent. In the evaluation of liver transplant candidates these lesions must be taken into account so that appropriate treatment can be administered before OLT. Although gastroscopy is a well established technique for the detection of upper PH-related lesions in liver transplant candidates, colonoscopy is not performed routinely in all centers.

In OLT candidates, it is important to identify and prevent the risk of bleeding from gastroesophageal varices (GEV) and portal hypertensive gastropathy. Furthermore, although colorectal lesions are a source of acute and chronic bleeding, they have received little attention in the literature. Colonoscopy allows us to evaluate the presence of PH-related lesions such as portal hypertensive colopathy (PHC), colorectal varices and hemorrhoids^[2,3]. The variability of the results of previous studies does not allow us to define with any certainty the prevalence of these lesions. Thus prevalence ranges from 3%^[4] to 84%^[5] for PHC, and from 3.6%^[6] to 89%^[7] for colorectal varices and from 22%^[8] to 79%^[9] for hemorrhoids.

The association between portal hypertensive vasculopathy and the severity of PH has been evaluated elsewhere. Four studies have evaluated this association by measuring indirect parameters of PH^[10-13], while four other authors have evaluated it using the gold-standard measurement of PH grade, that is, the hepatic venous pressure gradient (HVPG). Nevertheless the results are contradictory^[9,14-16].

On the other hand, recent studies have demonstrated an increase in the risk of adenomatous polyps and neoplasm in liver transplant recipients, so the detection of these lesions prior to OLT is essential^[17]. The presence of these lesions has been reported to be as high as 42%. The question is that whether colorectal PH-related lesions influence the development of polyps is unknown.

The objectives of the present study were to define the prevalence of lower gastrointestinal abnormalities detected as a result of an endoscopic screening of cirrhotic patients being evaluated for liver transplantation, and to relate the occurrence of these lesions to the degree of PH measured using the HVPG, and the severity of liver disease.

MATERIALS AND METHODS

Patients

The study was designed and performed according to the principles of the Declaration of Helsinki, and informed consent was obtained from each patient. The protocol was reviewed and approved by the Hospital Ethics Committee.

Between October 2004 and December 2005, one hundred and forty-nine patients were considered for OLT due to acute or chronic decompensated liver

disease. One hundred and twenty-one patients had liver cirrhosis. Of these, 92 were evaluated by colonoscopy as a part of pre-OLT screening for colorectal cancer or preneoplastic manifestations. The selection criteria for colonoscopy were age over 50 years and/or clinical symptoms such as abdominal pain or rectal bleeding, or family history of colorectal cancer. Diagnosis of cirrhosis was based on histology assessment or a combination of clinical, laboratory and ultrasonography findings. The severity of cirrhosis was classified according to the Child-Pugh classification. Four patients were excluded due to the presence of an implanted permeable transjugular intrahepatic portosystemic shunt before evaluation for OLT. Therefore the final cohort consisted of 88 patients. Patients with previous abdominal or pelvic surgery, hemorrhoidectomy or a previous history of malignancy (except primary liver cancer) and those who refused to undergo colonoscopic examination were not included in the study. Of the 88 patients evaluated, 50 (56.8%) were receiving non-selective β -blockers as primary or secondary prophylaxis for PH bleeding, and 12 (13.6%) had received previous endoscopic band ligation (EBL).

Information on epidemiological features, etiology of cirrhosis, Child-Pugh grade, blood test results, presence of hepatocellular carcinoma, clinical manifestations of PH [hepatic encephalopathy, ascites, spontaneous bacterial peritonitis (SBP), and variceal bleeding], and upper PH-related endoscopic findings (GEV, portal hypertensive gastropathy and duodenopathy) were analyzed. In addition, the severity of PH was quantified by measuring portal pressure.

Endoscopic examinations

An upper gastrointestinal endoscopy was performed in all patients to evaluate the presence of GEV, portal hypertensive gastropathy and duodenopathy. All colonoscopies were performed by well-experienced endoscopists who were unaware of the diagnosis and the severity of liver disease using a Pentax EC-3840LK model videoscope (Hoya Corporation, Tokyo, Japan). After an overnight fast, patients were administered a polyethylene glycol electrolyte lavage solution (Solución Evacuante Bohm®; Laboratorios Bohm S.A., Madrid, Spain) as a bowel-cleansing regimen. Colorectal portal hypertensive vasculopathy lesions included internal or mixed hemorrhoids, colonic varices and PHC. Hemorrhoids were described as vascular swellings affecting the internal and external arteriovenous vascular plexuses of the anal canal and were classified as external, internal or mixed (Figure 1A). Colonic varices were bluish, dilated, tortuous submucosal veins extending from the anal canal above the level of the hemorrhoids into the colon (Figure 1B). According to previous reports^[14], PHC was considered to be present if there were nonspecific inflammatory changes, resembling the lesions found in subjects with inflammatory chronic colitis and defined as granularity, diffuse hyperemia,

Figure 1 Endoscopic portal hypertension-related lesions. A: Mild portal hypertensive colopathy; B: Severe portal hypertensive colopathy; C: Colonic varix; D: Hemorrhoids.

edema and friability in mild grades (Figure 1C), and lesions such as vascular ectasias, angiodysplasia, arterial spider, and diffuse cherry red spots, in severe grades (Figure 1D). Arterial spider-like lesions are defined as the presence of a central arteriole, which blanches with pressure for a forceps biopsy and from which numerous small vessels radiate. The angiodysplasia-like lesions are defined by an irregular margin with a fern-like pattern and sometimes a pale halo around them, whereas the cherry red spots-like lesions are defined by the presence of a red spot in the colonic mucosa, similar to that seen in the gastric mucosa in patients with portal hypertensive gastropathy. Polyps and neoplasms were also described. Polyps were classified as hyperplastic or adenomatous.

Hemodynamic measurements

A splanchnic hemodynamic study with portal pressure measurement was performed in 77 of 88 patients. The time between the colonoscopy and the hemodynamic study was no more than 1 mo in all cases. The hemodynamic study was not performed in 11 patients because of previous clinical, laboratory or imaging findings that contraindicated the OLT. In all cases if the patient had significant ascites, a total paracentesis was performed before the study to avoid interference in the measurement of HVP, to diminish complications, and to make catheterization easier. After an overnight fast, the patient was prepared for the study in the supine position. Under local anesthesia, a vascular introducer sheath (Medikit Co. Ltd., Tokyo, Japan) was in-

serted into the right internal jugular vein. Then, under fluoroscopy, a 7F balloon catheter (Cordis Corporation, Miami, Florida, USA) was placed in the right hepatic vein to measure free and wedged hepatic venous pressure (FHVP and WHVP) as described previously^[18]. The wedged position was confirmed by the absence of reflux after injection of 2 mL of contrast medium, and FHVP was measured in the hepatic vein with the tip of the catheter just beyond the junction with the inferior cava vein. The HVP was calculated as WHVP minus FHVP. PH was defined as the presence of an HVP value > 5 mmHg. All hemodynamic measurements were performed using a previously calibrated strain-gauge transducer and recorded at least in duplicate. Two independent investigators who were unaware of the diagnosis, evaluated the tracings from the hemodynamic studies.

Statistical analysis

Quantitative variables were expressed as the mean \pm SD or median (range) if parametric or non-parametric, respectively, and qualitative variables were expressed as frequencies. Categorical and continuous variables were compared using the χ^2 and the Student's *t* test or the Mann-Whitney *U* test respectively, when appropriate. One-way analysis of variance (ANOVA) with polynomial contrasts was applied. A two-tailed 0.05 significance level was used in all statistical tests. Statistical analysis was performed using the Statistical Program for the Social Sciences version 13.0 (SPSS® 13.0; SPSS Inc, Chicago, Illinois, USA).

RESULTS

Clinical characteristics and endoscopic findings

The clinical characteristics and hemodynamic data of the study population are shown in Table 1. Men comprised 80.7% of the sample and the median age was 55 (29-69) years. The main etiologies of cirrhosis were alcohol consumption (45.5%) and hepatitis C virus infection (31.8%). Most patients were Child-Pugh grade B-C (80.7%) and the HVPG tended to be high in relation to the severity of cirrhosis (Child-Pugh A 15.3 ± 6.6 mmHg *vs* Child-Pugh B-C 18.2 ± 5.4 mmHg, $P = 0.07$).

The colonoscopy revealed no lesions in 20.7% of the patients. The endoscopic PH-related lesions of the 88 patients evaluated are shown in Table 2. PHC was discovered in 23.9% of patients, colonic varices in 8% and internal or mixed hemorrhoids in 52.3%. No differences were observed between the colorectal manifestations of PH and the etiology of liver cirrhosis, Child-Pugh grade, history of ascites, hepatic encephalopathy, hepatocellular carcinoma or levels of serum albumin, total bilirubin, alanine aminotransferase, carcinoembryonic antigen, international normalized ratio or platelet count. Instead, we found a significant association between a history of SBP and PHC (45.5% *vs* 16.7%, $P = 0.006$).

Association between upper and lower gastrointestinal PH-related lesions

Table 3 compares clinical and endoscopic findings between the PHC and non-PHC groups. As for the lower and upper gastrointestinal tract, we found no association

Table 2 Portal hypertension-related endoscopic variables

^a $P < 0.05$ (ANOVA) *vs* PHC group. PHC: Portal hypertensive colopathy; PH: Portal hypertension.

between PHC and portal hypertensive gastropathy or duodenopathy. Of the patients with PHC, 90.5% had GEV. On the other hand, colonoscopy revealed that 27.5% of patients with GEV had PHC compared with 10.5% of patients without GEV ($P = 0.12$). We did not find an association between colonic varices and GEV.

Clinical implication of the presence of gastrointestinal PH-related lesions

Anemia is one of the most important consequences of chronic bleeding from PH-related lesions. We did not observe differences in hemoglobin values between patients with and without PHC (11.8 ± 2.6 g/dL *vs* 11.8 ± 2.4 g/dL, $P = 0.93$). There were also no differences in PHC grade (11.8 ± 2.6 g/dL *vs* 11.7 ± 2.7 g/dL, $P = 0.94$), although an association was found between the presence of anemia and portal hypertensive gastropathy (11.2 ± 2.4 g/dL *vs* 12.4 ± 2.3 g/dL, $P = 0.022$).

Relation between HVPG and colorectal PH-related lesions

In the whole cohort, a greater mean HVPG was found in patients with PHC than in those without (19.9 ± 6.3 mmHg *vs* 16.8 ± 5.5 mmHg, respectively, $P = 0.045$) (Figure 2), but it was not associated with PHC grade (mild PHC 19.8 ± 7.3 mmHg *vs* severe PHC $20.2 \pm$

Figure 2 Comparison of HVP between PHC and non-PHC groups.

4.1 mmHg, $P = 0.91$). When we analyzed only the patients who had not previously been treated with non-selective β -blockers we found a higher association between the presence of PHC and HVP (22.9 \pm 6.7 mmHg *vs* 16.0 \pm 5.2 mmHg, $P = 0.007$).

HVP did not differ significantly between patients with or without colonic varices (17.8 \pm 3.2 mmHg *vs* 17.5 \pm 5.9 mmHg, respectively, $P = 0.91$) or with or without hemorrhoids (17.9 \pm 5.7 mmHg *vs* 17.1 \pm 5.8 mmHg, respectively, $P = 0.54$).

Influence of treatment of PH in the development of colorectal PH-related lesions

We did not find a significant association between treatment with non-selective β -blockers and the presence of PHC (24% *vs* 23.7%, $P = 0.97$) or colonic varices (10% *vs* 5.3%, $P = 0.69$). We could not demonstrate an influence of previous EBL in the development of these lesions.

Relation between PHC and colonic polyps and neoplasia

The prevalence of colonic polyps in our patients was 39.7% (35/88). Sixty-five percent of patients with polyps had adenomas and 30.4% had hyperplastic polyps. Six patients (40%) with adenomatous polyps presented with mild dysplasia. One asymptomatic patient (1.1%) had a well-differentiated adenocarcinoma. When we analyzed the association between PHC and polyps and/or adenocarcinoma we found that 42.9% of PHC patients had preneoplastic lesions or neoplasms compared with 10.4% of non-PHC patients ($P = 0.02$) (Table 3).

DISCUSSION

In the present study we suggest that colorectal endoscopic evaluation of OLT candidates can reveal findings that are directly related to the PH grade. It is reasonable to think that PH causes hemodynamic changes not only in the upper gastrointestinal tract but also in other areas, especially in the colon, a condition that is now receiving increasing attention in the literature. In our study, the prevalence of PHC was 23.9%, similar to that found previously^[6], although the prevalence is highly variable. These discrepancies may be due to the lack of

consensus on the endoscopic appearance of PHC, unlike portal hypertensive gastropathy, in which there does appear to be a certain degree of consensus. In our study we have chosen a simple classification of PHC: mild and severe grades. The reason for these categories is the higher risk of chronic or acute bleeding for severe grade lesions and their importance in clinical management and therapeutic options.

Several studies have demonstrated the relationship between PHC and indirect measurements of PH, for example low platelet counts^[10], the presence of portal hypertensive gastropathy^[11,13] or large esophageal varices^[11,12]. In our study we found an association between PHC and GEV, although it was not statistically significant.

Our main objective was to assess the association between PH vasculopathy and the severity of PH. We found a clear association between PHC and higher values of HVP, with a higher PH grade in the PHC group. This difference was maintained in patients who were not treated with non-selective β -blockers, avoiding possible bias from treatment influence. Few studies have compared this association with a hemodynamic measurement of PH. Sugano *et al.*^[15] and Yamakado *et al.*^[16] also demonstrated, as we did, an association between PHC and higher values of HVP. Unlike Sugano *et al.*^[15], we found that the presence of higher HVP values was related to the existence of PHC but not to PHC grade. Chen *et al.*^[14] also studied the relationship between colorectal portal hypertensive vasculopathy and PH severity, although they did not find a relationship between them.

We found no association between colorectal manifestations of PH and etiology of liver disease, Child-Pugh grade or previous history of hepatic decompensation, results which are consistent with those of some authors^[9,15]. Furthermore, like other authors, we were unable to demonstrate a relationship between HVP and colonic varices^[14,15]. However, we did find a statistical association between a history of previous SBP and the presence of PHC. In this sense, the main pathogenic mechanism of SBP, that is bacterial translocation, may be favoured by increased intestinal permeability at this site due to mucosal damage and vasodilatation in PHC.

The clinical implications of the presence of PH lesions and the therapeutic approach to chronic or acute bleeding have not been fully evaluated. Although the cross-sectional design of our study does not allow us to analyze adequately the effect of β -blockers on the outcome of these lesions, we observed no relationship between these drugs and PHC or colonic varices. In this sense, only two studies have evaluated the influence of β -blockers and nitroglycerin on the outcome of PHC, demonstrating that PHC improves after treatment with these drugs^[11,15]. Although there are no evidence at the moment that these treatments improve anemia or recurrent bleeding from PHC, the lesser presence and grade of these lesions should improve the clinical status of the patients, so the classification of PHC used in

our study is adequate, which is consistent with overall thinking in daily clinical practice.

A remarkable association was observed between preneoplastic lesions, neoplasms and PHC. In our study, the prevalence of polyps was 38%. Many of these were adenomatous (65.2%) and one adenocarcinoma was discovered. This association has not been previously described, suggesting that involvement of the colonic mucosal microvasculature in PHC could stimulate the proliferation of polyps, although the pathologic mechanisms are unknown and any explanation at this time would be highly speculative.

Although the best indicator of PH grade is the direct measurement of portal pressure by portal vein catheterisation, the difficulty and the morbidity of the procedure impede the habitual performance of this technique, particularly in patients with cirrhosis with altered coagulation factors and risk of complication. It is well documented that WHVP correlates well with direct portal pressure measurement and the agreement is sufficiently good to use it as a surrogate measurement of PH^[19], and it has been demonstrated in patients with hepatitis C^[20] and hepatitis B-related cirrhosis^[21]. In our study all the patients were cirrhotic and nearly 90% had viral or alcoholic etiology. In spite of this, the HVP is less accurate in liver diseases with a presinusoidal component and in our study this situation may occur only in a few patients.

Finally, our sample size was probably too small to obtain sufficient statistical power to extrapolate the results, although we do report the largest number of patients to date. Likewise, the same team of gastroenterologists were responsible for the endoscopic procedures and reporting and for reviewing the photographs taken during the explorations, thus ensuring the reliability of our data. However, the cross-sectional design of the study prevents us from evaluating the influence of β -blockers on the outcome of the lesions. Future prospective studies must take this into account if they are to improve the quality of life of these patients.

In conclusion, we demonstrated a high prevalence of colorectal hypertensive vasculopathy lesions in this cohort of patients, and a higher severity of PH with increased HVP values in patients with PHC, although we were unable to show an effect on PHC grade. Previous treatment with β -blockers does not appear to affect the outcome of PHC.

ACKNOWLEDGMENTS

We are indebted to Mr. Tom O'Boyle for his expert management of the manuscript.

COMMENTS

Background

Preoperative liver transplantation evaluation is performed to exclude contraindications and end-stage liver disease must be completely studied. Colonoscopy allows researchers to evaluate the presence of portal hyperten-

sion (PH)-related lesions such as portal hypertensive colopathy (PHC), colorectal varices and hemorrhoids. PHC is an area of increasing interest but little is known about its relation with the severity of PH. The measurement of the hepatic venous pressure gradient (HVPG) is the gold standard of PH grade.

Research frontiers

The relation between PHC and the severity of PH is not well established. In this study, the authors demonstrate that a higher value of HVPG is associated with the presence of PHC but not with other manifestations of PH-related colorectal lesions.

Innovations and breakthroughs

Previous reports remark on the association between PHC and the severity of PH with indirect measurements, and some studies with the gold standard of the HVPG, with contradictory results. The present study is the biggest cohort of patients in which HVPG measurement is performed to demonstrate this association.

Applications

Their study demonstrates that this association reflects a broad spectrum of lesions covering the whole gastrointestinal tract related with PH, so this supposes an advance in the knowledge of these lesions. Treatment of PH-related colorectal lesions is not well established and it must be elucidated.

Peer review

The authors exposed cirrhotic candidates for liver transplantation in which colonoscopy was performed, searching the association between PH-related colorectal lesions and the severity of PH measured by HVPG. The article is well written and the contents are credible.

Kupffer's cell hyperplasia were higher ($P < 0.05$) in the study groups than the control group. However, there were no significant differences ($P > 0.05$) between HOCM (2, 2p) and iso-osmolar CM (3, 3p) groups. Bile duct proliferation and regeneration in the Urographin® groups (2, 2p) were significantly higher ($P < 0.05$) than the Visipaque® groups (3, 3p) or the control groups (1, 1p). Although CM caused minor damage to the pancreas, there were no statistically significant differences ($P > 0.05$) between the groups. Application of the CM with pressure did not cause additional damage to the HPB system.

CONCLUSION: Iso-osmolar, non-ionic CM could be more reliable than the ionic HOCM, whereas the application of pressure during the CM application had no effect on the HPB system.

Abstract

AIM: To determine the effects of high osmolarity contrast media (HOCM) and iso-osmolar contrast media (CM) application, with or without pressure, on hepato-pancreato-biliary (HPB) system.

METHODS: Sixty rats were divided into six equal groups as follows: Group 1: (0.9% NaCl, control), Group 2: (diatrizoate meglumine Na, ionic HOCM, Urographin®), Group 3: (iodixanol, iso-osmolar non-ionic CM, Visipaque®); each of which was applied without pressure, whereas the animals of the remaining three groups (1p, 2p, 3p) were subjected to the same CM with pressure. We performed a duodenal puncture and introduced a catheter into the ampulla. After the catheterization, 0.2 mL CM or 0.9% NaCl was injected with or without pressure. Blood samples were taken for biochemical evaluations. The histopathological examinations of liver, common bile duct, and pancreas were performed.

RESULTS: There were no significant differences between the six groups for blood amylase, alanine aminotransferases, aspartate aminotransferases, bilirubin levels ($P > 0.05$). Alkaline phosphatase and γ glutamyl transaminase levels were higher ($P < 0.05$) in the Urographin® groups (2, 2p) than the Visipaque® groups (3, 3p), or control groups (1, 1p). Hepatocyte necrosis, portal area inflammation, and

INTRODUCTION

Contrast media (CM) are commonly used in diagnostic imaging methods such as, computerized tomography, magnetic resonance, angiography, cardiac catheterization along, and imaging of the hepato-pancreato-biliary (HPB) system using endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography, and intra- and post-operative cholangiography^[1].

ERCP is both a diagnostic and therapeutic procedure that has been used for 35 years. Complications of diagnostic ERCP include acute pancreatitis, cholangitis, and cholecystitis^[2-4]. Pancreatitis is a major cause of

the morbidity and the mortality related to ERCP^[2-6]. Hyperamylasemia (biochemical pancreatitis) and clinical pancreatitis are seen 20%-70% and 1.8%-6.4% of cases, respectively^[7-9]. It is caused by technical reasons such as the type of CM, frequency of application, fast and pressured injection of the CM, trauma of the sphincterotomy, and the type of diathermy^[5,10-12]. It is also affected by previous history of pancreatitis, the degree of experience of the endoscopist, and the amount of the injection^[2-5]. Intra- and extra-hepatic bile ducts, along with the pancreatic duct, are imaged during ERCP. Acute cholangitis is another serious complication of ERCP^[3-5]. Most studies on the adverse effects of CM used in ERCP have focused primarily on post-ERCP pancreatitis (PEP). However, the biliary epithelial cells are also exposed to CM during ERCP. Inflammation of the biliary tree, including acute cholangitis and cholecystitis, is another important complication of diagnostic ERCP^[3-5].

CM can be classified in two groups depending on their ionic properties (ionic or non-ionic) and three types according to their osmolality (high, low or iso-osmolar)^[13]. The effect of a CM on image quality during ERCP depends on its density, viscosity, and osmolality. The image quality appears to be similar when comparing high osmolality contrast media (HOCM) and low osmolality contrast media (LOCM)^[14]. The osmolality and the ionic nature of the CM are believed to be the major factors responsible for the adverse reactions^[13]. Systemic adverse reactions of CM used in ERCP could be characterized as idiosyncratic (anaphylactic; nasal congestion, laryngeal edema, and bronchospasm) or non-idiosyncratic (dose-dependent; renal tubular damage, vascular damage, cardiac depression, and arrhythmia)^[13,15]. The prevalence of CM reactions is lower with LOCM (1%-3%) than with HOCM (5%-12%). Fatal reactions are rarely seen, and there is no difference in mortality rates between the two types^[15-17]. An ideal contrast agent must be water soluble, biologically inert, of low viscosity, and should be thermally and chemically stable. It must also have lower or the same osmolality as human serum, be selectively excreted (*via* the kidney), and be safe and low cost^[18].

The osmolality of CM has been implicated as a contributing factor for the development of PEP. However, results of clinical trials are conflicting^[19]. One randomized crossover study^[20] and four randomized control trials^[10,21-23] have suggested a benefit from LOCM, while 10 others^[9,14,24-31] have not. Animal studies examining pancreatic duct epithelium damage due to CM have also been conflicting. In cats, Bub *et al.*^[32] demonstrated morphologic changes in the pancreatic duct epithelium shortly after injection with CM. Less damage was noted after injection with LOCM. However, Saari *et al.*^[33] demonstrated less acinar destruction with HOCM in pigs. Pfau *et al.*^[34] noted that there were no differences between HOCM and LOCM on pancreatic histology in a canine model.

Damage is caused by technical reasons, such as the type of CM, frequency of application, and the fast and

pressured injection of the CM. Haciahmetoglu *et al.*^[35] evaluated how intraductal pressure and the use of a contrast agent affect the development of pancreatitis after ERCP. The results of their study^[35] suggested a contrast agent should be administered under low pressure when it is needed.

In the present study, the effects of diatrizoate meglumine Na (ionic HOCM, Urographin®) and iodixanol (iso-osmolar, non-ionic CM, Visipaque®) application with or without pressure on the HPB system were determined.

MATERIALS AND METHODS

Ethics

This experimental study was performed in accordance with the guidelines for the care and use of laboratory animals established by the Ethics Committee of the Cumhuriyet University.

Animal studies

Sixty, three-month-old wistar male rats weighing 250 ± 50 g were used in the present study. The randomly selected animals were supplied by the Animal house of the Faculty of Medicine, Cumhuriyet University. Rats were randomly divided into six equal groups: Group 1: (control, 0.9% NaCl), Group 2: (diatrizoate meglumine Na, Urografin®, ionic HOCM), Group 3: (iodixanol, Visipaque®, iso-osmolar, non-ionic CM); CMs were used without pressure. The same CMs were applied with pressure in the remaining three groups (1p, 2p, 3p). Rats were anesthetized by an intramuscular injection of ketamine HCL 40 mg/kg body weight (Ketalar: Parke-Davis Eczacıbaşı, Istanbul, Turkey) and xylazin 5 mg/kg body weight (Rompum: Bayer Leverkusen, Germany). All animals were allowed to breath spontaneously during the experiments. After the abdomen was shaved and cleaned with povidone iodine, a 2 cm midline laparotomy was carried out, and the intestines were covered with sterile gauze pads soaked with isotonic saline at 37°C to minimize evaporation from the tissue. Body temperature was maintained between 36 and 38°C using a heating lamp. In addition, 5 mL Ringer's lactate solution was given subcutaneously to prevent dehydration of the animals during the experimental period. After making a midline abdominal incision, we performed a duodenal puncture by a sharp pointed lancet. We introduced a catheter (0.7 mm diameter) into the ampulla. After catheterization, 0.2 mL CM or 0.9% NaCl was injected with or without pressure. The catheter was then withdrawn. The duodenal puncture was closed by only one suture with an 8-0 polypropylene (prolene). There were no operative and post-operative mortalities. On the second day, blood samples were taken for biochemical assays, including blood amylases, alanine aminotransferases (ALT), aspartate aminotransferases (AST), bilirubin levels, alkaline phosphatase (ALP), and γ glutamyl transaminase (GGT). Animals were kept in separate cages for 15 d, during that time they were fed with rat chow *ad libitum* and tap water, and kept at room temperature (18-20°C). Fifteen days later, all rats were

killed (in a humanitarian way by cervical dislocation) under anesthesia, and a second laparotomy was performed. The liver, pancreas, and the extra hepatic biliary tracts were resected *en bloc* and fixed in 10% formalin solution. For microscopic examination, tissues were fixed in formalin, and embedded in paraffin.

Histopathological evaluation

Tissue sections from each block were stained with hematoxylin/eosin for histopathological evaluation. We performed histopathological examination of the liver to assess the following: (1) lesions of the lining of the portal and centrilobular areas; (2) lesions of the hepatocytes (focal necrosis, regeneration); (3) biliary duct proliferations; (4) Kupffer's cell hyperplasia; (5) periductal fibrosis; (6) sinusoidal lesions (distention, fibrosis); (7) parenchymal necrosis; and (8) biliary duct inflammation.

Histopathological examination of the common bile duct was performed in order to assess inflammation, fibroblastic proliferation, and necrosis. We examined the pancreas specimens histopathologically in order to assess inflammation, hemorrhage, and necrosis. The histopathological alterations were evaluated by one pathologist who was blinded as to which group the specimen belonged.

Statistical analysis

All data were analyzed using Kruskal-Wallis variance analysis, and Mann-Whitney *U* test. The SPSS computer program software (version 9.0; SAS Institute, Cary, NC, USA) was used. A value of $P < 0.05$ was accepted as the significance level.

RESULTS

Biochemical evaluations

There were no significant differences ($P > 0.05$) between

the six groups for blood amylase, ALT, AST, bilirubin levels. ALP and GGT levels were higher ($P < 0.05$) in the Urographin[®] groups (2, 2p) than in the Visipaque[®] groups (3, 3p), or the control groups (1, 1p). There were no significant differences ($P > 0.05$) between administrations with or without pressure.

Histopathological alterations

All histopathological findings for the liver are given in Table 1. In the liver, there were no significant differences ($P > 0.05$) between the groups for bile duct inflammation, periductal fibrosis, fibrosis, and parenchymal necrosis. Hepatocyte necrosis, portal area inflammation, and Kupffer's cell hyperplasia were higher ($P < 0.05$) in the study groups than in the control group. However, there were no significant differences ($P > 0.05$) between HOCM [Urographin[®], (2, 2p)] and iso-osmolar CM [Visipaque[®], (3, 3p)] groups. On the other hand, the above features were not affected by pressure when all the groups were compared. Bile duct proliferation (Figure 1A) and regeneration findings (Figure 1B) in the Urographin[®] groups (2, 2p) were significantly higher ($P < 0.05$) than the Visipaque[®] groups (3, 3p), or the control groups (1, 1p). There were no differences ($P > 0.05$) between any groups when CM applications were done with or without pressure (Table 1). Histopathological findings of extrahepatic biliary tract (EBT) are given in Table 1. Necrosis of the EBT was not seen in any of the groups. Inflammation of EBT was similar in each of the groups. Fibroblastic proliferation in the EBT for the Urographin[®] groups (2, 2p) were significantly higher ($P < 0.05$) than in the Visipaque[®] groups (3, 3p), or the control groups (1, 1p). There were no significant differences ($P > 0.05$) between administrations with or without pressure (Table 1).

Histopathological findings of the pancreas are given in Table 1. Necrosis and hemorrhage of the pancreas

Figure 1 Proliferation (A) and regeneration findings (B) in the HOCM (Urographin®) group (HE, × 25).

were not seen in any of the groups. There were no significant differences ($P > 0.05$) between the groups for inflammation of the pancreas (Table 1).

DISCUSSION

The most feared ERCP complication is pancreatitis^[2-6,36]. It results in morbidity and occasional mortality. Osmolarity of the CM has been suggested to be a risk factor in the development of PEP. There are controversial data in current literature^[19]. O'Connor *et al.*^[22] noted that there was no difference in median increments of serum amylase at 6 h after ERCP, but there was a significant difference at 18 h after ERCP in the LOCM (iopamidol) group compared to the HOCM (meglumine diatrizoate) group. No patient, however, developed clinical pancreatitis. Banerjee *et al.*^[23] determined a significant difference between the abilities of HOCM and LOCM to cause pancreatitis. Their results proved that the incidence of pancreatitis is higher when HOCM is used^[23]. Barkin *et al.*^[10] determined the effects of LOCM (iohexol and ioxaglate) and HOCM (meglumine diatrizoate) agents in a prospective, double-blind, randomized study. The clinical symptoms of pancreatitis were lower in patients who received non-ionic LOCM than in those who received ionic HOCM^[10]. George *et al.*^[19] determined the incidence of PEP associated with HOCM and LOCM in their meta-analytical study. Clinical pancreatitis was evidenced by both elevation of pancreatic enzymes and pain. The results of their study indicated that there was no significant difference between HOCM and LOCM with respect to clinical pancreatitis^[1]. Although CM caused minimal adverse effects on the pancreatic tissue, there were no differences between the groups in the present study.

Bub *et al.*^[32] demonstrated morphologic changes in the pancreatic duct epithelium shortly after injection with CM in cats. Less damage was noted after injection with LOCM. Pfau *et al.*^[34] noted that there were no differences between HOCM and LOCM on pancreatic histology in a canine model. Saari *et al.*^[33] performed experimental pancreaticography on 25 piglets using three CM [diatrizoate meglumine Na (ionic HOCM)], meglumine

ioxaglate (ionic LOCM), and iohexol (non-ionic LOCM). They also injected the CM very slowly in order to avoid elevation of intraductal pressure and used a narrow cannula to enable free escape of pancreatic fluid and CM from the ductal system during injection, thus prevented overfilling. Minimal acinar destruction was seen on histological examination in all cases. This study showed that diatrizoate meglumine Na was rapidly emptying compared to the other CM; therefore the changes were least when diatrizoate was used. The emptying of CM from the ducts was significant. Saari *et al.*^[33] noted that rapid emptying might be an advantage in clinical ERCP. Hacıahmetoglu *et al.*^[35] evaluated how intraductal pressure and contrast agent affect the development of pancreatitis after ERCP. The results of their study suggested that the main mechanism for preventing pancreatitis after ERCP is to minimize trauma to the pancreatic canal, to cannulate the pancreas only when it is necessary, and to give contrast agent under low pressure when it is needed. In the present study, all of the CM were applied with and without pressure, but no difference ($P > 0.05$) was observed between them.

Mäkelä *et al.*^[27] determined no difference in the incidence of hyperamylasemia between diatrizoate meglumine (ionic HOCM) and iohexol (non-ionic LOCM) groups. The authors concluded that acute hyperamylasemia after ERCP was a complication of relatively minor importance, unlikely to be reduced by the use of LOCM^[27]. In the present study, there was no difference between the groups for the serum amylase measures.

Biliary epithelial cells are also exposed to CM after the ERCP procedure. Ju *et al.*^[37] performed a study to compare the cytotoxicity with gallbladder epithelial cells of ionic and non-ionic CM. They tested HOCM and LOCM for their effects on monolayer cell cultures of dog gallbladder epithelial cells. According to their results, HOCM were more cytotoxic than LOCM in gallbladder epithelial cells. In the present study, we observed that ionic HOCM were more destructive for the biliary tracts. In the literature, there are numerous studies on the effects of CM on pancreas, but fewer studies on the biliary tract^[37] and liver^[38]. In our study, we also evaluated biliary tract and liver. The findings revealed that HOCM

were more destructive than the iso-osmolar CM on the biliary tract and liver. These histopathological findings were also confirmed biochemically in the HOCM groups (group 2, 2p) by elevated ALP and GGT levels.

In conclusion, the findings of the present study have pointed out that iso-osmolar non-ionic CM could be more reliable than the ionic HOCM during the application of ERCP and diagnostic methods used for the imaging of the extra-hepatic biliary tracts. On the other hand, CM application with pressure might not cause additional damage to the HPB system.

COMMENTS

Background

Contrast media (CM) are commonly used in diagnostic imaging methods in visualizing the hepato-pancreato-biliary (HPB) system using Endoscopic retrograde cholangio pancreatography (ERCP), percutan transhepatic cholangiography, and intra- and post-operative cholangiography. Complications of diagnostic ERCP include acute pancreatitis, cholangitis, and cholecystitis.

Research frontiers

There are no experimental studies on effects of the iso-osmolar, non-ionic CM on the HPB system. Most studies on the adverse effects of CM used in ERCP have focused primarily on post-ERCP pancreatitis (PEP). However, the biliary epithelial cells are also exposed to CM during ERCP. Inflammation of the biliary tree, including acute cholangitis and cholecystitis, is another important complication of diagnostic ERCP. Therefore, the present study involved in the effects of high osmolarity contrast media (HOCM) and iso-osmolar CM on HPB system histopathologically and biochemically. In addition, the present study has also studied the effects of pressure during the injection of CM into the HPB system.

Innovations and breakthroughs

Although osmolarity of the CM has been suggested to be a risk factor in the development of PEP, there are controversial data in current literature. While there are several studies comparing the effects of low osmolarity contrast media and HOCM in the development of PEP, there are no studies on the comparison of the effects of non-ionic, iso-osmolar CM.

Applications

Findings of the present study have pointed out that iso-osmolar non-ionic CM could be more reliable than the ionic HOCM during the application of ERCP and diagnostic methods used for the imaging of the HPB system. On the other hand, CM application with pressure might not cause additional damage to the HPB system.

Peer review

The paper on the effect of the osmolarity of CM on the hepato-biliary tract is an interesting topic.

Abstract

AIM: To examine the effects of long-term proton pump inhibitor (PPI) therapy on body weight (BW) and body mass index (BMI) in patients with gastroesophageal reflux disease (GERD).

METHODS: The subjects were 52 patients with GERD and 58 sex- and age-matched healthy controls. GERD patients were treated with PPI for a mean of 2.2 years (range, 0.8-5.7 years), and also advised on lifestyle modifications (e.g. selective diet, weight management). BW, BMI and other parameters were measured at baseline and end of study.

RESULTS: Twenty-four GERD patients were treated daily with 10 mg omeprazole, 12 with 20 mg omeprazole, 8 with 10 mg rabeprazole, 5 with 15 mg lansoprazole, and 3 patients with 30 mg lansoprazole. At baseline, there were no differences in BW and BMI between reflux patients and controls. Patients with GERD showed increases in BW (baseline: 56.4 ± 10.4 kg, end: 58.6 ± 10.8 kg, mean \pm SD, $P < 0.0001$) and BMI (baseline: 23.1 ± 3.1 kg/m², end: 24.0 ± 3.1 kg/m², $P < 0.001$), but no such changes were noted in the control group. Mean BW increased by 3.5 kg (6.2% of baseline) in 37 (71%) reflux patients but decreased in only 6 (12%) patients during treatment.

CONCLUSION: Long-term PPI treatment was associated

with BW gain in patients with GERD. Reflux patients receiving PPI should be encouraged to manage BW through lifestyle modifications. *World J Gastroenterol* 2009; 15(38): 4794-4798 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4794.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4794>

INTRODUCTION

Gastroesophageal reflux disease (GERD) is the most common esophageal disorder, and frequently encountered in the primary care setting. It has been estimated that 15%-25% of persons experience reflux symptoms at least weekly, and 5%-12% suffer on a daily basis^[1].

The risk of reflux symptoms, erosive esophagitis, or esophageal adenocarcinoma increases with excessive weight and obesity^[2]. Accumulating evidence has confirmed the excellent efficacy and safety of proton pump inhibitor (PPI) therapy in patients with all grades of GERD, making these agents the mainstay of treatment. Consequently, PPIs comprise the largest outpatient pharmacy expenditure in the United States. Body weight loss is commonly recommended as part of a first-line therapeutic measure for GERD, although lifestyle modifications have been relegated to a minor role in the therapeutic regime due to the effectiveness and availability of PPIs as an acid-suppressive therapy^[3].

GERD is a chronic condition, necessitating continuous therapy for many patients to control symptoms and

prevent complications. Long-term therapeutic options include PPI therapy and surgical or endoscopic procedures^[4]. Recently, body weight loss after laparoscopic Nissen fundoplication was reported^[5]. There is an extensive literature database that addresses the efficacy and safety of long-term PPI therapy. However, the possible impact of changes in body weight or body mass index (BMI) in reflux patients while on long-term PPI therapy has not been examined. We present herein the first report elucidating the effect on nutritional parameters such as body weight and BMI in patients receiving long-term PPI therapy.

MATERIALS AND METHODS

Subjects

We evaluated 52 adult patients with GERD and 58 healthy controls. We selected patients undergoing daily maintenance therapy of PPI for at least 10 mo at the University Hospital of Occupational and Environmental Health and four Gastroenterology Clinics between June and November 2005. Patients who had prior fundoplication or poor compliance with medication were excluded. Patients with GERD had received advice on lifestyle modifications such as selective diet and weight management to accompany the PPI treatment.

The controls were sex- and age-matched subjects who visited the clinic for a yearly medical examination; they were free of reflux symptoms, and did not take PPIs or histamine receptor antagonists. They did not receive advice on lifestyle modifications. Informed consent was obtained from all subjects and the study was performed in accordance with the Declaration of Helsinki as revised in 1989.

Diagnosis of GERD

The diagnosis of GERD was made based only on the typical symptoms of GERD such as troublesome heartburn and/or acid regurgitation. Endoscopy at presentation was performed in patients with alarm symptoms such as dysphagia, odynophagia, bleeding, weight loss, and anemia that together suggested a complicated disease.

Treatment of GERD

Initial therapy was a standard dose of PPI (omeprazole 20 mg, rabeprazole 20 mg, or lansoprazole 30 mg) once daily for 8 wk followed by a daily maintenance half-dose therapy. The patients were followed-up at 4-wk intervals in the clinics to assess symptom recurrence. Patients found to have recurring symptoms of heartburn or acid regurgitation were placed back on their initial PPI dose. The patients were educated on lifestyle modifications by their physicians in addition to the PPI treatment. These instructions included avoidance of overeating, decreased fat intake, elevation of the head of the bed, cessation of smoking, avoiding recumbency for postprandial 3 h, and body weight control.

Nutritional parameters and blood pressure

Body weight, height, and blood pressure, as well as

Table 1 Baseline demographics and characteristics of reflux patients treated with long-term daily maintenance proton pump inhibitor therapy and healthy controls (mean \pm SD)

	Patients	Control	P
Number of subjects	52	58	-
Gender (male/female)	36/16	38/20	NS
Age (yr)	68.1 \pm 10.4	68.8 \pm 1.5	NS
Duration of observation (yr)			NS
PPI therapy	2.1 \pm 1.1	-	-
Medical checkup	-	2.0 \pm 0.4	-
Body weight (kg)	56.4 \pm 10.4	58.6 \pm 8.4	NS
Height (cm)	156.0 \pm 9.8	156.0 \pm 8.9	NS
Body mass index (kg/m ²)	23.1 \pm 3.1	24.1 \pm 2.7	NS
Blood pressure (mmHg)			-
Systolic	133 \pm 17	132 \pm 16	NS
Diastolic	75 \pm 11	75 \pm 9	NS
Serum total protein (g/dL)	7.2 \pm 0.3	7.2 \pm 0.3	NS
Serum total cholesterol (mg/dL)	210 \pm 39	210 \pm 25	NS
Serum triglyceride (mg/dL)	121 \pm 52	107 \pm 43	NS

PPI: Proton pump inhibitor.

fasting serum levels of total protein, total cholesterol, and triglycerides were determined at baseline and at the last visit. The BMI was calculated as body weight (kg)/[height (m)]². These parameters obtained within four weeks before the commencement of PPI therapy were defined as baseline data.

Statistical analysis

All results were expressed as mean \pm SD. Categorical outcome variables were analyzed with Fisher's exact test. For continuous variables, the Mann-Whitney *U*-test and Student's *t*-test were used where appropriate. A *P* value less than 0.05 denoted the presence of a statistically significant difference between the groups.

RESULTS

Characteristics and demographics of subjects

Table 1 details the characteristics of the 52 reflux patients and 58 healthy controls. There were no significant differences between the patient and control groups with regard to age, sex, duration of observation, body weight, body height, BMI, blood pressure, and serum values of total protein, total cholesterol, and triglycerides. *Helicobacter pylori* status, endoscopic findings, and PPI regimens of daily maintenance therapy in reflux patients are listed in Table 2.

Effect of long-term daily PPI maintenance therapy on nutritional parameters and blood pressure

No significant differences were found between patient and control groups with respect to changes in blood pressure or serum values of total protein, total cholesterol, and triglycerides. In contrast, patients treated with PPI experienced significantly greater increases from the baseline to the last visit in body weight (*P* < 0.0001) and BMI (*P* < 0.0005) than controls (Table 3).

The differences in body weight and BMI between the baseline and the last visit were analyzed separately

for both groups (Table 3). Body weight ($P < 0.0001$) and BMI ($P < 0.0001$) significantly increased at the last visit in reflux patients. In contrast, there was no significant difference in body weight or BMI at the last visit in controls.

Categorical changes in body weight at the last visit compared to the baseline values are shown in Figure 1. Most of the control group (91%) remained stable, defined by a change of no more than 5% compared to baseline weight; however, only 60% of the PPI group remained stable. In addition, 36% of these patients had an increase in body weight above baseline of more than 5%, compared with 4% of the control group ($P < 0.0001$).

DISCUSSION

This study demonstrated for the first time that long-term PPI treatment is associated with undesirable body weight gain in patients with GERD, despite lifestyle modification recommendations by their physicians. Heartburn is the classical symptom of GERD, with patients generally reporting a burning feeling, rising from the stomach and radiating toward the neck and throat. It usually occurs postprandially, particularly after large meals or the consumption of fats. Untreated patients suffering from reflux symptoms find it difficult to have large meals, because this generally aggravates their symptoms. Untreated patients may therefore reduce their meal sizes and intake of fats intentionally or unintentionally. It is conceivable, therefore, that the resolution of reflux symptoms by PPI treatment leads to a higher food intake resulting in body weight gain.

Laparoscopic Nissen fundoplication has evolved as a gold standard in antireflux surgery. This surgical therapy induces a significant and persistent reduction in body weight, possibly due to postoperative dysphagia or delayed gastric emptying^[5]. In contrast, the option of long-term PPI therapy was associated with a significant

Table 3 Mean changes in nutritional parameters and blood pressure at the last visit compared to the baseline

	Patients (n = 52)	Control (n = 58)	P
Body weight (kg)	+2.2 ^b	-0.1 ^a	< 0.0001

Figure 1 Categorical change in body weight at the last visit compared to the baseline reading. Most of the control group (91%) remained stable, within a 5% change, compared to weight at the baseline. However, only 60% of the PPI group remained stable. In addition, compared with 4% of the control group, 36% of patients had a more than 5% increase above the baseline in body weight ($P < 0.0001$). n: Number of patients or control subjects.

body weight gain in the present study. Omeprazole and other PPIs delay gastric emptying^[6-9], which induces postprandial fullness, dyspeptic symptoms, gastrointestinal bacterial overgrowth, and subsequent weight loss^[10,11]. Our results have clearly demonstrated that long-term PPI therapy contributed significantly to body weight changes in patients with GERD by relieving the adverse symptoms rather than altering the state of gastric emptying.

Numerous circulating peptides influence appetite. Ghrelin is produced in the stomach and acts as a meal initiator. A recent report revealed that long-term PPI therapy did not change the serum ghrelin level^[12]. Another peptide, leptin, is produced in the stomach and acts as an enteric signal involved in energy homeostasis. Change of this peptide associated with PPI therapy has not been reported.

A practice guideline for patients with GERD recommends the use of lifestyle modifications such as elevation of the bed head, a decreased intake of fat, chocolate, alcohol, peppermint, coffee, onions and garlic, cessation of smoking, and avoiding recumbency for three hours postprandially, in addition to taking antireflux medications^[13]. However, the positive advantage of such lifestyle modifications on the patient's condition is not well substantiated. Among these lifestyle interventions, elevation of the bed head, left lateral decubitus positioning, and weight loss are associated

with improvement in reflux symptoms in case-control studies^[14,15]. These modifications alone, however, are unlikely to control symptoms in the majority of patients^[13]. Our results support the finding that lifestyle modifications are an essential component of the treatment for GERD and the prevention of weight gain during PPI treatment.

There is a growing body of literature regarding the association between BMI and GERD^[2,16-24]. A recent large meta-analysis of previous studies demonstrated a strong positive relationship between BMI and reflux symptoms^[2]. In addition, moderate weight gains, even among normal-weight persons, resulted in the development or exacerbation of symptoms in GERD patients^[16]. In the present study, the patients significantly increased their body weight during PPI therapy. Appropriate management of body weight during PPI treatment should reduce the duration of PPI use or PPI dosage.

Excessive weight is associated with an increased risk of coronary heart disease, hypertension, angina, stroke, and diabetes, and constitutes an important cardiovascular health burden^[25]. Body weight gain associated with lifetime GERD treatment may induce further medical costs in addition to the PPI therapy. Unfortunately, potentially effective diet modifications are often underestimated in the presence of various PPI regimens. Healthcare providers still recommend lifestyle changes in a moderate percentage of GERD patients^[26], and while PPIs have become of pivotal importance for the initial and maintenance treatment of GERD, repeated lifestyle modification recommendations are required.

In conclusion, we elucidated in the present study the impact of long-term PPI therapy on body weight. Undesired body weight gain was observed in GERD patients on long-term PPI treatment. Reflux patients treated with a daily maintenance therapy of PPI should be strongly encouraged to manage their body weight through lifestyle modifications such as proper diet and avoidance of overeating. This measure may reduce the overall medical costs associated with obesity-related illness as well as GERD. Lifestyle modification must therefore remain the backbone of treatment for all patients with GERD, even in the PPI era.

COMMENTS

Background

Gastroesophageal reflux disease (GERD) is the most common esophageal disorder, and frequently encountered in the primary care setting. The risk of reflux symptoms and erosive esophagitis increases with excessive weight and obesity.

Research frontiers

Many studies have confirmed the efficacy and safety of proton pump inhibitor (PPI) therapy in patients with GERD, making these agents the mainstay of treatment.

Innovations and breakthroughs

This study demonstrated for the first time that long-term PPI treatment is associated with undesirable body weight gain in reflux patients, despite lifestyle modification recommendations by their physicians.

Applications

Reflux patients treated with a daily maintenance therapy of PPI should be strongly encouraged to manage their body weight through lifestyle modifications such as proper diet and avoidance of overeating.

Terminology

GERD is a common esophageal disorder which is becoming increasingly prevalent in the population in parallel with similar rises in the frequency of metabolic disorders.

Peer review

This study showed that long-term PPI treatment is associated with body weight gain and that lifestyle modification must therefore remain the backbone of treatment for patients with GERD. This report would impact on the ongoing treatment of GERD.

Abstract

AIM: To observe the effects of traditional anti-inflammatory medicine *Lonicerae Flos* (LF) on rat reflux esophagitis (RE) induced by pylorus and forestomach ligation compared with the well-known proton antioxidant, α -tocopherol.

METHODS: Rats were pretreated with three different dosages of LF (500, 250 and 125 mg/kg) orally, once a day for 14 d before pylorus and forestomach ligation. Nine hours after pylorus and forestomach ligation, changes to the stomach and esophagus lesion areas, gastric volumes, acid and pepsin outputs, antioxidant effects, esophageal lipid peroxidation, superoxide dismutase (SOD), catalase (CAT), malondialdehyde (MDA), myeloperoxidase and glutathione (GSH) levels, and collagen contents (marker of flexibility) were observed on the esophageal and fundic histopathology. The results were compared with an α -tocopherol (once orally, 1 h before operation, 30 mg/kg) treated group in which the effects on RE were already confirmed.

RESULTS: Pylorus and forestomach ligations caused marked increases of gross esophageal and gastric mucosa lesion areas, which corresponded with histopathological changes. In addition, increases of esophageal lipid peroxidation, decreases of SOD, CAT, and GSH-free radical scavengers, increases of collagen were observed. However, these pylorus and forestomach ligation induced RE were dose-dependently inhibited by treatment of 500, 250 and 125 mg/kg of LF extract, mediated by antioxidant effects. RE at 250 mg/kg showed similar effects α -tocopherol.

CONCLUSION: The results suggest that antioxidant effects of LF could attenuate the severity of RE and prevent the esophageal mucosal damage, and validate its therapeutic use in esophageal reflux disease.

INTRODUCTION

Lonicerae Flos (LF), also called Jinyinhua, is a widely used herb prescribed in many Chinese formulas. It has latent-heat-clearing, antipyretic, detoxicant, and antiinflammatory actions^[1].

It has been prescribed to treat fever due to common cold, febrile disease, dysentery, carbuncles, and virulent swellings, in Chinese medicine. Many previous reports have shown that LF is an effective antioxidant^[2,3]. Chlorogenic acid, one of the major components in LF, has been widely adopted to control the quality of LF, owing to its high content and antibiotic property. Chlorogenic acid was

revealed as having an effective activity in the 2,2-diphenyl-1-picrylhydrazyl (DPPH) free radical scavenging assay and ferric reducing antioxidant power assay. In addition, 14 compounds in LF were found to possess a potential antioxidant activity. They were identified as chlorogenic acid, 1-O-caffeoylquinic acid (CQA), caffeic acid, 4-O-CQA, rutin, isoquercitrin, luteolin-7-O-glucoside, lonicerin, 4,5-O-dicaffeoylquinic acid, 3,5-O-diCQA, 1,3-O-diCQA, 3,4-O-diCQA, 1,4-O-diCQA, and luteolin^[4] and the antioxidant capacity of LF extracts in water, methanol and 70% ethanol to scavenge DPPH radical and reduce Fe^{3+} to Fe^{2+} was evaluated^[1].

Esophageal reflux disease has gained clinical and surgical importance over the past decade. It is one of the most common complaints, affecting approximately 10% of the population^[5].

More recent investigations confirmed that the pathogenesis of esophageal reflux seems to be multifactorial and the gastric contents refluxing into the esophagus contain complex components^[6,7].

Acid secreted from gastric parietal cells is a potentially damaging factor in the gastric lumen, and oxidative stress also plays an important role in depletion of the adherent mucus layer and damage the esophageal mucosa from the mechanical forces associated with digestion. Reflux of caustic gastric contents, reactive oxygen species such as superoxide radical and hydroxyl radical, and release of lysosomal enzymes, is known to directly or indirectly cause symptoms such as heartburn and nausea^[8,9].

Therapy that merely suppresses gastric acid secretion does not improve the function of the lower esophageal sphincter and oxidative stress is an added important factor in the pathogenesis of reflux esophagitis (RE) in rats^[8].

LF has oxidant and antiinflammatory activities^[1-4,8-10]; therefore, in the present study, we determined if an extract of LF could be useful for treating RE in rats, by detecting mucosal damages in an RE rat model.

MATERIALS AND METHODS

Animals

Ninety-six female SD rats (6-wk old upon receipt, SLC, Japan) were used after acclimatization for 7 d. The animals were allocated five per polycarbonate cage in a temperature (20-25°C) and humidity (40%-45%) controlled room. The light/dark cycle was 12 h/12 h, and feed and water were supplied ad libitum. The experimental protocols were carried out in accordance with internationally accepted principles for laboratory animal use and care, as stated in the US guidelines.

Preparation of drugs

A sample of LF was purchased from Omniherb Co. (Daegu, South Korea) in 2008. The plant was identified by Professor Seongsoo Roh and a reference specimen (Dipsacales) was deposited in our laboratory. Plant material (200 g) was extracted three times with distilled water. The extract was filtered and evaporated on a rotary evaporator (Buchi, Switzerland), dried in a freeze drier (Eyela FDU-540, Tokyo, Japan). The yield (w/w)

of the extract was about 12%. α -tocopherol was purchased from Sigma (MO, USA).

Induction of RE and treatment

RE was induced in fasted rats after 24 h under 25 mg/kg of Zoletile mixture (Vibrac, France). After anesthesia, the abdomen of the animal was opened by a median incision of about 2 cm, the transitional region between the forestomach and corpus was ligated with a silk thread (2-0), and the contiguous pylorus portion was ligated. A longitudinal cardiomyotomy of about 1 cm length across the gastro-esophageal junction was performed to enhance reflux from the stomach contents into the esophageal body. The incised regions were immediately sutured and the animals were kept in a recovery chamber before being returned to their home cages. 500, 250, and 125 mg/kg of LF were orally administered, once a day for 14 d before the operation, using distilled water as vehicle. α -tocopherol [diluted in corn oil (Sigma, MO, USA)] was administered once orally at doses of 25 mg/kg, 1h before ligation. In sham and vehicle control rats, only distilled water was orally administered, once a day, for 14 d.

Esophageal lesion scores

After nine hours, the animals were sacrificed and the esophagus and stomach were removed. The organs were opened along the greater curvature of the stomach, and the esophagus was longitudinally dissected out. The tissues were washed with physiological saline and examined for ulceration under a dissecting microscope (Nikon, Japan) according to a method described by Nagahama *et al*^[11]. Photographs were taken of specified areas of damage and the width of the damaged esophagitis area (mm^2) was determined and named the lesion score.

Tissue glutathione (GSH) and malondialdehyde (MDA) assays

Stomach samples were homogenized in ice-cold 150 mmol/L KCl for determination of MDA and GSH levels. The MDA levels were assayed for products of lipid peroxidation^[12]. Results were expressed as nmol MDA/g tissue. GSH was determined by a spectrophotometric method using Ellman's reagent^[13]. Results were expressed as μmol GSH/g tissue.

Tissue superoxide dismutase (SOD) activity

SOD was determined by the modified version from the method of Minami and Yoshikawa^[14]. Briefly, 15 μL of gastric homogenate were mixed with 450 μL of cold deionized water, 125 μL of chloroform, and 250 μL of ethanol. The mixture was then, centrifuged at 8000 g for 2 min at 4°C. 500 μL of the extracts were added to a reaction mixture containing 500 μL of 72.4 mmol/L triscacodylate buffer with 3.5 mmol/L diethylene pentaacetic acid (pH 8.2; Sigma, MO, USA), 100 μL of 16% Triton X-100, and 250 μL of 0.9 mmol/L nitroblue tetrazolium (Sigma, MO, USA). The reaction mixture was incubated for 5 min at 37°C before adding 10 μL of 9 mmol/L of pyrogallol (Sigma, MO, USA) dissolved in

10 mmol/L HCl. The reaction was incubated for exactly 5 min at 37°C, before being stopped by the addition of 300 µL of 2 mol/L formic buffer (pH 3.5) containing 16% Triton X-100. The absorbance was measured at 540 nm in a spectrophotometer. One unit of SOD enzymatic activity is equal to the amount of enzyme that diminishes the initial absorbance of nitroblue tetrazolium by 50%.

Tissue catalase (CAT) activity

CAT was determined according to the method of Rice Evans and Diplock^[15]. Homogenate of rat gastric mucosa was diluted with buffer, as described before, to obtain an adequate dilution of the enzyme. Then, 2 mL of the enzyme dilution were added to a cuvette and mixed with 1 mL of 30 mmol/L H₂O₂, and the absorbance at 240 nm was measured for 100 s. Initial absorbance of the reaction mixture should be around 0.5. The enzyme activity (U/g of tissue) is expressed as the first order constant that describes the decomposition of H₂O₂ at room temperature.

Tissue myeloperoxidase (MPO) activity

The tissue samples (about 0.2 g) were homogenized in 10 volumes of ice-cold potassium phosphate buffer (50 mmol/L K₂HPO₄, pH 6.0; Sigma, MO, USA) containing hexadecyltrimethyl-ammonium bromide (HETAB; 0.5% w/v; Sigma, MO, USA). The homogenate was centrifuged at 12000 g for 10 min at 4°C, and the supernatant was discarded. The pellet was then re-homogenized with an equivalent volume of 50 mmol/L K₂HPO₄ containing 0.5% (w/v) HETAB and 10 mmol/L EDTA (Sigma, MO, USA). MPO activity was assessed by measuring the H₂O₂-dependent oxidation of o-dianisidine-2 HCl. One unit (U) of enzyme activity was defined as the amount of the MPO present/g tissue weight that caused a change in absorbance of 1.0/min at 460 nm and 37°C^[16].

Tissue collagen measurement

Tissue samples were fixed in 10% formalin in 0.1 mol/L phosphate buffer (pH 7.2) in paraffin and 15 µm thick sections were obtained. Collagen content was measured according to a method described by López-De León *et al*^[17]. The method is based on selective binding of the dyes Sirius Red (Sigma, MO, USA) and Fast Green FCF (Sigma, MO, USA) to collagen and non-collagenous components respectively. Both dyes were eluted readily and simultaneously by using 0.1 mol/L NaOH-methanol (1:1). Finally, the absorbances at 540 and 605 nm were used to determine the amount of collagen and protein respectively.

Histopathological studies

Nine hours after the operations of pylorus and fore-stomach ligation, the junction area from the esophagus to the cardia (about 5 cm) and a part of the fundus tissue were separated and fixed in 10% neutral buffered formalin, after paraffin embedding, 3 µm serial sections were prepared and stained with hematoxylin and eosin. Thickness of mucosa, submucosa in the esophagus, and full thickness of esophagus were measured in

each prepared specimens using a CCD image analyzer (DMI-300, DMI, South Korea) as mm/crossly trimmed tissues. The invasive percentages of lesions in the fundus and percentage of mucosal damage of the esophagus were enumerated as follows: Invasive percentages of lesions (%) = (Length of lesions on the crossly trimmed esophageal or fundic walls/total thickness of crossly trimmed esophageal walls) × 100; Mucosal damage protecting percentages (%) = (Length of lesions on the crossly trimmed esophageal mucosa/total length of crossly trimmed esophageal mucosa) × 100.

Statistical analysis

Multiple comparison tests for different dose groups were conducted. Variance homogeneity was examined using the Levene test. If the Levene test indicated no significant deviations from variance homogeneity, the obtain data were analyzed by one way ANOVA test, followed by least-significant differences (LSD) multi-comparison test to determine which pairs of group comparison were significantly different. In cases where significant deviations from variance homogeneity were observed using the Levene test, a non-parametric comparison test, the Kruskal-Wallis *H* test, was conducted. When a significant difference was observed in the Kruskal-Wallis *H* test, the Mann-Whitney U-Wilcoxon Rank Sum *W* test was conducted to determine the specific pairs of group comparison that are significantly different. Statistical analyses were conducted using SPSS for Windows (Release 12.0K SPSS Inc., IL, USA).

RESULTS

Esophageal lesion scores

A significant ($P < 0.01$) increase of esophageal lesion scores was detected in RE control as compared with sham control. However, these increases of esophageal lesion scores were markedly decreased by treatment with all three dosages of LF and α-tocopherol, as compared with the RE control (Figure 1).

Histopathological changes

We examined hole sizes of mucosa on histological images, measured damaged sizes of the mucosa, and calculated esophagus damage protecting percentages. Lesions on the mucosa in the sham are not shown. Lesions in the RE control, α-tocopherol, and LF groups were significantly ($P < 0.01$) increased compared to the sham. However, lesions in the α-tocopherol and LF groups were significantly ($P < 0.05$ and $P < 0.01$) decreased compared to the RE control. Infiltrations of inflammatory cells in esophagus tissue of the α-tocopherol and LF groups were significantly ($P < 0.05$ and $P < 0.01$) decreased compared to the RE control. In addition, the hemorrhage depth in the stomach of the α-tocopherol and LF groups was decreased compared to the RE control. Thicknesses of esophagus tissue in the RE control, α-tocopherol and LF groups were increased compared to the sham, but the thicknesses of esophagus tissue of α-tocopherol and LF groups were significantly

Table 1 Changes on the esophageal and gastric histomorphometry in RE rats

Group	Damage protecting percentages (%)	Inflammatory cells infiltration in esophagus (%)	Thickness of mucosa in esophagus (μm)	Hemorrhage depth in stomach (mm)
Controls				
Sham	1.23 \pm 0.13	0.86 \pm 0.7	261.89 \pm 23.67	0.003 \pm 0.005
RE	12.72 \pm 3.81 ^b	94.80 \pm 4.07 ^b	20.81 \pm 46.53 ^b	0.963 \pm 0.343

500	10.54 \pm 1.54 ^d	1.31 \pm 0.20 ^{b,d}	60.26 \pm 5.22 ^d	4.41 \pm 0.46 ^d

Values are expressed mean \pm SD of five rats; ^a P < 0.05 and ^b P < 0.01 compared to sham control; ^c P < 0.05 and ^d P < 0.01 compared to RE control; MDA: Malondialdehyde; GSH: Glutathione; SOD: Superoxide dismutase; CAT: Catalase.

Figure 2 Changes of the histopathological profiles of esophagus of Sham (A), RE (B) controls, α -tocopherol (C), LF 125 (D), 250 (E) and 500 mg/kg (F) treated rats. Sham: Normal rats had a laparotomy not pylorus and forestomach ligation operation; RE: Rats had a pylorus and forestomach ligation operation not treated with drug; Tocopherol: Rats had a pylorus and forestomach ligation operation treated with α -tocopherol (30 mg/kg); and LF extract: Rats had a pylorus and forestomach ligation operation treated with extract of LF (respectively 125, 250 and 500 mg/kg). All HE stains; Scale bars: 80 μ m.

the gastric mucosa after the induction of RE. α -tocopherol and all three dosages of LF, significantly (P < 0.01) inhibited MDA production as compared with the RE control (Table 2). GSH levels increased with esophageal mucosal damage. Significant differences were found between rats with gastroesophageal reflux as compared to normal esophagus. Gastric GSH contents of all experiment group were significantly (P < 0.01) lower than in normal esophageal mucosa (Table 2). However, those of the α -tocopherol and LF groups were significantly (P < 0.05, P < 0.01) higher than in RE control esophageal mucosa (Table 2). SOD content showed a significant decrease in biopsies taken from RE control group with erosive esophagitis, when compared to that of sham rats. However, of the SOD levels in the α -tocopherol and LF groups were significantly (P < 0.05, P < 0.01) higher than in the RE control group (Table 2). Gastric catalase content decreased in the RE control group compared to sham rats. However, of the catalase activities of the α -tocopherol and LF groups were significantly (P < 0.05, P < 0.01) higher than in the RE control group (Table 2).

Myeloperoxidase activity

Accumulation of polymorphonucleocytes (PMNs) in the surgically induced reflux esophageal tissue is considered one of the primary contributory mechanisms to esophageal injury. The myeloperoxidase (MPO) activity in the esophageal tissue was measured as a marker for PMN accumulation (Figure 3A). The MPO activity was low in sham rats. However, the surgically induced esophagitis rats showed a large increase in esophageal MPO activity (P < 0.01). Treatment of esophagitis rats with α -tocopherol and LF significantly attenuated esophageal MPO activity in comparison with untreated rats (P < 0.05, P < 0.01), indicating that α -tocopherol and LF retarded the accumulation of PMNs in the RE model.

Collagen contents

The collagen contents rose significantly (P < 0.01) in the RE-induced experiment groups; however, α -tocopherol and LF significantly (P < 0.05, P < 0.01) attenuated the elevated levels of collagen in esophageal tissue compared to the RE control (Figure 3B).

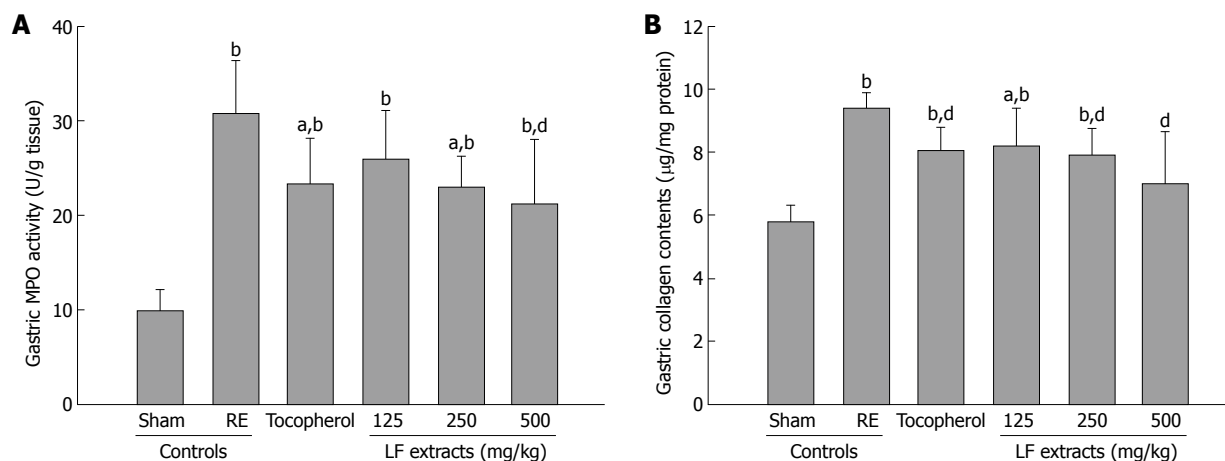

Figure 3 Changes on the gastric MPO activity (A) and gastric collagen contents (B) in RE rats. Values are expressed mean \pm SD of five rats. ^b $P < 0.01$ compared to Sham control; ^a $P < 0.05$ and ^d $P < 0.01$ compared to RE control.

DISCUSSION

Many researches have reported that LF had an antioxidant effect^[1,2,4,18], and the protection provided by the dose of α -tocopherol was chosen according to an earlier report^[19] in which 16 mg/kg prevented oxidative stress in gastric ulcers. α -tocopherol is the most potent antioxidant that can break the propagation of the free radical chain reaction in the lipid part of the biological membrane. Chandana and Madhavan^[20] reported that α -tocopherol has efficacy to esophagitis. Thus, we attempted to determine any anti-esophagitis effects of LF in a rat model of RE induced by pylorus and forestomach ligation. The RE control group showed induced esophageal inflammation, edema, and ulcer. Histology revealed increasing of thickness, damage to the mucosa, and hemorrhages in esophagus tissues. However, the experimental groups treated with α -tocopherol (30 mg/kg) and LF (at doses of 500, 250 and 125 mg/kg) showed decreased lesions of esophagitis and reduced edema, damage to the mucosa and hemorrhages in the stomach (Table 1 and Figure 1).

It has been suggested that lipid peroxidation, a sensitive marker of membrane damage caused by free radicals, is involved in reflux oesophagitis^[21]. Antioxidants constitute the foremost defense system for limiting the toxicity associated with free radicals. Under physiological conditions, oxygen radicals are part of normal regulatory circuits, and the cellular redox state is very sensitive to antioxidants^[22]. In recent years, there has been an upsurge in research on medicinal herbs and plant derived compounds, especially in combating oxidative stress and free radical damage^[23]. GSH, SOD, and catalase are important radical superoxide scavengers that provide major protection by participating in the cellular defense systems against oxidative damage^[8,9,24]. The gastric mucosa contains high levels of glutathione, which is important for maintenance of mucosal integrity, because depletion of GSH from the gastric mucosa by electrophilic compounds induces macroscopic mucosal ulceration^[25]. In the present study, marked increases in lipid peroxidation were detected in the gastric mucosa of the RE control with decreases

of endogenous antioxidants, GSH, SOD, and catalase, respectively (Table 2).

Many studies have focused on the role of neutrophil infiltration in the development of gastric mucosal injury^[26-28]. Besides their direct damaging effects on tissues, it is well established that oxygen metabolites play a role in the recruitment of neutrophils, preferentially PMNs, into injured tissues^[29]. Activated PMNs are also a potential source of oxygen metabolites^[30] and MPO an activating cytotoxic enzyme released from PMNs^[31]. In the present study, marked increases of gastric MPO activities were detected in the RE control compared with the intact control. We examined infiltration percentages of inflammatory cells in the esophagus and stomach. Inflammation cells infiltrations in esophageal tissue of α -tocopherol and LF-treated groups were decreased compared to the RE group ($P < 0.05$ and $P < 0.01$) (Table 1 and Figure 1). Figure 3A shows the changes to the levels of in gastric MPO.

The severity of RE impairs the strength and flexibility of collagen fibers. Collagen constitutes the major structural protein in the extracellular matrix, providing mechanical strength and structural integrity to the various connective tissues of the body^[32]. In the present study, gastric collagen contents were determined as a marker of oxidant-induced fibrosis^[31], and marked increases of gastric collagen contents were observed in the RE control as compared with the sham control (Figure 3B). Collagen contents rose significantly in the esophagitis-induced experiment groups; however, α -tocopherol and LF significantly attenuated the elevated levels of collagen in esophageal tissue as that of RE control (Figure 3B).

In conclusion, LF has an effective antioxidant activity and the clinical administration of LF could attenuate the severity of RE and prevent direct esophageal mucosal damage. The present study validates the potential therapeutic use of LF for gastroesophageal reflux disease.

COMMENTS

Background

Reflux esophagitis (RE) is occurs widely in the world and is generally treated

with antacids, prokinetics, histamine type 2 receptor antagonists, and proton pump inhibitors (PPI). Especially, antioxidants having antiinflammatory activity are useful for treating RE. *Lonicerae* Flos (LF) might be effective for RE-induced by pylorus and forestomach ligation through its antioxidant activity.

Research frontiers

The research field of this research is RE, which is one of the most common complaints, affecting approximately 10% of the population. An important focus of the authors' research is that effective antioxidants in Chinese medicine have potential for use in RE.

Innovations and breakthroughs

Omeprazol is a representative PPI drug that also has antioxidant activity. As alternatives, natural medicines having antioxidant effects and no side effects could be potential remedies. This article might lead a researcher of natural products to study drug treatments for RE.

Applications

By examining which components of LF are more effective against RE, a natural new drug could be manufactured. The ability to easily obtain LF from the environment will encourage patients with RE to take folk remedies as medicines to cure RE.

Terminology

In RE, the acid secreted from gastric parietal cells is a potentially damaging factor in the gastric lumen and oxidative stress also plays an important role in depletion of the adherent mucus layer. Damage to the esophageal mucosa from the mechanical forces associated with digestion might also occur. Reflux of caustic gastric contents, reactive oxygen species such as superoxide radicals and hydroxyl radical, and release of lysosomal enzymes can also cause damage.

Peer review

In this article, the authors determined that the antioxidant effects of LF could attenuate the severity of RE and prevent esophageal mucosal damage. α -tocopherol is a major antioxidant, a previous report explained that it was useful in RE of pylorus and forestomach ligation. LF is an antioxidant and anti-inflammatory agent, and has effective activity on RE in the pylorus and forestomach ligation rat model.

Abstract

AIM: To evaluate the clinicopathologic characteristics of patients with metastases to the gallbladder (MGBs).

METHODS: We performed a single-center retrospective study of 20 patients with MGBs diagnosed pathologically from 1999 to 2007.

RESULTS: Among 417 gallbladder (GB) malignancies, 20 (4.8%) were MGBs. The primary malignancies originated from the stomach ($n = 8$), colorectum ($n = 3$), liver ($n = 2$), kidney ($n = 2$), skin ($n = 2$), extrahepatic bile duct ($n = 1$), uterine cervix ($n = 1$), and appendix ($n = 1$). Twelve patients were diagnosed metachronously, presenting with cholecystitis ($n = 4$), abdominal pain ($n = 2$), jaundice ($n = 1$), weight loss ($n = 1$), and serum CA 19-9 elevation ($n = 1$); five patients were asymptomatic. The median survival after the diagnosis of MGB was 8.7 mo. On Cox regression analysis, R0 resection was the only factor associated with a prolonged survival [hazard ratio (HR): 0.01, $P = 0.002$]; presentation with cholecystitis was associated with poor survival (HR: 463.27, $P = 0.006$).

CONCLUSION: MGBs accounted for 4.8% of all pathologically diagnosed GB malignancies. The most

INTRODUCTION

Metastases to the gallbladder (MGBs) are rare in clinical practice^[1]. Although malignant melanoma^[2] and renal cell carcinoma^[3] are reported to metastasize to the gallbladder (GB), these data are based on autopsy series of these tumors. Reports on MGBs arising from malignancies other than malignant melanoma and renal cell carcinoma are usually in the form of single case reports^[4,5]. There are few, if any, reports that describe MGBs from the perspective of the GB to this date.

This paper describes the clinicopathologic features of 20 patients with MGBs diagnosed over a period of 9 years at a single tertiary hospital.

MATERIALS AND METHODS

We reviewed the pathology reports of all GB malignancies diagnosed with pathological confirmation from January 1999 to December 2007 at Seoul National University Hospital. We evaluated the clinicopathologic characteristics of the patients with MGBs. Patients were excluded when direct invasion of the GB from the primary malignancy was confirmed on imaging or intraoperatively.

By reviewing the medical records, sex, the primary origin of the MGB, age at diagnosis of the primary malignancy, age at diagnosis of the MGB, presenting

Table 1 Origin and pathology of the primary malignancies

Site of origin	Pathology
Stomach (<i>n</i> = 8)	Adenocarcinoma (<i>n</i> = 7) Signet ring cell carcinoma (<i>n</i> = 1)
Colorectum (<i>n</i> = 3)	Adenocarcinoma (<i>n</i> = 3)
Liver (<i>n</i> = 2)	Hepatocellular carcinoma (<i>n</i> = 2)
Kidney (<i>n</i> = 2)	Renal cell carcinoma (<i>n</i> = 2)
Skin (<i>n</i> = 2)	Melanoma (<i>n</i> = 2)
Extrahepatic bile duct (<i>n</i> = 1)	Adenocarcinoma (<i>n</i> = 1)
Uterine cervix (<i>n</i> = 1)	Squamous cell carcinoma (<i>n</i> = 1)
Appendix (<i>n</i> = 1)	Mucinous adenocarcinoma (<i>n</i> = 1)

symptoms and signs at diagnosis of the MGB, time interval between the diagnoses of the primary malignancy and the MGB, involvement of organs other than the GB, diagnosis of secondary involvement of the GB before surgery, treatment after the diagnosis of the MGB, and survival after the diagnosis of the MGB were evaluated. Overall follow-up survival information was obtained by contacting the Resident Service Division of the Ministry of Public Administration and Security, Seoul, Korea, and by reviewing medical records. The endpoints of this study were patient death or June 30, 2008.

The median survival was estimated using the Kaplan-Meier method. Factors associated with prolonged survival were determined using the log-rank test. The factors including age at diagnosis of the MGB, sex, and factors associated with survival in the univariate analysis at $P < 0.20$ were included as covariates in the Cox regression analysis. Values are reported as the median. Two-sided P values of < 0.05 were considered statistically significant. All analyses were performed using SPSS for Windows Ver. 11.0 (SPSS Inc., Chicago, Ill., USA). This study was approved by the institutional review board at our hospital.

RESULTS

Overview of the patients

A total of 417 cases of GB malignancies were diagnosed with pathological confirmation. Among these, 20 cases (14 male and six female) were MGBs, accounting for 4.8% of the GB malignancies.

The median age at diagnosis of MGB was 65 years (range, 28-76 years). The median age at diagnosis of the primary malignancy was 62.5 years (range, 27-76 years). The primary malignancies originated from the stomach ($n = 8$), colorectum ($n = 3$), liver ($n = 2$), kidney ($n = 2$), skin ($n = 2$), extrahepatic bile duct ($n = 1$), uterine cervix ($n = 1$), and appendix ($n = 1$) (Table 1). Cancer involvement of organs other than the GB was present in 11 patients.

Eight MGBs were diagnosed synchronously. The primary origins were the stomach ($n = 3$), colorectum ($n = 3$), extrahepatic bile duct ($n = 1$), and liver ($n = 1$). Twelve MGBs were diagnosed metachronously with a median interval of 24.9 mo (range, 5-191 mo). The primary origin in these patients were the stomach ($n = 5$), kidney ($n = 2$), skin ($n = 2$), liver ($n = 1$), uterine

Table 2 Concurrent procedures at the time of cholecystectomy

Synchronously diagnosed	Metachronously diagnosed
Anterior resection and liver tumorectomy	Distal pancreatectomy (for pancreatic metastasis)
Low anterior resection and liver tumorectomy	Right hemicolectomy
Total colectomy and liver tumorectomy	Debulking surgery
Palliative common bile duct resection	
Palliative gastrojejunostomy	
Palliative total gastrectomy	
Palliative left lobectomy of the liver	
Palliative subtotal gastrectomy and palliative right hemicolectomy	

cervix ($n = 1$), and appendix ($n = 1$). Metachronously diagnosed patients presented with cholecystitis ($n = 4$), abdominal pain ($n = 2$), jaundice ($n = 1$), weight loss ($n = 1$), and elevation of serum CA 19-9 ($n = 1$); five patients were asymptomatic and the MGBs were detected during follow-up of the primary malignancy. In the four patients that presented with cholecystitis, only one patient had gallstones. Recurrence of the primary malignancy in the remaining primary origin was detected in one patient.

Treatment and prognosis

Treatment consisted of surgery ($n = 9$), surgery plus chemotherapy ($n = 8$), surgery plus chemoradiation ($n = 2$), and surgery plus transarterial chemoembolization ($n = 1$). All synchronously diagnosed patients underwent concurrent surgical procedures; three of 12 metachronously diagnosed patients underwent concurrent surgical procedures (Table 2). The preoperative radiological diagnosis of MGB was made in 9 (45%) patients. Complete surgical resection of all tumors present, i.e. R0 resection, was achieved in nine patients. There was a tendency to achieve R0 resection in patients with preoperative diagnosis of MGBs (66.7% in patients with preoperative diagnosis *vs* 27.3% in patients without preoperative diagnosis, $P = 0.078$).

The overall median survival after the diagnosis of MGB was 8.7 mo (Figure 1). On univariate analysis, R0 resection ($P < 0.001$), asymptomatic on diagnosis of MGB ($P = 0.023$), and preoperative diagnosis of MGB ($P = 0.007$) were associated with a prolonged survival; presentation with acute cholecystitis ($P < 0.001$) and age at diagnosis of MGB ≥ 70 years ($P = 0.009$) were associated with a poor survival (Table 3). On multivariate analysis, the only factor associated with prolonged survival was R0 resection [hazard ratio (HR): 0.01, 95% confidence interval (CI): 0.001-0.20, $P = 0.002$]; presentation with acute cholecystitis was associated with poor survival (HR: 36.12, 95% CI: 2.82-463.27, $P = 0.006$) (Table 4).

DISCUSSION

The present retrospective analysis of 9 years' experience at a single tertiary hospital contributes to our understanding

Table 3 Univariate analysis of the factors associated with survival after a diagnosis of MGB

Factor	Median survival ¹	P value
Sex		0.794
Male (n = 14)	11.2	
Female (n = 6)	6.2	
Primary origin		0.224
Gastrointestinal organs (n = 15)	8.2	
Non-gastrointestinal organs (n = 5)	35.0	
Chronological relationship between primary malignancy and MGB		0.913
Synchronous (n = 8)	11.2	
Metachronous (n = 12)	6.9	
Asymptomatic upon diagnosis of MGB		0.023
Yes (n = 5)	40.0	
No (n = 15)	6.9	
Presentation with acute cholecystitis		< 0.001
Yes (n = 4)	2.8	
No (n = 16)	15.6	
Preoperative diagnosis of MGB		0.007
Yes (n = 9)	35.0	
No (n = 11)	4.7	
Age at diagnosis of the MGB (yr)		0.009
≥ 70 (n = 5)	6.2	
< 70 (n = 15)	21.2	
Secondary involvement of organs other than the GB		0.586
Yes (n = 11)	15.6	
No (n = 9)	8.7	
Recurrence at the remaining primary site		0.252
Yes (n = 1)	4.7	
No (n = 19)	11.2	
R0 resection		< 0.001
Yes (n = 9)	40.0	
No (n = 11)	6.2	

¹Value in months. Results of log-rank test. MGB: Metastasis to the gallbladder; GB: Gallbladder.

of the clinicopathologic features of MGBs. MGBs accounted for 4.8% of all GB malignancies. The most common primary origin was the stomach. Twelve cases (60%) of MGBs were diagnosed metachronously with a median interval of 24.9 mo. The median survival after the diagnosis of MGB was 8.7 mo. On multivariate analysis, R0 resection was the only factor associated with prolonged survival; presentation with acute cholecystitis was associated with poor survival.

Malignant melanoma and renal cell carcinoma are reported to metastasize to the GB. In an autopsy series of 125 patients with malignant melanoma, nineteen (15%) had MGBs^[2]. In an analysis of 687 necropsies of patients with renal cell carcinoma, four cases had MGBs^[3]. However, the data available on MGBs are only from autopsy series of certain malignancies such as melanoma or renal cell carcinoma, or reviews of a certain metastatic carcinoma to the GB such as melanoma^[6,7], or in the form of single case reports of tumors such as melanoma^[8-11], breast cancer^[4], and hepatocellular carcinoma^[5]. Furthermore, there is limited data on the proportion of MGBs among GB malignancies.

Malignant melanoma is reported to be the most common origin of MGBs^[1]. In this study, malignant melanoma accounted for 10% of primary malignancies.

Table 4 Multivariate analysis of the factors associated with survival after a diagnosis of MGB

Factor	HR	95% CI	P value
Male sex	5.78	0.84-39.87	0.075
Asymptomatic upon diagnosis of the MGB	0.79	0.15-4.18	0.781
Presentation with acute cholecystitis	36.12	2.82-463.27	0.006
Preoperative diagnosis of MGB	0.58	0.13-2.62	0.477
Age at diagnosis of the MGB ≥ 70 yr	3.69	0.42-32.38	0.239
R0 resection	0.01	0.001-0.20	0.002

HR: Hazard ratio; CI: Confidence interval.

**Figure 1** Cumulative survival after the diagnosis of metastasis to the gallbladder.

Interestingly, the stomach was the most common primary origin of MGB in our study. This may result from bias arising from the small number of patients. However, the fact that stomach cancer is the most common cancer in Korea may have resulted in this finding^[12].

In the analysis of the factors associated with survival, R0 resection was the only factor associated with prolonged survival, which can be taken as a matter of course. The presentation of MGB with acute cholecystitis was associated with poor survival. A possible explanation for this finding is that a major infectious episode, such as acute cholecystitis, may have had a major negative impact on the patient's survival.

Our study has certain limitations. This study is based on information collected from patients with pathologically diagnosed GB malignancies only. The number of patients is small. In addition, the primary malignancies and treatments are varied. Nevertheless, this study provides some insight into the nature of MGBs.

In conclusion, MGBs accounted for 4.8% of all pathologically diagnosed GB malignancies over a period of 9 years. The stomach was the most common site of the primary malignancy. The overall median survival after diagnosis of the MGB was 8.7 mo. R0 resection was the only factor associated with a prolonged survival.

COMMENTS

Background

Metastases to the gallbladder (MGBs) are rare. There is limited data on the characteristics of patients with MGBs.

Innovations and breakthroughs

Although malignant melanoma and renal cell carcinoma are reported to metastasize to the GB, these data are based on autopsy series of these tumors. Despite the small number of cases, this report of 20 MGB cases is one of the largest among reports on MGBs.

Applications

The proportion of MGBs among pathologically confirmed GB malignancies is 4.8%. R0 resection is the only factor associated with a prolonged survival in MGB patients.

Peer review

This is a well-written paper presenting material on patients with metastasis of the gallbladder. Although the series of patients is rather small, which is also discussed in the paper, it gives some information which is new and of scientific and clinical interest as well.

Abstract

AIM: To evaluate the effectiveness of three-dimensional endoanal ultrasound (3D-EAUS) in the assessment of anal fistulae with and without H₂O₂ enhancement.

METHODS: Sixty-one patients (37 males, aged 17-74 years) with anal fistulae, which were not simple low types, were evaluated by physical examination and 3D-EAUS with and without enhancement. Fistula classification was determined with each modality and compared to operative findings as the reference standard.

RESULTS: The accuracy of 3D-EAUS was significantly higher than that of physical examination in detecting the primary tract (84.4% vs 68.7%, $P = 0.037$) and secondary extension (81.8% vs 62.1%, $P = 0.01$) and localizing the internal opening (84.2% vs 59.7%, $P = 0.004$). A contrast study with H₂O₂ detected several more fistula components including two primary suprasphincteric fistula tracks and one supralelevator secondary extension, which were not detected on non-contrast study. However, there was no significant difference in accuracy between 3D-EAUS and H₂O₂-enhanced 3D-EAUS with respect to classification of the primary tract (84.4% vs 89.1%, $P = 0.435$) or secondary extension (81.8% vs 86.4%, $P = 0.435$) or localization of the internal opening (84.2% vs 89.5%, $P = 0.406$).

CONCLUSION: 3D-EAUS was highly reliable in the diagnosis of an anal fistula. H₂O₂ enhancement was

INTRODUCTION

Despite the fact that anal fistulae are very common and have been studied extensively, some complex forms still continue to pose a difficult surgical problem. The aim of treatment for an anal fistula is to permanently eliminate abscess formation and achieve healing while preserving anal function and continence. Overly aggressive fistulotomy can lead to postoperative fecal incontinence, whereas inappropriate conservative treatment could lead to fistula recurrence. Therefore, accurate preoperative assessment of a fistula is necessary for optimal surgical results.

Inspection and digital examination with or without anesthesia are basic diagnostic methods. However, digital examination may fail to detect complex fistulae or to localize the internal opening. It is now well established that preoperative imaging modalities can alert the surgeon to fistula components that might otherwise be missed^[1,2].

Endoanal ultrasonography (EAUS) has been increasingly used in the preoperative evaluation of anal fistulae. Initial EAUS evaluation was not satisfactory^[3], but the diagnostic accuracy of EAUS has improved with technical advancements in ultrasonography, including the use of H₂O₂ as a contrast agent and 3D image reconstruction^[4,5]. The image is no longer limited to the axial plane in 3D-EAUS. Instead, it is possible to cut

across any part of the data set in the coronal, sagittal, or oblique plane. This property is expected to be helpful in tracing the tract and internal opening.

The H₂O₂-enhanced 3D-EAUS is the latest development in EAUS and is expected to diagnose anal fistulae with high accuracy. However, there is limited data on the accuracy and clinical usefulness of 3D-EAUS and H₂O₂-enhanced 3D-EAUS. The purpose of this study was to evaluate the accuracy of 3D-EAUS with or without H₂O₂ enhancement in identifying the primary tract, secondary extension, and internal opening in an anal fistula, compared to surgical findings as the standard reference.

MATERIALS AND METHODS

Patients and clinical evaluation

Between January 2007 and February 2009, 61 patients (37 men and 24 women; mean age 39 years, range 17-74 years) with anal fistulae were preoperatively evaluated with physical examination, 3D-EAUS with and without enhancement, and subsequently underwent surgery. EAUS was performed when the surgeon thought preoperative imaging was clinically necessary. EAUS was not performed in patients with obvious simple fistulae with low, straight configuration and external openings close to the anus. Patients without visible external openings were also excluded.

Three patients had known Crohn's disease, and two patients had a history of anal trauma leading to anal fistula formation. All other patients were believed to have fistulae of cryptoglandular origin. Twelve patients, including the three patients with Crohn's disease, had previously undergone 15 fistula operations.

Physical examination was performed during the first visit to the outpatient clinic. Patients were examined in the left lateral position without any anesthesia. By inspection and palpation of the perianal area and by digital rectoanal examination, the fistula anatomy was determined by a single surgeon. Insertion of a probe was attempted on each occasion, provided it did not cause significant discomfort. The relationship between the components of the anal fistula and the sphincter complex was categorized (whether diagnosed with full confidence or by suspicion only) and recorded.

Physical examination aimed to determine the following fistula characteristics: (1) the primary tract, categorized according to the criteria of Parks *et al.*^[6] as intersphincteric, transsphincteric, extrasphincteric, or suprasphincteric; (2) secondary extension, including horseshoe tract and abscess formation; and (3) the internal opening, localized with respect to a clock face and categorized as anterior, left lateral, posterior, or right lateral. The anatomic location of any secondary extension arising from the primary fistula track was recorded as intersphincteric, ischiorectal, or supralevator. A horseshoe extension was defined as any extension from the primary track that appeared to extend to both sides of the internal opening, and such an extension was classified as intersphincteric or ischiorectal.

Patients underwent surgical treatment after these ex-

aminations, and each component of the anal fistula was categorized and recorded using the same criteria.

EAUS

Images were acquired with a 10-MHz, 360°, rotating endoprobe (type 2050, BK Medical, Herlev, Denmark). The data from a series of closely spaced EAUS images (0.25 mm) were combined to create a 3D volume displayed as a cube. The endoprobe was introduced into the anal canal with the patient in the left lateral position. Serial radial images were made of the distal part of the rectum and the anal canal using the automatic probe withdrawal system. Three-dimensional ultrasound images were obtained with a software program used for 3D reconstruction (Life Imaging System 2000, L3D1 version 3.5.5; B-K Medical). Fistula tracks were visualized as tube-like, hypoechoic lesions. The internal fistula opening was identified as a hypoechoic area in the intersphincteric plane, as a defect in the internal anal sphincter, or as a subepithelial breach that connected to the fistulous tract through an internal sphincter defect^[7].

After the pre-enhanced data set was saved, H₂O₂-enhanced sonography was performed as previously described, with some modifications^[8]. Briefly, a flexible intravenous cannula (16-21 G Angiocath) was inserted into the fistula tract through the external opening and fixed with adhesive tape. This cannula was connected to a 10 mL syringe containing 3% H₂O₂. Ultrasonic scanning was started approximately 20 s after instillation of H₂O₂ to allow time for bubble release. The contrast study was usually performed with infusion of a small amount (0.5-3.0 mL) of H₂O₂. Further injection of H₂O₂ at a little higher pressure was performed when contrast was not sufficient. The low echogenic tract seen on the non-enhanced study became bright due to reflection from the gas, with acoustic shadowing deep to the track after H₂O₂ installation.

After the EAUS procedures, the characteristics of the fistula were classified according to the same criteria used in the clinical evaluation.

Statistical analysis

The accuracy of the preoperative diagnosis established through physical examination, 3D-EAUS, and H₂O₂-enhanced 3D-EAUS was compared against the surgical findings. Primary fistula tracts were considered correctly classified when placed in the correct anatomic group of the Parks classification^[6]. Secondary extensions (abscess and/or horseshoe extension) were considered to be correctly classified when placed in the correct anatomical compartment and quadrant, and internal openings were considered to be correctly classified when placed in the correct quadrant and level. The accuracy of 3D-EAUS and H₂O₂-enhanced 3D-EAUS in detecting and classifying components of a given fistula was compared with the surgical findings as a reference standard. Fisher's exact test was used to detect significant differences in diagnostic accuracy. Statistical significance was defined as $P < 0.05$.

RESULTS

Preoperative clinical assessment and 3D-EAUS were

Table 1 Results of physical examination and 3D-EAUS findings in the identification of the primary fistula tract

Intersphincteric	24 ¹	3	0	89.1% (57/64) ^c
Transsphincteric	2	30 ¹	1	
Suprasphincteric	0	1	3 ¹	

Data represent number of primary tracts. ¹Absolute agreement; $P = 0.037$ between a and b, $P = 0.005$ between a and c, $P = 0.435$ between b and c.

Figure 1 Pre-enhanced and H₂O₂ enhanced 3D-EAUS image of fistula tract in the same patient. A: Hypoechoic fistula tract is seen at pre-enhanced scan (arrows); B: The fistula tract became hyperechoic due to the gas generated from H₂O₂; the tract is more clearly discriminated from adjacent tissue than at the pre-enhanced scan (arrows).

conducted in all 61 patients. One patient complained of severe local pain, and another patient noted lower abdominal pain during the instillation of H₂O₂. The instillation was stopped instantly, and the patient with abdominal pain was closely monitored. The symptoms spontaneously subsided the next day without any problems. There were no adverse effects from the instillation of H₂O₂ except in these cases. The mean duration between ultrasound and surgery was 6 d (range, 0-18 d).

Primary tract

After the surgical procedures, we identified a total of 64 primary fistula tracts in 61 patients: 26 intersphincteric fistulae, 34 transsphincteric fistulae, and 4 suprasphincteric fistulae. The accuracy of physical examination in detecting the primary fistula tract was 68.7%, with surgical findings serving as the standard reference.

The concordance rates of 3D-EAUS and H₂O₂-enhanced 3D-EAUS with surgical findings with respect to identification of the primary tract were 84.4% and 89.1%, respectively (Table 1). These figures indicate that both 3D-EAUS and H₂O₂-enhanced 3D-EAUS

were superior to physical examination in detecting the primary tract ($P = 0.037$ and $P = 0.005$, respectively). The H₂O₂ enhancement enabled detection of one more transsphincteric fistula and two more suprasphincteric fistulae. Apart from the effect on accuracy, H₂O₂ enhancement made the tract more conspicuous in ambiguous cases (Figure 1). However, there was no statistically significant difference between 3D-EAUS and H₂O₂-enhanced 3D-EAUS with respect to accurate detection of the primary tract ($P = 0.435$).

Secondary extension

Twenty-nine secondary extensions, including abscesses and horseshoe tracts, were detected in 26 patients during surgical exploration: 7 intersphincteric, 19 ischiorectal, and 3 supralelevator. The overall accuracy of clinical evaluation in identifying secondary extension was 62.1%, as shown in Table 2. The overall accuracy of 3D-EAUS (81.8%) was significantly higher than that of physical examination ($P = 0.01$). The use of H₂O₂ did not further improve the diagnostic accuracy ($P = 0.482$), but one ischiorectal extension and one supralelevator type

Table 2 Results of physical examination and 3D-EAUS findings in classification of secondary extensions

extension that were not clear on non-enhanced study were identified in enhanced study.

Internal opening

A total of 57 internal openings were detected in 54 patients at the time of surgery. No internal openings were found in seven patients, while two openings were found in three patients. The internal opening was most frequently found in the posterior position (36 patients), followed by anterior, right, and left positions. The concordance between physical examination and surgery with respect to the location of the internal opening was 59.7%. The concordance between surgical finding and 3D-EAUS was 84.2%, and that between surgical finding and H₂O₂-enhanced 3D-EAUS was 89.5%. Statistical analysis indicated that both 3D-EAUS and H₂O₂-enhanced 3D-EAUS were more accurate than physical examination (Table 3). No difference in diagnostic accuracy was noted

between 3D-EAUS and H₂O₂-enhanced 3D-EAUS, with respect to identifying the internal opening ($P = 0.406$).

DISCUSSION

There has been much controversy regarding the accuracy and usefulness of EAUS in anal fistula. According to our literature review, the accuracy of EAUS compared with surgery in the detection of the internal opening has varied between 28% and 94%, and the accuracy in the detection of the primary tract and secondary extension have been in the range of 36%-100% and 23%-92%, respectively^[9-12]. Such a wide range of accuracy rates could be related to differences in the criteria used to identify the internal opening, differences in operator experience, and differences in the complexities of fistulae recruited. In addition, the use of H₂O₂ and variable ultrasound equipment in individual studies may also

be responsible for such differences.

The most noticeable improvement in the accuracy of EAUS may derive from the use of H₂O₂ as a contrast material. Many studies have shown significantly superior results in H₂O₂-enhanced EAUS, compared to unenhanced study^[4,13,14]. Another technical development is the use of high frequency transducers and the introduction of 3D technology in EAUS^[15].

In the present study, the agreement of 3D-EAUS with surgery was excellent: 84% in the detection of primary tracts, 84% in internal openings, and 82% in secondary extensions. These outcomes are consistent with recent data concerning 3D-EAUS^[16-18].

Most reports using conventional 2D-EAUS have shown superior results with H₂O₂ enhancement. However, only a few reports have addressed the effect of H₂O₂ in 3D-EAUS. Ratto *et al*^[16] obtained improved diagnostic accuracy by using H₂O₂, and West *et al*^[5] reported high diagnostic accuracy with H₂O₂ enhanced 3D-EAUS, comparable to MRI. However, the improved accuracy was not apparent in the study of Buchanan *et al*^[17]. We identified a few more primary tracts and secondary extensions by using H₂O₂. However, there was no statistically significant difference between 3D-EAUS and H₂O₂ enhanced 3D-EAUS with respect to classifying primary tracks, internal openings, and secondary tracks.

Several explanations may be offered concerning the lack of favorable results with H₂O₂. First, 3D-EAUS was already highly accurate prior to the use of H₂O₂ in this study. The already elevated baseline may have left little room for improvement on the contrast study.

One of theoretical limitations of non-contrast EAUS is difficulty discriminating between an active tract and scar tissue since both tissues appear hypoechoic on noncontrast EAUS^[19]. The gas generated after H₂O₂ instillation makes the active tract hyperechoic. In this regard, contrasting with H₂O₂ could be more useful in patients with recurrent fistulae, which usually accompany previous operative scars. Several authors have suggested that H₂O₂ might be more helpful in recurrent cases^[8,17]. The number of recurrent or Crohn's disease cases in this study was relatively low. The paucity of recurrent and complicated cases might have limited the advantages of H₂O₂ enhancement.

Instillation of H₂O₂ is generally accepted to be very safe, but several complications have been reported, including air embolism^[20,21]. Such complications have been associated with large infusion volume or forceful instillation. Of note, one patient in this study complained of abdominal pain in the early period of this study, although symptoms subsided spontaneously. The cause for the abdominal pain is not clear, but it might be associated with the relatively large volume (10 mL) of H₂O₂ and the high injection pressure. We were very careful not to inject forcefully after that event, and no patients experienced complications thereafter. Such gentle instillation might negatively influence the usefulness of enhancement.

Another point to consider is that although H₂O₂ enhancement had little influence on diagnostic accuracy improvement, H₂O₂ enhancement often improved

the quality of images in cases where the unenhanced study barely delineated the tract as shown in Figure 1 of this study and in another report^[17]. The presence of gas in the internal opening or fistula track made the tract more obvious. It is notable that this beneficial effect was observed often in difficult cases including suprasphincteric fistula tract and recurrent fistulae, in which accurate anatomical assessment is far more important.

Considering these results, selective use of H₂O₂ in difficult cases rather than routine use may be economical and helpful.

EAUS was inferior to MRI in most earlier studies^[11,22], and it was inferior^[2,23] or equivalent^[24,25] in subsequent studies. A conventional 2D-EAUS was used in most of these comparative studies. In the only prospective comparative study evaluating 3D-EAUS and MRI, both modalities were shown to be equally accurate^[18]. The high accuracy of 3D-EAUS, which is comparable with MRI, indicates that 3D-EAUS may be the first choice in the assessment of anal fistulae, since it has advantages over MRI including easier use and lower cost.

In addition to the high accuracy and low cost, EAUS provides additional usefulness in clinical practice. Yee *et al*^[26] recognized a high incidence (92%) of coexisting occult sphincter defects in the evaluation of rectovaginal fistulae. Sphincter defects were noted more frequently based on EAUS than based on manometry or a history of fecal incontinence. In fact, the ability to accurately display the anal sphincter muscle anatomy is an inherent advantage of EAUS. This method clearly shows the overall volume of the sphincter muscle, as well as sphincter injury. Knowledge of sphincter status and associated injuries recognized on EAUS facilitates surgical decisions on whether to proceed with a sphincter-saving procedure or lay open. Surgical treatment in this study was chosen largely based on preoperative EAUS findings. Seton or mucosal advancement flap was favored over lay open when there was associated sphincter damage or a high type fistula.

Most previous reports have regarded surgical results as the reference standard. However, surgery as a gold standard has been questioned, as studies have shown that EAUS and MRI are able to detect fistula tracts that are not seen on surgical exploration^[13,18]. Buchanan *et al*^[2] suggested using clinical outcomes rather than surgical findings as a reference standard because missed occult infection is possible during surgical exploration. In view of the high accuracy of 3D-EAUS, the lack of data on clinical outcomes and the use of surgical findings as the gold standard in this study might in part have biased our results. This study was also limited by the retrospective study design and the low prevalence of high type fistulae. The latter made it difficult to draw clear conclusions as to how adequate 3D-EAUS was in detecting high type fistulae.

In conclusion, 3D-EAUS is highly reliable in the preoperative evaluation of anal fistulae. The use of H₂O₂ for enhancement offers some benefits, although it did not significantly improve the diagnostic accuracy in this

study. The selective use of H₂O₂ may be economical and reliable in difficult cases.

COMMENTS

Background

Accurate preoperative assessment of anal fistula is very important for optimal surgical results. Physical examination is a basic diagnostic method, but it often fails to accurately diagnose complex fistula. Endoanal ultrasonography (EAUS) is a useful tool in this situation, and recently introduced 3D-EAUS is expected to further increase diagnostic accuracy.

Research frontiers

In this study, the authors demonstrated that 3D-EAUS is highly accurate in the evaluation of anal fistula without or without H₂O₂ enhancement. They also showed that the selective application of H₂O₂ enhancement in difficult cases is an effective and economic strategy.

Innovations and breakthroughs

Recently, EAUS has been widely applied in the diagnosis of anal fistula. However, only a few reports have been published regarding the diagnostic accuracy of 3D-EAUS. This report would be helpful in accumulating data in this field.

Applications

This study would be a useful guideline to the surgeon dealing with anal fistula.

Peer review

The author evaluated the effectiveness of 3D-EAUS in the assessment of the anal fistula with and without H₂O₂ enhancement. This paper is written well and is an important paper for further studies.

Abstract

AIM: To evaluate the hepatoprotective activity of a hydroalcoholic extract of the bark of *Anogeissus latifolia*; *in vitro* in primary rat hepatocyte monolayer culture and *in vivo* in the liver of Wistar rats intoxicated by carbon tetrachloride (CCl₄).

METHODS: In the *in vitro* study, a primary hepatocyte monolayer culture was treated with CCl₄ and extract of *Anogeissus latifolia*. Hepatoprotective activity was demonstrated in the CCl₄ damaged primary monolayer culture. In the *in vivo* study, the hepatoprotective activity of a hydroalcoholic extract of *Anogeissus latifolia* was analyzed in liver injured CCl₄-treated rats. Biochemical parameters including serum transaminases [aspartate aminotransferase (AST) and alanine aminotransferase (ALT)] and alkaline phosphatase (ALP) in serum were

analyzed. The biochemical findings were supplemented with histopathological examination of rat liver sections.

RESULTS: *In vitro*: primary hepatocyte monolayer cultures were treated with CCl₄ and extract of *Anogeissus latifolia*. A protective activity could be demonstrated in the CCl₄ damaged primary monolayer culture. *In vivo*: Hydroalcoholic extract of *Anogeissus latifolia* (300 mg/kg) was found to have protective activity in rats with CCl₄-induced liver damage as judged from serum marker enzyme activity.

CONCLUSION: The above findings lead to the conclusion that the hydroalcoholic extract of *Anogeissus latifolia* is hepatoprotective. Hence, we suggest that the inclusion of this plant in the management of liver disorders is justified.

INTRODUCTION

Oxidative stress has been implicated in the pathogenesis of acute and chronic liver injury in a variety of pathophysiological conditions such as hepatotoxin exposure, intrahepatic cholestasis, alcoholic liver injury, liver ischemia and viral hepatitis^[1-4]. Over-production of reactive oxygen species (ROS) and nitrogen species (RNS), along with significant decrease of antioxidant defense in these pathological conditions, impairs

various cellular functions through the processes of lipid peroxidation, protein oxidation and nucleic base oxidation. Lipid peroxidation causes changes in the physical and chemical properties of cellular membranes, thus altering their fluidity and permeability, leading to impairment in membrane signal transduction and ion exchange, resulting in swelling, cytolysis, and finally, cell death. The oxidation of proteins and DNA also relates directly to cellular dysfunction and death^[5]. Accordingly, effects of antioxidants or free radical scavengers have been widely tested for the prevention and treatment of acute and chronic liver injuries. In some of the studies, antioxidants have shown beneficial effects, specifically for prevention and treatment of chronic liver injury^[6-8].

Anogeissus latifolia Wall (Combretaceae) is a large or moderate-sized tree characteristic of dry deciduous forests and available throughout India. The plant is traditionally used for the treatment of dysentery, snakebite, leprosy, diabetes, wounds and ulcers and skin diseases, in addition to hepatopathy^[9]. The hydroalcoholic extract is reported to have antioxidant activity. It has been studied for total antioxidant activity, hydrogen-donating ability, nitric oxide, superoxide scavenging activity and hydrogen peroxide decomposition activity. Integral antioxidative capacity has been determined by chemiluminescence assay. It has also been studied in a lipid peroxidation assay with a thiobarbituric acid-reactive substances (TBARS) method using rat liver homogenate^[10]. A variety of substances which might contribute to hepatoprotective activity have been identified in extracts of *Anogeissus latifolia* including tannins, gallic acid, ellagic acid and flavonoids such as lutein and quercetin, which are potential antioxidants^[11-16]. The bark of the plant is also reported to possess several biological activities such as antiulcer, antimicrobial and wound healing activities. Gastroprotective potential of *Anogeissus latifolia* extract has been studied in aspirin-, cold-resistant stress (CRS)-, pylorus ligated- and ethanol-induced ulcers. The status of the antioxidant enzymes, superoxide dismutase and catalase, has also been studied in CRS-induced ulcers^[17,18]. The bark of the plant was standardized for the presence of chemical constituents such as gallic acid and ellagic acid (0.95% w/w and 0.25% w/w, respectively) using High Performance Thin Layer Chromatography (HPTLC) by Govindrajan *et al.*^[17]. Further, we identified and quantified the other constituents of the bark, quercetin and rutin (1.875% w/w, 0.1617% w/w, respectively) using HPTLC; these are reported as potent antioxidants^[15,16] and hepatoprotective agents^[19,20]. Antioxidant action has been reported to play a crucial role in hepatoprotection^[6-8]. The hydroalcoholic extract of *Anogeissus latifolia* is reported to have chemoprotective activity in paracetamol-induced toxicity in a rat model^[21]. Thus, the present study was therefore undertaken to investigate the hepatoprotective activity of hydroalcoholic extract of *Anogeissus latifolia* *in vitro* and *in vivo* against CCl₄ intoxicated rats.

MATERIALS AND METHODS

Materials

Plant material and extraction: Bark of *Anogeissus latifolia* was collected from Chikmagalur, Karnataka, South

India during the month of May. It was authenticated by Botanical survey of India, Coimbatore, Tamilnadu, India (No. BSI/SC/5/23/06-07/Tech.880).

The bark was shade-dried and powdered coarsely. The coarse powder (250 g) obtained was treated with n-hexane to remove the fatty substances; the bark was further submitted to exhaustive lipid extraction with 70% ethanol in Soxhlet apparatus and filtered. The extract was concentrated under reduced temperature and pressure to obtain dry residue (26.8 g)^[10].

Chemicals: All chemicals and solvents used were obtained from S.D. Fine Chemicals, Mumbai, Loba Chemie Indo Austranel Co., Mumbai, Ranbaxy laboratories Ltd., Punjab, Sigma Fine Chemicals, Mumbai and Hi media Laboratories, Mumbai, India. For various biochemical estimations, kits were procured from Ecoline, E. Merck Ltd., M.I.D.C., Taloja. Liv-52 syrup was procured from Market, manufactured by Himalaya Drug Company, Bangalore.

Animals: Healthy, adult female albino rats of Wistar strain, weighing 180-220 g were obtained from the animal house of J.S.S College of Pharmacy, Ooty, India. The animal house was well ventilated and the animals were exposed to 12 h day and night cycles at a temperature of 20 ± 2°C. The animals were housed in large spacious, hygienic polypropylene cages during the course of the experimental period. The animals were fed with water and standard rat pellet obtained from M/s Hindustan Lever Ltd., Bangalore, India (CPCSEA-JSSCP/IAEM/PHY.PHARM/2006-07).

Autoanalyser and UV spectrophotometer

Microlab 100, manufactured by M/s Vital Scientific N.V., The Netherlands, was used to estimate biochemical parameters for aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP). UV-160 Spectrophotometer, manufactured by Shimadzu Corporation, Japan, was used to estimate total phenol content, total flavonol content and lipid peroxidation.

Methods

Estimation of total phenolic content: Phenolic compounds are commonly found in both edible and inedible plants and they have been reported to have multiple biological effects, including antioxidant activity^[22]. Total phenol was determined using the Folin-Ciocalteu method. This test is based on the oxidation of phenolic groups with phosphomolybdic and phosphotungstic acids. After oxidation a green blue complex is measured at 750 nm. The total phenol content of a tested material is related to its antioxidant activity^[23].

Estimation of total flavonol content: Total flavonol content was determined by the method of Woisky^[24]. This involved an aluminum chloride colorimetric method. The principle of this method is that aluminum chloride forms an acid stable complex with the C-3 or C-5 hydroxyl group of flavones and flavonols. In addition, aluminum

chloride forms acid labile complexes with the ortho-dihydroxyl groups in the A or B ring of flavonoids^[25].

Preparation of drug solution: The 70% ethanolic extract of *Anogeissus latifolia* was suspended in 1% carboxy methyl cellulose (CMC), for oral administration. The concentrations of extract selected were 100 mg and 300 mg/kg body weight. Liv-52 syrup was administered orally at 2 mL/kg body weight.

Carbon tetrachloride-induced hepatotoxicity: It is emphasized that hepatotoxins which cause acute hepatitis should have close resemblance with viral hepatitis, clinically, biochemically and histologically. Certain drugs are responsible for chronic hepatic disease. Chemically-induced hepatic injury for experimental studies should be severe enough to cause cell death or to modify hepatic functions. The mechanism of acute hepatic injury depends upon the chemical compounds used to induce toxicity. Carbon tetrachloride (CCl₄) is one of the most powerful hepatotoxins in terms of severity of injury. It causes toxic necrosis leading to biochemical changes, having clinical features similar to those of acute viral hepatitis^[26,27]. CCl₄ at a dose of 0.5 mL/kg was dissolved in olive oil (1:1) and 0.1 mL was administered for each 100 g of rat body weight intraperitoneally.

Standard Liv-52 Syrup: Liv-52 is a poly herbal formulation introduced in 1954 as a specially formulated ayurvedic herbal remedy for the treatment of viral hepatitis and has been widely prescribed for infective hepatitis ever since^[28]. It is an ayurvedic formulation available as tablets and syrup containing the following herbs: *Caparis spinosa*, *Cichorium intybus*, *Solanum nigrum*, *Terminalia arjuna*, *Cassia occidentalis*, *Achillea millefolium*, *Tamarix galica* and *Phyllanthus amarus*.

In-vitro hepatoprotective activity

Hepatotoxin and test substances: For *in vitro* studies, CCl₄ (0.1 mol/L), was used to produce submaximal toxicity in isolated rat hepatocytes. The test solutions were administered at dose levels of 125, 250 and 500 µg/mL. Liv-52 was used as a positive control at a dose level of 250 µL/mL. All the substances were dissolved in DMSO^[29].

Isolation of rat hepatocytes: The rat hepatocytes were isolated according to the method of Seglen *et al*^[30]. The livers were isolated under aseptic conditions and placed in HEPES (N-2-hydroxyethylpiperazine-N-2-ethanesulphonic acid) buffer I containing HEPES (0.01 mol/L), NaCl (0.142 mol/L) and KCl (0.0067 mol/L), pH 7.4. The livers were cut into small pieces and then incubated with a second buffer containing HEPES (0.1 mol/L), NaCl (0.0667 mol/L), KCl (0.0067 mol/L) and 0.5% Collagenase type IV, pH 7.6, for about 45 min at 37°C in an incubator with constant shaking. Hepatocytes were obtained after filtration and cold centrifugation (4°C, 200 rpm for 2 min, three times) and suspended in HEPES buffer I. The viability of the hepatocytes was assessed by trypan blue (0.2%) exclusion method^[30].

Primary cultures of rat hepatocytes: The method of Tingstrom and Obrink^[31] with slight modifications was used for the culturing of rat hepatocytes. The freshly isolated viable hepatocytes were suspended in culture medium RPMI-1640 supplemented with calf serum (10%), HEPES and gentamycin (1 µg/mL). These cells (approximately $1-1.2 \times 10^6$ /mL) were then seeded into culture bottles and incubated at 37°C in an atmosphere of 5% CO₂ in a carbon dioxide incubator. Upon incubation for 24 h the hepatocytes formed a monolayer. The newly formed cells were round and most appeared as individual cells. These cells were 95%-96% viable as confirmed by trypan blue exclusion test.

Hepatic cytotoxicity testing: The hydroalcoholic extract of *Anogeissus latifolia* was tested for hepatic cytotoxicity at 250, 500 and 1000 µg/mL on isolated rat hepatocytes. After 24 h of incubation at 37°C in a CO₂ incubator, the percentage viability of hepatocytes was tested using trypan blue exclusion^[32].

Hepatoprotective activity: Twenty-four hours after the establishment of the monolayer of hepatocytes, the medium was decanted and the culture was washed with HEPES buffer-I and finally the hepatocytes were suspended in Buffer-I. The hepatic cytotoxicity was induced with CCl₄ (0.1 mol/L). Triplicate hepatocyte suspensions (0.1 mL) from different cultures were distributed into various culture tubes labeled as control, toxicant, standard (Liv-52 + toxicant) and test (test sample + toxicant). The control group received 0.1 mL of vehicle (30% DMSO) and toxicant groups received 0.1 mL of CCl₄, while the test groups received 0.1 mL of respective test solutions (250, 500 and 1000 µg/mL) followed by 0.1 mL (0.1 mol/L) of hepatotoxin. The standard groups received 0.1 mL of Liv-52 (250 µL/mL) followed by hepatotoxin. The contents of all culture tubes were made up to 1 mL with HEPES buffer I. The contents of all the tubes were mixed well and incubated in a CO₂ incubator for 24 h at 37°C. In test and standard groups the hepatocytes were preincubated with respective solutions for 30 min and then exposed to hepatotoxin. After incubation, hepatocyte suspensions were collected to assess cell damage. Cell viability was evaluated by trypan blue exclusion method. Hepatocyte suspensions were centrifuged at 200 rpm. The leakage of the enzymes ALT and AST secreted outside the cells was determined from the supernatant.

Assessment of hepatoprotective activity: The effect of different extracts on liver protection was determined by measuring an increase in the percentage of viable cells in that group of cells incubated with extracts, compared with the control and toxicant-alone groups. Reversal of toxin-induced elevations in the level of enzymes was also considered to assess hepatoprotective activity. Kits procured from Ecoline, E. Merck Ltd., using an auto-analyser, carried out the biochemical estimations (Table 1).

In vivo acute toxicity studies: Acute oral toxicity was induced according to the Organization for Economic Co-

Table 1 Effect of *Anogeissus latifolia* extract (ALE) on CCl₄-induced toxicity in rat hepatocytes (mean \pm SE)

Treatment	Viable cells (%)	ALT (IU/L)	AST (IU/L)
Cell control	93.88 \pm 0.81	18.70 \pm 0.46	21.53 \pm 0.63
Toxicant (1 mol/L CCl ₄)	33.06 \pm 114	50.20 \pm 0.61	57.50 \pm 0.94
Std Liv52 (250 μ L/mL)	85.84 \pm 1.19 (86.7) ^a	19.46 \pm 0.35 (97.59) ^a	24.10 \pm 0.37 (92.85) ^a
ALE (250 μ g/mL)	57.63 \pm 1.58 (40.39) ^a	41.33 \pm 0.62 (28.16) ^a	44.53 \pm 1.25 (36.05) ^a
ALE (500 μ g/mL)	77.60 \pm 0.57 (73.72) ^a	38.50 \pm 0.45 (37.14) ^a	32.80 \pm 0.65 (68.66) ^a
ALE (1000 μ g/mL)	81.24 \pm 1.67 (79.20) ^a	22.23 \pm 0.50 (88.48) ^a	27.33 \pm 0.69 (83.87) ^a

Values in brackets indicate percentage protection against toxicant. Significant reduction compared to hepatotoxin (^a $P < 0.05$). ALT: Alanine aminotransferase; AST: Aspartate aminotransferase.

Operation and Development (OECD) 423 guidelines procedure^[33]. Healthy, young adult Wistar albino rats of weight variation not exceeding $\pm 20\%$ of the mean weight were selected. The animals were fasted for 4 h with free access to water only. *Anogeissus latifolia* was administered orally at a dose of 5 mg/kg initially. Mortality, if any, was observed for 3 d. If mortality was observed in two out of three animals, then the dose administered was considered as toxic dose. However, if the mortality was observed in only one animal out of three animals then the same dose was repeated again to confirm the toxic effect. If no mortality was observed, then higher doses (50, 300, 2000 mg/kg) of *Anogeissus latifolia* were employed for further toxicity studies. *Anogeissus latifolia* did not produce any behavioral changes and mortality up to the dose of 3000 mg/kg body weight. Hence, 1/10th of this dose, i.e. 300 mg/kg (high dose) was used for the study.

In-vivo hepatoprotective activity and estimation of biochemical parameters

Experimental design: Twenty four albino Wistar rats, weighing about 180–220 g were divided into 4 groups of six animals each. Group I served as solvent control (normal animals). Group II served as CCl₄ toxicant control and received 1% CMC, 2 mL/kg b.w. Group III served as positive control and received Liv-52, 2 mL/kg b.w., while Group IV received the freshly prepared *Anogeissus latifolia* suspended in 1% CMC at a dose level of 300 mg/kg b.w. The animals were treated for 7 d and on the 7th d after one hour of dosing, the toxicant CCl₄ (500 μ L/kg i.p.) was administered to all the groups except Group I. After 24 h, the animals were anesthetized and blood was collected by sino-orbital puncture for the assessment of various enzyme activities. The blood was centrifuged at 2000 rpm for 10 min. The serum was separated and was used for various biochemical estimations such as AST, ALT, and ALP. The animals were sacrificed later and the liver was perfused and excised. Part of the liver was stored in 10% formalin saline for histopathological studies. The remaining was frozen at -70°C and was used for the estimation of lipid peroxidation.

Estimation of lipid peroxidation by thiobarbituric acid reactive substances (TBARS): The level of lipid peroxidation in liver homogenate was determined by the method of Niehaus and Samuelson^[34]. Malondialdehyde

and other thiobarbituric acid reactive substances were quantified by their reactivity with thiobarbituric acid in acidic conditions. The reaction generates a pink colored chromophore, which can be read in a colorimeter at 535 nm.

Statistical analysis

The statistical analysis was carried out by one-way analysis of variance (ANOVA). The values are represented as mean \pm SE. Comparison of mean values of different groups treated with different dose levels of extracts and positive controls were estimated by Tukey's Multiple Comparison Test. $P < 0.05$ was considered significant.

RESULTS

Hepatic cytotoxicity

When normal hepatocytes were treated with the extracts under test conditions, there were no alterations in the values of percentage viable cells as compared to the control at the dose level up to 1000 μ g/mL, indicating that the extracts were not toxic to the cells.

Effects against CCl₄-induced toxicity

Incubation of hepatocytes with CCl₄ (0.1 mol/L) resulted in 65% depletion in viability of hepatocytes. Similarly an elevation of about 268.45% and 267.06% of ALT and AST levels were observed, respectively, upon intoxication with CCl₄. Hepatocytes treated with *Anogeissus latifolia* showed a concentration-dependant (100–1000 μ g/mL) protective effect by restoring the viability of hepatocytes (40.36%–79.20%), AST (28.16%–88.48%) and ALT (36.05%–83.87%) levels, while the positive control Liv-52 showed good protective effect by restoring viability (86.7%), AST (97.5%) and ALT (92.8%). The maximum protection was seen with 1000 μ g/mL of *Anogeissus latifolia*. Results are represented in Table 1.

In vivo hepatoprotective screening

Single administration of CCl₄ (500 μ L/kg, i.p) to vehicle control rats showed significant increases in ALT (222.8 \pm 10.14 IU/mL, $P < 0.001$), AST (254.9 \pm 19.3 IU/mL, $P < 0.001$) and ALP (328.5 \pm 25.36 IU/mL, $P < 0.01$) levels when compared to normal control rats (54 \pm 2.7 IU/mL, 88.17 \pm 5.47 IU/mL and 249.5 \pm 18.2 IU/mL, respectively) (Figure 1). *Anogeissus latifolia* administered at 300 mg/kg produced significant reductions in ALT 66.2 \pm 6.1 IU/mL

Table 2 Effect of *Anogeissus latifolia* on plasma biochemical parameters and lipid peroxidation in CCl₄-intoxicated rats liver (*n* = 6, mean \pm SE)

Treatment (<i>n</i> = 6)	AST (IU/L)	ALT (IU/L)	ALP (IU/L)	Lipid peroxidation nmol of MDA/mg protein
Normal	88.17 \pm 5.47	54 \pm 2.7	249.5 \pm 18.2	4.1 \pm 0.5
CCl ₄ (500 μ L/kg)	254.9 \pm 19.3 ^c	222.8 \pm 10.14 ^c	328.5 \pm 25.36 ^a	14.8 \pm 1.3 ^c
Liv52 (2 mL/kg)	111.7 \pm 8.7 ^b	71.4 \pm 5.6 ^b	255 \pm 24.1 ^b	5.4 \pm 0.6 ^b
ALE (300 mg/kg)	117 \pm 6.7 ^b	66.2 \pm 6.1 ^b	258 \pm 15.54 ^b	6.1 \pm 0.5 ^b

^a*P* < 0.01, ^c*P* < 0.001 vs normal; ^b*P* < 0.01 vs carbon tetrachloride. ALP: Alkaline phosphatase.

(*P* < 0.01), AST 117 \pm 6.7 IU/mL (*P* < 0.01) and ALP 258 \pm 15.54 IU/mL (*P* < 0.01) levels when compared to CCl₄-administered rats. Liv-52 also showed significant reductions in ALT 71.4 \pm 5.6 IU/mL (*P* < 0.01), AST 111.7 \pm 8.7 IU/mL (*P* < 0.01) and ALP 258 \pm 15.54 IU/mL (*P* < 0.01) levels when compared to CCl₄-administered rats (Table 2).

Lipid peroxidation

Lipid peroxidation was significantly elevated following CCl₄ administration (14.8 \pm 1.3 nmol, *P* < 0.001) when compared to normal control (4.1 \pm 0.5 nmol) (Figure 1). *Anogeissus latifolia* at a dose of 300 mg/kg, b.w., resulted in significant (*P* < 0.01) reductions in lipid peroxidation (6.1 \pm 0.5 nmol) when compared to toxicant control. Liv-52 at 2 mL/kg b.w., showed significant (*P* < 0.01) reductions in lipid peroxidation (5.4 \pm 0.6 nmol) when compared to CCl₄-administered rats (Table 2).

Histopathology

The protective effect of the hydroalcoholic extract of *Anogeissus latifolia* was further confirmed by histopathological examination of the control (Figure 1A), CCl₄-treated and extract-treated groups. The liver of CCl₄-treated rats (Figure 1B) shows damaged liver cells and ballooning changes of the hepatocytes. The histopathological pattern of the livers treated with extracts at 100 mg and 300 mg/kg (Figure 1C) shows mild feathery changes, little ballooning degeneration of hepatocytes along with normal hepatocytes. Positive control liver treated with Liv 52 (Figure 1D) shows a normal lobular pattern with minimal pooling of blood in the sinusoidal spaces. The present study reveals the hepatoprotective activity of the hydroalcoholic extract of *Anogeissus latifolia* against well-known hepatotoxin CCl₄.

DISCUSSION

The bark of *Anogeissus latifolia* was selected to evaluate its antihepatotoxic effect in preclinical models on the basis of its utility profile in the traditional system of medicine. Subsequently, a survey of literature suggested that it has been used for different diseases including inflammation, diabetes, diarrhoea and skin diseases, as well as hepatopathy. The bark has been evaluated scientifically for its antioxidant and wound healing activity. There was, however, no evidence of any scientific studies on its hepatoprotective action. A qualitative chemical examination showed the presence of carbohydrates, glycosides, phenolic compounds, flavonoids and tannins. The presence of

Figure 1 Photograph of rat liver (\times 100). A: Liver of a control rat showing normal hepatocytes and normal architecture; B: Liver section from a CCl₄-treated rat demonstrating damaged liver cells and ballooning changes in the hepatocytes; C: Liver section from a Liv-52-treated rat showing mild feathery change, little ballooning degeneration of hepatocytes with associated normal hepatocytes; D: Liver section from a latifolia-treated rat showing a normal lobular pattern with minimal pooling of blood in the sinusoidal spaces.

polyphenols and flavonoids supports its antioxidant potential. Total phenol content and total flavonol content was estimated in the extract, and found to be 64.43% and 43.9 mg/g of extract respectively. Since the bark has been reported to contain quercetin and rutin^[9], we estimated the quantity of these substances in the extract by HPTLC and this was found to be 1.875% w/w, and 0.1617% w/w respectively. The drug also contains gallic acid. The high percentage of quercetin, rutin and gallic acid in the extract justifies the potent antioxidant activity^[13,15,16] which results in the hepatoprotective potential of the extract. Quercetin and rutin are reported to be potential therapeutic agents as they reduce oxidative DNA damage, lipid peroxidation and quench free radicals^[35,36]. The drug, thus, is a rich source of various antioxidant chemicals which may exert a cumulative antioxidant effect producing favourable actions in various disease conditions such as hepatopathy, diabetes, inflammation and wound healing.

The hepatotoxicity induced by CCl₄ is due to its metabolite CCl₃^{*}, a free radical that binds to lipoprotein and leads to peroxidation of lipids of the endoplasmic reticulum^[37]. The ability of a hepatoprotective drug to reduce the injurious effects, or to preserve the normal hepatic physiological mechanisms which have been disturbed by a hepatotoxin, is an index of its protective effects. Although serum enzyme levels are not a direct measure of hepatic injury, they show the status of the liver. The lowering of enzyme levels is a definite indication of hepatoprotec-

tive action of the drug. The serum ALT, AST, and ALP levels are reliable markers of liver function^[38]. In our study, an increase in LPO level in liver suggests enhanced lipid peroxidation leading to tissue damage and failure of antioxidant defense mechanisms resulting in excessive free radical. In CCl₄-induced hepatitis, administration of *Anogeissus latifolia* at 300 mg/kg b.w. produced significant reductions in ALT, AST, ALP levels and lipid peroxidation. Thus it could be suggested that *Anogeissus latifolia* has hepatoprotective activity in this model, a concept which was further supported by the histopathological results. The reactive species-mediated hepatotoxicity can be effectively managed upon administration of agents possessing antioxidant^[39], free radical scavenger^[40] and anti-lipid peroxidant^[41] activities. The inhibitors of cytochrome P450 isoenzymes (CYPs) are known to reduce the toxicity of CCl₄^[19]. Rutin and quercetin, which are constituents of *Anogeissus latifolia* extract, have been reported to inhibit CYPs^[42] and might have contributed favorably toward the observed hepatoprotection. *Anogeissus latifolia*, being a potent antioxidant, free radical scavenger, contributed favourably in this regard towards the observed hepatoprotection. The *in vitro* and histopathological studies are direct evidence of efficacy of this drug as a hepatoprotectant. Thus, the presence of rutin, quercetin and other antioxidants in *Anogeissus latifolia* may be the contributing factor towards its hepatoprotective activity and justifies the folkloric use of the plant in liver diseases.

ACKNOWLEDGMENTS

We are very grateful to Mr. Mohammed Jafer, Chairman, Nizam group of Institutions, Mr. Mohammed Fathe Azmath, Secretary, Nizam group of Institutions, and Mr P Chakrabarty, Director, Nizam group of Institutions, for patronage, encouragement, guidance, and financial support extended to us during the course of the study.

COMMENTS

Background

To evaluate the hepatoprotective activity of a hydroalcoholic extract of the bark of *Anogeissus latifolia*; *in vitro* in primary rat hepatocyte monolayer culture and *in vivo* in the liver of Wistar rats intoxicated by CCl₄.

Research frontiers

Great effort has been and is still being made to minimize costs and side effects of synthetic drugs, which are being used in the treatment of liver diseases.

Innovations and breakthroughs

This product is effective both in *in vitro* and *in vivo* studies with no side effects and is cost effective. The product was observed to have an excellent reparative effect on the CCl₄-damaged hepatocytes.

Applications

This article helps to understand and implement the process of treatment with herbal medicines in liver diseases, which is safe in every aspect.

Peer review

The author/authors of this manuscript have assessed the protective effect of *Anogeissus latifolia* in CCl₄-induced hepatotoxicity of rats. Their study has shown that *Anogeissus latifolia* contributes to increased viability of cultured hepatocytes *in vitro* and also causes reduced ALT and AST levels in intoxicated rats.

group and one patient (3%) in the combination therapy group required angiographic embolization or surgery ($P = 0.31$). The total number of blood transfusions was not significantly different between the two groups (3.5 ± 4.6 U vs 3.5 ± 4.5 U, $P = 0.94$). There was no bleeding-related death in either group.

CONCLUSION: Epinephrine injection alone is as effective as epinephrine injection combined with thermotherapy for the management of delayed post-ES bleeding.

Abstract

AIM: To compare the hemostatic efficacy between epinephrine injection alone and epinephrine injection combined with thermotherapy for delayed post-endoscopic sphincterotomy (ES) bleeding.

METHODS: Cases with delayed post-ES bleeding undergoing epinephrine injection alone (epinephrine injection group, $n = 26$) or epinephrine combined with thermotherapy (combination therapy group, $n = 33$) in our institution between 1999 and 2007 were retrospectively investigated. The main outcome measurements were: initial endoscopic hemostasis, re-bleeding, complications, requirement of angiographic embolization or surgery, requirement for blood transfusion, and mortality.

RESULTS: The initial hemostatic efficacy was 96.2% for epinephrine injection alone and 100% for combination therapy ($P = 0.44$). There were four patients with re-bleeding in each group (16.0% vs 12.1%, $P = 0.72$). There was only one complication of pancreatitis from the combination therapy group. Three patients (11.5%) in the epinephrine injection

INTRODUCTION

Endoscopic sphincterotomy (ES) is the cornerstone of therapeutic endoscopic retrograde cholangiopancreatography (ERCP). The incidence of post-ES bleeding varies from 0.76%-2% to 10%-48%, depending on the definition applied^[1-6]. Post-ES bleeding is classified as immediate or delayed according to the timing of presentation^[7]. Although endoscopically observed bleeding at the time of ES occurs in approximately 10%-30% of cases, the majority of immediate post-ES bleeding episodes are self-limiting and can usually be managed conservatively^[5,8-10]. In contrast, delayed post-ES bleeding is often of clinical significance and requires more invasive intervention^[10-13].

The methods of endoscopic hemostasis for post-ES bleeding mirror those for peptic ulcer bleeding. For a bleeding peptic ulcer, epinephrine injection therapy is effective to stop bleeding and additional endoscopic treatment such as thermocoagulation after epinephrine injection can reduce the re-bleeding rate, need for surgery, and mortality^[14]. However, the bleeding mechanism for post-ES bleeding is different from that of peptic ulcer bleeding^[15]. It is unclear whether the hemostatic effect for post-ES bleeding would be similar to that of peptic ulcer bleeding if the same endoscopic methods are applied. There are a few series that specifically describe endoscopic hemostasis of post-ES bleeding, but none of them have a comparative study design^[4,5,9,13,15-17]. Therefore, this retrospective study was conducted to compare the hemostatic efficacy between epinephrine injection alone and epinephrine injection combined with thermotherapy in patients with delayed post-ES bleeding.

MATERIALS AND METHODS

Ethics

The study protocol was approved by the ethical committee at Chang Gung Memorial Hospital (IRB No.: 98-0734B).

Definitions in this study

Immediate post-ES bleeding: Any hemorrhage induced by ES and warranting endoscopic hemostasis within the procedure of ERCP.

Delayed post-ES bleeding: Any hemorrhage after completion of ERCP and manifested by melena, hematemesis or hematochezia associated with a decreased hemoglobin level from baseline.

Re-bleeding: Patients had clinical evidence of recurrent bleeding after initial successful endoscopic hemostasis, and underwent another endoscopy or procedure for the treatment of bleeding.

Coagulopathy: Patients with thrombocytopenia (defined as platelet count $< 80\,000/\mu\text{L}$), coagulopathy (defined as prolonged prothrombin time > 3 s of the control value) and renal failure requiring hemodialysis were considered for statistical analysis as a combined “coagulopathy” group^[18].

Patients

Between 1999 and 2007, 3542 patients underwent 3654 biliary ES procedures at Chang-Gung Memorial Hospital, Linkou Medical Center. ES was performed with a standard pull-type sphincterotome (KD-6G10Q-1; Olympus Co., Tokyo, Japan, or Ultratome and Tapertome; Boston Scientific Co., Spencer, IN, USA). A feedback-controlled generator was used (Erbe, ICC350; Erbe, Tübingen, Germany) and set for Endocut

mode (output limit 120 W). In difficult cases (279 cases; 7.64%) for deep cannulation, precut sphincterotomy was carried out using a needle-knife papillotome (267 cases, Huibregtse single lumen needle knife; Cook Medical Inc., Winston-Salem, NC, USA) or a standard pull-type sphincterotome (12 cases). Sixty-six patients (1.86% of patients or 1.81% of procedures) met the criteria of delayed post-ES bleeding during the study period. Seven of the 66 patients were excluded because they underwent thermal therapy alone (five cases), epinephrine injection plus hemoclippping (one case), or epinephrine injection combined with thermocoagulation and hemoclippping (one case). The remaining 59 patients were enrolled in the study. Of these 59 patients, 26 patients who underwent epinephrine injection therapy alone were classified as the “epinephrine injection group” and 33 patients who underwent epinephrine injection combined with thermotherapy were classified as the “combination therapy group”.

This study retrospectively analyzed the hemostatic efficacy for control of delayed post-ES bleeding between epinephrine injection therapy alone and epinephrine injection combined with thermotherapy. The outcome assessments compared between the groups were; initial endoscopic hemostasis, re-bleeding, complications, requirement of angiographic embolization or surgery, requirement for blood transfusion, and mortality.

Endoscopic therapy

Dilute epinephrine (1:10000) was injected in 0.5-2 mL aliquots into and around the bleeder at the sphincterotomy site until the bleeding was controlled. The group undergoing dual treatments received additional thermotherapy, including heat probe coagulation (18 cases), bipolar coagulation (gold probe, three cases), monopolar coagulation (hot biopsy forceps, 11 cases), and argon plasma coagulation (APC, one case). The heat probe device was not available in our institution after September 2007, and the gold probe was used as the substitute instrument. The settings and application were similar to those used for peptic ulcer bleeding^[19,20]. Endoscopic therapies were carried out within 24 h after initial symptoms of bleeding for inpatients (50 cases), or after arrival in the emergency room for outpatients (nine cases). Epinephrine monotherapy or dual therapy was carried out according to the endoscopist's preference. There was a trend towards performing combination therapy after 2004 (only five patients underwent combination therapy before 2004).

Statistical analysis

Data in the text and tables are expressed as mean \pm SD. The difference was compared using the two-sample *t*-test for continuous variables and the χ^2 -test or Fisher's exact test for categorical variables. The analyses were performed with statistical software of SPSS 15.0 version for Windows. A *P* value of < 0.05 was considered statistically significant.

Table 1 Clinical characteristics of patients in the two groups (mean \pm SD)

	Epinephrine injection group (<i>n</i> = 26)	Combination therapy group (<i>n</i> = 33)	<i>P</i> value
