World Journal of Gastroenterology®

Weekly Established in October 1995

Volume 15 Number 33
September 7, 2009

Contents

EDITORIAL	4097	Iatrogenic bile duct injuries: Etiology, diagnosis and management <i>Jabłońska B, Lampe P</i>
TOPIC HIGHLIGHT	4105	What is artificial endocrine pancreas? Mechanism and history <i>Nishida K, Shimoda S, Ichinose K, Araki E, Shichiri M</i>
	4111	Perioperative intensive insulin therapy using artificial endocrine pancreas in patients undergoing pancreatectomy <i>Maeda H, Okabayashi T, Yatabe T, Yamashita K, Hanazaki K</i>
	4116	Perioperative insulin therapy using a closed-loop artificial endocrine pancreas after hepatic resection <i>Okabayashi T, Maeda H, Sun ZL, Montgomery RA, Nishimori I, Hanazaki K</i>
	4122	Relationship between perioperative glycemic control and postoperative infections <i>Hanazaki K, Maeda H, Okabayashi T</i>
	4126	Intraoperative glycemic control procedures and the use of an artificial pancreas <i>Yamashita K, Yatabe T</i>
	4132	Blood glucose control in patients with severe sepsis and septic shock <i>Hirasawa H, Oda S, Nakamura M</i>
	4137	Problems associated with glucose toxicity: Role of hyperglycemia-induced oxidative stress <i>Kawahito S, Kitahata H, Oshita S</i>
ORIGINAL ARTICLES	4143	Molecular determinants of the profibrogenic effects of endothelin-1 in pancreatic stellate cells <i>Jonitz A, Fitzner B, Jaster R</i>
	4150	Measuring Ca ²⁺ influxes of TRPC1-dependent Ca ²⁺ channels in HL-7702 cells with Non-invasive Micro-test Technique <i>Zhang ZY, Wang WJ, Pan LJ, Xu Y, Zhang ZM</i>
BRIEF ARTICLES	4156	Effect of early preoperative 5-fluorouracil on the integrity of colonic anastomoses in rats <i>Ozel L, Ozel MS, Toros AB, Kara M, Ozkan KS, Tellioglu G, Krand O, Koyuturk M, Berber I</i>
	4163	Fentanyl inhibits glucose-stimulated insulin release from β -cells in rat pancreatic islets <i>Qian TL, Wang XH, Liu S, Ma L, Lu Y</i>
	4170	Indicators of prognosis after liver transplantation in Chinese hepatocellular carcinoma patients <i>Li J, Yan LN, Yang J, Chen ZY, Li B, Zeng Y, Wen TF, Zhao JC, Wang WT, Yang JY, Xu MQ, Ma YK</i>

Contents		<i>World Journal of Gastroenterology</i> Volume 15 Number 33 September 7, 2009
	4177	Overexpression of polo-like kinase1 predicts a poor prognosis in hepatocellular carcinoma patients <i>He ZL, Zheng H, Lin H, Miao XY, Zhong DW</i>
	4183	Expression and clinical significance of S100A2 and p63 in esophageal carcinoma <i>Cao LY, Yin Y, Li H, Jiang Y, Zhang HF</i>
CASE REPORT	4189	Dysplasia in perforated intestinal pneumatosis complicating a previous jejuno-ileal bypass: A cautionary note <i>Portolani N, Baiocchi GL, Gadaldi S, Fisogni S, Villanacci V</i>
	4193	Neuroendocrine carcinomas arising in ulcerative colitis: Coincidences or possible correlations? <i>Grassia R, Bodini P, Dizioli P, Staiano T, Iiritano E, Bianchi G, Buffoli F</i>
	4196	Successful interferon desensitization in a patient with chronic hepatitis C infection <i>Taghavi SA, Eshraghian A</i>
	4199	Composite neuroendocrine and adenomatous carcinoma of the papilla of Vater <i>Musialik JA, Kohut MJ, Marek T, Wodolazski A, Hartleb M</i>
	4201	Placement of percutaneous transhepatic biliary stent using a silicone drain with channels <i>Yoshida H, Mamada Y, Taniai N, Mineta S, Mizuguchi Y, Kawano Y, Sasaki J, Nakamura Y, Aimoto T, Tajiri T</i>
	4204	Sclerosing epithelioid fibrosarcoma of the liver infiltrating the inferior vena cava <i>Tomimaru Y, Nagano H, Marubashi S, Kobayashi S, Eguchi H, Takeda Y, Tanemura M, Kitagawa T, Umeshita K, Hashimoto N, Yoshikawa H, Wakasa K, Doki Y, Mori M</i>
	4209	Priapism secondary to penile metastasis of rectal cancer <i>Park JC, Lee WH, Kang MK, Park SY</i>
	4212	Retroperitoneal desmoplastic small round cell tumor: Pediatric patient treated with multimodal therapy <i>Kim YS, Cha SJ, Choi YS, Kim BG, Park SJ, Chang IT</i>
	4215	Enterovesical fistula caused by a bladder squamous cell carcinoma <i>Ou Yang CH, Liu KH, Chen TC, Chang PL, Yeh TS</i>
LETTERS TO THE EDITOR	4218	Early aggressive therapy for severe extensive ulcerative colitis <i>Cui DJ</i>

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

EDITORS FOR THIS ISSUE

Responsible Assistant Editor: *Xiao-Fang Lin*
Responsible Electronic Editor: *Xiao-Mei Zheng*
Proofing Editor-in-Chief: *Lian-Sheng Ma*

Responsible Science Editor: *Lin Tian*
Proofing Editorial Office Director: *Jian-Xia Cheng*

NAME OF JOURNAL

World Journal of Gastroenterology

RESPONSIBLE INSTITUTION

Department of Science and Technology of Shanxi Province

SPONSOR

Taiyuan Research and Treatment Center for Digestive Diseases, 77 Shuangta Xijie, Taiyuan 030001, Shanxi Province, China

EDITING

Editorial Board of *World Journal of Gastroenterology*, Room 903, Building D, Ocean International Center, No.62 Dongsihuan Zhonglu, Chaoyang District, Beijing 100025, China

Abstract

Iatrogenic bile duct injuries (IBDI) remain an important problem in gastrointestinal surgery. They are most frequently caused by laparoscopic cholecystectomy which is one of the commonest surgical procedures in the world. The early and proper diagnosis of IBDI is very important for surgeons and gastroenterologists, because unrecognized IBDI lead to serious complications such as biliary cirrhosis, hepatic failure and death. Laboratory and radiological investigations play an important role in the diagnosis of biliary injuries. There are many classifications of IBDI. The most popular and simple classification of IBDI is the Bismuth scale. Endoscopic techniques are recommended for initial treatment of IBDI. When endoscopic treatment is not effective, surgical management is considered. Different surgical reconstructions are performed in patients with IBDI. According to the literature, Roux-en-Y hepaticojejunostomy is the most frequent surgical reconstruction and recommended by most authors. In the opinion of some authors, a more physiological and equally effective type of reconstruction is end-to-end ductal anastomosis. Long term results are the most important in the assessment of the effectiveness of IBDI treatment. There are a few classifications for the long term results in patients treated for IBDI; the Terblanche scale, based on clinical biliary symptoms, is regarded as the most useful classification. Proper diagnosis and treatment of IBDI may avoid many serious complications and improve quality of life.

INTRODUCTION

Iatrogenic bile duct injuries (IBDI) remain an important problem in gastrointestinal surgery. They are most frequently caused by laparoscopic cholecystectomy, which is one of the commonest surgical procedures in the world^[1]. The early and accurate diagnosis of IBDI is very important for surgeons and gastroenterologists, because unrecognized IBDI lead to serious complications such as biliary cirrhosis, hepatic failure and death^[2,3]. The choice of the appropriate treatment for IBDI is very important, because it may avoid these serious complications and improve quality of life in patients. Therefore, the question regarding the type of treatment for patients with IBDI is still a matter of debate. Initially, endoscopic treatment is recommended in patients with IBDI. When endoscopic techniques are not effective, different surgical reconstructions are performed^[4,5]. The goal of surgical treatment is reconstruction to allow good bile flow to the alimentary tract. In order to achieve this goal, many techniques are used. There are some contradictory opinions on different surgical reconstructions in the literature.

HISTORICAL PERSPECTIVES OF RECONSTRUCTIVE BILIARY SURGERY

Anatomic knowledge of the liver and bile ducts can be traced to Babylon in 2000 BC^[6]. Gallstone disease has been found in one mummy from Amen of the 21st Dynasty. Historic notes from Mesopotamia, Greece, Egypt and Roma also show an occurrence of bile duct

disease in ancient history^[6]. The first surgical procedures performed on bile ducts were not complicated. In 1618, Fabricius removed gallstones. In 1867, Bobbs performed cholecystostomy. Cholecystostomies were also performed by Sims (1878), Kocher (1878) and Tait (1879)^[6-8]. The first planned cholecystectomy in the world was performed by Langenbuch in 1882^[6-9]. The first choledochotomy was performed by Couvoissier in 1890. Widespread use of surgical procedures on bile ducts was associated with occurrence of IBDI. The first iatrogenic bile duct injury was described by Sprengel in 1891. He also reported the first choledochoduodenostomy (ChD) for calculi (1891)^[7,10]. In 1892, Doyenn reported the first choledochocholedochostomy for the same condition^[7]. Cholecystoenterostomy to the colon was the first biliary-alimentary anastomosis and it was performed by Winiwater in 1881^[7]. The first surgical reconstruction ("end-to-side" ChD) of IBDI was performed by Mayo in 1905^[7]. The first Roux-en-Y hepaticojejunostomy (HJ) was described by Monprofit in 1908. Dahl noted Roux-en-Y HJ for surgical treatment of IBDI in 1909^[7]. In 1969, Smith created a mucosal graft anastomosis in the repair of the damaged proximal bile duct^[7]. In 1954, Hepp and Couinaud described the hilar plate and long extrahepatic course of the left hepatic duct. The left hepatic duct, after dissection of the hilar plate, was used in the repair of high strictures^[7]. In 1948, Longmire and Sanford described a technique of finding of a branch of the left hepatic duct for anastomosis in the high biliary strictures. This technique was based on partial resection of the left hepatic lobe. In 1957, this technique was modified by Soulpaut and Couinaud. They described finding much larger ductal structures in the left lobe by following the round ligament to the origin of the 3rd segment duct^[7]. In 1994, Hepp and Blumgart described a technique of hilar and intrahepatic biliary-enteric anastomosis^[11].

ETIOLOGY AND PATHOGENESIS OF IBDI

Etiology of IBDI

IBDI present about 95% of all benign biliary strictures^[12,13]. Benign biliary strictures encompass a wide spectrum involving not only IBDI, but also biliary disorders caused by other pathogenetic factors. The main causes of benign biliary strictures are presented in Table 1.

There are two main groups of surgical procedures leading to IBDI. The first group involves surgical procedures performed on the biliary tract such as open and laparoscopic cholecystectomy, choledochotomy and previous operations on bile ducts. The second group involves operations performed on other organs of the epigastrium such as gastric resection (most frequently the Billroth II partial gastric resection), hepatic resection and liver transplantation, pancreatic resections, biliary-enteric anastomoses, portacaval shunts, lymphadenectomy and other procedures within the hepato-duodenal ligament^[12,13]. IBDI occur most frequently during cholecystectomy. Recently, the number of patients with

Table 1 Main causes of benign biliary strictures

Congenital strictures	Biliary atresia and congenital cysts
Bile duct injuries	Iatrogenic: postoperative, following endoscopic and percutaneous procedures
	Following blunt or penetrating trauma of the abdomen
Inflammatory strictures	Cholelithiasis and choledocholithiasis
	Mirizzi's syndrome
	Chronic pancreatitis
	Chronic ulcer or diverticulum of the duodenum
	Abscess or inflammation of the liver or subhepatic region
	Parasitic, viral infection
	Toxic drugs
	Recurrent pyogenic cholangitis
	Primary sclerosing cholangitis
	Radiation-induced strictures
	Papillary stenosis

IBDI: Iatrogenic bile duct injuries; OC: Open cholecystectomy; LC: Laparoscopic cholecystectomy.

IBDI has increased two-fold, which has been associated with widespread use of laparoscopic cholecystectomy^[11]. The incidence of IBDI following open and laparoscopic cholecystectomy according to different authors in the literature is presented in Table 2.

Pathogenesis of IBDI

There are several factors associated with an increased risk of IBDI. Coexisting acute or chronic inflammation around the gallbladder and hepato-duodenal ligament can increase the difficulty of the surgical procedure and increase the risk of IBDI. Other factors such as patient obesity, fat within the hepato-duodenal ligament, poor exposure and bleeding in the surgical area also increase the risk of IBDI. Poor prognostic factors are also male gender and long duration of symptoms before cholecystectomy.

Anatomical anomalies of the bile ducts and hepatic arteries significantly increase the risk of IBDI. The most frequent cause of IBDI is misidentification of the bile duct as the cystic duct in cases of anomalies of cystic duct insertion into the common hepatic duct. About 70%-80% of all IBDI are a consequence of

misidentification of biliary anatomy before clipping, ligating and dividing structures^[12,13,25,26]. Excessive dissection along the common bile duct margins during open cholecystectomy can lead to biliary stricture because of damage to the three o'clock and nine o'clock axial arteries and their branches to the pericholedochal plexus. According to the literature, distal IBDI are accompanied by damage of axial arteries (10%-15%) and proximal IBDI are usually associated with damage to the hepatic artery and its branches (40%-60%)^[26-30].

Clinical presentation of IBDI

The common clinical symptoms are jaundice, fever, chills, and epigastric pain. The clinical presentation depends on the type of injury and is divided into two groups. In patients with bile leaks, bile is present in the closed-suction drain located in the subhepatic region. If the subhepatic region is not drained, subhepatic bile collection (biloma) or abscess develops. In these patients fever, abdominal pain and other signs of sepsis occur. Generally, jaundice is not observed in these patients because cholestasis does not appear. In the second group of patients with biliary strictures, jaundice caused by cholestasis is the commonest clinical symptom^[12,13].

Diagnostics of IBDI

Laboratory and radiological investigations are used in diagnosis of IBDI. Among laboratory examinations, indicators of cholestasis and liver function play an important role: serum bilirubin, alkaline phosphatase, γ -glutamyl transpeptidase, alanine and aspartate aminotransferases. In patients with IBDI without complications, the liver is not damaged. Therefore, cholestasis indicators are increased but aminotransferases are not increased in these patients. Pathological levels of aminotransferases are present in cases of secondary biliary cirrhosis as a serious complication of unrecognized or improperly treated biliary injuries. In patients with secondary biliary cirrhosis, hypoalbuminemia and coagulation defects (prolonged prothrombin time) are observed. They are the most frequently used parameters of synthetic capacity of the liver. Imaging diagnostics in IBDI involve ultrasonography of the abdominal cavity, cholangiography, endoscopic retrograde cholangiopancreatography (ERCP), computed tomography, and magnetic resonance-cholangiography. Ultrasonography of the abdominal cavity allows imaging of intrahepatic and extrahepatic bile ducts with measurement of the diameter of the common bile duct or common hepatic duct. It also shows biloma or intraabdominal abscesses in patients with bile leaks. Computed tomography is useful for more specific investigation in doubtful cases in patients with bile leaks. Percutaneous transhepatic cholangiography is useful in assessment of the bile tract proximal to the location of the damage. ERCP is a very useful method of investigation in imaging of damaged bile ducts and it allows the repair of small bile duct injuries by insertion of a biliary prosthesis. Magnetic resonance cholangiography is a sensitive (85%-100%) and non-invasive imaging modality

Figure 1 Bismuth classification of IBDI. I : Common bile duct and low common hepatic duct (CHD) > 2 cm from hepatic duct confluence; II : Proximal CHD < 2 cm from the confluence; III : Hilar injury with no residual CHD-confluence intact; IV : Destruction of confluence: right and left hepatic ducts separated; V : Involvement of aberrant right sectoral hepatic duct alone or with concomitant injury of CHD.

for the biliary tract. Currently, it is the “gold standard” in preoperative diagnosis of IBDI in patients qualifying for surgical reconstruction^[12,13,31,32].

Almost 85% of IBDI are not recognized during the primary iatrogenic surgical procedure^[33]. According to the literature, only 15%-30% of IBDI are recognized during the initial operation^[34]. According to other data, 70% of IBDI are diagnosed within 6 mo and 80% within 12 mo after the initial operation^[31].

Classification of IBDI

A number of classifications have been proposed by different authors. In our opinion, the Bismuth scale is the most useful and simple classification. It is based on the location of the injury in the biliary tract^[35]. This classification is very helpful in prognosis after repair, but does not involve the wide spectrum of possible biliary injuries. The Bismuth classification is described in Figure 1. Another classification is the Strasberg scale which, in contrast to the Bismuth scale, allows differentiation between small (bile leakage from the cystic duct) and serious injuries performed during laparoscopic cholecystectomy, but it does not play an important role in the choice of surgical treatment^[15,34,36]. The Mattox classification of IBDI takes into consideration the type of injuring factor (contusion, laceration, perforation, transection, diversion or interruption of the bile duct or the gallbladder)^[37]. There are several classifications in the literature for IBDI induced during laparoscopic cholecystectomy (Stewart *et al*^[38], Schmidt *et al*^[27], Bektas *et al*^[39]).

MANAGEMENT OF IBDI

Endoscopic and radiological treatment of IBDI

Non-invasive, percutaneous radiological and endoscopic techniques are recommended as initial treatment of IBDI. When these techniques are not effective, surgical management is considered. According to the literature, the effectiveness of a radiological approach with transhepatic stenting of the damaged biliary tract is 40%-85%. The common complications of the radiological procedures are as follows: hemorrhage (hemobilia, bleeding from hepatic parenchyma or adjacent vessels), bile leakage and cholangitis. The other complications such as pneumothorax resulting from pleural violation, bilio-pleural fistula and perforation of adjacent abdominal

structures including the gallbladder and large bowel, are described less frequently. Percutaneous dilatation is less effective (52%) than surgical treatment (89%). According to the literature, the radiological approach is also associated with a higher number of complications (35%) than surgical management (25%). Most frequently, it is recommended in very difficult cases of very high, hilar biliary strictures or in the treatment of very small diameter bile ducts^[12,13,31,40].

Endoscopic dilatation associated with insertion of biliary prosthesis during ERCP investigation is the most frequently used non-surgical method in the treatment of IBDI. According to the literature, the success of endoscopic (72%) and surgical (83%) management of IBDI is comparable. Frequency of complications in both treatment methods is also comparable (35% *vs* 26%). The common complications of endoscopic techniques regarding placement of biliary prostheses include cholangitis, pancreatitis, prosthesis occlusion, migration, dislodgement and perforation of the bile duct. Endoscopic treatment is recommended as initial treatment of benign biliary strictures, in patients with biliary fistula or when surgical treatment is not warranted^[12,13,41].

Surgical treatment of IBDI

The goal of surgical treatment is to reconstruct the bile duct to allow proper bile flow to the alimentary tract. In order to achieve this goal, many techniques are used. There are contradictory reports on the effectiveness of bile duct reconstruction methods in the literature. The following operations have been reported for surgical treatment of IBDI: Roux-en-Y HJ, end-to-end ductal biliary anastomosis (EE), ChD, Lahey HJ, jejunal interposition hepaticoduodenostomy, Blumgart (Hepp) anastomosis, Heinecke-Mikulicz biliary plastic reconstruction and Smith mucosal graft^[11,18,42-46].

Various surgical techniques including immediate surgical repair: In the case of recognition of IBDI during laparoscopic cholecystectomy, immediate cholangiography and conversion to an open procedure in order to define the extent of the injury are required. The injury should be repaired by an experienced hepatobiliary surgeon. If this is impossible, a patient should be transferred to a hepatobiliary surgery referral center after adequate drainage of the subhepatic region. Bile ducts of diameter less than 2-3 mm without communication with a main biliary tract, should be ligated in order to avoid postoperative bile leak leading to development of biloma and abscess in the subhepatic region. Bile ducts of diameter more than 3-4 mm should be repaired, not ligated, because they drain a wider hepatic area. Interruption of common hepatic duct or common bile duct continuity can be repaired by immediate tension-free EE with or without a T tube, using absorbable sutures. Security of the immediately repaired bile duct with a T tube is controversial. According to the literature, in liver transplantation, EE over a T tube is

associated with a significantly higher stricture rate than choledochostomy without a T tube (25% *vs* 11%). If the bile duct loss is too long and immediate and EE is not possible without tension, Roux-en-Y HJ is recommended^[5,12,13,25,31,47].

Surgical reconstructions: A number of reconstructions are used in surgical treatment of IBDI. There are a few conditions for proper healing of each biliary anastomosis. The anastomosed edges should be healthy, without inflammation, ischemia or fibrosis. The anastomosis should be tension-free and properly vascularized. It should be performed in a single layer with absorbable sutures^[25,38].

Currently, Roux-en-Y HJ is the most frequently performed surgical reconstruction of IBDI. In this surgical technique, a proximal common hepatic duct is identified and prepared and the distal common bile duct is sutured. End-to-side or end-to-end HJ is performed in a single layer using interrupted absorbable polydioxanone (PDS 4-0 or 5-0) sutures^[48,49]. Most authors prefer HJ because of the lower number of postoperative anastomosis strictures. According to Terblanche *et al*^[45], HJ is effective in 90% of cases. However, after this reconstruction, bile flow into the alimentary tract is not physiological, because the duodenum and upper part of the jejunum are excluded from bile passage. Physiological conditions within the proximal gastrointestinal tract are changed as a result of duodenal exclusion from bile passage. An altered bile pathway is a cause of disturbances in the release of gastrointestinal hormones^[48-50]. There is a hypothesis that in patients with HJ, the bile bypass induces gastric hypersecretion leading to a pH change secondary to altered bile synthesis and release of gastrin. A higher number of duodenal ulcers is observed in patients with HJ, which may be associated with a loss of the neutralizing effect of the bile, including bicarbonates and secondary gastric hypersecretion^[51]. Laboratory investigations revealed increased gastrin and glucagon-like immunoreactivity plasma levels and decreased triglycerides, gastric inhibitory polypeptide and insulin plasma levels in patients with HJ^[51]. An altered pathway of bile flow is also a cause of disturbance in fat metabolism in patients undergoing HJ^[51,52]. Moreover, the total surface of absorption in these patients is also decreased as a result of exclusion of the duodenum and upper jejunum from the passage of food. This hypothesis was supported by a study performed in our center. We compared early and long term results of two surgical reconstructions of IBDI: Roux-en-Y HJ and EE. The study showed a significantly lower weight gain in patients undergoing HJ in comparison to patients following physiological EE^[49]. The other disadvantage of HJ is a lack of ability to control endoscopic examination and endoscopic dilatation of the strictured biliary anastomosis. In order to resolve this problem, a longer jejunal loop (jejunostomy) is prepared and sutured to the abdominal subcutaneous tissue in the right subcostal region. Jejunostomy can be open or closed with the possibility of opening in a case of biliary

anastomosis stricture, which should be endoscopically dilated. Jejunostomy is associated with bile loss of about 40 mL/d^[53].

EE is a physiological biliary reconstruction^[49,54]. In this type of reconstruction, extensive mobilization of the duodenum with the pancreatic head through the Kocher maneuver, excision of the bile duct stricture, and refreshment of the proximal and distal stumps should be performed. Anastomosis is performed in a single layer with interrupted absorbable PDS 4-0 or 5-0 sutures^[49]. This reconstruction is not recommended by most authors because of the higher number of anastomosis strictures in comparison with HJ. We recommend EE first, because in some patients, extensive mobilization of the duodenum with the pancreatic head by the Kocher maneuver allows tension-free anastomosis after the extensive bile duct length loss. Excision of the bile duct stricture, dissection and refreshing of the proximal and distal stumps as far as the tissues are healthy and without inflammation, and the use of non-traumatic, monofilament-interrupted 5-0 sutures allows the achievement of good long term results. Use of an internal Y tube conducting the right and left hepatic ducts into the duodenum through the EE and the papilla of Vater also allows the proper healing of this anastomosis. In our department, this reconstruction was performed when the bile duct loss was from 0.5 to 4 cm. It allowed the achievement of very good long term results with effectiveness comparable to HJ. Establishing a physiological bile pathway allows proper digestion and absorption, which causes a greater weight gain in patients following EE, as noted in our study^[49]. Another essential advantage of EE is the possibility of control of the endoscopic examination in these patients. Fewer early complications are observed after EE than HJ, which is associated with opening of the alimentary tract and a higher number of anastomoses (biliary-enteric and entero-enteric)^[49].

Other biliary reconstruction methods are used less frequently. ChD is actually a rarely performed operation recommended by some authors only in cases of injury within the distal portion of the common bile duct. It guarantees physiological bile flow into the duodenum and anastomosis endoscopic control, as well as being technically easier. It is recommended in some cases of distal strictures, when use of the jejunal loop, as a result of numerous adhesions, is impossible. It should be performed on the large common bile duct (> 15 mm diameter) because the postoperative strictures are more frequent within the narrow duct. ChD should be created between the duodenum and the distal common bile duct in order to decrease the risk of so-called sump syndrome noted in 0.14%-3.3% of cases in the literature. Following ChD, recurrent ascending cholangitis because of bile reflux is noted in 0%-4% of patients^[11,51]. A higher rate of bile duct cancer in patients with ChD in comparison to HJ was noted by Tocchi *et al*^[55] during a 30-year observation period (7.6% *vs* 1.9%).

Jejunal interposition hepaticoduodenostomy, using 25-35 cm of the jejunal loop, is performed in some

surgical centers. This reconstruction includes three types of anastomosis (biliary-enteric, enteric-duodenal and entero-enteric). Biliary-enteric anastomosis is performed in a single layer with interrupted absorbable 5-0 sutures and enteric-duodenal anastomosis in a single layer with interrupted or continuous absorbable 4-0 sutures. The advantage of this reconstruction is physiological bile flow into the duodenum, which prevents duodenal ulcers caused by changes in the neurohormonal axis within the upper alimentary tract^[10,56].

The repair of hilar IBDI requires special surgical techniques. In the past, the so-called "mucosal graft technique" described by Smith in the 1960s was performed^[57,58]. This reconstruction involves creating a mucosal dome of jejunum (by removing a seromuscular patch) near the end of the Roux-en-Y loop through which a straight rubber tube is passed *via* hepatic ducts and through the liver parenchyma. This technique is based on the hypothesis that the jejunal mucosa grafts to the biliary epithelium, and a mucosa-to-mucosa anastomosis is created. Short-term results were good, but in the long term a high number of anastomosis strictures was observed. Therefore, currently, not Smith but the Blumgart-Hepp technique is used in reconstruction of hilar IBDI. In this technique, the dorsal surface of the left hepatic duct is placed parallel to the quadrate hepatic lobe; dissection and opening of the left hepatic duct longitudinally allows creation of a wide anastomosis of 1-3 cm in diameter^[11,25,57-60].

Biliary drainage: There are several methods of biliary drainage securing the anastomosis: external T tube, external Y tube, Rodney Smith drainage and internal Y tube. External T drainage involves using a typical Kehr tube with insertion of its short branches into the bile duct and passage of its long branch through the abdominal wall to the outside. Y drainage involves insertion of short branches of the Kehr tube into both right and left hepatic ducts, splinting of the anastomosis and passage of its long branch through the jejunal loop and abdominal wall to the outside (external Y drainage) or into the duodenum by the papilla of Vater (internal Y drainage). An external T or Y tube is removed percutaneously and an internal Y tube is removed endoscopically. Most frequently, external T drainage is used in biliary-enteric anastomosis and internal Y drainage in EE. In Rodney Smith drainage, two straight rubber tubes splinting the biliary-enteric anastomosis are passed *via* the hepatic ducts, through the liver parenchyma and through the abdominal wall to the outside. This drainage type is used in high intrahilar biliary-enteric anastomosis. In the past, it was used in the Smith "mucosal graft technique"^[54,58-60].

The use and duration of biliary drainage is still controversial. The advantage of biliary drainage is limitation of the inflammation and fibrosis occurring after the surgical procedure. In the opinion of some authors, the presence of the biliary tube prevents anastomosis stricture^[61]. The disadvantage of biliary drainage is a higher risk of postoperative complications^[62]. Mercado *et al*^[63]

Table 3 Terblanche clinical classification for assessment of long-term results of surgical bile duct repair

Grade	Result	
I	Excellent	No biliary symptoms with normal liver function
II	Good	Transitory symptoms, currently no symptoms and normal liver function
III	Fair	Clearly related symptoms requiring medical therapy and/or deteriorating liver function
IV	Poor	Recurrent stricture requiring correction, or related death

recommend using transanastomotic stents when there is a thin bile duct less than 4 mm in diameter, and when there is inflammation within the ductal anastomosed edges which makes proper healing of the anastomosis questionable. The duration of drainage is also controversial. According to most authors, the optimal length of time for biliary drainage is about 3 mo. Investigations showed that longer durations of biliary drainage do not provide any advantage^[18,64].

RESULTS OF SURGICAL TREATMENT OF IBDI

Short-term results and early complications

According to most authors, the early postoperative morbidity rate is 20%-30% and mortality rate 0%-2%^[31,42,44]. The most frequent early complication is wound infection, which is described in 8%-17.7%^[32,48,60,65]. Other complications reported in the literature are the following: bile collection, intra-abdominal abscess, biliary-enteric anastomosis dehiscence, biliary fistula, cholangitis, peritonitis, eventration, pneumonia, circulatory insufficiency, intra-abdominal bleeding, sepsis, infection of the urinary tract, pneumothorax, acute pancreatitis, thrombosis and embolic complications, diarrhea, ileus and multi-organ insufficiency^[18,32,42,66].

Long term results

Assessment of long term results is the most important in surgical treatment of IBDI. Proof of successful surgical treatment is the absence of biliary anastomosis stricture. In referral centers, a successful outcome after surgical repair of IBDI is observed in 70%-90% of patients^[3,5,45]. Two-thirds (65%) of recurrent biliary strictures develop within 2-3 years after the reconstruction, 80% within 5 years, and 90% within 7 years. Recurrent strictures 10 years after the surgical procedure are also described in the literature^[3,31,67]. A satisfactory length of follow-up, which is necessary in order to assess the long term results of the repair procedure, is 2-5 years^[18,31,64]. Some authors recommend 10 or 20 years of observation^[43,45].

There are a number of classifications in order to assess the long term outcomes of bile duct surgical repairs. In our opinion, the Terblanche clinical grading (1990) is the most useful classification. It is based on clinical biliary symptomatology and is presented in Table 3^[45]. Other less frequently used classifications by Nielubowicz *et al*^[68]

(1973), Lygidakis *et al*^[69] (1986), Muñoz *et al*^[70] (1990) and McDonald *et al*^[66] (1995) are described in the literature.

CONCLUSION

Surgical procedures performed within the biliary tract are very common. The incidence of IBDI has increased recently, and has been associated with increased use of laparoscopic cholecystectomy worldwide. It is essential to be careful in the proper visualization of the surgical area and the identification of structures before ligation or transection in order to decrease the risk of bile duct injuries during surgery. When biliary injury develops, early recognition and appropriate treatment are most important. Early and correct treatment allows avoidance of serious complications in patients with IBDI. Following bile duct repair, patients require long term and careful postoperative observation because of the possibility of biliary anastomosis stricture.

Abstract

The artificial endocrine pancreas is a feedback control instrument that regulates insulin delivery on a minute-by-minute basis according to measured blood glucose levels. Only one type of bedside-type artificial endocrine pancreas is now available in Japan: STG-22 (Nikkiso Co. Ltd., Japan). In the insulin infusion algorithm, insulin is infused on the basis of its proportional and derivative actions, to blood glucose concentrations with a constant time delay. The bedside-type artificial endocrine pancreas has been proven to be useful not only as a therapeutic tool for diabetes mellitus, but also as an elegant research tool for investigating the pathophysiology of the disease, by using the euglycemic hyperinsulinemic glucose clamp technique. The wearable type of closed-loop system has been developed recently. The breakthrough is the establishment of a needle-type glucose sensor. The development of closed-loop glycemic control systems that enable long-term physiological regulation has focused on implantable devices. Much effort has been expended to realize these devices.

INTRODUCTION

The strategy used in the therapy of diabetes mellitus can be divided into three periods. First, doctors attempted to prevent acute metabolic derangements and prolong the lifespan of patients through use of insulin (discovered in 1921 by Banting and Best) and through the introduction of oral hypoglycemic agents. Second, in association with prolongation of lifespan, an increase in chronic complications, especially microangiopathy, was observed. To counter these, the techniques of hemodialysis or kidney transplantation were established. The application of photocoagulation for preventing the blindness caused by diabetic retinopathy became popular. We are now in the third stage, in which we are attempting to prevent the onset of these chronic complications. Many retrospective studies and recently performed prospective studies have revealed that strict glycemic regulation is essential to prevent the onset of microangiopathy^[1-3].

HISTORY OF ARTIFICIAL ENDOCRINE PANCREAS

As early as 1959, Professor E Perry McCullagh, an endocrinologist at The Cleveland Clinic, demonstrated the concept of an implantable artificial endocrine pancreas. The closed-loop regulatory system, which consisted of a glucose monitoring device, transmitter, and insulin syringe, was looked upon as the future treatment device for diabetes mellitus.

The development of an artificial endocrine pancreas to substitute for the diseased pancreatic β cell function

has been attempted widely. Albisser *et al*^[4] in Toronto in 1974 and Shichiri *et al*^[5] in Osaka in 1975 succeeded with the clinical use of an artificial endocrine pancreas that consisted of an autoanalyzer for blood glucose determination, a minicomputer system, and a pump driving system. Next, the size of the whole system was reduced, which created a bedside-type artificial endocrine pancreas; Biostator (Miles Laboratory Inc., Elkhart, IN, USA) was developed (no longer available)^[6] and another type was developed by the Osaka University group^[7]. These devices have been used clinically on a short-term basis, and have a good reputation as elegant research tools to study the pathophysiology of diabetes mellitus.

BEDSIDE-TYPE ARTIFICIAL ENDOCRINE PANCREAS

Principle of the system

The artificial endocrine pancreas is a device that is composed of a sensor, computer and set of pumps. These components are connected in such a way as to form a closed loop for the subjects. The system is shown in Figure 1. By means of an indwelling dual-lumen catheter, venous blood is drawn into an analyzer that is modified for continuous blood glucose measurement. The computer receives the electrical signals generated by the glucose analyzer and interprets these in accordance with its internal algorithms that are programmed with specific parameters. In turn, the computer instructs one pump to delivery insulin, the amount varying according to the level of the blood glucose and its rate of change. Similarly, glucose or glucagon may be administered by another pump in a counter-regulatory manner when hypoglycemia tends to occur.

Glucose sensor

In our first artificial endocrine pancreas system, continuous glucose measurement was conducted with a Technicon AutoAnalyzer II using a modification of the glucose oxidase method^[5-7]. However, to minimize the blood sampling volume and to make the whole system smaller, a glucose sensor for continuous glucose monitoring of the whole blood was developed by combining glucose oxidase membrane with an electrode that measures hydrogen peroxide, one of the reaction products, polarographically. A key component of a low-noise blood glucose sensor with long-term stability is its membrane, therefore, hydrophilic Cuprophane 100 pmol/L with a pore size of 3 nm, was applied to cover the immobilized glucose oxidase (Figure 2).

Intravenous insulin infusion algorithm

To develop an insulin infusion algorithm, mathematical models and a computer algorithm are required. By applying the mechanical control theory, Albisser *et al*^[4] have proposed a set of relationships to translate information about blood glucose levels into rates of delivery of insulin

Figure 1 Schematic diagram of the bedside-type artificial endocrine pancreas.

Figure 2 Structure of a glucose sensor of the bedside-type artificial endocrine pancreas. The immobilized glucose oxidase was covered with hydrophilic Cuprophane 100 pmol/L.

and glucagon (or glucose). In this algorithm, the rate of insulin infusion is regulated by the proportional (static) and derivative (dynamic) control mechanisms, which provides for single-phase insulin release, as well as a biphasic response to measured blood glucose concentrations. However, glucose infusion is necessary to prevent severe hypoglycemia caused by excessive insulin infusion in response to a hyperglycemic state.

It is well known that, in rat islets perfused with glucose, a biphasic response of insulin secretion is observed. With the aid of a control theory, we assume that insulin secretion responds not only to the glucose concentration itself, but also to the rate of change in glucose concentration. In other words, against the stepwise input of glucose concentration, an initial rapid insulin secretion is achieved by the derivative action and a second milder increase in secretion is achieved by the proportional action as an output. This relationship has been simulated successfully by using the transfer function with the first-order delay in both proportional and derivative action as shown in Figure 3^[8]. By applying this principle, an insulin infusion algorithm has been developed.

The characteristics of our insulin infusion algorithm are as follows: (1) the amount of insulin infusion is small enough to keep or mimic the physiological plasma insulin concentration; and (2) glucagon infusion is

Figure 3 Mathematical model for insulin infusion algorithm. The stepwise input of glucose concentration $X(t)$ and biphasic response of insulin secretion $I(t)$ are depicted. The relationship between input and output is expressed in the transfer function. $I(s)$, $X(s)$ and $dX(s)$ are the Laplace transformed form of $I(t)$, $X(t)$ and $dX(t)/dt$, respectively. T_1 and T_2 are the first order delay in response.

not necessarily needed because the negative derivative action of blood glucose concentration reduces the insulin infusion rate when blood glucose is falling. The details of the computer algorithm have been described previously^[6,8-10].

Self-adaptive control algorithm for compensating insulin sensitivity changes

Even though the insulin secretory dynamics of healthy subjects are accomplished in patients with diabetes whose insulin sensitivity is low or super-normal, it is necessary to change manually the parameters for deciding insulin infusion rates for the adaptive control of blood glucose. Therefore, a computer algorithm for self-adaptive control has been established. Firstly, under the blood glucose regulation with artificial endocrine pancreas, the real rate of change in blood glucose concentration in each subject is calculated, and the difference between this and the projected rate of change in blood glucose concentration is assumed to be the index of insulin sensitivity. Secondly, according to the calculated insulin sensitivity, the computer automatically changes the parameters that regulate the insulin infusion rate^[11].

Glucose infusion algorithm

A counter-regulatory system might be useful and safe for the prevention of hypoglycemia caused by increased endogenous insulin secretion, and the change in insulin sensitivity that is observed frequently during insulin treatment with the artificial endocrine pancreas in patients with diabetes. In the glucose infusion algorithm, glucose is infused on the basis of proportional and

derivative actions of blood glucose concentration with a time delay constant between blood withdrawal and initiation of glucose infusion^[10,12].

Clinical application of bedside-type artificial endocrine pancreas

Only one type of bedside-type artificial endocrine pancreas is now available in Japan: STG-22 (Nikkiso Co. Ltd., Japan; Figure 4). Using this system, perfect blood glucose regulation with physiological plasma insulin profiles can be obtained in patients with diabetes. At present, clinical applications of the bedside-type artificial endocrine pancreas on a short-term basis include: blood glucose control in diabetic coma or diabetic ketoacidosis^[13], during surgery^[14-16], delivery^[17], during hemodialysis in diabetic nephropathy^[18], the prediction of the insulin requirement^[19], and blood glucose control in a hypoglycemic state such as in the case of insulinoma^[20].

In addition, by using this system, the euglycemic hyperinsulinemic glucose clamp study for the determination of insulin sensitivity in patients with diabetes is now applied widely^[21,22]. The euglycemic hyperinsulinemic clamp study was performed using an artificial pancreas according to the method of DeFronzo *et al.*^[23]. In brief, insulin is infused in a continuous fashion at a rate of 1.12-1.50 mU/kg per minute, after the priming insulin infusion during the first 10 min of the clamp at the same doses. Blood glucose levels were determined every 5 min during the 2-h clamp study, and euglycemia (5.0 mmol/L) was maintained by infusion of variable amounts of 10%-20% glucose solution. The total-body glucose disposal rate was evaluated as the mean of the glucose infusion rate during the last 30 min of the clamp. The insulin resistance index by the clamp was calculated by dividing the mean glucose infusion rate by the steady-state plasma insulin levels during the last 30 min of the clamp. The Artificial Organs Registry in Japan shows that the clinical applications of this bedside-type artificial endocrine pancreas have been increasing over time. The cumulative number of cases, including clinical and experimental applications, reached 14418 from 1983 to 2002. The number of applications was 465 in 2002 (29 for blood glucose control, 341 for laboratory and clinical research, and 95 for animal experiments) (Figure 5).

TREND IN THE DEVELOPMENT OF ARTIFICIAL ENDOCRINE PANCREAS

Wearable artificial endocrine pancreas

The ultimate goal of the development of the artificial endocrine pancreas is to achieve long-term strict glyce-mic regulation. In 1982, we succeeded in miniaturizing a glucose monitoring system to a needle-type, which consisted of a platinum anode and a silver cathode (0.4 mm in diameter and 2 cm in length). The electrode loaded with 0.6 V polarographic voltage measures hydrogen

Figure 4 Bedside-type artificial endocrine pancreas (STG-22, Nikkiso Co. Ltd. Japan).

Figure 5 Number of cases to whom the bedside-type artificial endocrine pancreas had been applied in Japan. Artificial Organs Registry Report in Japan, 2002.

peroxide produced. It has been demonstrated that this sensor possesses excellent sensor characteristics suitable for application *in vivo*. We then developed a wearable type artificial endocrine pancreas, which consisted of a needle-type glucose sensor, microcomputer system, insulin and glucagon infusion pump systems, and a battery. The total system was packed into a small unit (12 cm × 15 cm × 6 cm in size and 400 g in weight)^[24-26]. However, the major obstacle in extending the term of glycemic control is the lack of a stable and reliable glucose sensor.

To obtain stable and reliable measurement of subcutaneous tissue glucose concentrations for at least 4 d, we have developed two types of glucose sensors: a miniaturized extracorporeal glucose monitoring system based on a microdialysis sampling method^[27]; and a ferrocene-mediated needle-type glucose sensor covered with biocompatible membrane^[28]. We have also reported that subcutaneous tissue glucose concentration was monitored continuously using these systems for 4 d. Furthermore, we have developed a newly designed wearable type artificial endocrine pancreas (12.6 cm × 2.9 cm × 9.6 cm in size and 250 g in weight) (KAP-003; Nikkiso, Tokyo, Japan), which consists of a glucose sensing system, microcomputer system, syringe pump for insulin infusion, and a battery^[29] (Figure 6).

Figure 6 Newly designed wearable artificial endocrine pancreas. The total system is packed into a small unit (12.6 cm × 2.9 cm × 9.6 cm) weighing 250 g (KAP-003, Nikkiso). A glucose sensor is placed in the subcutaneous tissue and measures glucose concentration continuously. The blood glucose concentration (BG, in mg/dL) and the insulin infusion rate (IIR, in mU/min) appear every minute on a large LCD display.

Implantable artificial endocrine pancreas

The trend in the development of an artificial endocrine pancreas is now from a wearable to an implantable one. However, many problems remain to be solved for each part of the devices. Technology derived from the development of various implantable artificial organs will be beneficial for the accomplishment of the long-term clinical application of the devices.

Our study has suggested that although closed-loop portal and peripheral venous insulin delivery systems are equally effective in terms of blood glucose control and insulin requirements, portal insulin delivery is superior to peripheral delivery in maintaining more appropriate hepatic glucose handling and physiological insulin profiles. These results indicate that the portal vein is the most suitable insulin delivery route for the implantable artificial endocrine pancreas^[30,31].

With regard to the metabolic efficacy and insulin requirement, intraportal insulin therapy is expected to be more effective than intraperitoneal insulin therapy. However, because the technique of placing an insulin catheter into the portal vein in humans is associated with severe invasion and high risks, such as infection and catheter thrombosis, there have been few reports of applying intraportal insulin therapy to patients with diabetes. Recently, there have been several reports of new methods that overcome these problems^[32,33]. Thus, with technical improvement, it should be possible to safely infuse insulin intraportally.

The application of a one-chip microcomputer could make the processor system smaller. The technology derived in the process of developing the clinical applications of implantable insulin infusion pumps has contributed to the completion of the effector implantation. Implantation of the entire system requires a small and powerful long-life battery. A transcutaneous energy transmission system is one of the candidates for this. As a stable and reliable long-life implantable glucose sensor is not yet available, it is not practical to implant

all these parts of these apparatus intracorporeally. It would be adequate to implant the computer and infusion pumps and retain the glucose sensor extracorporeally to regulate insulin infusion rates by telemetric means. In the near future, an implantable artificial endocrine pancreas with a telecommunications system will be available for the treatment of diabetes mellitus.

CONCLUSION

Successful glycemic control in patients with diabetes using the artificial pancreas emphasizes the importance of continuous glycemic monitoring for strict glycemic control. However, the major obstacle for extending the term of glycemic control in patients with diabetes is the development of an implantable, high-precision glucose sensor for tissue glucose determination. A needle-type glucose sensor, which is a miniature hydrogen peroxide electrode covered by membrane with biological activity, can be implanted easily and is exchangeable. The sensor has the *in vitro* and *in vivo* characteristics suitable for continuous tissue glucose monitoring. A wearable artificial endocrine pancreas, which incorporates a needle-type glucose sensor, has been devised and has regulated glycemia physiologically in patients with diabetes for > 6 d. Further improvements in sensor design, especially in membranes with biocompatibility, might reduce the host reactions to the sensor implanted in tissue and thus extend its biological life.

and safe, without the occurrence of hypoglycemic episodes, even in patients after total pancreatectomy. Considering the increasing requirement for tight perioperative glycemic control and the recognized risk of hypoglycemia, we propose the use of an artificial endocrine pancreas that is able to monitor continuously blood glucose concentrations with proven accuracy, and administer automatically substances to return blood glucose concentration to the optimal narrow range.

Abstract

Perioperative glycemic control is important for reducing postoperative infectious complications. However, clinical trials have shown that efforts to maintain normoglycemia in intensive care unit patients result in deviation of glucose levels from the optimal range, and frequent attacks of hypoglycemia. Tight glycemic control is even more challenging in those undergoing pancreatic resection. Removal of lesions and surrounding normal pancreatic tissue often cause hormone deficiencies that lead to the destruction of glucose homeostasis, which is termed pancreatogenic diabetes. Pancreatogenic diabetes is characterized by the occurrence of hyperglycemia and iatrogenic severe hypoglycemia, which adversely effects patient recovery. Postoperatively, a variety of factors including surgical stress, inflammatory cytokines, sympathomimetic drug therapy, and aggressive nutritional support can also affect glycemic control. This review discusses the endocrine aspects of pancreatic resection and highlights postoperative glycemic control using a closed-loop system or artificial pancreas. In previous experiments, we have demonstrated the reliability of the artificial pancreas in dogs with total pancreatectomy, and its postoperative clinical use has been shown to be effective

INTRODUCTION

Under normal conditions, blood glucose homeostasis is regulated by hepatic and/or pancreatic metabolism^[1-3]. The role of the hepatocyte in producing glucose in the fasting and stressed state, or for postprandial glucose uptake is critical for metabolic homeostasis^[1,2]. These functions depend largely on three circulating glucoregulatory hormones that are secreted by the pancreas: insulin, glucagon, and pancreatic polypeptide (PP)^[1-3]. After pancreatectomy, insufficiency or deficiency of these hormones causes glucose intolerance, a form of secondary diabetes mellitus termed pancreatogenic diabetes^[4-7]. The appropriate method for glycemic control in pancreatogenic diabetes after pancreatectomy has yet to be established because of the instability of blood glucose levels, especially in patients after total pancreatectomy. In this Topic Highlight, we review the problem of pancreatogenic diabetes in patients who have undergone pancreatectomy. In addition, as a solution

to pancreatogenic diabetes, we demonstrate the safety and usefulness of tight blood glucose control using an artificial endocrine pancreas, following proximal, distal and total pancreatectomy.

PANCREATOGENIC DIABETES

Pancreatogenic diabetes is characterized by diabetes with frequent episodes of iatrogenic hypoglycemia and hyperglycemia^[8], which is referred to as brittle diabetes (Figure 1). This is true particularly for patients after total or subtotal pancreatectomy. The condition is difficult to treat because of a paradoxical combination of enhanced peripheral insulin sensitivity and decreased hepatic insulin sensitivity, in addition to decreased glucagon secretion^[8-12]. Patients become hyperglycemic because of unsuppressed hepatic glucose production, when insulin replacement is insufficient. In contrast, patients become hypoglycemic when insulin replacement is barely excessive, as a result of the enhanced peripheral insulin sensitivity and a deficiency of pancreatic glucagon secretion^[10].

Shortly after surgical resection of the pancreas, 8%-23% of patients develop pancreatogenic diabetes, which increases to 40%-50% during follow-up^[5-7]. With the increasing incidence of pancreatectomy^[13,14], pancreatogenic diabetes as a sequela to surgical resection is an urgent medical issue.

ACTIONS OF THE GLUCOREGULATORY HORMONES

Insulin

Insulin-secreting β cells are distributed evenly throughout the pancreas. Insulin decreases serum glucose concentration through suppressing hepatic gluconeogenesis, glycogenolysis and facilitating hepatic glycogen synthesis^[1,2]. Insulin receptors are expressed on nearly every cell throughout the body and insulin decreases blood glucose concentration through facilitating glucose uptake into insulin-receptor-bearing cells^[10]. In addition to the glucoregulatory effect, insulin also has an anti-inflammatory effect^[15,16].

Glucagon

Glucagon-secreting α cells are located predominantly in the body and tail of the pancreas. Together with the β cells, the function of α cells is essential for maintaining the remarkable consistency of glucose levels under various states of supply and demand^[17]. During fasting, glucagon is responsible for maintaining adequate glucose production in hepatocytes by stimulating glycogenolysis and gluconeogenesis. Thus, glucagon works as a counter-regulatory mechanism for hypoglycemia. Surgical resection that causes reduction of α cells may be associated with severe hypoglycemic episodes, especially after total or distal pancreatectomy.

PP

PP-secreting cells are located mainly in the ventral pancreatic head and uncinate process^[18-20]. Studies on a

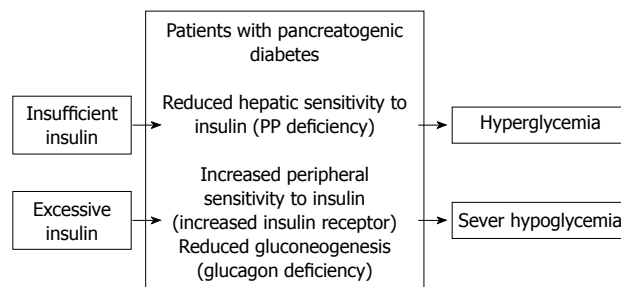

Figure 1 Pathophysiology of pancreatogenic diabetes according to published reports^[10-14].

canine model of chronic pancreatitis with accompanying PP deficiency have demonstrated hepatic resistance to insulin and inappropriate hepatic glucose production, despite physiological levels of insulin^[21]. Kono *et al*^[22] have shown that with co-infusion of PP in total pancreatectomized dogs, smaller amounts of insulin infusion are required to normalize glucose levels. Earlier studies have also demonstrated that PP reverses abnormal glucose production after pancreatectomy^[11]. Therefore, PP deficiency may serve as a potentially reversible pathophysiological factor that contributes to altered glucose metabolism^[8] following proximal or total pancreatectomy.

GLUCOSE CONTROL AFTER PANCREATECTOMY

Diabetes mellitus is a well-established risk factor for postoperative infectious complications^[23-25], and much effort has focused on preoperative glycemic control. However, after van den Berghe *et al*^[26] reported that tight glycemic control had a beneficial impact on the mortality rate of patients admitted to the intensive care unit (ICU), increased attention has been paid to postoperative glycemic control. Hyperglycemia itself, even in non-diabetic patients, has also been reported to be associated with an adverse outcome in surgical patients^[27].

Despite this increasing attention to postoperative glycemic control, tight control of blood glucose levels is still not practiced widely, because of the difficulty of keeping glucose levels within the aimed-for range, and frequent occurrences of hypoglycemia^[28,29]. Therefore, we recommend strongly the use of an artificial endocrine pancreas equipped with the ability to monitor accurately and control automatically blood glucose levels efficiently, safely and in a hands-free manner^[22,30-34].

EXPERIMENTAL STUDY

The initial aim of this experimental study was to investigate the effect of PP infusion on insulin requirements after total pancreatectomy in dogs^[22]. However, the study also demonstrated clearly the usefulness and safety of the artificial pancreas in controlling blood glucose after total pancreatectomy^[22]. We have used STG-22 (Nikkiso Co. Ltd., Tokyo, Japan) which is a bedside-type artificial

Figure 2 STG-22, a bedside-type artificial endocrine pancreas system with closed-loop.

Figure 3 Continuous blood glucose levels over 72 h in 10 dogs after total pancreatectomy^[22].

Figure 4 Postoperative blood glucose levels in the sliding scale ($n = 13$) and artificial pancreas ($n = 17$) groups during the first 18 h following pancreatectomy^[38]. Significant statistical difference ($^aP < 0.05$).

endocrine pancreas^[34]. The Nikkiso Company developed the STG-22 unit in 1984 as an artificial endocrine pancreas, which was only a single device with a closed-loop system (Figure 2). Peripheral venous blood for glucose monitoring was sampled continuously at 2 mL/h. STG-22 is capable of measuring continuously the blood glucose level with its glucose sensor, and automatically infuses insulin and/or glucose to adjust the blood glucose level in accordance with a target glucose value, which is the so called closed-loop system^[34]. Ten dogs underwent total pancreatectomy. Following surgery, five dogs were supported solely by the artificial pancreas for 72 h, while the other five were supported by the artificial pancreas plus an infusion of bovine PP at 2 pmol/kg per minute. Mean blood glucose levels and insulin requirements were compared between the two groups. In all 10 dogs, the blood glucose concentration was controlled tightly at a mean level of 110 ± 4 mg/dL, and there was no difference in mean blood glucose level between the two groups (Figure 3). The insulin requirement in the group treated with PP was 90.0 ± 20.8 mU/kg for the first day and 562.7 ± 126.5 mU/kg for the second day. This requirement was significantly less than that of the group without PP: 445.0 ± 151.9 mU/kg

for the first day and 1007.7 ± 144.9 mU/kg for the second day. During the operation of the artificial pancreas, there were no serious complications, such as catheter thrombosis, migration, infection, or episodes of hypo/hyperglycemia.

CLINICAL STUDY

In addition to endocrine insufficiency after pancreatic surgery, other factors such as surgical stress, inflammatory proteins^[35], sympathomimetic drug therapy^[3], and aggressive nutritional support can also make glycemic control difficult. To date, only one study has focused on tight postoperative glycemic control in patients undergoing pancreatic resection^[36]. Thirty patients with pancreatic neoplasia were divided prospectively into two groups: sliding scale ($n = 13$) and artificial pancreas ($n = 17$) groups. Blood glucose concentrations were monitored continuously by an artificial pancreas and glycemic control was achieved using the sliding scale method or the artificial pancreas itself.

In the sliding scale group, postoperative blood glucose levels rose steadily, and reached a maximum value of approximately 200 mg/dL between 4 and 6 h after pancreatectomy. In the artificial pancreas group, blood glucose levels decreased gradually, and reached the target range (80-110 mg/dL) by 6 h postoperatively (Figure 4). Total insulin administered per patient during the first 18 h after surgery was significantly higher in the artificial pancreas group (107 ± 109 IU) compared to the sliding scale group (8 ± 6 IU; $P < 0.01$). No hypoglycemia was recorded in either group. This study demonstrated the usefulness of the artificial pancreas for the first time in a clinical setting, using a number of cases and a prospective design.

TOTAL PANCREATECTOMY AND POSTOPERATIVE GLYCEMIC CONTROL

Total pancreatectomy results in an extreme form of pancreatogenic diabetes. The blood glucose concentration

Figure 5 Blood glucose concentration during and after total pancreatectomy in a middle-aged female patient. Blood glucose is shown by the black line. The insulin infusion rate (light grey line) increased according to the increase in glucose concentration. A: Beginning of surgery; B: Wound closure; C: Beginning of parenteral nutrition in ICU; D: Beginning of combined enteral and parenteral nutrition; GIR: Glucose infusion rate; IIR: Insulin infusion rate.

goes up and down within a short duration, and iatrogenic hypoglycemia frequently affects prognosis. The patient described here was a middle-aged woman who underwent total pancreatectomy, and during the acute postoperative phase, received catecholamines to maintain blood pressure, and nutritional support of 25 kcal/kg per day soon after transfer from the operating theatre to the ICU.

Her blood glucose concentration profile is shown in Figure 5. An artificial pancreas (STG-22) was operated for 1994 min, automatic and manual calibration was performed seven times, and each calibration took approximately 8 min. Failure of blood withdrawal occurred seven times, which was a total of 20 min (data during calibration and failure of blood withdrawal was eliminated from the data analysis). Blood sample failures were resolved easily by trained ICU nurses.

The glucose concentration was stable during surgery and immediately after completion of total pancreatectomy (A to B in Figure 5). The glucose concentration increased with the beginning of parenteral nutrition in the ICU, and immediate administration of insulin suppressed the severe hyperglycemia. With the reduction in glucose concentration, the insulin infusion rate decreased to avoid hypoglycemia (the glucose surge after C in Figure 5). Her glucose concentration increased again with the beginning of enteral nutrition (Figure 4D), followed by increased insulin infusion. Total insulin administered during the operation of STG-22 was 96 IU. Her blood glucose concentration was 80-139 mg/dL for 91.3% of the time (Figure 6). No episode of hypoglycemia, defined as a blood glucose concentration < 40 mg/dL, occurred. The artificial pancreas was shown to be safe and efficient in the patient after total pancreatectomy.

FUTURE DIRECTIONS

Recently, the Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study has reported that glycemic control for critically ill patients in the ICU

Figure 6 Histogram depicting the range and cumulative time for the blood glucose concentration of a middle-aged female who underwent total pancreatectomy.

results in beneficial effects on survival when the blood glucose concentration is targeted at ≤ 180 mg/dL^[37]. However, when limited to the surgical ICU setting, tight glycemic control also provides benefits for postoperative patients, according to a recent meta-analysis which included the results of the NICE-SUGAR study^[38]. In light of current knowledge, a prospective randomized control trial using the artificial endocrine pancreas is needed urgently to compare different ranges of blood glucose concentrations after major surgery. Such a study would ascertain the optimal range for blood glucose concentrations without hypoglycemia, which presumably weakens the potency of tight glycemic control.

In the future, along with efforts to reduce postoperative complications after pancreatectomy by improving surgical methods, drainage and patient selection, glycemic control should receive more attention, especially during the early postoperative period. Undoubtedly, it is very important to find out the optimal range for blood glucose levels and the optimal caloric intake shortly after pancreatectomy, and develop more sophisticated mechanical devices to control blood glucose.

CONCLUSION

Pancreatectomy often results in pancreatogenic diabetes for which insulin treatment is known to be difficult. To reduce the postoperative infectious complications related to hyperglycemia and iatrogenic hypoglycemia caused by conventional blood glucose control, perioperative use of an artificial pancreas is recommended as an ideal method for tight glycemic control after pancreatic surgery. The operation of an artificial endocrine pancreas is still somewhat resource-intensive and expensive, but if mortality and morbidity are reduced, it is worthwhile.

Abstract

Postoperative hyperglycemia is common in critically ill patients, even in those without a prior history of diabetes mellitus. It is well known that hyperglycemia induced by surgical stress often results in dysregulation of liver metabolism and immune function, impairing postoperative recovery. Current evidence suggests that maintaining normoglycemia postoperatively improves surgical outcome and reduces the mortality and morbidity of critically ill patients. On the basis of these observations, several large randomized controlled studies were designed to evaluate the benefit of postoperative tight glycemic control with intensive insulin therapy. However, intensive insulin therapy carries the risk of hypoglycemia, which is linked to serious neurological events. Recently, we demonstrated that perioperative tight glycemic control in surgical patients could be achieved safely using a closed-loop glycemic control system and that this decreased both

the incidence of infection at the site of the surgical incision, without the appearance of hypoglycemia, and actual hospital costs. Here, we review the benefits and requirements of perioperative intensive insulin therapy using a closed-loop artificial endocrine pancreas system in hepatectomized patients. This novel intensive insulin therapy is safe and effectively improves surgical outcome after hepatic resection.

INTRODUCTION

Anatomically, the liver is situated downstream from the pancreas. It is a primary site for the metabolism of pancreatic hormones, such as insulin and glucagon, which have a central role in the regulation of peripheral blood glucose levels^[1]. In addition, the liver is positioned downstream from the gut, from which it absorbs a large amount of ingested glucose, and is involved in glycogenolysis and gluconeogenesis. Accordingly, reduced liver function following hepatic resection using the Pringle procedure^[2] may result in metabolic disturbances of the pancreatic hormones and glucose intolerance.

Hyperglycemia has a deleterious effect on cells that passively take up glucose independent of insulin, including hepatocytes, alveolar cells, endothelial cells, neurons, and immune cells. Postoperative hyperglycemia is common in critically ill patients, even in those without a prior history of diabetes mellitus^[3-5]. It is well known that hyperglycemia induced by surgical stress often results in dysregulation of liver metabolism and immune function, leading to impaired postoperative recovery^[6,7]. Thus, the prevention of glucose toxicity in the mitochondrial compartment is important^[8].

In this Topic Highlight, we review the benefits and requirements of tight glycemic control in hepatic surgery, with a focus on postoperative infection control. We suggest that perioperative intensive insulin therapy using a closed-loop artificial endocrine pancreas system is safe and effectively improves surgical outcome after hepatic resection.

CURRENT STATE OF TIGHT GLYCEMIC CONTROL IN CRITICALLY ILL PATIENTS

In large randomized trials in which the use of tight blood glucose control (80-110 mg/dL) with intensive insulin therapy was compared with standard blood glucose control (< 200 mg/dL) in surgical intensive care unit (ICU) patients, strict control of postoperative blood glucose levels was shown to significantly reduce patient mortality and morbidity^[9,10]. In addition, postoperative hyperglycemia has been shown to be associated with an increased risk of surgical site infection (SSI)^[11,12]. Current evidence suggests that maintaining normoglycemia postoperatively improves surgical outcome and reduces mortality and morbidity in critically ill patients^[8,11,12]. These observations led to several short-lived multicenter randomized controlled studies designed to evaluate the benefit of tight glycemic control with intensive insulin therapy^[13,14]. The main reason for the early cessation of these clinical trials was the high incidence of hypoglycemia (10%-17%) induced by the intensive insulin therapy^[15,16], which could not be prevented because of technical limitations at that time^[17-19]. However, the subsequent development of accurate continuous blood glucose monitoring devices and closed-loop systems for computer-assisted blood glucose control in the ICU will likely reduce the incidence of hypoglycemia in these situations^[8].

For the reasons described above, achieving tight glycemic control with intensive insulin therapy has come under increased scrutiny in the management of patients in the surgical ICU. Recently, we demonstrated in two retrospective studies and in one randomized clinical trial that perioperative tight glycemic control using a closed-loop glycemic control system for patients undergoing liver resection was safe and effective in decreasing the incidence of SSI without increasing the risk of hypoglycemia.

INSULIN THERAPY IN THE SURGICAL ICU

In all three studies, perioperative blood glucose concentrations were monitored continuously using the STG-22 system, developed by Nikkiso Co. (Tokyo, Japan). Patients were divided into two groups: one in which glucose levels were controlled by manual injection of insulin according to the commonly used sliding-scale method (SS group)^[20,21], and a second group in which programmed infusions of insulin were administered as determined by the control algorithm of a closed-loop artificial endocrine system (AP group).

Conventional insulin therapy using the sliding-scale method

Blood glucose levels in patients in the SS group were monitored continuously by the artificial pancreas and patients were checked routinely by nursing staff every 2 h. Blood glucose levels in these patients were controlled by subcutaneous injections of regular human insulin, with the dose determined by the sliding-scale method and the target blood glucose level to avoid hypoglycemia set at 150-200 mg/dL^[20,21].

Novel insulin therapy using a closed-loop artificial endocrine pancreas system

The STG-22 unit was developed in 1984 by Nikkiso Co. as a closed-loop artificial endocrine pancreas system. The STG-22 system is a reliable and accurate device that measures blood glucose concentrations continuously and is comparable to the ABL 800FLEX machine (Radiometer Medical ApS, Brønshøj, Denmark) recommended by the National Committee for Clinical Laboratory Standards^[22,23]. The STG-22 closed-loop glycemic control system is composed of a glucose sensor for the detection and/or monitoring of glucose and pumps for the infusion of appropriate amounts of insulin or glucose^[24,25]. The insulin and glucose pumps are regulated by a computer on the basis of target blood glucose values that are defined prior to initiation of the system. The STG-22 maintains stable blood glucose concentrations by automatic infusion of regular insulin or glucose into the circulation^[24,25]. In the ICU, peripheral blood was sampled continuously at 2 mL/h over the first 18 h postoperatively to monitor glucose levels. In addition, the STG-22 was used to evaluate the patients' insulin requirements.

Statistical analysis

Continuous variables are presented as the mean \pm SD. Dichotomous variables are presented as both absolute numbers and percentages. Data were analyzed using Student's *t*-test (two-tailed), with dichotomous variables analyzed by the χ^2 test (two-tailed) or Fisher's exact test (two-tailed). *P* < 0.05 was considered significant. All analyses were performed using SPSS software (SPSS, Chicago, IL, USA).

RETROSPECTIVE STUDIES

The benefits of using a closed-loop glycemic control system in patients after hepatectomy were investigated in two retrospective studies. The aim of the first study was to evaluate the usefulness of the closed-loop system in providing continuous monitoring and strict control of postoperative blood glucose levels in patients after hepatic resection^[25]. The aim of the second study was to identify, using multivariate analysis, risk factors and predictors of SSI, as well as how to prevent the development of SSI, in a consecutive series of patients undergoing hepatic resection for liver disease in a single institution.

In the first study^[25], postoperative blood glucose levels increased initially in the SS group, reaching a plateau of approximately 250 mg/dL between 4 and 7 h after hepatectomy. Thereafter, blood glucose levels decreased, returning to normal within 16 h after surgery. In the AP group, blood glucose decreased gradually, reaching target levels (90-110 mg/dL) within 12 h after surgery. Total insulin administered per patient during the first 16 h after surgery was significantly higher in the AP group compared with the SS group (183 ± 188 IU *vs* 8 ± 7 IU, respectively, $P < 0.001$). These data suggest that the sliding-scale method is not as effective as the closed-loop artificial endocrine system in preventing hyperglycemia resulting from disturbed glucose metabolism following liver resection.

In the second study^[26], the association between SSI and various clinical parameters was investigated in 152 patients following hepatic resection. The incidence of SSI in these patients was 14.5%. Multivariate analysis identified four independent parameters that were correlated with the occurrence of SSI, namely (1) body mass index > 23.6 kg/m², (2) estimated blood loss volume > 810 mL, (3) the presence of postoperative bile leak organ/space SSI; and (4) use of the sliding-scale method for postoperative glucose control. No SSI was observed after liver resection in patients in whom postoperative blood glucose levels were controlled by an artificial pancreas. The results of this second retrospective study demonstrated that a lack of postoperative glycemic control is associated with a significantly higher incidence of postoperative infectious complications and a longer period of hospitalization.

PROSPECTIVE RANDOMIZED CLINICAL TRIAL

A prospective randomized trial was conducted in patients undergoing hepatic resection to evaluate the postoperative condition of the patients and the effects of a closed-loop artificial pancreas on tight glycemic control during intensive insulin therapy after hepatectomy^[27]. Patients were randomly assigned to receive intensive insulin therapy using a closed-loop glycemic control system (i.e. an artificial pancreas; target

Figure 1 Postoperative blood glucose levels in hepatectomized patients in whom blood glucose was controlled using either the sliding-scale method or a closed-loop artificial endocrine pancreas system (Okabayashi et al^[27] *Diabetes Care* 2009).

blood glucose 80-110 mg/dL; AP group) or conventional insulin therapy using the sliding-scale method (target blood glucose 150-200 mg/dL; SS group). Perioperative blood glucose levels were monitored continuously in both groups using a closed-loop system. Neither group experienced hypoglycemia (blood glucose < 40 mg/dL). Although perioperative blood glucose levels in the AP group were close to 100 mg/dL, those in the SS group were > 150 mg/dL, which is the same as in our first retrospective study^[25] (Figure 1). The incidence of SSI was significantly lower in the AP than in the SS group (2.3% *vs* 18.2%, respectively, $P = 0.030$), the duration of hospitalization was significantly shorter for patients in the AP group compared with the SS group (14.3 ± 5.9 d *vs* 18.7 ± 11.7 d, respectively, $P = 0.049$). The impact on hospital costs is one of the most frequently discussed consequences of SSI within a clinical setting. A few studies have presented data on the incidence and costs of infection for the hospital and post-discharge periods. As there were no incidences of post-discharge SSI in the current study, the costs-of-illness during hospitalization were incorporated into the overall costs. Total hospital costs were significantly lower for patients in the AP group than in the SS group ($16\,407 \pm 5\,284$ \$ *vs* $21\,879 \pm 15\,784$ \$, respectively, $P = 0.047$). There is evidence suggesting that SSI prolongs the length of hospitalization for patients undergoing cardiac surgery, caesarean section, orthopedic surgery and general surgery, and increases the total costs of a patient's treatment^[28]. These results support the notion that intensive insulin therapy using a closed-loop glycemic control system after hepatic resection results in the maintenance of near normoglycemia, contributing to a reduction in both the incidence of SSI and total hospital costs per patient due to a decreased duration of hospitalization. Thus, the closed-loop system promises more effective and safer intensive insulin therapy in hepatectomized patients. An important question that has arisen from this study is how to choose candidates for intensive insulin therapy using a closed-loop system. This important issue must be addressed in future studies.

Figure 2 Typical trend of blood glucose concentrations during the Pringle maneuver for hepatic resection (Maeda *et al*^[32] *Am J Surg* 2009).

PROBLEMS ASSOCIATED WITH INTENSIVE INSULIN THERAPY IN LIVER SURGERY

The possible risks of targeting normoglycemia include intraoperative hyperglycemia, hypoglycemia, and the need for perioperative parenteral nutrition.

The Pringle maneuver was introduced in liver surgery to reduce hepatic hemorrhage^[2] and is now widely used in hepatic resections to control intraoperative bleeding^[29-31]. This inflow-occlusion technique involves total compression of the hepatoduodenal ligament, generally by clamping it for 15 min during hepatic parenchymal resections, followed by 5 min of unclamping^[31,32]. The clamping-unclamping procedure is repeated until the hepatic resection is complete. Glucose concentrations just before the first Pringle maneuver were significantly higher than baseline, but decreased gradually with the first clamping of the hepatoduodenal ligament. After unclamping of the hepatoduodenal ligament, there was an immediate and marked increase in glucose levels. The decrease and subsequent increase in glucose levels are seen with following rounds of clamping and unclamping of the hepatoduodenal ligament. After the surgery is completed, glucose concentrations gradually decline (Figure 2)^[32]. In future studies, we will determine whether the rapid fluctuations in blood glucose levels during the Pringle maneuver should be controlled.

The most feared risk associated with intensive insulin therapy is postoperative hypoglycemia, which may cause convulsions, coma, and brain damage, as well as cardiac arrhythmias^[15]. In ICU studies, the risk of severe hypoglycemia (glucose < 40 mg/dL) has been shown to increase from 5.0% to 18.7% with intensive insulin therapy^[10,15,16]. Van den Berghe^[8] suggested that clinical outcome by intensive insulin therapy (targeting blood glucose level of 80-110 mg/dL) was more effective for reducing hospital mortality and morbidity in critically ill adult patients compared with moderate intensive insulin therapy (targeting blood glucose level of 110-150 mg/dL). However, a large international randomized trial in 2009

showed that a blood glucose target of less than 180 mg/dL resulted in lower mortality than a target of 81-108 mg/dL^[16]. Furthermore, contrary to this report^[8], a recent meta-analysis^[15] did not support the benefits of intensive insulin therapy that it was not associated with significantly reduced hospital mortality but was associated with an increased risk of hypoglycemia. These randomized trials had several issues as follows: (1) trials were not blinded, (2) unusually high mortality in the usual care group, (3) parenteral nutrition (different administration of energy at the ICU), and (4) a markedly increased risk of hypoglycemia. To address this issue on the focus of a more effective blood glucose control method under impartial conditions without hypoglycemia, we are constructing a prospective randomized comparison study between intensive insulin therapy and moderate intensive insulin therapy using a closed-loop artificial endocrine pancreas. There were no occurrences of hypoglycemia during intensive insulin therapy using a closed-loop glycemic control system in our series of studies. In our experience of more than 200 patients in the surgical and medical ICU, we have not seen hypoglycemia develop in any patient when intensive insulin therapy is administered using a closed-loop glycemic control system (data not shown).

Enteral feeding was started as soon as possible after patients were hemodynamically stable. However, if the energy intake target could not be achieved, parenteral feeding was initiated to compensate for the deficit. In our series, all patients were given parenteral nutrition following surgery^[33], with the total caloric requirement calculated according to the Harris-Benedict equation^[34]. Based on the results of our studies, maintaining an adequate calorie level, and controlling postoperative glucose levels with insulin therapy contributed to a reduction in the incidence of SSI. Moreover, the duration of hospitalization after liver surgery was reduced in patients who received perioperative tight glycemic control with intensive insulin therapy, and it is likely that this is related to a reduction in postoperative complications due to infection (SSI). In our studies, tight glycemic control was maintained for 18 h in patients in the surgical ICU after liver resection, and excellent glucose control was achieved without hypoglycemia using the closed-loop system.

Another outcome of our studies was that a brief period of glycemic control impacted on the incidence of SSI. Bacterial growth curves for *Escherichia coli*, *Streptococcus*, *Proteus*, *Staphylococcus* and *Pseudomonas*, among others, indicate that under optimum conditions the greatest growth occurs between 2 and 18 h^[35]. We strongly believe that by instigating perioperative tight glycemic control for a brief period (at least 18 h) after surgery, postoperative infectious morbidity is decreased.

FUTURE DIRECTIONS

Clearly, we support a recent report that suggests that the development of accurate, continuous blood glucose

monitoring devices (preferably closed-loop systems) for computer-assisted blood glucose control in the ICU will help prevent hypoglycemia^[17]. However, using currently available technology, tight glucose control (i.e. targeting blood glucose levels of 80-110 mg/dL) using a closed-loop system in the surgical ICU was not achieved in 100% of cases, with the reported range being 60%-100%. Thus, further studies are needed to determine a better algorithm with which more accurate tight glucose control can be achieved. Regardless, we believe that by using the closed-loop glycemic control system during intensive insulin therapy in the ICU, the incidence of hypoglycemia and/or problems of nutritional support are reduced, as is the burden on nursing staff that is normally associated with the requisite frequent monitoring of blood glucose levels.

CONCLUSION

Intensive insulin therapy using a closed-loop artificial endocrine pancreas system during hepatic resection not only maintained near normoglycemia, but also contributed to a reduction in the rate of SSI and a decrease in total hospital costs due to shortened hospitalization. The closed-loop glycemic control system promises to revolutionize intensive insulin therapy for patients with disturbed glucose metabolism after liver resection.

Abstract

Perioperative hyperglycemia in critically ill surgery patients increases the risk of postoperative infection (POI), which is a common, and often costly, surgical complication. Hyperglycemia is associated with abnormalities in leukocyte function, including granulocyte adherence, impaired phagocytosis, delayed chemotaxis, and depressed bactericidal capacity. These leukocyte deficiencies are the cause of infection and improve with tight glycemic control, which leads to fewer POIs in critically ill surgical patients. Tight glycemic control, such as intensive insulin therapy, has a risk of hypoglycemia. In addition, the optimal targeted blood glucose range to reduce POI remains unknown. Since 2006, we have investigated tight perioperative blood glucose control using a closed-loop artificial endocrine pancreas system, to reduce POI and to avoid hypoglycemia. In this Topic Highlight, we review the relationship between perioperative glycemic control and POI, including the use of the artificial pancreas.

INTRODUCTION

Recent evidence suggests that perioperative hyperglycemia is the main risk factor for the development of postoperative infection (POI)^[1,2]. Intensive glucose control^[3-7] leads to fewer POIs in critically ill surgical patients^[1]. However, tight glycemic control^[8-12] such as intensive insulin therapy (IIT)^[3-7] has a risk of hypoglycemia. In addition, the optimal target range for blood glucose to reduce POI remains unknown^[1,2,13-15]. We recently demonstrated that tight perioperative glycemic control can be achieved by using an artificial endocrine pancreas^[16,17] for surgical patients, and that it was a safe and effective treatment for decreasing the incidence of POI, without increasing the risk of hypoglycemia^[18-22].

In this Topic Highlight, we review the relationship between perioperative glycemic control and POI, including the use of an artificial pancreas.

RELATIONSHIP BETWEEN PERIOPERATIVE HYPERGLYCEMIA AND POI

Perioperative hyperglycemia in critically ill surgery patients increases the risk of POI, which is a common, and often costly, surgical complication^[1,2,18-22]. It is well known that diabetic patients are at higher risk of postoperative complications, including POI, than non-diabetic surgery patients. Indeed, hyperglycemia correlates positively with POI in diabetic surgical patients^[23] and with a poor prognosis following stroke or head injury^[24,25]. POI is exacerbated by perioperative hyperglycemia in critically ill surgery patients^[1].

Strict glycemic control decreases the risk of infection

and improves other outcomes for trauma, cardiac, and critically ill non-diabetic surgery patients. Ramos *et al*^[1] associated postoperative hyperglycemia with an increased risk of 30 d postoperative infectious complications and a longer hospital stay, independent of diabetic status. On the basis of these findings, they recommended evaluation of the possible benefits of postoperative glycemic control in general surgical patients^[1].

Hyperglycemia is also associated with a sustained decrease in polymorphonuclear leukocyte function^[26]. Abnormalities in leukocyte function^[27] have been identified that are caused by the hyperglycemic state. These include abnormalities in granulocyte adherence^[28], impaired phagocytosis^[29], delayed chemotaxis^[30], and depressed bactericidal capacity^[29,31]. The degree of hyperglycemia that has been shown to impair phagocytic function is as low as 200 mg/dL^[32]. These leukocyte deficiencies appear to improve with tight glycemic control^[33]. Together with the demonstrated role of perioperative hyperglycemia in POI, it is clear that tight glycemic control should improve the clinical outcome for all surgical patients.

Insulin displays a potent and acute anti-inflammatory effect by inhibiting the tissue factor, plasminogen activator inhibitor-1^[34], and the intranuclear nuclear factor κ B (NF κ B)^[35]. Insulin plays a vital role, not only in blood glucose control, but also as an anti-inflammatory and anti-oxidant agent. Insulin suppresses the proinflammatory effects of NF κ B, activator protein 1, early growth response 1, and high mobility group box 1^[34-36], as well as inhibiting nicotinamide hypoxanthine dinucleotide oxidase action to reduce reactive oxygen species production^[34,35].

IIT has been reported to reduce infection rates after neurosurgery; therefore, this approach might be an appropriate blood glucose control method to prevent POI^[37]. However, clinical evidence is still needed to confirm the efficacy of IIT for strict blood glucose control in preventing POI. Although improved control of blood glucose fluxes have high potential to improve survival and decrease morbidity in surgical patients, the association between perioperative blood glucose range and the incidence of POI remains unclear in the majority of surgical patients due to lack of evidence. Further studies, including prospective randomized controlled trials, are necessary to clarify this issue.

THE OPTIMAL TARGET RANGE FOR BLOOD GLUCOSE TO PREVENT POI IN SURGICAL PATIENTS

Good long-term glycemic control is strongly associated with significantly fewer POIs in diverse surgical populations^[38]. Zerr *et al*^[39] reported that elevated blood glucose levels of more than 200 mg/dL in diabetic patients are associated with a higher incidence of deep sternal wound infection. Use of perioperative glycemic control in the range of 150-200 mg/dL significantly reduced POI in diabetic patients undergoing open heart surgery^[40].

Van den Berghe *et al*^[3] demonstrated that tight glycemic control (IIT) to maintain blood glucose levels in the target range of 80-110 mg/dL improved morbidity and mortality in the surgical intensive care unit (ICU). However, a recent large study by NICE-SUGAR Study Investigators^[15] completely denied the effectiveness of IIT shown by Van den Berghe *et al*^[3]. Contrary to Van den Berghe's first trial^[3], IIT increased mortality among adults in the ICU and a blood glucose target less than 180 mg/dL (most frequent blood glucose value of 142 mg/dL) resulted in lower mortality than did a target of 81-108 mg/dL (most frequent blood glucose value of 107 mg/dL)^[15]. Recent meta-analysis^[41] including NICE-SUGAR^[15], concluded that IIT significantly increased the risk of hypoglycemia and conferred no overall mortality benefit among critically ill patients; however, this therapy might be beneficial to patients admitted to a surgical ICU. Some patients might benefit from IIT, although the characteristics of such patients remain to be clearly defined, as does the effect of different blood glucose algorithms, the method of measuring blood glucose, and the influence of nutritional strategies^[41]. Unfortunately, however, the optimal targeted blood glucose range to prevent POI remains unclear, especially in the intraoperative targeted blood glucose zone. IIT is also a risk factor for hypoglycemia (≤ 40 mg/dL)^[3,4,12-15], which is linked to serious neurological events. Hypoglycemia is the major potential harm of tight glucose control. Tight glycemic control without hypoglycemia will be required in the future.

TIGHT PERIOPERATIVE GLYCEMIC CONTROL USING A CLOSED-LOOP ARTIFICIAL ENDOCRINE PANCREAS SYSTEM

Since 2006, we have been developing a closed-loop artificial pancreas system^[16-20] (STG-22, Nikkiso Co. Ltd., Tokyo) to achieve perioperative glycemic control and prevent POI in general surgery, without the risk of hypoglycemia associated with tight glycemic control.

Firstly, we confirmed that the STG-22^[21,22] could reliably and accurately measure blood glucose concentration similarly to the ABL 800FLEX machine (Radiometer Medical Aps, Brønshøj, Denmark) recommended by the National Committee for Clinical Laboratory^[21,22]. This closed-loop glycemic control system maintained stable blood concentrations by the automatic infusion of regular insulin and/or glucose into the circulation^[18].

Secondly, we performed two prospective randomized clinical trials and found that tight perioperative glycemic control using a closed-loop artificial pancreas system (STG-22, Nikkiso Co. Ltd., Tokyo) decreased surgical site infection (SSI) in patients who underwent pancreatectomy^[19] or hepatectomy^[20]. In our reports, perioperative blood glucose levels were continuously monitored using an artificial endocrine pancreas^[16-20] and glucose levels were controlled using either the sliding scale method^[42] (SS group: targeted blood glucose zone

of 150-200 mg/dL) or the artificial pancreas (AP group: targeted blood glucose zone of 80-110 mg/dL). In our study of patients who had undergone a pancreatectomy, the AP group, maintained near-normal glycemia, whereas the blood glucose levels of the SS group plateaued at approximately 200 mg/dL between 4 and 6 h after pancreatectomy^[19]. In addition, the incidence of SSI in the AP group (0%) was significantly lower than that of the SS group (about 30%). In our study of patients who had undergone a hepatectomy^[20], the AP group again maintained near-normal glycemic control and a reduction in the incidence of SSI. As a consequence, the length of stay and cost of hospitalization was reduced. It is worth noting that there were no incidents of hypoglycemia using a closed-loop artificial pancreas system, despite maintaining blood glucose levels similar to those obtained with IIT. Our results support the conclusions of previous reports^[1,38-40] that glycemic control could be a simple intervention to decrease the risk of infectious complications resulting from hyperglycemia after surgery.

Thirdly, to date, more than 200 general surgeries (hepatic resection, pancreatic resection, esophageal resection, and emergency operations) have been performed under tight perioperative glycemic control using an artificial pancreas (STG-22) with no incidence of hypoglycemia^[20]. To avoid hypoglycemia in tight glycemic control and improve POI in surgery, the closed-loop artificial endocrine pancreas system is an effective and safe means. Furthermore, novel perioperative glycemic control using an artificial pancreas markedly improved the labor burden on nursing staff, and hence reduced concerns about hypoglycemia^[43].

Finally, because an ideal comparative study of tight glycemic control should be carried out under conditions without risk of hypoglycemia, blood glucose control using a closed-loop artificial pancreas system might be beneficial for the detection of the optimal target range for blood glucose in surgical patients.

CONCLUSION

Perioperative hyperglycemia increases the risk of POI. Therefore, perioperative glycemic control in patients undergoing surgery is beneficial to reduce POI. As a closed-loop artificial pancreas system is able to perform tight glycemic control without increasing the risk of hypoglycemia, it might be a safe and useful blood glucose control system in critically ill surgical patients. At present, however, the perioperative optimal target range for blood glucose to reduce POI remains uncertain. Further studies are needed to address this issue.

Abstract

Strict intraoperative glycemic control can significantly decrease the incidence of postoperative infection; however, anesthesiologists must carefully control blood glucose levels as well as properly manage the respiratory and cardiovascular systems. However, standard blood glucose measurement systems and insulin dosing algorithms, which are necessary for achieving strict glycemic control, have not yet been developed. An artificial pancreas (STG-22™; Nikkiso Co., Tokyo, Japan) is considered a highly accurate blood glucose monitoring system capable of closed-loop control of blood glucose. The device has, however, many problems to be addressed since it is a large and expensive system with little versatility, and it requires a large amount of blood to be collected. Therefore, the development of less invasive and inexpensive systems with future technological progress is greatly anticipated.

INTRODUCTION

Management of the respiratory and cardiovascular systems is the most important task of an anesthesiologist. Traditionally, the purpose of intraoperative glycemic control is to prevent three major problems: hypoglycemia, ketoacidosis, and hyperglycemia-associated osmotic diuresis (dehydration). So far, particular attention has been given only to the case of abnormal hyperglycemia. On the other hand, postoperative glycemic control appears to influence a patient's prognosis, and as a result, this has drawn attention to intraoperative glycemic control^[1,2]. In this report, the recent concept of glycemic control, problems of glycemic control procedures and effects of intraoperative glycemic control on a patient's prognosis are reviewed based on recent publications.

NEW CONCEPT OF GLYCEMIC CONTROL

The concept of glycemic control in the care of critically ill patients largely changed after van den Bergh *et al*^[3] published a report in 2001. They comparatively investigated two groups of patients admitted to a surgical intensive care unit. In the first group, insulin control was instituted when the blood glucose level exceeded 100 mg/dL in order to maintain the blood glucose level in the target range from 80 to 110 mg/dL (strict glycemic control group). In the second group, insulin control was instituted if the blood glucose level exceeded 215 mg/dL in order to maintain the blood glucose level in the target range from 180 to 200 mg/dL (conventional glycemic control group). The results of insulin control were remarkable. The mortality rate of patients during the stay in the intensive care unit was 4.6% for the strict glycemic control group *vs* 8.0% for the conventional treatment group. The mortality rate among patients who remained in the intensive care unit for five or more days was 10.6% for the strict glycemic control group *vs* 20.2% for the conventional treatment group. The in-hospital mortality rate was reduced by 3.7% by strict

glycemic control. However, the test protocol has been questioned since there is a large discrepancy between the actual mortality rate of 26.3% in the examined group and the mortality rate predicted by APACHE II score (median score 7). To address this criticism, a study was conducted in a medical intensive care unit and results were reported in 2006^[4]. This study, where long-term prognosis following a similar glycemic control was monitored for one year or longer, showed the benefits of strict glycemic control in patients who remained in the intensive care unit for three or more days, but not in those who stayed for a shorter period. The mortality rate of the strict glycemic control group was 41.5% compared with the 50.9% of the conventional treatment group. However, the underlying detailed mechanism was not clarified and various basic and clinical studies to clarify this mechanism are presently ongoing.

DOES INTRAOPERATIVE GLYCEMIC CONTROL INFLUENCE PATIENT PROGNOSIS?

To date, there have been no randomized controlled trials to assess the effects of intraoperative glycemic control on patient prognosis. However, it is likely that intraoperative hyperglycemia decreases immunocompetence and increases the incidence of wound infection^[5-10]. Various types of anesthetic agents also alter blood glucose level^[11]. Furthermore, it has been reported that the incidence of wound infection is markedly high among hyperglycemic patients whose blood glucose level was reported to be 149 mg/dL or above intraoperatively^[12,13]. Moreover, every 18 mg/dL increase in blood glucose level from 110 mg/dL is reported to increase the risk of wound infection by 17%^[14]. Based on these results, intraoperative glycemic control that maintains blood glucose at a level not higher than 150 mg/dL is considered necessary. On the other hand, intraoperative glycemic control reportedly increases the risks of hypoglycemia due to unstable actions of insulin owing to hypothermia and impaired tissue perfusion^[15,16]. Therefore, the establishment of concrete glycemic control procedures is eagerly anticipated, and the development of a continuous intraoperative blood glucose monitoring system is considered very important.

CURRENT STATUS OF GLYCEMIC CONTROL PROCEDURES

As mentioned above, concrete glycemic control procedures for achieving strict glycemic control have not yet been established. The detailed procedures described by van den Bergh *et al.*^[3] in 2001 were not very clear. According to another line of thought, full-time staff can be designated to carry out frequent blood glucose measurements in order to achieve glycemic control. While this validates this line of thought, it can not

be executed in general practice. To perform accurate and safe glycemic control, the following elements are considered important: (1) frequency of blood glucose measurements, (2) accuracy of blood glucose measurement results, (3) accuracy of the insulin dosing algorithm, and (4) blood collection volume.

FREQUENCY OF BLOOD GLUCOSE MEASUREMENT

As for the frequency of blood glucose measurement, continuous monitoring is preferable to intermittent measurements. Two types of system capable of continuous blood glucose monitoring are currently used. One measures glucose concentration in the intracellular substance obtained by directly inserting an electrode subcutaneously, and the other collects venous blood continuously for blood glucose monitoring^[17,18]. The former system is based on the near proportional relation between glucose concentration in the intracellular substance and blood glucose level. However, the measurement stability of this type of system is in question because rapid changes in blood glucose level are not readily reflected in the intracellular substance. On the other hand, an artificial pancreas (STG-22TM) was developed by Nikkiso (Tokyo, Japan) and this device is considered the only system in the world representing the latter type of system, which collects venous blood continuously and performs blood glucose monitoring. Furthermore, this system carries out direct measurements of blood glucose and can therefore show rapid changes in blood glucose level (Figures 1 and 2). Although STG-22TM is expected to serve as a standard blood glucose monitoring system, it cannot be used for all patients because of its high cost. Generally, intermittent blood glucose measuring systems are highly versatile and can be used in any facility. However, many difficulties are encountered in their use for strict glycemic control, mostly attributed to increased workloads from frequent measurements and large measurement errors^[19]. It is considered that the achievement of strict glycemic control is currently supported by the efforts and dedication of medical staff as well as through proper education^[18].

PROBLEMS ENCOUNTERED REGARDING THE VOLUME OF BLOOD COLLECTED

To achieve successful strict glycemic control, blood glucose measurement must be performed at least every hour. Since around 0.5 mL of blood is required for a single blood glucose measurement, a total of 12 mL of blood in point-of-care blood glucose testing must be collected daily. When blood glucose control is unstable, more frequent measurements are needed and approximately 20 mL of blood must be collected daily solely for blood glucose measurement. This becomes a considerable burden for patients with anemia and for

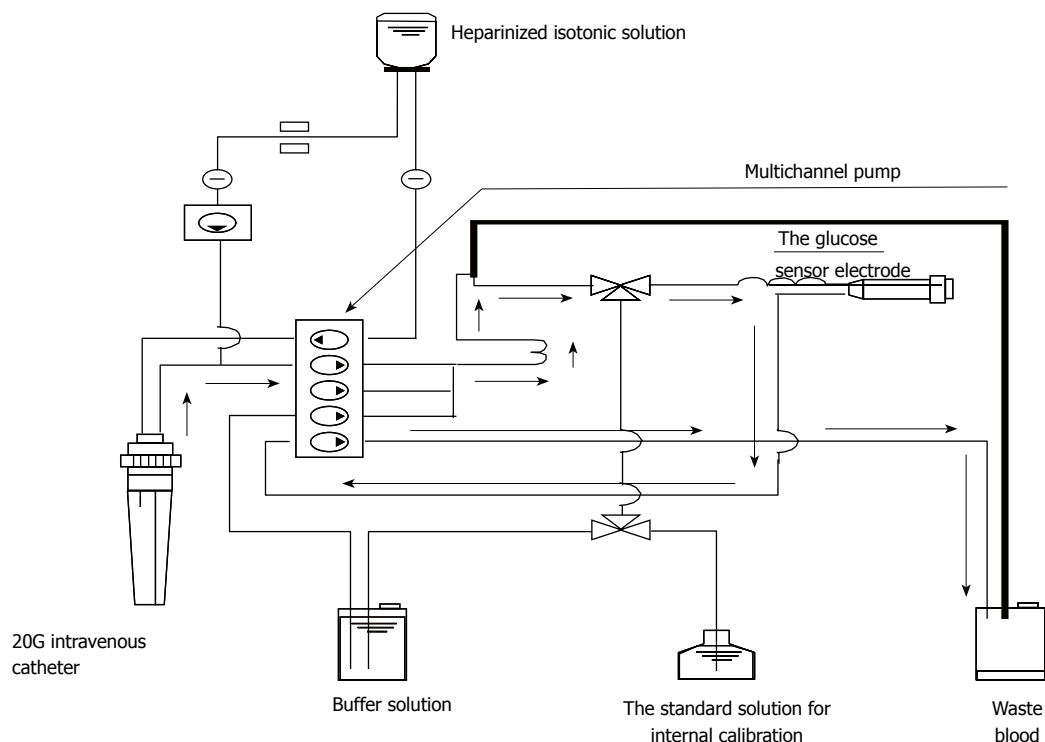

Figure 1 The whole circuit of the STG-22™. Arrows indicate the direction of blood sampling.

Figure 2 This figure shows the dual lumen catheter technique.

Figure 3 Scatter plot of individual blood glucose levels measured by both STG-22™ and ABL™ 800FLEX during surgery^[20].

glucose measurement technologies requiring no blood collection is greatly anticipated.

ACCURACY OF BLOOD GLUCOSE MEASUREMENT RESULTS

Measurement errors become an issue during strict glycemic control for maintaining blood glucose at a level between 80 and 110 mg/dL. According to the standards established by the International Organization for Standardization, the errors defined for glucose concentrations of 4.1 mmol (74 mg/dL) or above must not be greater than 20%, and those for glucose concentrations of 4.1 mmol (74 mg/dL) or below must not be greater than ± 0.8 mmol (14 mg/dL), and these values are not guaranteed by the accuracy of portable blood glucose measurement systems. STG-22™, which is currently being used for a clinical study by our group, is a highly accurate and reliable system. Its measurement errors are below 21% during intraoperative measurement^[20] (Figure 3) and not more than 15% during postoperative measurements^[21] (Figures 4-6). These findings suggest that STG-22™ can sufficiently perform closed loop control of blood glucose based on measurement results.

ACCURACY OF INSULIN DOSING ALGORITHMS

Sliding scale dosing of insulin, described previously as a special feature, is not described here. A program that calculates insulin dosage based on the blood glucose level, rate of its change and target blood glucose level

pediatric patients, and thus the development of blood

is expected to be used widely in clinical applications, since such a program has been reported to decrease the incidence of hypoglycemia by approximately 0.3%^[22]. On the other hand, STG-22™ is the only system equipped with a closed-loop algorithm that enables continuous measurement of blood glucose levels and provides updated results. This system utilizes Shichiri's algorithm, which calculates insulin dosage on the basis

of the fact that glucose-stimulated insulin secretion is based on the proportional-derivative action^[23]. The results of our previous studies have proven that use of STG-22™ achieves good postoperative glycemic control among patients who received surgical treatments^[24,25]. Here, we aim to further evaluate the applicability of this system to intraoperative glycemic control.

NEW BLOOD GLUCOSE MEASUREMENT TECHNOLOGY

A continuous noninvasive blood glucose monitoring system is an ideal instrument for strict glycemic control. Pasic *et al*^[26] previously developed a blood glucose measurement system by combining microdialysis and an optic fiber, and they succeeded in performing continuous *in vitro* measurement for 3 d. Maruo *et al*^[27] have also developed a near-infrared based blood glucose monitoring system, and its application to patients in the intensive care unit showed a good outcome. However, these systems present disadvantages in terms of convenience and accuracy, making strict glycemic control difficult. Further improvements to these systems are needed.

NEW INSULIN DOSING TECHNOLOGIES

Recently, an insulin inhalant has been approved in the US and Europe. In terms of drug assimilation, the lung possesses a large surface area for drug absorption. Moreover, the rate of solute absorption is fast in the alveolar epithelium, and mucosal clearance in the alveoli is slower than that in the bronchi. Therefore, the lung is a very suitable route for administering high-molecular-weight insulin. Because of the reasons mentioned above, the lung can therefore possibly be used as a new route for administering drugs when peripheral circulation is impaired. In support of this, Barnett *et al*^[28] have reported that long-term inhaled insulin therapy has no adverse effects on pulmonary function and thus its wide application is expected in the future.

CONCLUSION

A highly accurate continuous blood glucose monitoring system and closed-loop control of blood glucose are essential for anesthesiologists to achieve strict intraoperative glycemic control. STG-22TM is the only system that performs both functions; however, it requires 50 mL of blood per day for continuous blood glucose monitoring, and the collection of such a volume is invasive and remains laborious. With technological progress, the development of blood glucose monitoring systems with improved convenience, accuracy and minimal invasiveness are anticipated in the future.

Abstract

The main pathophysiological feature of sepsis is the uncontrollable activation of both pro- and anti-inflammatory responses arising from the overwhelming production of mediators such as pro- and anti-inflammatory cytokines. Such an uncontrollable inflammatory response would cause many kinds of metabolic derangements. One such metabolic derangement is hyperglycemia. Accordingly, control of hyperglycemia in sepsis is considered to be a very effective therapeutic approach. However, despite the initial enthusiasm, recent studies reported that tight glycemic control with intensive insulin therapy failed to show a beneficial effect on mortality of patients with severe sepsis and septic shock. One of the main reasons for this disappointing result is the incidence of harmful hypoglycemia during intensive insulin therapy. Therefore, avoidance of hypoglycemia during intensive insulin therapy may be a key issue in effective tight glycemic control. It is generally accepted that glycemic control aimed at a blood glucose level of 80-100 mg/dL, as initially proposed by van den Berghe, seems to be too tight and that such a level of tight glycemic control puts septic patients at increased risk of hypoglycemia. Therefore, now many researchers suggest less strict glycemic control with a target blood glucose level of 140-180 mg/dL. Also specific targeting of glycemic control in diabetic patients should be considered. Since there is a significant

correlation between success rate of glycemic control and the degree of hypercytokinemia in septic patients, some countermeasures to hypercytokinemia may be an important aspect of successful glycemic control. Thus, in future, use of an artificial pancreas to avoid hypoglycemia during insulin therapy, special consideration of septic diabetic patients, and control of hypercytokinemia should be considered for more effective glycemic control in patients with severe sepsis and septic shock.

INTRODUCTION

There are many pathophysiological changes during severe sepsis and septic shock, and one of the most striking is metabolic derangement. Among the metabolic changes, hyperglycemia is the most important^[1,2]. Accordingly therapeutic approaches to hyperglycemia in the management of severe sepsis and septic shock have had much attention. Intensive insulin therapy became popular in the intensive care unit (ICU) after Van den Berghe's research reporting its effectiveness on glycemic control^[3,4]. However, a recent large-scale randomized trial indicated that such glycemic control is not effective in reducing ICU mortality and that glycemic control with intensive insulin therapy increases the risk of hypoglycemia, and complications arising from hypoglycemia^[5]. Therefore, in this paper we will discuss the effectiveness of intensive insulin therapy in the ICU and the future perspectives on tight glycemic control from the viewpoint of the correlation between inflammatory hypercytokinemia and hyperglycemia.

METABOLIC CHANGE IN SEPSIS

Recent advances in molecular biology have contributed to the tremendous progress in understanding the pathophysiology of sepsis. Now it is widely accepted that the main features of sepsis are the uncontrollable activation of not only pro-inflammatory, but also anti-inflammatory responses, because of overwhelming production of pro-inflammatory and anti-inflammatory mediators^[6-8]. Such overwhelming production of mediators causes many pathological changes in vital organs and systems including metabolic changes^[9]. One such metabolic change is hyperglycemia arising from muscle glycolysis and lipolysis, and subsequent gluconeogenesis and glycolysis in the liver^[9-12]. The other feature of metabolic change in sepsis is hyperlactatemia due to glycolysis in muscle caused by counterregulatory hormones and cytokines, sometimes referred to as the "lactate shuttle"^[9,13]. Hyperglycemia in critical illness, such as severe sepsis, is not only a marker of severity of illness and the predictor of poor outcome^[1,2], but also has many kinds of adverse effects on vital organs. One such adverse effect on the innate immune system impairs the ability of the host to combat infection, resulting in reduced neutrophil activity such as chemotaxis, formation of reactive oxygen species, and phagocytosis of bacteria despite accelerated diapedesis of leukocytes into peripheral tissue, as well as specific alterations in cytokine patterns, with increased concentrations of the early proinflammatory cytokines, tumor necrosis factor- α and interleukin (IL)-6, and a reduction of endothelial nitric oxide formation^[14]. Recently it has also been reported that the variability of the glucose level in blood is independently associated with hospital mortality in septic patients^[15,16] and that severity of sepsis has a strong effect on glycemic variability in blood^[13].

Without question, treatment of severe sepsis and septic shock starts with control of the infection source. Antibiotics, drainage of abscesses, and operations to control the source, when indicated, are essential in the initial treatment^[17]. Furthermore, hemodynamic stabilization is also very important for the initial treatment of such patients^[18].

On the other hand, an epoch-making paper by Van den Berghe in 2001 reported that tight glycemic control with intensive insulin therapy in the surgical ICU, to control the blood glucose level between 80 and 110 mg/dL, resulted in improvement in survival and a shortened length of hospital stay^[3]. The same authors reported later that intensive insulin therapy reduced morbidity but not mortality in the medical ICU^[4]. These studies^[3,4] led the influential guidelines for the management of severe sepsis and septic shock to recommend tight glycemic control as one of the most important therapeutic approaches^[19]. Since the publication of the guidelines, tight glycemic control in ICU patients has become popular and it is now one of the standard clinical practices in the ICU. This recommendation remained the same in the revised version of the guidelines published in 2008^[20].

CLINICAL EFFECT OF GLYCEMIC CONTROL IN SEPTIC PATIENTS

Since the publication of the papers by Van den Berghe^[3,4], indicating that tight glycemic control between 80 and 110 mg/dL with intensive insulin therapy reduces morbidity and mortality among critically ill patients in the surgical ICU, and that the intensive insulin therapy significantly reduces morbidity but not mortality among all patients in the medical ICU, many secondary clinical trials on tight glycemic control have been carried out. A meta-analysis and systematic reviews on tight glycemic control were also published. In a review, the Van den Berghe group reconfirmed that maintaining strict normoglycemia with the use of intensive insulin improves the outcome of critically ill patients^[21]. They also published a paper in which they concluded that intensive insulin therapy reduced mortality of all medical/surgical ICU patients, except those with a prior history of diabetes, that intensive insulin therapy did not cause harm, and that a blood glucose target < 110 mg/dL was most effective, but also carried the highest risk of hypoglycemia^[22].

On the other hand, Brunkhorst and the SepNet group from Germany published a paper which found that use of intensive insulin therapy placed critically ill patients with sepsis at increased risk for serious adverse events related to hypoglycemia, without showing any benefit, and they stopped the trial for safety reasons^[23]. Treggiari and colleagues also showed that a policy of intensive insulin therapy in a group of ICU patients was not associated with a decrease in hospital mortality, and they concluded that further study was needed prior to widespread implementation of intensive insulin therapy in critically ill patients^[24]. The meta-analysis by Wiener and colleagues published in JAMA concluded that, in critically ill adult patients, tight glucose control is not associated with significantly reduced hospital mortality, but that it is associated with an increase risk of hypoglycemia^[25]. Finally, the long-awaited result of the NICE-SUGAR (Normoglycemia in Intensive Care Evaluation-Survival Using Glucose Algorithm Regulator) trial was published recently. This concluded that intensive glucose control increased mortality among adults in the ICU and that a blood glucose target of 180 mg/dL or less resulted in lower mortality than did a target of 81-108 mg/dL^[5]. Furthermore it was also pointed out that intensive insulin therapy increased the labor requirement of nursing staff in the ICU^[26]. Now the statement by Merz and Finfer, that each ICU should define a blood glucose range which can be achieved without causing a significant increase in severe hypoglycemia, and which fits within the constraints of their nursing and economic resources sounds fair and acceptable^[26]. They also concluded that the upper limit of glucose control should currently be 140-180 mg/dL^[26]. Preiser also suggested that a blood glucose range of 80-110 mg/dL may not be normal or desirable and that lowering of blood glucose by intensive insulin therapy can induce a shortage in the provision of glucose, the predominant source of energy useable by the

myocardium during ischemia, and neuroglycopenia in cases of cerebral injury^[27].

MECHANISM OF BENEFICIAL OR HARMFUL EFFECTS OF TIGHT GLYCEMIC CONTROL

There are many papers which illustrate the mechanism of the beneficial effect of tight glycemic control. Wade tell us that hyperglycemia can alter cytokine production and phagocytosis both by means of hyperosmotic stress and by mechanisms other than hyperosmolality^[28]. Egi from Bellomo's group suggested that variability of glucose concentration is a significant independent predictor of ICU and hospital mortality, and that decreasing the variability of blood glucose concentration might be an important aspect of glucose management^[29]. The question whether intensive insulin therapy *per se* or a lowered glucose level by intensive insulin therapy is the main mechanism of the beneficial effect of tight glycemic control with intensive insulin therapy has not yet been answered.

On the other hand, Jeschke *et al*^[30] reported that insulin therapy improves the systemic inflammatory reaction to severe trauma. Vanhorebeek from Van den Berghe's group reported that protection of hepatocyte mitochondrial ultrastructure and function is one of the mechanisms of the beneficial effect of strict blood glucose control with insulin in critically ill patients^[31]. Another researcher from Van den Berghe's group also reported that intensive insulin therapy prevented critical polyneuropathy/myopathy and the necessity for treatment with prolonged mechanical ventilation^[32,33]. Dugo and colleagues showed, in an experimental study, that the inhibitory effect of insulin on the activity of glycogen synthase kinase-3 β , contributed to the protective effect of insulin against organ injury/dysfunction caused by excessive systemic inflammation, independently of any effects on blood glucose^[34]. Another possible mechanism of the beneficial effect of intensive insulin therapy or tight glycemic control is through RAGE (receptor of advanced glycation end product). Now RAGE is considered to play an important role in the pathophysiology of severe sepsis and septic shock. It is possible that tight glycemic control can reduce the production of AGE (advanced glycation end product), and that tight glycemic control can thereby reduce the inflammatory response mediated through AGE and RAGE interaction^[35]. This could be another mechanism of the beneficial effect of tight glycemic control in severe sepsis.

There are many papers reporting that hypoglycemia during intensive insulin therapy is the main reason why intensive insulin therapy cannot show a beneficial effect on mortality in severe sepsis and septic shock. Waeschle *et al*^[16] showed that the risk of hypoglycemia with intensive insulin therapy is very high among patients with severe sepsis and septic shock. The meta-analysis mentioned above on the benefit and risks of

Figure 1 Correlation between IL-6 blood level on ICU admission and success rate of blood glucose control among patients with severe sepsis and septic shock. The blood glucose level is targeted to be between 110 and 150 mg/dL with intensive insulin therapy.

tight glucose control in critically ill adults by Wiener^[24], indicated that intensive insulin therapy increased the risk of hypoglycemia among critically ill patients including those with severe sepsis and septic shock. Krinsley and Grover indicated that even a single episode of severe hypoglycemia was independently associated with increased risk of mortality and therefore that safe implementation of tight glycemic control requires appropriate monitoring to reduce the risk of this complication^[36]. They proposed to move beyond tight glucose control to safe effective glucose control avoiding hypoglycemia^[37]. The mechanism by which hypoglycemia increased mortality in severe sepsis and septic shock has not yet been fully elucidated. However, brain damage because of an energy deficit in the brain through hypoglycemia is possibly one mechanism^[38].

FUTURE PERSPECTIVES ON TIGHT GLYCEMIC CONTROL

It is now clear that to benefit from tight glycemic control, we should avoid hypoglycemia. On the other hand it has also become clear that it is not so easy to keep the blood glucose level within the targeted range even though the targeted range is not very tight such as between 150 and 180 mg/dL in patients with severe sepsis and septic shock.

In our ICU, we routinely check IL-6 blood levels in every patient every day. The reason why we specifically measure IL-6 is not that we think IL-6 is the most important proinflammatory cytokine, but rather that IL-6 is the most easily measurable cytokine because of its relatively high blood level and relatively long half-time in the blood^[39]. Since blood levels of many kinds of cytokines change synergistically in sepsis, we do not need to measure blood levels of various cytokines to make a diagnosis of hypercytokinemia but we can measure only one of the most easily measurable cytokines to make the diagnosis of hypercytokinemia in

sepsis. It is reported that if a patient has an IL-6 level of more than 1000 pg/mL, this patient can be diagnosed with systemic inflammatory response syndrome or hypercytokinemia^[40].

We applied tight glycemic control with a target blood glucose level of 110-150 mg/dL in patients with severe sepsis and septic shock. The overall success rate for tight glycemic control was only 53.9%. However when we subgrouped the patients according to the IL-6 blood level on ICU admission, we found that the success rate of tight glycemic control was relatively high in subgroups whose IL-6 blood level on ICU admission was lower than 1000 pg/mL. On the other hand, the success rate of tight glycemic control was very low among the patients whose initial IL-6 blood level in the ICU was higher than 10000 pg/mL as shown in Figure 1. These data indicate that hypercytokinemia correlates with hyperglycemia in sepsis and that countermeasures to hypercytokinemia in sepsis would be one of the key factors for successful glycemic control. Recently, we published a paper showing the efficacy of continuous hemodiafiltration (CHDF) with a cytokine-adsorbing hemofilter made from polymethyl methacrylate (PMMA) membrane in patients with septic shock^[41]. We found that, in septic patients with severe hypercytokinemia, blood glucose control became easier once we lowered the blood level of cytokines with PMMA-CHDF.

Since one of the reasons why tight glycemic control could not show a beneficial effect on critically ill patients is hypoglycemia during intensive insulin therapy, avoidance of hypoglycemia should always be considered^[36,37]. For this purpose an artificial pancreas has promising potential^[42]. On the other hand, a pharmacological dose of a steroid is recommended in the guidelines for the management of severe sepsis and septic shock^[18,19]. However, steroid administration may create some difficulties in glycemic control in septic patients^[43]. An artificial pancreas may be most effective on such patients with severe sepsis and septic shock receiving steroid therapy.

Another important issue of tight glycemic control in critically ill patients, including those with severe sepsis and septic shock, is whether tight glycemic control would also be effective in critically ill diabetics. It is proposed that precisely defined target glucose levels, treatment intervention and the avoidance of hypoglycemic episodes during insulin therapy should be studied before the widespread application of tight glycemic control in critically ill diabetic patients^[44]. Egi and colleagues reported that, unlike nondiabetic patients, diabetic patients showed no clear association between hyperglycemia during the ICU stay and mortality, and there were markedly lower odds ratios of death at all levels of hyperglycemia suggesting that hyperglycemia may have different biological and/or clinical implications in critically patients with diabetes mellitus^[45].

As mentioned above, it has not yet been fully elucidated whether intensive insulin therapy or normoglycemia with intensive insulin therapy really has the beneficial effect on severely septic patients. However, if normoglycemia is the key mechanism of tight glycemic control with

intensive insulin therapy, modulation of glucose use and gluconeogenesis in sepsis with adrenergic β receptor blockade is one of the future approaches in this area^[46].

CONCLUSION

It is now suggested that tight glycemic control with a target blood glucose level of 90-110 mg/dL does not improve clinical outcome and that less strict glycemic control with a target blood glucose level of 140-180 mg/dL is more effective. Also specific targeting of glycemic control in diabetic patients should be considered. Since there is a significant correlation between success rate of glycemic control and the degree of hypercytokinemia in septic patients, some countermeasures to hypercytokinemia may be an important aspect of successful glycemic control. Thus, in future, use of an artificial pancreas to avoid hypoglycemia during insulin therapy, special consideration of septic diabetic patients, and control of hypercytokinemia should be considered for more effective glycemic control in patients with severe sepsis and septic shock.

Abstract

Glucose homeostasis deficiency leads to a chronic increase in blood glucose concentration. In contrast to physiological glucose concentration, chronic super-physiological glucose concentration negatively affects a large number of organs and tissues. Glucose toxicity means a decrease in insulin secretion and an increase in insulin resistance due to chronic hyperglycemia. It is now generally accepted that glucose toxicity is involved in the worsening of diabetes by affecting the secretion of β -cells. Several mechanisms have been proposed to explain the adverse effects of hyperglycemia. It was found that persistent hyperglycemia caused the functional decline of neutrophils. Infection is thus the main problem resulting from glucose toxicity in the acute phase. In other words, continued hyperglycemia is a life-threatening risk factor, not only in the chronic but also the acute phase, and it becomes a risk factor for infection, particularly in the perioperative period.

Kawahito S, Kitahata H, Oshita S. Problems associated with glucose toxicity: Role of hyperglycemia-induced oxidative

INTRODUCTION

Chronic hyperglycemia is a characteristic of the diabetic condition, while glucose toxicity is the main cause of diabetic complications, which are often observed only several years after the beginning of the illness^[1]. Glucose toxicity, in its narrow sense, can indicate a clinical condition where control of diabetes in particular is poor, since hyperglycemia itself reduces the insulin secretion capacity of pancreatic β -cells, and the resultant increase in insulin resistance leads to further hyperglycemia. This vicious circle finally leads to the total incapacity of β -cells to secrete insulin^[2,3].

On the other hand, acute hyperglycemia, similar to chronic hyperglycemia, is known to cause injury to many organs. Hyperglycemia in the acute phase causes the functional decline of neutrophils, and is a risk factor that causes infection in the perioperative period. In the first half of this review, we will present an introduction to the various mechanisms known to be involved in the control of glucose homeostasis and in the development of glucose toxicity. In the latter half, diabetic complications (chronic and acute) and implications for the fields of surgery, emergency and critical care medicine will be presented and discussed.

GLUCOSE HOMEOSTASIS

Glucose homeostasis is maintained by the highly coordinated interaction of three physiologic processes: insulin secretion, tissue glucose uptake and hepatic glucose production. In this way, the body tries to maintain a constant supply of glucose for cells by keeping glucose concentration in the blood constant. Normal glucose homeostasis represents the balance between intake (glucose absorption from the gut), tissue utilization (glycolysis, pentose phosphate pathway activity, tricarboxylic acid cycle activity, glycogen synthesis) and endogenous production (glycogenolysis and gluconeogenesis)^[4]. The most important metabolic fuels are glucose and fatty acids. Glucose is preferentially used by brain and muscles,

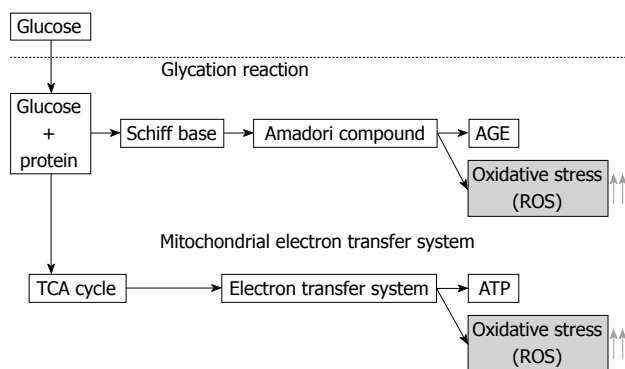

Figure 1 Increase in oxidative stress in the diabetic state. Acceleration of glycation response and the intramitochondrial electron transfer system was detected in the diabetic state, causing oxidative stress as the responses accelerated. Black arrows indicate pathway, grey arrows indicate increase or decrease. AGE: Advanced glycosylation end products; ROS: Reactive oxygen species; TCA cycle: Tricarboxylic acid cycle; ATP: Adenosine tri-phosphate.

and to ensure a continuous supply of glucose to the brain and other tissues, metabolic fuels are stored for use in time of need. Glucose homeostasis is controlled primarily by the anabolic hormone insulin and also by some insulin-like growth factors^[5]. Several catabolic hormones (glucagons, catecholamines, cortisol, growth hormone, and adrenocorticotrophic hormone) may antagonize the action of insulin and are known as anti-insulin or counter-regulatory hormones^[6].

It is often found that critically ill patients incur hyperglycemia because of insulin resistance even if it is not complicated by diabetes^[7]. When severe stress occurs, insulin resistance and an insulin secretion decrease result from the response to stress by the neuroendocrine system because secretion of anti-insulin hormones is enhanced. This leads to enhancement of glucogenesis in the liver, of lipolysis in adipose tissue, and of protein catabolism in skeletal muscle. This is known as surgical diabetes. Patients with diabetes are more susceptible to stress and easily develop exacerbation of diabetes, resulting in an increase in the incidence of complications.

MECHANISM OF GLUCOSE TOXICITY

It has been found that oxidative stress is associated with the molecular mechanism of the decreased insulin biosynthesis and secretion, which is the main etiology of glucose toxicity. Because pancreatic islet cells show extremely weak manifestation of antioxidative enzymes^[8,9], it is thought that the pancreas may be more susceptible to oxidative stress than other tissues and organs.

Pathway of oxidative stress production

Metabolic reactions continuously produce reactive oxygen species (ROS), such as superoxides (O_2^-), hydroxyl radicals (OH^\cdot), peroxy radicals (ROO^\cdot) or nitric oxide. ROS are involved in a diversity of biological phenomena, such as inflammation, carcinogenesis, aging, and atherosclerosis. However, several antioxidant enzymes help to maintain low levels of ROS. Oxidative stress corresponds

Figure 2 The mechanism of insulin secretion reduction due to glucose toxicity. DNA binding capacity of PDX-1 decreases as a result of oxidative stress caused by hyperglycemia, while insulin biosynthesis and secretion also decrease. Black arrows indicate pathway, grey arrows indicate increase or decrease. PDX-1: Pancreatic duodenal homeobox-1.

to the overproduction of ROS that can damage cellular components, such as lipids, proteins or DNA^[10]. There are strong indications that oxidative stress may be a key event in diabetic complications^[11,12]. It is reported that 8-hydroxy-2-deoxyguanosine (8-OHdG), which is an indicator of oxidative damage of DNA, increases in patients with type 2 diabetes mellitus^[13], and that 8-OHdG, 4-hydroxy-2-nonenal and heme oxygenase-1, all oxidative stress markers, increase in the pancreatic islet cells of type 2 diabetes mellitus animal models^[14,15]. Generation of ROS in diabetes seems to be directly linked to chronic hyperglycemia. Various pathways are thought to be involved in the increase in oxidative stress in a hyperglycemic state (Figure 1). With the first pathway, more oxidative stress is caused by hyperglycemia because a non-enzymatic glycosylation reaction (glycation) is enhanced in the hyperglycemic state. ROS are then generated by the Amadori compound, which is an intermediate metabolite, before leading to the production of metabolites, known as advanced glycosylation end products (AGE) as the result of a glycation reaction^[16]. Another pathway involves the mitochondrial electron transfer system, which also becomes a source of oxidative stress. This system is located in the mitochondrial inner membrane, where Adenosine tri-phosphate is produced as an important organic energy source. In this electron transfer system, water molecules are generated by deoxidation of four of the electrons of oxygen molecules, ROS is produced as an intermediate product in this process, and some of the ROS leak out from this system. Part of the oxygen used for this process is produced as superoxide anions even under physiological conditions, and their production increases in the hyperglycemic state^[17]. Furthermore, the hexosamine pathway also becomes a source of oxidative stress. It was found that glucosamine, which is an intermediate metabolite in this process, also brings about oxidative stress^[18]. Because this hexosamine pathway is enhanced in the diabetic state, the oxidative stress thus generated will increase.

Reduction of insulin biosynthesis and secretion by oxidative stress

Figure 2 shows the mechanism of the reduction of insulin secretion by oxidative stress. It is known that biosynthesis

of insulin decreases when pancreatic β -cells are exposed to chronic hyperglycemia in animal models of type 2 diabetes mellitus, and a similar phenomenon was induced by oxidative stress caused in the diabetic state. In other words, promoter activity of the insulin gene and mRNA expression decrease, and insulin gene expression is thus inhibited, when the β -cell line and isolated pancreatic islet cells are exposed to oxidative stress. It was also found that the DNA binding capacity of Pancreatic duodenal homeobox-1 (PDX-1), which is a very important transcription factor for insulin genes, decreases^[18,19]. Finally, as for the control of glucokinase transcription by PDX-1, it is reported the promoter activity, manifestation, and the enzyme activity of glucokinase decreases with oxidative stress^[20]. In fact, the use of antioxidant drugs resulted in an improvement of insulin secretion capacity as well as an increase in insulin mRNA expression^[21]. On the other hand, it was also found that oxidative stress and activation of the c-Jun N-terminal kinase pathway are involved in a decline in insulin biosynthesis and secretion due to chronic hyperglycemia^[22].

Increase in insulin resistance caused by oxidative stress

Glucotoxicity not only affects the secretion of pancreatic hormones but also participates in insulin resistance of insulin-sensitive tissues, which include liver, skeletal muscle, and adipose tissue. Insulin resistance has been shown to be present before the onset of chronic hyperglycemia, although the latter may contribute to aggravation of the diabetic state by increasing insulin resistance^[23].

Oxidative stress is also strongly suspected to be involved in chronic hyperglycemia-induced insulin resistance^[24]. Indeed, it is known that incubation of primary adipocyte cells with chronic high glucose concentration can induce oxidative stress^[25]. Moreover, it was demonstrated that oxidative stress induces insulin resistance in the 3T3-L1 adipocyte cell line by inhibiting the translocation of Glut 4 to the plasma membrane^[26]. Finally, it was found that oxidative stress can induce insulin resistance in intact rat muscle^[27].

GLUCOSE TOXICITY AND DIABETIC COMPLICATIONS

The prevalence of diabetes mellitus is increasing worldwide at an alarming rate due to population growth, obesity, sedentary life style and aging. Consequently, diabetic complications are also on the increase. Prevention and treatment of complications are considered to be most important for general care of diabetic patients. The basic causes of complications include tissue metabolism disorders caused by chronic hyperglycemia, which results in damage to many organs. The main diabetic complications are listed in Table 1. They are divided into chronic and acute complications based on the disease course.

Chronic complications

When metabolic disorders due to diabetes continue

Table 1 Types of diabetic complications

Chronic complications
Microvascular diseases: retinopathy, neuropathy, nephropathy
Macrovascular diseases: aortic sclerosis, stroke, myocardial infarction, angina pectoris, obstructive peripheral vascular disease, <i>etc</i>
Others: cataract, dermatopathy, hypertension, osteopenia, osteomalacia, arthropathy, soft tissue fibromatosis, <i>etc</i>
Acute complications
Diabetic coma: ketoacidotic coma, non-ketotic hyperosmolar coma, lactic acidosis
Acute infection: bacterial, mycotic, viral, <i>etc</i>

for many years, vascular tissue is affected the most. Chronic complications are divided into microvascular diseases that are specific to and common in diabetes and macrovascular diseases that are not specific but frequent and thus important for a prognosis. Vascular endothelial cell function in the blood vessels of diabetic patients is impaired, and many basic research endeavors have demonstrated that vasodilative reaction is also impaired^[28,29]. Hyperglycemia-induced oxidative stress is also involved in the development of both macrovascular and microvascular diabetic complications^[30].

Chronic hyperglycemia can induce microvascular complications such as retinopathy, neuropathy or nephropathy^[31]. The retina is highly sensitive to oxidative stress since it has higher oxygen uptake and glucose oxidation than any other tissue^[32]. Studies of diabetic rat retina and retinal cells incubated with a high-concentration of glucose have shown that the concentration of superoxides is elevated^[33]. It has been demonstrated in animal models that oxidative stress is not only involved in the development of retinopathy but also in the persistence of the pathology after normalization of glucose concentration, probably as the result of persistent ROS^[34]. Oxidative stress is also strongly suspected to be involved in the development of diabetic neuropathy^[35]. Several studies have shown the capacity of antioxidant enzymes to prevent or reverse the toxic effect of chronic hyperglycemia in the nerves^[36]. Moreover, oxidative stress may contribute to the pathogenesis of diabetic nephropathy since the presence of high concentrations of mitochondrial oxidative stress markers has been demonstrated in the urine and kidneys of diabetic rats^[37].

Chronic hyperglycemia can also induce macrovascular complications. Cardiovascular complications are the most prevalent cause of death in diabetic patients. Moreover, it has been clearly shown that chronic hyperglycemia during diabetic and pre-diabetic states is linked to an increased risk for the development of cardiovascular diseases^[38]. Long-term incubation of macrovessels with high-concentration glucose was found to strongly increase the risk of cardiovascular, cerebrovascular and peripheral arterial diseases^[39]. Activation of protein kinase C by hyperglycemia is thought to play a central role in vascular complications since it leads to: (1) modification

of contractile protein function, (2) an increase in the activity of nitric oxide synthase, and (3) activation of the angiotensin-converting enzyme (ACE). Activation of ACE has been linked with apoptosis and necrosis of cardiomyocytes and endothelial cells^[40]. The importance of ACE in cardiovascular disease development was confirmed by studies showing the inhibition of ACE can protect against cardiovascular diseases^[41]. Finally, protein glycation is another factor probably involved in the development of cardiovascular diseases^[42].

Acute complications

Hyperglycemia can exacerbate a number of perioperative problems, including cardiac, neurologic, and infectious complications. In general, most outcomes tend to improve with treatment of hyperglycemia^[43]. Diabetic coma is a form of consciousness disturbance that is characteristic of diabetes in acute complications. Diabetic coma has three categories, ketoacidotic coma due to hyperglycemia, non-ketotic hyperosmolar coma without ketoacidosis, and, rarely, lactic acidosis.

Infection in acute complications is a clinical condition that is not specific to but can easily become complicated in diabetic states. Diabetic patients have reduced immune function and enhanced bactericidal activity, so that special attention is required since the infection focus expands much faster than in non-diabetic patients. This becomes a problem particularly in the fields of surgery, emergency and critical care medicine.

Association between hyperglycemia and infection

It has been confirmed that perioperative appropriate glycemic control promotes wound healing. Perioperative infectious complications, including surgical site infection, represent serious postoperative complications. It is well known that, compared with non-diabetic patients, diabetic patients suffer from an increased incidence of perioperative infections, especially surgical site infection. It was reported that patients with preoperative elevation of HbA1c levels show a significantly higher incidence of surgical site infection than patients with normal HbA1c levels^[44,45].

Recent basic researches have found that the functional decline of neutrophils is caused by a hyperglycemic state^[46], and that the mechanism of this decline includes increased adhesive capacity and diminished chemotaxis, phagocytic activity and bactericidal capacity^[47,48]. Neutrophilic function is reduced in proportion to an increase in the blood glucose level, and 200 mg/dL is assumed to be the threshold of neutrophil dysfunction. Furnary *et al*^[49] reported that the incidence of deep sternal wound infection decreased from 2.0% to 0.8% in a patient group whose blood glucose level was kept below 200 mg/dL by insulin administration, and there are other reports of reduced infectious risk due to strict glycemic control^[50]. Maintenance of a perioperative hyperglycemic state, since the stress response is a risk factor of postoperative infection, is extremely important for postoperative infection prophylaxis.

CONCLUSION

Several recent clinical studies have demonstrated the efficacy of strict glycemic control for reducing the mortality rate of post-operative or emergency patients^[51-53]. It was thought that perioperative strict glycemic control was essential to relieve a perioperative inflammatory response and improve patient outcome. However, despite frequent blood glucose testing, it has been shown that intensive insulin therapy is sometimes difficult to perform when using sliding-scale manual insulin injection. Consequently, hypoglycemic events could not be avoided during intensive insulin therapy with intermittent blood glucose sampling. It has therefore been suggested that continuous blood glucose monitoring would be beneficial for maintaining target blood glucose levels^[54,55]. We also believe that it is necessary to establish more accurate glycemic control methods because, in view of the global increase in diabetes, it is expected that glycemic control in surgical and emergency settings will become increasingly important.

Recently the usefulness of a closed-loop system (artificial endocrine pancreas), which provides continuous monitoring and strict control of blood glucose, was reported. STG-22™ (Nikkiso, Tokyo, Japan) is a novel artificial endocrine pancreas with a closed-loop glycemic control system that provides continuous blood glucose monitoring through a glucose sensor electrode and subsequent automatic insulin and glucose infusion to maintain appropriate blood glucose levels^[54-57]. The usefulness of a closed-loop system providing continuous monitoring and strict control of post-operative blood glucose in patients after hepatic resection was also reported^[58]. Accurate and continuous blood glucose monitoring and close glycemic control may be possible with an artificial endocrine pancreas. Establishment of a new perioperative blood glucose control method with the aid of an artificial endocrine pancreas is urgently needed.

Abstract

AIM: To gain molecular insights into the expression and functions of endothelin-1 (ET-1) in pancreatic stellate cells (PSC).

METHODS: PSCs were isolated from rat pancreas tissue, cultured, and stimulated with ET-1 or other extracellular mediators. Cell proliferation was assessed by measuring the incorporation of 5-bromo-2'-deoxyuridine into DNA and cell migration was studied in a transwell chamber assay. Gene expression at the level of mRNA was quantified by real-time Polymerase chain reaction. Expression and phosphorylation of proteins were monitored by immunoblotting, applying an infrared imaging technology. ET-1 levels in cell culture supernatants were determined by an enzyme immunometric assay. To study DNA binding of individual transcription factors, electrophoretic mobility shift assays were performed.

RESULTS: Among several mediators tested, transforming growth factor- β 1 and tumour necrosis factor- α displayed the strongest stimulatory effects on ET-1 secretion. The cytokines induced binding of Smad3 and NF- κ B, respectively, to oligonucleotides derived from the ET-1 promoter, implicating both transcription factors in the induction of ET-1 gene expression. In accordance with previous studies, ET-1 was found to stimulate migration but not proliferation of PSC. Stimulation of ET-1 receptors led to the activation of two distinct mitogen-activated protein kinases, p38 and

extracellular signal-regulated kinases (ERK)1/2, as well as the transcription factor activator protein-1. At the mRNA level, enhanced expression of the PSC activation marker, α -smooth muscle actin and two proinflammatory cytokines, interleukin (IL)-1 β and IL-6, was observed.

CONCLUSION: This study provides novel lines of evidence for profibrogenic and proinflammatory actions of ET-1 in the pancreas, encouraging further studies with ET-1 inhibitors in chronic pancreatitis.

INTRODUCTION

Pancreatic fibrosis represents a key feature of chronic pancreatitis and pancreatic cancer. Fibrosis not only accompanies the tumour, but plays an active role in its progression^[1,2]. The cellular and molecular basis of pancreatic fibrogenesis has therefore attracted significant interest in pancreatologists in recent years. In 1998, pancreatic stellate cells (PSC) were identified as the main source of extracellular matrix (ECM) proteins in the diseased pancreas^[3,4]. In response to profibrogenic stimuli, PSC undergo phenotypic changes termed activation, which include proliferative activity, expression of myofibroblastic markers [such as α -smooth muscle actin (α -SMA)], and enhanced synthesis of ECM components. The activation process is also triggered when PSC are isolated from healthy pancreas and when cultured in cell culture dishes. Numerous extracellular mediators and intracellular pathways of PSC activation have been described since 1998, which are summarized in recent reviews^[2,5]. Thus, platelet-derived growth factor

(PDGF) has been identified as a strong PSC mitogen, while transforming growth factor (TGF)- β 1 is considered the most relevant stimulator of ECM synthesis^[6,7]. In addition, proinflammatory cytokines, including tumour necrosis factor (TNF)- α , and ethanol metabolites, have been implicated in pancreatic fibrogenesis^[7-9]. Despite many efforts, however, little progress has been made so far with respect to the development of therapeutic strategies to interrupt fibrogenesis in the context of chronic pancreatitis and pancreatic cancer. One reason is the lack of efficient antifibrotic drugs that are applicable in patients and not in experimental settings only.

Recent studies on fibroproliferative disorders in different organs have indicated an antifibrotic effect of endothelin (ET)-receptor antagonists^[10]. Using bosentan, a clinically available dual ET-receptor antagonist targeting the two receptor types ET_{RA} and ET_{RB}, we recently observed inhibition of key functions of activated PSC, including proliferation and collagen synthesis^[11]. When bosentan was applied to rats with chronic pancreatitis, at least a tendency towards a diminished disease progression was observed in a subgroup of animals with less severe disease. Based on the results of these experiments, we were further interested in the molecular role of the ET-1/ET receptor axis in the process of stellate cell activation.

In the present study, we have analyzed the biological and molecular effects of ET-1 in PSC and addressed the question of how ET-1 expression in PSC is regulated. The experiments were built on earlier reports by our group and others, which had suggested an autocrine loop of ET-1. Specifically, ET-1 was previously shown to activate extracellular signal-regulated kinases (ERK) 1 and 2, and to enhance PSC contraction and migration^[11-13]. Our novel data deciphers ET-1 signalling in greater detail, and identifies, for the first time, target genes of ET-1 in PSC. Interestingly, these genes include not only α -SMA (which is directly linked to the activation process), but also two proinflammatory cytokines, interleukin (IL)-1 β and IL-6. Furthermore, our investigations revealed TGF- β 1 and TNF- α as potent inducers of ET-1 expression in PSC. Together, the data suggest that ET-1 is an important player in a network of proinflammatory and profibrogenic mediators that fosters interactions between inflammatory cells and PSC in a vicious cycle of inflammation and fibrosis.

MATERIALS AND METHODS

Materials

Iscove's modified Dulbecco's medium (IMDM) and all supplements for cell culture were obtained from Biochrom (Berlin, Germany), Nycodenz from Nycomed (Oslo, Norway), the rat-specific ET-1 enzyme immunometric assay (EIA) kit from Biotrend (Köln, Germany), and the 5-bromo-2'-deoxyuridine (BrdU) labelling and detection enzyme-linked immunosorbent assay kit as well as the polynucleotide kinase from Roche Diagnostics (Mannheim, Germany). Human connective tissue growth factor (CTGF) was delivered by EMP Genetech (Ingolstadt, Germany),

and recombinant cytokines [rat interferon (IFN)- γ and PDGF, human TNF- α and TGF- β 1] by R&D Systems (Minneapolis, MN, USA). TRIzol and all reagents used for reverse transcription and TaqmanTM real-time polymerase chain reaction (PCR) were from Applied Biosystems (Foster City, CA, USA). PVDF membrane was supplied by Millipore (Schwalbach, Germany), protein- and phospho-protein specific antibodies to ERK1/2 and p38 (all raised in rabbits) by New England BioLabs (Frankfurt, Germany), and Odyssey[®] blocking buffer, stripping buffer and secondary antibodies for immunoblotting by LI-COR (Bad Homburg, Germany). Immunoglobulins used in gel shift assays were purchased from Santa Cruz Biotechnologies (Santa Cruz, CA, USA), DNA oligonucleotides from BioTeZ (Berlin, Germany), and [γ -³²P] ATP from Hartmann Analytic (Braunschweig, Germany). Collagenase, ET-1, tissue culture dishes (Corning plasticware), carboxyfluorescein succinimidyl ester (CFSE), as well as standard laboratory chemicals were from Sigma-Aldrich (St. Louis, MO, USA).

Cell culture

PSC were isolated from the pancreas of male LEW.1W inbred rats by collagenase digestion of the organ and Nycodenz (120 g/L) density gradient centrifugation essentially as previously described^[14]. The cells were resuspended in IMDM supplemented with 17% foetal calf serum (FCS), 10 mL/L non-essential amino acids (dilution of a 100 \times stock solution), 10⁵ U/L penicillin and 100 mg/L streptomycin, and cultured at 37°C in a 5% CO₂ humidified atmosphere. All experiments were performed with cells that were passaged only once. Therefore, PSCs in primary culture were grown to subconfluency, harvested by trypsinization (usually, on day seven after isolation), and recultured at equal seeding densities.

Quantification of DNA synthesis

Cell proliferation was assessed by measuring incorporation of BrdU into newly synthesized DNA. Therefore, cells growing in 96-well plates were treated under serum-free conditions with ET-1 as indicated. At the time of ET-1 application, BrdU labelling was initiated by adding labelling solution at a final concentration of 10 μ mol/L (in the culture medium). Twenty-four hours later, labelling was stopped, and BrdU uptake was measured according to the manufacturer's instructions.

Cell migration assay

Serum-starved PSC were labelled with the fluorescence dye CFSE, which was dissolved in dimethyl sulfoxide and applied at a final concentration of 333 μ mol/L (chosen based on the results of assay optimization). The cells were incubated with the dye for 20 min in darkness at room temperature. Migration assays were performed under serum-free conditions in 24-transwell plates using inserts with a pore size of 8 μ m. Therefore, labelled cells were seeded at a density of 50 000 cells per well into the upper chamber, while ET-1 was added to the medium of the lower chamber as indicated. After an incubation period of 24 h, cells in the transwell inserts were removed by medium aspiration and mechanical

detachment from the upper side of the membrane. Cells adhering to the lower side of the filter or the bottom of the lower chamber were harvested by trypsinization and transferred into 96-well plates. Fluorescence intensity was then measured using a fluorescence microplate reader ($\lambda_{\text{ex}} = 492 \text{ nm}$, $\lambda_{\text{em}} = 517 \text{ nm}$).

Immunoblotting

Protein extracts from equal numbers of PSCs (pretreated as indicated) were prepared and subjected to immunoblot analysis as previously described^[14]. After electrophoresis, proteins were blotted onto PVDF membrane. The filters were rinsed in phosphate-buffered saline (PBS) and blocked for 1 h using Odyssey® Blocking Buffer, before primary antibodies were added to the blocking solution. One hour later, the blots were washed four times for 5 min in PBS containing 0.1% Tween 20 (PBS-T), and exposed to secondary antibody (IRDye® 800CW conjugated goat anti-rabbit IgG) for 1 h. Subsequently, the membranes were washed again (PBS-T, three times for 5 min), rinsed in PBS and scanned at a wavelength of 800 nm using an Odyssey® Infrared Imaging System. Signal intensities were quantified by means of the Odyssey® software version 3.0. Prior to reprobing with additional primary antibodies, the blots were treated with stripping buffer according to the instructions of the manufacturer.

Quantitative reverse transcriptase-PCR using real-time TaqMan™ technology

Total RNA from cells pretreated as indicated was isolated with TRIzol reagent according to the manufacturer's instructions. Next, RNA was reverse transcribed into cDNA by means of TaqMan™ Reverse Transcription Reagents and random hexamer priming. Relative quantification of target cDNA levels by real-time PCR was performed in an ABI Prism 7000 sequence detection system (Applied Biosystems) using TaqMan™ Universal PCR Master Mix and the following Assay-on-Demand™ rat gene-specific fluorescently labelled TaqMan™ MGB probes: Rn00573960_g1 (CTGF), Rn00561129_m1 (ET-1), Rn00580432_m1 (IL-1 β), Rn00561420_m1 (IL-6), Rn00572010_m1 (TGF- β 1), and Rn01527838_g1 [hypoxanthine phosphoribosyl transferase (HPRT), used as house-keeping control gene]. The Custom TaqMan Gene Expression Assay specific for rat α -SMA (GenBank Accession Number: X06801) has been described previously^[11]. Following the guidelines of the manufacturer, PCR was performed under the following conditions: 95°C for 10 min, 50 cycles of 15 s at 95°C, 1 min at 60°C. The reactions were performed in triplicate, and repeated six times with independent samples. Relative expression of each mRNA compared with HPRT was calculated according to the equation $\Delta\text{Ct} = \text{Ct}_{\text{target}} - \text{Ct}_{\text{HPRT}}$. The relative amount of target mRNA in control cells and cells treated as indicated was expressed as $2^{-(\Delta\Delta\text{Ct})}$, where $\Delta\Delta\text{Ct}_{\text{treatment}} = \Delta\text{Ct}_{\text{ET-1}} - \Delta\text{Ct}_{\text{control}}$.

ET-1 polypeptide quantification

ET-1 polypeptide concentrations in PSC culture supernatant

were determined by EIA. Therefore, cells were seeded at a density of 50000 cells per well into 24-well plates. After an overnight incubation, medium was replenished and cells were exposed to different mediators as indicated. 48 h later, supernatants were collected and stored at -80°C until they were subjected to EIA analysis. The assay was performed according to the instructions of the manufacturer. FCS of the culture medium was also analyzed and found to contain no detectable amounts of ET-1 (data not shown).

Electrophoretic mobility shift assays (EMSA)

PSC growing in six-well plates were incubated for 16 h in FCS-free culture medium, before they were treated as indicated. Nuclear extracts were prepared as previously described^[14,15]. For EMSA experiments, nuclear proteins of 10^5 cells were incubated with double-stranded oligonucleotides which were end-labelled with [γ -³²P] ATP by polynucleotide kinase. The sequence of the activator protein (AP)-1 probe was 5'-CGCTTGA TGACTCAGCCGATC-3' (consensus binding motif underlined). To study inducible protein binding to the ET-1 promoter, the following probes derived from the rat promoter sequence^[16] (accession number: S76970) were applied: 5'-GATTGTCAGACGGCGGGCGTCTGCCTCTGAAG-3' (corresponding to bases -196 to -165), and 5'-AGCCGTGATTTCCTCTAGAGC-3' (-163 to -144). The first oligonucleotide contains two consensus motifs for Smad transcription factors (underlined), which in the homologous region of the human ET-1 promoter have been identified as core sequences within a TGF- β response element^[17]. The underlined bases of the second oligonucleotide correspond to a putative, although imperfect NF- κ B/c-Rel binding site. Binding reaction and supershift analysis (initiated by adding 0.5 μ g antibody) were performed as described^[14,15]. Protein-DNA complexes were analyzed by electrophoretic separation on a 6% non-denaturing polyacrylamide gel. Dried gels were exposed to X-ray film.

Statistical analysis

Results are expressed as mean \pm SE for the indicated number of separate cultures per experimental protocol. Statistical significance was analyzed using Wilcoxon's rank sum test. $P < 0.05$ was considered to be statistically significant.

RESULTS

Effects of ET-1 on PSC functions and gene expression

Initial studies dealt with the biological effects of ET-1 in PSC. In accordance with previous reports^[12,13], ET-1 stimulated migration but had no effect on PSC proliferation (Figure 1). Next, we analyzed regulation of gene expression by ET-1, using real-time PCR. Interestingly, ET-1 significantly enhanced expression of α -SMA, suggesting direct stimulation of myofibroblastic differentiation (Figure 2). Furthermore, we focussed on cytokines and growth factors that have previously been implicated in autocrine or paracrine maintenance and

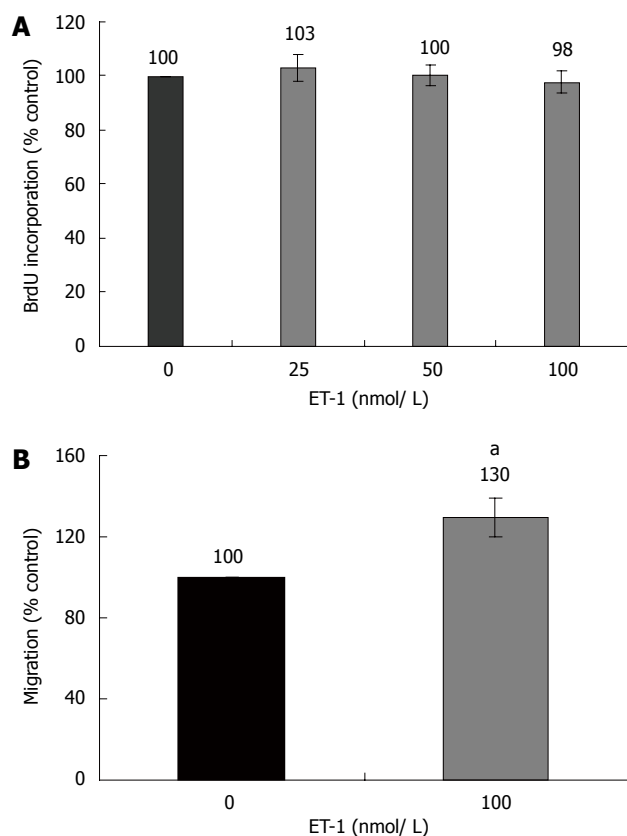

Figure 1 Effects of ET-1 on PSC proliferation and migration. A: PSCs growing in 96-well plates were treated, under FCS-free conditions, with ET-1 at the indicated concentrations for 24 h. Cell proliferation was assessed with the BrdU DNA-incorporation assay. One hundred percent BrdU incorporation corresponds to untreated PSCs; B: CFSE-labelled cells were seeded into the upper chamber of 24-transwell plates, whereas ET-1 (100 nmol/L) was added to the lower chamber as indicated. Cell migration under FCS-free conditions was analyzed as described in the "Materials and Methods" section. One hundred percent cell migration corresponds to the intensity of the fluorescence signal received from untreated PSCs. Data in (A) and (B) are presented as mean \pm SE ($n \geq 6$ separate cultures); ^a $P < 0.05$ vs control cultures.

Figure 2 Effects of ET-1 on PSC gene expression. PSC growing in 6-well plates were starved of serum for 1 h before they were stimulated with ET-1 (100 nmol/L) as indicated. The mRNA expression of TGF-β1, CTGF, IL-6, α-SMA, IL-1β and the housekeeping gene HPRT was analyzed by real time PCR, and relative amounts of target mRNA were calculated. One hundred percent mRNA expression of each gene corresponds to untreated PSC. Data of 6 independent experiments (with triplicate samples) were used to calculate mean \pm SE; ^a $P < 0.05$ vs control cultures.

enhancement of PSC activation^[6-8,18,19]. ET-1 significantly increased expression of two proinflammatory mediators,

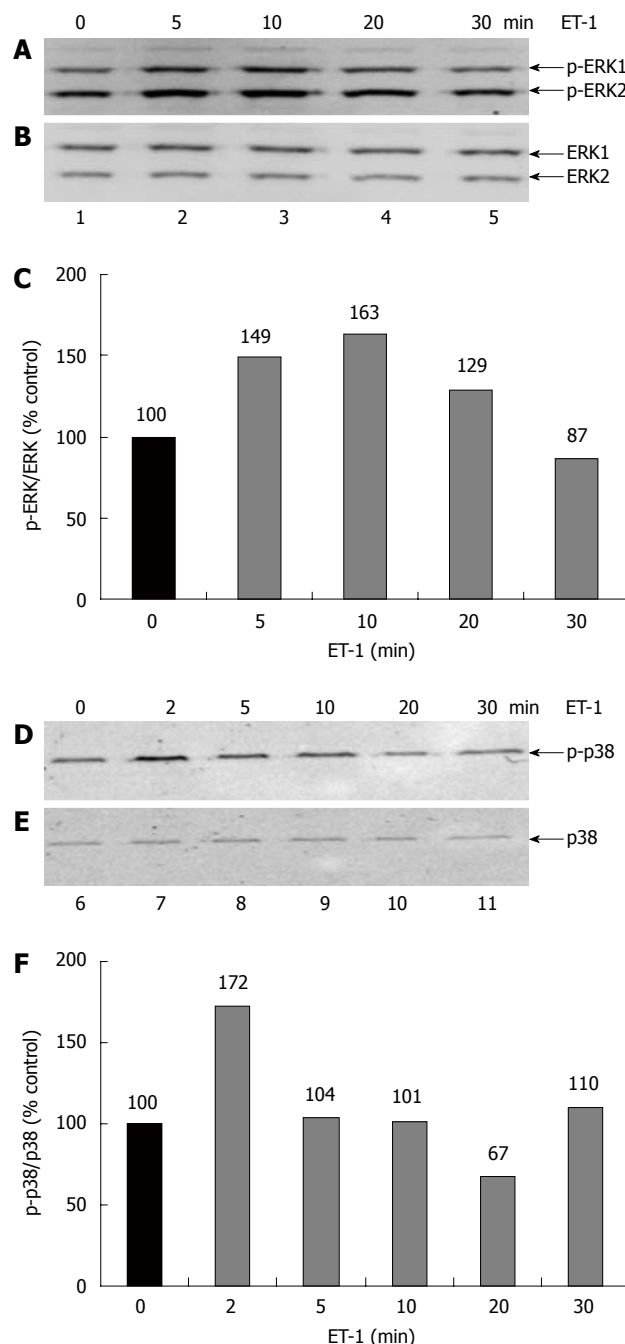

Figure 3 ET-1 induces phosphorylation of ERK1/2 and p38. PSC were starved of serum for 16 h before they were stimulated with ET-1 (100 nmol/L) for the indicated periods of time (A, D). ERK1/2 and p38 phosphorylation were analyzed by immunoblotting (B, E). Reprobing of the blots with anti-ERK1/2 and anti-p38 protein-specific antibodies revealed no systematic differences in the ERK1/2 and p38 amount among the samples (C, F). Fluorescence signal intensities of phospho (p)-ERK1/2, ERK1/2 protein, phospho (p)-p38 and p38 protein were quantified using Odyssey[®] software version 3.0. Subsequently, the ratios of phospho-ERK/ERK protein (C) and phospho-p38/p38 (F) protein were calculated. A ratio of one hundred percent corresponds to unstimulated control cultures. The data shown are representative of three independent experiments.

IL-1β and IL-6, but not of TGF-β1 and CTGF, two potent inducers of collagen synthesis.

Transduction of the ET-1 signal in PSC

Extending our previous pilot study^[11], we observed that ET-1 induced a rapid and transient phosphorylation of two

Figure 4 ET-1 activates DNA binding of AP-1. Serum-starved PSC growing in 6-well plates were incubated with ET-1 (100 nmol/L) for the indicated periods of time. Nuclear extracts were subjected to EMSA analysis using a [32 P]-labelled oligonucleotide with an AP-1 binding motif. Supershift analysis was performed by incubating the binding reaction with a c-Fos-specific antibody. Shifted complex and supershifted band (lane 6, faint since antibody binding may diminish binding of c-Fos to the oligonucleotide) are pointed out by arrows. Results are representative of three independent experiments.

Figure 5 Regulation of ET-1 expression in PSC. PSC growing in 24-well plates were treated with PDGF (10 μ g/L), IFN- γ (100 μ g/L), CTGF (2 mg/L), TNF- α (10 μ g/L), and TGF β 1 (5 μ g/L) for 48 h as indicated. Afterwards, supernatants were collected and subjected to EIA analysis of the ET-1 content. Data from six separate cultures were used to calculate mean \pm SE; $^aP < 0.05$ vs control cultures.

distinct types of mitogen-activated protein (MAP) kinases, ERK1/2 and p38 (Figure 3). EMSA experiments revealed that ET-1 stimulation strongly increased DNA binding of the transcription factor complex AP-1 (Figure 4). As indicated by the results of a supershift analysis, the DNA/protein complex contained the AP-1 subunit c-Fos (Figure 4, lane 6). ET-1 stimulation of PSC was also associated with some enhancement of the DNA binding of NF- κ B. The relevance of this finding, however, remained uncertain since activation of NF- κ B was quite weak (data not shown).

Regulation of ET-1 gene expression

In the course of the studies, four mediators involved in PSC activation (PDGF, CTGF, TNF- α and TGF- β 1)^[2] as well as one antagonist, the antiproliferative and antifibrotic cytokine IFN- γ ^[20], were tested regarding their effects on ET-1 synthesis in PSC (Figure 5). TGF- β 1 and TNF- α strongly stimulated secretion of ET-1 by the cells, whereas PDGF displayed the opposite effect. After application of CTGF or IFN- γ , statistically significant but nevertheless small increases of ET-1 levels in culture supernatants were observed.

Figure 6 Effects of TGF- β 1 and TNF- α on protein binding to the ET-1 promoter. Serum-starved PSC growing in 6-well plates were incubated with (A) TGF- β 1 (5 μ g/L) and (B) TNF- α (10 μ g/L) for the indicated periods of time. Nuclear extracts were subjected to EMSA analysis using [32 P]-labelled oligonucleotides derived from the ET-1 promoter as described in the "Materials and Methods" section. Supershift analysis was performed by incubating binding reactions with the indicated protein-specific antibodies. Inducible complexes and supershifted bands (lane 6 in A and B) are pointed out by arrows. Addition of c-Rel antibody (B, lane 7) weakened protein binding to the oligonucleotide, suggesting the presence of the c-Rel protein in the complex (competitive binding of antibody and oligonucleotide to c-Rel). Results in (A) and (B) are representative of three independent experiments.

To study the molecular mechanisms underlying the effects of TGF- β 1 and TNF- α , EMSA experiments using oligonucleotides derived from the rat ET-1 promoter were performed. TGF- β 1 induced the binding of a transcription factor complex containing Smad3 to a DNA sequence that corresponds to the TGF- β response element of the human ET-1 gene^[17] (Figure 6A). TNF- α stimulation of PSC was associated with enhanced protein binding to a putative NF- κ B site in the ET-1 promoter. Antibodies to the NF- κ B subunits p65RelA and c-Rel shifted the protein/DNA complex or weakened DNA/protein interaction, suggesting the presence of both proteins (Figure 6B).

DISCUSSION

PSC are the principal effector cells in pancreatic fibrosis^[2,21]. Progressive replacement of pancreatic parenchyma by connective tissue promotes the development of exocrine and endocrine organ failure in the course of chronic pancreatitis. Furthermore, paracrine interactions between stroma cells and pancreatic cancer cells have been implicated in accelerated tumour growth and resistance to chemotherapeutics^[22-24]. PSC are therefore considered attractive targets for the adjuvant treatment of pancreatic cancer based on inhibition of fibrogenesis. One important prerequisite for such an antifibrotic therapy is to understand the molecular processes underlying PSC activation in pancreatitis and cancer.

We and others have recently shown that ET-1 acts on PSCs in an autocrine fashion^[11-13]. In agreement with a previous study^[13], we have now found that application of ET-1 to PSC cultures promotes migration. Furthermore, our novel data indicate that ET-1 directly fosters exhibition of an activated, myofibroblastic phenotype, since α -SMA expression in PSC was enhanced. As previously suggested by Masamune *et al*^[13], exogenous ET-1 did not stimulate cell proliferation. Nevertheless, the dual-specific ET receptor antagonist bosentan significantly inhibits PSC growth^[11], suggesting a contribution of endogenous ET-1 to the induction of mitogenesis. Together, these findings clearly point to a profibrogenic role of the ET-1/ET receptor axis in PSC. Additional support for this conclusion comes from our studies at the molecular level: ET-1 induced an activation of the MAP kinases ERK1/2, p38 and the transcription factor AP-1. All these signalling molecules have previously been identified as key components of the intracellular network triggering PSC activation^[14,15,25]. Furthermore, ET-1 significantly stimulated expression of two cytokines that have previously been suggested as autocrine enhancers of PSC activation, IL-1 β and IL-6^[18,19]. Since both cytokines are well-established pro-inflammatory mediators, our data also implicate, for the first time, ET-1 in the enhancement of local inflammatory reactions in the pancreas.

In the present study, experiments aimed at elucidating regulation of ET-1 gene expression in PSC revealed that TGF- β 1 and TNF- α strongly enhanced the release of ET-1 by culture-activated PSC. Based on our molecular studies, Smad transcription factors and NF- κ B are likely to be involved in the induction of ET-1 expression by TGF- β 1 and TNF- α , respectively. Although both cytokines have previously been shown to stimulate ET-1 synthesis in other types of cells^[17,26], this finding is interesting since it suggests the existence of a regulatory network in which TGF- β 1 and TNF- α exert their biological effects on stellate cells in part through the ET-1/ET receptor axis. Given that ET-1 induces expression of IL-1 β /IL-6, and TGF- β 1 is secreted by PSC^[27], a vicious cycle may develop which leads to enhanced inflammation and progressive fibrosis.

Unexpectedly, IFN- γ displayed a small stimulatory effect on ET-1 release by PSC, although it inhibited expression of the ET-1 gene in a cell line of immortalized PSC^[28]. Here and in the case of PDGF, which diminished ET-1 synthesis, the underlying molecular mechanisms warrant further investigation.

As indicated by the results of our previous study^[11], interruption of autocrine and paracrine loops at the level of ET-1 action represents a suitable approach to target activated PSC. However, the antifibrotic efficiency of the ET receptor antagonist bosentan in our rat model of severe chronic pancreatitis^[29] was quite limited. Based on our previous and novel data, we therefore suggest that in future preclinical studies ET-1 receptor antagonists should be combined with drugs interfering with a different critical step of fibrogenesis and inflammation, such as transduction of profibrogenic signals in PSC.

COMMENTS

Background

Fibrosis is a key feature of chronic pancreatitis and pancreatic cancer. The extensive deposition of extracellular matrix (ECM) proteins fosters the development of an exocrine and endocrine organ insufficiency, and accelerates progression of the tumour. Pancreatic stellate cells (PSC) are the principal effector cells in pancreatic fibrosis. They are activated by profibrogenic stimuli, which include, for example, cytokines and ethanol metabolites. So far, there are no specific therapies available to interfere with dysregulated fibrogenesis in the diseased pancreas.

Research frontiers

The molecular mechanisms underlying induction and maintenance of PSC activation are incompletely understood. This deficit hampers to some degree the development of therapeutic approaches aimed at the inhibition of pancreatic fibrosis in pancreatitis and cancer.

Innovations and breakthroughs

The results of this study provide molecular insights into endothelin-1 (ET-1) action in PSC. The data indicate that ET-1 stimulates exhibition of an activated stellate cell phenotype. The intracellular signalling molecules found to be activated by ET-1, ERK1/2, p38 and AP-1, have previously been linked to the process of stellate cell activation. With IL-1 β and IL-6, two proinflammatory cytokines were identified as target genes of ET-1, suggesting for the first time a direct link between inflammation and fibrosis at the level of ET-1 action. In addition, studies on the regulation of ET-1 expression revealed that transforming growth factor- β 1 and tumour necrosis factor- α strongly stimulate ET-1 secretion by PSC. Together, these data suggest that ET-1 is part of a network of proinflammatory and profibrogenic mediators that fosters interactions between inflammatory cells and PSC, ultimately enhancing inflammation and fibrosis.

Applications

The results encourage further studies aimed at the inhibition of fibrogenesis by targeting the ET-1/ET receptor axis. The authors suggest that combinations of ET receptor antagonists with drugs interfering with independent steps of stellate cell activation should be tested in animal models of pancreatic fibrosis.

Terminology

Pancreatic fibrosis refers to the process of progressive replacement of pancreatic tissue by connective tissue. PSC are fibroblast-like cells that produce most of the ECM in the diseased organ. ET-1 is a polypeptide originally identified as an endothelial cell-derived hormone with vasoconstrictive activity. Additional cellular origins and functions of ET-1 have been described.

Peer review

The authors revealed alteration of several factors involved in inflammation and fibrogenesis focusing on ET-1 action in isolated PSC. The study is well designed and provided some interesting results of scientific value, implying future therapeutic strategy using ET-1 receptor antagonists against chronic pancreatitis.

Abstract

AIM: To explore the possibility of using the Non-invasive Micro-test Technique (NMT) to investigate the role of Transient Receptor Potential Canonical 1 (TRPC1) in regulating Ca^{2+} influxes in HL-7702 cells, a normal human liver cell line.

METHODS: Net Ca^{2+} fluxes were measured with NMT, a technology that can obtain dynamic information of specific/selective ionic/molecular activities on material surfaces, non-invasively. The expression levels of TRPC1 were increased by liposomal transfection, whose effectiveness was evaluated by Western-blotting and single cell reverse transcription-polymerase chain reaction.

RESULTS: Ca^{2+} influxes could be elicited by adding 1 mmol/L CaCl_2 to the test solution of HL-7702 cells. They were enhanced by addition of 20 $\mu\text{mol/L}$ noradrenalin and inhibited by 100 $\mu\text{mol/L}$ LaCl_3 (a non-selective Ca^{2+} channel blocker); 5 $\mu\text{mol/L}$ nifedipine did not induce any change. Overexpression of TRPC1 caused increased Ca^{2+} influx. Five micromoles per liter nifedipine did not inhibit this elevation, whereas 100 $\mu\text{mol/L}$ LaCl_3 did.

INTRODUCTION

Changes in the concentration of Ca^{2+} in the cytoplasmic space play a central role in intracellular signaling pathways in liver cells, including glucose, fatty acid, amino acid and xenobiotic metabolism, bile acid secretion, protein synthesis and secretion, the movement of lysosomes and other vesicles, the cell cycle and cell proliferation, and apoptosis and necrosis^[1-4]. In earlier reports, it has been shown that ligand-gated, store-operated, receptor-activated, and stretch-activated Ca^{2+} -permeable channels are expressed in hepatocytes and in liver cell lines. No voltage-operated Ca^{2+} channels (VOCCs) have been detected^[5-8]. There is increasing evidence that members of the canonical subgroup of Transient Receptor Potential (TRP) proteins constitute tetramers of both receptor-activated and store-operated Ca^{2+} channels (SOCs)^[9-11], and Transient Receptor Potential Canonical 1 (TRPC1) is considered as one of the most likely candidates in forming Ca^{2+} channels in mammalian cells^[12-15].

The Non-invasive Micro-test Technique (NMT) was developed in the late 20th century, and is a new

technology for obtaining dynamic information on specific ionic/molecular activities on material surfaces, non-invasively. This technique incorporates different temporal and spatial resolution domains from other traditional methods, and its 3-dimensional measurement capability enables us to observe the physiological characteristics of biological phenomena that would be difficult or even impossible with other techniques^[16]. To date, Ca^{2+} , H^+ , K^+ , Cl^- , NO^- , Mg^{2+} , Cd^{2+} , Al^{3+} , and O_2 have been detected as sensors for ionic/molecular species.

In the present study, we used NMT to study the Ca^{2+} influxes elicited by extracellular elevations of Ca^{2+} concentration, and the inhibitory effects of several Ca^{2+} channel blockers, to investigate the role of TRPC1 in regulating Ca^{2+} fluxes in HL-7702 cells.

MATERIALS AND METHODS

Materials

Nifedipine, noradrenalin, protease inhibitor Cocktail, Fast Red TR, Naphthol AS-MX phosphate, and Calcium Ionophore I [Cocktail A were bought from the Sigma-Aldrich Company (Catalog Number: 21048)]. Lipofectamine 2000 was purchased from Invitrogen. The TRPC1 polyclonal antibody was acquired from the Abnova Company. Peroxidase-conjugated secondary antibody was obtained from the Beijing Zhongshan Golden Bridge Co.. All the other reagents were of reagent grade.

Cell culture, plasmid construction and transfection

The human liver cell line, HL-7702, bought from the Shanghai Institute for Biological Sciences, Chinese Academy of Sciences, was maintained in RPMI-1640 containing 10% FBS, 1% Penicillin, and Streptomycin. Plasmid pBS-T-TRPC1 was constructed and verified as previously described^[17]. HL-7702 cells were grown to 75%-80% confluence in 35 mm dishes in advance and transfection was carried out with 1 $\mu\text{g}/\text{mL}$ of the recombinant plasmid and Lipofectamine 2000 according to the manufacturer's protocol.

Measurements of extracellular Ca^{2+} influxes

Measurements of net influxes of Ca^{2+} were performed using NMT (BIO-001A, Younger USA Sci. & Tech. Co., Amherst, MA, USA; Applicable Electronics Inc., Forestdale, MA, USA; and ScienceWares Inc., East Falmouth, MA, USA). The electrode was controlled to move with an excursion of 10 μm at a programmable frequency in the range of 0.3-0.5 Hz; this minimized mixing of the bathing saline.

To construct the microelectrodes, borosilicate micropipettes (2-4 μm aperture, XYPG120-2, Xuyue (Beijing) Science and Technology Co., Ltd., Beijing, China) were silanized with tributylchlorosilane and the tips filled with Calcium Ionophore I - Cocktail A. An Ag/AgCl wire electrode holder (XYEH01-1) was inserted in the back of the electrode to make electrical contact with the electrolyte solution. Only electrodes with Nernstian slopes > 25 mV were used. Ca^{2+} fluxes were calculated by Fick's law of

diffusion: $J_0 = -[D \times (dC/dX)]$ where J_0 represents the net Ca^{2+} flux (in $\mu\text{mol}/\text{cm}$ per second), D is the self-diffusion coefficient for Ca^{2+} (in cm^2/s), dC is the difference value of Ca^{2+} concentrations between the two positions, and dX is the 10 μm excursion over which the electrode moved in our experiments. Data and image acquisition, preliminary processing, control of the three-dimensional electrode positioner, and stepper-motor-controlled fine focus of the microscope stage were performed with ASET software.

Single cell reverse transcription-polymerase chain reaction (RT-PCR)

Single cell RT-PCR was performed to determine whether the cells measured by NMT were successfully transfected, using a previously described method, with some modifications^[18]. Directly after the Ca^{2+} influx assay, the contents of tested cell were aspirated into a microelectrode. The tip of the electrode was then broken in a PCR tube and stored at -80°C until use. Reverse transcription was carried out using a kit from TIANGEN (Beijing, China) according to the manufacturer's instructions. The first PCR was performed using specific primers (Forward: GCAATGATACCTTCCATTTCGTTTC; Reverse: CGATGCACTAGGCAGCAGATC) and the following conditions: pre-denaturation at 94°C for 3 min; followed by 30 cycles of denaturation at 94°C for 30 s and annealing at 60°C for 30 s, then synthesis at 72°C for 60 s; the last step was extension at 72°C for 5 min. After the first PCR, 1 μL of the reaction products was used as the template for a secondary PCR with the same conditions as above and 25 cycles. The predicted size of the TRPC1 amplicons were 455 bp and reaction products were confirmed and analyzed by agarose gel electrophoresis.

Western blotting

Total proteins were obtained from cultured cells by using lysis buffer (35 mmol/L Tris at pH 7.4, 0.4 mmol/L EDTA, 10 mmol/L MgCl_2 , 0.1% protease inhibitor Cocktail). For western blotting analysis, 20 μg proteins were resolved by 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and transferred onto to polyvinylidene difluoride membranes for 2 h at 20 V. The membranes were then blocked for 2 h with blocking solution (5% bovine serum albumin) and probed with anti-TRPC1 antibodies. The primary antibodies were incubated for 1 h at room temperature and, after washing, the membranes were incubated with peroxidase-conjugated secondary antibodies for 1 h. Finally, the proteins on the membranes were dyed by staining solution containing Fast Red TR and Naphthol AS-MX phosphate. Immunoblots were then scanned to obtain images.

Statistical analysis

Data were expressed as mean \pm SD of n cells from at least six cell culture dishes. The statistical significance of diversities between means was determined using the DUNNET t -test. A value of $P < 0.05$ was considered significant.

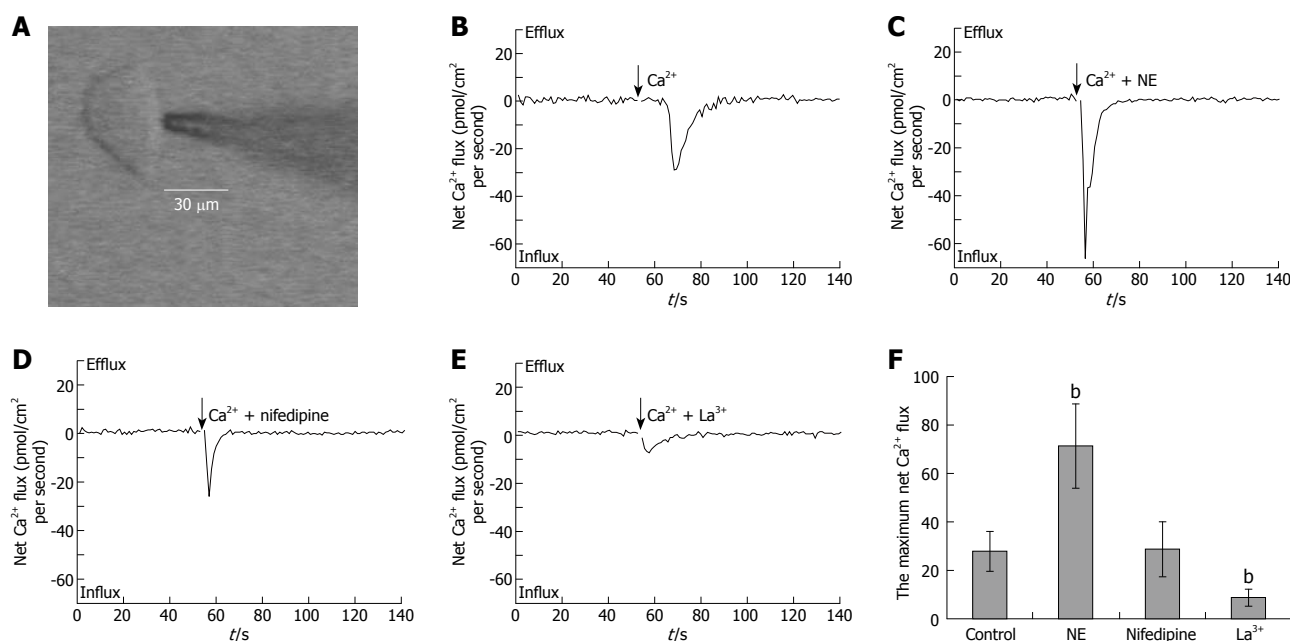

Figure 1 The Ca^{2+} fluxes of HL-7702 cells. A: A screen-printed picture of a cell measured by NMT; B: Net Ca^{2+} fluxes of a HL-7702 cell. The maximum values were 28.2 ± 8.2 pmol/cm² per second ($n = 6$); C: Net Ca^{2+} fluxes of a noradrenalin-treated HL-7702 cell. The maximum values were 71.7 ± 17.5 pmol/cm² per second ($n = 6$); D: Net Ca^{2+} fluxes of a nifedipine-treated HL-7702 cell. The maximum values were 29.0 ± 11.3 pmol/cm² per second ($n = 6$); E: Net Ca^{2+} fluxes of a La^{3+} -treated HL-7702 cell. The maximum values were 9.0 ± 3.5 pmol/cm² per second ($n = 6$); F: Bar graph of the maximum net Ca^{2+} influxes in four groups. $^bP < 0.01$, control group vs noradrenalin-treated or La^{3+} -treated group.

RESULTS

The Ca^{2+} influxes of HL-7702 cells were measured by NMT

Before the experiment, 35 mm dishes with pre-dispersed normal HL-7702 cells were perfused with test solution containing (in mmol/L): 2.3 NaHCO_3 , 27 Na_2SO_4 , 9.7 KCl, 61.1 MgCl_2 , and 366.7 NaCl. The Ca^{2+} influxes were then measured by NMT. The background noise was recorded for three min before 1 mmol/L CaCl_2 was added to elicit an inward Ca^{2+} current. As shown in Figure 1A, the Ca^{2+} selective microelectrode moved between two positions close to the tested cells constantly to acquire experimental data. Net Ca^{2+} fluxes are depicted in Figure 1B, a giant wave trough emerged shortly after CaCl_2 was added.

Effects of noradrenalin, nifedipine and La^{3+} on Ca^{2+} influxes of HL-7702 cells

To further identify the property of the Ca^{2+} influxes of HL-7702 cells, three drugs were selected as tools in the following experiments. After background noise was recorded for three min, a Ca^{2+} channel agonist, noradrenalin (20 $\mu\text{mol/L}$), or two types of inhibitors, nifedipine (5 $\mu\text{mol/L}$) or LaCl_3 (100 $\mu\text{mol/L}$) were added into the test solution together with 1 mmol/L CaCl_2 . The effects of the three drugs on Ca^{2+} influxes are shown in Figure 1C-E. Net Ca^{2+} fluxes were significantly influenced by noradrenalin and La^{3+} ; however, nifedipine did not induce any change. A bar graph of the maximum net Ca^{2+} fluxes in the four groups (three drug-treated groups and control group) is depicted in Figure 1F; these experiments were repeated six times ($n = 6$).

Effects of TRPC1-transfection on Ca^{2+} influxes of HL-7702 cells

When TRPC1-transfected HL-7702 cells were measured by NMT, the maximum net Ca^{2+} influxes increased to 48.9 ± 6.4 pmol/cm² per second ($n = 6$) and a deeper wave trough was observed (Figure 2A). The bar graph shown in Figure 2B shows that the statistical difference between the TRPC1-transfected group and the control group was significant ($P < 0.01$). Single cell RT-PCR and western blotting were performed after NMT experiments. The results of agarose gel electrophoresis and SDS-PAGE are shown in Figure 2C and D, respectively. They demonstrated that TRPC1-expressions in tested cells were elevated after transfection.

Effects of nifedipine and La^{3+} on Ca^{2+} influxes of TRPC1-transfected HL-7702 cells

TRPC1-transfection induced increases in Ca^{2+} influxes. To investigate the effects of nifedipine and La^{3+} on these increased Ca^{2+} influxes, the two drugs were added into the test solution together with 1 mmol/L CaCl_2 . As shown in Figure 3A-C, the maximum net Ca^{2+} fluxes maintained an average of 44.0 ± 5.7 pmol/cm² per second ($n = 6$) when 5 $\mu\text{mol/L}$ nifedipine was applied, whereas 100 $\mu\text{mol/L}$ LaCl_3 made reduced the maximum value to 7.6 ± 1.9 pmol/cm² per second ($n = 6$). A significant statistical difference only existed between the TRPC1 + La^{3+} -treated group and the TRPC1-transfected group ($P < 0.01$). Single cell RT-PCR and western blotting were performed after NMT experiments to confirm the increased TRPC1 expression (data not shown).

Figure 2 TRPC1-transfection influences Ca^{2+} influxes of HL-7702 cells. A: Net Ca^{2+} fluxes of a TRPC1-transfected cell. The maximum values were 48.9 ± 6.4 pmol/cm² per second ($n = 6$); B: Bar graph of the maximum net Ca^{2+} fluxes in the control group and the TRPC1-transfected group. The statistical difference between the two groups was significant ($^bP < 0.01$); C: Single cell RT-PCR products from cultured HL-7702 cells and TRPC1-transfected cells using primers for human TRPC1 (455 bp); lane M: DNA marker, lane 1: TRPC1 amplified from HL-7702 cells, lane 2: TRPC1 amplified from transfected cells; D: TRPC1 protein was detected in cultured HL-7702 cells and TRPC1-transfected cells using western-blotting analysis; lane 1: TRPC1 protein extracted from HL-7702 cells, lane 2: TRPC1 protein from transfected cells. The molecular mass of TRPC1 is 88 kDa.

Figure 3 Nifedipine and La^{3+} influence Ca^{2+} influxes of TRPC1-transfected HL-7702 cells. A: Net Ca^{2+} fluxes of a TRPC1 + nifedipine-treated cell. The maximum values were 44.0 ± 5.7 pmol/cm² per second ($n = 6$); B: Net Ca^{2+} fluxes of a TRPC1 + La^{3+} -treated cell. The maximum values were 7.6 ± 1.9 pmol/cm² per second ($n = 6$); C: Bar graph of the maximum net Ca^{2+} fluxes in the TRPC1-transfected group, TRPC1 + nifedipine-treated group, and TRPC1 + La^{3+} -treated group. A significant statistical difference only existed between the TRPC1-transfected group and the TRPC1 + La^{3+} -treated group ($^bP < 0.01$).

DISCUSSION

Initially, we detected Ca^{2+} influxes in HL-7702 cells using NMT when 1 mmol/L CaCl_2 was added to the test solution and the extracellular Ca^{2+} concentration markedly changed. Ca^{2+} influx could be influenced by two drugs, noradrenalin, and LaCl_3 ; however nifedipine did not induce any change.

As a known neurotransmitter, noradrenalin can act through α_1 -adrenoceptors to activate phospholipase C. This generates inositol 1,4,5-trisphosphate (IP_3) within the cell, which in turn mediates the rise of Ca^{2+} concentration by release from intracellular stores^[19,20] and opening of receptor operated Ca^{2+} entry at the plasma membrane^[21-23]. Thus, the increase in Ca^{2+} influx induced by noradrenalin together with 1 mmol/L external CaCl_2 could be explained if receptor operated Ca^{2+} channels played a central role in these experiments. On the other hand, Ca^{2+} influxes were prominently inhibited by La^{3+} . Analogs often effect their action through competitive inhibition with their common receptors or channels. La^{3+} has a similar size of ionic radius to that of Ca^{2+} , which enables La^{3+} to compete with Ca^{2+} , which makes La^{3+} a non-selective Ca^{2+} channel blocker. In addition, a study showed that La^{3+} could inhibit both influx and efflux of Ca^{2+} in lacrimal cells^[24], which was consistent with the present study. Most importantly, nifedipine, as an antagonist of L-type Ca^{2+} channels, did not induce any change in Ca^{2+} influxes, which would indicate that

no VOCCs existed or that transmembrane Ca^{2+} influxes elicited by external Ca^{2+} did not pass through VOCCs in HL-7702 cells.

TRPC1 is one of seven members of the TRPC sub-family of non-selective cation channels and is expressed in a wide variety of cell types and tissues^[25-27]. It is likely that TRPC1 plays a significant part in intracellular Ca^{2+} homeostasis. In salivary gland cells, the current through the endogenous SOCs was the same as the membrane current which was activated by the depletion of intracellular Ca^{2+} stores in cells in which TRPC1 was ectopically expressed and the endogenous SOCs were decreased by transfection with antisense TRPC1^[28]. In kidney epithelial cells, a new receptor-operated channel formed by heteromeric assembly of TRPP2 and TRPC1 subunits was discovered^[29]. In T cells, intracellular Ca^{2+} elevation induced by $\Delta 9$ -tetrahydrocannabinol was attributable entirely to extracellular Ca^{2+} influxes, which were not dependent on store depletion, but mediated through TRPC1 channels^[30]. The results of the second part of our study do not conflict with these reports. In HL-7702 cells, overexpression of TRPC1 causes an increase of Ca^{2+} influxes induced by adding external Ca^{2+} , and the non-selective Ca^{2+} channel blocker, La^{3+} , can attenuate this elevation. In summary, there is a TRPC1-dependent Ca^{2+} -type channel(s), either receptor-activated or store-operated present in HL-7702 cells, which can be inhibited by La^{3+} .

Taken together, NMT is a powerful tool for ion

channel research, which has been effectively applied in various systems^[31-33]. We used NMT to explore the properties of Ca^{2+} channels, and found that there was a TRPC1-dependent Ca^{2+} -type channel(s), which could be detected *via* NMT and inhibited by La^{3+} , in HL-7702 cells.

COMMENTS

Background

Ca^{2+} plays an important role in intracellular signaling pathways and Transient Receptor Potential Canonical 1 (TRPC1) is considered as one of the most likely candidates in forming Ca^{2+} channels in mammalian cells. As a technology to obtain dynamic information of specific ionic/molecular activities on material surfaces non-invasively, Non-invasive Micro-test Technique (NMT) is being increasingly applied to study characters of ion channels.

Research frontiers

TRPC1 has been verified as a molecular candidate or a regulator of Ca^{2+} channels in several mammalian cells. However, the role of TRPC1 in normal human liver cells has not been elucidated. In this study, the authors demonstrate that a TRPC1-dependent Ca^{2+} -type channel(s) exists in HL-7702 cells, using NMT, a non-invasive technique.

Innovations and breakthroughs

This is the first study to investigate the role of TRPC1 in regulating Ca^{2+} channels in normal human liver cells. Furthermore, measuring Ca^{2+} influxes was performed non-invasively, which cannot be accomplished with other traditional techniques.

Applications

Cytoplasmic Ca^{2+} overloading might cause damage to liver cells. By understanding the role of TRPC1 in mediating extracellular Ca^{2+} influxes, this study might represent a future strategy for preventing or treating diseases induced by dysfunctions of Ca^{2+} channels in the clinic, such as hepatic ischemia-reperfusion injury.

Terminology

The canonical transient receptor potential (TRPC) channel subfamily consists of seven mammalian cation channels and is expressed in almost every tissue, including the liver. The TRPC1 channel is permeable to Ca^{2+} and is the most likely candidate for receptor-operated Ca^{2+} channels. In addition, TRPC1 also plays a dominant role in mediating store-operated Ca^{2+} channels in many types of cells.

Peer review

The authors recorded Ca^{2+} influxes elicited by adding external Ca^{2+} into a test solution in several different conditions. It revealed that there is a TRPC1-dependent Ca^{2+} -type channel(s), which can be detected *via* NMT, in normal human liver cells. This is an interesting study.

Abstract

AIM: To determine the effect of chemotherapy on wound healing by giving early preoperative 5-fluorouracil (5-FU) to rats with colonic anastomoses.

METHODS: Sixty Albino-Wistar male rats (median weight, 235 g) were used in this study. The rats were fed with standard laboratory food and given tap water *ad libitum*. The animals were divided into three groups: Group 1: Control group (chemotherapy was not administered), Group 2: Intraperitoneally (IP) administered 5-FU group (chemotherapy was administered IP to animals at a dose of 20 mg/kg daily during the 5 d preceding surgery), Group 3: Intravenously (IV) administered 5-FU group. Chemotherapy was administered *via* the penil vein, using the same dosing scheme and duration as the second group. After a 3-d rest to minimize the side effects of chemotherapy, both groups underwent surgery. One centimeter of colon was resected 2 cm proximally from the peritoneal reflection, then

sutured intermittently and subsequently end-to-end anastomosed. In each group, half the animals were given anaesthesia on the 3rd postoperative (PO) day and the other half on the 7th PO day, for *in vivo* analytic procedures. The abdominal incisions in the rats were dissected, all the new and old anastomotic segments were clearly seen and bursting pressures of each anastomotic segment, tissue hydroxyproline levels and DNA content were determined to assess the histologic tissue repair process.

RESULTS: When the IV group was compared with the IP group, bursting pressures of the anastomotic segments on the 3rd and 7th PO days, were found to be significantly decreased, hydroxyproline levels at the anastomotic segment on the 7th PO day were significantly decreased ($P < 0.01$).

CONCLUSION: In this study, we conclude that early preoperative 5-FU, administered IV, negatively affects wound healing. However, IP administered 5-FU does not negatively affect wound healing.

Effect of early preoperative 5-fluorouracil on the integrity of colonic anastomoses in rats. *World J Gastroenterol* 2009; 15(33): 4156-4162 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4156.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4156>

INTRODUCTION

Colorectal cancer is a common malignancy in most developed countries worldwide^[1]. Metastasis frequently occurs before clinical detection of the primary tumour. Despite the advances in surgical techniques, this characteristic of the malignancy prevents a significant

improvement in cure rates for colorectal cancers^[2]. While cancer therapy was limited to surgery in the past, nowadays therapy includes the combination of surgical radiotherapy, chemotherapy, hormonal and biological therapies^[3,4]. 5-fluorouracil (5-FU) treatment has been accepted as standard chemotherapy for colorectal cancers for a long time. Recently, high recurrence rates, the presence of distant metastasis, the possibility of complete resection, and the removal of circulating tumour cells after curative resection of colorectal cancers constitute a new therapeutic approach known as neo-adjuvant chemotherapy^[5-7]. While the integrity of anastomoses after colorectal cancer resection is an important parameter on mortality and morbidity, the effects of preoperative chemotherapy on wound healing and anastomoses are also important and have not been clearly outlined.

This study investigates the effects of early preoperative administration of 5-FU, given intravenously (IV) and intra-peritoneally (IP), on wound healing in colon anastomoses.

MATERIALS AND METHODS

Sixty male Wistar-Albino rats weighing between 225 and 315 g were used in this study. All rats were clinically healthy and were fed with standard laboratory food and water. The animals were numbered at the beginning of the study and weighed every day during the study. There were three groups: Group I, a control group ($n = 20$); group II which received 5-FU IP ($n = 20$); group III which received 5-FU IV ($n = 20$). The study was approved by the local Ethics Committee of Haydarpaşa Numune Hospital.

Drug administration

When pilot studies and related literature were taken into account, a dose of 20 mg/kg 5-FU was calculated to be the maximum non-lethal dose^[8]. Chemotherapy was not administered to the control group. The second group was administered 5-FU IP at a dose of 20 mg/kg in saline at a concentration of 5 mg/mL each day prior to surgery. The third group was given 5-FU *via* the penile vein at a dose of 20 mg/kg in saline at a concentration of 2 mg/mL each day for 5 d before surgery. Both groups underwent surgery on the 3rd d after chemotherapy to reduce the adverse effects of chemotherapy.

Operative procedure

The same operative procedure was performed in all groups by the same surgeon. 10 mg/kg of ketamine was given subcutaneously to rats under ether anaesthesia. After shaving the frontal abdominal wall, this area was cleaned with povidone iodine and covered with sterile cloths. The abdomen was entered through a 3 cm mid-line incision, 1 cm of colon 2 cm proximal of the peritoneal reflection was resected, and a side-to-side anastomosis was made using ten intermittent sutures with 6/0 polypropylene (Ethicon). Muscles of the front abdominal wall and skin were closed by continuous suture with 3/0 silk. Half the

animals in each group were anaesthetized again either on day 3 or 7 after surgery for *in vivo* analytic procedures. The animals were then killed by haemorrhage for *in vitro* analytic procedures.

Analytic procedures

After making an abdominal incision, macroscopic evaluations of the anastomotic segment were performed. Adhesions surrounding the anastomoses were not cut, and bursting pressure was measured for every anastomotic segment during the internal passage of 200 mL/h saline. For this purpose, a 10/0 silicon catheter was passed *via* the anus to 2 cm distal of the anastomosis and the colon was ligated with silk suture above the catheter. The colon was cut 3 cm proximal to the anastomotic segment. The catheter, which had its end fixed to a standard sphygmomanometer (Petaş, Turkey), was moved 1 cm to the anastomotic segment from the cut end of the colon and the colon was ligated with silk suture around the catheter. The perfusator (Becton Dickinson, France) was maintained at a speed of 200 mL/h and saline was given continuously through the catheter situated in the anus. Increased pressure on the sphygmomanometer was observed. Pressure values of the first leakage from the anastomotic segments, when increased pressure on the sphygmomanometer stopped and the time of falling pressure were recorded as bursting pressures. These bursting pressures were recorded in mmHg for each animal.

After measuring the anastomotic pressures and just before the animals were sacrificed, 5 mL blood samples were taken from the inferior vena cava to determine white blood cell, haemoglobin and platelet counts.

Anastomotic segments were isolated from the surrounding tissues. One cm of colonic segment, including the anastomotic area was resected and was longitudinally separated into two parts. One of the segments was frozen at -45°C for hydroxyproline measurements (hydroxyproline was used as a marker of collagen content) which were calculated as nanograms per gram of tissue. Anastomotic hydroxyproline content was measured by spectrophotometric determination using the method described by Bergman *et al*^[9]. The other segment was embedded in paraffin for DNA content measurement and histological assay. Tissue DNA content was determined by flow cytometry using Mod-Fit Ver 5.01 software^[10].

Tissue sections from routinely embedded paraffin blocks were stained with hematoxylin-eosin and examined by light microscopy. Histological examination was evaluated using the criteria determined by de Roy van Zuidewijn *et al*^[11]. Slides were evaluated twice by the same observer in a blind fashion. Granulation tissue was evaluated as; 1-low; 2-medium; 3-high (intense) and histological parameter scores related to muscular tissue were evaluated as; 1-negative; 2-medium; 3-complete. According to a seven-point scale, mucosal re-epithelization scores were as follows; 1-negative, 2-little-one line cubic, 3-lot-one line cubic, 4-nearly one line cubic, 5-finished-one line cubic, 6-one line glandular, 7-normal glandular mucosa.

Table 1 Leukocyte, platelet and haemoglobin values of blood samples in each group (mean \pm SE)

Groups	Leukocytes ($10^9/L$)		Platelets ($10^9/L$)		Haemoglobin (g/dL)	
	3rd d	7th d	3rd d	7th d	3rd d	7th d
Control	9.0 \pm 3.04	7.6 \pm 3.4	1117 \pm 169	1270 \pm 229	11 \pm 1.7	12.6 \pm 1.2
IP	9.1 \pm 3.3	9.7 \pm 2.4	808 \pm 203	1228 \pm 194	10.5 \pm 1.7	11.9 \pm 0.45
IV	7.4 \pm 4.7	15.9 \pm 5.2	736 \pm 243	1542 \pm 289	9.6 \pm 1.13	11.16 \pm 1.9

Figure 1 Weights of rats during experimental procedure. Preop: Pre-operation; Postop: Post-operation.

Statistical analysis

All data are presented as means \pm SE. Non-parametric Kruskal Wallis variant analysis was used for multiple group comparisons of statistical analysis and subgroup comparisons were performed with Dunn's test. Pair group analysis was evaluated using Mann-Whitney *U* test.

RESULTS

During the experimental procedure, two animals died on the 3rd and 7th postoperative (PO) days in the IV group. The cause of death was leakage from the anastomotic site. No mortality was observed in the control and IP groups. Dead rats were replaced with new animals.

Weight measurements

Rats were weighed at the beginning of the study, during the chemotherapy period and in the postoperative period. Weight loss was observed in all animals in the chemotherapy groups (IP and IV) compared with baseline values, whereas control animals gained weight during the preoperative period. Animals in the control group also lost weight during the PO period. Weight loss in the rats is shown in Figure 1. On the 3rd PO day, the IV 5-FU group weighed significantly less than the control group ($P < 0.01$) and the IP group ($P < 0.01$). Weight loss in the IV 5-FU group on the 7th PO day was found to be significantly lower than the control group ($P < 0.01$) and the IP group ($P < 0.001$).

Hematological effects

Haemoglobin, white blood cell and platelet counts in the blood samples taken on the 3rd and 7th PO days after chemotherapy are shown in Table 1. There was no statistically significant difference between the groups for

Figure 2 Bursting pressure values of experimental groups on postoperative 3rd and 7th d.

haemoglobin counts on the 3rd and 7th PO days. On the 3rd PO day in the IV 5-FU group, the platelet count was found to be significantly lower than the control group ($P < 0.05$).

Bursting pressure

Bursting pressures were measured at anastomotic segments on the 3rd and 7th PO days (Figure 2). Bursting pressure values were significantly lower than the control ($P < 0.01$) and IP group on ($P < 0.05$) the 3rd PO day in the IV 5-FU group. On the 7th PO day, bursting pressure values in the IV and IP groups were not significantly different from the control group. However, bursting pressure values in the IV 5-FU group were significantly lower when compared with the IP group ($P < 0.01$).

Tissue hydroxyproline

Anastomotic hydroxyproline values were statistically significantly higher in the IP group compared to the control and IV group on the 3rd PO day ($P < 0.01$). There were no statistically significant differences between the IV and control groups on PO day 3, regarding hydroxyproline levels. Hydroxyproline levels in the IP group were the highest and anastomotic hydroxyproline levels in the IV group were significantly lower than the IP group on PO day 7 ($P < 0.01$) (Figure 3).

DNA analysis

DNA contents in the anastomotic segments were evaluated using a flow cytometer technique in this study^[10]. When the anastomotic segments were examined, a decrease in cell proliferation was noted on the 3rd PO day in the IV group, when compared to the control group, and on the 7th PO day between the control and the IP group. However, this decrease was not statistically significant.

Table 2 Histological scores of anastomotic colon healing in all groups on the 3rd and 7th postoperative days (mean \pm SE)

Groups	3rd d			7th d		
	Control	IP	IV	Control	IP	IV
Granulation	1.66 \pm 0.70	2.14 \pm 0.89	1.42 \pm 0.53	2.66 \pm 0.50	2.71 \pm 0.48	2.57 \pm 0.53
Re-epithelization	1.55 \pm 1.66	2.71 \pm 2.21	1.00 \pm 0.00	4.77 \pm 1.20	5.28 \pm 0.95	2.42 \pm 2.14
Muscular tissue	1.00 \pm 0.00	1.00 \pm 0.00	1.00 \pm 0.00	1.22 \pm 0.44	1.42 \pm 0.44	1.14 \pm 0.37

Figure 3 Hydroxyproline levels in anastomotic segment.

Figure 4 Proliferative cell rates of anastomotic segments.

The tissue proliferation index of anastomotic segments is shown in Figure 4.

Histological analysis

Scores for the histological parameters in the groups are given in Table 2. The best granulation tissue was observed on the 3rd and 7th d in the IP 5-FU group. On the 3rd d of re-epithelization, there was no statistically significant difference between the control and both 5-FU administered groups. However, on the 7th d there was a statistically significant difference between the control and the IV 5-FU group ($P < 0.05$), and between the IP 5-FU and IV 5-FU groups ($P < 0.05$). On multiple comparisons between the groups, the statistically significant difference was maintained ($P < 0.05$). Muscle tissue formation was not complete on the 3rd and 7th d and related values were not statistically different between the groups.

DISCUSSION

Colorectal cancer is the second most frequent type of cancer in industrialized countries. Despite improvements in surgical techniques, almost half of patients with colorectal cancer will eventually die of recurrent disease.

When colon cancer recurs after surgical resection, local disease is found in 25%-40% of patients, peritoneal implants in 12%-28% of patients, and liver metastases in 40% of patients. Hepatic and peritoneal metastases have been reported to be the most frequent failure patterns in resected colorectal cancer patients^[12,13].

Solomon *et al.*^[14] reported on the incidence of colorectal cancer cells on peritoneal surfaces. Overall, 15% of patients had positive cytology for cancer cells in the peritoneal or bowel surface. Stage II and III disease is treated with wide surgical resection in combination with

adjuvant or neo-adjuvant chemoradiation. The combined modality of chemotherapy and surgery increases overall survival and the disease-free period^[15-18]. 5-FU was first reported to be effective for colorectal cancer in the 1950s. For more than 10 years, 5-FU was the only adjuvant drug given as a single agent. Since its introduction, 5-FU has remained the cornerstone of adjuvant treatment for colorectal cancer. A number of clinical and experimental data are available on the effects of 5-FU, either alone or in combination with other chemotherapeutic agents, on wound healing^[19-22].

In the adjuvant therapy of colorectal cancers, 5-FU was used alone in prolonged systemic regimens or in combination with other agents^[22-25]. Fundamentals of preoperative chemotherapy were based on the results of Cole *et al.*^[5]. According to these results, numerous malignant cells pass into the peripheral circulation during surgical manipulations for localized carcinomas. Preoperatively administered cytotoxic agents may allow tumour resectability and decrease the incidence of distant or local metastases^[26].

5-FU can be injected IV and hepatic concentrations can also be achieved intraportally and IP^[22,27,28]. In addition, intravenous administration may not allow sufficient penetration in the abdominal cavity. This could be the reason why chemotherapeutic agents may not be effective enough to eliminate micrometastases, especially at the resection site and peritoneal surfaces, which are high risk sites for local recurrence. When the drug is administered *via* the intraperitoneal route, high local and hepatic concentrations can be achieved^[28]. Local peritoneal recurrence and haematological toxicity were lower when 5-FU was administered IP. A prospective trial showed that 5-FU administered IP reduced peritoneal failure significantly more than intravenous 5-FU^[29]. There

is an increased interest in the use of intraperitoneal chemotherapy with 5-FU to treat advanced colon cancer. Randomised clinical trials have reported a reduction in local recurrence rate with either intraperitoneal 5-FU alone or combined with intravenous 5-FU^[30].

Toxic side effects are the major dose-limiting factors in chemotherapy. In patients with advanced primary colon cancer, a significantly higher dose of 5-FU can be given by the intraperitoneal route than by the intravenous route^[29]. We used the intraperitoneal approach to deliver high concentrations of 5-FU into the peritoneal cavity without increasing the risk of systemic toxicity. In addition, previous clinical and experimental studies have shown that immediate postoperative 5-FU given IP has no adverse effect on outcome^[8].

In 1994, Kelsen *et al*^[31] reported a phase I trial of postoperative intraperitoneal floxuridine and leucovorin plus systemic 5-FU and levamisole after resection of high-risk colon cancer. Intraperitoneal therapy appeared to be well tolerated, with no substantial increase in postoperative morbidity and no operative mortality.

In 1998, Scheithauer *et al*^[30] accepted 241 patients with resected stage III or high-risk stage II colon cancer into a trial, comparing intravenous 5-FU and levamisole given for a period of 6 mo with a treatment program consisting of leucovorin plus 5-FU given IV and IP. In patients with stage III disease, a significant improvement in disease-free survival and overall survival rates was observed using the systemic plus intraperitoneal treatment, with an estimated 43% reduction in mortality rate. Intraperitoneal and systemic chemotherapy markedly reduced local regional recurrences^[30].

It is stated that the highest non-lethal dose of 5-FU is 20 mg/kg for rats and this was the dose administered in our previous trial^[11]. The 500 mg/m² human dose is equal to the animal dose used in this study. A 3 d interval between the last day of chemotherapy and the surgical procedure was approved to reduce the strong side effects of chemotherapy^[6,22].

Weight reductions were detected both during 5-FU injections and after surgery. The weight of the rats was recorded during the 5-FU injection period and days after the operation. All rats lost weight compared with baseline values during 5-FU administration and after the operation, which was statistically significant in the IV group. These results were concordant with reports from the literature^[6,8,32]. Weight loss after 5-FU is related to anastomotic healing.

The burst pressure values of the anastomotic segments were measured *in vivo* on the 3rd and 7th PO days in rats receiving and not receiving 5-FU in this study, similar to that in the study by Kuzu *et al*^[6]. Anastomotic burst pressures have been measured *in vitro* in most previous similar reports^[8,22]. We think that *in-vivo* measurements reflect the clinical status much better. The bursting sites we found in this study are in accordance with those in other studies which reported that the anastomosis is the most common bursting point^[22,33]. On the 3rd

PO day, bursting pressure values for the IV 5-FU group were found to be significantly lower than the control and IP groups. On the 7th PO day, bursting pressure values in the IV 5-FU group were significantly lower than the IP group. Similar results have been found in previously reported studies^[22,32,33].

Graf *et al*^[32] reported that early postoperative 5-FU administration had a negative impact on the bursting strength of colonic anastomosis.

5-FU administered preoperatively may also have a negative influence on the ability of fibroblasts to proliferate and synthesize collagen. Reduced collagen synthesis can lead to anastomotic dehiscence^[22].

Collagens which guarantee tissue continuity in the tissue repair period contain high proportions of glycine, proline and hydroxyproline. Tissue hydroxyproline levels are important parameters in the tissue repair process^[34,35]. Some studies have found that 5-FU decreases the hydroxyproline content of wounds^[19,21]. There were significant differences in hydroxyproline levels at the anastomotic segments on both the 3rd and 7th PO days in the IV group compared to the IP group. The decrease in collagen content was correspondant with the decrease in bursting pressures.

It is already known that the chemotherapeutic agent 5-FU inhibits DNA synthesis and cell proliferation, by affecting the cell cycle^[36]. Based on this mechanism of action, the effect of chemotherapy on cell proliferation at the anastomotic segment was evaluated by DNA analysis. An obvious decrease in cell proliferation was found at the anastomotic segment of the IV chemotherapy group, compared with the IP and control groups on the 7th PO day. This decrease was not statistically significant. The effects of 5-FU on cancer kinetics determined by DNA analysis, was reported to stress the importance of neo-adjuvant chemotherapy. It was thought that available parameters could be used to determine the anti-tumour effects of 5-FU^[37]. The DNA proliferation index can be used as a parameter to determine the effect of chemotherapy on tissue repair; however, further clinical and experimental studies are required.

We looked at histological aspects of the colon during a 7-d period. Although there were no statistically significant differences between the granulation tissues on the 3rd and 7th PO days in our study, the decrease in re-epithelization, as a sign of a mucosal improvement, was statistically significant in the IV group compared with the control and IP groups. According to the results of de Roy van Zuidewijn *et al*^[11], completion of colonic muscular tissue repair takes about 21 d. Consistent with our study, muscular repairs were not complete in any of the groups at the 3rd and 7th d of the early tissue repair period, and no difference was found between the control and the experimental groups. Our histological findings suggested that IP 5-FU administration may be preferred over IV administration which was in accordance with our previous results.

All anastomoses were examined macroscopically during the second laparotomy, before the bursting pressure

measurements. Intra-abdominal adhesions were not classified but the integrity of anastomoses, the existence of perianastomotic abscess or peritonitis and the formation of adhesions were less frequent in the IP group, when compared to the control and IV groups.

5-FU derivatives inhibit DNA synthesis by inhibiting thymidylate synthetase, and reduce the biological activity of RNA in both human cells and growing bacteria^[38,39].

When applied locally, 5-FU seems to behave like an antibiotic. This confirms certain studies which implied an increasing bactericidal effect when antimicrobial drugs and antineoplastic drugs were administered together. Nyhlén *et al.*^[40] reported that against two of the three tested strains of *Staphylococcus epidermidis*, the combination of ciprofloxacin and 5-FU resulted in a synergistic prolongation of the postantibiotic effect (PAE) in comparison with the PAE induced by the drugs alone. However, these results need to be confirmed clinically.

In conclusion, our results demonstrate that, early preoperative IV administration of 5-FU has a negative effect on anastomotic healing of the colon. However, the IP route of 5-FU administration has no adverse effect on the healing process of colon anastomoses and burst pressure. This study was performed on healthy animals and may not reflect the exact situation in the case of malignant tumors.

COMMENTS

Background

For cancers of the large bowel, multi-institutional trials have demonstrated a significant reduction in mortality with adjuvant chemotherapy compared with surgery alone. 5-fluorouracil (5-FU) was therefore used as a neoadjuvant therapy in the present study where it had no adverse effect on anastomotic healing and burst pressure.

Research frontiers

5-FU is the mainstay of systemic treatment for colorectal cancer. Intravenous administration may not allow sufficient penetration in the abdominal cavity. This may be the reason why chemotherapeutic agents are not effective enough to kill all micrometastases, especially at the resection site and peritoneal surfaces. Because of these theoretical advantages, neoadjuvant intraperitoneal chemotherapy may be a new treatment option for colorectal cancer. This study investigated the effect of preoperative 5-FU on the healing of colorectal anastomoses in the rat.

Innovations and breakthroughs

5-FU can be injected not only intravenously, but also intraportally and intraperitoneally (IP). When administered by the intraperitoneal route, high local and hepatic concentrations can be achieved. Whether 5-FU compromises wound healing is still controversial. Previous clinical and experimental studies have shown that immediate postoperative 5-FU given IP has no adverse effect on outcome. Therefore, 5-FU was used as neoadjuvant therapy in the present study.

Applications

This study may represent a future strategy for neoadjuvant chemotherapy in colonic cancer.

Terminology

5-FU is the most widely used chemotherapeutic agent in the adjuvant treatment of colon cancer. 5-FU acts during synthesis by interfering with normal pathways. 5-FU might also have a negative influence on the ability of fibroblasts to proliferate and synthesize collagen. Reduced collagen synthesis could lead to anastomotic dehiscence.

Peer review

It is an interesting topic for the readers of *WJG*. The authors described pre- and postoperative variables after two methods of 5-FU administration.

Abstract

AIM: To explore the effects of fentanyl on insulin release from freshly isolated rat pancreatic islets in static culture.

METHODS: Islets were isolated from the pancreas of mature Sprague Dawley rats by common bile duct intraductal collagenase V digestion and were purified by discontinuous Ficoll density gradient centrifugation. The islets were divided into four groups according to the fentanyl concentration: control group (0 ng/mL), group I (0.3 ng/mL), group II (3.0 ng/mL), and group III (30 ng/mL). In each group, the islets were co-cultured for 48 h with drugs under static conditions with fentanyl alone, fentanyl + 0.1 μ g/mL naloxone or fentanyl + 1.0 μ g/mL naloxone. Cell viability was assessed by the MTT assay. Insulin release in response to low and high concentrations (2.8 mmol/L and 16.7 mmol/L, respectively) of glucose was investigated and electron microscopy morphological assessment was performed.

RESULTS: Low- and high-glucose-stimulated insulin release in the control group was significantly higher

than in groups II and III (62.33 ± 9.67 μ IU vs 47.75 ± 8.47 μ IU, 39.67 ± 6.18 μ IU and 125.5 ± 22.04 μ IU vs 96.17 ± 14.17 μ IU, 75.17 ± 13.57 μ IU, respectively, $P < 0.01$) and was lowest in group III ($P < 0.01$). After adding 1 μ g/mL naloxone, insulin release in groups II and III was not different from the control group. Electron microscopy studies showed that the islets were damaged by 30 ng/mL fentanyl.

CONCLUSION: Fentanyl inhibited glucose-stimulated insulin release from rat islets, which could be prevented by naloxone. Higher concentrations of fentanyl significantly damaged β -cells of rat islets.

Qian TL, Wang XH, Liu S, Ma L, Lu Y. Fentanyl inhibits glucose-stimulated insulin release from β -cells in rat pancreatic islets. *World J Gastroenterol* 2009; 15(33): 4163-4169 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4163.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4163>

INTRODUCTION

In recent years, anesthesiologists and surgeons have had to manage an increasing number of diabetic patients. A concern for the anesthesiologist is how to control blood glucose and protect islet function in the clinical setting. Because the risk of surgery and anesthesia is higher for these patients, it is particularly important to maintain whole-body glucose homeostasis during the perioperative period. It is well known that many drugs used during surgery for anesthesia or pain relief have effects on pancreatic islets, for example, one study has demonstrated that β -endorphin, an endogenous opioid peptide, can inhibit insulin secretion^[1]. Therefore, when administering drugs to diabetic patients, the surgeons and anesthesiologists must consider the protection of islet function in these patients. Fentanyl was first synthesized 60 years ago and is currently the most popular opioid used in the preoperative period because of its safety and efficacy. In addition,

fentanyl transdermal patches have been developed to manage chronic pain associated with diabetic neuropathy. These patches have been designed to provide continuous, rate-controlled systemic delivery of the fentanyl base for up to 72 h^[2,3].

The minimum effective plasma concentration of fentanyl is 0.63 ng/mL after intravenous administration and the therapeutic plasma concentration is 1-2 ng/mL. However, the plasma concentration often exceeds 3 ng/mL because many practitioners prefer to administer high doses of fentanyl^[4,5]. In most cancer cases secondary to disease progression, the initial median transdermal fentanyl dose is generally 60-70 µg/h (release rate), which increases to about 170 µg/h over time^[6]. Furthermore, a small proportion of patients require doses of between 400 and 1000 µg/h in the latter stages of therapy and the mean treatment period is often longer than 50 d. These large doses are associated with high plasma concentrations (up to 14.5 ng/mL) which are linearly related to the dose^[7,8]. Furthermore, fentanyl has been commonly used for patients undergoing cardiac operations because high doses of fentanyl can stabilize the cardiovascular circulatory system during operations. After administration of 50-100 µg/kg fentanyl, the plasma concentration of fentanyl in these patients is commonly above 20-30 ng/mL^[9]. However, high plasma concentrations of fentanyl are associated with clinical side effects such as nausea and vomiting, constipation, skin itching and respiratory depression. So far, the potential effects of fentanyl on pancreatic islet β-cells remain unknown.

Because some opioid receptor agonists affect insulin release^[10,11], it would be expected that high-doses of fentanyl would have an effect on islet insulin secretion. Studies have suggested that some opiates inhibit insulin secretion^[12]. In mouse pancreatic islets incubated under static conditions, glucose-stimulated insulin release is inhibited by β-endorphin and endomorphin-1, endogenous opioid receptor agonists. This inhibition could be prevented by naloxone, an opioid receptor antagonist^[13]. Therefore, we hypothesized that fentanyl would affect insulin release. Therefore, we investigated the effect of fentanyl on rat islets in a static culture model and believe the results have important implications on the use of fentanyl in clinical situations, particularly in people with diabetes.

MATERIALS AND METHODS

Animals

Male SD rats weighing 250-300 g were purchased from the Shanghai Laboratory Animal Center of the Chinese Academy of Sciences and housed under constant conditions of temperature (20-22°C) and artificial lighting (12-h light-dark cycle) before taking part in the study. The study was carried out in accordance with the Guidelines for Animal Experimentation, Tongji University of Shanghai, China, and all the tests were approved by the Animal Experimentation Committee of Tongji University of Shanghai.

Islet preparation

After male adult rats were anesthetized with 50-75 mg/kg sodium pentobarbital, the abdominal wall was cut open and 10 mL of Hank's buffered saline solution (HBSS) containing collagenase V 1.0-1.2 mg/mL (Sigma Chemical Co., St Louis, MO, USA) was injected into the common bile duct of the rat. The pancreas, which was swollen with the digestion solution, was quickly excised and immersed into a plastic culture bottle containing HBSS and incubated with shaking for 13-15 min at 37°C. The digested suspension was obtained by filtering the suspension through a 0.5-mm metal mesh and washed with HBSS containing 2% bovine serum albumin (BSA). A total of 300-400 islets were obtained from each rat by discontinuous Ficoll density gradient centrifugation (density: 1.100, 1.077) (Ficoll, Sigma Chemical Co., St Louis, MO, USA). After being washed with HBSS containing 2% BSA, the islets were cultured for 24 h with 5% CO₂ and collected for further tests^[14]. The islets were identified by dithizone (Sigma, USA) staining. Cells stained red under light microscopy were considered to be islets^[15]. The combination dyes acridine orange (AO) and propidium iodide (PI) (AO: 0.67 µmol/L; PI: 75 µmol/L) were applied to differentiate between viable and non-viable whole islets; the dyes stained living cells green and dead cells red using minimal background fluorescence^[16].

Groups

The islets were divided into four groups according to the fentanyl concentration used: control group (0 ng/mL), group I (0.3 ng/mL), group II (3.0 ng/mL), and group III (30 ng/mL). In each group, the islets were co-cultured for 48 h with drugs as follows: fentanyl alone, fentanyl + 0.1 µg/mL naloxone and fentanyl + 1.0 µg/mL naloxone. There were 12 wells in each group with 30 IEQ (islet equivalent, the diameter of an islet of 150-200 µm equates to 1.7 IEQ) islets/well. An additional two groups were co-cultured with naloxone alone at concentrations of 0.1 or 1.0 µg/mL.

Islet viability

The effect of fentanyl on cell viability was measured by MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] (Sigma, USA) assay to display a direct correlation with cell metabolism. After co-culturing with fentanyl for 48 h, 100 µL MTT solution was added to each well to a final concentration of 0.5 mg/mL per well and the plates were cultured for 4 h at 37°C. The supernatant was then removed by the addition of DMSO to each well to dissolve the deposition, and the optical density (OD) disparity was read at 490 nm using a spectrophotometer microplate reader (Labsystems, Finland). The inhibition of islet cells caused by the different concentrations of fentanyl was calculated using the formula: inhibition rate (%) = $(1 - \text{OD}_{\text{drug exposure}} / \text{OD}_{\text{control}}) \times 100$ ^[17,18].

Figure 1 The procedure of islets preparation. A: The islets were stained red by DTZ in digested pancreatic tissue; B: Pure islets isolated from digested pancreatic tissue; C: Pure islets stained by DTZ; D: The dye AO-PI stained living cells green and dead cells red in minimal background fluorescence ($\times 100$).

Glucose-stimulated insulin release assay in static culture

After incubating with the drugs for 48 h, the islets were washed with serum-free and glucose-free medium twice. The insulin release stimulation test was performed by first incubating the islets in low (2.8 mmol/L) and then high (16.7 mmol/L) concentrations of glucose in static culture medium for 1 h each. Supernatant from each well was collected and the insulin level was determined using a rat insulin radioimmunoassay kit (Linco Research, Inc, St Charles, MO, USA). The stimulation index (SI) was calculated by dividing the value of high glucose-stimulated secretion by the value of low glucose-stimulated secretion^[19,20].

Electron microscopy studies

After co-culturing with fentanyl for 48 h, the islets in the control group and those in group III were cut into thin sections and mounted on slides. Samples were stained with 2% uranyl acetate and lead citrate. The sections were viewed and photographed on a JEOL JEM-1230 transmission electron microscope (Jeol Ltd., Japan) at 80 kV.

Statistical analysis

Statistical and graphic analyses were performed with SPSS 13.0 software. Differences between groups were evaluated with one-way ANOVA or Kruskal-Wallis *H* tests, as appropriate, and the differences between two groups were analyzed with the LSD test or Mann-Whitney *U* test. $P < 0.05$ was considered statistically significant.

Figure 2 The cell viability after co-culture with fentanyl. The viability measured by MTT was 100% in the control group. The viability of islets exposed to 0.3, 3 and 30 ng/mL fentanyl was 94.3%, 91.3% and 96.9%, respectively. There was no difference between groups. The data represent means \pm SE.

RESULTS

Islet viability assessment

In this study, the rat islets were isolated from the rat pancreas with good quality. The viability was about 90% and the purification rate was about 95% (Figure 1). Fentanyl had no effect on cell viability (Figure 2).

Insulin release test

Fentanyl significantly inhibited the low and high concentration glucose-stimulated insulin release in a concentration-dependent manner ($P < 0.01$), and the insulin release was lowest at the concentration of 30 ng/mL ($P < 0.01$). After adding 0.1 $\mu\text{g/mL}$ naloxone, fentanyl still significantly inhibited glucose-stimulated insulin release ($P < 0.01$). However, after adding 1 $\mu\text{g/mL}$ naloxone,

Figure 3 Electron micrographs of β -cells in rat pancreatic islets of control group. N: Nucleus; SG: Secretory granule; V: Vesicle; E: Endoplasmic reticulum. The typical β -cells had an abundance of cytoplasmic granules and endoplasmic reticulum. The electron density of the granules increased when the granules were maturing in the vesicles. The mature secretory granules displayed a highly electron-dense core surrounded by a wide electron-lucent halo. The granules had a space between the core and the membrane. The vesicles showed a normal round outline (A, $\times 6000$). There were many nascent granules in the β -cells; subsequent maturation involved further condensation of the matrix constituents and a reduction in granule diameter (B, $\times 8000$).

Figure 4 Electron micrographs of rat pancreatic islet β -cells after exposure to 30 ng/mL fentanyl for 48 h. N: Nucleus; SG: Secretory granules; V: Vesicle; E: Endoplasmic reticulum. Chromatin margination and severe cytoplasmic vacuolization and degeneration were observed in the islets. Large and small vacuoles are present in the cytoplasm. The secretory granules and endoplasmic reticulum were much smaller than in the control group (A, $\times 10000$). In addition, endoplasmic reticulum and normal vesicles were almost never observed (B, $\times 12000$).

Table 1 The glucose-stimulated insulin release (μ IU) in response to fentanyl with different concentrations of naloxone (mean \pm SD, $n = 12$)

	Fentanyl alone		Fentanyl + 0.1 μ g/mL naloxone		Fentanyl + 1 μ g/mL naloxone	
	Low glucose	High glucose	Low glucose	High glucose	Low glucose	High glucose
Control (0 ng/mL)	62.33 \pm 9.67	125.5 \pm 22.04	62.33 \pm 9.67	125.5 \pm 22.04	62.33 \pm 9.67	125.5 \pm 22.04
I (0.3 ng/mL)	54.75 \pm 5.93 ^a	118.17 \pm 16.81	54.33 \pm 8.99	110.4 \pm 15.69	61.5 \pm 8.13	126.75 \pm 16.48
II (3 ng/mL)	47.75 \pm 8.47 ^b	96.17 \pm 14.17 ^b	45.92 \pm 7.63 ^b	88.25 \pm 11.22 ^d	59.75 \pm 8.42	118.33 \pm 21.09
III (30 ng/mL)	39.67 \pm 6.18 ^b	75.17 \pm 13.57 ^b	36.33 \pm 5.79 ^b	68.67 \pm 11.99 ^d	61.08 \pm 8.07	126.0 \pm 15.54
Naloxone			61.67 \pm 9.16	120.3 \pm 18.04	60.67 \pm 9.15	123.0 \pm 20.89

^a $P < 0.05$, ^b $P < 0.01$ vs control group (Mann-Whitney U test); ^d $P < 0.01$ vs control group (LSD test). Low- and high-glucose-stimulated insulin release in the 3 and 30 ng/mL fentanyl groups was significantly lower than in the control group ($P < 0.01$), and was lowest with 30 ng/mL fentanyl ($P < 0.01$). After adding 0.1 μ g/mL naloxone, insulin secretion in the 3 and 30 ng/mL fentanyl groups remained significantly lower than the control group ($P < 0.01$) and was lowest with 30 ng/mL fentanyl ($P < 0.01$).

the insulin release showed no difference from that of controls. Naloxone had no effect on insulin release (Table 1). There was no difference in SI between any of the groups (Table 2).

Evaluation of electron microscopy studies

Electron microscopy of β -cells in rat islets from the control group showed no pathological changes (Figure 3). After exposure to 30 ng/mL fentanyl for 48 h, the β -cells were in a poor morphological condition, and exhibited chromatin margination and severe cytoplasmic vacuolization and degeneration (Figure 4).

DISCUSSION

Many studies have focused on islet isolation, application and function in the diabetes field. Many factors affect the isolation of rat pancreatic islets; therefore, the yields and function of the isolated islets vary considerably,

Table 2 Stimulation index at different concentrations of fentanyl and naloxone (mean \pm SD, $n = 12$)

	Fentanyl	Fentanyl + 0.1 μ g/mL naloxone	Fentanyl + 1 μ g/mL naloxone
Control (0 ng/mL)	2.01 \pm 0.21	2.02 \pm 0.21	2.02 \pm 0.21
I (0.3 ng/mL)	2.17 \pm 0.36	2.07 \pm 0.35	2.08 \pm 0.26
II (3 ng/mL)	2.04 \pm 0.26	1.95 \pm 0.23	1.99 \pm 0.34
III (30 ng/mL)	1.89 \pm 0.16	1.89 \pm 0.19	2.08 \pm 0.27
Naloxone		1.97 \pm 0.29	2.04 \pm 0.28

despite the introduction of novel or improved methods. Large variations in yields and function have been found, even if the same sources of collagenase are used^[21]. In our study, the islets were isolated from the rat pancreas with good quality (viability rate was about 90% and purification rate was about 95%). Generally, we obtained 300-400 islets from each rat. This indicates that our method is efficient and provides high yields of islets.

The high yields and favorable function of the isolated islets were attributed to the pancreatic tissue being infused and fully digested. Low yields of islets typically result from insufficient digestion; therefore, we suggest that the digestion time and collagenase concentration should be optimized precisely for islet isolation.

Over the last two decades, despite the development of more potent, safer, faster onset, and shorter- and longer-lasting opioids, fentanyl has remained the mainstay of anesthesiologists and Certified Registered Nurse Anesthetists in the perioperative period, and for physicians involved in pain management. Because diabetic patients undergo higher risk procedures during the period of operation and anesthesia, anesthesiologists and surgeons should protect islet function and try to minimize any harmful medical effects on islets during the procedure. Although some studies have suggested that some opiates inhibit insulin secretion, it was unknown whether fentanyl has a similar effect^[12].

Before our current study, a number of studies have demonstrated direct effects of endogenous and selective opioid receptor agonists on insulin release^[10,11]. Some opioid receptor agonists, such as methadone, were found to improve multiple-low-dose streptozotocin-induced type 1 diabetes in mice, which suggests that the opioid receptor agonists improve insulin release *in vivo*^[22]. However, other studies have suggested that some opiates inhibit insulin secretion^[12]. β -endorphin seems to inhibit glucose-induced insulin secretion but, conversely, an excitatory effect has been reported in many studies^[11,23]. These observations have yielded conflicting results with marked variations between species. Therefore, it could not be hypothesized whether fentanyl inhibits insulin release^[13].

Our results clearly demonstrate that fentanyl inhibited glucose-stimulated insulin release from islets *in vitro*. Electron microscopy studies showed that the cells in the control group exhibited good viability but, after the cells were exposed to 30 ng/mL fentanyl for 48 h, chromatin margination and severe cytoplasmic vacuolization were observed, indicating that the cells were in a poor condition. Thus, our test suggests that the islets were injured by exposure to fentanyl at the concentrations tested.

We know that glucose uptake by tissues is as likely to play a decisive role as does the release of insulin. In the presence of insulin, opioid receptors in the pancreas have been reported to regulate plasma glucose and the activation of mu-opioid receptors, which could increase the utilization of glucose in peripheral tissue to lower the plasma glucose^[24,25]. *In vivo*, a potent opiate was shown to lower glucose levels by enhancing peripheral glucose utilization without improving insulin release^[26]. Also, serum glucose levels are responsible for the altered potency of mu-opioid agonists only during the early stages of diabetes^[27]. Thus, the plasma glucose-lowering response induced by mu-opioid receptor activation *in vivo* is not attributed to improved insulin release.

Endogenous opioid receptors are expressed in endocrine pancreas and studies have indicated that endogenous opioid peptides and selective opiate receptor agonists suppress insulin release^[28]. Thus, the effect of fentanyl on insulin release might be related to opiate receptor activation. Activation of the opioid receptor initiates a cascade of events that result in an array of biological effects, which inhibit insulin release^[29,30]. It seems that fentanyl-induced mu-opioid receptor activation leads to the inhibition of glucose-stimulated insulin release. This inhibitory effect could be reversed by high doses of naloxone, an opioid receptor antagonist. Therefore, the activation of opioid receptors induced by fentanyl appears to be a route by which insulin release is inhibited.

There are two processes that take place during insulin secretion: hormone biosynthesis and release. Many drugs affect insulin secretion, although the exact mechanism varies. Many drugs have different effects on either of the two processes. For example, long-chain fatty acids powerfully increase insulin release and inhibit glucose-stimulated pro-insulin biosynthesis^[31,32]. In the present study, it is unknown which of these processes are affected by fentanyl. Because fentanyl may be involved in both insulin release and biosynthesis^[33,34], the role of opioid receptor activation on insulin secretion requires further investigation.

There are certain limitations in our experiment. The pharmacology of the mu receptor signaling pathway involves G-protein coupling which, when activated, closes Ca^{2+} channels and opens K^{+} channels, resulting in a decline in intracellular Ca^{2+} levels and hyperpolarization; all of which are short-term effects. The magnitude of the insulin response to glucose is related not only to the absolute level of glucose but also to the rate of change in the glucose level. There are two phases of insulin release. An acute increase in glucose level elicits a rapid and transient secretion of insulin, called the first or acute-phase response, which subsides within 10 min. The second phase response begins when glucose levels increase slowly and progressively for up to 4 h^[35]. As in many other studies, we measured the insulin release over 60 min in static culture after incubating in low (2.8 mmol/L) and then high (16.7 mmol/L) glucose concentrations^[19,20,36]. Therefore, the effect of fentanyl on glucose-stimulated insulin release in rat islets in dynamic culture also needs to be investigated. In addition, perfusion of islets with glucose provides a dynamic profile of the characteristics of glucose-stimulated insulin release, which could be used to fully determine the effect of fentanyl on the inhibition of insulin release, and the ability of the cells to down-regulate insulin secretion after a fentanyl challenge are a focus of our future studies.

In conclusion, fentanyl inhibited glucose-stimulated insulin release from islets, and the inhibition could be reversed by naloxone. Because islet function varies between animal species, translation of our results to the

clinical setting will necessitate further studies. However, our results indicate the potential for fentanyl to inhibit insulin release; thus, it is necessary to test the plasma insulin level and the islet function regularly in patients treated with fentanyl, particularly patients treated with fentanyl for a long term and/or with high doses of fentanyl. Further studies are needed to explore the exact mechanism by which fentanyl affects islet insulin release.

COMMENTS

Background

Fentanyl citrate is a potent synthetic narcotic analgesic extensively used for anesthesia and analgesia in the operating room and intensive care unit. In recent years, anesthesiologists and surgeons have had to manage an increasing number of diabetic patients. However, the effects of fentanyl on the glucose-stimulated insulin secretion capacity of rat β -cells *in vitro* has remained unclear. Although some studies have suggested that some opiates inhibit insulin secretion, it could not be concluded whether fentanyl has a similar effect, because the earlier studies yielded conflicting results, with marked species variation. Therefore, this study investigated the effects of fentanyl on rat islets in static culture.

Research frontiers

This study is a novel field in diabetes investigation that has been largely overlooked. The research team used freshly isolated islets to study the effects of the opiate fentanyl on insulin release, which is an important subject for anesthesiologists and surgeons. In this study, the results demonstrated that fentanyl inhibited glucose-stimulated insulin release in rat islets and higher concentrations of fentanyl significantly damaged rat islets.

Innovations and breakthroughs

The study of effects of anesthetic and analgesic drugs on pancreatic islets is a novel field in diabetes management. This is the first study to report that fentanyl inhibits the release of insulin from rat islets. These findings would be helpful for clinicians who administer fentanyl.

Applications

The results may stimulate further investigation of diabetes management in the anesthesia field. These findings suggest that it is important to regularly test the plasma insulin level and islet function in patients treated with fentanyl for the long term and/or at high doses, and could help to develop novel approaches to help people with diabetes to maintain whole-body glucose homeostasis during the perioperative period.

Peer review

The author has used rat islets as a model to study the effect of the mu-opioid agonist fentanyl on glucose-stimulated insulin release. Generally, this is a topic that has been overlooked in the past, thus this study is important and unique. Also, the islet preparation and EM technology were good.

Abstract

AIM: To identify prognostic factors of patients with hepatocellular carcinoma (HCC), who were treated by orthotopic liver transplantation (OLT).

METHODS: From January 2000 to October 2006, 165 patients with HCC underwent OLT. Various clinicopathological risk factors for actuarial and recurrence-free survival were identified using the Kaplan-Meier method with the log-rank test. The Cox proportional hazards model was used to identify independently predictive factors for actuarial and recurrence-free survival, which were used to propose new selection criteria. We compared the outcome of the subgroup patients meeting different criteria. Survival analysis was performed using the Kaplan-Meier method with the log-rank test.

RESULTS: The median follow-up was 13.0 mo (2.8-69.5 mo). Overall, 1-, 2-, 3- and 5-year actuarial survival was 73.3%, 45.6%, 35.4% and 32.1%, respectively. One-, 2-, 3- and 5-year overall recurrence-free survival was 67.0%, 44.3%, 34.5% and 34.5%, respectively. In univariate analysis, number of tumors, total tumor size, lobar distribution, differentiation, macrovascular invasion, microvascular invasion, capsulation

of the tumor, and lymph node metastasis were found to be associated significantly with actuarial and tumor-free survival. By means of using the multivariate Cox proportional hazards model, total tumor size and macrovascular invasion were found to be independent predictors of actuarial and tumor-free survival. When the selection criteria were expanded into the proposed criteria, there was no significant difference in 1-, 2-, 3- and 5-year actuarial and tumor-free survival of the 49 patients who met the proposed criteria (97.6%, 82.8%, 82.8% and 82.8%, and 90.7%, 82.8%, 68.8% and 68.8%, respectively) compared with that of patients who met the Milan or University of California, San Francisco (UCSF) criteria.

CONCLUSION: Macrovascular invasion and total tumor diameter are the strongest prognostic factors. The proposed criteria do not adversely affect the outcome of liver transplantation for HCC, compared with the Milan or UCSF criteria.

INTRODUCTION

In the 1980s, outcomes for orthotopic liver transplantation (OLT) for hepatocellular carcinoma (HCC) were discouraging. There were high recurrence rates and a low patient survival of 30% at 3 years^[1]. After the Milan criteria (single tumor up to 5 cm or up to three tumors up to 3 cm) were introduced by Mazzaferro *et al*^[2] in the

early 1990s, recurrence rate fell to 8%, and tumor-free patient survival at 4 years was 83%. With worldwide adoption of these criteria, 5-year survival rates rose to 60%-80%^[3-5].

Recently, there have been numerous proposals for expanding the Milan criteria. The University of California, San Francisco (UCSF) proposed an expansion of transplantation criteria^[6]. The expanded criteria includes having a single tumor < 6.5 cm in diameter, or having no more than three tumors, the largest of which is < 4.5 cm in diameter, and with a total tumor diameter of < 8 cm. Using these criteria, 1- and 5-year recurrence-free survival rates were 90% and 75.2%, respectively. Marsh *et al*^[7] have studied 407 cases who underwent OLT at the University of Pittsburgh between 1981 and 2002, and found that patients who exceeded the Milan criteria had a 49.7% recurrence-free survival rate at 5 years. Todo *et al*^[8] have reported that patients with unresectable HCC who underwent living donor liver transplantation under the expanded indication criteria had 3-year survival and disease-free survival rates of 60.4% and 52.6%, respectively. In Kyoto^[9], the only OLT exclusion criteria are for patients with extrahepatic metastasis or macroscopic vascular invasion, and there are no restrictions based upon on the number or size of tumors. There was no difference in the 4-year survival rate in the Kyoto study between patients with HCC who fit (66%) or do not fit (60%) the Milan criteria. Therefore, it has been suggested that there are differences in OLT criteria between the East and West, which may be correlated with race or combinations of underlying hepatic diseases.

Worldwide, 55% of HCC cases and deaths occur in China^[10]. Over 90% of HCC patients in China are also infected with hepatitis B virus (HBV). These rates are different from those in Europe, America, and even Japan. To explore these issues, we evaluated the OLT outcomes for HCC patients at the Liver Transplantation Center of the West China Hospital, Chengdu, China. We aimed to analyze the effect of HCC prognostic factors on actuarial and recurrence-free survival after OLT, and to reevaluate the prediction criteria that are the basis for OLT selection.

MATERIALS AND METHODS

Patients

Between January 2000 and October 2006, a total of 424 OLTs were performed at the Liver Transplantation Center of the West China Hospital. Among these, 165 (38.9%) patients were diagnosed with HCC, and 148 underwent follow-up. Follow-up excluded 17 patients who died of complications during the 3-mo period after the operation. Of the 148 HCC patients, 146 were diagnosed with HCC before liver transplantation. In two patients, HCC was found incidentally by pathological examination of the explanted liver after transplantation. Preoperative clinical data of the 148 HCC patients are

shown in Table 1. Liver transplantation was considered for patients with HCC if the tumor was determined to be unresectable because of its location, or because of concomitant liver disease and HCC without extrahepatic spread.

Diagnosis

Preoperative diagnosis of HCC was made using artery high-flow perfusion and imaging examinations, which showed intrahepatic tumors. Examinations included at least two of the following three methods: ultrasound, contrast-enhanced computed tomography (CT) and magnetic resonance imaging (MRI). Macroscopic vascular invasion was observed using Doppler ultrasonography and contrast-enhanced CT before operation, and was validated through pathological examination of the impaired liver after operation. Diagnosis of HCC was confirmed by fine-needle aspiration cytology or biopsy of all known tumors. Pretransplant studies in patients with HCC included abdominal, thoracic, and head CT scans and bone scintigraphy to rule out extrahepatic tumor spread.

Follow-up

The patients were followed for tumor recurrence with CT scans and α -fetoprotein level (AFP) every 6 mo for 5 years. Annually thereafter, or as the clinical situation dictated, suspicious lesions in the liver or lung were biopsied. Bone lesions were not biopsied routinely but were observed for bone pain and progression of growth. A rising AFP level alone was not taken to be confirmatory

of tumor recurrence, but the date of recurrence was taken as the time that the AFP level began to rise once tumor recurrence had been confirmed.

Immunosuppression and antiviral protocols

Immunosuppression consisted of cyclosporine or tacrolimus and corticosteroids, with or without azathioprine and mycophenolate. In cases in which acute rejection was suspected, a liver biopsy was performed, and steroid pulse therapy was conducted after the rejection diagnosis was made. The steroids were withdrawn 3-6 mo after surgery to minimize the risk of tumor recurrence^[8,11]. Lamivudine was administered to hepatitis-B-surface-antigen-positive patients before and after surgery, and hepatitis B immune globulin was administered to HBV-DNA-positive patients before, during and after surgery.

Statistical analysis

Cumulative survival time was calculated from the date of transplantation to the date of death, from the date of transplantation to the date of final follow-up, or from the date of transplantation to the date of loss to follow-up. The latter two conditions were tabulated from censored data. Tumor-free survival (TFS) time was calculated from the date of transplantation to the date when tumor recurrence and metastases were discovered, from the date of transplantation to the date of final follow-up, or from the date of transplantation to the date of loss to follow-up. The latter two conditions were also tabulated from censored data. Statistical analysis software (SPSS 13.0) was used for data processing and analysis. The Kaplan-Meier method was used to calculate the cumulative survival rate (CSR), TFS rate, and to present the corresponding survival curves in graphical form. The log-rank test was used to compare the differences between groups. The univariate Cox proportional hazard regression model was used to analyze each factor that might have influenced liver transplantation prognosis in HCC patients, and to identify factors with statistical significance. The multivariate Cox proportional hazard regression model was used to analyze and confirm the independent prognostic factors for OLT in HCC patients. Statistical significance was defined as $P < 0.05$.

RESULTS

Pathological characteristics of explanted liver

The pathological data on HCC tumors and potential indicators are shown in Table 2. In general, OLT was offered when liver function was impaired, or when the HCC become unresectable. HCC was diagnosed before transplantation in 148 patients, and in two, we identified an incidental tumor during pathological examination of the explanted liver.

Survival

The median follow-up time for the 148 patients was 13.0 mo (2.8-69.5 mo). The follow-up time of 126 of these patients was ≥ 6 mo. Eighty-one patients survived,

with a median follow-up of 15.5 mo (2.8-69.5 mo). Sixty-two patients died, with a median follow-up of 11.0 mo (3.0-38.0 mo). Five patients were lost to follow-up, with a median follow-up of 16.0 mo (14.0-23.0 mo).

The mean total cumulative survival time of the entire group was 33.6 mo (95% CI: 27.5-39.6 mo). The CSR was 73.3% at 12 mo, 45.6% at 24 mo, 35.4% at 36 mo, and 32.1% at 60 mo. The average TFS time of the entire group was 32.8 mo (95% CI: 26.4-39.1 mo). The TFS rate was 67.0% at 12 mo, 44.3% at 24 mo, 34.5% at 36 mo, and 34.5% at 60 mo.

Predictors of actuarial survival

Based on the results of the univariate Cox regression model analysis, the following 10 variables significantly affected CSR: (1) age; (2) largest tumor size; (3) total tumor size; (4) tumor number; (5) bilobar disease; (6) macrovascular invasion; (7) microvascular invasion; (8) lymph nodes positive; (9) differentiation; and (10) capsule invasion. The above 10 variables were analyzed using the multivariate Cox proportional hazard regression model and the stepwise regression method, to identify the independent factors that influenced total survival rate. The results showed that total tumor size and macrovascular invasion were the two risk factors that affected total survival rate.

Predictors of recurrence-free survival

According to the results of the univariate Cox regression model analysis (Table 3), the following eight variables significantly affected tumor-free survival rate: (1) total tumor size; (2) tumor number; (3) bilobar tumor; (4) tumor differentiation; (5) macrovascular invasion; (6) microvascular invasion; (7) tumor capsular invasion;

Figure 1 Proposed prognostic criteria. A: CSR for proposed criteria. Log-Rank test: $P < 0.001$; B: TFS rate for proposed criteria. Log-Rank test: $P < 0.001$; C: Comparison of CSR for different criteria; D: Comparison of TFS rate for different criteria.

Table 3 Univariate analysis of all variables that significantly affected tumor-free survival

Predictors	Relative risk	95% CI	P
Total tumor size (≤ 9 cm vs > 9 cm)	2.291	1.654-3.173	0.000
Tumor number (≤ 4 vs > 4)	1.127	1.052-1.207	0.003
Bilobar disease	2.206	1.327-3.666	0.002
Macrovascular invasion	2.951	2.160-4.032	0.000
Microvascular invasion	4.479	2.126-9.436	0.000
Positive lymph nodes	12.472	4.457-34.898	0.000
Differentiation	1.641	1.014-2.654	0.044
Capsule invasion	1.462	1.092-1.957	0.011

and (8) lymph nodes positive. The above eight variables were analyzed using the multivariate Cox proportional hazard regression model and the stepwise regression method, to identify independent factors that influenced the TFS rate. The results showed that total tumor size, macrovascular invasion and lymph node status were the independent predictors of TFS.

Proposed criteria

Macrovascular invasion and total tumor size were prognostic factors that independently influenced CSR and TFS. Our proposed criteria for OLT selection included patients with total tumor size ≤ 9 cm and who were without macrovascular invasion or extrahepatic metastases, regardless of the number of tumor lesions.

For the cases which conformed to the proposed criteria ($n = 49$), the total survival rate at 1, 2, 3 and 5 years was 97.6%, 82.8%, 82.8% and 82.8%, respectively

(Figure 1A). The average survival time was 53.7 mo (43.8-63.6 mo). Among these 49 patients, 18 (16.3%) died by the end of follow-up, and seven (9.5%) died of recurrence. There were 41 cases of TFS (83.7%). The average TFS rate at 1, 2, 3 and 5 years was 90.7%, 82.8%, 68.8% and 68.8%, respectively (Figure 1B). The average TFS time was 60.0 mo (52.3-67.7 mo).

Comparisons of the CSR and the TFS at 1, 2, 3 and 5 years for different patient subgroups are shown in Figure 1C and D. CSR and TFS were similar in patients who met the proposed criteria and Milan criteria ($P = 0.321$, $P = 0.331$), and UCSF criteria ($P = 0.229$, $P = 0.257$). However, the patient number was increased more in the proposed criteria ($n = 49$), than the Milan ($n = 24$) or UCSF ($n = 33$) criteria. What's more CSR was similar in patients who met the proposed criteria and the Pittsburgh criteria ($P = 0.158$). Although the patient number was greater in the Pittsburgh ($n = 90$) than the proposed criteria, the TFS for the Pittsburgh criteria was lower than that for the proposed criteria ($P = 0.027$).

DISCUSSION

Numerous studies have shown that tumor size is an important prognostic factor for liver transplantation in patients with HCC^[8,12,13]. Bismuth *et al*^[12] have found that HCC patients with two or fewer tumors, each with a diameter ≤ 3 cm, had an 83% 3-year CSR and TFS following liver transplantation and hepatectomy. Roayaie *et al*^[14] have reported that HCC patients with tumor diameters > 7 cm (12 cases) and 5-7 cm (32 cases) had 5-year tumor-free rates of 34% and 55%, respectively,

following transplantation. Tumor diameter > 7 cm and the presence of vascular invasion were correlated with HCC recurrence. In this study, total tumor size was shown to influence prognosis in the univariate Cox regression model analysis, and was shown to be an independent prognostic factor in the multivariate analysis. Compared to largest tumor size, tumor number can better predict the OLT prognosis in HCC patients. Univariate Cox regression analysis showed that the 2-year CSR and TFS rates were 73.5% and 75.6%, respectively. These rates were significantly different compared to those in cases where total tumor size was > 9 cm. Tumor number and size are believed to have a combined effect on HCC recurrence probability, and this effect is taken into consideration during selection of HCC OLT recipients in many institutions^[2,6]. The total tumor size in the present study also reflects a combined effect of tumor number and size.

Many other studies have shown that macrovascular invasion is a primary factor that influences prognosis after OLT in HCC patients^[12,13,15-18]. Shetty *et al*^[18] have concluded that macrovascular invasion and AFP levels were prognostic factors that influenced CSR and TFS. Moreover, microvascular invasion had no significant influence on prognosis. Bismuth *et al*^[12] have reported that 10 of 60 (16.7%) HCC patients who underwent OLT had tumor thrombus in the main trunk of the portal vein, and had a 3-year survival rate of only 20%. Thus, they proposed that tumor thrombus in the main trunk of the portal vein was a major risk factor for OLT. Other studies have proposed that when HCC is accompanied by vascular invasion, tumor cells are more likely to be present in the circulation, rather than being restricted to the liver^[19,20]. While circulating tumor cells may not develop into distant metastases, immunosuppressive treatment after OLT may increase the possibility of tumor recurrence. Currently, most transplantation centers advocate exclusion of HCC patients with tumor thrombus in the main trunk or right and left branches of the portal vein, for these reasons. In the present study, multivariate Cox regression analysis showed that macrovascular invasion was an independent risk factor that affected CSR and TFS. In the 52 cases with macrovascular invasion, the recurrence rate was as high as 71.2% during follow-up. The 1-year CSR was 53.5%, and TFS was 14.4%. The 2-year CSR and TFS were 34.2% and 12.9%, respectively. Therefore, OLT patients with macrovascular invasion had poor long-term prognosis.

Univariate analysis identified hepatic lobar distribution, differentiation, and capsule invasion as prognostic factors that influenced CSR and TFS in the present study. However, multivariate analysis showed that only total tumor size and macrovascular invasion were independent prognostic factors that influenced CSR and TFS. Therefore, hepatic lobar distribution, differentiation, and capsule invasion may have a relationship with total tumor size or macrovascular invasion. We believe that these three indicators may reflect malignant tumor

invasion to a certain degree, since HCC patients who have bilobar distribution, low differentiation or capsular (or non-capsular) tumor invasion have a relatively high incidence of tumor recurrence and metastasis.

Our data showed that age was related significantly to CSR by univariate Cox regression analysis, with a relative risk of 0.963 (95% CI: 0.936-0.991). The younger the onset of HCC, the greater the possibility of tumor recurrence was after liver transplantation. An early age of HCC onset may lead to greater malignancy and faster disease development. An understanding of this mechanism requires further exploration.

Positive lymph nodes and distant metastasis are considered to be absolute contraindications for liver transplantation in HCC patients^[21]. Marsh *et al*^[22] have found that the average TFS time for 231 HCC liver transplantation cases with negative local lymph nodes was 140.6 ± 6.8 mo. The TFS time was significantly less, 5.3 ± 1.0 mo, for six cases with positive local lymph nodes. In the present study, five HCC cases (3.4%) had positive lymph nodes in the porta hepatis. Four of these patients died, and all five had tumor recurrence. The average survival time of these five patients was only 7.0 mo, and the average TFS time was 4.2 mo, in accordance with previous studies. Detection of lymph nodes can be observed in HCC patients with hepatitis, who have enlarged, inflammatory lymph nodes. Therefore, careful observations should be conducted during surgery, and all enlarged lymph nodes should be sent to the pathology department for intraoperative frozen-section examination. Liver transplantation should not be carried out in patients with confirmed positive lymph nodes.

China has the greatest incidence of liver cancer worldwide^[10]. Each year, over half of liver cancer detections and deaths occur in China. Liver cancer (mainly HCC) has been the primary indication for liver transplantation. It is worth noting that the hepatic disease background and epidemiology of HCC is unique to China and is considerably different from that in Europe and America. Therefore, prognostic factors for liver transplantation in Chinese HCC patients are likely different from those in other countries. It is therefore necessary to explore the novel criteria for HCC liver transplantation in China.

Here, we studied independent prognostic factors, and developed proposed criteria for liver transplantation in HCC patients. The proposed criteria are as follows: total tumor size ≤ 9 cm, and there should be no macrovascular invasion, positive lymph nodes or extrahepatic metastases, regardless of tumor number and distribution. According to the proposed criteria, we screened HCC patients with liver transplantation. The postoperative 2- and 5-year CSR was 82.8% and 68.8%, respectively, using our proposed criteria. There was no significant difference between the proposed and the Milan criteria (both 88.5%) ($P = 0.321$). Using the proposed criteria, the 2- and 5-year TFS rates were both 82.8%.

Compared to the Milan criteria (both rates 94.1%),

there was no significant difference ($P = 0.331$). We compared the HCC cases that fitted the proposed criteria (49 cases) and those that exceeded the criteria (99 cases) (Figure 1A and B). The 2- and 5-year CSR of the cases that fitted the proposed criteria were 82.8% and 68.8%, respectively, while the CSR for cases exceeding the criteria were 27.9% and 14.0%, respectively ($P < 0.001$). The 1- and 2-year TFS of the cases that fitted the proposed criteria were 97.6% and 82.8%, respectively, while the TFS for cases exceeding the criteria were 52.5% and 25.7%, respectively ($P < 0.001$). Use of our proposed criteria included 16.9% more cases than the Milan criteria and 10.8% more cases than the UCSF criteria. In this study, we also analyzed cases that fitted the proposed criteria, but exceeded the Milan criteria (25 cases). Our results showed that the 1-, 2- and 5-year CSRs were 85.2%, 77.4% and 48.4%, respectively, and the corresponding TFS rates were 95.0%, 70.4% and 70.4%, respectively. It is agreed generally in the field of transplantation that HCC patients whose 5-year, post-transplantation, survival rate is $\geq 50\%$ qualify as transplant candidates^[23,24]. The present study showed that the 5-year CSR and TFS of the HCC patients were 68.8% and 82.8%, respectively. The 5-year CSR and TFS of the HCC patients that fitted our proposed criteria but exceeded the Milan criteria (25 cases) were 48.4% and 70.4%, respectively. The CSR and TFS rate curves of these patients were not significantly different compared to those of patients who fitted the Milan criteria ($P = 0.105$ and $P = 0.115$, respectively).

In summary, we suggest that the proposed criteria function to predict the prognosis of liver transplantation in patients with HCC. The proposed criteria allow us to increase the range of indicators for HCC patients in need of liver transplantation, and decrease the exclusion rate, and they allow more patients to receive therapeutic liver transplantation in China.

COMMENTS

Background

In the 1980s, the outcome of orthotopic liver transplantation (OLT) for hepatocellular carcinoma (HCC) was discouraging. After the Milan criteria (single tumor up to 5 cm, or up to three tumors up to 3 cm) were introduced by Mazzaferro *et al* in the early 1990s, recurrence rate fell to 8%, and tumor-free patient survival at 4 years was 83%. The Milan criteria have long been considered to be the classical criteria for selection of patients with HCC for liver transplantation. Recently, there have been numerous proposals for expanding the Milan criteria, such as the University of California, San Francisco (UCSF) criteria.

Research frontiers

The Milan criteria have long been considered to be the classical criteria for selection of patients with HCC for liver transplantation. China has the greatest incidence of liver cancer worldwide. Each year, over half of liver cancer detections and deaths occur in China. A substantial proportion of adult Living donor liver transplantation patients not fulfilling the Milan or UCSF criteria have been found to survive longer than expected after transplantation. Therefore, it seems reasonable to attempt further reduction of unnecessary dropouts arising from the strict application of narrow selection criteria.

Innovations and breakthroughs

In the present study, the authors identified various clinicopathological risk factors for actuarial and recurrence-free survival of 165 patients with HCC who

underwent OLT using the Kaplan-Meier method with the log-rank test. They found that macrovascular invasion and total tumor diameter, as assessed on explanted liver, were the strongest prognostic factors.

Peer review

The authors reviewed their single-center experience with 148 OLTs for HCC and proposed a new prognostic score.

Overexpression of polo-like kinase1 predicts a poor prognosis in hepatocellular carcinoma patients. *World J Gastroenterol* 2009; 15(33): 4177-4182 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4177.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4177>

Abstract

AIM: To elucidate the role of overexpressed polo-like kinase1 (PLK1) in hepatocellular carcinoma (HCC).

METHODS: We prospectively collected clinicopathological, immunohistochemical and semi-quantitative reverse transcription-polymerase chain reaction (RT-PCR) data from 135 HCC patients undergoing successful hepatectomy. The correlations between PLK1 mRNA expression and clinicopathologic variables were analyzed by Mann-Whitney *U* test. Prognostic factors were identified by univariate and multivariate analyses.

RESULTS: Immunohistochemical results showed overexpression of PLK1 was mainly found in tumor tissues compared with tumor-free tissue. A similar mRNA result was obtained by semi-quantitative RT-PCR. A total of 111 samples were positive for PLK1 mRNA expression. The positive expression was correlated with venous invasion, tumor nodules and Edmondson grade. Furthermore, 1, 3, 5-year survival rates in the positive expression group were significantly lower than the negative control group. Multivariate analysis showed that positive PLK1 expression was an independent risk factor for HCC.

CONCLUSION: PLK1 could be a potential biomarker for diagnosis and therapy for HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the deadliest of all cancers, ranking third among all cancer-related mortalities^[1]. Surgical resection plays a major role in the treatment of HCC. However, less than 30% of HCC patients are surgical candidates^[2] due to limiting factors such as severe impairment of hepatic functional reserve, bilobar tumor distribution and extra-hepatic metastasis. No single-agent or combination chemotherapy regimen has been found to be particularly effective in HCC^[3]. Locoregional treatment is not the first choice for HCC^[4] and is reserved for non-surgical candidates.

The study of carcinogenesis mechanisms may provide new treatment regimens for cancer. Many key carcinogenetic pathways, such as increased angiogenesis, aberrant signal transduction and dysregulated cell cycle control, appear to be involved in tumor development^[5]. As a cell cycle control kinase, polo-like kinase1 (PLK1) and its overexpression are highly associated with many human cancers, including bladder^[6], breast^[7-10], colorectal^[11,12], endometrial^[13,14], esophageal^[15-17], gastric^[18-21], glioma^[22], hepatoblastoma^[23], hepatocellular carcinoma^[24], head and neck^[25], leukemia and lymphoma^[26,27], melanoma^[28,29], non-small-cell lung^[30], ovarian^[31], papillary^[32], pancreatic^[33,34], prostate^[35] and thyroid cancer^[36]. However, up to now, as far as we know, there are few studies available on the overexpression of PLK in HCC. The objective of our study was to understand the relevance of PLK1 expression in HCC.

MATERIALS AND METHODS

Patients

There were 135 successful hepatectomy procedures for HCC performed from January 2003 to September 2008 in our department. None of these patients were given preoperative transarterial chemoembolization as a neoadjuvant treatment, but they all regularly received postoperative chemoembolization by hepatic artery infusion. All specimens from 135 cases were collected, immediately frozen in liquid nitrogen and subsequently stored at -70°C for reverse transcription-polymerase chain reaction (RT-PCR). Five cases of liver regenerating nodule samples were obtained from patients with liver cirrhosis as controls. The clinicopathologic variables were recorded in detail including gender, age, liver cirrhosis, hepatitis B surface antigen, α -fetoprotein (AFP), venous invasion, Edmondson stage, tumor size (cm) and number of tumor nodules. Two expert pathologists who were blinded to the other results of the study, scored the HCC samples. The study protocol was approved by the Ethics Committee of Central South University, and written informed consent was provided by all participants prior to initiation of the study.

Follow-up

All patients were involved in our follow-up system, and were reviewed at 1-2 mo intervals. Routine post-operative medical examinations were carried out every 2 mo, including liver function, serum AFP level, B-ultrasound and CT. Follow-up ranged from 3-62 mo and ended on December 31, 2008. The median follow-up time was 18 mo.

Semi-quantitative RT-PCR

Total RNA was extracted from tumor and tumor-free tissues using the TRIzol reagent (Gibco BRL) according to the manufacturer's instructions (Gibco BRL). cDNA synthesis performed using the reverse transcription system. The primers were as follows: PLK1, 5'-GATTCCACGGCTTTTTCGAG-3', 5'-CCCACACAGGGTCTTCTTCC-3' (product size, 296 bp); β -actin: 5'-CGCGAGAA GATGACCCAGAT-3', 5'-GCACTGTGTTGGCGTACAGG-3' (product size, 550 bp). The following PCR cycling parameters were employed: at 95°C for 5 min, followed by 35 cycles at 95°C for 45 s, 56°C for 1 min, at 72°C for 1 min and then 72°C for 7 min. The PCR products were resolved on a 1.5% agarose gel. All experiments were carried out in triplicate.

Immunohistochemical tissue slides

Immunohistochemical reaction against PLK1 (BD Transduction, a monoclonal mouse antibody) was performed in 5 μm paraffin sections. Negative controls were processed without primary antibody. For antigen retrieval, deparaffinized slides were placed in 0.01 mol/L sodium citrate buffer, pH 6.0 and boiled for 5 min in a pressure cooker. Then, slides were allowed to cool down for an additional 5 min in the same buffer. After

several rinses in TBS and pre-treatment with blocking reagent (Dako, Glostrup, Denmark) for 5 min, slides were incubated with primary antibody diluted 1:500 (PLK1) and 1:50 (Ki-67) in antibody diluent solution (Zymed, San Francisco, CA, USA) for 20 min at room temperature and then at 4°C overnight. After slides were washed in TBS, The slides were visualized using Aquatex (Merck, Gernsheim, Germany).

Statistical analysis

Quantitative values were presented as mean \pm SD or median (range). Independent Student's *t*-test was used to compare PLK1 mRNA expression in HCC and non-cancer samples. The Mann-Whitney *U* test was used for correlations between PLK1 mRNA expression and clinicopathologic variables. The Kaplan-Meier method was employed to calculate survival and the log-rank test to compare survival among two patient groups. Cox regression was adopted for multivariate analysis of prognostic predictors. The statistical software package SPSS16.0 (SPSS Inc, Chicago, IL) was applied for all analyses. A statistically significant *P* value was defined as < 0.05 .

RESULTS

Immunohistochemical analysis of PLK1 protein expression

The pattern of PLK1 protein expression was examined by means of immunohistochemical analysis. Overexpression was detected in tumor tissues, especially in cytoplasm, compared with the tumor-free tissue. A more varied morphology of the cells was reflected by high expression in the cytoplasm. (Figure 1A and B). Tumor tissues had sharp margins under the microscope (Figure 1B and D). No or sporadic expression was observed in adjacent normal tissue or regenerating nodules (Figure 1C and D).

Expression of PLK1 mRNA in HCC

To compare the expression levels of PLK1 mRNA between neoplasm, adjacent normal tissue in the experimental group and regenerating nodules in the control group, total RNA was extracted for RT-PCR. The results indicate that HCC tissues expressed a significantly higher level of PLK1 mRNA than adjacent normal tissue and regenerating nodule (0.53 ± 0.05 vs 0.23 ± 0.04 and 0.20 ± 0.02 , respectively, $P < 0.01$). When regenerating nodules were compared with adjacent normal tissue, the mRNA levels of regenerating nodules were slightly elevated, but the difference was not statistically significant (0.23 ± 0.04 vs 0.20 ± 0.02 , $P > 0.05$) (Figure 2).

There were 111 samples (111/135, 82.22%) in which the OD values of PLK1 mRNA in HCC tissues were higher than those of adjacent normal tissue ($P < 0.05$). These were named the PLK1 positive group. The remaining 24 samples (24/135, 17.78%) were named the PLK1 negative group. There were statistically significant differences in PLK1 mRNA levels between the positive and negative groups ($P = 0.003$).

Figure 1 Expression of PLK1 in HCC tissue specimens. A: Expression of PLK1 in HCC tissue, especially in cytoplasm; B, D: Tumor tissue margins seen under the microscope (black arrows); C: Liver regenerating nodule sample; D: Adjacent normal tissue examined for PLK1 expression. Original magnifications, A and B $\times 200$; C and D $\times 100$.

Figure 2 Expression of PLK mRNA in HCC, adjacent normal and regenerating nodule tissues. Lanes 1 and 2, HCC tissues; Lanes 3 and 4, adjacent normal tissue; Lanes 5 and 6, regenerating nodule tissues. RT-PCR for β -actin was used to monitor the quality of the RNA sample. RT-PCR was performed in triplicate.

Correlations between PLK1 positive expression group and clinicopathologic variables

The relationship between PLK1 positive expression groups and clinicopathologic data was analyzed by statistical software (Table 1). By the Mann-Whitney *U* test, the positive expression group with multiple tumor nodules had values significantly higher than that with solitary tumor nodules ($P = 0.002$). The high Edmondson-Steiner grade (III, IV) in the positive expression group was also significantly stronger than those of low grade tumors (I, II) ($P = 0.022$). Furthermore, venous invasion was significantly correlated with the positive expression group ($P = 0.042$). However, this study also showed that positive expression had no significant relationship with gender, age, liver cirrhosis, HBsAg, AFP or tumor size ($P > 0.05$) (Table 1).

Survival analysis of prognostic factors

As mentioned above, 135 cases of HCCs were divided

into positive and negative expression groups. The Kaplan-Meier method was employed to analyze the correlation of PLK1 expression level and the prognosis of HCC patients. Our results indicated that the positive expression group correlated with a shorter survival time than the negative group. The median survival time was 22.53 mo *vs* 60.88 mo. In addition, the 1, 3 and 5 year survival rates for the patients with positive and negative expression in HCC were 91.3%, 67.1% and 50.3% and 67.8%, 42.3% and 20.9%, respectively. The overall survival rates in the two groups was significantly different ($P = 0.003$, log-rank test) (Figure 3). At the same time, all the clinicopathologic variables were also analyzed with the Kaplan-Meier method. The results showed that a high Edmondson grade, venous invasion and multiple tumor nodules were correlated with a poor prognosis in HCC while the other clinicopathologic variables did not provide any independent prognostic information (Table 2).

By multivariable Cox regression analysis, PLK1 mRNA positive expression (RR, 3.507; 95% CI: 1.386-8.874, $P = 0.008$), high Edmondson grade (RR, 1.929; 95% CI: 1.069-3.482, $P = 0.029$), multiple tumor nodules (RR, 2.377; 95% CI: 1.384-4.082, $P = 0.002$) and venous invasion (RR, 4.848; 95% CI: 2.649-8.871, $P < 0.001$) were found to be independent prognostic factors for survival (Table 3).

DISCUSSION

Polo-like kinase 1 (PLK1) belongs to a family of

Figure 3 Log-rank test shows that HCC patients in the positive PLK1 mRNA expression group had a lower survival than those in the negative group.

conserved serine/threonine kinases involved in multiple mitotic processes^[37], including functional maturation of centrosomes, establishment of the bipolar spindle^[38], chromosome segregation^[39] and response to DNA damage^[40]. PLK1 is essential in the G₂/M-phase transition. The enzyme is able to activate CDC25c which in turn activates the CDC2/cyclin B1 complex leading to the import of cyclin B1 into the nucleus^[41], and it is also able to phosphorylate cyclin B1 directly^[42]. Moreover, PLK1 has been implicated in the regulation of anaphase-promoting complex/cyclosome^[43]. Interestingly, overexpression of PLK1 has been associated with tumor

Table 2 Correlation of several clinicopathological factors and of PLK1 mRNA expression group with patient survival (log-rank test)

PLK1 positive expression	3.507	1.386-8.874	0.008

development and can serve as a prognostic marker for some cancers^[12,20,31]. However, few previous reports have examined the possible role of PLK1 in HCC.

In our study, overexpression of PLK1 by immunohistochemical analysis was detected in tumor tissues, while no or sporadic expression were observed in adjacent normal tissue or regenerating nodules. Further investigation showed that the degree of PLK1 mRNA expression was also higher in HCC tissues than in adjacent normal tissues and regenerating nodules; elevated mRNA levels of PLK1 were detected in 82.22% of tumor samples. These data indicate that overexpression of PLK1 was a frequent event in hepatocellular carcinoma.

In investigating the association between PLK1 expression and clinicopathological data, PLK1 positive expression was correlated with multiple tumor nodules, high Edmondson-Steiner grade (III, IV) and venous invasion; 1, 3 and 5 year survival rates of the positive expression group were 67.8%, 42.3% and 20.9%, respectively, lower than the negative group ($P < 0.01$); multivariate analysis showed that PLK1 was an independent prognostic factor. Thus, overexpression of PLK1 predicts a poor prognosis in HCC patients.

PLK1 is well known to be involved in cell proliferation. Was the PLK1 overexpression the cause of tumor formation or the consequence of high mitotic index during tumor cell proliferation? Others studies have shown that the overexpression of PLK1 in NIH3T3 leads to tumor formation^[44], and knockdown of PLK1 causes inhibition of growth and induction of apoptosis in human esophageal cancer cells^[17]. Furthermore, PLK1 was inhibited by DNA damage in the G₂ phase of mitosis. When the conserved threonine residue in the T-loop was changed to aspartic acid, expression of these mutants

was found to override the G2 arrest induced by DNA damage^[45]. In our studies, the level of PLK1 mRNA expression in HCC was obviously higher than in regenerating nodules, which also indicted that PLK1 might be a “proto-oncogene” for HCC.

In summary, this is the first attempt to clarify the relation of PLK1 expression and HCC. Our results indicate that high PLK1 expression predicts a poor prognosis in HCC patients. The data further suggest that PLK1 may serve as a potential biomarker for HCC. However, this is only a preliminary step. Further studies are warranted to understand the overexpression mechanism of PLK1 and to develop effective targeted interventions as a therapy for HCC.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the deadliest of all cancers with as yet incompletely elucidated causes. As a cell cycle control kinase, polo-like kinase1 (PLK1) and its overexpression are highly associated with many human cancers. However, few studies are available on the overexpression of PLK1 in HCC.

Research frontiers

PLK1 is involved in cell proliferation. Its overexpression is associated with many human cancers. It is unclear whether the overexpression was the cause of tumor formation or the consequence of a high mitotic index during tumor cell proliferation. The trigger mechanisms of PLK1 overexpression in tumor formation are also unknown. Effective targeted interventions against PLK1 overexpression may be possible strategies as a therapy for HCC. All these questions are hotspots in the research field related to the article.

Innovations and breakthroughs

As a preliminary study of the relation between overexpression of PLK1 and HCC, it was found that overexpression of PLK1 was mainly found in tumor tissues compared with tumor-free tissue by immunohistochemical tissue slides and semi-quantitative reverse transcription-polymerase chain reaction analysis. In all HCC patients involved in the follow-up system, the survival rates in the PLK1 positive expression group were significantly lower than the negative control group. Theses results indicate that PLK1 could be a potential biomarker for diagnosis and therapy for HCC.

Applications

Overexpression of PLK1 is correlated with tumors. However the mechanism remains unclear. Their studies find overexpression of PLK1 in HCC, analyze the relationship between the prognosis of HCC and the overexpression, and provide the theoretical basis for targeted intervention against PLK1 as a means of treatment of HCC.

Terminology

PLK1: PLK1 is an important regulator of cell cycle progression during M-phase, involved in the assembly and dynamics of the mitotic spindle apparatus and in the activation and inactivation of CDK/cyclin complexes.

Peer review

This is a good descriptive study in which authors correlated polo-like kinase 1 expression in human HCC with clinicopathological findings. The data are very informative and deserve publication in the journal. The results are interesting and suggest that PLK1 could be a potential biomarker for diagnosis and therapy for HCC.

Abstract

AIM: To investigate the expression and clinical significance of S100A2 mRNA and protein, p63 protein in esophageal squamous cell carcinoma (ESCC) and their roles in carcinogenesis and progression of esophageal carcinoma (EC).

METHODS: Immunohistochemical staining (S-P method) for S100A2 and p63 protein were performed in 40 samples of ESCC and 40 samples of normal esophageal mucosa. *In situ* hybridization (ISH) was used to detect the expression of S100A2 mRNA.

RESULTS: Expression of S100A2 mRNA in ESCC was positive in 77.5% of samples, which was lower than that in normal mucosa (100%) by ISH ($P = 0.002$). The expression level of S100A2 mRNA was closely related to differentiation and node-metastasis ($P = 0.012$, $P = 0.008$). Expression of S100A2 protein was positive in 72.5% of ESCC samples and expression of p63 protein was positive in 37.5% of ESCC samples, and was lower than that in normal mucosa (100%) ($P = 0.000$). The expression of S100A2 protein was correlated with the differentiation and node-metastasis ($P = 0.007$, $P = 0.001$), but no relationship was observed between the expression of p63 protein and clinical pathological manifestations. S100A2 protein was positively correlated with the expression of S100A2 mRNA, and negatively associated with the expression of p63 protein ($P = 0.000$, $P = 0.002$).

CONCLUSION: S100A2 and p63 protein both play important roles in the carcinogenesis of ESCC. An inves-

INTRODUCTION

Esophageal carcinoma (EC) is one of the most common malignant diseases in China and has a poor survival rate. The carcinogenesis and development of EC is a complex process referring to multiple factors, stages and genovariations, and to numerous changes in genes and proteins at the molecular level. However, the biological roles of these changes in esophageal carcinogenesis are still vague. Up to now, no specific tumor marker for EC has been identified, and there are no biomarkers for use in screening, early diagnosis and judgment of the biological behaviour of EC.

As a tumor suppressor gene, *S100A2* is located on human chromosome 1q21^[1] and its encoding protein is a calcium-binding protein constituted by 97 amino acids^[2]. As a member of the S100 family, S100A2 is individual compared with other members of this family. Firstly, S100A2 protein is predominantly located in the nucleus rather than the cytosol like other S100 proteins. Moreover, *S100A2* is down-regulated in several tumors and may play a role in inhibiting tumor initiation or in suppressing tumor cell growth, whereas other members of the S100 family are up-regulated in tumors and may play a promotional role in carcinogenesis. Therefore, *S100A2* is considered a candidate tumor-suppressor gene^[3].

p63 gene, a new member of the *p53* gene family, was identified and named in 1998 by Yang *et al*^[4]. *p63* gene is located on human chromosome 3q27-29 and expresses

at least six protein isoforms, which can be divided into two groups -TAp63 and Δ Np63^[5]. Among them, the transcription level of Δ Np63 α is the highest. TAp63 is able to activate the transcription of specific target genes and induce cell cycle arrest and apoptosis. Similar to p53, TAp63 has anti-oncogene activity. Δ Np63 is unable to activate transcription and inhibit transcription activation by both p53 and TAp63. Δ Np63 has anti-apoptosis and proto-oncogene activity^[6,7].

Normally, *p63* is mainly expressed in the basal lamina of many epithelial tissues and plays an important role in initiating epithelial stratification during development and in maintaining the proliferative potential of basal keratinocytes in mature epidermis. Recently, *p63* gene has been studied in the fields of tumorigenesis, cell apoptosis and tissue growth.

At present, few studies have been performed on the expression and relationship of *S100A2* and *p63* in EC. In this study, *in situ* hybridization (ISH) used to identify *S100A2* mRNA and immunohistochemical staining (S-P method) used to identify S100A2 and p63 protein, were performed in 40 samples of esophageal squamous cell carcinoma (ESCC) and 40 samples of normal esophageal mucosa. The purpose of this study was to investigate the expression of S100A2 mRNA, S100A2 protein and p63 protein in EC, and their relationship with clinical pathological features, and to explore their roles in the carcinogenesis and prognosis of EC.

MATERIALS AND METHODS

Patients and samples

Forty specimens of ESCC and matched adjacent normal mucosa were obtained from the Department of Pathology, First Affiliated Hospital, Anhui Medical University between 2005 and 2006. None of the patients had been treated with radiotherapy or chemotherapy prior to surgery. Samples were taken from tumor tissue without hemorrhage or putrescence, whereas the matched normal mucosa samples were taken from the surgical cutting edge, which was approximately 3-5 cm from the cancerous lesion. The clinical diagnosis in all 40 patients was confirmed by histological examination after surgery.

ISH and immunohistochemistry

ISH reagents were purchased from Boster Co. (Wuhan, China) and Zhong Shan Co. (Beijing, China). A digoxigenin-labeled oligonucleotide probe was used. The probe sequence of S100A2 is described as: 5'-TGATGTGCAGTTCTCTGGAGCAGGCGCTGGCTGTG-3'; 5'-ACTGTCATGTGCAATGACTTCTTCCAGGGCTGCCC-3'. ISH for S100A2 was performed as follows: The tissue sections were treated with 3% hydrogen peroxide and 10% pepsin (diluted with 3% citric acid), respectively, after deparaffinization and rehydration. The sections were prehybridized at 37°C for 4 h with a prehybridization solution (Boster Co., China). Next, the sections were incubated in 100 μ L hybridization solution/section containing 1 μ L of denatured probe and 400 μ L dilution of oligonucleotide probe (Boster Co., China) at 43°C for 16-20 h. The slides

were washed at 37°C in $2 \times$ SSC (5 min, three times), $0.5 \times$ SSC (5 min, three times) and $0.2 \times$ SSC (5 min, three times), respectively. During the color reaction procedure, the slides were incubated in sheep serum at 37°C for 30 min and then incubated with mouse antidigoxigenin antibody at 37°C for 60 min. After washing with PBS, the color was developed in DAB (3,3'-diaminobenzidine) (Zhongshan Co., China) for 15-30 min identified by occasional observation. Counterstaining of slides was then conducted with hematoxylin followed by a sealing procedure with neural gum.

S100A2 polyclonal antibody was purchased from Neomarker Co. (USA) and was used at a concentration of 1:100, and p63 monoclonal antibody was purchased from Maixin Co. (China). Immunohistochemistry for S100A2 and p63 were performed as follows: Deparaffinization and rehydration of sections (3×3 min with xylene; 3×2 min with 100% ethanol; 2 min with 95% ethanol, 2 min with 75% ethanol, and 2×1 min with distilled water), was performed using microwave repaired antigen. The samples were then washed 3×5 min with PBS. Endogenous peroxidases were blocked by soaking the slides in a solution of 3% H₂O₂ for 15 min at room temperature (RT). The samples were then washed 3×5 min with PBS, and 50 μ L of nonimmune animal blood serum was added to each section for 15 min at RT. The samples were shaken and excess PBS was wiped off. Primary antibody (50 μ L) was added to each section immediately, and incubated overnight at 4°C in a humidified chamber. The slides were washed 3×10 min in PBS. Fifty microliters of biotin labeling secondary antibody was added to each section for 15 min at 37°C, then the slides were washed 3×5 min with PBS. (ABC was made according to the Vector protocol 30 min before use (mix 5 mL PBS with two drops of solution A and two drops of solution B). The samples were incubated for 15 min at RT, then washed 3×5 min in PBS. Freshly prepared DAB (100 μ L) was added to the slides and the color change was observed approximately 5-20 min later. Coloration was stopped by flushing with water. The slides were then counterstained with hematoxylin followed by a sealing procedure with neural gum.

Normal epithelium showing strong S100A2 or a p63-positive section served as the positive control, and that without the antibody section served as the negative control.

ISH and immunohistochemistry evaluation

S100A2 mRNA and S100A2 protein were expressed in the nucleus or the nucleus and cytoplasm. The percentage of positive cells in each high power field was noted, and less than 10% of positive cells was considered negative and greater than 10% was considered positive. p63 protein was expressed in the nucleus. The grading of positive cells was as follows: no p63-positive cells was characterized as negative, less than 25% was weakly positive (+), 25%-75% was moderately positive (++), and greater than 75% was strongly positive (+++). The percentage of staining was estimated by two independent pathologists, respectively.

Statistical analysis

All data were analyzed with SPSS 13.0 software. Pearson's χ^2 test was used for data measurement. Using the Monte Carlo simulation method, the exact probability value was calculated for the data where the theoretical frequency was less than five. Non-parametric Spearman rank correlation analysis was used for correlation analysis of ranked data.

RESULTS

The expression of S100A2 mRNA and S100A2 protein in ESCC and normal mucosa

S100A2 mRNA and S100A2 protein were expressed in the nucleus or the nucleus and cytoplasm (Figure 1A and B, Figure 2A and B). All 40 samples of normal esophageal mucosa positively expressed S100A2 mRNA and

Table 3 Relationship between S100A2 mRNA and S100A2 protein in ESCC

S100A2 protein	S100A2 mRNA		Total
	+	-	
+	27	2	29
-	4	7	11
Total	31	9	40

$r = 0.607$, $P = 0.000$.

S100A2 protein. In 40 ESCC samples, 31 positively expressed S100A2 mRNA, and 29 expressed S100A2 protein. The positive rates of S100A2 mRNA and S100A2 protein in ESCC (77.5% and 72.5%, respectively) were significantly lower than that in normal mucosa (100% and 100%, respectively) ($P < 0.01$) (Table 1).

The relationship between expression of S100A2 mRNA and S100A2 protein and clinical pathological features in ESCC

S100A2 mRNA was positive in 93.3% (14/15), 85.7% (12/14), and 45.5% (5/11) in the well differentiated, moderately differentiated, and poorly differentiated groups, respectively. The differences were significant among the three groups ($P < 0.05$). Moreover, the expression level of S100A2 mRNA was significantly higher in the well and moderately differentiated groups than that in the poorly differentiated group ($P < 0.05$). The expression of S100A2 was positively correlated with node metastasis ($P < 0.01$). S100A2 protein was positive in 86.7% (13/15), 85.7% (12/14), and 36.4% (4/11) in the well differentiated, moderately differentiated, and poorly differentiated groups, respectively. The expression level of S100A2 protein was related to differentiation and lymph node metastasis. The expression of S100A2 mRNA and S100A2 protein was not correlated with gender, age, clinical stage, tumor location, tumor size, and depth of tumor invasion ($P > 0.05$) (Table 2).

Relationship between S100A2 mRNA and S100A2 protein in ESCC

A positive correlation was found between the expression of S100A2 mRNA and S100A2 protein ($r = 0.607$, $P < 0.001$). Of 40 ESCC samples, 27 expressed S100A2 mRNA and S100A2 protein at the same time, and seven cases did not express these parameters at the same time. Four cases expressed S100A2 mRNA but not S100A2 protein. Two cases did not express S100A2 mRNA but expressed S100A2 protein (Table 3).

The expression of p63 protein in ESCC and normal mucosa

p63 protein was expressed in the nucleus (Figure 3A and B). In 40 samples of normal esophageal mucosa, 10 expressed p63 but none were strongly positive. In 40 ESCC samples, 21 expressed p63. Among these, 15 cases were strongly positive. p63 protein was positive in 52.5% and

Figure 1 The expression of S100A2 mRNA. A: Normal mucosa (+) (ISH, $\times 100$); B: ESCC (+) (ISH, $\times 200$).

Figure 2 The expression of S100A2 protein. A: Normal mucosa (+) (S-P, $\times 200$); B: ESCC (+) (S-P, $\times 200$).

Figure 3 The expression of p63 protein. A: Normal mucosa (+) (S-P, $\times 100$); B: ESCC (+++) (S-P, $\times 200$).

Table 4 Expression of p63 protein in ESCC and normal mucosa

	<i>n</i>	p63 protein				Positive rate (%)	Strong positive rate (%)
		-	+	++	+++		
Normal mucosa	40	30	10	0	0	25.0	0.0
ESCC	40	19	2	4	15	52.5 ^a	37.5 ^b

^a $P < 0.05$, ^b $P < 0.001$ vs normal mucosa.

strongly positive in 37.5% of ESCC samples, and was higher than that in normal mucosa (25.0%) ($P < 0.05$, $P < 0.001$) (Table 4).

Relationship of p63 protein expression with clinical pathological features of ESCC

The expression of p63 protein was not correlated with gender, age, clinical stage, tumor location, tumor size,

depth of tumor invasion, degree of differentiation or lymph node metastasis ($P > 0.05$).

Relationship between S100A2 protein and p63 protein in ESCC

A negative correlation was found between the expression of S100A2 protein and p63 protein ($r = -0.474$, $P < 0.01$). Of 40 ESCC samples, 11 expressed S100A2 and p63 at the same time, and 1 did not express these parameters at the same time. 18 ESCC samples were S100A2-positive and p63-negative. 10 cases were S100A2-negative and p63-positive (Table 5).

DISCUSSION

Up to now, 21 genes encoding S100 calcium-binding proteins of the EF-hand type have been identified. Calcium ion (Ca^{2+}) plays an important role in the regulation of a number of cellular processes. The

Table 5 Relationship between S100A2 protein and p63 protein in ESCC

p63 protein	S100A2 protein		Total
	+	-	
+	11	10	21
-	18	1	19
Total	29	11	40

$r = -0.474$, $P = 0.002$.

second messenger role of Ca^{2+} is mediated, at least in part, by calcium-binding proteins which contain the EF-hand motif. Through modulating Ca^{2+} and interacting with the target proteins, S100 proteins have a multitude of biological functions *in vivo*. Many S100 genes were reported to be clustered in the epidermal differentiation complex in chromosome 1q21^[8-12]. This region is involved in epidermal differentiation and proliferation and is also frequently rearranged in tumors^[13]. Studies have shown that the S100 gene deregulated expression in human diseases, especially in tumors. Nowadays, S100 protein antibodies have widespread application for tumor diagnosis by immunohistochemistry.

As a member of the *S100* gene family, S100A2 is significantly downregulated in several malignant tumors, such as breast cancer^[14], melanoma^[15], prostatic carcinoma^[16], and pulmonary carcinoma^[17]. Moreover, S100A2 may be closely associated with the development and prognosis of tumors^[18].

Using semiquantitative reverse transcription-polymerase chain reaction (RT-PCR), Ji *et al.*^[19] examined the differential expression of *S100A2* and another 15 *S100* genes in 62 cases of ESCC *vs* the corresponding normal esophageal mucosa. Their results showed that the S100A2 gene was significantly downregulated ($P < 0.05$) in ESCC *vs* normal esophageal mucosa. Moreover, the deregulation of *S100A2* gene was significantly correlated with the deregulation of *S100A8*, *S100A14* and *S100P*. Kyriazanos *et al.*^[20] examined the clinical significance of *S100A2* expression in 116 resected specimens of ESCC using immunohistochemistry. Their results showed that S100A2 was positive in 49 cases (42.2%) and its expression was significantly higher in large and well differentiated tumors. Lymph node-positive tumors had a lower expression of S100A2 protein in comparison to the corresponding lymph node-negative equivalents in each of the T stages, but the difference was statistically significant only for T1b tumors. S100A2 status became an independent predictor of patient survival in lymph node-negative cases. Node-negative ESCC patients without S100A2 expression may be a high-risk group with poor survival and will need further attention to design appropriate adjuvant therapy.

We used ISH for the first time to detect the expression of *S100A2* mRNA and used immunohistochemical staining for S100A2 protein in 40 ESCC samples and 40 samples of normal esophageal mucosa. Our results showed that *S100A2* mRNA and S100A2 protein although positive in ESCC were both lower than that in

normal mucosa ($P < 0.01$). This indicated that S100A2 was downregulated in ESCC and that the *S100A2* gene is concerned with the carcinogenesis of EC. A positive correlation was found between the expression of *S100A2* mRNA and S100A2 protein ($P < 0.001$), which indicated that S100A2 protein expression is regulated mainly at the transcriptional level, and the decrease in S100A2 protein expression corresponded to the decrease in transcriptional activity. In addition, our findings on S100A2 mRNA are consistent with those of Ji *et al.*^[19]. We suggest that the positive rate in our study is higher than that in the study by Ji *et al.*^[19] due to the difference in case number (40 *vs* 62) and method (ISH *vs* RT-PCR).

Furthermore, we analyzed the relationship between S100A2 positive expression and the clinical pathological features of ESCC. We found that the expression level of S100A2 mRNA and S100A2 protein were both significantly higher in the well and moderately differentiated groups than in the poorly differentiated group ($P < 0.05$). These differences were also significant between the lymph node-positive group and the lymph node-negative group ($P < 0.01$), which is roughly consistent with the findings of Kyriazanos *et al.*^[20]. These results indicate that S100A2 plays an important role in tumor cell differentiation, and that S100A2 might be an important biomarker in the biological behaviour of EC.

A study on the course of EC, found that *p63* gene and its encoding protein played important roles in the early period of the physiological and pathological course of esophageal mucosa, compared with mutation of p53 which occurs in the last stage of cancerization lineage from metaplasia, atypical hyperplasia to adenocarcinoma. Glickman *et al.*^[21] detected p63 protein in EC by immunohistochemical staining. Their results showed that p63 protein was highly expressed in ESCC, but was not expressed in adenocarcinoma of the esophagus and colorectal cancer. This indicated that *p63* gene is upregulated in ESCC and is concerned with the development of ESCC.

We used immunohistochemical staining for p63 protein in 40 ESCC samples and 40 samples of normal esophageal mucosa. Our results showed that p63 protein in normal esophageal mucosa was positive in 25.0%, and the expression was weakly positive and localization in the basal cells or the bottom of the prickle cell layer of normal esophageal mucosa. This supports the view that p63 is mainly expressed in the corpus of many epithelial tissues, and plays an important role in the abstraction, differentiation and morphogenesis of many epithelial tissues^[22]. Moreover, our results showed that p63 protein has a high expression rate in the tissue of EC, which indicates that p63 is closely related to the carcinogenesis of EC. In contrast, we found that the expression of p63 protein was not correlated with the clinical pathological features of ESCC.

Our study showed that the expression of S100A2 protein was reduced and the expression of p63 protein was increased, and a negative correlation was observed between them ($P < 0.01$). This indicated that S100A2 protein and p63 protein may both play important roles in the carcinogenesis of EC. An investigation into the combined expression of S100A2 and p63 may be use-

ful in early diagnosis and in evaluating the prognosis of ESCC.

COMMENTS

Background

Esophageal carcinoma (EC) is one of the most common malignant diseases in China and has a poor survival rate. Up to now, no specific tumor marker of EC has been identified. Recently, *S100A2* has been considered a candidate tumor-suppressor gene, and *p63* gene has been studied in the fields of tumorigenesis, cell apoptosis and tissue growth.

Research frontiers

S100A2 is down-regulated in several tumors and may play a role in inhibiting tumor initiation or in suppressing tumor cell growth. Therefore, *S100A2* has been considered a candidate tumor-suppressor gene. *p63* gene, a new member of the *p53* gene family, is normally expressed in the basal lamina of many epithelial tissues and plays an important role in initiating epithelial stratification during development and in maintaining proliferative potential of basal keratinocytes in mature epidermis. Recently, *p63* gene has been studied in the fields of tumorigenesis, cell apoptosis and tissue growth.

Innovations and breakthroughs

At present, few studies have been carried out on the expression and the relationship of *S100A2* and *p63* in EC. In this study, *in situ* hybridization (ISH) to identify *S100A2* mRNA and immunohistochemical staining (S-P method) to identify *S100A2* and *p63* protein were performed in ESCC and normal esophageal mucosa samples.

Terminology

S100A2 gene is located on human chromosome 1q21 and its encoding protein is a calcium-binding protein constituted by 97 amino acids. *S100A2* protein is predominantly located in the nucleus rather than the cytosol like other *S100* proteins. *S100A2* is down-regulated in several tumors. Therefore, *S100A2* is considered a candidate tumor-suppressor gene.

Peer review

The study investigated *S100A2* and *p63* expression in EC tissue samples and paired normal mucosa samples. *S100A2* expression was analysed both on the mRNA and protein level by ISH and IH, respectively, *p63* expression was determined by IH. The authors described a decreased expression of *S100A2* and an increased expression of *p63* in tumor samples. Statistical analysis revealed an inverse correlation. This is a clear strength of this study.

Abstract

We present the case of an elderly woman who developed a bowel perforation related to pneumatosis intestinalis, 33 years after a jejunio-ileal bypass for severe obesity. Final histological examination revealed the presence of dysplasia in the resected specimen. On the basis of our case and a review of the literature, we discuss the etiopathogenesis, the clinical aspects and the treatment of this rare condition.

INTRODUCTION

Pneumatosis intestinalis (PI) is an unusual intestinal

pathology characterized by a collection of multiple gas-filled cysts within the wall of the gastrointestinal tract. According to this general definition, PI may be seen in some critical events, including necrotizing enterocolitis in the newborn and ischemic bowel disease in the adult, but also in innocuous conditions which are associated with a wide spectrum of diseases and situations which do not require surgery^[1-7]. Benign causes are statistically more prevalent; PI may resolve spontaneously, although recurrent episodes are reported and the long term outcome of patients is often unclear because of the absence of an exhaustive imaging follow up^[1]. The lack of reliable data regarding the outcome predictors for patients with PI complicates management decisions.

A pneumoperitoneum and a pneumoretroperitoneum can be present regardless of causes and are generally considered a complication of PI. Peritonitis may be consequent, but this is not the rule and a lack of perforation is reported in the presence of mild clinical symptoms^[3]. These conditions are difficult to manage, taking into account that some clinical conditions, such as immunodepression or obesity (not infrequent in these patients) may mask the clinical relevance of pneumoperitoneum so delaying treatment. On the other hand, an automatic referral to surgery may result in an unnecessary laparotomy.

Herein we present a case of PI associated with jejunio-ileal bypass performed many years previously and complicated by a pneumoperitoneum in an obese patient. The histological data, showing a dysplasia of the mucosa, are subsequently discussed.

CASE REPORT

C.D., a 73-year old woman, having undergone an end-to-side jejunio-ileal bypass for severe obesity 33 years previously, was admitted to the Medical Division of our hospital complaining of abdominal pain, constipation and mild dyspnea lasting 2 d. Relevant history included chronic obstructive pulmonary disease without dyspnea at rest, postsurgical hypothyroidism and atrial fibrillation with necessity of continuous warfarin administration recorded; no significant signs of digestive impairment were present. Weight was 105 kg and BMI was 41. At admission, the patient was oliguric, hypotensive (85/55 mmHg) and hypoxemic (PCO₂ 65 mmHg, SpO₂ 90%). On physical examination the abdomen appeared distended, with

Figure 1 Unenhanced CT scan, showing the presence of multiple gas-filled parietal cysts and huge pneumoperitoneum.

diffuse pain and a mild rebound tenderness; no peristalsis at auscultation. Laboratory investigations revealed mild metabolic acidosis (pH 7.3, bicarbonate 15.4 mmol/L) with normal lactate value, leukocytosis (14 000/mL) and acute renal failure (creatinine 2.6 mg/dL); PCR was 459, albuminemia 2.7 g/dL. A marked reduction of prothrombin value ($< 10\%$, INR > 8) was noted, requiring plasma transfusion. Thorax radiography was negative for pneumothorax or pneumomediastinum. Computed tomography (CT) without intravenous contrast medium showed some gas-filled cysts within the wall of the jejunum, ileum and mesentery, associated with massive free intraperitoneal air (Figure 1). A rapid worsening of the patient's general condition was observed, leading to urgent surgical intervention; the patient was classed as ASA four according to the American Society of Anesthesiology. At laparotomy, pneumatosis affected only the defunctionalized jejunal loop (Figure 2), which was abnormally dilated and distally anastomized end-to-side to the sigmoid loop. The first and the last segment of the bypassed bowel, including the ileocolic anastomosis, were relatively healthy. A transmural perforation was present in the antimesenteric border of the bowel along the tract with pneumatosis, in a context of fibrinous peritonitis, without evidence of free biliary or enteric fluid. A segmental 90 cm-long ileal resection with end-to-end anastomosis was performed, including the entire unhealthy bowel. The bacteriologic study on the peritoneal fluid showed the presence of *Difteroides*.

The macroscopic pathological analysis of the resected specimen showed a thickened bowel wall in the presence of multiple cysts without fluid, with a thin distended mucosa and absence of folded structure (Figure 3A and B). At the histological evaluation, the cysts were located in the submucosa and subserosa, with giant cells lining the cyst walls (Figure 3C and D). The mucosa was severely thinned, in some areas with a single cellular layer, and pseudo-atrophy of villi alternated with inflammation and ulceration. In some areas the epithelium was characterized by mild cytological atypia indicating low dysplasia (Figure 4A). Immunohistochemical staining with p53 (Thermo Fisher Scientific, Fremont, CA, USA, dilution 1:100) and p16 (Kit CINtec® Histology, MTM Laboratory, Germany) confirmed the diffuse positivity of epithelial

Figure 2 Intraoperative view of dilated and inflamed defunctionalized jejunal loop, with fibrous peritonitis. No clear evidence of enteric or biliary contamination was present.

cells in the focal mild dysplasia (Figure 4B and C). Marked flogistic reaction of the peritoneal serosa was reactive at the intestinal perforation.

The patient consequently became severely compromised during the whole surgical operation with prolonged hypotension and needed care in the intensive recovery room for 2 d. A progressive normalization of the septic signs and of renal function was then observed. Subsequently the patient's recovery was uneventful and she was discharged on post-operative day 14.

DISCUSSION

Pneumatosis intestinalis may occur in many different situations. The etiology actually favours iatrogenic conditions (surgery, endoscopy, enteric tube placement, positive pressure ventilation), immunodepression, collagen vascular disease and infectious agents^[2,4,5,7,8]. The jejunio-ileal bypass has accounted for some cases of PI; this condition is generally considered benign with a favourable outcome, supporting the concept that "surgical indication is not indicated under the usual circumstances"^[9]. The published experiences on this topic, generally in the form of single cases or small series of patients, refer to reports from the 1970s^[9-15], when this type of bariatric surgery was adopted in many centres. PI occurred any time during the first postoperative phase (mean delay 5 mo, range 1-20 mo)^[7] and patients recovered spontaneously in the majority of cases^[9,11].

Although responsible for a small number of cases, the "model" of jejunio-ileal bypass is well within the supposed pathogenetic mechanisms of PI, because these patients really present several predisposing factors. The first is ascribed to surgery alone with the consequent modification in bowel pressure^[16]. Another factor may be related to the marked obesity, as PI has been described in obese patients without a history of abdominal surgery^[9]. The type of reconstruction of bowel continuity also seems to play a central role; increased colonic gas secondary to fermentation of undigested lactose may reflux into the excluded segment of the small bowel. This occurs in particular when an ileum-sigmoid anastomosis has been performed, so favoring, because of abnormal

Figure 4 Histological appearance and immuno-histochemical staining. Focal area of mild dysplasia (HE, × 60) (A), Positivity for P53 (B) and P16 (C).

pressure, the dissolution of gas into the bowel wall. This mechanism may be augmented by the concomitant bacteria overgrowth, most likely anaerobic, in the bypassed small bowel segment, so assigning the etiology of PI a mechanical - infectious process^[12]. Our case tends to support this hypothesis. PI involved only the bypassed small bowel where the two mechanisms, high pressure and bacterial overgrowth, were more significant. An anastomosis had been built between the defunctionalized

ileum and the sigmoid, the excluded small bowel was significantly dilated, with a clear discrepancy of size compared with that of the functioning bowel, and it was edematous. Histology showed a severe mucosal injury with marked inflammation and signs of a remodeling reactive process.

Pneumoperitoneum is a complication of PI, but not an automatic indication for surgery. An increasing list of conditions relating to pneumoperitoneum without

peritonitis are now recognized^[17,18], PI being the most common. These cases have a benign progression without laparotomy^[17-22]. They are the prevalent situations where no transmural perforation exists: as a consequence, no peritoneal contamination results from the rupture of the intramural sterile blebs. According to these considerations, the demonstration of PI in a patient with pneumoperitoneum may allow us to avoid the need for a laparotomy^[19]. This assumption must be accepted with caution in our opinion. The presence of PI is not enough to consider pneumoperitoneum as a benign condition in every case, with a good spontaneous outcome. Surgical indication must rely above all on the clinical data; neither CT nor the amount of free air are reliable guides for therapy^[20]. A negative abdominal examination could exclude signs of peritonitis, but clinical signs may be minimal or absent, for example in immunodepressed patients, or difficult to discover, as in obese patients. These two situations clearly define an increased risk of a delayed diagnosis of peritonitis, which can present with an ominous course in these frail patients. In our patient, peritonitis was not clear at the time of admission owing to the marked obesity of the patient, but the general signs of septic compromise (hypotension, oliguria, leukocytosis, high PCR value) suggested the clinical relevance of the radiological images. Laparotomy became urgent within a few hours. A complete perforation was discovered in the defunctionalized bowel without extravasation of enteric content, but the presence of gram-positive bacteria in the peritoneal fluid together with the histological demonstration of inflamed peritoneal serosa confirmed the contamination from the intestinal lumen. In the context of a fibrinous peritonitis a simple suture of the perforation might be advised, but this was not our choice because the bowel appeared very dilated and inflamed. The possibility of saving the proximal and distal segments, which were macroscopically normal, directed us towards performing the resection of the pathological bowel.

The histological examination of the resected bowel showed obvious pathological aspects of the PI with typical submucosal cysts surrounded by granulomatous reaction; the peculiarity of the case is the discovery of focal areas of mild dysplasia confirmed by the immunohistochemical evaluation with p53 and p16. These findings have never been reported before. Owing to the rare indication for surgery in these patients, an exhaustive histological evaluation of the pathologic bowel is rare but generally marked by an intact, pale and sometimes transparent mucosa^[7]. These changes, together with the unusually long time between the intestinal bypass and the discovery of PI in our patient, support the hypothesis of a long standing remodeling process, promoting the concept of a preneoplastic condition. This possibility, together with the rare occurrence of malignant lymphomas developing in the excluded intestine^[23], leads us to advise a long term follow up. When surgery is indicated for this complication, complete resection of the tract with pneumatosis, if

technically possible in symptomatic patients, appears to us to be advisable.

Neuroendocrine carcinomas arising in ulcerative colitis: Coincidences or possible correlations? *World J Gastroenterol* 2009; 15(33): 4193-4195 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4193.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4193>

Abstract

Patients with inflammatory bowel disease (IBD) are at increased risk of colorectal malignancies. Adenocarcinoma is the commonest type of colorectal neoplasm associated with ulcerative colitis (UC) and Crohn's disease, but other types of epithelial and non-epithelial tumors have also been described in inflamed bowel. With regards to non-epithelial malignancies, lymphomas and sarcomas represent the largest group of tumors reported in association with IBD, especially in immunosuppressed patients. Carcinoids and in particular neuroendocrine neoplasms other than carcinoids (NENs) are rare tumors and are infrequently described in the setting of IBD. Thus, this association requires further investigation. We report two cases of neoplasms arising in mild left-sided UC with immunohistochemical staining for neuroendocrine markers: a large cell and a small cell neuroendocrine carcinoma of the rectum. The two patients were different in age (35 years *vs* 77 years) and disease duration (11 years *vs* 27 years), and both had never received immunosuppressant drugs. Although the patients underwent regular endoscopic and histological follow-up, the two neoplasms were locally advanced at diagnosis. One of the two patients developed multiple liver metastases and died 15 mo after diagnosis. These findings confirm the aggressiveness and the poor prognosis of NENs compared to colorectal adenocarcinoma. While carcinoids seem to be coincidentally associated with IBD, NENs may also arise in this setting. In fact, long-standing inflammation could be directly responsible for the

INTRODUCTION

It is well recognized that ulcerative colitis (UC) and Crohn's disease (CD) predispose to the development of colorectal adenocarcinoma (CRC). The duration and the anatomic extent of the disease have been shown to be independent risk factors for the development of CRC^[1]. Thus, cancer is infrequently encountered when disease duration is less than 8-10 years, thereafter the risk rises at approximately 0.5%-1% per year^[2]. Additional risk factors are the presence of primary sclerosing cholangitis and a family history of CRC. Younger age at diagnosis and the degree of endoscopic and histological activity may also play an important role^[1]. A comprehensive meta-analysis of all published studies reporting CRC risk in UC up to 2001 showed that the risk for any patients with colitis was 2% at 10 years, 8% at 20 years and 18% after 30 years of disease^[3].

Based on this evidence, guidelines for screening and surveillance of asymptomatic CRC in patients with inflammatory bowel disease (IBD) have been developed to detect either dysplasia or early cancer at a surgically curable stage, and to reduce CRC related mortality^[1,2].

While adenocarcinoma is the most common colorectal epithelial malignancy associated with UC

and CD, other types of carcinomas such as squamous cell carcinoma, small cell carcinoma and “hepatoid” carcinoma have been described in inflamed bowel. With regards to non-epithelial malignancies, lymphomas and sarcomas represent the largest group of tumors reported in association with IBD, especially in immunosuppressed patients^[4].

Carcinoid tumors and neuroendocrine neoplasms other than carcinoids (NENs) may also be associated with UC and CD of the colon based on the finding of increased numbers of neuroendocrine cells in inflamed mucosa, suggesting that long-standing inflammation is directly responsible for the development of this kind of neoplasia^[4].

NENs of the colon and rectum are rare tumors, and are infrequently described in the setting of IBD. Here we report two cases of NENs arising in UC.

CASE REPORT

Case 1

A 35-year-old man with an 11-year history of mild distal colitis was admitted due to constipation, proctorrhagia, tenesmus and perianal pain. Twelve months before admission, a surveillance colonoscopy with biopsy showed endoscopic remission of the inflammatory disease. His treatment consisted of oral mesalamine 2.4 g/d and he had never received immunosuppressant drugs.

A second colonoscopy indicated a rectal substenosis caused by a large ulcerated mass originating about 2 cm above the anorectal junction, with a proximal extension of about 4 cm.

Histological examination showed a high grade large cell neuroendocrine carcinoma. Immunohistochemical staining was positive for chromogranin, synaptophysin, cytokeratin 7 and chorioallantoic membrane 5.2. Laboratory findings including chromogranin A and neuron-specific enolase were negative.

A staging computed tomography scan and somatostatin receptors imaging were negative for further spread of the tumor. The patient underwent a low anterior colorectal resection and distal rectal mucosectomy with colo-anal anastomosis and loop ileostomy. A definitive pathological investigation confirmed the previous histological findings, and the proliferative marker Mib1/Ki67 was positive in about 50% of the neoplastic cells. The TNM stage was pT₃^{R1}pN₂^{17/30}M₀G3. He was treated with adjuvant radiotherapy and chemotherapy with cisplatin and etoposide. One year after surgery, multiple liver metastases were observed. The patient died 15 mo after diagnosis.

Case 2

A 77-year-old man presented with bloody diarrhea, anorectal pain, mild anemia and a 3 kg weight loss. The patient had a 27-year history of left-sided colitis with mild activity. Ten months before admission, a surveillance colonoscopy with biopsy showed mild left-sided inflammation. He was receiving oral mesalamine 2.4 g/d.

Another colonoscopy was performed, which showed

Figure 1 Small cell neuroendocrine carcinoma: endoscopic view.

Figure 2 Cells with minimal cytoplasm, fusiform cell shape, finely granular chromatin, small, or absent, nucleoli (HE stain, original magnification × 20).

Figure 3 Immunohistochemical analysis reveals neuroendocrine differentiation with positive staining for synaptophysin (original magnification × 20).

a large circular neoplasm of about 5 cm in length, 3 cm above the anorectal junction (Figure 1). Histological examination with immunohistochemical analysis excluded adenocarcinoma. A tumor with neuroendocrine differentiation and strong staining for synaptophysin was observed and a high grade small cell neuroendocrine carcinoma was diagnosed (Figures 2 and 3). The proliferative marker Mib1/Ki67 was positive in about 90% of the neoplastic cells. MR scanning and somatostatin receptors imaging were negative for further neoplastic localizations. The patient is scheduled to receive neoadjuvant radiotherapy.

DISCUSSION

The reported incidence of NENs is between 0.1% and 3.9% of all colorectal malignancies. Bernick *et al.*^[5], at New York Memorial Sloan-Kettering Cancer Center, reported an incidence of 0.6% in colon and rectal cancers.

NENs are subdivided on the basis of cytological-histological features and immunohistochemical findings into small cell neuroendocrine carcinoma (SCNC) and large cell neuroendocrine carcinoma (LCNC)^[5]. The criteria for separating small cell from large cell variants are similar to those proposed for the classification of pulmonary neuroendocrine tumors^[6]. SCNCs resemble their pulmonary homonyms, having minimal cytoplasm, fusiform cell shape, fine granular chromatin, small or absent nucleoli, and nuclear moulding. LCNCs are characterized by cells with more cytoplasm, a round or polygonal cell shape, prominent nucleoli, and a coarser chromatin pattern.

While the diagnosis of SCNC does not necessitate immunohistochemical documentation of neuroendocrine differentiation, the diagnosis of LCNC requires positive immunohistochemical staining for one of the three neuroendocrine markers (chromogranin, synaptophysin and neuron-specific enolase) in at least 10% of tumor cells^[5].

Even though they are extremely rare, it is important to recognize NENs pathologically, since they have a particularly poor prognosis compared to colorectal adenocarcinoma. NENs shows a high rate of liver metastasis (50%) and the reported 1-year survival rate is about 40%^[5]. Thus, patients could benefit from treatment with alternative cytotoxic chemotherapeutic agents^[6].

There have been reports of neuroendocrine tumors associated with UC, but many of these tumors are carcinoids, often well-differentiated and clinical indolent, and are found incidentally at a different site from dysplastic areas after surgery for IBD^[7]. Greenstein *et al.*^[7] believe that this association is coincidental, particularly since there are no significant demographic or clinicopathological differences between the carcinoids that occur in patients with and without IBD. Furthermore, the same authors point out that neuroendocrine cell hyperplasia, probably due to a trophic role of these cells in epithelial re-growth, is not itself an established association with carcinoids.

Sigel *et al.*^[8] reported the only series of NENs other than carcinoids arising in 14 IBD patients (eight CD; six UC). Similar to our findings, they observed that all the tumors arose in areas involved by IBD, and six of the 14 neoplasms affected the rectum. The NENs were well differentiated in 11 cases and poorly differentiated in three cases; two of these three patients died at 3 and 11 mo after tumor excision.

These authors suggested that neuroendocrine differentiation, different to carcinoids, might evolve from multipotential cells in dysplastic epithelium. This was based on their findings that dysplasia was found in adjacent mucosa in more than one-third of cases^[8].

Our cases confirm the aggressive biological behavior and poor response to chemotherapy of NENs compared to colorectal adenocarcinoma. Both NENs in these patients arose in mild left-sided UC, however, the patients were different in age (35 years *vs* 77 years) and disease duration (11 years *vs* 27 years). This raises the question as to whether these carcinomas represent an incidental finding in the background of IBD or if there is a real, although rare, association between IBD and these tumors.

The hypothesis of a pancellular dysplasia involving epithelial, goblet, Paneth and neuroendocrine cells in chronic inflamed mucosa cannot be confirmed from the few published case reports^[8-11]. In addition, the differences in terms of duration, extension, histological and endoscopic activity of the underlying IBD in our and other reported cases^[8-11] do not allow the identification of a subgroup of patients at risk.

INTRODUCTION

Chronic hepatitis C virus (HCV) infection is one of the leading known causes of chronic liver diseases, including cirrhosis and hepatocellular carcinoma^[1,2]. Risk factors associated with transmission of HCV include transfusion of infected blood products, injection drug use, employment in patient care or clinical laboratory work, exposure to an infected sex partner or household member, exposure to multiple sex partners, and low socioeconomic status^[3].

HCV has a positive-sense, single-stranded RNA genome that has been classified into six different genotypes from 1 to 6^[4,5]. The genotype determination is a relevant clinical practice, which not only helps predict the probability of sustained virological response (40%-45% for genotype 1 compared with 70%-80% for genotypes 2 and 3), but also is used routinely to determine duration of treatment (48 wk for genotypes 1 and 4 vs 24 wk for genotypes 2 and 3)^[6,7]. Various genotypes have distinct geographical distributions around the world^[8], and recent reports from Tehran and five cities from different locations in Iran, have shown that genotype 1a was predominant (47%), and 3a, 1b and 4 had a prevalence of 36%, 8% and 7%, respectively^[9].

Interferon, in various forms or combinations, is the only proven effective treatment for hepatitis C. It has a fundamental, irreplaceable role in the treatment of patients with HCV infection. Treatment of hepatitis C, even when absolutely necessary, is almost impossible when interferon cannot be administered for any reason.

Here, we report a patient with chronic HCV infection and advanced fibrosis who was unable to receive interferon because of systemic hypersensitivity. The patient was desensitized successfully through gradual incremental exposure, and HCV infection was eradicated after a complete course of treatment, with no further allergic reactions.

Abstract

Treatment of hepatitis C, even when absolutely necessary, is almost impossible when interferon cannot be administered for any reason. We report a 65-year-old patient with chronic hepatitis C virus (HCV) infection and fibrosis, who was unable to receive interferon because of systemic hypersensitivity. The patient was desensitized successfully through gradual incremental exposure to interferon, and HCV infection was eradicated after a complete course of treatment, with no further allergic reactions. This case report that describes successful eradication of hepatitis C in a patient with advanced liver disease after desensitization to interferon revealed that desensitization may not necessarily damage the therapeutic efficacy of the drug.

our liver clinic with a positive anti-HCV antibody ELISA. The patient's main complaint was fatigue. Past medical history was positive for two coronary angioplasties for ischemic heart disease. No other medical diseases were present in his past history. General physical examination was normal except for mild hepatomegaly. Results of laboratory tests were within normal ranges except for a marginally low albumin level (3.4 g/dL) and mildly elevated aspartate aminotransferase (45-80 IU/mL) and alanine aminotransferase (46-78 IU/mL).

Reverse transcription polymerase chain reaction (RT-PCR) revealed a cDNA band that indicated the presence of HCV (Figure 1). Genotype-specific primers for HCV genotyping showed the virus to be of genotype 1b. Liver needle biopsy showed chronic hepatitis with moderate activity and advanced fibrosis (grade 9/18, stage 5/6).

The patient was selected for treatment with interferon plus ribavirin. The dosage of ribavirin was kept constant at 1200 mg/d throughout treatment. Since he was not able to afford the cost of pegylated interferon therapy, PDferon®, a brand of interferon α -2b produced in Iran (Pooyeshdarou Pharmaceutical Co., Tehran, Iran), was used.

After administration of the first dose of interferon α 2b, the patient developed generalized maculopapular rash with severe itching and low-grade fever. As a result, treatment was stopped, with a diagnosis of hypersensitivity to interferon.

Since there was no other choice for treatment of hepatitis C, after careful discussion with the patient about possible benefits and side effects, a decision was made to proceed with a course of desensitization. The

Figure 2 No evidence of cDNA band of HCV with RT-PCR after treatment with interferon plus ribavirin following desensitization. P: Patient; PC: Positive control; NC: Negative control; M: Marker.

Table 2 Dosing protocol for day 2

Dose number	Time from first dose (h)	Strength	Volume	Drug dosage (IU)
1	0	1/100	0.1	3000
2	1	1/100	0.1	3000
3	2	1/10	0.1	30000
4	3	1/10	0.1	30000

Cumulative dose				1266000

patient was kept in hospital during the first and second day of the treatment, with close observation of his vital signs. Resuscitation equipment was kept at the bedside. A routine blood count and chemistry were performed on days 1 and 2 and revealed normal results. A 1-mL vial of PDferon® that contained 3000000 IU was diluted to 1/100000 concentration, and 0.1 mL of the resulting solution was injected subcutaneously.

Desensitization started from 8 am on the first day and dose escalation continued until the sixth dose (14.00 h). The dose was kept the same during the afternoon and injections stopped at 21.00 h to allow for patient rest (Table 1). Desensitization restarted on the next day at the same time, with a 1/100 concentration (Table 2). From day 3 onwards, until the end of the first week, the drug was given at a dose of 1500000 IU/d in the morning, with a 1-h period of observation after the injections. From the second week until the end of the treatment (54 wk), interferon was given at a dosage of 3000000 IU every other day.

The only observed reaction during the treatment was a mild generalized pruritus at the start of day 2, with no accompanying rash or change in vital signs. These symptoms responded to intramuscular injection of diphenhydramine. After completing the treatment course, the patient recovered from HCV and nested RT-PCR revealed no cDNA band, which indicated eradication of HCV (Figure 2). RT-PCR was repeated another two times at 6-wk intervals, with the last one at 18 mo after the end of treatment. All turned out to be negative.

DISCUSSION

Since the patient had advanced liver fibrosis and there was no alternative treatment for hepatitis C, after extensive

discussion with the patient about the possible side effects, as well as alternatives, a decision was made to proceed with desensitization. The protocol was based on previous experience with desensitization to penicillin. This decision was reviewed by another independent gastroenterologist and the patient gave written informed consent.

Interferon products are used worldwide as an effective treatment for chronic hepatitis C. Although several potential antiviral drugs are in the pipeline, interferon is still the only proven effective treatment for this viral disease.

Considering the above facts, when a patient is in great need of antiviral therapy for hepatitis C (advanced fibrosis for instance) and has an allergic reaction to interferon, there are very limited, if any, treatment options available. Although desensitization through gradual exposure to incremental doses is an established option for treatment of allergic reaction to protein and non-protein drugs^[10], there are no reports of its use for desensitization to interferon. The main theoretical risk (beside the proven risk of anaphylaxis) with desensitization to protein drugs such as interferon is that it induces neutralizing antibodies, which potentially are directed towards the effective sites of the drug, which renders it ineffective, or at least reduces its therapeutic potential.

This case report describes successful eradication of hepatitis C in a patient with advanced liver disease, and is an indication that desensitization may not necessarily damage the therapeutic efficacy of the drug. Although in this case a regular (non-pegylated) interferon product was used, it may be expected that the same procedure can be applied to pegylated interferon products, since it is the protein component towards which hypersensitivity is usually directed.

Further studies including measurement and characterization of possible contributing antibodies are needed

before this method can be suggested as a standard protocol for interferon desensitization.

Abstract

Malignant tumors of papilla are usually adenocarcinomas. We present a 67-year-old female who became icteric as result of a malignant tumor infiltrating the papilla of Vater. Histopathological assessment of surgically excised tumor showed both neuroendocrine and adenocarcinomatous features. To our knowledge, this is the seventh report of this rare neoplastic association in the duodenal periampullary region.

INTRODUCTION

In adults the commonest causes of obstructive jaundice

are biliary stone disease, pancreatic cancer or chronic pancreatitis. A less frequent cause is a benign or malignant tumor arising from the papilla of Vater. Malignant tumors of papilla are usually adenocarcinomas. We present a patient who became icteric as a consequence of a malignant tumor infiltrating the papilla of Vater which histologically showed both neuroendocrine and adenocarcinomatous features.

CASE REPORT

A 67-year-old cholecystectomized woman was admitted to our department with symptoms of obstructive jaundice and cholangitis. Severe epigastric pain, fever and jaundice developed 1 d before presentation. The serum bilirubin level was 5.3 mg/dL, white cell blood count was $20.4 \times 10^3/\mu\text{L}$ and serum amylase and lipase activities were elevated to about six times the normal upper limit. Abdominal ultrasonography showed moderate dilatation of common bile duct. The patient underwent endoscopic retrograde cholangiopancreatography (ERCP) revealing the papilla of Vater was suggestive of adenoma i.e., was markedly enlarged and covered with smooth surfaced mucosa. Sphincterotomy was performed and biopsies were taken from the inner part of the ampulla. The histopathological diagnosis from biopsy specimens was carcinoid tumor, staining positive for chromogranin A and synaptophysin. The patient underwent surgical transduodenal excision of the ampulla. The postoperative histopathological examination showed a composite tumor i.e. mixed neuroendocrine carcinoma (NE)-adenocarcinoma neoplasm (Figure 1A and B). Immunocytochemical studies were used to delineate the NE component (chromogranin, synaptophysin, EMA, cytokeratin). The NE-cell component represented about 80% of the tumor's area. NE tumor cells were well-differentiated, lacked significant atypia and showed low grade malignancy (Ki-67 labelling index was 5%). The glandular component presented well-differentiated tubules (grade I). No necrosis was found in either the NE or glandular areas. The tumor focally involved lymphatic vessels and nerves and infiltrated the muscle of the ampulla. The margins of the excised tissue specimen were free of neoplasm and no neoplastic cells were found in periduodenal lymphatic nodes (T1N0M0). The patient

has been put under endoscopic, serological (CA 19-9, CEA, chromogranin A) and ultrasound surveillance. Six months after surgery she is doing well.

DISCUSSION

Gastroenteropancreatic Neuroendocrine Tumors (GEP/NETs) are rare neoplasms originating from the diffuse neuroendocrine system, involving 15 types of highly differentiated ectodermal cells located in the gastrointestinal tract and pancreas. The most common location of GEP/NETs is in the appendix (62% of cases), but they may also be found in small intestine (27%), lung (15%), undefined primary locations with hepatic metastases (12%) and other organs (3%)^[1]. GEP/NETs secrete peptides and neuroamines that cause distinct clinical syndromes, including carcinoid syndrome. Many tumors are, however, clinically silent until late presentation associated with mass effects. The current WHO classification categorizes GEP/NETs into: (1) well-differentiated neuroendocrine tumor; (2) low-grade malignant carcinoma; (3) high-grade malignant carcinoma and (4) mixed tumor: adenocarcinoma/neuroendocrine carcinoma^[2]. At present 14 terms are used to define tumors with mixed exocrine-endocrine features. Volante *et al*^[3] proposed classification based on the extension of each component and structural features of the NE component. Three separate patterns can be distinguished i.e. (1) NE tumors with focal non-NE component occupying less than 30% of the tumor, (2) mixed exocrine-endocrine carcinomas (NE or non-NE cells > 30%) and (3) non-NE carcinoma with NE component (< 30%). The type of tumor influences the prognosis, which improves with increasing contribution of NE component^[3]. About 50% of GEP/NETs are carcinoids found by chance during laparotomy or as hepatic metastases.

Carcinoids involving the papilla of Vater are rare lesions, accounting for 0.35% of all gastrointestinal carcinoids. So far, only 110 cases have been reported in the literature, mostly as individual case reports^[4]. These tumors are predominantly found on ERCP in patients with obstructive jaundice or acute biliary pancreatitis. In the presented case the tumor histologically was a mixed carcinoid-adenocarcinoma neoplasm (type IV). The concurrence of carcinoid with adenocarcinoma is an unusual phenomenon in the gastrointestinal tract, that has been reported in the oesophagus, stomach, small intestine, appendix, colon and rectum^[5-7]. To our knowledge, this is the seventh report of this rare neoplastic association in the duodenal periampullary region.

Abstract

This report describes a method for percutaneous transhepatic biliary stenting with a BLAKE Silicone Drain, and discusses the usefulness of placement of the drain connected to a J-VAC Suction Reservoir for the treatment of stenotic hepaticojejunostomy. Percutaneous transhepatic biliary drainage was performed under ultrasonographic guidance in a patient with stenotic hepaticojejunostomy after hepatectomy for hepatic hilum malignancy. The technique used was as follows. After dilatation of the drainage root, an 11-Fr tube with several side holes was passed through the stenosis of the hepaticojejunostomy. A 10-Fr BLAKE Silicone Drain is flexible, which precludes one-step insertion. One week after insertion of the 11-Fr tube, a 0.035-inch guidewire was inserted into the tube. After removal of the 11-Fr tube, the guidewire was put into the channel of a 10-Fr BLAKE Silicone Drain. The drain was inserted into the jejunal limb through the intrahepatic bile duct and was connected to a J-VAC Suction Reservoir. Low-pressure continued suction was applied. Patients can be discharged after insertion of the 10-Fr BLAKE Silicone Drain connected to the J-VAC Suction Reservoir. Placement of a percutaneous transhepatic biliary stent using a 10-Fr BLAKE Silicone Drain connected to a J-VAC Suction Reservoir is useful for the treatment of stenotic hepaticojejunostomy.

INTRODUCTION

In most operations for hepatic hilum malignancy, the intrahepatic bile duct at the hilum is divided from the hepatic artery, portal vein, and surrounding tissues. Biliary complications, such as leakage or stenosis, are caused occasionally by the presence of several small bilioenteric anastomoses^[1]. Stenosis of a bilioenteric anastomosis increases the risk of cholangitis and requires the long-term placement of a stent.

The BLAKE Silicone Drain (Ethicon, NJ, USA) is made of silicone; the entire drain is flexible, and channels along the sides, instead of holes, facilitate drainage. It is always used with a continuous suction device (J-VAC Suction Reservoir; Ethicon), which creates a closed drainage system. Drainage is very efficient: a larger area is in contact with tissue as compared with perforated drains, and fluid is efficiently removed by capillary pressure.

We have reported previously the effectiveness of a BLAKE Silicone Drain connected to a J-VAC Suction Reservoir for the management of pancreatic fistula^[2]. We also reported that a 10-Fr BLAKE Silicone Drain has been used as an external stent for a bilioenteric anastomosis during surgery for hepatic hilar malignancy^[3].

This report describes a method for percutaneous transhepatic biliary stenting with a BLAKE Silicone Drain, and discusses the usefulness of placement of the drain connected to a J-VAC Suction Reservoir for the treatment of stenotic hepaticojejunostomy.

Figure 1 Percutaneous drainage catheters were inserted into each abscess, and pus was discharged. Abscessography demonstrated communications between the dilated intrahepatic bile duct of the anterior branch and each abscess.

Figure 3 One week after initial insertion of the 11-Fr tube, cholangiography was performed via the tube. After insertion of a 0.035-inch guide wire, the 11-Fr tube was switched to a 10-Fr BLAKE Silicone Drain.

CASE REPORT

A 68-year-old man with intrahepatic cholangiocarcinoma invading the hepatic hilum underwent extended left hepatectomy combined with *en bloc* resection of the extrahepatic bile duct and extended lymph node dissection.

Bilioenteric continuity was reestablished by two hepaticojejunostomies of the anterior and posterior branches of the hepatic ducts, performed using a Roux-en-Y jejunal limb. Silicone drains with an internal lumen and side holes, made by cutting a 5-Fr radiopaque tube for pancreatic drainage (Sumitomo Bakelite, Tokyo, Japan), were used as an internal stent for each bilioenteric anastomosis. Two external drainage catheters (19-Fr BLAKE Silicone Drain) were positioned at the cut surface of the liver and connected to the J-VAC Suction Reservoir. Fixation of the greater omentum was performed to avoid delayed gastric emptying^[4]. After operation, major bile leakage occurred, but resolved gradually. The drainage catheter was removed on postoperative day 12, and the patient was discharged on postoperative day 18.

Forty days after discharge, the patient was readmitted because of severe pyrexia. Upon admission, computed tomography demonstrated two low-density areas associated with dilatation of the intrahepatic bile ducts in the anterior segment. Hepatic abscesses caused by stenosis of the hepaticojejunostomy were diagnosed.

Figure 2 The catheter (11-Fr PTCS tube, Sumitomo Bakelite, Tokyo, Japan) with several side holes was placed in the jejunal limb through the intrahepatic bile duct and passed through the stenosis of the hepaticojejunostomy.

Percutaneous drainage catheters were inserted into each abscess, and pus was discharged. Abscessography demonstrated communications between the dilated intrahepatic bile ducts of the anterior branch and each of the abscesses (Figure 1). Pyrexia improved, and discharge of clear bile from one of the drainage catheters continued. One week after insertion of the drainage catheters, abscessography was repeated. It was difficult to insert the catheter from the abscess into the intrahepatic bile duct. Another percutaneous transhepatic biliary drainage catheter was inserted directly into the intrahepatic bile duct under ultrasonographic guidance. An 11-Fr tube (11 Fr PTCS tube; Sumitomo Bakelite) with several side holes was placed in the jejunal limb through the intrahepatic bile duct, and passed through the stenosis of the hepaticojejunostomy (Figure 2). Bile juice was discharged from the 11-Fr tube, and discharge from the drainage catheters of the abscess decreased. One of the catheters was removed from the abscess because pus discharge stopped. One week after initial insertion of the 11-Fr tube, cholangiography was performed *via* the tube. A 10-Fr BLAKE Silicone Drain is flexible, which made one-step insertion difficult. After insertion of a 0.035-inch guide wire, the 11-Fr tube was switched to a 10-Fr BLAKE Silicone Drain (Figure 3). The drain was connected to a J-VAC Suction Reservoir, and continued low-pressure suction was applied. The remaining catheter was removed from the abscess. The patient was discharged 5 d after switching the 11-Fr tube to a 10-Fr BLAKE Silicone Drain connected to the J-VAC Suction Reservoir. After 4 mo, the patient was readmitted because of liver failure. The portal vein was obstructed by recurrent carcinoma. Three weeks after readmission, the patient died. The 10-Fr Blake Silicone Drain was not occluded.

DISCUSSION

Diagnostic techniques for hepatobiliary disease have improved recently, but advanced hepatic hilum malignancy is still encountered frequently^[5-7]. Palliative treatment with a biliary stent is carried out in patients with inoperable malignancy in order to relieve symptoms related to obstructive jaundice^[8]. In patients undergoing hepatectomy for advanced hepatic hilum malignancy, aggressive dissection may compromise the ductal blood supply. Peripheral branches of blood vessels,

with small diameters and a poor blood supply, may be damaged along with the bile duct, which increases the risk of biliary leakage^[1]. The use of stents has been recommended to decompress the bile duct, reduce the risk of bile leakage, and decrease fibrotic narrowing of the anastomosis during early healing^[9-12]. However, the risk of biliary complications such as leakage or stenosis is increased by the presence of small several bilioenteric anastomoses^[1].

We performed placement of a percutaneous transhepatic biliary stent using a 10-Fr BLAKE Silicone Drain connected to a J-VAC Suction Reservoir for the treatment of stenotic hepaticojejunostomy. BLAKE Silicone Drains promote efficient drainage: a larger area is in contact with tissue as compared with perforated drains, which facilitates the effective removal of fluid by capillaries. These drains contain no plasticizing agents, which are considered to have deleterious effects in humans. The channels do not interfere with removal, and the drains can be removed easily, safely and securely. These drains also provide a high flow rate when connected to a closed suction device (J-VAC Suction Reservoir). The suction pressure of the J-VAC Suction Reservoir is lower than that with other portable low-pressure continuous suction devices. As a result of low suction pressure, the J-VAC Suction Reservoir does not damage tissue; therefore, we used this drainage system in the lumen of the bile duct and jejunum.

We have evaluated previously the efficacy of a BLAKE Silicone Drain connected to a J-VAC Suction Reservoir for the management of pancreatic fistula. In basic experiments, no collections of fluid were detected around the BLAKE Silicone Drain. When leakage occurred, it did not cause an abdominal abscess, and a “drain canal” linking the anastomosis with the extracorporeal orifice was formed all along the drainage route^[2].

In the patient described in this report, 5-Fr silicon drains were used as a stent for the bilioenteric anastomosis. Stenosis of the anastomosis occurred after leakage. We used a 10-Fr BLAKE Silicone Drain as an external stent for bilioenteric anastomosis after major hepatectomy with pancreatoduodenectomy. The drain is placed within the hepaticojejunostomy *via* the stump of the jejunal limb. It is then connected to the J-VAC Suction Reservoir. Bile and pancreatic juice can be drained by a single drain. Even if bilioenteric anastomosis leaks, a 10-Fr intraluminal diameter of the anastomosis is maintained^[3].

The treatment of stenotic bilioenteric anastomosis requires the long-term placement of a stent in the anastomosis. The BLAKE Silicone Drain is flexible and contains no plasticizing agents. It has four continuous channels instead of holes along the sides, and prevents obstruction of small biliary branches. The BLAKE Silicone Drain is therefore suited for long-term placement. The input port of the J-VAC Suction Reservoir has an anti-reflux valve, which reduces the risks of the reverse flow of fluid into the body and of retrograde infection. This valve enables the patient to use the reservoir without having to worry about the level of the drainage bag during position changes and

ambulation. The J-VAC Suction Reservoir is portable and convenient in size, which enables the patient to carry it around in a specially designed pochette on the shoulder. A BLAKE Silicone Drain connected to a J-VAC Suction Reservoir usually remains free of occlusion for about 6 mo.

In conclusion, placement of a percutaneous transhepatic biliary stent using a 10-Fr BLAKE Silicone Drain connected to a J-VAC Suction Reservoir was useful for the treatment of stenotic hepaticojejunostomy.

INTRODUCTION

Sclerosing epithelioid fibrosarcoma (SEF) is a rare and poorly defined variant of fibrosarcoma, first described by Meis-Kindblom *et al*^[1] in 1995^[2-4]. It is a mesenchymal neoplasm characterized histopathologically by a predominant population of epithelioid cells arranged in strands, nests, and sheets, embedded in a fibrotic and extensively hyalinized stroma. Although the SEF belongs to the low-grade sarcoma group of neoplasms, approximately 50% of patients with the tumor develop local recurrence and/or metastases^[3-5].

Several investigators have reported cases of SEF arising from various sites such as upper extremities, lower extremities, limb girdles, trunk, and the head and neck area, but there have been no reports of SEF of the liver^[1-10]. Recently, we experienced a patient with SEF of the liver with invasion of the inferior vena cava (IVC). Although the SEF in the patient was surgically resected, it recurred after surgery. The recurrent SEF was also surgically resected. In addition to the rarity of the SEF of the liver, the SEF displayed a rare extension pattern

Abstract

Sclerosing epithelioid fibrosarcoma (SEF) is a rare and distinct variant of fibrosarcoma, composed of epithelioid tumor cells arranged in strands, nests, cords, or sheets embedded within a sclerotic collagenous matrix. We report a 39-year-old man with SEF of the liver, which infiltrated the inferior vena cava (IVC). The SEF of the liver was successfully resected, and the infiltrated IVC was also removed together with the liver tumor. Histopathological examination of the tumor showed typical histopathology of SEF. Immunohistochemically, the tumor was positive for vimentin. Recurrence was noted 7 mo after surgery. After chemotherapy, the recurrent tumor was resected surgically, and histopathological examination showed similar findings

of infiltration in the IVC. To our knowledge, there have been no previous reports of such kinds of tumor extension in SEF. In this article, we report the first case of SEF of the liver with invasion of the IVC.

CASE REPORT

A 39-year-old man presented with the chief complaint of general fatigue and abdominal uncomfotableness. Laboratory findings included no thrombocytopenia and liver enzymes above the normal range (alanine transaminase: 44 U/L, lactate dehydrogenase: 267 U/L, alkaline phosphatase: 412 U/L, and γ -glutamyltranspeptidase: 187 U/L). Hepatitis virus markers and autoantibodies were negative. Tumor markers including protein induced by vitamin K absence or antagonist II, α -fetoprotein (AFP), carbohydrate antigen 19-9 (CA19-9), and carcinoembryonic antigen were all within the normal ranges. Serum soluble interleukin-2 receptor level was not elevated. The patient did not consume alcohol and had no history of exposure to radiation. Computed tomography (CT) and magnetic resonance imaging (MRI) demonstrated a huge liver tumor measuring about 70 mm in diameter located in segment 1 based on Couinaud's classification, with invasion of the IVC adjacent to the site adjacent to the right atrium^[11] (Figure 1A and B). In addition, another liver tumor measuring 18 mm was found in segment 8 on the CT and MRI. Fluorodeoxyglucose-positron emission tomography/CT showed abnormal accumulations in both tumors.

With a preoperative diagnosis of primary malignant liver tumor of unknown origin with invasion of the IVC and possibly intrahepatic metastasis, laparotomy was performed. The huge tumor, which was located mainly in the liver, adhered to the diaphragm, right lower lobe of the lung, and pericardium. The tumor also adhered to the suprahepatic IVC. By using the total hepatic vascular exclusion technique (THVE), extended left hepatectomy with resection of the caudate lobe of the liver was performed. The diaphragm, the right lower lobe of the lung, and the pericardium were resected. Next, after clamping the suprahepatic IVC below the right atrium and the retrohepatic IVC above the renal veins, the adhered IVC wall was removed together with the liver. The resected IVC wall was replaced with an expanded polytetrafluoroethylene graft. Since the tumor in segment 8 was suspicious of intrahepatic metastasis, partial hepatectomy of segment 8 was also performed. No other liver tumors were found during surgery.

A macroscopic view of the resected tumor was shown in Figure 2. The tumor, measuring 68 mm \times 54 mm, was mainly located in segment 1 of the liver. Microscopically, the tumor mainly existed in the liver with invasion into neighboring extrahepatic soft tissue including the wall of the IVC and diaphragm. Moreover, tumor thrombi were identified in the left portal vein and its branches. The tumor consisted of uniformly round or polygonal epithelioid cells with a faintly eosinophilic cytoplasm (Figure 3A and B). The tumor cells were arranged in strands, nests, cords or sheets and embedded in a heavily hyalinized matrix. The microscopic findings of the

tumor in segment 8 were similar to those of the primary tumor, and that tumor was diagnosed as an intrahepatic metastasis. Immunohistochemical staining of the main tumor was positive for vimentin (Dakopatts, Glostrup, Denmark), bcl-2 (Dakopatts), and CD99 (Dakopatts), and was negative for AE1/AE3 (Dakopatts), CAM5.2 (Becton Dickinson, San Jose, CA), desmin (Dakopatts), epithelial membrane antigen (EMA) (Dakopatts), CD34 (Nichirei, Tokyo, Japan), S100, α -smooth muscle actin (α -SMA) (Dakopatts), neuron-specific enolase (Dakopatts), CD56 (Dakopatts), leukocyte common antigen (LCA) (Dakopatts), CD30 (Dakopatts), HMB45 (Dakopatts), AFP (Dakopatts), and CA19-9 (Zymed Laboratories Inc., San Francisco, CA) (Figure 3C). The MIB-1 labeling index (Dakopatts) was 30%. Moreover, cytogenetic analysis did not show t (X; 18) chromosomal translocation, which is frequently observed in synovial sarcoma^[12,13]. Based on the results of histopathological examination, cytogenetic analysis, and immunohistochemical patterns, the tumor was finally diagnosed as SEF. Although the tumor was associated with invasion to the wall of the IVC and diaphragm, the most part of the tumor existed in segment 1 of the liver. Moreover, tumor thrombi were identified in the right portal vein and its peripheral branches, and intrahepatic metastases, which were frequently seen in the primary liver malignant tumor. Therefore, the SEF probably originated from the liver. The resection margins were free of tumor. The noncancerous area of the liver was histologically normal. The patient had an uneventful postoperative course and was discharged from the hospital 24 d after surgery.

Seven months after surgery, the patient complained of back pain. CT examination showed recurrent SEF in the extrahepatic retroperitoneal tissue (Figure 1C and D). Systemic chemotherapy consisting of adriamycin and ifosfamide was applied. Close follow-up showed arrest of tumor growth and no new metastatic lesions within the first 3 mo. Subsequently, laparotomy was performed for the excision of the recurrent tumor 12 mo after the initial surgery. The recurrent tumor, located in the retroperitoneal tissue and adherent to the remnant liver, also infiltrated the graft IVC. Using the THVE approach, the tumor was resected with the adherent liver tissue and the infiltrated IVC graft. The resected IVC was again replaced with an expanded polytetrafluoroethylene graft. The microscopic findings of the resected tumor were similar to those of the primary SEF. The immunohistochemical staining patterns of the primary tumor and the recurrent tumor were also similar. The patient had an uneventful postoperative course and was discharged from the hospital 30 d after the surgery.

At the last follow-up examination 6 mo after the second surgery, he remains in good condition, with no evidence of recurrence.

DISCUSSION

SEF is a rare tumor characterized histopathologically by a predominant population of epithelioid cells arranged in strands, nests, cords, or sheets, which are

Figure 1 CT of the patient, showing the liver tumor infiltrating the suprahepatic inferior vena cava (A: Axial scan; B: Coronal scan), and showing the recurrent tumor (C: Axial scan; D: Coronal scan).

embedded within a sclerotic collagenous matrix^[1-4]. Immunohistochemically, staining for vimentin is positive in all SEF whereas staining for CD34, leukocyte markers, HMB45, CD68, desmin, glial fibrillary acidic protein, and TP53 is negative. Focal and weak immunostaining for EMA, S100 and more rarely for cytokeratins may be seen in a minority of cases.

The histopathological differential diagnosis of SEF generally includes a wide variety of tumors with sclerotic or epithelioid features, and thus immunohistochemical analysis is essential for precise diagnosis of SEF. In the present case, differential diagnosis was challenging for the following reasons. Undifferentiated hepatocellular carcinoma and infiltrating adenocarcinoma should be differentiated from SEF, but immunohistochemical staining for AFP, CAM5.2, and AE1/AE3 was negative in the present case. Synovial sarcoma should also be differentiated from SEF. Cytogenetic identification of t (X: 18), which is found in synovial sarcoma, could differentiate synovial sarcoma from SEF^[12,13]. No chromosomal translocation was observed in the present case. Furthermore, smooth muscle neoplasms, such as hyalinized leiomyoma or leiomyosarcoma, frequently resemble SEF histopathologically, but they are characterized by immunohistochemical positivity for α -SMA and desmin. Clear cell sarcoma and malignant peripheral nerve sheath tumors may need to be distinguished from SEF. However, these tumors are positive for S100 immunostaining. Moreover, sclerosing lymphoma and malignant melanoma of the soft part are also on the list of differential diagnoses,

but these tumors are usually positive for LCA and HMB45, respectively, and were negative in our case. Epithelioid hemangioendothelioma could be ruled out based on immunonegativity for CD34, and alveolar rhabdomyosarcoma could be excluded by the negative result of desmin and absence of rhabdomyoblasts. Moreover, absence of osteoid formation excluded traosseous osteosarcoma in the present case. Thus, taking into consideration not only the histopathological findings but also the results of cytogenetic analysis and immunohistochemical examinations, the tumor was finally diagnosed as SEF.

In reviewing previous reports, SEFs usually arise in the deep soft tissue and are frequently associated with the adjacent fascia or periosteum. Most SEFs are located in the lower extremities and limb girdles, followed by the trunk, upper extremities, and the head and neck area^[1-10].

In this case, although the tumor was associated with invasion to the wall of IVC and diaphragm, the most part of the tumor existed in the liver. Moreover, in this case, tumor thrombi and intrahepatic metastases were concurrently identified. These features might suggest that the tumor had originated in the liver. To our knowledge, there have been no reports of SEF originating from the liver.

The etiology of most malignant soft tissue tumors, including SEF, is generally unknown. A recent report reviewed 90 patients with SEF and found no significant gender difference with a mean patient age of 47 years (range, 14-87 years)^[5]. The average tumor size at diagnosis is about 8 cm. Several investigators reported previously

Figure 2 Macroscopic findings of the resected tumor. A: The tumor was directly contiguous to the normal liver parenchyma; B: Tumor thrombus was identified in the left portal vein (arrow).

the association between radiation and occurrence of fibrosarcoma, though our patient had no history of radiation^[9,14].

The established treatment for SEF is complete resection. There is no evidence to support the effect of chemotherapy and/or radiotherapy, though these therapies were used in some previous reports^[3,10]. As for prognosis, Chow *et al*^[4] reported 57 patients with SEF with a local recurrence rate of 48%, metastasis rate of 60%, and mortality rate of 35%. Moreover, in a study of 16 patients with SEF by Antonescu *et al*^[3], the local recurrence rate, metastasis rate, and mortality rate were 50%, 86% and 57%, respectively^[5]. Distant metastasis is reported to be most common in the lung, followed by bone, soft tissue, brain, and lymph nodes^[1-5]. These previous reports of poor prognosis suggest that SEF is a clinicopathologically distinct soft tissue tumor with malignant potential although it is categorized as a low-grade neoplasm in the sarcoma group.

In our case, since no distant metastasis was found preoperatively and since complete resection was thought possible, we selected surgical resection although the tumor had extended at the time of surgery into the IVC, in addition to local intrahepatic metastasis. Indeed, we could completely resect the tumor macroscopically, but the tumor recurred postoperatively. It is quite possible that malignant cells remained at the tumor bed after the resection despite our careful endeavor. Alternatively, considering the high recurrence rate of SEF reported previously, it is also possible that malignant cells might have already exfoliated from the tumor extending to IVC and presumably reached other organs before the resection. Thus, when surgical resection is selected for

Figure 3 Histopathological findings of the resected liver tumor. A, B: Hematoxylin-eosin staining; C: Immunohistochemical staining for vimentin. A: The tumor (right side) was close to the normal liver parenchymal tissue (left side) ($\times 4$); B: The tumor consisted of uniformly round or polygonal epithelioid cells, which were arranged in strands, nests, cords or sheets and embedded in a heavily hyalinized matrix ($\times 40$); C: Positive immunohistochemical staining for vimentin ($\times 40$).

SEF, perioperative chemotherapy and/or radiotherapy, in addition to macroscopic complete resection, may be necessary to prevent recurrence, though there is no established effective and standardized regimen of chemotherapy and/or radiotherapy. To clarify the effect of perioperative chemoradiotherapy, in addition to surgical resection, further study with a larger number of SEF cases treated perioperatively is needed.

Abstract

Metastatic penile carcinoma is rare and usually originates from genitourinary tumors. The presenting symptoms or signs have been described as nonspecific except for priapism. Rectal adenocarcinoma is a very unusual source of metastatic penile carcinoma. We report a case of metastatic penile carcinoma that originated from the rectum. Symptomatic improvement occurred with palliative radiotherapy.

INTRODUCTION

Metastatic tumors of the penis are rare despite an abundant blood supply to the penis. Approximately 300 cases have been reported in the clinical literature^[1]. Primary sites of origin are the bladder (33%), prostate (30%), colon (17%)

and kidney (7%)^[2]. Extra-pelvic sites including the lung, pancreas, stomach, esophagus, melanoma and testis have been noted^[3-6]. Fewer than 60 cases of penile metastasis from colon cancer have been reported. Penile metastasis has been a part of more widespread disease in about 90% of reported cases^[7]. We report a case of a painful penile metastasis as a manifestation of rectal cancer dissemination that was improved by the use of palliative radiotherapy.

CASE REPORT

A 43-year-old man was admitted to our clinic with a penile erection and pain. Two years earlier, the patient had undergone abdominoperineal resection for adenocarcinoma of the rectum, followed by adjuvant chemoradiotherapy with capecitabine. Postoperative pathology revealed a moderately differentiated adenocarcinoma and pathological T3 tumor with metastases in 15 out of 37 regional lymph nodes. Thirteen months earlier, recurrence of rectal cancer was detected in the abdominal para-aortic nodes. Various palliative chemotherapeutic agents were administered for 11 mo and the patient received no further treatment. One month earlier, penile erection and pain developed.

Physical examination showed no visible skin lesions, but multiple palpable hard nodules were present over the penile shaft. Tenderness developed following palpation of the penis.

The penile lesions had multifocal, irregular-shaped, low-density areas as depicted on pelvic computed tomography (CT) images, and these lesions had increased in size and number as compared with previous CT images obtained 3 mo previously (Figure 1). Positron emission tomography (PET) showed low 18F- fluorodeoxyglucose uptake in the lesions (Figure 2). Penile magnetic resonance imaging (MRI) showed low to iso-intensity signals as compared with the surrounding corpus cavernosum on an axial T1-weighted image, low to intermediate signal intensity on an axial T2-weighted image, and the presence of non-enhanced lesions on a gadolinium-enhanced image (Figure 3). Other sites of metastasis were noted in several para-aortic lymph nodes, lung and vertebral body of the L2 spine.

Fine needle aspiration of the nodules was performed and histological examination showed nests of acinar-like cells with cytological atypia, consistent with metastatic adenocarcinoma from primary rectal cancer (Figure 4).

Intravenous morphine infusion and spinal nerve block were given for control of penile pain, but were ineffective. Other treatment options were required but

Figure 1 CT image. A: Multifocal irregular shaped low-density areas along the penis; B: Multifocal irregular shaped low density areas are also seen in an CT image obtained 3 mo earlier.

Figure 2 PET image showed low 18F-fluorodeoxyglucose uptake in the lesions.

the patient was in a chemotherapy refractory and systemic disseminated state. As a result of poor performance status, the patient was not allowed to undergo palliative partial or total penectomy. We offered the patient the option of undergoing palliative external beam radiation (2600 cGy, 13 fractions), which was preformed successfully. Penile pain was relieved and the patient was discharged from the hospital.

DISCUSSION

The reason why the penis is a rare site for metastasis despite rich vascularization is not clear. Various mechanisms for penile metastasis have been suggested. These include retrograde venous spread, retrograde lymphatic spread,

Figure 3 Penile MRI. A: Low to iso signal intensity as compared with the surrounding corpus cavernosum on an axial T1-weighted image; B: Low to intermediate signal intensity on an axial T2-weighted image; C: The presence of non-enhanced lesions on a gadolinium-enhanced image.

Figure 4 Fine-needle aspiration of penile mass showed nests of acinar-like cells with cytological atypia, consistent with metastatic adenocarcinoma (Papanicolaou stain, $\times 400$).

arterial embolism and local direct extension^[3]. Currently,

a route that involves retrograde venous spread from the pudendal into the dorsal venous system of the penis is considered as the most likely mechanism.

Presenting symptoms and signs in order of frequency are malignant priapism (40%), urinary retention, penile nodules, ulceration, perineal pain, edema, generalized swelling, broad infiltrative enlargement, dysuria and hematuria^[1]. Penile metastasis must be differentiated from primary penile cancer, chancre, chancroid, non-tumorous priapism, Peyronie's disease, tuberculosis and other inflammatory and suppurative diseases^[8]. The corpus cavernosum is usually the site of involvement of metastatic penile carcinoma. The glans penis and corpus spongiosum are involved rarely.

Penile lesions require an excisional or fine-needle aspiration biopsy for pathological confirmation. However, radiological evaluations such as CT, MRI and PET are useful noninvasive methods for the evaluation of lesions^[3,9].

Penile metastases typically manifest as multiple discrete masses in the corpus cavernosum. Noninvasive modalities such as CT, MRI and PET are being used increasingly. CT has been used in the evaluation of penile lesions. Due to only single-plane imaging, its use is limited and it may not detect penile metastasis^[9]. MRI is a most reliable alternative for diagnosis and assessing the extent of penile metastasis, with its multi-plane imaging and superior soft tissue contrast. These masses have low signal intensity relative to normal corporal tissues in T1-weighted images, and low or high signal intensity in T2-weighted images^[9-11]. PET is also useful for detection of clinically silent metastatic sites in hypermetabolic cancer^[5,11].

The treatment plan depends on the performance status and primary cancer state of the patient. Treatment modalities include local excision, penectomy, chemotherapy and radiotherapy. Most patients with penile metastasis already have widely disseminated disease, and > 80% of the patients will die within 6 mo, irrespective of the primary tumor and the treatment method, making palliative noninvasive treatment advisable.

In conclusion, we report a case of painful priapism secondary to penile metastasis of rectal cancer, which was improved by palliative radiotherapy. Most patients with metastatic penile carcinoma have developed systemic dissemination and early detection, precise diagnosis and noninvasive treatment are required for improvement of quality of life.

Abstract

A desmoplastic small round cell tumor (DSRCT) is a rare, aggressive mesenchymal neoplasm. Although a DSRCT can develop at various sites, the intra-abdominal site is the most common location. These tumors are found most commonly among young adolescents and the prognosis is extremely poor. Multimodal treatment with surgery, chemotherapy and radiotherapy is very important for these rare cases, and this treatment can improve patient survival. In this report, we describe the case of an 8-year-old boy diagnosed with DSRCT located in the retroperitoneal space. The patient has undergone surgical resection and adjuvant chemoradiation therapy, and is currently alive without disease recurrence.

INTRODUCTION

A desmoplastic small round cell tumor (DSRCT) is a rare, aggressive mesenchymal neoplasm with an extremely poor prognosis. It was described initially as a distinct clinicopathological entity by Geral and Rossi in 1989^[1]. This rare, highly malignant tumor belongs to the primitive tumor family of small round cell tumors (lymphoma, neuroblastoma, alveolar rhabdomyosarcoma, Ewing's sarcoma, neuroectodermal tumor, and DSRCT)^[2,3]. Young adolescent males are most commonly affected^[4]. Its primary location is in intra-abdominal sites, but it can also be found at other sites such as the kidney and ovary, as well as in the retroperitoneal space^[5-7]. In addition, these tumors are associated with a specific reciprocal translocation t (11;22) (p13;q12) that leads to the fusion of the WT1 (Wilms' tumor gene) and EWS (Ewing's sarcoma gene). Patients with this tumor have a very poor prognosis, but multimodal treatment with surgery, chemotherapy and radiotherapy can improve survival^[8,9].

We describe here a case of retroperitoneal DSRCT in a boy, who was treated with surgery and adjuvant chemoradiotherapy.

CASE REPORT

An 8-year-old boy with no previous health problems was referred to our hospital with a 2-wk history of a palpable abdominal mass. The family history was non-contributory and there were no complaints except for abdominal pain and indigestion. The physical examination showed an approximately 20-cm palpable abdominal mass predominantly on the right side of the abdomen, with mild tenderness. The laboratory tests showed no significant abnormalities. Computed tomography (CT) showed a septated, very large (21 cm × 17 cm), predominantly cystic, lobulated mass in the right upper quadrant of the abdomen between the liver and the right kidney (Figure 1). The vena cava and the duodenum were deviated to the left side of the abdomen because of the mass effect of the lesion. Upon magnetic resonance imaging (MRI), the lesion had a T1-attenuated high signal suspicious for a high protein content, a predominantly cystic portion with a large solid portion on the medial aspect, and no definite direct invasion into the major vessels. The radiologist suspected an undifferentiated embryonal sarcoma that originated from the liver, or a

Figure 1 CT (A and B) shows a septated, very large (about 21.8 cm × 16.7 cm), predominantly cystic, lobulated mass in the right upper quadrant between the liver and the right kidney.

Figure 3 Histopathological findings. Tumor cells consist of small round, hyperchromatic nucleus and scanty cytoplasm (Hematoxylin and eosin stain, × 400).

mesenchymal hamartoma. Surgery was planned for a definitive diagnosis and a proper management.

The operative findings revealed a mass of about 20 cm, irregular in shape, with cystic and solid components. As it was located in the retroperitoneal space, the liver, inferior vena cava, duodenum, right kidney, and intestine were deviated to the left and downward. To obtain a good operative field, we aspirated about 500 mL of brown-colored cystic fluid from the cystic portion of the tumor, and a small portion was excised for frozen sections. Examination of frozen sections revealed that the tumor was highly suggestive of malignancy, and we excised the entire lesion. Since there were severe adhesions to the surrounding tissue and important abdominal vessels such as the inferior vena cava, right renal vessels and celiac trunk, the dissection required a long time and there was a large amount of bleeding. Grossly, there was no evidence of peritoneal seeding or hepatic metastasis. The mass was totally removed without significant problems (Figure 2). The operative time was 500 min, blood loss was about 2 L and eight units of packed red blood cells were transfused. The microscopic examination confirmed a retroperitoneal DSRCT, with the typical appearance of well-defined nests or clusters of small undifferentiated round cells, surrounded by a prominent desmoplastic stroma (Figure 3). Upon immunohistochemical staining, there were positive responses to cytokeratin, vimentin, CD99, and desmin (Figure 4). In addition, there were focal weak positive responses to S-100 and neuron-specific enolase (NSE).

Figure 2 Gross findings after resection show a hemorrhagic and necrotic solid mass with a focal fibrotic, granular cut surface.

After confirmation of the diagnosis, postoperatively, the patient received adjuvant chemotherapy (vincristine, ifosfamide, doxorubicin, etoposide and cyclophosphamide) in combination with consolidating radiotherapy (25 times 180 cGy/d, a total dose of 45 Gy). The patient is free of disease recurrence 24 mo after resection and adjuvant chemoradiotherapy.

DISCUSSION

DSRCT is an aggressive malignant tumor with a poor prognosis. Abdominal pain or discomfort is the most common presentation for this rare neoplasm. Its primary location is the intra-abdominal peritoneal cavity, but many other sites have been described^[10]. The most common sites of peritoneal involvement have been reported to be the pelvic space, omentum, small bowel mesentery, and the retroperitoneal space. This tumor is typically found in young adolescent men (male:female ratio = 5:1). Usually, it is accompanied by extensive peritoneal seeding at the time of diagnosis^[9,10].

Although the findings are nonspecific, CT is the most widely used diagnostic modality for identifying this tumor. It can detect a bulky, lobulated and heterogeneous mass with or without calcification. Sometimes, ascites, adenopathy or liver metastases are found. Upon MRI, T2-weighted imaging shows a heterogeneous hyperintense signal with low or isodense T1-weighted signals. No specific tumor markers have been identified^[11].

Histopathologically, the characteristic findings are well-defined nests or clusters of undifferentiated small round cells, surrounded by a prominent desmoplastic stroma. The tumor cells are characterized by small hyperchromic nuclei with scanty cytoplasm. Immunohistochemistry can be positive for AE1/AE3 (88%), desmin (dot pattern, 81%), CD99 (23%), or NSE (84%)^[11]. This tumor is associated with a specific reciprocal translocation t (11:22) (p13;q12), which leads to fusion of the WT1 and EWS genes; this rearrangement is detected in almost all cases. The resulting chimeric protein is thought to be a transcriptional activator that fails to suppress tumor cell growth^[3].

Although the prognosis is very poor, aggressive surgical tumor resection is the major determinant of patient survival. Lal *et al*^[9] recommended surgical resection

Figure 4 Immunohistochemical staining was positive for cytokeratin (A), vimentin (B), CD99 (C) and desmin (D) ($\times 400$).

of $> 90\%$ of the tumor burden. Attempts were not made to achieve microscopically negative resection margins. They used systemic chemotherapy, with the P6 protocol including cyclophosphamide, doxorubicin, vincristine, ifosfamide and etoposide. They reported a good response with this regimen. Adjuvant radiotherapy to the whole abdominopelvic area was also delivered. With this multimodal therapy, including the P6 protocol, $> 90\%$ resection, and adjuvant radiotherapy, there was a statistically significant prolongation of patient survival^[9]. The presence of nodal invasion and metastasis does not appear to correlate with overall patient survival. The expected 3-year survival was only 27% when multimodal treatment was not used^[9]. We used a similar strategy for the treatment of our patient; the patient is free of disease recurrence 2 years after surgery and adjuvant chemoradiotherapy. The platelet-derived growth factor receptor pathway inhibitor SU101 (leflunomide) is being studied in a pediatric phase I trial. The possibility of improved future treatments might help to prolong the survival of patients with DSRCT^[12].

In summary, we present a patient with retroperitoneal DSRCT, and expect a longer survival as a result of our aggressive surgical resection and adjuvant chemoradiotherapy.

Abstract

Enterovesical fistulas are not uncommon in patients with inflammatory or malignant colonic disease, however, fistulas secondary to primary bladder carcinomas are extremely rare. We herein reported a patient presenting with intractable urinary tract infection due to enterovesical fistula formation caused by a squamous cell carcinoma of the urinary bladder. This patient underwent *en bloc* resection of the bladder dome and involved ileum, and recovered uneventfully without urinary complaint. To the best of our knowledge, this is the first case reported in the literature.

INTRODUCTION

Enterovesical fistulas are not uncommon in patients with inflammatory or malignant colonic disease, however, fistulas secondary to primary bladder carcinomas are extremely rare^[1-3]. We herein report a patient presenting with intractable urinary tract infection due to enterovesical fistula formation caused by a squamous cell carcinoma of the urinary bladder. To the best of our knowledge, this is the first case reported in the literature.

CASE REPORT

An 83 year-old male presented with a 4-mo history of recurrent urinary tract infection. He had a history of benign prostate hyperplasia (American Urology Association score 24) that was under medical treatment. In order to correct urine retention and prevent urinary tract infection, photosensitive vaporization of the prostate had been performed. One month after the operation, the patient suffered from urinary tract infection again. The urine culture contained multiple flora of the gastro-intestinal tract including: *Escherichia coli*, *Viridans streptococcus*, *Klebsiella*, *Pneumoniae* and *Enterococcus faecium*. Retrograde urethrography showed leakage of the contrast and cystoscopy disclosed a fistula in the right posterior wall of the bladder with edematous tissue surrounding the fistula (Figure 1). Abdominal and pelvic computed tomography showed a very large neoplasm in the pelvic cavity with suspicion of vesicoileal fistula formation. Under the impression of malignant enterovesical fistula, the patient underwent surgical intervention. At laparotomy, a 10 cm-diameter whitish stony hard tumor was located in the pelvis, involving the distal ileum and urinary bladder, with a frank fistula formation. Resection of the urinary bladder dome and the involved ileum was performed in *en bloc* fashion (Figure 2). The pathology report yielded a moderately differentiated squamous cell carcinoma of the urinary bladder with direct invasion of the terminal ileum (Figure 3). This patient recovered uneventfully and was discharged without urinary tract infection on post-operative day 7.

DISCUSSION

Enterovesical fistula is a rare disease, with an estimated two to three patients per 10 000 hospital admissions, with annular incidence of 0.5 per 100 000^[1]. In a literature

Figure 1 Cystography showed an enterovesical fistula (arrow). B: Urinary bladder; I: Ileum.

Figure 2 Surgical specimen of urinary bladder dome and ileum resected *en bloc*. B: Urinary bladder; I: Ileum.

Figure 3 Microscopic examination yielded the diagnosis of squamous cell carcinoma of the urinary bladder. HE staining, original magnification $\times 40$. T: Tumor burden.

review, 20% of vesicoenteral fistulas were rectovesical fistulas and 4%-5% were appendicovesical fistulas. Carson *et al*^[2] reported 100 cases of enterovesical fistulas with 51% colonic diverticulitis, 16% colorectal cancer, 5% urinary bladder carcinoma and 16% due to other causes, including secondary to radiation necrosis, cervical cancer, tuberculoma and iatrogenic perforation.

The most common histologic type of bladder cancer leading to enterovesical fistula is transitional cell carcinoma. Primary squamous cell carcinoma of the bladder is a relatively rare tumor. The prevalence of squamous cell carcinoma varies depending on geographic location. It accounts for only 3%-7% of bladder cancers in the United States and 1% in England, but up to 75% in Egypt, where schistosomiasis is endemic^[4]. Squamous cell carcinoma are usually related to chronic infection, bladder stones, chronic indwelling catheters or bladder diverticula. To our knowledge, this is the first report of vesicoenteral fistula as a result of bladder squamous cell carcinoma. Only one case of vesicorectal fistula from invasive rectal squamous cell carcinoma cancer had been reported^[5]. Almost all squamous cell carcinomas are already advanced and muscle-infiltrative at the time of diagnosis^[6]. Squamous cell carcinomas of the bladder have an unfavorable prognosis due to a local advanced stage at the time of presentation.

The most common clinical presentations of entero-

vesical fistulas are urinary tract infection (100%), pneumaturia (66%), fecaluria (50%), and hematuria (22.6%)^[3].

Diagnostic tests include cystoscopy examination, retrograde cystography, and computed tomography. The diagnostic rate using cystoscopy examination is 77%-79%^[2,7], while retrograde cystogram and computed tomography showed the fistulous tract in 66.6% and 83.3%, respectively^[8,9]. Barium enema or small bowel series have a 20%-35% diagnostic rate to indicate the fistula^[4]. Under cystoscopy examination, the fistula may be seen within a hyperemic area at an early stage of the disease, and with cystic mucosal hyperplasia or localized granulation tissue at the late stage^[10,11]. Computed tomography has the advantage of showing the fistula tract or gas distinctly in the bladder. In addition, it is useful in delineating the extent of disease involvement, visualizing the anatomic relationship of the adjacent organs and detecting distant metastasis for malignant diseases, which accordingly allows tailoring of the management strategy^[7,12,13].

Optimal work-up of a malignant of enterovesical fistula includes detection of the fistula and anatomic extension using the aforementioned diagnostic tests and definitive pathological confirmation, if possible. Except for elderly people in generally poor condition, diverting enterostomy and indwelling urethral catheters are not recommended as permanent treatments for enterovesical fistulae^[3].

Whitely and Grabtald proposed that a one-stage *en bloc* resection of the colonic malignancy and involved bladder portion is a reasonable and safe procedure^[7,11], avoiding a total cystectomy. Patients must be well-prepared, non-obstructive and without systemic infection before the surgery^[1,11,12,14,15]. However, if resection of the bladder is too wide, resulting in a total cystectomy, reconstruction to restore intestinal continuity and provide adequate bladder capacity and continence is pertinent. On the other hand, if the tumor is deemed unresectable and there is a short life expectancy, a palliative surgical procedure with enterostomy, with or without urinary diversion, is suggested^[12,16].

The 5-year survival rate for colon cancer with enterovesical fistula is 81% in nodal negative patients (T4N0), compared with 27% in nodal positive patients (T4N1)^[17].

Looser *et al*^[16] also suggested that colonic cancer with a perforation into the bladder could be treated by resection for a curative purpose, obtaining long-term survival in 50% of the patients^[7,16]. Nevertheless, Vidal Sans *et al*^[3] reported that surgical morbidity and mortality is relatively high, especially in fistula resulting from malignancy. Despite various methods of treatment for enterovesical fistula, the prognosis for patients with an advanced stage of malignant fistulae is dismal.

Abstract

The current ulcerative colitis (UC) treatment algorithm involves a step-up therapeutic strategy, mainly aiming at inducing and maintaining its clinical remission. Although this therapeutic strategy may seem to be cost-efficient and reduce the risk of side effects, recent trials and case reports have shown that top-down therapy using infliximab induces a rapid clinical response, enhances patient quality of life, promotes mucosal healing, reduces surgeries and indirect cost of treatment for patients with severe UC. Moreover, since long-term treatment with infliximab is safe and well tolerated, early aggressive top-down therapeutic strategy may be a more effective approach, at least in a subgroup of severe extensive UC patients.

INTRODUCTION

Since ulcerative colitis (UC) cannot be cured by

medication, therapeutic strategy is very important for patients with UC. The UC treatment algorithm includes a early aggressive or top-down therapeutic strategy and a sequential or step-up regimen. Recently, the emergency of effective biological therapy in the treatment of UC has led to a clinical debate about “top-down *vs* step-up strategy” which describes two opposite approaches. Since one approach is not suitable for all patients with UC, therapeutic strategy ought to be tailored to the individual patient so as to maximize efficacy while balancing risk and cost. In this letter the benefits, safety and costs of alternative strategies will be critically appraised.

TO THE EDITOR

I read with great interest the case report recently published in the *World Journal of Gastroenterology* by Cury *et al*^[1]. The authors reported a case in which infliximab was safely and effectively administered to a patient with severe and extensive UC. Upon reading this interesting case report, two questions arose in my mind.

First, the white blood cell (WBC) count of 161 000/mm³ or $161 \times 10^9/L$ reported in the case, which is markedly elevated because the normal WBC concentration is 4000-10 000/mm³, remains to be elucidated. Although a high WBC count can occur in infections, toxins, acute hemolysis, trauma and malignancies, the leukocytosis described in the case report might be due to leukemoid reaction, leukemia and other myeloproliferative disorders since WBC concentration is over 30 000/mm³. However, the leukocytosis reported in the case report was not permanent and progressive, and infectious precipitants were ruled out^[1]. Moreover, since no endoscopic evidence is available to support toxic megacolon, there might be an error in the WBC count or in a leukemoid reaction in the case report, the cause for which is not clear.

Second, whether top-down therapeutic strategy should be implemented in patients with severe and extensive UC which extends beyond the splenic flexure but not to the cecum. In a recently published consensus, a sequential or step-up therapy, mainly aiming at inducing and maintaining its clinical remission, has been advocated for patients with severe extensive UC which is best defined by True-love and Witts criteria^[2]. The step-up therapeutic strategy may seem to be cost-efficient for the vast majority of UC patients and reduce the risk of side effects. However, this sequential strategy did not induce mucosal healing

and could not achieve the best attainable quality of life until infliximab was administered to the reported patient. In addition, early aggressive therapy with infliximab and azathioprine may reduce the indirect cost of treatment for patients. More recent studies have shown that top-down therapy using infliximab induces a rapid clinical response, has a steroid-sparing effect, enhances patient quality of life, promotes mucosal healing, and reduces hospital stay time and surgeries^[3-6]. The reasons why the step-up strategy is advantageous over the top-down are concerned with its side effects and costs of biological agents. However, it was reported that long-term treatment with infliximab is safe and well tolerated and not associated with excess mortality or malignancies^[5,7]. Moreover, an 8-wk maintenance treatment schedule with infliximab appears to be a cost-effective treatment option for adult patients suffering from moderate to severe UC^[8]. Therefore, the top-down approach is appealing and can result in a modification in the natural course of UC, at least in a subgroup of patients with severe and extensive UC.

Since the top down approach is not suitable for all patients with UC, the future challenge is to identify a subgroup of patients who will develop complicated diseases or are therapy refractory at a later time point and for whom infliximab treatment in the early phase may change the natural history of UC.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (World J Gastroenterol ISSN 1007-9327, DOI: 10.3748) is a weekly, peer-reviewed, online, open-access (OA) journal supported by an editorial board of 1126 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in *WJG* will include the following. (1) Editorial: to introduce and comment on major advances in rapidly developing areas and their importance. (2) Frontier: to review recent developments and comment on current research status in important fields, and propose directions for future research. (3) Topic Highlight: this column consists of three formats, including: (a) 10 invited review articles on a hot topic; (b) a commentary on common issues associated with this hot topic; and (c) a commentary on the 10 individual articles. (4) Observation: to update the development of old and new questions, highlight unsolved problems, and provide strategies for their resolution. (5) Guidelines for Basic Research: as suggested by the title. (6) Guidelines for Clinical Practice: to provide guidelines for clinical diagnosis and treatment. (7) Review: to review systemically the most representative progress and unsolved problems, comment on current research status, and make suggestions for future work. (8) Original Article: to report original and innovative findings. (9) Brief Articles: to report briefly on novel and innovative findings. (10) Case Report: To report a rare or typical case. (11) Letters to the Editor: to discuss and reply to contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest. (12) Book Reviews: to introduce and comment on quality monographs. (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities on basic research and clinical practice

The WJG Press and Baishideng

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments,

References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS AND DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of *P* values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: <http://www.wjgnet.com/wjg/help/14.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No.62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Telephone: +86-10-59080039

Fax: +86-10-85381893

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Language evaluation

The language of a manuscript will be graded before it is sent for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

World Journal of Gastroenterology®

Weekly Established in October 1995

Volume 15 Number 34
September 14, 2009

Contents

EDITORIAL

- 4225 Overview of immunosuppression in liver transplantation
Pillai AA, Levitsky J
- 4234 Prevalence, predictors, and clinical consequences of medical adherence in IBD: How to improve it?
Lakatos PL

REVIEW

- 4240 Advances in diagnosis, treatment and palliation of cholangiocarcinoma: 1990-2009
Aljiffry M, Walsh MJ, Molinari M
- 4263 Emerging treatments for complex perianal fistula in Crohn's disease
Taxonera C, Schwartz DA, García-Olmo D

BRIEF ARTICLES

- 4273 Meta-analysis and systematic review of colorectal endoscopic mucosal resection
Puli SR, Kakugawa Y, Gotoda T, Antillon D, Saito Y, Antillon MR
- 4278 Sirolimus, bevacizumab, 5-Fluorouracil and irinotecan for advanced colorectal cancer: A pilot study
Ghiringhelli F, Guiu B, Chauffert B, Ladoire S
- 4284 Effect of early propranolol administration on portal hypertensive gastropathy in cirrhotic rats
Rafailidis S, Demertzidis C, Ballas K, Alatsakis M, Symeonidis N, Pavlidis T, Psarras K, Tzioufa-Asimakopoulou V, Sakadamis A
- 4290 Does *Helicobacter pylori* eradication therapy for peptic ulcer prevent gastric cancer?
Mabe K, Takahashi M, Oizumi H, Tsukuma H, Shibata A, Fukase K, Matsuda T, Takeda H, Kawata S
- 4298 Small sphincterotomy combined with endoscopic papillary large balloon dilation *versus* sphincterotomy
Kim HG, Cheon YK, Cho YD, Moon JH, Park DH, Lee TH, Choi HJ, Park SH, Lee JS, Lee MS
- 4305 Prognostic analysis of patients with pancreatic head adenocarcinoma less than 2 cm undergoing resection
Chiang KC, Yeh CN, Lee WC, Jan YY, Hwang TL

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

Continued advances in surgical techniques and immunosuppressive therapy have allowed liver transplantation to become an extremely successful treatment option for patients with end-stage liver disease. Beginning with the revolutionary discovery of cyclosporine in the 1970s, immunosuppressive regimens have evolved greatly and current statistics confirm one-year graft survival rates in excess of 80%. Immunosuppressive regimens include calcineurin inhibitors, anti-metabolites, mTOR inhibitors, steroids and antibody-based therapies. These agents target different sites in the T cell activation cascade, usually by inhibiting T cell activation or *via* T cell depletion. They are used as induction therapy in the immediate peri- and post-operative period, as long-term maintenance medications to preserve graft function and as salvage therapy for acute rejection in liver transplant recipients. This review will focus on existing immunosuppressive agents for liver transplantation and consider newer medications on the horizon.

Pillai AA, Levitsky J. Overview of immunosuppression in liver transplantation. *World J Gastroenterol* 2009; 15(34): 4225-4233 Available from: URL: <http://www.wjgnet.com>

INTRODUCTION

Due to advances in immunosuppression and improvements in surgical techniques, liver transplantation has become an extremely successful treatment option for patients with end-stage liver disease, with one-year graft survival rates exceeding 80%^[1]. Currently, there are eight patients worldwide who have survived more than three decades after liver transplantation^[2].

Organ transplantation initially came to light with the first successful kidney transplantation in 1954 on monozygotic twins; however, immunosuppression was limited to total body irradiation which was largely fatal^[3,4]. With the invention of 6-mercaptopurine (6-MP) and azathioprine (AZA) in the 1950s along with the introduction of corticosteroids as combination therapy by Starzl in the 1960s, there was noticeable improvement in kidney allograft survival, although one-year survival still did not exceed 50%^[4]. Multiple interventions including splenectomy, thymectomy and thoracic duct drainage were employed with minimal success.

The first successful human liver transplant was performed by Thomas Starzl in Denver in 1967 on an 18-month-old child with unresectable hepatoblastoma^[2]. The immunosuppressive regimen included anti-lymphocyte globulin (ALG), AZA and prednisolone and the child survived for more than a year.

However, the next significant breakthrough in immunosuppression did not occur until the discovery of cyclosporine (CYA) in 1972 from the soil fungus *Tolypocladium inflatum*. Borel *et al*^[5] first described its remarkable immunosuppressive properties in 1976 and by the 1980s there was international affirmation of its effectiveness. CYA quickly became the standard of care for maintenance immunosuppression in solid organ transplant recipients. This paved the way for the current era of liver transplantation, which has since continued to evolve with the discovery of multiple novel immunosuppressive agents.

IMMUNOSUPPRESSION

Effective immunosuppression in transplantation relies on preventing the immune system from rejecting the allograft while preserving immunologic control of infection and

Table 1 Drugs that increase CNI and sirolimus levels

Drugs that increase CNI levels
Macrolides: clarithromycin, erythromycin, azithromycin
Antifungals: fluconazole, itraconazole, ketoconazole, voriconazole, clotrimazole
Calcium channel blockers: verapamil, diltiazem, nifedipine
Others: cisapride, metaclopramide, amiodarone, cimetidine, protease inhibitors
Drugs that decrease CNI and sirolimus levels
Antibiotics: rifabutin, rifampin
Anticonvulsants: carbamazepine, phenobarbital, phenytoin, fosphenytoin
Others: St. John's Wort

CNI: Calcineurin inhibitor.

neoplasia. Although the mechanism is not completely understood, transplanted livers rarely reject compared to other organs, do not require an HLA-matched donor, and may offer a protective effect for other simultaneously transplanted organs^[6,7]. Both micro- and macrochimerism models have been used to explain this phenomenon, as well as that of hepatic dissolution of donor specific antibodies. Ideally, the long-term objective is to achieve immune tolerance or the ability to alter the recipient's immune system in order to promote long-term graft function without immunosuppressive therapy, while maintaining immunity to infectious agents^[8]. Unfortunately, except for a small minority of patients (approximately 20%) who have been successfully weaned off immunosuppressive medications, most experience immunologic rejection with the discontinuation of these drugs and have to be maintained on at least low doses of these medications^[9-13].

Immunosuppressive regimens include calcineurin inhibitors, anti-metabolites, mTOR inhibitors, steroids and antibody-based therapies. These agents target different sites in the T cell activation cascade, usually by inhibiting T cell activation or proliferation or *via* T cell depletion. The selection of agents is based on an individual's medical history as well as on institution experience and preference. Most immunosuppressive regimens combine drugs with different sites of action of T cell response, allowing for dosage adjustments to minimize side effects and toxicities. Currently, the mainstay of maintenance immunosuppressive regimens are calcineurin inhibitors (CNIs), used in greater than 95% of transplant centers upon discharge, although there is a known increased risk of renal impairment^[14,15], metabolic derangements, neurotoxicity and *de novo* malignancies^[16] with the long-term use of these medications.

CALCINEURIN INHIBITORS

CYA and tacrolimus are the two CNIs approved for use in organ transplantation and are the principal immunosuppressives used for maintenance therapy. The routine use of these medications in liver transplant recipients has dramatically decreased the incidence of rejection and graft loss. The primary mode of action is inhibition of T cell activation. CYA binds to

Table 2 Common side effects of immunosuppressive agents

Drug	Adverse effects
Tacrolimus	Nephrotoxicity, neurotoxicity ¹ , diabetes ¹ , hyperkalemia, metabolic acidosis, hypertension, hyperlipidemia
Cyclosporine	Nephrotoxicity, neurotoxicity, diabetes, hyperlipidemia ¹ , hypertension ¹ , hyperkalemia, metabolic acidosis, gingival hyperplasia, hypertrichosis
MMF	Myelosuppression, gastrointestinal side effects, viral infections (CMV, HSV), spontaneous abortions in pregnant women
Sirolimus	Hyperlipidemia, myelosuppression, proteinuria, poor wound healing, pneumonitis, skin rash
Corticosteroids	Diabetes, hypertension, obesity, osteoporosis, avascular necrosis, growth retardation, Cushingoid features, psychosis, poor wound healing, adrenal suppression, cataracts

¹More common in respective agent. MMF: Mycophenolate mofetil; CMV: Cytomegalovirus; HSV: Herpes simplex virus.

cyclophilin which results in inhibition of the calcium/calmodulin-dependent phosphatase, calcineurin. The binding to cyclophilin interferes with calcineurin's de-phosphorylation of nuclear factor of activated T cells (NFAT), preventing translocation of NFAT into the nucleus and up-regulation of pro-inflammatory cytokines. The end result is the inhibition of IL-2 gene transcription and T cell activation and proliferation^[4,8]. Tacrolimus also inhibits calcineurin but binds specifically to FK506-binding protein (FKBP-12).

The immunosuppressive effects of the CNIs are related to total drug exposure which can be estimated by measuring blood 12-h troughs. The potency of tacrolimus is estimated to be 100 times greater on a molar level^[8] when compared to CYA. Although several earlier studies showed tacrolimus to be superior to CYA in the prevention of cellular rejection^[17-19], another more recent multi-center trial showed no significant differences between the two medications with regard to acute rejection episodes, death or graft loss^[20]. Both CNIs are metabolized principally by the cytochrome P450 system and therefore have significant interactions with multiple medications requiring careful monitoring of drug levels (Table 1).

CNIs have a wide range of toxicities, many of which are dose-dependent (Table 2). Nephrotoxicity is a well-recognized side effect and it has been documented that nearly 20% of liver transplant recipients experience chronic renal failure within 5 years^[15]. This can be best managed by either discontinuation or reduction of the medication. Neurotoxicity is another common problem; one which is more predominant with tacrolimus. The clinical presentation varies from headaches and tremors to agitation, confusion, hallucinations or overt psychosis. Hypertension, hyperlipidemia, hyperkalemia, metabolic acidosis and diabetes are also frequent side effects. Diabetes is more common with tacrolimus use, whereas hypertension and hyperlipidemia tend to be more prominent with CYA use. Gingival hyperplasia and hypertrichosis are specific side effects of CYA only.

Another important feature of CNIs is their interaction with transforming growth factor- β (TGF- β), a cytokine that augments fibrosis development and promotes tumor cell invasiveness^[21]. TGF- β transcription is increased with CNI use, which is of concern given the possibility of hepatocellular carcinoma (HCC) recurrence or the emergence of post-transplant lymphoproliferative disorder (PTLD).

ANTIMETABOLITES

Both mycophenolate mofetil (MMF) and mycophenolate sodium (MPS) undergo immediate first-pass metabolism in the liver into the active compound mycophenolic acid (MPA), which was first discovered in 1893^[22]. However, the immunosuppressive properties of MPA were not recognized until the 1990s. MPA inhibits inosine-5'-monophosphate dehydrogenase (IMPDH)^[23], the rate-limiting enzyme in the *de novo* synthesis of guanosine nucleotides. Inhibition of the IMPDH pathway results in selective blockade of lymphocyte proliferation^[24].

The major advantage in using the MPAs is their lack of renal toxicity. In patients with pre-existing renal disease, they have been used in conjunction with low-dose CNIs as part of a renal-sparing protocol with promising results^[25,26]. Ideally, these medications should be initiated when renal dysfunction is first noted, although emerging data suggests the benefits of MPAs in reversing long-standing renal disease due to its association with decreased TGF- β levels^[27-29]. MPAs are rarely used as monotherapy in transplant recipients given their higher rates of rejection compared to the CNIs^[30,31], although more recent data demonstrate the safety of this approach when carried out carefully^[32,33]. However, in patients previously on CNIs or mTOR inhibitors with evidence of acute rejection, MPAs are often added as supplemental immunosuppressive therapy.

The predominant side effects of MPAs are related to gastrointestinal disorders and bone marrow suppression (Table 2). Diarrhea is the most common dose-limiting adverse effect, although abdominal pain, nausea and vomiting can frequently occur^[34]. Studies have also shown increased incidences of cytomegalovirus (CMV)^[35-37], herpes simplex virus (HSV)^[38,39], *Candida* infections, and, rarely, progressive multifocal leukoencephalopathy (PML)^[40] with the use of MPAs. In pregnant patients, increased risks of spontaneous abortions during the first trimester and serious congenital malformations have also been reported (www.fda.gov). Routine monitoring of MPA levels is not generally employed in clinical practice.

Azathioprine is another antimetabolite which was predominantly used for the prevention of rejection in the 1960s but has since been largely replaced by the MPAs. It is selectively used in a few centers in combination with other immunosuppressive medications, primarily CNIs and steroids.

mTOR INHIBITORS

The two mTOR inhibitors approved for organ trans-

plantation are sirolimus (SRL) and everolimus (EVL), although neither has been approved for use in liver transplantation to date. They bind intracellularly to FK506 binding protein (FKBP12) but unlike tacrolimus, they do not inhibit calcineurin activity. Rather, the complex is a highly specific inhibitor of mammalian target of rapamycin complex 1 (mTORC1)^[41] which has a direct effect on the cell signaling pathway required for cell cycle progression. This subsequently inhibits IL-2 signaling to T cells, thus preventing T cell proliferation. Similar to the CNIs, sirolimus is metabolized by the cytochrome P450 system and requires therapeutic drug monitoring (Table 1).

The first reported study illustrating the effectiveness of sirolimus monotherapy for maintenance of immunosuppression in liver transplantation was in 1999 by Watson *et al*^[42]. However, two subsequent large studies examining sirolimus *de novo* therapy with tacrolimus and corticosteroids were terminated early due to excess hepatic artery thrombosis (HAT). As a result, sirolimus carries a black box label warning which cautions against the possible development of early post-transplant HAT. Subsequent studies have since disputed this finding^[43-45], however, mTOR inhibitors are rarely used as *de novo* therapy.

Importantly, in patients with CNI-induced nephrotoxicity, conversion to sirolimus therapy has proved to be effective with ensuing improvements in renal function^[46-48]. Again, sirolimus conversion should be initiated early since late conversion rarely improves chronic renal dysfunction^[49]. In fact, several studies have shown that in patients with pre-existing renal disease, sirolimus can worsen nephrotoxicity and promote proteinuria^[50-52].

Recent studies have also shown potential anti-tumor properties of sirolimus^[53-56] which might be of importance in patients undergoing liver transplantation for HCC. Zimmerman *et al*^[57] examined the role of sirolimus-based maintenance therapy in post-transplant recipients with a history of HCC and found that overall survival was increased in the sirolimus arm compared to the CNI arm. Clinical trials examining the anti-cancer effects of mTOR inhibitors in liver transplant recipients with HCC have been encouraging^[44,58] and new trials are ongoing.

Metabolic side effects of mTOR inhibitors include proteinuria and increases in serum cholesterol and triglycerides (Table 2). Bone marrow suppression, interstitial pneumonitis, peripheral edema, dermatological effects (acne, mouth ulcers) and delayed wound healing are all well-documented. Inhibition of fibroblast growth factor by sirolimus impairs tissue repair and plays a role in delayed wound healing^[59]. Interstitial pneumonitis is rarely life-threatening, is dose-dependent and resolves on withdrawal of the drug^[60].

CORTICOSTEROIDS

Corticosteroids are well-known for their anti-inflammatory properties such as suppression of prostaglandin synthesis,

stabilization of lysosomal membranes and reduction of histamine and bradykinin release^[30,31]. They also exhibit various immunomodulatory effects including effects on antigen presentation by dendritic cells and induction of a decrease in the number of circulating CD4+ T cells, IL-1 transcription and IL-1-dependent lymphocyte activation^[4,8].

High-dose corticosteroids were used judiciously in the 1960s in post-transplant recipients, with resulting increased morbidity due to their well-known deleterious side effects. This led to several studies in the 1980s on renal transplant recipients which confirmed that graft and patient survivals, as well as rejection episodes, were similar in the high- and low-dose steroid groups as long as AZA was also used^[61-63]. Currently, intravenous corticosteroids are predominantly used as first-line therapy for the treatment of acute cellular rejection. Regarding maintenance therapy, they are often successfully withdrawn within 3-6 mo post-transplantation in patients without evidence of rejection or liver disease attributed to autoimmune disorders^[64]. The primary concern with corticosteroid use is exacerbation of hepatitis C virus (HCV) recurrence and liver fibrosis with high-dose pulsed therapy^[65]; however, this has not been evident with low, gradually tapered doses^[66,67].

Well-documented side effects of corticosteroids include diabetes, hypertension, central obesity, Cushingoid features, osteoporosis, avascular necrosis, psychosis, poor wound healing, adrenal suppression and cataracts (Table 2).

ANTIBODY-BASED THERAPIES

Polyclonal antibodies

Polyclonal antibodies, including anti-thymocyte (ATG) and anti-lymphocyte globulins (ALG), have been used since the early days of liver transplantation and are prepared by inoculating rabbits or horses with human lymphocytes or thymocytes^[4]. Their mechanism of action is rapid lymphocyte depletion due to complement-mediated cell lysis and uptake by the reticulo-endothelial system (RES) of opsonized T cells^[68]. In addition, they may also cause partial T cell activation and blockade of T cell proliferation^[69]. Polyclonal antibodies were routinely used as induction therapy in liver transplantation along with corticosteroids and AZA before the discovery of CYA.

Lymphocyte depletion is believed to play a role in preparing the recipient's immune system to adapt and recognize the transplanted organ as self and prevent destruction of the allograft. Accordingly, studies have shown that ATG administration results in regulatory T cell (Treg) expansion *in vitro* and *in vivo*^[70-72]. Tregs or suppressor T cells are responsible for preventing activation of the immune system and maintaining tolerance to self-antigens.

Currently, approximately 20% of transplant centers use these agents for induction purposes^[73] and recent data support the administration of thymoglobulin induction to delay CNi use and avoid renal toxicity without increasing the risk of rejection or HCV recurrence^[74-76]. A few

studies have also successfully shown the benefit of using these medications as induction therapy to avoid post-transplant corticosteroid use^[77,78] without an increased incidence of acute rejection. This is especially important in HCV recipients where high-dose pulsed corticosteroid therapy can significantly accelerate liver fibrosis. At present, anti-lymphocyte antibodies are used extensively to treat steroid-resistant acute rejection and are successful in 70%-96% of patients^[79-81].

The main side effect of these medications, affecting 80% of patients, is a "first-dose reaction" and febrile episode which can often be ameliorated by pre-medication with antipyretics, antihistamines and intravenous steroids. This effect is likely due to pyrogen release from the massive destruction of lymphocytes^[69,82]. Other adverse effects include thrombocytopenia, anemia, CMV infection, PTLN, pruritic skin rashes, serum sickness and anaphylaxis^[83-85].

Monoclonal antibodies

Monoclonal antibodies include the anti-IL-2 receptor (CD25) antibodies, anti-CD52 antibody and muromonab-CD3 (OKT3). The two anti-IL-2 receptor antibodies approved for clinical use are basiliximab (Simulect), a chimeric protein, and daclizumab (Zenapax), a humanized protein. Both antibodies are specific for the α chain of the IL-2 receptor, CD25, which is only expressed on activated T cells^[8]. These antibodies remain in the circulatory system for weeks after initiation of therapy and have been used successfully with low-dose CNIs in preventing acute rejection in the early post-transplant period^[86-88]. They also have fewer side effects compared to the anti-lymphocyte globulins, rarely cause the typical first-dose infusion reactions and are associated with less risk of opportunistic infections and PTLN.

Muromonab-CD3 (OKT3) targets the CD3 molecule on T cells and causes depletion of lymphocytes by massive T cell lysis^[89] and cytokine release^[90]. This profound cytokine release can lead to pulmonary edema and acute respiratory distress and rarely, intra-graft thrombosis and aseptic meningitis^[91,92]. As a result, antihistamines and intravenous steroids are routinely used as pre-medication to reduce this "cytokine release syndrome". Several days after OKT3 administration, T lymphocytes no longer express CD3 and are considered to be immunologically incompetent^[93]. OKT3 is primarily used in liver transplantation for steroid-resistant acute rejection^[94,95] and has a success rate of complete recovery in 50% of patients. OKT3 use should be limited in the HCV population as several studies have confirmed exacerbation of disease recurrence with this agent^[96,97].

The humanized anti-CD52 antibody, alemtuzumab (Campath-1) targets lymphocytes, monocytes, macrophages, natural killer cells and thymocytes but spares plasma cells and memory lymphocytes^[8,98]. It is unique in that it depletes lymphocytes from the circulation as well as peripheral lymph nodes. Several studies in renal transplant patients have shown its efficacy in preventing rejection when used in

combination with low-dose CNIs or sirolimus^[99-101]. Tzakis *et al.*^[102] compared the use of alemtuzumab induction therapy combined with low-dose tacrolimus in liver transplant recipients receiving standard doses of tacrolimus and corticosteroids. Although patients who received alemtuzumab had less renal dysfunction and acute rejection in the first two months post-transplant, the overall incidence of rejection was not significantly different between the two groups. Similarly, Marcos *et al.*^[103] proposed that alemtuzumab, in conjunction with minimal CNI use, is a successful treatment strategy in liver transplant recipients, improving overall graft and patient survival, especially in HCV-infected subjects.

FUTURE DIRECTION OF IMMUNOSUPPRESSION

Costimulation blockade (Belatacept)

Belatacept is a soluble cytotoxic T-lymphocyte antigen-4 (CTLA-4) agent which binds CD80 and CD86 and inhibits T cell activation^[4,8]. Belatacept competes with the CD28 receptor on T cells which normally binds CD80 and CD86 on the antigen presenting cell (APC) as a co-stimulatory signal required for T cell activation. Belatacept is administered intravenously once a month and does not carry the renal toxicity of CNIs. Clinical trials in liver transplant patients are currently ongoing with this agent.

Efalizumab

Efalizumab is a humanized leukocyte function-associated antigen-1 (LFA-1; CD11a) specific monoclonal antibody that inhibits T cell-APC stabilization and blocks lymphocyte adhesion to endothelial cells^[104,105]. This agent was approved for the treatment of psoriasis in 2003 and has not yet been used in liver transplantation, although a few clinical trials have been carried out in renal transplant patients with mixed results^[106]. Although the results regarding immunosuppression were promising, an increased risk for PTLT was shown when efalizumab was used in combination with high-dose CYA.

Other newer agents on the horizon undergoing phase II/III trials include Janus Kinase (JAK) 3 inhibitors, AEB071 (a protein kinase C (PKC) isoforms inhibitor), and Alefacept (a LFA3-IgG1 fusion receptor protein). JAKs are intermediaries between cytokine receptors and signal transducers and activators of transcription (STATs) which lead to immune cell activation^[107,108]. JAK-3, a cytoplasmic tyrosine kinase, is primarily found on hematopoietic cells and its stimulation is specific for the IL-2 family of cytokines which makes it a very attractive target for immunosuppression. Clinical trials are underway in renal transplant patients using these agents. AEB071 (PKC inhibitor) is an oral agent that blocks early T cell activation and IL-2 production^[109]. Three phase II renal transplant trials using AEB were started, two of which had to be stopped due to increased episodes of acute rejection; the third trial is ongoing

in Europe^[110]. Alefacept, a LFA3-IgG1 fusion receptor protein initially approved for the treatment of psoriasis, interferes with T-cell activation and produces a dose-dependent reduction in T-effector memory cells^[111]. A multi-center clinical trial in renal transplant recipients is currently underway.

CONCLUSION

The current era of immunosuppressive therapy continues to evolve with the discovery of novel agents, targeting different sites of the immune cascade. Important objectives when using these medications include decreasing the incidence of renal toxicity from CNIs while preserving graft function as well as optimizing immunosuppression without creating an environment for increased infections, aggressive recurrence of hepatitis C or triggering PTLT and other malignancies.

At our institution, high-dose intravenous corticosteroids are used in the immediate peri- and post-operative period and then tapered accordingly. In patients without renal dysfunction post-transplantation, CNIs are the mainstay of therapy with the long-term goal of low levels of immunosuppression and minimization of medication. In patients with renal insufficiency, we have had success with a combination of low-dose CNI therapy and MPAs or a switch to mTOR inhibitors to preserve graft function and prevent further renal deterioration. We typically avoid the switch to mTOR inhibitors within the first 3-6 mo post-transplantation given the risk of hepatic artery thrombosis, rejection, and wound healing. Patients are weaned off corticosteroids within 6 mo to 1 year, providing they do not have evidence of autoimmune disease or recurrent episodes of rejection.

As evidenced by prior studies, the recommended approach to the patient with HCV infection is gradual, cautious weaning of corticosteroids within the first 3-6 mo while continuing low levels of maintenance immunosuppression, typically with CNIs. While HCV recurrence is universal after liver transplantation, avoiding excessive and erratic changes in the immunosuppressive regimen should prevent clinically aggressive disease.

The ultimate goal remains the ability to induce tolerance in transplant recipients. While this is not a current available practice, data from selected patients demonstrate that it may become a viable option with advances in future research and improved understanding of the genetic make-up and predisposition of this population. Until then, finding the balance between preserving graft function and optimizing immunosuppression while minimizing toxicities remains a challenge.

Lakatos PL. Prevalence, predictors, and clinical consequences of medical adherence in IBD: How to improve it? *World J Gastroenterol* 2009; 15(34): 4234-4239 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4234.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4234>

Abstract

Inflammatory bowel diseases (IBD) are chronic diseases with a relapsing-remitting disease course necessitating lifelong treatment. However, non-adherence has been reported in over 40% of patients, especially those in remission taking maintenance therapies for IBD. The economical impact of non-adherence to medical therapy including absenteeism, hospitalization risk, and the health care costs in chronic conditions, is enormous. The causes of medication non-adherence are complex, where the patient-doctor relationship, treatment regimen, and other disease-related factors play key roles. Moreover, subjective assessment might underestimate adherence. Poor adherence may result in more frequent relapses, a disabling disease course, in ulcerative colitis, and an increased risk for colorectal cancer. Improving medication adherence in patients is an important challenge for physicians. Understanding the different patient types, the reasons given by patients for non-adherence, simpler and more convenient dosage regimens, dynamic communication within the health care team, a self-management package incorporating enhanced patient education and physician-patient interaction, and identifying the predictors of non-adherence will help devise suitable plans to optimize patient adherence. This editorial summarizes the available literature on frequency, predictors, clinical consequences, and strategies for improving medical adherence in patients with IBD.

INTRODUCTION

Inflammatory bowel disease (IBD) is a multifactorial entity with both genetic and environmental factors contributing to disease pathogenesis^[1]. Worldwide, the incidence rates for IBD vary from 0.5 to 24.5 per 100 000 person-years^[2], with the majority of patients being disabled during various parts of their lives. This characteristic may also suggest poor adherence (i.e. a percentage of the prescribed doses is not taken) outside the clinical trial settings^[3-5].

Treatment of IBD can involve several medications with varying regimens, dietary modifications, and potentially, surgery, depending on symptoms, severity of illness, and response to treatment. Adherence to the pharmacological treatment is a complex process, where the doctor-patient relationship, treatment regimen and other disease-related factors play key roles. The undesirable side effects of some medications (e.g. weight gain, cushingoid appearance, and immune suppression) and the complex treatment regimens for IBD patients (e.g. varying dosing schedules and pill quantities for each medication) are likely to disrupt adherence and the effective management of this condition. These data are consistent with the hypothesis that many patients engage in an implicit cost-benefit analysis in which beliefs about the necessity of their medication are weighed against concerns about the potential adverse effects of taking it, and that these beliefs are related to medication adherence, as in other chronic conditions^[6]. This scenario has been also proven in patients with IBD in a very recent paper^[7]. In contrast, the impact of medication non-adherence on the hospitalization risk and health care costs in chronic conditions (e.g. diabetes, hypertension, and congestive heart failure) is enormous^[8]. It has been estimated to cost as much as \$100 billion in the US annually, and accounts for 10% of all hospital admissions.

However, there are no studies that directly assess the costs associated with non-adherence in patients with IBD. Recently, it has been estimated in the UK that relapse was associated with a two- to threefold increase in the costs for those who did not require hospital care and a 20-fold increase for those who were hospitalized^[9].

Research on adherence in IBD is limited. Studies in adults have revealed medication non-adherence rates ranging from 35% to 45%^[3,5,10]. Unfortunately, most of these studies used different, unimodal indirect assessment methods including non-standardized self-report questionnaires, non-standardized patient/parent interviews, pill counts, pharmacy records, and measurements of health outcomes. A drawback of this method is that it can overestimate adherence, and its accuracy depends on the patient's cognitive abilities, the honesty of replies, as well as the interviewer's correct interpretation of responses. The patient may forget doses taken or missed. Prescription refills are also considered questionable for assessing dosing compliance because they provide no information on timing or quantity of pills ingested. In addition, pill counts are often erroneous because patients do not always return bottles with leftover pills. Thus, until now, the methods for assessing compliance have varied in terms of prospective *versus* retrospective or objective *versus* subjective measurement, target behaviour assessed (e.g. consumption of medication and refill of prescription), medication assessed, and method of assessment. This variability resulted in different estimates of the prevalence of non-adherence and diminished generalizability and the validity of data. Furthermore, these studies were limited by potential response bias in the self-report measures or behavioural manipulation, such as discarding pills to influence pill count data^[11].

In general, direct methods for measuring medication adherence include drug concentration monitoring through blood and urine assays. This strategy is expensive and inconvenient for patients, and, moreover, only a limited number of drugs can be monitored in this manner. The bioavailability and completeness of absorption of various drugs, as well as the rate of metabolism and excretion, are factors that make it difficult to correlate drug concentrations in blood or urine with adherence. The ability of direct methods to identify non-adherence also depends on the accuracy of the test and the degree to which the patient was non-adherent before the urine or blood sample was taken. Drug concentration monitoring can also be misleading because most drugs are rapidly absorbed following administration. Thus, even if numerous doses were omitted, yet a few doses were taken immediately prior to the blood test, the results would show the presence of a moderate amount of drug, or *vice versa*.

In IBD, bioassays measuring 6-thioguanine nucleotide (6-TGN) and 6-methylmercaptopurine nucleotide (6-MMPN) levels have been suggested as potentially useful objective adherence markers for 6-mercaptopurine (6-MP)/azathioprine (AZA)^[11,12]. However, they have not been validated against traditional measures of adherence. Moreover, like other bioassays, they are subject to pharmacokinetic variation in absorption, metabolism,

and excretion. Despite their limitations, bioassays provide key adherence data in that they can confirm ingestion. Non-therapeutic metabolite levels can suggest either non-adherence or pharmacokinetic influence, or both; cases where both 6-TGN and 6-MMPN levels are subtherapeutic/unquantifiable are likely to indicate non-adherence. Thus, although there is no gold standard in adherence assessment, and limitations exist with any measure of adherence, both behavioural and biological measures offer unique data that could be used to better understand non-adherence. Moreover, determining the most advantageous approach to assessing adherence is critical to the clinical care of these patients. This editorial summarizes the available literature on frequency, predictors, clinical consequences, and strategies for improving medical adherence in patients with IBD.

PREVALENCE OF NON-ADHERENCE IN IBD

In normal clinical practice, adult studies have revealed medication non-adherence prevalence rates ranging from 35% to 72%^[3,5,10,13,14]. For example a cross-sectional study of US outpatients with quiescent ulcerative colitis (UC) found that only 40% were adherent to maintenance mesalazine (mesalamine) therapy^[3]. In the UK, approximately 15% of patients fail to even redeem prescriptions at the pharmacy^[15]. Moreover, treatment non-adherence rates might vary considerably between countries. In Europe, a survey of 203 IBD patients revealed self-reported non-adherence rates ranging from 13% in France, to 26% in Italy, 33% in the UK and 46% in Germany. The overall non-adherence rate was 29% across Europe^[4], where non-adherence was defined as taking < 80% of prescribed medication. Similarly high rates of non-adherence were reported from Eastern Europe. Overall intentional non-adherence was reported by 38.9% of patients, and 18.6% of the patients at least once discontinued the treatment^[5]. In a Canadian study, UC diagnosis was associated with higher risk of non-adherence (OR: 4.42)^[16].

Significant differences may exist in children and adolescents, given the complex developmental challenges unique to childhood and adolescence, including the maturation of cognitive and behavioral patterns (e.g. health beliefs) that affect self-management. However, only a few studies have examined adherence rates in pediatric IBD, with the results indicating the prevalence of non-adherence ranging from 50% to 66%^[17,18]. Moreover, special attention should be paid to the method of assessment, because significant differences may be present in objective methods *versus* subjective self-report methods. In a recent paper, Hommel *et al*^[11] reported an objective non-adherence frequency of 38% for 6-MP/AZA and 49% for 5-ASA medications, while the subjective non-adherence frequency was reported to be as low as 6% for 6-MP/AZA and 3% for 5-ASA. In contrast, in a prospective, single-center study from Germany^[19] both objective (9.2%) and self-reported (7.1%) non-adherence rates were low in 65 adult Crohn's disease (CD) patients.

PREDICTIVE FACTORS FOR NON ADHERENCE AND CLINICAL CONSEQUENCES

Gender

Conflicting data are available on the role of gender in predicting non-adherence to medical therapy. Kane *et al*^[3] and Mantzaris *et al*^[20] related poor adherence with the male gender. In the study by Kane *et al*^[3] non-adherent patients were statistically more likely to be males (67% *vs* 52% in adherent patients). Gender interactions also proved relevant in a recent population-based study, in which young females proved to be less adherent than males^[17], while other studies could not find a significant difference^[5]. In addition there may be different factors affecting medication adherence in men and women. In the study by Ediger *et al*^[16] a diagnosis of ulcerative colitis (*vs* Crohn's disease) having high scores on the Obstacles to Medication Use Scale and a low level of the personality trait of agreeableness, were important predictors of low adherence in males. For women, important predictors of low adherence included an age younger than 30 years, having high scores on the Obstacles to Medication Use Scale, and having a low level of the personality trait of agreeableness. Immunosuppressant use was associated with high adherence in women.

Similarly, data are conflicting with regards to marital status, type of education, employment status, or type of disease. A higher education level and full time employment was also associated with a non-adherent patient behavior in some^[5,16,21], but not all, studies^[14].

Age and disease duration

Age seems to be an important factor, as younger patients tend to be less adherent than older patients^[10,18]. In a recent Italian study^[22] non-adherence was 43% in patients < 40 years old compared to 34% in those older than 40 years ($P = 0.041$, OR: 1.5, CI: 1.01-2.13). Recently, diagnosis and disease duration shorter than 5 years was also associated with significantly worse adherence (24% of the patients) than a longer-standing disease (15% of the patients; $P = 0.001$, OR: 2.1, CI: 1.30-3.39) in the same study. Moreover, non-adherence increased to 75% when both age (< 40 years) and disease duration (< 5 years) were considered. This may have to do with the fact that IBD primarily affects young individuals with greater personal and social goals, being busy at work, and having some degree of rebelliousness, but it may also be that a younger age is associated with a more recent diagnosis, with less experience with the burden of relapse or surgery. This was, however, not a universal finding^[5].

Phenotype, disease activity and surgery

In UC, Kane *et al*^[3] reported by means of univariate analysis, that male gender, being without a relationship partner, left-sided disease, and a history of more than four concomitant medications, were negatively associated with adherence. Conversely, being married, having a recent colonoscopy, and a greater extent of disease supported

adherence. A UK-based cross-sectional study, using data extracted from general practitioner (GP) clinical records, examined the usage of long-term aminosalicylate therapy in patients with UC^[13]. It was found that 38% of the patients with extensive colitis, 37% of the patients with left-sided colitis and 46% of those with proctitis did not take medications for maintenance therapy. This was not, however, confirmed in all studies^[5].

An association between medical adherence and complicated disease course in CD was reported by Spanish authors^[14]. Better adherence was significantly associated with a more complicated disease course (steroid dependency, steroid refractoriness, need for infliximab treatment, hospitalization, or surgery) in patients with short disease duration. Similarly, in a recent Hungarian study^[23], a higher number of previous surgeries was associated with improved self-reported adherence in patients with CD.

Active disease was associated with higher adherence, even if steroids were included in the treatment regimen in both CD and UC^[10]. In contrast, other studies reported low adherence rates after long-term remission^[3,22]. Very high non-adherence rates (74.3%) were reported for azathioprine in CD patients who were in long-term (> 48 mo) clinical remission^[20].

Moreover, a direct association between adherence and risk of relapse was reported in UC. Kane *et al*^[24] prospectively studied the risk factors associated with relapse among 99 patients who were in remission for more than six months and prescribed 5-ASA maintenance therapy. The clinical recurrence of UC was defined as four or more bowel movements per day. At a 12-mo follow-up, 19 of 86 patients had recurrent disease, 13 (68%) of whom were non-adherent. Patients who were non-adherent with medication had a greater risk of recurrence than adherent patients (OR: 5.5, 95% CI: 2.3-13). A Kaplan-Meier curve constructed to compare outcomes stratified by adherence status for 24 mo also showed that UC patients adherent to their 5-ASA therapy had a significantly greater chance of remaining in remission than those who were non-adherent (89% *vs* 39%; $P = 0.001$).

Drug type and dosing regimes

Non-adherence to therapy might also be due to the drug formulation causing discomfort (difficulty in swallowing tablets or using enemas) or side effects (pain, abdominal distension, or difficulty in retaining enemas). Most studies are consistent in finding that topical therapy with enemas, suppositories or foams is more likely to be associated with non-adherence than oral therapy. In an Italian study^[22], topical therapy with enemas was associated with significantly more non-adherence (68% of users) than oral therapy (40% of users; $P = 0.001$, OR: 0.25, CI: 0.11-0.60). Similarly, analyzing a national prescription-based database also showed that overall adherence to mesalazine was unexpectedly low and the rectal formulation was among the factors influencing non-adherence^[25]. Enemas were judged difficult to use, painful or to cause bloating, and were difficult to manage during working hours.

The association between the type of oral medications and non-adherence is more controversial. The undesirable

side effects of some medications (e.g. weight gain, cushingoid appearance, or immune suppression) and the complex treatment regimens for IBD patients (e.g. varying dosing schedules and pill quantities for each medication) are likely to disrupt adherence and effective management of this condition. Interestingly, some studies did not report a direct association. For example, in the study by Cervený *et al*^[5], the non-adherence rate at any time point was 40% on aminosalicylates, 29% in patients on systemic steroids, and 31% in patients on immunosuppressants in CD. Similar data were reported in UC, supporting the notion that adherence is influenced by multiple parallel factors, including gender, age, disease activity, and so on. Interestingly, the same study, using a factor analysis, reported a strong influence of adverse drug effects on adherence. Intentional non-adherent behavior due to adverse drug effects was the second most common cause reported during a patient interview. In addition, adverse drug effects were independently proven by factor analysis to affect a patient's confidence in treatment.

Reasons for non-adherence to oral therapy include multiple daily doses and a high number of concomitant medications. In the study by Kane *et al*^[3], besides being males, single, and having left-sided disease, non-adherent patients were statistically more likely to be taking four or more concomitant medications (60% *vs* 40%). Similarly, in the study of Shale and Riley^[21], in addition to being young, having education beyond the age of 16 years and being in full-time employment, being prescribed a 3-times-a-day regimen was identified as predictor for non-adherence. The need to take medicine during working hours ($P = 0.001$, OR: 3.5, 95% CI: 2.27-5.26), and multiple daily doses ($P = 0.045$, OR: 2.8, 95% CI: 0.99-7.70) were significantly associated with non-adherence in adults^[22], which was also confirmed by other studies^[20,21]. Similarly, adolescents whose regimen involved more than one daily medication administration had more adherence barriers^[26]. In addition, lack of time and medication side effects were also commonly reported barriers. Other adolescent-reported barriers included missing medication due to feeling well or discontinuing medication based on the belief that the medication was not working. In contrast, a recent retrospective cohort study suggests that adherence in UC patients is independent of drug formulation^[27]. Magowan *et al*^[27] used records from multiple US health plans to compare the refill prescription profiles of 1680 UC patients who had initiated 5-ASA therapy with one of four formulations: delayed-release mesalamine (Asacol), controlled-release mesalamine (Pentasa), sulfasalazine (Azulfidine), or balsalazide (Colazal). Upon initiation of treatment, the median daily dose and respective tablet/capsule load were 2.4 g (6 tablets) for delayed-release mesalamine, 4.0 g (16 capsules) for controlled-release mesalamine, 2.0 g (4 tablets) for sulfasalazine, and 6.75 g (9 capsules) for balsalazide. Comparison of the refill profiles over 12 mo, however, indicated that adherence in these patients was not affected by formulation type and/or dose regimen.

The use of once-daily treatment for improving medical compliance is further supported by a recent randomized, multicentre, investigator-blinded study of 362

patients who were randomised to receive mesalazine granules (Pentasa®) 2 g once daily or 1 g twice daily. It showed an 11.9% greater remission rate at one year (73.8% *vs* 63.6%, respectively) in the single daily dose group^[28]. Patient questionnaires showed significantly greater self-reported compliance ($P < 0.05$) and acceptability ($P < 0.001$) in the once-daily group. High compliance rates were reported for the once-daily MMX mesalazine and Salofalk® granules^[29,30]; therefore the effect is likely to be generic rather than compound-specific. Thus, new mesalazine formulations offer a simplified dose regime, resulting in presumably improved long-term compliance that can be considered an important advantage in the management of UC patients.

Patient-doctor relationship

The partnership between patient and the treating physician is of utmost importance in determining medical adherence, where effective patient-physician dialog is central to promoting patient adherence^[22]. Studies have also shown that the interaction between the patient and the physician has a huge impact on health outcomes and costs. Both the quality and quantity of the visits are important. Sewitch *et al*^[10] found an increased risk of intentional non-adherence to be associated with being treated by the same physician for more than one year, not scheduling another appointment, and greater total discordance between the patient and the physician. Similarly, a higher degree of intentional non-adherence in the study by López San Román *et al*^[31] was associated with greater patient depression and patient-physician discord. Patients trusted their physician less, and considered themselves to be less informed about their treatment.

A direct association between the total number of health care visits and medical adherence was proven in children with CD^[18]. In addition, patients under specialist care were significantly more likely to be taking an aminosalicylate than those definitely discharged to general practitioner's care in adults with UC^[13]. In contrast, however, a European cohort showed no correlation between the number of times an IBD patient had seen the physician and self-reported medication adherence rates^[4].

STRATEGIES TO IMPROVE ADHERENCE

A large body of evidence supports the key role of the physician-patient relationship in achieving higher patient medication-adherence rates. Psychology literature points out to using COPE principles as a way for physicians to improve their relationship with patients and optimize patient adherence to their medication. The COPE principles encompass the following: communicate with patients; obtain patient's commitment to therapeutic objectives; promote emotional/psychological/physical support as necessary; educate the patient and their family. In addition, trust in the physician and continuity of care by the same doctor are also important to patients.

In the everyday practice, the physician's willingness to allow patients to contribute input and become involved in their illness during the medical visits was suggested to

facilitate treatment decisions that are meaningful to both parties^[32]. The consultation style adopted by the physician is also an important factor in building the physician-patient relationship. Indeed, when physicians adopted a mutual, co-operative relationship, and exhibited less control dominance, a reported increase in patient adherence and satisfaction was observed.

During consultations, all factors affecting adherence need to be explored, including the patient's level of knowledge, belief systems and support environment, for example their network of family and friends.

Written and oral education (on the disease, management algorithm and medications) has been shown to increase adherence by approximately 6%-25%^[33]. Written information is more effective when verbally reinforced. In addition, a study of 69 patients with IBD demonstrated improved knowledge, patient satisfaction, and a positive trend towards greater adherence in patients who had undertaken the IBD education program (consisting of pamphlets and ad hoc physician education), which is the standard of care in many referral centers, compared with patients who received standard care^[34].

Guided self-management involving the provision of a shared set of guidelines containing action plans for the prevention of disease activity and/or symptom relief, have been used in the management of many chronic illnesses. A randomized, controlled study evaluating guided self-management programs in patients with IBD has demonstrated, a reduction in hospital visits without an increase in morbidity and greater confidence in the patient's ability to cope with IBD^[35]. Further studies are needed in order to assess whether such interventions will improve adherence to medication and clinical outcomes in patients with IBD. Furthermore, a special form of patient education could be successfully implemented using an internet-based patient education platform, as suggested by Elkjaer *et al*^[36].

Another approach that could be used to optimize patient adherence involves individualized therapy, where physicians review the patient's disease and therapeutic history, and identify which treatment(s) were effective/ineffective in the past to avoid prescribing the same unsuccessful medication. Simplification of treatment (e.g. reduced dosing frequency and the use of long-acting agents) and avoidance of unnecessary multiple concomitant medications is preferable, where feasible, and are associated with better adherence and improved clinical outcome^[3,21,24]. Furthermore, this patient review process could also provide predictive information on medication non-adherence behavior, and thus help identify those patients at high risk who might require longer consultation slots than those at low risk. Patients could also be prompted to take their medications via simple pill-taking cues, such as placing pills close to something they use daily, for example the toothpaste, breakfast table, glasses/contact lenses case, and so on. In addition, telephone support, postal reminders, and setting alarms on watches/mobile phones have been suggested. Nevertheless, combining education and behavioral interventions has been suggested to be the most effective approach to improving adherence.

CONCLUSION

Non-adherence is common in IBD and has been reported in 40%-60% of patients, especially those in remission and taking maintenance therapies for IBD. The economical impact of medication non-adherence, including absenteeism, hospitalization risk, and health care costs in chronic conditions, is enormous. The causes of medication non-adherence are multi-factorial, including forgetfulness, gender, new diagnosis, disease phenotype, patient-physician relationship, complicated dosing regimens, side-effect profile of the drugs, and treatment delivery methods. The associated factors may vary in each country because of the difference in the healthcare systems and the population. Moreover, a gold standard method to estimate the prevalence of non-adherence does not exist. Subjective assessment may underestimate adherence, while recent episodes of non-adherence may result in high non-adherence rates if measured by direct methods (e.g. drug concentration monitoring using blood and urine assays). Moreover, this latter strategy is expensive and inconvenient for patients, and only a limited number of drugs can be monitored in this way. Poor adherence may result in more frequent relapses, disabling disease course, and in ulcerative colitis, in increased risk for colorectal cancer. Improving medication adherence in patients is an important challenge for physicians. Understanding the different patient types, the reasons given by patients for non-adherence, simpler and more convenient dose regimens, dynamic communication within the healthcare team, self-management package incorporating enhanced patient education and physician-patient interaction and identifying the predictors of non-adherence, will help devise suitable plans to optimize patient adherence.

Abstract

Several advances in diagnosis, treatment and palliation of cholangiocarcinoma (CC) have occurred in the last decades. A multidisciplinary approach to this disease is therefore recommended. CC is a relatively rare tumor and the main risk factors are: chronic inflammation, genetic predisposition and congenital abnormalities of the biliary tree. While the incidence of intra-hepatic CC is increasing, the incidence of extra-hepatic CC is trending down. The only curative treatment for CC is surgical resection with negative margins. Liver transplantation has been proposed only for selected patients with hilar CC that cannot be resected who have no metastatic disease after a period of neoadjuvant chemo-radiation therapy. Magnetic resonance imaging/magnetic resonance cholangiopancreatography, positron emission tomography scan, endoscopic ultrasound and computed tomography scans are the most frequently used modalities for diagnosis and tumor staging. Adjuvant therapy, palliative chemotherapy and radiotherapy have been relatively ineffective for inoperable CC. For most of these patients biliary stenting provides effective palliation. Photodynamic therapy is an emerging palliative treatment that seems to provide pain relief, improve biliary patency and increase survival. The clinical utility of other emerging therapies such as transarterial chemoembolization, hepatic arterial chemoinfusion and high intensity intraductal ultrasound needs further study.

INTRODUCTION

Cholangiocarcinomas (CC) are malignant tumors originating from epithelial cells lining the biliary tree and gallbladder^[1]. Intrahepatic CCs (ICC) arise within the liver and extra-hepatic CCs (ECC) originate in the bile duct along the hepato-duodenal ligament. ICCs usually present as masses in the liver while jaundice is the most common presentation of ECCs. CCs are relatively rare tumors although their incidence is rising worldwide^[2,3]. Several advances in the diagnosis, therapy and palliation of patients affected by CC have occurred during the last decades. The aim of this article is to review the most recent high quality literature on this topic.

EVIDENCE ACQUISITION

We sought studies that reported at least one of the following aspects of CC: epidemiology, diagnosis, therapy (e.g. surgery, radiotherapy, chemotherapy, phototherapy), and palliation. Preference was given to randomized controlled trials (RCT) and prospective observational studies. For each of these topics we searched MEDLINE, Ovid MEDLINE In-Process, Cochrane Database of Systematic Reviews, Database of Systematic Reviews, Database of Abstracts of Reviews of Effects, EMBASE, PubMed, National Library of Medicine Gateway by established systematic review methods (Jadad Scale for RCT controlled studies, Downs and Black checklist for observational studies^[4-6]). We further reviewed reference lists and articles from the authors' libraries. We limited our search to English-language articles published from January 1990 to June 2009. We then developed a comprehensive

Table 1 Summary of the terms used singly or in combination for evidence acquisition

Primary MeSH terms	Secondary MeSH terms (Epidemiology, diagnosis)	Secondary MeSH terms (treatment, palliation)
Cholangiocarcinoma(s)	Epidemiology	Hepatectomy
Adenocarcinoma(s)	Classification	Resection
Carcinoma(s)	Diagnosis	Therapeutic(s)
Bile duct neoplasm(s)	Differential diagnosis	Treatment outcome(s)
Biliary tract neoplasm(s)	Early diagnosis	Surgery
Common bile duct neoplasm(s)	Risk factor(s)	Transplantation
Liver neoplasm(s)	Diagnostic imaging	Biliary tract
Bile duct(s)	Magnetic resonance imaging	Surgical procedures
Common bile duct	Endosonography	Liver transplantation
Intrahepatic bile duct(s)	Ultrasonography	Organ transplantation
Extrahepatic bile duct(s)	Emission computed tomography	Clinical trial
Biliary tract disease(s)	Radionuclide imaging	Controlled clinical trial(s)
Bile duct disease(s)	Positron emission tomography	Randomized controlled trial(s)
	X-ray	Clinical trial (phase I)
	Computed tomography	Clinical trial (phase II)
	Biopsy (needle)	Clinical trial (phase III)
	Biopsy (fine needle)	Clinical trial (phase IV)
	Cytology	Drug therapy
	Cytodiagnosis	Chemotherapy
	Tumor markers (biological) antigen(s)	Adjuvant
	Carcinoembryonic antigen	Antineoplastic agent(s)
	Ca 19-9 antigen	Combined modality therapy
	Ca 125 antigen	Antineoplastic
	Endoscopic retrograde cholangiopancreatography	Combined chemotherapy protocols
	Cholangiography	Neoadjuvant therapy
	<i>In situ</i> hybridization	Radiotherapy
	Fluorescence <i>in situ</i> hybridization	Adjuvant embolization
	Nucleic acid hybridization	Portal vein embolization
	Computed assisted image processing	Drainage
		Cholestasis
		Obstructive jaundice

and current database to catalog the medical literature on CC. The evidence database for the catalog was assembled only for CC arising in the intra- and extra-hepatic bile ducts. Our review did not include the management of gallbladder cancer, as several other comprehensive articles had already covered this topic^[7-10]. To identify all potential papers, we searched medical subject headings reported in Table 1. Two authors (Aljiffry M and Molinari M) independently performed the selection of the articles based on the content of titles and abstracts. When in doubt, each article was reviewed entirely. The decision to include articles in this review was reached by consensus. For conciseness, a full list of search strategies, search results, and quality assessment for each included study are available on request from the corresponding author.

EPIDEMIOLOGY

The incidence of CC is rising in most countries and it is the second most common primary malignancy of the liver after hepatocellular carcinoma^[1]. In the USA, approximately 5000 new cases are diagnosed every year^[11] accounting for almost 3% of all tumors of the gastrointestinal tract^[12]. While the incidence of ICC is rising, the occurrence of ECC is trending down^[13,14] suggesting that different risk factors may be involved^[15]. Caution should be used when interpreting these results as misclassification bias may have influenced these observations^[2,16]. In fact, analysis of the Surveillance Epidemiology and End Results database from 1975 until

1999 has shown that most hilar tumors (more than 90%) were classified as ICC^[2,16] while ECC were often combined with gallbladder cancers^[2,13]. Nevertheless, evidence that ICC and ECC may be dissimilar tumors is supported by the recent discovery that, *in vitro*, they express diverse cellular proteins and have different cellular shape, doubling time, chromosome karyotype and chemosensitivity^[17]. Similarly, researchers from France showed that hilar CC (HCC) express higher levels of MUC5AC (60% *vs* 22%), Akt2 (64% *vs* 36%), CK8 (98% *vs* 82%), annexin (56% *vs* 44%) and less vascular epithelial growth factor (22% *vs* 78%) in comparison to ICC^[18]. These findings support the hypothesis that the heterogeneous protein and receptor expression of ECC and ICC may be due to different carcinogenic pathways^[17,18].

ICC

The estimated age-adjusted incidence rates of ICC in the USA has increased by 165% over the last thirty years (from 0.32 per 100 000 in 1975-1979 to 0.85 per 100 000 in 1995-1999^[2,19] accounting for 10% to 15% of all primary hepatic cancers^[20]. The average age at presentation is the seventh decade of life^[2] with a male to female ratio of 1.5^[20]. The mortality rate and incidence of ICC have parallel trends^[13] as age-adjusted mortality rate increased from 0.07 per 100 000 in 1973 to 0.69 per 100 000 in 1997^[21].

ECC

In the USA, the age-adjusted incidence of ECC has

Figure 1 Bismuth's classification of cholangiocarcinomas. Type I: Cholangiocarcinoma is confined to the common hepatic duct; Type II: Cholangiocarcinoma involves the common hepatic duct bifurcation; Type IIIa: Cholangiocarcinoma affects the hepatic duct bifurcation and the right hepatic duct; Type IIIb: Cholangiocarcinoma affects the hepatic duct bifurcation and the left hepatic duct; Type IV: Cholangiocarcinoma is either located at the biliary confluence with both the right and left hepatic ducts involvement or has multifocal distribution.

decreased by 14% compared to data from two decades earlier. Currently it is 1.2 per 100 000 in men and 0.8 per 100 000 in women^[2,22]. Similarly to ICC, 65% of ECC present in the seventh decade of life^[22]. The mortality rate of ECC parallels its incidence and in the USA, the age-adjusted mortality rates for ECC declined from 0.6 per 100 000 in 1979 to 0.3 per 100 000 in 1998^[14,21].

CLASSIFICATION

Anatomical classification

ICCs arise within the liver parenchyma while ECCs involve the biliary tree within the hepatoduodenal ligament and gallbladder. ECCs are further divided into hilar or distal tumors. HCC, also called Klatskin tumors, are located within 2 cm from the bifurcation of the common duct and were described for the first time by Klatskin in 1965^[22]. Ten years later, Bismuth and Corlette proposed

Figure 2 Anatomical presentation of cholangiocarcinomas. The majority of cholangiocarcinomas (60%-70%) present in the area of the biliary duct bifurcation and are called Klatskin tumors. The extra-hepatic bile duct is involved in 20%-30% of cases while intrahepatic cholangiocarcinomas represent 5%-10% of the tumors originating from the biliary system.

a clinical classification that stratifies these tumors by anatomical location (Figure 1)^[23]. Approximately 60% to 70% of CC are located in the hylum, 20% to 30% are ECC, and 5% to 10% are ICC (Figure 2)^[24,25].

Pathological classification

More than 90% of CC are well- to moderately-differentiated adenocarcinomas^[26,27] with tendency to develop desmoplastic reaction and early perineural invasion. Macroscopically, ICC may develop in solid masses, infiltrate periductal tissues, grow intraductally or have mixed characteristics. On the other hand, ECC develop nodular lesions, sclerosing strictures, or papillary growth patterns. Sclerosing CC are the most common^[28] while papillary adenocarcinomas are rare and associated with more favorable prognosis^[22].

RISK FACTORS FOR CHOLANGIOCARCINOMA

Only a minority of patients presenting with CC have known risk factors such as chronic biliary inflammation, cholestasis or congenital abnormalities (Table 2)^[29].

Primary sclerosing cholangitis (PSC)

In Western countries, PSC is the most important predisposing factor for CC^[30,31]. The cumulative annual risk of CC in patients with PSC is 1.5% per year after the development of jaundice^[32] and the prevalence of CC in patients with PSC ranges between 8% and 40%^[30,33,34]. A recent epidemiological study from the Netherlands has shown that the risk of CC for patients with PSC is 9% after 10 years from the time of the diagnosis^[35]. In patients with concomitant inflammatory bowel disease, the 10-year and 20-year risks for CC are 14% and 31% respectively, which are significantly higher than patients without inflammatory bowel disease (2% and 2%

Table 2 Known risk factors for cholangiocarcinomas

General risk factors
Old age (older than 65 years)
Smoking
Obesity

Oral Contraceptive Pills
Isoniazid

respectively; $P = 0.008$)^[35]. Individuals with PSC frequently develop CC at younger age (30-50 years) compared to the general population (60-70 years)^[50,32]. The diagnosis of CC in this group is challenging because clinical presentation and radiological findings of CC and PSC are similar. As a result, most cases of CC complicating PSC are detected at advanced stages and have poor prognosis^[36]. Predictive factors of CC in PSC patients are: sudden progressive jaundice, unintentional weight loss, marked dilation of bile ducts proximal to biliary strictures, serum level of Ca 19-9 tumor marker above 100 U/mL, and presence of cellular dysplasia on cytological specimens obtained by brushing of the biliary ducts^[37].

Parasitic infections

Infestation with liver flukes (*Opisthorchis viverrini* and *Clonorchis sinensis*) has been strongly associated with an increased risk of CC in South-East Asia^[3,38,39]. In areas where *Opisthorchis viverrini* is endemic, the adjusted prevalence for CC by age and gender is as high as 14%^[40]. The pathophysiology causing CC in these patients is not completely understood, however it is hypothesized that parasites colonize the biliary system causing chronic inflammation and predisposing to malignant transformation.

Intrahepatic biliary stones (Hepatolithiasis)

Oriental cholangiohepatitis (also known as recurrent pyogenic cholangiohepatitis) has a prevalence of 20% in South-East Asia^[41] and almost 10% of affected patients develop ICC^[42-45]. Recurrent episodes of cholangitis aggravate the chronic inflammatory process that persists

between flare ups. Risk factors associated with CC in these patients are: age over 40 years, long history of hepatolithiasis, unintentional weight loss, increasing serum alkaline phosphatase, decreasing serum albumin, and serum CEA tumor marker above 4.2 ng/mL^[46].

Congenital biliary cystic diseases

Patients with choledochal cysts have low risk for CC if the cyst is excised early in their life^[46]. On the other hand, the incidence of malignant degeneration is between 10% and 20% if the cyst is not excised by the age of 20 years^[28,47]. The mechanism of malignant transformation is not totally understood although biliary stasis and reflux of pancreatic secretions are suspected of causing neoplasia through chronic inflammation^[48]. CC can occur years after resection of the cyst suggesting that there might be a genetic defect predisposing to tumors of the biliary system^[49].

Liver cirrhosis and viral infections

The risk of developing CC in cirrhotic patients is ten-fold higher than the general population (0.7% *vs* 10.7%)^[2,50]. Among patients with CC in the USA, the prevalence of hepatitis C viral infection (HCV) was found to be four times higher than the general population (0.8% *vs* 0.2%)^[20]. These results have been confirmed in Italy^[51], in Taiwan^[52] and in Japan where HCV and viral hepatitis B (HBV) infection were detected in 23% and 11.5% of CC compared to 6% and 5.5% of controls, respectively, with cumulative rates 1000-times greater than the general population^[53]. Similar results were recently confirmed in a case-control study performed in China, where researchers found that at multivariate analysis, significant risk factors for the development of ICC were hepatolithiasis (adjusted OR: 5.7; 95% CI: 1.9-16.8) and HBV infection (adjusted OR: 8.8; 95% CI: 5.9-13.1)^[15]. A large epidemiological study from the United States validated that HCV infection is a risk factor for ICC (hazard ratio 2.55; 95% CI: 1.3-4.9) but not for ECC (hazard ratio 1.5; 95% CI: 0.6-1.85)^[54]. Although human immunodeficiency virus (HIV) does not cause cirrhosis *per se*, 0.5% of patients infected with HIV have been found to have CC in comparison to 0.1% among controls, confirming previous observations which suggested that chronic viral infections might predispose to neoplastic transformation of some cell lines^[20].

Chemical agents

Several compounds have been suspected of causing CC. Thorotrast (thorium dioxide) needs a special mention because it was used as a radiological contrast in the period between 1920-1950 and was found to increase the risk of CC up to 300-times in comparison to the general population^[16,55]. Because of its long biological half-life (400 years), the latency period of thorotrast-induced CC ranges between 16 to 45 years^[56], with the highest incidence between 20 to 30 years after exposure^[57]. A few studies have shown an association between CC and other chemical agents such as asbestos^[58], vinyl chloride^[59] and nitrosamines^[60]. Medications such as isoniazide^[61] and first generation of oral contraceptives^[62] are also suspected of increasing the risk of CC.

Other risk factors

Tobacco smoking is weakly associated with CC in the general population^[20] while it appears to be a strong risk factor for PSC patients^[63]. Other predisposing factors for CC are diabetes, obesity, presence of bile duct adenomas and biliary papillomatosis^[64,65]. Although there is no evidence that endoscopic sphincterotomy increases the risk of CC, biliary-enteric bypasses may do so^[66].

DIAGNOSIS

Clinical presentation

CCs are usually clinically silent or associated with nonspecific symptoms in early stage (Table 3)^[67,68]. ICCs are often diagnosed by imaging tests, and rarely during physical exams, as asymptomatic hepatic masses^[26]. On the other hand, ECC usually present with painless jaundice^[69] and symptoms related to biliary obstruction such as itching, clay-colored stool and hyperpigmented urine^[69]. Only 10% of cases present with ascending cholangitis^[70]. Jaundice is usually persistent and progressive while intermittent biliary obstruction may be observed in patients with papillary lesions that cause a ball-valve effect^[71]. Physical examination of patients with CC may reveal hepatomegaly, palpable gallbladder (Courvoisier sign), or signs of portal hypertension due to portal vein thrombosis secondary to tumor invasion or compression^[33,69].

Laboratory investigations

Serum biochemical tests usually support the clinical suspicion of CC but they are rarely diagnostic. Jaundice occurs only if there is obstruction of the two main intra-hepatic biliary ducts or common bile duct. In these circumstances, elevation of the serum levels of bilirubin and markers of biliary epithelial injury, such as alkaline phosphatase (ALP) and gamma glutamyltransferase (GTT)^[33], are common^[72,73]. On the other hand, in the presence of unilateral intrahepatic biliary obstruction, elevation of ALP or GTT may be present without increase in the serum bilirubin level^[33]. Other abnormal laboratory findings include hypoalbuminemia and prolonged prothrombin time, which reflect the combination of diminished hepatic synthetic function, cachexia and malabsorption of vitamin K^[33].

Serum tumor markers

Several tumor markers may support the diagnosis of CC, although none of them is sensitive enough to be used for screening purposes. The most commonly used markers are carbohydrate antigen (Ca 19-9) and carcinoembryonic antigen (CEA)^[73]. These tumor markers are not very specific as they can be elevated in the presence of other malignancies (e.g. pancreas and stomach) and with benign conditions such as cholangitis and hepatolithiasis^[73-75]. In patients without PSC, serum Ca 19-9 values above 100 U/mL have a sensitivity of 53% and specificity of 75%-90% for the diagnosis of CC^[74]. In patients with PSC, serum Ca 19-9 levels above 100 U/mL have sensitivity of 75%-89% and specificity of 80%-86% for the diagnosis

Table 3 Presenting symptoms of patients affected by cholangiocarcinomas

Symptoms	Percentage (%)
Jaundice	84
Weight loss	35
Abdominal pain	30
Nausea and vomiting	20
Fever	10

of CC^[75-77]. In a recent study from the Mayo Clinic, the optimal cutoff value for serum Ca 19-9 in patients with PSC was 20 U/mL which provided a sensitivity of 78%, specificity of 67%, positive predictive values of 23% and negative predictive value of 96%^[78]. Serum Ca 19-9 combined with either ultrasonography, computed tomography, or magnetic resonance imaging provided a sensitivity of 91%, 100% and 96% respectively for CC diagnosis^[78]. The levels of Ca 19-9 seem to correlate with the stage of the disease. Patel *et al*^[72] reported that the sensitivity of Ca 19-9 above 100 U/mL for the diagnosis of CC in patients with resectable tumors was 33% compared to 72% in patients with unresectable tumors. Using more than one tumor marker for patients with PSC may improve the detection rate of CC. In one study, using Ca 19-9 levels above 180 U/mL in combination with CEA levels above 5.2 ng/mL had a sensitivity of 100% and a specificity of 78.4%^[79]. Several new markers are currently being investigated. The human mucin 5, subtypes A and C (MUC5AC) are the most promising for future clinical use with sensitivity and specificity of 71% and 90%, respectively^[80].

Imaging modalities

Imaging modalities are essential for the diagnosis and treatment planning of patients with CC^[73].

Abdominal ultrasound (US)

US is usually the initial imaging test performed to evaluate patients with biliary obstruction^[81]. The sensitivity and accuracy of US for ECC diagnosis are 89%^[82] and 80%-95%, respectively^[83,84]. On the other hand, ICC are difficult to distinguish from other solid intra-hepatic masses as they lack specific US features^[83,84]. The use of duplex US with color Doppler technology is helpful in assessing portal venous invasion and hepatic parenchymal involvement. In a small series of patients with HCC, duplex US detected portal vein invasion correctly in 86% of patients^[85]. In a larger study, duplex US was 93% sensitive and 99% specific for detecting portal vein involvement^[86]. As the sensitivity and specificity of US are operator-dependent, most patients with suspected CC undergo further imaging modalities to confirm and stage suspected tumors^[87]. The sensitivity of US improves significantly in the presence of elevated serum tumor marker Ca 19-9^[80]. Serum level of Ca 19-9 above 20 U/mL in patients with PSC has been shown to increase the diagnostic sensitivity of abdominal US up to 91%, with specificity of 62%, positive predictive value of 23%, and negative predictive value of 98%^[80].

Computed tomography (CT)

Triple-phase CT scan is widely used to diagnose and stage CC^[88] as it provides valuable information regarding local spread, vascular invasion, lymph node involvement and presence of distant metastases^[89,90]. On CT scans, ICC usually present as hypodense lesions with irregular margins on initial images and a variable degree of delayed venous phase enhancement^[86]. These characteristics have been shown to correlate with prognosis as hyperattenuating CC have a more aggressive behavior^[91]. Other CT findings of ICC include dilatation and thickening of the peripheral intra-hepatic bile ducts and liver capsular retraction^[92]. ECC may be seen as a focal thickening of the ductal wall with various enhancement patterns^[93]. However, in many cases of ECC, visualization of the neoplasms is not definitive because they are too small to be detected. More recent studies^[92,94] have shown that modern contrast-enhanced multidetector row computed tomography was 78.6%-92.3% accurate for the diagnosis of ECC, although there was a strong tendency to underestimate the longitudinal extension of the tumor (77.8%) in comparison with the pathological results of the excised specimens^[95,96]. Four-channel multidetector-row CT has been shown to correctly diagnose hepatic artery invasion with 100% sensitivity and 90% specificity and portal vein invasion with 92.3% sensitivity and 90.2% specificity^[96]. Regular enhanced CT can be extremely useful by showing indirect signs of ECC such as biliary ductal dilatation and hepatic lobar atrophy. Atrophy of one hepatic lobe could be associated with hypertrophy of the opposite lobe, a condition known as the atrophy-hypertrophy complex. This phenomenon is seen when CC obstruct the biliary outflow of a single lobe and invade the ipsilateral portal vein causing compensatory hypertrophy of the opposite hepatic lobe^[97]. The sensitivity of triple-phase helical CT in the detection of HCC is in the range of 90% to 100%^[92,98] and it is even more sensitive in detecting ICC greater than 1 cm in size^[90]. These results show a marked improvement in the diagnostic yield of CT compared to previous reports in which the tumor detection rate was only 60%^[99]. CT is also useful for assessing the vascular and lymph node status of patients affected by CC. In a series of 55 patients with HCC, CT accurately predicted portal vein invasion, arterial invasion, and lymph node involvement in 86%, 93%, and 84% of patients, respectively^[100]. The overall accuracy of CT for determining resectability of CC is in the range of 60% to 85%^[90,100,101]. Recently, CT cholangiography (CTC) has been shown to be a promising modality for delineating the biliary tree. In a large study, CTC was superior to conventional CT or US and equal to endoscopic retrograde cholangiopancreatography (ERCP) for the diagnosis of HCC^[102]. In another smaller study, the sensitivity and specificity of CTC for malignant biliary obstruction were both 94%^[103]. One of the limitations of CTC is that optimal imaging quality depends on the secretory function of the liver^[104]. For patients affected by PSC, the combination of tumor serology (serum level of Ca 19-9 above 20 U/mL) and

contrast-enhanced abdominal CT scan has been shown to improve the diagnostic sensitivity (100%), specificity (38%), positive predictive value (22%) and negative predictive value (100%) of the test^[80].

Magnetic resonance imaging (MRI) and Magnetic resonance cholangiopancreatography (MRCP)

MRI with concurrent MRCP can provide three-dimensional reconstruction of the biliary tree by using magnetic resonance technology^[105]. Multiple studies have demonstrated the utility of MRCP in evaluating patients with CC^[106,107]. MRCP has diagnostic accuracy comparable to invasive cholangiographic techniques such as ERCP or percutaneous transhepatic cholangiography (PTC)^[108-111]. A further advantage of MRCP over invasive cholangiographies is that it does not require biliary instrumentation^[112]. Therefore, MRI along with MRCP is considered the radiological modality of choice for evaluating patients with suspected CC^[113]. MRCP/MRI allows definition of the anatomy and extent of CC within the hepatobiliary system^[108,110,114] vascular invasion, local lymphadenopathy and distant metastases^[108,113,115]. Ideally, MRCP should be performed before decompressing the biliary tree^[86]. ICC appear as a hypointense lesion on T1- and hyperintense on T2-weighted images with pooling of contrast within the tumor on delayed pictures as seen with CT^[116,117]. On MRCP, ECC may appear as extrahepatic lesions with similar signal intensity of ICC on both T1- and T2-weighted images, in addition to proximal biliary dilatation^[106,116]. A meta-analysis of 67 studies (4711 patients) evaluating MRCP performance in patients with suspected biliary diseases showed an overall sensitivity of 88% and specificity of 95%^[107]. In a series of 99 patients with HCC, MRCP accurately determined the longitudinal extension of the tumor in 88% of patients^[118]. In another smaller study, MRCP predicted the extent of biliary ductal involvement in 96% of cases with malignant hilar obstructions^[115]. Regarding surrounding structures, MRI has been shown to have 66% accuracy for detection of lymph node metastases^[119], 78% sensitivity and 91% specificity for portal vein invasion, 58%-73% sensitivity^[120] and 93% specificity for arterial invasion^[121]. In a comparative study the relationship of ICC to the vessels and surrounding organs was more easily evaluated on CT compared to MRI^[89]. For patients affected by PSC and CC, the diagnostic capacity of MRI is enhanced by the presence of serum tumor marker Ca 19-9 above 20 U/mL; as a recent study has shown that the sensitivity of the test in this case was 96%, specificity 37%, positive predictive value 24%, and negative predictive value 98%^[80].

Cholangiography

ERCP and PTC provide dynamic images but require invasive access to the biliary system. Both techniques can detect biliary abnormalities and determine the location and extent of ECC within the biliary tree. The choice between PTC and ERCP is generally dictated

by the availability of local expertise and the anatomical characteristics of the tumor^[69]. In patients with complete biliary obstruction, ERCP often cannot assess the proximal biliary tree while PTC cannot assess the distal extent of the tumor^[33,122].

The sensitivity and specificity of cholangiography range between 75%-85%, and 70%-75%, respectively^[110,116] with accuracy of 95%^[123]. Recent data have shown that in the presence of PSC, the association of an elevated level of serum Ca 19-9 increases the diagnostic utility of ERCP as its sensitivity was 91%, specificity 69%, positive predictive value 42%, and negative predictive value was 96%^[80]. A drawback of these invasive procedures is the risk of complications such as post-ERCP pancreatitis (4%-10%)^[123], bacteriobilia (30%-100%)^[73], bleeding, sepsis, vascular injury and death^[124]. On the other hand, ERCP and PTC have the advantage of providing brush cytology and bioptic specimens that can confirm the diagnosis of CC. The sensitivity of biopsy and brush cytology for diagnosing CC has been low due to the desmoplastic reaction associated with the tumor which is characterized by the presence of few malignant cholangiocytes within an extensive fibrous stroma^[11]. In a large prospective study, the sensitivity of routine cytology varied from 9%-24% and the specificity varied from 61%-100% with a high rate of inter-pathologist variation; the best diagnostic yield was obtained when the pathologists were aware of the patient's clinical condition^[125]. This was recently confirmed by a study from the Mayo Clinic which showed that in patients affected by PSC, the simultaneous presence of an elevated serum tumor marker level (Ca 19-9 above 20 U/mL) increased the sensitivity (50%), specificity (97%), positive predictive value (86%) and negative predictive value (88%) of cytological specimens^[80]. In another study, repeated brushing appeared to be a valuable strategy to improve the sensitivity of cytological analysis up to 44%^[126]. Endoscopic transpapillary forceps biopsies had a diagnostic sensitivity of 52% and a specificity of 100%^[127]. Advanced cytologic techniques, including digitized image analysis (DIA) and fluorescence *in situ* hybridization (FISH), have been recently used to increase the sensitivity of cytology^[128] especially in patients with PSC^[80]. The DIA technique quantitates nuclear DNA *via* special stains to assess the presence of aneuploidy, whereas FISH analysis detects chromosomal polysomy by using fluorescent probes. In a prospective study, DIA increased the sensitivity from 18% to 39% but decreased the specificity from 98% to 77%^[129]. In another comparative study, FISH increased the sensitivity from 15% to 34% compared to routine cytology, with similar specificities (91% for FISH and 98% for routine cytology)^[130]. For patients with PSC, the presence of elevated serum level of Ca 19-9 (above 20 U/mL) increases the diagnostic capacity of DIA and FISH; as a recent study measuring these parameters has shown that their sensitivity was 57% and 86%, specificity 94% and 83%, positive predictive value 89% and 80%, and negative predictive value was 74% and 88%, respectively^[80]. The use of peroral cholangioscopy

(POCS) or choledochoscopy has been shown to improve the diagnostic capacity of ERCP by directing tissue sampling. Fukuda *et al*^[131] reported a sensitivity of 100% and a specificity of 87% for diagnosing the etiology of bile duct strictures by adding POCS to ERCP. At this moment, the availability of POCS is limited to a few centers due to lack of expertise and the high costs of instrumentation. The introduction of new technologies such as SpyGlass[®], a single operator peroral cholangiopancreatography, has eliminated the need for two ERCP operators and has the potential of becoming an important tool to improve the diagnostic capacities of endoscopic techniques, and it is currently under investigation^[132-134].

Endoscopic ultrasound (EUS)

EUS is performed by using high frequency ultrasound probes placed on the endoscope. EUS has the advantage of interrogating tissues and organs in direct proximity to the stomach and duodenum, increasing the ability to detect abnormalities that would not be easily identified by percutaneous approach. In a prospective study of patients with suspected CC, EUS had a diagnostic sensitivity of 79% and specificity of 62%^[111]. This was confirmed in a recent meta-analysis where EUS had sensitivity and specificity of 78% and 84%, respectively^[135]. Two of the most attractive features of EUS are the ability to perform direct-guided fine needle aspirations (FNA) of the tumors in patients with negative cytology or the ability to sample enlarged lymph nodes for preoperative staging^[136-138]. However, caution should be applied in patients with potentially curative CC as this approach has some risk of peritoneal seeding^[65,130]. A recent prospective study evaluated the diagnostic yield of EUS-guided FNA of suspected HCC in potentially operable patients with negative brush cytology. The study showed sensitivity and specificity of 89% and 100%, respectively, and changed the preplanned surgical approach in 61% of patients^[136]. In another prospective study, EUS-guided FNA of suspected CC reported a diagnostic sensitivity of 86%, with a specificity of 100%. In the same study, EUS-guided FNA had a positive impact on the treatment management of 84% of patients^[139].

Intraductal ultrasound (IDUS)

IDUS is performed by using high frequency US probes placed into the common bile duct under ERCP guidance^[140]. Malignant biliary strictures often appear on IDUS as a hypoechoic infiltration of the ductal wall with irregular margins^[141,142]. In a prospective study of 62 patients with biliary strictures, IDUS had a diagnostic sensitivity of 90% and specificity of 93%^[143]. In another study by Stavropoulos *et al*^[144], IDUS increased the diagnostic accuracy of ERCP from 58% to 90% in a series of patients with biliary strictures and no mass detected on CT.

Positron emission tomography (PET)

PET is a non-invasive imaging modality that provides

functional images by detecting radiotracer 18F-fluorodeoxyglucose (FDG) uptake in neoplastic cells^[145]. Currently it is considered a standard modality for the staging of many malignancies^[146]. In the last decade, integrated PET and CT imaging systems (PET/CT) have combined the ability to obtain anatomical and functional images^[146,147]. PET and PET/CT are proven to be useful in the diagnosis and staging of CC. In a recent study, PET showed sensitivity and specificity of 90% and 78% respectively^[148]. In another study by Anderson *et al*^[149], PET had sensitivity of 85% for CC measuring at least 1 cm in size although its sensitivity was only 18% for infiltrating CC. These values were confirmed by Kluge *et al*^[150] who reported sensitivity of 92% and specificity of 93% for the detection of any type of CC by PET scan. A more recent study has shown that the sensitivity of PET/CT is correlated with the stage of CC as the sensitivity of the study was 25% for T2 tumors, 70% for T3 tumors and 66.7% for T4 tumors^[151]. The rate of detecting distant metastases by PET and PET/CT in patients with CC is in the range of 70% to 100%, while the detection of regional lymph node metastases is only about 12%^[152]. The sensitivity and specificity of PET/CT for detecting lymph node metastasis and distant metastasis were 41.7% and 80%, and 55.6% and 87.5%, respectively^[146]. Another study from the Memorial Sloan Kettering Cancer Center has shown that PET/CT had an overall sensitivity for identifying the primary tumor of 80% (78% for CC and 86% for gallbladder cancer) and changed management in nearly a quarter of all patients^[153]. PET has been shown to be useful in monitoring tumor response to treatment. In a small series by Chikamoto *et al*^[154], PET had a sensitivity of 80% for detecting local recurrence after resection in patients with HCC. One of the limitations of PET is that patients with biliary inflammatory conditions such as PSC or cholangitis may have false positive results^[152,155] while patients with mucinous CC may have falsely negative scans due to poor uptake of FDG^[155].

Optical coherence tomography (OCT)

OCT is a new technique that produces cross-sectional images using infrared light. Preliminary studies have demonstrated the ability of OCT to generate high resolution images of the biliary tree that correlate with histological findings^[156,157]. OCT has the potential to identify early CC^[104] but it is not widely available except in a few centers. Therefore the role of OCT in the diagnostic workup of CC is not yet established.

Non diagnostic work-up

Non-diagnostic cytology or biopsy results should not rule out CC in the presence of appropriate clinical and radiological findings^[73]. In the absence of other explainable causes of biliary strictures, patients should be considered to have CC and treated as such, accepting that 10% to 15% will have benign lesions on final pathology^[158,159]. For high risk patients, no surveillance or screening programs have been validated. Some authors

advocate annual follow up with non-invasive modalities (tumor markers and radiological tests), reserving invasive methods only when cytology and bioptic specimens or stenting are indicated^[160].

TUMOR SPREAD

Understanding the patterns of spread of CC is essential for staging and treatment planning. CC can spread along biliary ducts, invade perineural and vascular tissues, spread directly into adjacent structures, invade lymph nodes or develop distant metastasis. Longitudinal extension of CC consists of mucosal (superficial) or submucosal (invasive) infiltration depending on the tumor growth pattern. Mucosal extension is predominantly seen with papillary (intraductal) and nodular (mass-forming) tumors, while submucosal extension is mainly seen with sclerosing (infiltrating) tumors^[161]. The length of longitudinal extension is determined by the type of invasion, with a mean length of 6-10 mm for the submucosal spread and 10-20 mm for the mucosal spread^[162]. Therefore, a gross surgical margin of more than 1 cm in the infiltrating type and more than 2 cm in the papillary and nodular types is recommended to achieve negative microscopic resection margins. One of the special characteristics of CC is the presence of perineural invasion that is seen in about 75% of cases^[163,164]. Perineural invasion is a prognostic factor for poor survival^[164,165]. In a retrospective review by He *et al*^[164], the 5-year survival rate was 47% for patients without perineural invasion compared to 13% for those with perineural invasion. HCC can spread directly into the hepatic parenchyma and the hepatoduodenal ligament where the proper hepatic artery and the portal vein are in close proximity to the bile duct, while distal ECC may directly infiltrate into the pancreas or the duodenum^[166]. Up to 80% of HCC have extension into the liver parenchyma^[166,167] by direct infiltration or by longitudinal extension along the biliary ducts^[168]. The latter mechanism explains the caudate lobe involvement by HCC and tumors involving the left hepatic duct^[169]. Hence, the practice of partial hepatectomy with caudate lobectomy for the surgical treatment of patients with hilar tumors is associated with improved survival^[168]. Tumors at the biliary confluence involve the portal vein in 30% of cases and often result in hepatic lobar atrophy^[166,167]. The significance of portal vein involvement in patients' survival is controversial. Some studies have shown that tumor invasion of the portal vein has a negative impact^[170,171] while other investigators reported opposite findings^[166]. This is most likely due to the fact that patients with portal vein invasion may tolerate more extensive surgical resections as the contralateral lobe becomes hypertrophied, therefore decreasing the risk of perioperative mortality and enhancing the chances of negative resection margins. Lymph node metastases usually involve the regional hilar nodes and to a lesser extent the para-aortic lymphatic nodes^[172]. The prevalence of lymph node involvement is approximately 45% for all CC with distal ECC having the highest incidence of nodal metastases^[68,172]. Several studies have confirmed

Table 4 AJCC staging of ICC

Stage	Tumor	Node	Metastasis
I	T1	N0	M0
II	T2	N0	M0
III A	T3	N0	M0
III B	T4	N0	M0
III C	Any T	N1	M0
IV	Any T	Any N	M1

T1: Solitary tumor without vascular invasion; T2: Solitary tumor with vascular invasion or multiple tumors none > 5 cm; T3: Multiple tumors > 5 cm or tumor involving a major branch of the portal or hepatic vein(s); T4: Tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of visceral peritoneum; N0: No regional lymph node metastasis; N1: Regional lymph node metastasis; M0: No distant metastasis; M1: Distant metastasis. AJCC: American Joint Committee on Cancer; ICC: Intrahepatic cholangiocarcinoma.

that lymphatic tumor involvement is an important prognostic factor. Survival rates for patients undergoing surgical resection with positive lymphatic invasion at 5 years are 10% to 15% in comparison to 30% to 40% for patients without lymph node metastasis^[164,172]. Presence of distant metastases (e.g. lung, bone, peritoneal, distant lymph nodes) is observed in 30% of patients at the time of diagnosis and is associated with survival of only a few months^[166].

STAGING

ICC and ECC are staged differently.

ICC

ICC are classified as primary liver malignancies in the new American Joint Committee on Cancer (AJCC) staging system, also known as the TNM staging (Table 4)^[173]. The AJCC staging system for primary liver tumors was based on data provided by patients affected by hepatocellular carcinomas and therefore is not sufficiently accurate for ICC^[174]. A new staging system for ICC was proposed by Nathan *et al*^[174] based on the number of tumors, vascular invasion, lymph node status and presence of metastatic disease. The presence of multiple tumors may be indicative of satellite neoplastic deposits or intrahepatic metastatic disease from hematogenous or lymphatic spread; similarly to vascular and lymph node invasion, it is associated with poor survival.

ECC

Giving the proximity of ECCs to the portal vein and hepatic artery, the goal of staging is to determine the local extent of the disease as it predicts resectability and the extent of the resection. The AJCC staging system for ECC (Table 5)^[173] is based on pathological data useful in identifying the patients' prognosis but with little applicability for assessing the feasibility of surgical treatment^[174]. Bismuth-Corlette classification for HCC is useful for describing the tumor location and its spread within the biliary tree but it is not predictive of resectability. The Memorial Sloan-Kettering Cancer

Table 5 AJCC staging of ECC

Stage	Tumor	Node	Metastasis
0	Tis	N0	M0
I A	T1	N0	M0

II B	T1-T3	N1	M0
III	T4	Any N	M0
IV	Any T	Any N	M1

Tis: Carcinoma *in situ*; T1: Tumor confined to the bile duct histologically; T2: Tumor invades beyond the wall of the bile duct; T3: Tumor invades the liver, gallbladder, pancreas, and/or unilateral branches of the portal vein (right or left) or hepatic artery (right or left); T4: Tumor invades any of the following: main portal vein or its branches bilaterally, common hepatic artery, or other adjacent structures, such as the colon, stomach, duodenum, or abdominal wall; N0: No regional lymph node metastasis; N1: Regional lymph node metastasis; M0: No distant metastasis; M1: Distant metastasis.

Table 6 Proposed T-Stage criteria for hilar cholangiocarcinomas (MSKCC)

Stage	Criteria
T1	Tumor involving biliary confluence with or without unilateral extension to second-order biliary radicles
T2	Tumor involving biliary confluence with or without unilateral extension to second-order biliary radicles and ipsilateral portal vein involvement with or without ipsilateral hepatic lobar atrophy
T3	Tumor involving biliary confluence with bilateral extension to second-order biliary radicles; or unilateral extension to second-order biliary radicles with contralateral portal vein involvement; or unilateral extension to second-order biliary radicles with contralateral hepatic lobar atrophy; or main or bilateral portal vein involvement

Center (MSKCC) has proposed a staging system known as T-stage criteria^[174]. The MSKCC staging system is based on the location and extent of ductal involvement, presence or absence of portal vein invasion, and presence or absence of hepatic lobar atrophy irrespective of metastases or lymph node status (Table 6). The MSKCC staging system for HCC correlates with resectability and survival, as 59% of T1 lesions are resectable with median survival of 20 mo compared to 0% resectability for T3 lesions with a median survival of only 8 mo^[174].

THERAPY

Surgical resection

Tumor resection is the only potential cure for CC and the median survival of patients with unresectable disease is 6 to 12 mo^[26]. All patients with resectable ICC and HCC, and the majority of patients with ECC, require partial hepatectomy to increase the chances of negative resection margins. Preoperative patients' evaluation includes an extensive assessment of their fitness for major surgery, the absence of any metastatic disease and the possibility of resection margins free from cancer^[175]. If any of these conditions are not satisfied, surgical therapy is not indicated and palliative modalities should be recommended.

Table 7 Criteria for unresectability of HCC

Local tumor invasion
Bilateral hepatic duct involvement up to secondary biliary radicles
Encasement or occlusion of the main portal vein
Unilateral tumor extension to secondary biliary radicles with contralateral portal vein or hepatic artery encasement or occlusion
Hepatic lobar atrophy with contralateral portal vein or hepatic artery encasement or occlusion
Hepatic lobar atrophy with contralateral tumor extension to secondary biliary radicles
Metastatic disease
Lymph node metastases beyond the hepatoduodenal ligament (N2 lymph nodes) ¹
Distant metastasis (e.g. lung, liver, peritoneal)

¹Peripancreatic, periduodenal, periportal, celiac, or superior mesenteric lymph nodes.

Preoperative patient preparation

Many patients are not considered surgical candidates because of the presence of comorbidities or advanced age. A patient's performance status, nutritional conditions, and comorbidities need to be carefully evaluated before considering surgery^[176]. A retrospective review of patients with resected HCC showed that the presence of preoperative serum albumin less than 3 g/dL was a significant predictive factor for high postoperative mortality^[177]. In the same study, a preoperative serum total bilirubin above 10 mg/dL was associated with lower survival rates^[177]. The role of preoperative biliary drainage (PBD) in jaundiced patients remains controversial. A recent meta-analysis failed to demonstrate any benefit^[178]. Furthermore, PBD seems to increase the risk of perioperative infections and a longer postoperative hospital stay^[124,178].

Nevertheless, prolonged preoperative biliary obstruction is associated with increased postoperative morbidity and mortality after hepatic resection due to the presence of severe cholestatic liver dysfunction^[177,179]. Currently, preoperative PBD is not routinely recommended, but it has been shown to be beneficial in the presence of cholangitis, severe malnutrition, coagulation abnormalities^[180,181] and when patients require major hepatic resection^[175,182]. When preoperative drainage is performed, definitive surgery should be deferred for a few weeks to allow sufficient restoration of hepatic function^[168]. The use of liver volumetric and/or hepatic functional studies is warranted when anticipating an extended hepatic resection, to estimate the future liver remnant and minimize the risk of liver failure caused by insufficient function or small residual liver parenchyma.

Assessment of resectability

Meticulous interpretation of all the available clinical and radiological data is recommended to determine resectability and avoid unnecessary interventions. Despite the improvement of diagnostic modalities, about 16%-25% of patients are found to have more extensive disease preventing resection at the time of laparotomy^[68,183]. The major determinants of resectability

are the extent of tumor within the biliary tree, the amount of hepatic parenchyma involved, vascular invasion, hepatic lobar atrophy, and metastatic disease^[166,179]. A review of 294 cases of CC demonstrated that resectability rates are higher for more distal tumors^[69]. The determination of resectability is most challenging in patients with HCC. It is reported that about half of patients with HCC deemed to be resectable preoperatively have unresectable disease when explored^[174]. The radiological criteria defining unresectability in patients with HCC are listed in Table 7^[174,175]. With regard to distal ECC and ICC, AJCC stages III and IV are generally considered unresectable (Table 8).

Generally, invasion of the main portal vein or invasion of the vasculature supplying the planned hepatic remnant preclude resection. Nevertheless, recent reports have shown that en-bloc resection with vascular reconstruction may achieve negative margins and potential cure with only 10% perioperative mortality in very selected patients^[184,185]. The application of staging laparoscopy has been recently advocated as it can reduce the number of unnecessary laparotomies by identifying metastatic lesions in the liver and in the peritoneal cavity^[186]. The yield of laparoscopy for detecting unresectability in patients with potentially resectable CC on preoperative imaging modalities is about 25% with an overall accuracy of 50%^[187,188]. Moreover, laparoscopy offers the addition of intraoperative hepatic US, which can increase the diagnostic yield up to 42%^[189]. One of the limitations of laparoscopy is the inability to detect vascular or nodal involvement^[188,189]. Peritoneal washings to obtain cytology specimens have not been shown to predict occult metastasis in patients with CC^[190]. Ultimately, true resectability is determined after a complete abdominal exploration.

Operative procedures and survival

The goal of surgery is to obtain complete excision of the tumor with negative histological margins (R0 resection), as this is associated with marked survival advantages compared to margin positive resections (R1 or R2 resection)^[26,68,176,191]. To confirm histologically-negative margins, many authors advocate the use of intraoperative frozen section examinations of the bile ducts^[174]. A very important study from the MSKCC has recently evaluated the clinical significance of intraoperative frozen section for patients affected by HCC^[192]. The primary aim of

¹Five-year survival for patients with R1 resection is 6%; NR: Not reported.

this study was to assess the importance of obtaining frozen sections of the bile duct margins for the planning of the extent of the surgical dissection. Frozen sections were obtained in 101 patients: among them 20 (19.8%) had positive and 81 (80.1%) had negative results. Among the patients who had negative frozen sections, 8 (9.8%) individuals were found to have positive margins at subsequent histopathology. In this study, intraoperative frozen section was shown to be 71.4% sensitive, 100% specific, and with a positive predictive value of 100% and negative predictive value of 80.2%^[192].

ICC

Surgical therapy for ICC is based on the same principles used for hepatic resections performed for hepatocellular carcinomas or secondary tumors. The operative approach should be aimed at ensuring R0 resection margins whenever it is possible. Lymph node dissection during resection of ICC is not recommended as it does not improve patients' survival^[193,194]. Current outcomes after surgical resection have improved in comparison to historical data with 5-year survival rates ranging from 20% to 40% (Table 9)^[195-201]. Predictors of poor outcomes include: positive resection margins, lymphatic and vascular invasion and periductal infiltrating disease^[202,203]. The most common site of recurrence after surgical resection is within the liver^[196].

HCC

Curative surgery of HCC usually requires the excision of the extrahepatic bile duct, regional lymphadenectomy, cholecystectomy and in most cases some sort of partial hepatectomy including the caudate lobe, especially for tumors mainly extending in the left hepatic duct^[174,207]. The rationale behind performing partial hepatectomies in HCC is to ensure histologically negative margins. Several studies have shown that this strategy increases R0 resections in up to 80% of patients^[174,182,205]. Extended lymphadenectomy is not recommended as there is no evidence showing survival advantage^[168,172].

Radical resection of HCC has 5%-10% perioperative mortality rate, especially when extended hepatectomy (5 or more segments) is required^[174,206-208]. This partly

¹Patients had node negative tumors as well.

relates to the increased rate of postoperative liver failure with major hepatic resections. Portal vein embolization (PVE) is a valuable preoperative measure when anticipating extensive liver resections with subsequent small hepatic residual volume^[209]. A compensatory hypertrophy of the remnant hepatic parenchyma is induced by selectively occluding the main portal vein branch to the lobe that will be resected. This can increase the volume of the anticipated liver remnant by 12%-20%, thereby reducing the rate of postoperative liver dysfunction^[210,211]. PVE is useful when the anticipated liver remnant volume is less than 20%-25% of the total liver volume in patients with normal liver function, and when the anticipated liver remnant volume is 40% or less in patients with compromised liver function^[212].

The average 5-year survival rates post-resection for HCC are 25%-40% (Table 10)^[68,174,182,209,213-218]. Factors associated with favorable outcome include; R0 resection, no lymph node metastasis, absence of perineural invasion, and well-differentiated histological grade^[174,185].

ECC

The same principle of achieving a negative resection margin applies to ECC. The resectability rate has been reported as being up to 90% with distal extrahepatic tumors^[68,219]. Complete removal of distal ECC usually requires a pancreaticoduodenectomy (Whipple procedure)^[73,220,221]. Even in these circumstances, extended lymphadenectomy is not justified as it does not provide survival advantages and it is associated with increased perioperative morbidity^[222]. Segmental bile duct excision is rarely an option, except for CC located in the middle of the common duct in the absence of periductal invasion or spread to the surrounding structures. Only 10% of patients undergoing bile duct excision alone obtain curative resection margins on final pathology^[222,223]. Most commonly, when approaching patients with CC arising midway along the extrahepatic duct, surgeons should assess whether a pancreaticoduodenectomy or a partial hepatectomy is more appropriate with regard to the tumor extension. In these patients, curative resections are associated with a 25%-50% 5-year survival rate (Table 10)^[68,220,223-225]. The main determinants of poor outcomes are positive surgical margins and lymph node involvement^[220,223]. Other factors associated with unfavorable prognosis include pancreatic invasion, duodenal invasion, perineural invasion, and a poorly-differentiated histology^[68,220].

Liver transplantation

Transplantation is an emerging therapy for unresectable CC without evidence of metastatic disease. Candidates are individuals who would require a total hepatectomy to achieve clear margins and those with underlying liver failure precluding hepatic resection. The early experience of transplantation for CC reported early recurrence rates of more than 50% and a 5-year survival of 10%-20%^[226-228]. More recently, in highly selected patients undergoing neoadjuvant protocols, promising results have been reported. In 2002, Sudan *et al*^[229] reported a series of 11 patients transplanted for CC after neoadjuvant chemoradiation with 45% tumor free survival and median follow up of 7.5 years. Similar reports have been reported by Becker *et al*^[230] who observed a 45% 5-year survival for patients who were diagnosed as being affected by CC prior to undergoing transplantation, and a 33% 5-year survival was observed by Sotiropoulos *et al*^[231] in Germany. At the Mayo Clinic, Rosen *et al*^[232,233] have developed a liver transplantation protocol for HCC that provides a disease-free 5-year survival of 82%. This protocol is aimed at treating unresectable HCC or CC in PSC patients. To be eligible for this protocol, the diagnosis of CC is confirmed histologically, considered unresectable and with no evidence of metastatic disease. Eligible patients receive neoadjuvant chemoradiation therapy followed by staging laparotomy to rule out metastatic disease followed by living-related or cadaveric liver transplantation. Currently, the use of liver transplantation for the treatment of CC is reserved only for highly selected patients in specialized centers.

ADJUVANT THERAPY

The use of postoperative chemotherapy, radiotherapy or chemoradiation therapy have been evaluated as means of improving disease-free survival in patients with resected tumors since CC have high rates of local and distant recurrence.

Adjuvant chemotherapy

Postoperative chemotherapy has failed to show significant survival benefits^[234,235]. A recent multicenter RCT evaluated the effect of postoperative chemotherapy with mitomycin C and 5-fluorouracil (5FU) versus surgery alone for individuals affected by cancers of the pancreas and biliary system^[236]. Among 508 patients post-R0 resection, 139 individuals were affected by CC and for these individuals no survival benefit was seen after chemotherapy treatment^[237].

Adjuvant radiotherapy

The use of postoperative external beam radiation with or without intraoperative radiotherapy and intraluminal radiotherapy (brachytherapy) has been explored in the adjuvant setting without significant benefits after R0 resections^[125,237,238]. On the other hand, several studies showed that adjuvant radiotherapy may benefit patients with positive resection margins^[239-241]. Todoroki *et al*^[241] showed that the 5-year survival in patients with

R1 resections was 34% when adjuvant radiotherapy (intraoperative and external beam) was used compared to 14% with surgery alone.

Adjuvant chemoradiation therapy

The radiosensitizing effect of chemotherapeutic agents has been evaluated in the adjuvant setting with positive results only for distal ECC. In a retrospective cohort study of 94 individuals who underwent resection for CC, 34% received postoperative chemoradiation^[242]. Longer survival was seen in patients who received adjuvant therapy (median survival 41 mo *vs* 24 mo)^[243]. Other retrospective studies demonstrated similar results and showed that patients with distal ECC had a superior survival advantage in comparison to more proximal CC following adjuvant therapy^[243,244]. Recently, Hughes *et al*^[245] have confirmed a slight 5-year survival advantage with postoperative chemoradiation therapy in patients with distal ECC compared with surgical resection alone (35% *vs* 27%). In line with these findings, Figueras *et al*^[246] did not demonstrate a significant survival benefit with adjuvant chemoradiation therapy for HCC. These results need to be confirmed further with larger prospective trials. For ICC, evidence to support the use of adjuvant chemoradiation therapy is very limited. In a recent retrospective study of 3839 patients, Shinohara *et al*^[247] have shown that the overall survival rate was significantly different between groups receiving surgery alone and surgery plus adjuvant radiation therapy ($P = 0.014$) and between radiation therapy alone and no treatment ($P < 0.0001$). The combination of surgery and adjuvant radiation therapy conferred the greatest benefit on overall survival (HR: 0.40; 95% CI: 0.3-0.47), followed by surgery alone (HR: 0.49; 95% CI: 0.44-0.54) and radiation therapy alone (HR: 0.68; 95% CI: 0.59-0.77) compared with no treatment.

There is a lack of RCT evaluating the utility of adjuvant therapy following R0 resections of CC. Moreover, most of the current studies are small and retrospective in nature and incorporated CC with cancers of the gallbladder and pancreas. Therefore, no standard adjuvant modalities are universally embraced for the treatment of CC.

Neoadjuvant therapy

The role of preoperative chemoradiation therapy has been evaluated in a small series of patients with ECC^[248]. Among nine patients who underwent neoadjuvant therapy, McMasters *et al*^[248] observed pathological complete response in 3 individuals and negative resection margins were obtained in all subjects. More recently, neoadjuvant therapy has been used in the setting of liver transplantation for CC with promising results. Further trials are required to better assess its efficacy.

PALLIATION

Nearly half of the patients with CC are considered candidates only for palliative treatments due to the advanced stage of their disease at the time of diagnosis or the

presence of significant comorbidities that prevent surgical therapy^[68,174]. Therefore, palliation plays an important role in the management of these individuals. The primary aim of palliative interventions is to improve quality of life by relieving symptoms and prolonging survival by preventing cholestatic liver failure. In the presence of incurable CC, tissue diagnosis should be obtained whenever possible to direct palliative therapy planning.

Biliary drainage

Biliary obstruction is the major cause of morbidity and mortality in patients with CC. The goals of biliary decompression are to relieve jaundice, pain, pruritus, and to prevent cholangitis and cholestatic liver failure^[249]. Different modalities are currently available to drain the biliary system and these include: endoscopic, percutaneous and surgical bypass. The ideal palliative biliary decompression should be effective, provide durable results, and have low risks of morbidity and mortality.

Biliary endoprosthesis (stenting)

Biliary stenting can be achieved endoscopically or percutaneously. Endoscopic biliary stenting is the most widely used method and the percutaneous approach is usually performed when endoscopic drainage fails or cannot be performed. Percutaneous stents can be either internal, external or both. External stents have the disadvantage of draining bile without the ability of enteric recycling and are associated with more discomfort and reduced quality of life. Little is known as to whether percutaneous or endoscopic biliary drainage have different overall efficacy in palliating patients with unresectable disease. Generally, only patients with advanced tumors that are totally obstructed are candidates for percutaneous external biliary drainage. A recent multicenter retrospective study from South Korea has shown that the placement of percutaneous self-expanding metallic stents across HCCs is associated with a higher success rate and lower risk of procedure-induced cholangitis^[250].

Endoscopic stents can be either self-expanding metallic or plastic (polyethylene). Metal stents are more expensive than plastic stents but have larger diameters and provide better patency rates^[251]. Metal stents can be either uncovered or covered by sealing the metallic mesh with a membrane which prevents tumor growth through the stent, increasing patency rates. Plastic stents often need to be changed at 2 to 3-mo intervals, while metal stents can remain patent up to 9 mo^[252]. Several RCT have compared metal to plastic stents for the treatment of patients with inoperable malignant biliary obstruction^[253,254]. These studies concluded that metal stents are more cost-effective for patients who are expected to survive more than 5 mo as they need less interventions and shorter hospitalizations^[254,255]. Patency rates are generally higher for ECC^[255] and metal stents provide superior palliation for HCC as compared to plastic stents^[256,257]. Draining about 25% of the hepatic parenchyma is usually sufficient for adequate palliation in the absence of infection^[250]. A RCT comparing unilateral versus bilateral drainage in patients with malignant hilar obstruction found that

drainage of one functional hepatic lobe is sufficient to relieve obstruction with no difference in complication and survival rates^[258]. It is important to note that stents placed for hilar lesions will require re-intervention in about 30% of patients due to stent occlusion^[259,260]. A RCT comparing covered to uncovered stents in patients with unresectable distal biliary malignancies showed that the patency of covered stents was significantly higher than that of uncovered stents^[261]. However, multiple studies report an increased risk of cholecystitis (5%) with the covered stents due to cystic duct occlusion^[262].

Surgical biliary drainage

Biliary-enteric anastomosis can be performed by open or laparoscopic approach. Studies comparing surgical to non-surgical biliary drainage showed similar overall palliative effects but with higher perioperative morbidity and mortality^[263,264]. Surgical drainage has the advantage of superior patency rates and prevents the need for stent exchanges required when using endoscopic or percutaneous stents due to clogging^[265]. Currently, the main candidates for surgical drainage are patients found to have unresectable CC at the time of exploration, individuals who are not able to undergo repeat endoscopic or percutaneous stent exchanges, and those who have long expected survival and who are fit for surgery^[183,266].

Palliative radiotherapy

Palliative radiotherapy may benefit patients with locally advanced unresectable CC or those who have undergone palliative bypass in the absence of distant metastases. The use of palliative radiotherapy has beneficial effects on pain relief, biliary patency and overall patient survival^[267,268]. The two most commonly used radiotherapy modalities are external beam radiation with 30 to 50 Gy, intraluminal brachytherapy with 10 to 20 Gy or the combination of both. Intraluminal brachytherapy is delivered by using iridium-192 seeds mounted on a catheter that is deployed across the tumor by endoscopic or percutaneous approach^[269]. It appears that brachytherapy is able to deliver more effective doses of radiation without damaging the surrounding organs. Generally, the majority of studies that demonstrated benefit of radiotherapy used combinations of both modalities with median patient survival ranging between 9 and 14 mo^[270-273]. Palliative radiotherapy is associated with increased incidence of complications such as cholangitis, gastroduodenitis and longer hospital stay in comparison to best supportive care and therefore it is not routinely used in many centers^[274]. Moreover, higher doses of radiation (more than 55 Gy) may be required to obtain an improved survival, with increased toxicity rates^[275]. Controlled studies are required to better evaluate the effectiveness and safety of these palliative treatments. For ICC, brachytherapy can be delivered by radioembolization with yttrium-90 microspheres^[276]. This approach has been shown to provide partial response in 27% of patients and stable disease in 68% with limited side effects; therefore it is not surprising that it has become the leading modality for palliation of CC in centers where this technique is available^[277].

Palliative chemotherapy

There is no standard chemotherapy option for patients with CC. Patients with widespread disease considered for palliative chemotherapy undergo treatment in an attempt to control the disease and improve their overall survival. Owing to the lack of RCT and the retrospective nature of observational studies with heterogeneous patient populations currently available, the interpretation of the survival benefit of palliative chemotherapy is difficult. Various chemotherapeutic agents with different dosing regimens have been tested with overall poor survival improvement. Historically, 5FU was the first chemotherapeutic agent used for palliation of CC patients with only 10% response rates when used alone. Several subsequent studies have evaluated 5FU in combination with other agents such as leucovorin, interferon-alpha, cisplatin, and oxaliplatin, with an overall response rate of 25% to 55% and a median survival ranging between 6 and 12 mo^[278-281]. Multiple phase II trials have evaluated the use of oral 5FU prodrugs (uracil-tegafur and capecitabine) in patients with advanced CC^[282,283]. For example, the combination of capecitabine and cisplatin had mild toxicity and produced a response in 41% of patients with a median survival of 12 mo^[283]. Gemcitabine proved to have good efficacy as a single agent in biliary malignancies with response rates of 30%^[284]. Several gemcitabine-based combinations, including cisplatin, capecitabine, and oxaliplatin have reported response rates up to 36% and median survival of 10 to 15 mo^[285-287]. Finally, a recent analysis of all the published chemotherapy trials in individuals affected by advanced CC from 1985 to 2006 concluded that gemcitabine combined with platinum compounds (cisplatin or oxaliplatin) had the best patient response rates^[288,289]. Recently, the roles of transcatheter arterial chemoembolization (TACE) and transcatheter arterial chemoinfusion (TACI) have been assessed for patients affected by unresectable ICC^[290,291]. Although TACE and TACI with gemcitabine, cisplatin and doxorubicin in different combinations^[292] are well tolerated, survival benefits have not been proven in large studies and will require further evidence before becoming widely accepted in the scientific community.

Photodynamic therapy (PDT)

PDT is an emerging palliative strategy based on the intravenous administration of photosensitizing agents that preferentially accumulate in malignant cells. After the delivery of these photosensitizing agents, specific wavelengths of light are administered causing activation of the photosensitizer and thus tumor cell necrosis^[293]. The depth of tumor necrosis obtained by this technique is between 4 mm and 6 mm^[294]. This modality is currently used as a palliative measure in conjunction with biliary stenting for nonresectable CCs. Improvements in quality of life, biliary drainage, and survival in patients with advanced CCs post-PDT have been reported in several case series^[294]. Furthermore, a RCT compared PDT with endoscopic stenting to stenting alone in patients with unresectable CC^[295]. The

study was terminated prematurely because PDT proved to be markedly superior to simple stenting. The PDT group in that trial had higher median survival (493 d *vs* 98 d), improved biliary drainage and better quality of life than the stenting alone group^[296]. Recently, PDT was investigated as a neoadjuvant modality before surgical resection of advanced HCC in 7 patients^[296]. Tumor-free resection margins were achieved in all patients with a 1-year recurrence-free survival rate of 83%^[297]. A recent study confirmed that the use of PDT as a neoadjuvant therapy is safe and can downstage tumors from unresectable to resectable^[297]. The main side effects of PDT include photosensitivity caused by the administration of photosensitizer agents and cholangitis related to biliary instrumentation^[294,298].

Other palliative measures: Several other palliative modalities have shown some benefits in selected groups of patients. Radiofrequency ablation has been used for patients unfit for surgery who have small intrahepatic CC^[299]. In a single-centre cohort of patients with unresectable intrahepatic CC, TACE has shown some survival advantage in comparison to best supportive care (median survival: 23 mo)^[300]. Hepatic arterial chemoinfusion offers tumor-directed chemotherapy and it has been proven to be safe^[301] as has localized ablation of tumor cells by high intensity intraductal ultrasound^[302]. Another promising area is the use of molecular targeting agents for chemoprevention and adjuvant therapy of CC such as cyclooxygenase-2 and nitric oxide inhibitors^[303]. The clinical utility of these emerging therapies needs further investigation before gaining wide acceptance.

CONCLUSION

Over the last decades several advances have occurred in the fields of epidemiology, diagnostic modalities, medical and surgical treatment of CC as well as in palliation. The diagnosis, staging and further management of patients affected by this disease may be a complex issue and requires expertise in many fields. To optimize the outcome of patients with suspected or proven CC, a multidisciplinary approach is recommended.

INTRODUCTION

Crohn's disease is a chronic inflammatory disease of the intestine of unknown etiology. It is characterized by focal or segmental transmural inflammation which can occur in any part of the digestive tract with occasional granuloma formation. This transmural inflammation disrupts intestinal mucosal integrity, favoring the development of abscesses and fistulas. When fistulas form, they can track between intestinal segments or between an intestinal segment and other organs (bladder, vagina), adjacent tissue or the skin. Fistulas are classified as internal when they communicate with adjacent organs (e.g. entero-enteric and rectovaginal fistulas) and external when they communicate with the dermal surface (e.g. enterocutaneous, peristomal and perianal fistulas).

The cumulative incidence of perianal fistulas in Crohn's disease varies between 20% and 25% in population studies^[1-3]. Perianal disease is associated with high morbidity and, typically, with local pain and discharge; it therefore has a very negative impact on the quality of life of the affected patients. In Crohn's patients, perianal disease is more common when the colon is affected and particularly when the rectum is involved^[2].

The ideal therapeutic goal in perianal fistulizing Crohn's disease is complete and sustained closure of the fistulas without the development of abscesses, thereby avoiding the need for surgical interventions, and improving the patients' quality of life. In an appreciable number of patients, complete closure cannot be achieved despite intensive medical treatment (including infliximab) and surgery in accordance with normal practice. Currently the goal of therapy for these patients has shifted from complete fistula closure to reduction in drainage from the fistula tract in order to improve their

Abstract

Complex perianal fistulas have a negative impact on the quality of life of sufferers and should be treated. Correct diagnosis, characterization and classification of the fistulas are essential to optimize treatment. Nevertheless, in the case of patients whose fistulas are associated with Crohn's disease, complete closure is particularly difficult to achieve. Systemic medical treatments (antibiotics, thiopurines and other immunomodulatory agents, and, more recently, anti-tumor necrosis factor- α agents such as infliximab) have been tried with varying degrees of success. Combined medical (including infliximab) and less aggressive surgical therapy (drainage and seton placement) offer the best outcomes in complex Crohn's fistulas while more aggressive surgical procedures such as fistulotomy or fistulectomy may increase the risk of incontinence. This review will focus on emerging novel treatments for perianal disease in Crohn's patients. These include locally applied infliximab or tacrolimus, fistula plugs, instillation of fibrin glue and the use of adult expanded adipose-derived stem cell injection. More well-designed controlled studies are required to confirm the effectiveness of these emerging treatments.

quality of life. In these patients with complex perianal fistulizing disease that persists despite intensive medical and surgical treatment, a therapeutic gap exists for new treatments which aim for complete and sustained closure of the perianal fistulas.

In this review, after a brief discussion of the diagnosis, characterization, classification, and current systemic treatments of perianal fistulas in patients with Crohn's disease, we shall discuss some of the newer local therapies and their potential applications.

DIAGNOSIS AND CHARACTERIZATION

The starting point for management of perianal fistulas is a complete and accurate diagnosis of the lesions, which requires careful exploration of the anal and perianal region. An inadequate examination which fails to detect occult lesions (abscesses or fistula branches) may result in perianal disease becoming persistent or recurrent. An endoscopic examination is needed to determine the presence of macroscopic inflammation in the rectum and/or rectal stenosis, as such findings are important for the prognosis and treatment of the disease. There is consensus among the American Gastroenterological Association (AGA)^[4,5] and European Crohn's & Colitis Organization (ECCO)^[6] working groups concerning the need to complement the study of perianal disease with other diagnostic tools such as examination under anesthesia (EUA), magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS).

In the hands of expert surgeons, EUA is considered the gold standard against which other techniques are compared. EUA has an accuracy of 90% for diagnosis and classification of fistulas and abscesses^[7]. With this technique, it is possible to perform concomitant surgery of the lesions: incision and drainage of abscesses with seton placement, and other procedures to treat fistulas. MRI has an accuracy of between 76% and 100% for diagnosis and classification of perianal fistulas^[7,8]. With MRI, the surgeon who performs EUA can obtain important additional information in 15%-21% of patients^[7,9]. In view of its harmless nature and the additional information it provides, MRI is the initial diagnostic technique of choice according to the ECCO consensus statement^[6]. EUS offers a diagnostic accuracy of between 56% and 100%, and the findings change the surgical approach in 10%-15% of cases^[7,10], helping to guide medical-surgical treatment of perianal fistulas in Crohn's disease, resulting in a high response rate^[11]. Sometimes, the pain caused by the lesions or stenosis makes EUS difficult.

The combination of either of these imaging techniques (MRI or EUS) with EUA yields a diagnostic accuracy of 100% for perianal disease^[7]. Imaging techniques are essential to provide surgeons with a virtual view which allows them to treat all lesions during the surgical procedure.

CLASSIFICATION OF PERIANAL FISTULAS

A number of classification systems have been proposed

in the past^[12,13], but perhaps the most anatomically accurate is the Parks classification^[14], which takes the external anal sphincter as the central reference point and describes 5 types of perianal fistula: superficial, inter-sphincteric, trans-sphincteric, supra-sphincteric and extra-sphincteric. The Parks classification is however limited in that it does not take into account the presence of abscesses and/or connections with other organs such as the vagina or bladder, even though such information is important for determining the medical and surgical management of the disease.

The AGA technical review proposed a more clinically useful classification system with just 2 categories: simple and complex fistulas^[4,5]. Simple fistulas are low (superficial, low inter-sphincteric or low intra-sphincteric), have a single external opening and are not associated with perianal abscess, connection to the vagina or bladder, rectal stenosis or macroscopic proctitis. In contrast, complex fistulas are high (high inter-sphincteric, high intra-sphincteric, supra-sphincteric or extra-sphincteric) and/or can have several external openings and may be associated with perianal abscess, connection to the vagina or bladder, rectal stenosis or macroscopic proctitis. This classification has greater clinical relevance: simple fistulas respond better to treatment whereas complex ones have lower cure rates with medical treatment and, with this type of fistula, an aggressive surgical procedure will often lead to incontinence.

MEASURES OF HEALING

The Crohn's Disease Activity Index (CDAI) is widely used in Crohn's disease as an outcome measure but it is not designed or able to assess perianal fistulous disease activity, thus the Perianal Disease Activity Index (PDAI) is often used as an equivalent of this index for measurement of morbidity associated with perianal disease^[15]. This index assesses 5 categories related to fistulas: discharge, pain, restriction of sexual activity, type of perianal disease and degree of induration. The advantage of the PDAI is that it assesses aspects of the quality of life that are most affected in patients with perianal disease and that it has been validated in recent clinical studies^[16].

The most widely used instrument for assessing treatment outcomes in clinical trials is the Fistula Drainage Assessment. This measure classifies fistulas as open (i.e. purulent material is expelled with gentle pressure) or closed^[17]. A fistula has to remain closed for 2 consecutive visits (at least 4 wk apart) to be considered in remission. The Fistula Drainage Assessment does not consider changes in anal pain, which is also an important marker of treatment response.

Consideration of complete re-epithelization of the external openings supported by MRI studies could represent a major improvement in the assessment of fistula closure. Long term maintenance of the healing is of great therapeutic relevance. Indeed, the drafted guideline of the European Medicines Agency (EMA)

on “The clinical development of new medicinal products for the treatment of Crohn's Disease (Doc. Ref. CPMP/EWP/2284/99 Rev. 1)” states that “the therapeutic goals of management of fistulizing Crohn's disease are to close fistulas and maintain their closure, to reduce the incidence of infections in persisting fistulas, and to limit the need for surgical interventions. Clinical studies in fistulizing Crohn's disease should reflect this. The primary endpoint of the clinical trials should then be complete closure of fistulas and maintenance of a closed fistula without development of new fistulas.”

An MRI-based activity score was developed to assess the anatomical evolution of perianal fistulas in Crohn's disease^[18]. MRI imaging demonstrates that despite closure of draining external orifices after infliximab treatment, inflammatory changes in the fistula track persist for a long time. It has been suggested that this residual activity may cause recurrent fistulas and pelvic abscesses but a *post hoc* analysis of the ACCENT II study showed that maintenance infliximab therapy does not result in increased abscess development in patients with fistulizing Crohn's disease^[19].

TREATMENT

Crohn's disease cannot be cured by medical or surgical treatment. The aim of therapy is to alleviate symptoms and treat complications of the disease in order to improve the patients' quality of life. The strong negative impact of symptomatic perianal disease on quality of life justifies aggressive treatment to facilitate healing. The spontaneous cure rate for perianal fistulas is very low, ranging from 6% to 13% in the placebo arm of 3 controlled studies^[17,20,21].

Medical treatments

Antibiotics: Bacteria may in theory play a role in the appearance and persistence of perianal fistulous disease. Thus antibiotics are sometimes used as first-line therapy for fistula healing. In other cases antibiotics, in view of their prophylactic effects against infections and abscesses, are used as adjuvant (or bridging) therapy. Most of the studies of perianal fistulizing disease treated with antibiotics are uncontrolled and the sample sizes are small. In these studies, both metronidazole^[22-24], and ciprofloxacin^[25], as well as a combination of the 2 drugs^[26], showed an initial beneficial effect on the perianal fistula. Response typically occurs after 6 to 8 wk of treatment and is usually manifest in the form of decreased drainage. Fistula closure is uncommon and symptoms tend to recur after suspending treatment^[24].

Recently, a small randomized, double-blinded, placebo-controlled study evaluated ciprofloxacin or metronidazole for the treatment of perianal fistulas in patients with Crohn's disease^[27]. Twenty-five patients were randomized to ciprofloxacin 500 mg (10 patients), metronidazole 500 mg (7 patients) or placebo (8 patients) twice daily for 10 wk. Response ($\geq 50\%$ reduction in the number of draining fistulas) at week 10 was seen in 4 patients (40%) treated with ciprofloxacin,

1 patient (14.3%) treated with metronidazole, and 1 patient (12.5%) treated with placebo ($P = 0.43$). One patient from both the ciprofloxacin and placebo arm and 5 (71.4%) treated with metronidazole dropped out of the study ($P < 0.02$). This study was probably too small to detect differences between treatment arms.

In two studies, antibiotics were used as an adjuvant or a bridge to other drugs. The use of metronidazole and/or ciprofloxacin induced a response ($\geq 50\%$ reduction in the number of draining fistulas) at week 8 with fistula closure occurring in 25% of cases^[28]. At week 20, those patients who received additional azathioprine therapy had a better medium-term response (48% *vs* 15%). It should be pointed out that most of the patients in that study had simple fistulas and that only 9 of the 52 cases were classed as complex fistulas. In a placebo-controlled study, all patients received infliximab (3 induction doses at weeks 6, 8 and 12) and were randomized to receive either 500 mg ciprofloxacin twice daily or a placebo for 12 wk^[16]. The response rate (defined as $\geq 50\%$ reduction from baseline in the number of draining fistulas) at week 18 showed a tendency in favor of ciprofloxacin in combination with infliximab compared to infliximab alone (OR: 2.37; 95% CI: 0.94-5.98)^[16].

Thiopurines: Azathioprine and 6-mercaptopurine have shown efficacy in the treatment of Crohn's perianal fistulas. In a meta-analysis of 5 controlled studies, a response (defined as complete closure or decreased drainage) was found in 54% of the patients treated with azathioprine or 6-mercaptopurine compared to 21% in the placebo group (OR: 4.44; 95% CI: 1.50-13.2)^[29]. This meta-analysis is limited in that fistula response was a secondary endpoint and not the primary one in all of the studies included. There have been no controlled trials in which the primary endpoint was assessment of the effect of thiopurines on the closure of fistulas in patients with Crohn's disease.

Anti-tumor necrosis factor (TNF)- α agents: The efficacy of the anti-TNF- α antibody infliximab in fistulizing perianal disease refractory to 3 mo of conventional treatment has been shown in a controlled clinical study^[19]. The most favorable outcomes were obtained at doses of 5 mg/kg body weight and 3 induction infusions at 0, 2 and 6 wk. This regimen achieved complete fistula closure (no drainage in 2 visits 4 wk apart) in 55% of the patients compared to only 13% in the placebo group. The mean time to response was 2 wk and the mean duration of response was 12 wk after the last infusion. The ACCENT II study later confirmed the response rate to induction (69% at week 14) in the open-label extension^[30]. Responders were randomized to infliximab 5 mg/kg body weight or placebo every 8 wk. At week 54, 36% of the patients on infliximab were able to maintain complete closure compared to 19% of those on placebo ($P = 0.009$). Similar results have also been reported in clinical practice in a large uncontrolled series^[31].

Infliximab maintenance treatment has been shown to decrease the use of hospital resources (fewer hospitalizations and less need for surgery) in patients with fistulizing Crohn's disease^[32]. Nevertheless, it has been reported that in perianal disease, early relapse was common after stopping infliximab treatment, with only 34% of patient maintaining remission at 1 year^[33].

Adalimumab, another anti-TNF- α antibody, may also prove effective in perianal Crohn's disease. In the CHARM study, 33% of the patients randomized to adalimumab achieved long term complete fistula closure versus 13% in the placebo group (secondary endpoint; placebo *vs* adalimumab group combined; $P = 0.043$)^[34]. Complete fistula healing was sustained for up to 2 years by most of the patients in the open extension trial ADHERE. In a prospective open-label study in patients with active perianal fistulous disease who stopped responding or developed intolerance to infliximab, adalimumab induction therapy (160 mg at week 0 and 80 mg at week 2) induced complete fistula closure at week 4 in 23% of the cases^[35].

Other immunomodulators: Randomized studies designed specifically to assess the efficacy of cyclosporine in the closure of fistulas in patients with fistulizing Crohn's disease have not been published. However, there are several uncontrolled case series which used continuous cyclosporine infusion in patients who had failed conventional therapy^[36]. Many patients showed an initial response and were switched to oral cyclosporine; however the response was rapidly lost on drug withdrawal.

Uncontrolled case series suggested that tacrolimus may be useful in the treatment of perianal disease^[37,38]. In a small controlled clinical trial, patients treated with tacrolimus (0.2 mg/kg per day) had a higher response rate (defined as closure of at least 50% of fistulas) at week 4 compared to placebo (43% *vs* 8%), but no differences were observed in terms of complete fistula closure (10% *vs* 8%)^[21].

In a retrospective study methotrexate was used in patients with fistulizing Crohn's disease; after 6 mo 44% of the patients had partial or complete fistula closure^[39]. An early case series suggested that the antimetabolite agent mycophenolate mofetil could be effective in Crohn's perianal disease^[40]. In a more recent uncontrolled study from the same group mycophenolate mofetil induced a partial response in 7 out of 8 patients with perianal fistulas, but the response was subsequently lost in 5 of these 7 patients for several reasons including side effects^[41].

In refractory Crohn's disease, small uncontrolled series showed that thalidomide may be effective in treating complex perianal fistulas^[42,43]. Severe side effects, including neuropathy, were common and limited the long term use of the drug. Lenalidomide, an analogue of thalidomide, with lower toxicity and powerful anti-TNF properties was not effective in active luminal Crohn's disease^[44], and has not yet been tested for perianal Crohn's disease.

Miscellaneous therapies: A pilot open-label study provided data suggesting granulocyte colony-stimulating factor (GM-CSF) is a safe and potentially effective agent for the treatment of active perianal Crohn's disease^[45]. GM-CSF has been used in a placebo-controlled study in patients with luminal Crohn's disease, some of whom had draining fistulas at study entry. At 6 mo, 4 out of 8 patients in the GM-CSF group and 2 out of 5 in the placebo group had complete fistula closure^[46].

Octreotide, a somatostatin analogue, may have a role in treating Crohn's enterocutaneous fistulas, but has not been used in perianal disease^[47]. The effect of elemental diet on perianal Crohn's disease has been studied in a small retrospective series. Fistulas improved in some patients but early relapse occurred in almost all the cases^[48]. In a review of 22 patients with active and refractory perianal Crohn's disease treated with hyperbaric oxygen, 73% achieved a response^[49]. In a randomized, placebo-controlled trial oral, spherical adsorptive carbon was effective for the control of perianal fistulas in patients with Crohn's disease (remission rates were 29.6% *vs* 6.7% for placebo)^[50]. There is not sufficient evidence for any of these agents to support their use in patients with Crohn's perianal fistulas outside of clinical trials.

Summary of medical treatment in current guidelines: Despite methodological limitations in the supporting studies, antibiotics and azathioprine or 6-mercaptopurine are considered first-line therapy in complex perianal disease in the ECCO consensus statement^[6], and infliximab is reserved as a second-line treatment in case of failure. In the AGA technical review^[4,5] infliximab is recommended for treatment of complex perianal disease along with azathioprine or 6-mercaptopurine and antibiotics for the induction phase. Maintenance is recommended with azathioprine or 6-mercaptopurine, in association with infliximab in some cases.

Surgical treatment

Surgical treatment of complex perianal fistulizing disease aims to control sepsis through abscess drainage and intervention in the fistula tracts, including placement of non-cutting setons^[51]. Fistulectomy or fistulotomy are rarely indicated in complex fistulas in view of the high rate of proctectomy because of nonhealing or incontinence associated with the procedure^[6,51,52]. In severe cases with high fistulas, endorectal flaps are useful^[51,53]. In patients with severe refractory disease, diversion with ostomy (loop ileostomy or end sigmoid colostomy) or even proctectomy might be necessary.

In an uncontrolled study carbon dioxide laser ablation has been used as an alternative treatment in patients with perianal Crohn's disease^[54].

Combined medical and surgical treatment

The ideal treatment goal for complex perianal fistulas associated with Crohn's disease is the closure of all the fistulas and the prevention of recurrence. The

best outcomes have been achieved in studies using a combination of medical and surgical therapy^[55,56].

Surgery may offer some advantages when combined with medical treatment, for example, infliximab. There is concern, however, that use of infliximab may cause abscesses by inducing rapid closure of the fistulas. This problem might be reduced by performing MRI or EUS-guided EUA to detect all fistula tracks and to insert draining setons. Regueiro *et al.*^[55] observed that patients who underwent an EUA before infliximab administration were significantly less likely to have fistula recurrence compared to those treated with infliximab alone (44% *vs* 79%).

Hyder *et al.*^[57] investigated such a strategy in patients with perianal Crohn's disease. After EUA, 12 out of 22 patients required abscess drainage and 17 out of 22 had at least one drainage seton inserted. The short-term efficacy of that strategy was as high as 85% as measured by the PDAI; although the authors noted that long term healing rates were low. Talbot *et al.*^[58] reported a similar strategy in patients with complex fistulas-setons were inserted and removed after the second infliximab infusion. Complete healing of the perianal fistula was obtained in 47% of the patients and all showed at least a partial response.

The presence of active proctitis has a negative impact on the outcome of the surgical treatment of Crohn's fistulas. A pilot study suggested that infliximab treatment has a beneficial additive effect in the multistep treatment to first improve the proctitis before performing surgery in complex perianal Crohn's disease with active proctitis^[59].

In one recent retrospective study, 21 patients with Crohn's perianal fistulas and symptomatic perianal disease were treated according to a treatment protocol of serial EUS examinations^[60]. Surgical and medical therapy was tailored to the results of the EUS findings with seton placement and incision and drainage procedures performed when appropriate. Follow-up EUS examination guided when to remove setons or when to stop infliximab or antibiotics. Median follow-up was 68 wk (35-101 wk). No abscesses developed in any patient. Eighteen out of 21 patients (86%) had complete drainage cessation initially, and 16 out of 21 (76%) had long term cessation of drainage. Eleven (52%) had no persistent fistula activity on EUS. In 7 of these, the fistula remained closed after stopping infliximab or antibiotics while the remaining 4 continued infliximab for mucosal disease. This study showed that EUS-guided combination surgical and medical treatment with infliximab had high short and long term fistula response rates^[60].

In a recent randomized prospective study, 10 patients with active Crohn's perianal fistulas were randomized to either EUS guidance or control^[61]. All patients underwent an initial EUS. Patients in the EUS cohort were evaluated by a colorectal surgeon who had access to the EUS findings. The surgeon was blinded to the results of the initial EUS for those in the control group. EUA with seton placement or incision and drainage

was done at the surgeon's discretion, and all patients received optimal medical therapy including antibiotics, azathioprine or 6-mercaptopurine and infliximab. Patients in the control group received further therapy at the surgeon's discretion without EUS guidance. Those in the EUS cohort had additional EUS evaluations at weeks 22 and 38 with further therapy based on EUS results. One of 5 (20%) in the control group and 4 of 5 (80%) in the EUS group had complete cessation of drainage. In this small study, EUS guidance for combination medical and surgical therapy in perianal Crohn's disease appeared to improve outcomes.

Local treatments

Fistula healing is not possible in a significant percentage of patients with complex fistulizing Crohn's disease managed according to the currently accepted treatment algorithms^[4-6]. In addition, systemic medical treatments may be subject to intolerance or loss of response and surgical treatments such as fistulotomy should be used with caution given the risk of incontinence. Thus there is a therapeutic gap in the management of perianal Crohn's disease, and a number of local therapies which aim to achieve complete closure are under development. Table 1 summarizes studies of these new local treatments. The following sections will discuss these new local treatments in more detail.

Topical tacrolimus: Topical tacrolimus has been used successfully in the treatment of skin diseases with an immune component such as atopic dermatitis^[62]. Casson *et al.*^[63] therefore decided to investigate whether an in-house-prepared topical formulation could be beneficial in a series of pediatric patients with different manifestations of Crohn's disease including one case of perianal fistula; the patient responded to treatment although details of fistula healing were not presented.

The efficacy of topical tacrolimus in perianal Crohn's disease was recently investigated in a randomized placebo-controlled study^[64]. In that study, 19 patients, 12 of whom had fistulizing perianal Crohn's disease, were randomized to topical tacrolimus (1 mg in 1 g ointment applied twice daily) or placebo for 12 wk. In the case of patients with fistulas, the primary outcome measure was improvement defined as $\geq 50\%$ decrease in actively draining fistulas on 2 consecutive visits. Treatment showed a beneficial effect on anal and perianal ulcerating disease but lacked efficacy in the treatment of fistulizing Crohn's disease.

Fibrin glue: Instilling fibrin glue into fistulas is a simple and safe procedure which does not preclude the use of other techniques or repeat procedures in the case of failure^[65]. Several studies have been published of series of patients treated with fibrin glue and success rates vary from 0% to 80% (Table 1). This variability can be attributed, among other things, to the different types of fistulas treated (simple or complex; cryptoglandular, Crohn's, or traumatic etiology), and the differences in the definition of healing.

Table 1 Summary of studies of local treatments

Intervention reference	Study design and patients	Main findings
Topical tacrolimus		
Casson <i>et al</i> ^[63] , 2000	Case study of series of pediatric Crohn's patients including 1 patient with perianal fistula	Response reported in patient with perianal fistula
Hart <i>et al</i> ^[64] , 2007	Randomized, placebo-controlled study in 19 patients (12 Crohn's)	Treatment found not to be beneficial in perianal fistulas
Fibrin glue		
Abel <i>et al</i> ^[79] , 1993	Uncontrolled study of use of fibrin glue in 10 patients (2 Crohn's)	0/2 patients with Crohn's disease achieved healing
Cintron <i>et al</i> ^[80] , 2000	79 patients (6 Crohn's) assigned to 3 types of fibrin glue treatment	2/6 Crohn's patients (33%) achieved healing (no drainage)
Lindsey <i>et al</i> ^[66] , 2002	Randomized trial comparing fibrin glue with conventional surgery (fistulotomy or loose seton placement) in 42 patients (6 Crohn's and complex perianal fistula)	Healing (no drainage) in 2/6 Crohn's patients (33%) who received fibrin glue. No Crohn's patients received conventional surgery
Sentovich ^[81] , 2003	Uncontrolled study: 48 patients (5 Crohn's) underwent seton placement followed by instillation of fibrin glue	Healing in 4/5 (80%) Crohn's patients
Zmora <i>et al</i> ^[82] , 2003	Retrospective review of 37 patients with perineal fistula (7 Crohn's) treated with fibrin glue	Healing in 3/7 Crohn's patients (43%) (2 patients also treated with endorectal advancement flap)
Loungnath <i>et al</i> ^[83] , 2004	Retrospective review of 42 patients with perianal fistula (13 Crohn's) treated with fibrin glue	Lasting fistula healing in 4/13 (31%)
Singer <i>et al</i> ^[84] , 2005	Randomized trial comparing fibrin glue + antibiotics, fibrin glue + surgery, and fibrin glue + antibiotic and surgery in 75 patients (3 Crohn's)	Treatment failed in all 3 Crohn's patients (fibrin glue + antibiotic in 1 patient and fibrin + antibiotic and surgery in 2 patients)
Intralesional infliximab		
Poggioli <i>et al</i> ^[68] , 2005	Uncontrolled study of 15 Crohn's patients with complex perianal fistulas	Healing in 10/15 patients after 3-12 infusions
Asteria <i>et al</i> ^[69] , 2006	Uncontrolled study of 11 Crohn's patients with complex perianal fistulas naïve to infliximab	8/11 patients responded ($\geq 50\%$ reduction in fistula drainage) to treatment
Adipose-derived stem cell (ASC) therapy with fibrin glue		
García-Olmo <i>et al</i> ^[72] , 2005	Uncontrolled proof-of-concept study in patients with fistulizing Crohn's disease, including 1 perineal fistula	Perineal fistula healed after 8 wk
García-Olmo <i>et al</i> ^[73] , 2009	Randomized controlled phase II study comparing fibrin glue + ASCs with fibrin glue in 49 patients with complex perianal fistula (14 Crohn's)	Healing in 5/7 Crohn's patients (71%) in fibrin glue + ASCs group compared to 1/7 (14%) in the control group
Fistula plugs		
O'Connor <i>et al</i> ^[75] , 2006	Uncontrolled study of fistula plug in 20 Crohn's patients with fistula tracts not amenable to fistulotomy	Success rate of 80%, lower in the case of complex fistulas
Schwandner <i>et al</i> ^[76] , 2008	Uncontrolled study of 19 patients (7 Crohn's) with trans-sphincteric anorectal fistulas	Treatment success in 6/7 patients with Crohn's disease (86%)
Ky <i>et al</i> ^[77] , 2008	Prospective analysis of 45 patients (20 with complex fistulas and 14 with Crohn's disease) receiving anal fistula plug	Healing in 4/14 Crohn's patients (29%) after a median follow-up of 6.5 mo

Only one controlled study with patients with Crohn's disease has compared fibrin glue with surgical treatment not involving fibrin glue. In that study, Lindsey *et al*^[66] randomized patients with simple and complex fistulas to treatment with fibrin glue or conventional treatment (fistulotomy or loose seton placement with or without subsequent flap advancement). For the purposes of the study, complex fistulas were defined as high fistulas, fistulas associated with Crohn's disease, and low fistulas with compromised sphincters. Both Crohn's patients with complex fistulas reported healing, in one case after a second procedure. Healing among Crohn's patients in the other arm was not reported.

Intralesional infliximab: Although systemic infliximab administration is considered one of the more efficacious therapeutic options available for complex perianal fistulas associated with Crohn's disease, several authors have investigated the efficacy of local application of this drug. The main rationale for this approach is to try and avoid the potential systemic toxicity associated with infliximab. The first study to employ this approach was

published by Lichtiger *et al*^[67] in 2001. Nine patients with perianal Crohn's disease refractory to antibiotics or 6-mercaptopurine were treated with a circumferential and intrafistulous injection of infliximab at 0, 4, and 7 wk. Remission or partial response was achieved in 83% of the patients.

Since then, a number of uncontrolled studies have been conducted to assess the feasibility of local infliximab therapy. Poggioli *et al*^[68] included 15 patients with complex perianal fistulas associated with Crohn's disease. In 9 of these, intravenous infusion of infliximab was felt to be contraindicated because of fibrostenotic disease. The patients were injected with 15-21 mg of infliximab at the internal and external openings and along the fistula tract. The injections were well tolerated and 10 of the 15 patients achieved healing after 3 to 12 injections. A similar study was reported by Asteria *et al*^[69], although patients were excluded if they had received prior treatment with infliximab. Up to 3 injections of 20 mg of infliximab were made along the fistula tract and at both openings. The efficacy endpoint was reduction in fistula drainage of 50% or more (response)

or complete cessation of fistula drainage for at least 4 wk (remission). Overall, 8 patients achieved a response (73%) and, of these, 3 achieved remission (27%). After a longer follow-up (mean 10.5 mo, range 7-18 mo), 6 patients were responders and 4 were in remission.

Adipose-derived stem cell therapy: Adult stem cell therapy has promising applications in a number of areas of medicine and has no ethical concerns. Given that liposuction is a relatively safe procedure, an appealing source of adult stem cells is lipoaspirate^[70]. The stromal cells obtained are subsequently cultured and expanded to produce autologous adipose-derived adult stem cells (ASCs). Trials of ASCs in the treatment of fistulizing Crohn's disease have delivered the expanded ASCs by injecting them around the fistula opening and directly into the fistula tract.

The first procedure of this type published in the literature was a case report of a 33-year-old woman with Crohn's disease and a rectovaginal fistula refractory to treatment^[71]. ASCs were injected into the rectal mucosa, close to the sutured internal opening. After resection of the posterior vaginal wall and construction of an advancement vaginal flap, the accessory perineal hole was sealed with 2 mL of fibrin glue. One week after the intervention, the wound had completely healed. In 3 mo of follow-up, no recurrence of the rectovaginal fistula was reported.

A subsequent phase I study assessed 9 ASC injection procedures in 4 patients with fistulizing Crohn's disease^[72]. The series included 3 rectovaginal fistulas and 1 perineal fistula. As before, cells were injected into the rectal mucosa, close to the sutured opening and fistula tracks were then filled with fibrin glue. Two of the 3 rectovaginal fistulas and the perineal fistula had healed after 8 wk.

One randomized clinical trial using ASCs has also been conducted. In a recently completed phase II study, 49 patients with perianal fistula-14 of whom had Crohn's disease-were randomized to receive ASC therapy and fibrin glue or to receive fibrin glue alone (control group)^[73]. The primary outcome measure was the proportion of patients with complete fistula closure. An investigator blinded to the treatment confirmed healing by examination of a digital photograph. Five of the 7 patients with Crohn's disease assigned to ASC therapy achieved healing compared to one of 7 patients in the control group. The difference was not statistically significant but the study was not powered to detect differences in small subgroups such as those with Crohn's disease. Healing in this trial was defined as the absence of drainage, as well as complete epithelization of external openings. No severe adverse events related to ASCs have been reported when utilized for fistulizing Crohn's disease.

Fistula plugs: Recently, the use of bioprosthetic plugs made from porcine intestinal submucosa has been tried in patients with perianal fistula. In a prospective study which excluded patients with Crohn's disease, Johnson

et al^[74] randomized patients with high transsphincteric or deeper fistulas to either fistula plug or fibrin glue therapy. Of the 10 patients who underwent fibrin glue treatment, 6 (60%) had persistence of one or more fistulas at 3 m compared to 2 out of 15 (13%) of those who underwent the procedure with the fistula plug ($P < 0.05$). In a subsequent prospective but uncontrolled study, 20 Crohn's patients with a total of 36 fistula tracts not amenable to fistulotomy were treated with fistula plugs^[75]. After irrigation with hydrogen peroxide, each primary opening was occluded with a fistula anal plug. The authors found an overall success rate of 80%, although they noted that patients with complex fistulas with multiple primary openings were less likely to achieve success. Success appeared to be independent of the presence of setons or the use of anti-TNF- α therapy.

Schwandner *et al*^[76] have reported their experience in a series of 19 patients with transsphincteric anorectal fistulas. Seven of these patients had Crohn's disease. The surgical procedure comprised irrigation of the fistula tract and placement and internal fixation of the anal fistula plug without flap advancement or excision of the fistula tract. Success was defined as closure of both the internal and external openings with no further interventions and absence of abscess formation. Six of the 7 patients with Crohn's disease achieved success (85.7%).

In another retrospective study, anal fistula plugs were more successful in the treatment of simple anorectal fistulas but were associated with a high failure rate in complex perianal fistulas and particularly in patients with Crohn's disease (closure rate of 26.6% of fistulas in this group)^[77].

In a recent retrospective review reported at the 2008 Digestive Diseases Week conference^[78], the use of anal fistula plugs was associated with a lower success rate than previously reported: only 2 of the 22 (15%) Crohn's disease-associated fistulas healed. In 87% of the procedures the reason for failure was sepsis. These controversial results in an uncontrolled series await confirmation by randomized trials.

CONCLUSION

Symptomatic perianal fistulas in patients with Crohn's disease can have a large negative impact on quality of life. Treatment of complex perianal fistulas remains a difficult problem. Use of anti-TNF- α antibody therapy is widespread and supported by randomized clinical trials. Nevertheless, some patients fail anti-TNF- α treatment and, given the risk of incontinence associated with aggressive surgical procedures, there remains an unmet therapeutic need. Some of the emerging local therapies have obtained promising results in patients with fistulizing Crohn's disease in uncontrolled studies and case series but, for the most part, this promise has still to be confirmed in randomized trials. Adipose-derived stem cell therapy has compared favorably with fibrin glue alone in a randomized phase II trial, and high

healing rates were observed. Once the efficacy of these new local therapies has been confirmed, further effort will be required to optimize their use in the management of fistulizing Crohn's disease, which is necessarily complex and multidisciplinary.

ACKNOWLEDGMENTS

The authors thank Greg Morley for his invaluable contribution in the writing of this article.

Abstract

AIM: To evaluate the proportion of successful complete cure *en-bloc* resections of large colorectal polyps achieved by endoscopic mucosal resection (EMR).

METHODS: Studies using the EMR technique to resect large colorectal polyps were selected. Successful complete cure *en-bloc* resection was defined as one piece margin-free polyp resection. Articles were searched for in Medline, Pubmed, and the Cochrane Control Trial Registry, among other sources.

RESULTS: An initial search identified 2620 reference articles, from which 429 relevant articles were selected and reviewed. Data was extracted from 25 studies ($n = 5221$) which met the inclusion criteria. All the studies used snares to perform EMR. Pooled proportion of *en-bloc* resections using a random effect model was 62.85% (95% CI: 51.50-73.52). The pooled proportion for complete cure *en-bloc* resections using a random effect model was 58.66% (95% CI: 47.14-69.71). With higher patient load (> 200 patients), this complete cure *en-bloc* resection rate improves from 44.19% (95% CI: 24.31-65.09) to 69.17% (95% CI: 51.11-84.61).

CONCLUSION: EMR is an effective technique for the resection of large colorectal polyps and offers an alternative to surgery.

INTRODUCTION

The use of endoscopic mucosal resection (EMR), pioneered in Japan for the treatment of early gastric cancer, has expanded to include therapy of other early gastrointestinal malignancies and pre-cancerous lesions such as adenomas. At the same time, this technique has gained acceptance in Europe and in the US, especially for the treatment of Barrett's esophagus with high grade dysplasia^[1-3]. Several variations of the EMR technique have been devised such as inject-lift-cut, strip biopsy, suction cup (EMRC), and EMR with a ligating device.

Throughout the world, adenomas of the colorectum represent the single most important premalignant lesion of the GI tract. Large (> 2 cm) colorectal polyps have been found in 0.8%-5.2% of patients undergoing colonoscopies for different indications^[4].

Large sessile and flat polyps represent a major technical challenge to conventional snare resection. Additional procedures and therapies such as Argon plasma coagulation are frequently needed to destroy remnant tissue after resection^[5]. When these techniques are not used or possible, patients are frequently referred for surgical resection^[6].

EMR has been shown to be useful in the removal of large colorectal sessile and flat lesions^[7]. However, there are limits to the size of lesions which can be removed *en-bloc* with the various EMR techniques, with 1.5-2 cm generally being the upper limit^[8].

En-bloc removal of large polyps is desirable as it facilitates thorough histological evaluation related to the

completeness of resection, and is associated with a lower recurrence rate as compared to piecemeal removal^[19-14].

MATERIALS AND METHODS

Study selection criteria

Studies using EMR technique to resect large (> 2 cm) colorectal polyps were selected. Successful cure *en-bloc* resection was defined as one piece removal with tumor-free vertical and lateral margins.

Data collection and extraction

Articles were searched for in Medline, Pubmed, Ovid journals, Japanese language literature, Cumulative Index for Nursing & Allied Health Literature, ACP journal club, DARE, International Pharmaceutical Abstracts, old Medline, Medline non-indexed citations, OVID Healthstar, and the Cochrane Controlled Trials Registry. The search terms used were EMR, endoscopic mucosal resection, colon polyps, lateral spreading tumors, large polyps, nonpolypoid colon lesions, flat colon polyps, and flat adenomas. Two authors (SP and YK) independently searched and extracted the data for revising into an abstracted form. Any differences were resolved by mutual agreement.

Quality of studies

Clinical trials with a control arm can be assessed for the quality of the study. A number of criteria have been used to assess the quality of a study (e.g. randomization, selection bias of the arms in the study, concealment of allocation, and blinding of outcome)^[15,16]. There is no consensus regarding how to assess studies without a control arm. Hence, these criteria do not apply to studies without a control arm^[16]. Therefore, for this meta-analysis and systematic review, studies were selected based on completeness of data and inclusion criteria.

Statistical methods

This meta-analysis was performed by calculating pooled proportions, i.e. pooled proportion of *en-bloc* resections and complete cure *en-bloc* resections. Firstly, the individual study proportions of successful resections were transformed into a quantity using Freeman-Tukey variant of the arcsine square root transformed proportion. The pooled proportion was calculated as the back-transform of the weighted mean of the transformed proportions, using inverse arcsine variance weights for the fixed effects model and DerSimonian-Laird weights for the random effects model^[17,18]. Forrest plots were drawn to show the point estimates in each study in relation to the summary pooled estimate. The width of the point estimates in the Forrest plots indicated the assigned weight to that study. The heterogeneity among studies was tested using Cochran's Q test based upon inverse variance weights^[19]. If P value was > 0.10, the null hypothesis was rejected that the studies were heterogeneous. The effects of publication and selection bias on the summary estimates were tested by Begg-Mazumdar bias indicator^[20]. Also, funnel plots were constructed to evaluate potential publication bias using the standard error and diagnostic odds ratio^[21,22].

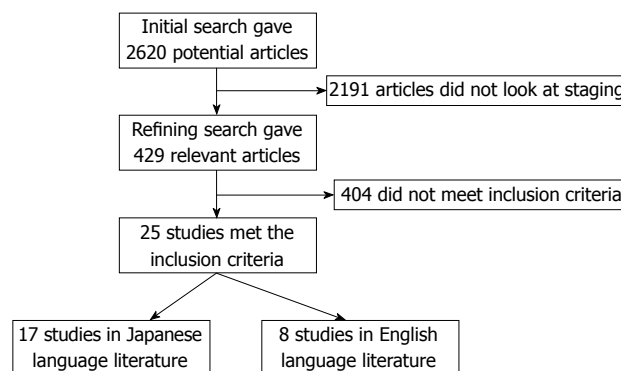

Figure 1 Search results.

RESULTS

An initial search identified 2620 reference articles from which 429 relevant articles were selected and reviewed. Data was extracted from 25 studies ($n = 5221$) which met the inclusion criteria^[23-46]. The search results are shown in Figure 1. All the studies used snare to perform EMR. Two studies used a strip biopsy technique^[42,43]. The mean size of the polyps was 22.48 ± 4.52 mm. There were 3755 successful *en-bloc* resections. The study characteristics are shown in Table 1.

The pooled proportion of *en-bloc* resections using a random effect model was 62.85% (95% CI: 51.50-73.52). Forest plot in Figure 2A depicts the individual study proportion of successful *en-bloc* resections in relation to the pooled estimate. The pooled proportion for complete cure *en-bloc* resections using a random effect model was 58.66% (95% CI: 47.14-69.71). Figure 2B shows Forrest plot depicting the individual study successful cure *en-bloc* resections in relation to the pooled estimate. The fixed effect model was not used because of the heterogeneity of studies.

Subgroup analysis was carried out by grouping studies according to the study population. This was done because the expertise needed to perform procedures might have affected the outcome. Studies were categorized into three groups: < 100 patients, 100-200 patients and > 200 patients. The proportions for successful *en-bloc* and successful cure *en-bloc* resections are shown in Table 2.

The publication bias calculated by Begg-Mazumdar bias indicator for successful cure *en-bloc* resections concluded that the Kendall's tau b value was -0.19 ($P = 0.17$). The funnel plot in Figure 3 shows that there was no publication bias for successful cure *en-bloc* resections.

DISCUSSION

Some colorectal cancers develop from adenomas. The risk of high grade dysplasia and cancer increases with the size of the lesion. Endoscopic removal of large (> 2 cm) sessile and flat polyps represents a difficult challenge for conventional snare resection and they are frequently managed by piecemeal resection or surgically^[6,47]. EMR was the definitive procedure in all the collated studies. The data for complications was not available for the majority of the studies, so this data was not collected. EMR is a technique that can be applied to sessile and flat

Figure 2 Forrest plot showing successful *en-bloc* (A) and cure *en-bloc* (B) resection.

lesions. Though initially used for the treatment of early gastric cancer in Japan, the technique has been expanded to the therapy of large colorectal neoplasms^[7].

This meta-analysis revealed that *en-bloc* resection was achieved in 62.85% of lesions and tumor-free vertical and lateral margins were achieved in 58.6%. These results compare well to *en-bloc* resection rates achieved by conventional polypectomy snare, which have been reported

to be between 7% and 34% for large sessile polyps^[6,48].

Furthermore, our meta-analysis revealed that experience performing EMR plays an important role in achieving a better *en-bloc* resection and cure *en-bloc* tumor-free rate. Studies reporting more than 200 lesions removed reported a 71.39% *en-bloc* resection of lesions and tumor-free vertical and lateral margins in 69.17% of cases, while studies reporting less than a 100 lesions reported a

Table 2 Results based on study size

Study size	No. of studies	Successful <i>en-bloc</i> resection (95% CI)	Successful cure <i>en-bloc</i> resection (95% CI)
< 100 patients	9	48.07% (28.36-68.09)	44.19% (24.31-65.09)
100-200 patients	9	68.93% (50.39-84.76)	63.32% (43.50-81.04)
> 200 patients	7	71.39% (52.24-87.20)	69.17% (51.11-84.61)

Figure 3 Funnel plot showing publication bias for successful cure *en-bloc* resection.

48.07% *en-bloc* removal and tumor-free vertical and lateral margins in 44.19% of cases. This indicates that experience in the technique of EMR increase the cure *en-bloc* rate.

In the present meta-analysis we searched the world literature which included articles published in Japanese language literature. We believe that our results are a reasonable reflection of the status of EMR in the therapy of large colorectal polyps.

EMR is an effective technique for resection of large colorectal polyps. The technique offers an alternative to surgery. This meta-analysis shows that the success rate for *en-bloc* margin-free resection is not high but improves with experience. Improvements in techniques and equipment are needed to increase complete cure *en-bloc* resection rates.

COMMENTS

Background

Endoscopic mucosal resection (EMR) has emerged as an alternative to surgery for the resection of large colorectal polyps. Complete cure with tumor-free lateral and vertical margins would prevent further therapy. Published data regarding successful *en-bloc* resection with tumor-free margins by EMR has been varied.

Innovations and breakthroughs

EMR has been shown to be useful in the removal of large colorectal sessile and flat lesions. However, there are limits to the size of lesions which can be removed *en-bloc* with the various EMR techniques, with 1.5-2 cm generally being the upper limit. *En-bloc* removal of large polyps is desirable as it facilitates thorough histological evaluation related to the completeness of resection, and is associated with a lower recurrence rate as compared to piecemeal removal.

Applications

EMR is an effective technique for resection of large colorectal polyps and offers an alternative to surgery. This meta-analysis shows that the success rate for *en-bloc* margin-free resection is not high but improves with experience. Improvements in techniques and equipment are needed to increase complete cure *en-bloc* resection.

Peer review

The authors evaluated the proportion of successful complete cure *en-bloc*

resections of large colorectal polyps achieved by EMR. They found that EMR is an effective technique for resection of large colorectal polyps. This article is well written and easy to read.

Sirolimus, bevacizumab, 5-Fluorouracil and irinotecan for advanced colorectal cancer: A pilot study. *World J Gastroenterol* 2009; 15(34): 4278-4283 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4278.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4278>

Abstract

AIM: To evaluate the efficacy and the safety of combined 5-Fluorouracil, irinotecan, bevacizumab and sirolimus in refractory advanced colorectal carcinoma.

METHODS: We initiated a regimen with at day 1 an injection (*iv*) of bevacizumab at 5 mg/kg, followed by 180 mg/m² irinotecan, followed by Leucovorin 400 mg/m², followed by a 5-Fluorouracil bolus 400 mg/m² and a 46-h infusion 2400 mg/m². Sirolimus was given orally as continuous administration of 2 mg twice a day every days. This treatment was repeated every 14 d.

RESULTS: A total of 12 patients were enrolled. All patients presented with metastatic disease that had failed at least three lines of chemotherapy that contained oxaliplatin, irinotecan and bevacizumab. Cetuximab failure was also observed in all K-Ras wild-type patients. The median number of cycles was 8.5 (range 2-20) and clinical benefit was observed in eight patients. The median time to progression was 5 mo and the median survival was 8 mo. Grade 3 neutropenia developed in four patients, and grade 3 diarrhea and stomatitis in two.

CONCLUSION: The combination regimen of 5-Fluorouracil,

INTRODUCTION

Colorectal cancer is the third most common cancer worldwide^[1]. Approximately 25% of patients with colorectal cancer present with overt metastatic disease, and metastatic disease develops in 40%-50% of newly diagnosed patients. Standard first-line treatments include fluorouracil (5-FU) with leucovorin and irinotecan^[2,3] or oxaliplatin^[4], alone or combined with bevacizumab^[5]. Cetuximab, a chimeric IgG1 monoclonal antibody against epidermal growth factor receptor (EGFR), has efficacy as monotherapy and in combination with irinotecan in irinotecan-resistant patients, if the tumor expresses wild-type K-RAS and B-RAF^[6,7]. However if these standard treatments fail, there are no accepted treatment options, and for such patients historical estimation of progression-free survival (PFS) and overall survival (OS) are about 2 and 4 mo, respectively^[8].

Recent results have suggested that inhibitors of mTor (mammalian target of rapamycin) signal are able to improve survival and induce tumor response in patients with poor-prognosis renal cell carcinoma^[9], and combination of mTor inhibitors and classical

chemotherapy is currently under clinical investigation. In colorectal carcinoma cell lines *in vitro*, rapamycin enhances the antitumor effect of irinotecan through Hypoxia-inducible factor-1 α inhibition (a key transcription factor that regulates angiogenesis) and by disruption of tumor vasculature^[10]. Therefore, we hypothesize that, in multi-treated colorectal patients, multimodal angiogenesis targeting using irinotecan, bevacizumab and the mTor inhibitor sirolimus can have a therapeutic effect.

The goal of this pilot study was to evaluate the safety and efficacy of sirolimus, bevacizumab, leucovorin, 5-FU, and irinotecan (FOLFIRI) in patients with advanced colorectal cancer that had progressed after treatment with 5-FU, irinotecan, oxaliplatin, bevacizumab and anti-EGFR therapy.

MATERIALS AND METHODS

Eligibility criteria

The eligibility and exclusion criteria, and pretreatment characteristics of the patients are presented in Table 1. Written informed consent was required before chemotherapy.

Treatment protocols and dose modification

On day 1, irinotecan (180 mg/m²) was administered as a 2-h *iv* infusion. Then leucovorin 400 mg/m² followed by a 5-Fluorouracil bolus 400 mg/m² was administered as a bolus *iv* injection. Then 5-Fluorouracil 2400 mg/m² was given as a 46-h *iv* infusion. Bevacizumab was given at 5 mg/kg as an *iv* infusion every two weeks over 60 min before the beginning of the chemotherapy. Sirolimus was given orally as continuous administration of 2 mg twice a day every days. The doses used for fluorouracil, irinotecan and bevacizumab were the classical recommended doses^[2-5]. For sirolimus, a dose of 4 mg/d was chosen because a phase I study has demonstrated that this is tolerable and sufficient to achieve mTor inhibition^[11]. Dose modifications of irinotecan or 5-FU were made for hematological or non-hematological toxicity, on the basis of the most severe grade of adverse effect that occurred during the previous cycle. Treatment was delayed until the absolute number of neutrophils was > 1000/ μ L, platelets were > 100 000/ μ L, and mucositis, diarrhea, or skin toxicity had recovered to grade 1 or less. The 5-FU dose was reduced after the occurrence of National Cancer Institute Common Toxicity Criteria (NCI-CTC) grade 3 diarrhea, stomitis or dermatitis. For toxicity of grade 3 or higher, a 20% dose reduction for irinotecan was prescribed by the protocol. Bevacizumab was retained for uncontrolled hypertension or proteinuria of > 3 g in 24 h. Bevacizumab was discontinued for grade 3 or 4 hemorrhage, thromboembolic events that required full dose anticoagulation, or any grade 4 toxicity. Sirolimus was discontinued for grade 3 or 4 diarrhea or stomatitis. Treatment was administered until the disease progressed, unacceptable toxic effects developed, or the patient refused further treatment.

Table 1 Inclusion and exclusion criteria

Inclusion criteria	Exclusion criteria
Histologically confirmed colorectal cancer (adenocarcinoma)	Thromboembolism that required therapeutic anticoagulation
Measurable disease	Central nervous system metastasis
No secondary malignancy	Major surgery within 6 wk
Age > 18 years	Nonhealing wounds
ECOG performance status 0-2	Uncontrolled hypertension
Adequate hematological, hepatic and renal function (including urinary excretion of no more than 500 mg protein/d)	Pregnant or lactating women
Failure of bevacizumab, oxaliplatin and irinotecan-based treatment	Bleeding diathesis, active or recent
For wild-type K-Ras: failure with cetuximab and irinotecan combination was required	Cardiovascular disease
Failure caused by significant intolerance to either drug was allowed	Cerebrovascular accident

Pretreatment and follow-up evaluation

Pretreatment evaluation included physical examination, complete blood cell counts, blood chemistry, tumor marker level (carcinoembryonic antigen, CEA), and computed tomography (CT) within 15 d of starting chemotherapy. Tumor responses were determined by RECIST and Choi criteria^[12,13]. Complete blood cell counts, serum chemistry, including liver and renal function, were performed at least every two weeks, and tumor assessment by CT was performed every three cycles.

Statistical analysis

Efficacy analysis was performed according to the intention-to-treat principle. Patients were considered assessable for response if they were eligible, had measurable disease, and had received at least one dose of study therapy. In the analysis of survival and subsequent treatment, all patients were followed until death, loss to follow-up, or termination of the study. PFS and OS were calculated using the Kaplan-Meier method. PFS was calculated from the date therapy started to the date of disease progression, and OS was calculated from the date therapy started to the date of death.

RESULTS

Patient characteristics

Between January 2008 and December 2008, a total of 12 patients were included in this pilot study at the Department of Medical Oncology, Georges-Francois Leclerc Cancer Center, Dijon, France. Demographic details of the patients included in the study are shown in Table 2. There were seven male and five female patients, median age 61 years (range 51-75). All patients had progressed after prior 5-FU, irinotecan and bevacizumab therapy, and 5-FU, oxaliplatin and bevacizumab therapy. Importantly, all patients had been treated previously with FOLFIRI bevacizumab chemotherapy and experienced progression according to the RECIST criteria following this treatment. Nine patients harbored wild-type K-Ras tumor and progressed on irinotecan plus cetuximab

therapy. All 12 patients were assessable for response, for toxicity and survival.

Objective tumor responses and survival

There were a median 8.5 cycles (range 2-20) of chemotherapy. Chemotherapy was stopped because of disease progression in 10 patients, and two discontinued because of toxicity (grade 3 diarrhea and stomatitis). Median follow-up duration was 9 mo. At 2 mo, CEA level decreased in all except one patient (mean level 882 ± 510 vs 579 ± 320 ; $P = 0.025$, Wilcoxon test; Figure 1). According to RECIST criteria, one patient had a partial response, seven had stable disease for > 3 mo, and four had progressive disease. According to the Choi criteria, three patients had a partial response, five had stable disease, and four had progressive disease (Figure 2). PFS was 5 mo (95% CI: 2.5-6), and median OS was 7 mo (95% CI: 4-NR). Figure 3 shows PFS and OS curves.

Toxicity

A total of 116 cycles of chemotherapy were administered.

Figure 2 Representative CT scan of patients responding according to Choi criteria. A: (Patient 5) Contrast-enhanced CT-scan (arterial phase) showed three large liver metastases before inclusion; B: Two months later, a significant decrease in the enhancement of the metastases was observed by CT performed under the same conditions (arterial phase). Although lesions were classified as stable disease using RECIST criteria, they could be considered as a partial response using Choi criteria; C: (Patient 8) Contrast-enhanced CT-scan (arterial phase) showed two latero aortic lymph node metastases. Density was 82.8 UH (arrow). To assure comparability, density was also measured in muscle (72.8 UH) (arrow head); D: After 2 mo, although size of lymph node metastases was stable, there was a significant decrease in density (59 UH) (arrow), which led to a partial response using Choi criteria. In comparison, muscle exhibited no decrease in density (73 UH) (arrow head).

Figure 3 Kaplan-Meier curves of progression-free survival (PFS) and overall survival (OS).

All patients received at least 1 mo of the chemotherapy and sirolimus regimen. Dose modifications or interruptions were required in three patients. The incidence of hematological and non-hematological toxicity is summarized in Table 3. The major grade 3/4 hematological toxicity included neutropenia in three patients (25%) and thrombocytopenia in two (16%). No neutropenic fever was observed. Grade 1/2 nausea, vomiting and diarrhea developed in five patients; however, this toxicity was mild and manageable. In two patients, sirolimus-related grade 3 stomatitis led to treatment discontinuation. Only grade 2 nose bleeding were observed and did not require therapeutic modification. Hypertension occurred in three patients and was managed without drug modification. Proteinuria > 2 g/24 h occurred in one patient and was treated by angiotensin-converting enzyme inhibitors. All patients with stable disease had minor grade 1/2 manageable adverse effects. There was no treatment-related death. Eight deaths were caused by disease progression.

DISCUSSION

Recent trials with advanced colorectal carcinoma have shown that patients may survive for 24-30 mo^[14]. However, after failure of irinotecan, oxaliplatin, bevacizumab and anti-EGFR therapy, there are no accepted treatment options. Estimated PFS is about 2 mo and OS is 4 mo^[8].

Few nonrandomized trial have demonstrated that association of fluorouracil or capecitabine with mitomycin may give some response in heavily pretreated patients^[15-18]. Such treatments give an objective response rate of about 10% and PFS of 2-3 mo. Although, in these trials, patients did not benefit from new target therapies.

Recently, target therapy such as sorafenib and sunitinib have given some promising results in patients with end-stage colorectal cancer. Sunitinib was tested in a phase II trial in patients with previously treated colorectal metastases at a dose of 50 mg/d for 4 wk, followed by 2 wk off treatment^[19]. Median time to progression was 2.5 mo and median OS was 7 mo in bevacizumab-

pretreated patients and 10 mo in those not pretreated with bevacizumab. Sorafenib has been tested in association with oxaliplatin in a phase I trial in patients with oxaliplatin-refractory colorectal cancer. The recommended dosage was 130 mg/m² oxaliplatin and continuous sorafenib 400 mg twice daily. This treatment showed promising efficacy^[20].

The phosphoinositide 3-kinase/mTOR axis is a pivotal pathway in cell growth and cell-cycle progression, in response to different stimuli, such as nutrients and growth receptors^[21]. The mTor pathway is activated aberrantly in around half of human tumors and plays a crucial role in angiogenesis. mTor inhibition is now considered as an important target for new anticancer drugs^[22]. In a phase I trial, mTor inhibitors showed minor efficacy in colorectal carcinoma^[23]. *In vitro* and preclinical studies have demonstrated the synergistic efficacy of combined rapamycin and irinotecan^[10]. In fact, irinotecan and rapamycin act on tumor growth by inhibiting angiogenesis by acting on Hypoxia inducible factor-1 α ^[24,25]. Recently, combination of everolimus and bevacizumab has demonstrated some activity in patients with refractory metastatic colorectal cancer who had progressed on a bevacizumab-based regimen, which suggests that bevacizumab and mTor inhibitors overcome resistance to bevacizumab^[26]. Therefore, we hypothesized that combination of sirolimus, bevacizumab and irinotecan may provide some synergistic antiangiogenic effects that can reverse resistance to bevacizumab- and irinotecan-based chemotherapy.

In our pilot study, combination of sirolimus, bevacizumab, 5-FU and irinotecan demonstrated that, for patients with advanced colorectal cancer, some clinical stabilization and prolonged stable disease can be obtained. CT monitoring suggested an antiangiogenic effect of the therapy, with tumor necrosis obtained in three patients. Median PFS of 5 mo and median OS of 8 mo suggest a potential clinical benefit of a such treatment. Despite its potent efficacy, this target therapy can have adverse effects, and we have to balance the efficacy, toxicity and cost of such therapy. Further studies will be needed to confirm our results.

COMMENTS

Background

Novel combinations of new chemotherapeutic agents and target therapies have demonstrated an improvement in tumor response and overall survival in patients with advanced colorectal cancer. Although, after failure of irinotecan, oxaliplatin, bevacizumab and cetuximab, no treatment demonstrates efficacy.

Research frontiers

The phosphoinositide 3-kinase/mTOR (mammalian target of rapamycin) axis is activated aberrantly in around half of human tumors and plays a crucial role in angiogenesis. In a phase I trial, mTor inhibitors showed minor efficacy in colorectal carcinoma. *In vitro* and preclinical studies have demonstrated the synergistic efficacy of combined rapamycin and irinotecan. Recently, combination of everolimus (an mTor inhibitor) and bevacizumab have demonstrated some activity in patients with refractory metastatic colorectal cancer who had progressed on a bevacizumab-based regimen, which suggests that bevacizumab and mTor inhibitors overcome resistance to bevacizumab. Therefore, the authors hypothesized that combination of sirolimus, bevacizumab and irinotecan provides some synergistic antiangiogenic effects that can reverse resistance to bevacizumab- and irinotecan-based chemotherapy.

Innovations and breakthroughs

This is believed to be the first study to investigate the capacity of an mTor inhibitor to reverse resistance to conventional therapies. The data suggest that both treatment regimens demonstrate efficacy and tolerable toxicity in this setting.

Applications

These data are in accordance with the preliminary findings from ASCO 2009, which demonstrate that sirolimus may reverse resistance of colorectal cancer to bevacizumab therapy. The data suggest that the therapy may have some clinical efficacy but substantial adverse effects.

Terminology

Sirolimus, also called rapamycin, is an mTor inhibitor. This drug is used as an immunosuppressant but demonstrates antitumor efficacy by inhibiting the mTor/AKT pathway. Irinotecan kills cells by inhibiting the enzyme topoisomerase I, which is also involved in DNA synthesis in proliferating cells. Bevacizumab is a monoclonal antibody that inhibits VEGF, which is expressed in some cases of colorectal cancer and aids the blood supply to tumors; bevacizumab inhibits this process and tumor cell growth.

Peer review

This is an interesting small pilot study that investigated fourth-line chemotherapy in patients with advanced metastatic colorectal cancer that had failed at least three previous chemotherapeutic regimens. A major finding was that clinical benefit was observed in 8/12 patients with severe adverse effects and relatively short overall survival.

Abstract

AIM: To investigate any protective effect of early propranolol administration in the development of portal hypertensive gastropathy in cirrhotic rats.

METHODS: For the development of liver cirrhosis and portal hypertensive gastropathy, 60 rats underwent ligation of the left adrenal vein and complete devascularization of the left renal vein, followed by phenobarbital and carbon tetrachloride (CCl₄) administration. After two weeks of CCl₄ administration, the rats were randomly separated into two groups. In group A, propranolol was continuously administered intragastrically throughout the study, whereas in group B normal saline (placebo) was administered instead. Hemodynamic studies and vascular morphometric analysis of gastric sections were performed after complete induction of cirrhosis.

RESULTS: Vascular morphometric studies showed higher numbers of vessels in all mucosal layers in

the control group. Statistical analysis revealed a significantly higher total vascular surface in the control group compared to the propranolol group, but with no statistically significant difference between the mean vascular surfaces between the groups. Our study clearly shows that the increased mucosal blood flow is manifested by a marked increase of vessel count.

CONCLUSION: Early propranolol's administration in portal hypertensive cirrhotic rats seems to prevent intense gastric vascular congestion that characterizes portal hypertensive gastropathy.

INTRODUCTION

Portal hypertension is a clinical syndrome characterized by elevation of portal pressure and accompanies most cases of hepatic cirrhosis. Most liver cirrhosis complications are attributable to concomitant portal hypertension and the consequent development of portosystemic collaterals and hyperdynamic circulation^[1-4]. Portal hypertensive

gastropathy (PHG) represents a clinical entity in portal hypertension and is endoscopically characterized by a mosaic-like or snake skin pattern of the gastric mucosa, mainly in the body and fundus of the stomach and more rarely in the gastric antrum^[5,6]. These gastric mucosal lesions represent another frequent cause of upper gastrointestinal bleeding, even though esophagogastric varices remain the major source of bleeding in patients with portal hypertension^[5,7].

Non-selective β -blockers have largely been used for primary prophylaxis of bleeding from gastroesophageal varices^[8-12]. Their effect though, as well as of many other agents, on the development of varices has yet to be clarified because there are conflicting results from several studies, both clinical and experimental^[13-17]. On the other hand, development of PHG seems to follow a different pathophysiological pathway and there are relatively few studies investigating drugs' effect on PHG. Propranolol, for example, has been shown to reduce bleeding related to PHG in small studies^[11,12] and these observations were confirmed in a randomized controlled trial of 56 patients with PHG^[18]. We therefore decided to investigate propranolol's effect on PHG and to clarify more precisely if early propranolol administration has any preventive effect on the development of PHG in rats with carbon-tetrachloride (CCl₄)-induced cirrhosis.

MATERIALS AND METHODS

Animals

Sixty four-month-old-male Wistar rats, weighting 280-350 g, were used. They were housed one per cage, kept on an artificial 12-h light-dark cycle and at stable room temperature of 20-22°C. They had free access to tap water and standard laboratory pulverized rat chow throughout the study.

For all animal experiments the "Principles of laboratory animal care" (NIH publication No. 86-23, revised 1985) were followed. The study was approved by the Ethical Committee of the Aristotle University of Thessaloniki.

Experimental model

Liver cirrhosis, portal hypertension and esophagogastric varices were induced using a model, originally developed in our department, which has been proved to be very effective for the induction of cirrhotic portal hypertension as well as of esophageal and gastric varices^[19].

Briefly, all animals underwent ligation of the left adrenal vein and complete devascularization of the left renal vein. Two weeks later, induction of liver cirrhosis started according to the model of weekly intragastric administration of CCl₄ in the phenobarbitone-induced rat^[20,21].

Animal groups and drug administration

Two weeks after the beginning of carbon tetrachloride administration, the rats were randomly separated into two groups. In Group A, comprising 30 rats, propranolol was continuously administered throughout the study, whereas in Group B (30 rats), normal saline (placebo)

was continuously administered instead of propranolol. This early commencement of drug administration, before the full development of liver cirrhosis, aimed to simulate clinical practice, where any kind of preventive treatment should begin soon after initiation of the effect of a hepatotoxic agent. Propranolol (Inderal®, Wyeth Pharmaceuticals Inc., USA), dissolved in normal saline, was administered intragastrically, at a dose of 30 mg/kg per day.

Experimental period - animal sacrifice

CCl₄ was administered weekly until stable ascites developed (8-10 wk) as previously described^[16,17,19,22]. Ascites development was easily recognized by an abrupt increase in body weight and confirmed by the abdominal distention observed in the anesthetized rat in the prone position. Once stable ascites developed, CCl₄ administration was discontinued; one week later, rats were re-operated, portal pressure was measured and then the animals were sacrificed with an *iv* bolus administration of 0.5 mL of potassium chloride. The liver, stomach, and esophagus were carefully dissected and removed.

Portal pressure measurement

Portal pressure measurements were performed before animal sacrifice under light ether anesthesia; the rats were kept fasting for 12 h, with free access only to water. The peritoneal cavity of the animal was carefully accessed through the old midline incision, the presence of ascites was confirmed and ascitic fluid was carefully collected and measured. Portal pressure measurement was conducted by catheterization of a mesenteric vein with a PE-50 catheter, which was advanced until its tip reached the origin of the portal vein, while its other end was connected to a Space Labs, Inc. (Model 90308-11-14) pressure recorder. The external zero reference point was placed at the mid portion of the rat.

Histopathological study

The liver, stomach, and esophagus were fixed in 10% buffered formalin solution and embedded in paraffin soon after their removal.

Two sections of the stomach, the first at the cardioesophageal junction and the second at the body of the stomach, were stained with hematoxylin-eosin and initially examined on a light microscope (magnification $\times 4$ and $\times 10$). A liver section was also examined to confirm development of liver cirrhosis.

Morphometric analysis

Following light microscopy, all sections to be studied were scanned by a high resolution frame capture camera (JVC TK-F7300U), processed with computer software (Tema v1.00) and reproduced on a high-contrast, high-resolution PC monitor.

By use of the above mentioned software, delineating the outlines of vessels led to an easy calculation of the following parameters per optical field: (1) Total number of veins counted in gastric submucosa; (2) Total submucosal area occupied by vessels; (3) Mean

cross sectional vessel area (this variable was calculated by dividing total submucosal vessel area by the number of submucosal vessels); (4) Total number of superficial vessels in the gastric mucosa; (5) Total area of superficial vessels in the gastric mucosa; (6) Mean cross sectional vessel area of superficial gastric mucosal vessels; (7) Total number of deep gastric mucosal vessels; (8) Total area of deep gastric mucosal vessels; and (9) Mean cross sectional area of deep gastric mucosal vessels

All calculations were performed blindly by an experienced pathologist who was not informed as to the origin of the preparations.

Statistical analysis

Statistical version 6.0 (Stat Soft Inc.) was used for statistical analysis. First, the distribution of each parameter was determined according to its histograms and normal plots and was confirmed by application of the Shapiro-Wilk W test. Results were expressed as mean \pm SD for variables with normal distribution and as median - interquartile range for skewed distribution. Comparison between groups was performed using Student's t -test for unpaired data to evaluate differences in portal pressure and total submucosal area occupied by vessels; values of these variables followed a normal distribution. For all other variables, the non-parametric Mann Whitney U -test was applied. $P < 0.05$ were considered statistically significant.

RESULTS

Mortality

Forty-eight rats survived the study. There were no significant differences in body weight of rats among the two groups. There were seven deaths in group A and five in group B. As shown in Table 1, one of the propranolol group rats and two of the control group died from variceal bleeding before the end of the study (large amounts of blood were found in the stomach and upper jejunum). Two rats of group A and three rats of group B died from improper manipulation (administration of carbon tetrachloride into the tracheal-bronchial tree), while the deaths of four group A rats were attributed to CCl_4 toxicity.

Ascites

No significant difference in the amount of ascitic fluid was observed between the two groups ($P > 0.05$).

Portal pressure

Portal pressure values followed a normal distribution in both groups. Mean portal pressure was lower in the propranolol group (11.6 ± 1.36) compared to mean portal pressure of control group (14.61 ± 1.84) (Table 2). Comparison between groups revealed a portal pressure decrease of 21.5% in the propranolol group, which was proved to be statistically significant ($P < 0.05$).

Liver cirrhosis

All rats developed micronodular cirrhosis within 8-10 wk.

Table 1 Number of rats and causes of death

	Total number of deaths <i>n</i> (%)	Cause of death		
		Variceal bleeding	CCl_4 toxicity	Improper manipulation
Group A (<i>n</i> = 30)	7 (23.3)	1	4	2
Group B (<i>n</i> = 30)	5 (16.67)	2	-	3

Table 2 Portal pressure in group A and B

	Portal pressure (mmHg)			
	Mean	Minimum	Maximum	SD
Group A (<i>n</i> = 23)	11.60	9.20	14.3	1.36
Group B (<i>n</i> = 25)	14.61	11.3	18.2	1.84

Propranolol causes significant decrease ($P < 0.05$) in portal pressure.

Regenerating nodules surrounded by thickened septa of connective tissue with obvious architectural distortion were present on all hepatic sections. There was no obvious difference in the degree of hepatic fibrosis between the groups.

Gastric sections on light microscopy

Microscopic examination of the stomach revealed excessive mucosal and submucosal vascular congestion. Besides congestion, animals of group B (placebo treated groups) were found with more mucosal and submucosal vessels, while in some of them the development of smooth muscle cells in the mucosa was noticed.

Morphometric analysis of gastric mucosa and submucosa

Measurements and calculations were performed by image analysis in both groups. From the variables studied, only total and mean cross sectional area of superficial gastric mucosal vessels followed a normal distribution in both groups, while all other variables studied presented skewed distributions in either group or were non-continuous scale variables. Comparison between groups was performed using Student's t -test for unpaired data for the variables "total area of gastric superficial mucosal vessels" and "mean cross sectional area of gastric superficial mucosal vessels", and the non-parametric Mann Whitney U -test for all other variables. The summarized analysis and comparison of data are shown in Table 3. Statistically significant differences ($P < 0.05$) between groups were revealed for the variables "total area occupied by vessels" and "total number of counted veins" in the submucosa, the deep and superficial layers of gastric mucosa. On the other hand, the variable "mean cross sectional area" of gastric submucosal vessels as well as of deep and superficial gastric mucosal vessels did not differ significantly between the groups.

DISCUSSION

Esophageal varices have long been considered the major cause of upper gastrointestinal hemorrhage in patients

Table 3 Results of morphometric analysis and comparison between groups

	Group A	Group B	P
Total area of submucosal vessels (μm^2)	47 441.37 \pm 24 299.48	47 539.12 (33 295.84, 55 931.07)	0.0037
Mean cross sectional area of submucosal vessels (μm^2)	4682.70 (3571.92, 6350.68)	5911.17 \pm 1963.34	0.09
Number of submucosal vessels	5 (4, 7)	8 (7, 9)	0.01
Total area of superficial gastric mucosal vessels (μm^2)	7004.03 \pm 2438.37	10 994.49 \pm 3746.56	0.0001
Mean cross sectional area of superficial mucosal vessels (μm^2)	642.78 \pm 432.59	573.70 (475.08, 623.39)	0.25
Number of superficial gastric mucosal vessels	12 (9, 14)	20 (17, 24)	0.00001
Total area of deep gastric mucosal vessels (μm^2)	6916.76 (3694.98, 8016.40)	19 367.84 \pm 7034.08	0.0008
Mean cross sectional area of deep gastric mucosal vessels (μm^2)	834.88 (554.05, 953.04)	982.90 (697.11, 1249.35)	0.1
Number of deep gastric mucosal vessels	9 (7, 11)	20 (16, 22)	0.00001

Figure 1 Vascular ectasia and congestion of gastric submucosa in group B (HE, \times 400).

with portal hypertension. However, gastric mucosal lesions have lately been considered as another frequent cause of upper gastrointestinal bleeding in these patients, accounting for 20% to 40% of all cases^[23,24]. Dilated precapillaries, capillaries and submucosal veins, extensive submucosal edema, thickening of the submucosal arteriolar walls and submucosal veins showing features of arterIALIZATION, are all observed in patients with portal hypertension^[5,25-28], while morphometric analyses have shown an increase of mean mucosal capillary cross-sectional area^[29-32]. Clinically significant bleeding is seen in association with severe portal hypertensive gastropathy (PHG) and non-selective beta-blockers, such as propranolol and nadolol, have been shown to reduce portal pressure and gastric mucosal blood flow. Previous experimental studies using propranolol^[13,14,33,34] and clonidine^[35] early in the process of portal hypertension induction have been proven effective in prevention of complications.

However, these studies, mainly based on hemodynamic measurements, are very sensitive and easily affected by a number of imponderable and in many cases unknown factors^[36-38]. This might explain why similar studies from various research centers often resulted in completely different conclusions^[39-43].

To avoid these problems, we decided to directly investigate the effects of early propranolol administration on gastric mucosal and submucosal pathology. The gastric mucosal and submucosal vein plexus (Figure 1) was meticulously studied and measurements of vessels'

and submucosa's areas were carefully performed with the aid of an image analysis system. Portal pressure was the only hemodynamic parameter studied. Measurements revealed a 21.5% decrease of portal pressure in propranolol treated rats; these results are fully compatible with literature data^[13,14,33,34]. On the other hand, careful analysis of morphometric data revealed that early propranolol administration significantly affects the total area of gastric submucosal and mucosal vessels as well as the number of gastric submucosal and mucosal vessels of cirrhotic rats, while the mean cross sectional area does not seem to be significantly affected.

In clinical practice, cirrhosis represents the major cause of portal hypertension. Induction of cirrhotic portal hypertension by carbon tetrachloride administration was therefore considered to be an appropriate experimental model for our study. In this model, portal hypertensive syndrome is fully developed after a reasonable time, permitting the study of chronic and early propranolol administration. All similar studies presented in the literature^[13,14,33-35], were carried out either in prehepatic portal hypertension or in cases of schistosomiasis, probably due to lack of reliable models capable of developing esophagogastric varices in cirrhotic rats. This is mainly due to the development of extended collaterals from the portal vein to the left renal vein via the left adrenal vein. These collaterals, which are non-functional in normal rats, prevent portosystemic shunt through the gastric and lower esophageal veins in case of portal hypertension. We overcame this problem by using a modification of the well-known model of carbon tetrachloride induced cirrhosis. This included the induction of cirrhosis in rats that had previously undergone ligation of the left adrenal vein and complete devascularization of the left renal vein. The effectiveness of this model has already been demonstrated in previous studies^[15-17,19].

Gastric submucosal vessels, as well as superficial and deep gastric mucosal vessels, were meticulously studied, and various measurements were carefully performed using an image analysis system, which permitted objective determination of numerous parameters. All gastric submucosal, as well as deep and superficial gastric mucosal vessels per optical field, were counted, and their borders were carefully delineated, to calculate the total and mean cross sectional area of submucosal gastric

veins, and deep and superficial gastric mucosal vessels. An accurate method of measuring vessel cross-sectional areas and comparing them would be to perfuse fix the vessels with a controlled perfusion pressure; however, the significant in vivo differences in portal pressure between the groups, and their effect on gastric vessels, would be masked. We also thought to perfuse fix vessels with pressures comparative to portal pressures; however, this was technically difficult. Thus, the final choice was to use no perfusion fixation and compare simple sections, by measuring several parameters, including vessel numbers. Several factors, besides portal pressure, affect vein development and gastric mucosal and submucosal congestion in cirrhotic animals. It is a general belief that portal pressure increase is the main causative factor for the development of portosystemic collaterals^[1-3], which are considered to be the result of widening, distension, and hypertrophy of pre-existing vessels. Additionally, active angiogenesis can also participate in their formation. Propranolol, by reducing the hepatic venous pressure gradient and azygos blood flow, seems to contribute to the reducing opening of pre-existing blood vessels. On the other hand, neoangiogenesis seems to be prevented by abolishing the norepinephrine inducing effect on vascular endothelial growth factor (VEGF) expression^[44-46]. Morphometric analysis in our study revealed a statistically significant difference ($P < 0.05$) between groups in the number of mucosal and submucosal vessels, as well as in the total area occupied by vessels, which was significantly greater ($P < 0.05$) in the placebo group compared to the propranolol treated group. On the other hand, there was no difference in mean cross sectional area of submucosal and mucosal vessels between the groups.

We can therefore claim, based on the results of this experimental study, that early propranolol administration in portal hypertensive cirrhotic rats could be useful in prevention of portal hypertensive gastropathy and its complications.

COMMENTS

Background

Patients with portal hypertension are at substantial risk of bleeding from small gastric mucosal lesions that have been largely described as portal hypertensive gastropathy.

Research frontiers

Propranolol is a well-known and extensively used beta-blocker that has been shown to reduce bleeding related to portal hypertensive gastropathy in small studies. In the area of prevention of portal hypertensive gastropathy, previous experimental studies have shown that early continuous administration of non-selective β -blockers, such as propranolol, could ameliorate portosystemic hemodynamics and therefore reduce complications. The sensitive and easily affected hemodynamic measurements used in previous studies have resulted in different conclusions and led to an effort to directly investigate the effects of early propranolol administration on gastric mucosal and submucosal pathology.

Innovations and breakthroughs

The concept that early continuous administration of drugs is capable of reducing portal pressure and could prevent the development of extended portosystemic collaterals and consequently esophagogastric varices or portal hypertensive gastropathy, has led to a series of experimental and clinical studies. Many agents with a known lowering effect on portal pressure (including propranolol, nadolol, clonidine, octreotide, isosorbite mononitrate and, more recently, endothelin

receptor antagonists) have already been tested for their effect on portosystemic shunting and development of esophageal varices, when administered early, that is before the full development of portal hypertension syndrome. Several studies have been published, both clinical and experimental, with controversial results on the protective role of non-selective beta-blockers. To avoid complicated and easily affected hemodynamic measurements the authors decided to directly investigate the effects of early propranolol administration on gastric mucosal and submucosal pathology. The gastric mucosal and submucosal vein plexus was meticulously studied and measurements of vessels' and submucosa's area were carefully performed with the aid of an image analysis system. Portal pressure was the only hemodynamic parameter studied in order to confirm the already known propranolol's effect on it.

Applications

The study results suggest that early propranolol administration in portal hypertensive cirrhotic rats could prevent intense gastric vascular congestion, which characterizes portal hypertensive gastropathy and could therefore be useful in preventing its complications.

Peer review

This is a well designed study to look at the effects of a non selective β blocker in the prevention of portal hypertensive gastropathy in a rat model for cirrhosis and portal hypertension.

Abstract

AIM: To investigate the effects of *Helicobacter pylori* (*H. pylori*) eradication therapy for treatment of peptic ulcer on the incidence of gastric cancer.

METHODS: A multicenter prospective cohort study was conducted between November 2000 and December 2007 in Yamagata Prefecture, Japan. The study included patients with *H. pylori*-positive peptic ulcer who decided themselves whether to receive *H. pylori* eradication (eradication group) or conventional antacid therapy (non-eradication group). Incidence of gastric cancer in the two groups was determined based on the results of annual endoscopy and questionnaire surveys, as well as Yamagata Prefectural Cancer Registry data, and was compared between the two groups and by results of *H. pylori* therapy.

RESULTS: A total of 4133 patients aged between 13 and 91 years (mean 52.9 years) were registered, and 56 cases of gastric cancer were identified over a mean follow-up of 5.6 years. The sex- and age-adjusted incidence ratio of gastric cancer in the eradication group, as compared with the non-eradication group, was 0.58 (95% CI: 0.28-1.19) and ratios by follow-up period (< 1 year, 1-3 years, > 3 years) were 1.16 (0.27-5.00), 0.50 (0.17-1.49), and 0.34 (0.09-1.28), respectively. Longer follow-up tended to be associated with better prevention of gastric cancer, although not to a significant extent. No significant difference in incidence of gastric cancer was observed between patients with successful eradication therapy (32/2451 patients, 1.31%) and those with treatment failure (11/639 patients, 1.72%). Among patients with duodenal ulcer, which is known to be more prevalent in younger individuals, the incidence of gastric cancer was significantly less in those with successful eradication therapy (2/845 patients, 0.24%) than in those with treatment failure (3/216 patients, 1.39%).

CONCLUSION: *H. pylori* eradication therapy for peptic ulcer patients with a mean age of 52.9 years at registration did not significantly decrease the incidence of gastric cancer.

INTRODUCTION

Yamagata Prefecture is an area in which gastric cancer

is particularly common. In Cancer Incidence in Five Continents, published by the International Agency for Research on Cancer (IARC) of the World Health Organization (WHO), it is reported that the incidence of gastric cancer for men in Yamagata Prefecture, was the second highest in the world, at 91.6/100 000 (ASR world) in 1993-1997^[1]. Yamagata Prefecture therefore has attempted aggressively to achieve secondary prevention of gastric cancer. In 1994, IARC/WHO concluded that *Helicobacter pylori* (*H. pylori*) is a definite carcinogen in humans^[2], and the results of a prospective cohort study^[3] and animal studies^[4-6] have demonstrated that *H. pylori* causes gastric cancer. The possible role of *H. pylori* eradication therapy in primary prevention of gastric cancer has thus attracted substantial interest in Yamagata Prefecture. In November 2000, when coverage of *H. pylori* eradication for patients with *H. pylori*-positive peptic ulcer by the National Health Insurance system in Japan began, the Yamagata *H. pylori* Clinical Study Group was established to design a multicenter prospective cohort study to investigate whether *H. pylori* eradication therapy for patients with peptic ulcer can decrease the incidence of gastric cancer.

Although animal studies have revealed that primary prevention of gastric cancer by *H. pylori* eradication is more effective as the duration between *H. pylori* infection and eradication is decreased^[7], the effects in humans of this type of prevention have not been determined sufficiently. Non-randomized prospective studies^[8,9] and retrospective studies^[10,11] in Japan have suggested that *H. pylori* eradication therapy prevents the development of gastric cancer, while a large-scale randomized controlled study in China did not support this conclusion. Although, a sub-population analysis of patients who did not have precancerous change at the time of eradication therapy has suggested gastric-cancer-preventive effects of *H. pylori* eradication therapy^[12]. No significant reduction in the incidence of gastric cancer by *H. pylori* eradication therapy was observed in a meta-analysis^[13]. In a multicenter, randomized controlled study in patients who underwent endoscopic resection of early gastric cancer and were thus at high risk of secondary gastric cancer, occurrence of secondary gastric cancer was prevented significantly by *H. pylori* eradication therapy^[14]. Evidence of prevention of gastric cancer by *H. pylori* eradication therapy thus needs to be obtained.

This report describes the results of a multicenter, prospective cohort study that investigated whether *H. pylori* eradication therapy in patients with peptic ulcer, living in an area where the incidence of gastric cancer is especially high, was effective in primary prevention of gastric cancer. The results of the present study, including endoscopy findings, were reconciled with those of the Yamagata Prefecture Cancer Registry to ensure accurate detection of gastric cancer.

MATERIALS AND METHODS

Study design

The present study was designed at Yamagata Prefectural Central Hospital, where the office of the Yamagata

H. pylori Clinical Study Group was located in May 2000. It included 82 participating institutions, 26 hospitals and 56 clinics, in Yamagata Prefecture. For ethical reasons, we selected performance of a non-randomized, multicenter, prospective cohort study in which patients decided themselves whether to receive *H. pylori* eradication therapy (eradication group) or conventional antacid therapy (non-eradication group) for the treatment of *H. pylori*-positive peptic ulcer. The sample size was calculated to detect a significant difference in incidence of gastric cancer in patients who received *H. pylori* eradication therapy or conventional antacid treatment over a 7-year period (a 2-year registration period and a 5-year follow-up period), with a power of 90% and an alpha error of 5% on the basis of the following assumptions: the incidence of gastric cancer in patients who received conventional antacid therapy was 0.5%; *H. pylori* eradication therapy decreased the incidence of gastric cancer by 50%-90%; the percentage of withdrawals was 20%; and patients were allocated to the non-eradication and eradication groups at a ratio of 1:5. We estimated that 560-2467 patients and 2797-12 333 patients were required for the non-eradication and eradication therapy groups, respectively. All tests and treatments performed were covered by the National Health Insurance (NHI) as determined by the Ministry of Health and Welfare of Japan (currently the Ministry of Health, Labor, and Welfare of Japan), and the study protocol was approved by the Ethics Committee of Yamagata Prefectural Central Hospital. All patients received a full explanation of the study using a standardized document, and provided written informed consent before registration in the study.

Patients with *H. pylori*-positive peptic ulcer were considered eligible. Patients with a history of gastric cancer and those in whom endoscopy or biopsy at the time of registration revealed gastric cancer were excluded from the study. Patients were registered between November 2000 and December 2003, and followed up until the end of December 2007.

Diagnosis of *H. pylori*-positive peptic ulcer and treatment

Prior to registration, all patients underwent upper gastrointestinal endoscopy and biopsy, if necessary, to diagnose peptic ulcer and exclude gastric cancer. During endoscopy, biopsy samples were collected from the greater curvature of the upper body and antrum of the stomach. The presence/absence of *H. pylori* infection was evaluated by rapid urease test.

H. pylori eradication therapy consisted of 30 mg lansoprazole or 20 mg omeprazole, plus 750 mg amoxicillin and 200 or 400 mg clarithromycin, all twice daily for 7 d. At least 1 mo after the completion of eradication therapy, patients underwent upper gastrointestinal endoscopy with the rapid urease test and urea breath test (with a cut-off value of 2.5‰; Ubit, Otsuka Pharmaceuticals, Tokyo, Japan). Successful *H. pylori* eradication was defined as negative results on the rapid urease and urea breath tests. When the results of the two tests were inconsistent, retesting was performed.

Conventional antacid therapy consisted of antacids such as proton-pump inhibitors and histamine- H_2 blockers.

Detection of gastric cancer

During the follow-up period up to December 2007, endoscopy was performed annually, in principle, to determine the presence/absence of gastric cancer. When follow-up endoscopy was performed, the investigators reported its results to the study office using a follow-up report form to provide information on the date of endoscopy, stage of ulcer, results of *H pylori* testing, and presence/absence of newly developed gastric cancer or other gastrointestinal diseases (such as reflux esophagitis, erosive gastritis/duodenitis, and esophageal adenocarcinoma).

To avoid overlooking gastric cancer due to the absence of annual endoscopy, a questionnaire survey was conducted and the data obtained in the present study were reconciled with those of the Yamagata Prefecture Cancer Registry. In October 2006, a questionnaire was mailed to all registered patients to determine the presence/absence of gastric cancer diagnosed after registration. The results of the questionnaire were compared with the data at registration to identify patients who might have developed gastric cancer after registration. Such cases were referred to the participating medical institutions to confirm the diagnosis of gastric cancer. In March 2008, record linkage between the cohort and Yamagata Prefectural Cancer Registry was conducted for identification of previous and new gastric cancer cases during the follow-up period up to the end of December 2007.

Statistical analysis

Person-years were calculated from the date of recruitment to the date of incidence of gastric cancer; end of follow-up in December 2007; date of change of residence to outside Yamagata Prefecture; death from causes other than gastric cancer; or the initiation of *H pylori* eradication therapy for patients in the antacid therapy group, whichever came first. For comparison between groups at baseline, Fisher's exact test was used for sex and type of peptic ulcer, and Student's *t* test or χ^2 test for histological type, location and stage of cancer, and treatment, with a level of significance of $P < 0.05$ (two-tailed).

Poisson regression was used to estimate the relative risk of gastric cancer in relation to eradication therapy for *H pylori*. Analyses were adjusted routinely for sex and age (< 60 , $60-70$, > 70 years), and stratified for duration of follow-up (< 1 , $1-3$, > 3 years) and location of ulcer (gastric, gastroduodenal or duodenal). We also examined the effects of adjustment for other risk factors including location of ulcer, intake of salt, and smoking. These statistical analyses were performed using Intercooled Stata 8.0 for Windows software (StataCorp LP, College Station, TX, USA).

The accumulated incidence of gastric cancer in patients with successful and unsuccessful *H pylori*

eradication was determined using data for patients for whom the results of *H pylori* eradication therapy were confirmed using the Kaplan-Meier method, and were tested for significance of difference between patients with and without successful eradication using the log-rank method. These analyses were performed using Dr. SPSS II for Windows (SPSS Inc., Chicago, IL, USA).

RESULTS

Baseline characteristics of study subjects

A total of 4203 patients were registered, and 70 patients who had a history of gastric cancer or had gastric cancer at the time of registration were excluded. Intention-to-treat (ITT) analysis was performed for the data from the remaining 4133 patients (2964 male and 1169 female), who were aged between 13 and 91 years (mean 52.9 years).

H pylori eradication therapy was administered to 3781 patients (91.5%; eradication group) and conventional antacid therapy to 352 patients (8.5%; non-eradication group). Table 1 summarizes the characteristics of the 4133 patients included in the present study. There were no significant differences between the eradication and non-eradication groups in baseline characteristics such as distribution of sex or location of ulcers, while mean age was lower in the eradication than in the non-eradication group (52.4 years *vs* 58.1 years). No results of *H pylori* eradication therapy were reported for 691 (18.3%) of the 3781 patients who received *H pylori* eradication therapy. The eradication rate evaluated in the ITT analysis and the per-protocol (PP) analysis were 64.8% (2451/3781) and 79.3% (2451/3090), respectively. There were no significant differences in any factors, including age, between patients with and without successful *H pylori* eradication (mean ages of patients with and without successful *H pylori* eradication were 52.5 ± 12.3 years and 52.1 ± 13.5 , respectively; $P = 0.51$).

Development of gastric cancer

During a total of 22 900 person-years of follow-up (mean follow-up period: 5.6 years), gastric cancer was found in 56 patients, including 47/3781 patients (1.24%, 0.21%/year) who received *H pylori* eradication therapy and 9/352 patients (2.56%, 0.50%/year) who received conventional antacid therapy. There were no differences in sex distribution; location of ulcer lesions; histological type, location or stage of cancer; or type of treatment for gastric cancer between patients with and without *H pylori* eradication therapy (Table 2). Poisson regression analysis of factors that affected the incidence of gastric cancer revealed that sex, age group, and location of ulcers were independent factors that affected the differences in incidence rate ratio (IRR) of gastric cancer between patients receiving and not receiving *H pylori* eradication therapy (Table 3). The IRR of gastric cancer adjusted for sex and age group was 0.58 (95% CI: 0.28-1.19). *H pylori* eradication therapy decreased the incidence of gastric cancer by about 40%, although this change was not statistically significant. IRR was

¹ χ^2 test; ²*t* test. Eradication group: patients who received *Helicobacter pylori* eradication therapy with or without successful eradication. Non-eradication group: Patients who received conventional antacid therapy. GU: Gastric ulcer; GDU: Gastroduodenal ulcer; DU: Duodenal ulcer.

by duration of follow-up 1.16 (0.27-5.00) for patients followed up for < 1 year, 0.50 (0.17-1.49) for 1-3 years, and 0.34 (0.09-1.28) for > 3 years. There were no significant differences in the incidence of gastric cancer between any subgroups of the eradication and non-eradication groups, although the difference in incidence between the groups tended to increase as the duration of follow-up was prolonged (Table 4). Gastric cancer was found in 6/1375 patients with duodenal ulcer (0.44%). All six patients were > 50 years of age at the time of registration. No cases of Barrett's adenocarcinoma, for which the possibility of increase in occurrence after *H. pylori* eradication therapy was a concern, were found in either of the two groups.

In a separate analysis, 3090 patients who received *H. pylori* eradication therapy, with known results, were compared for incidence of gastric cancer according to presence/absence of successful eradication. Gastric cancer was detected in 43 of the 3090 patients, including 32/2451 patients (1.31%) and 11/639 patients (1.72%) with and without successful eradication, respectively. No significant difference in incidence of gastric cancer was observed between patients with and without successful eradication. Analysis by type of peptic ulcer at the time of registration revealed that the incidence of gastric cancer did not differ between patients with and without successful eradication in subgroups of patients

Figure 1 Proportion free of gastric cancer in the eradication group was compared according to results of eradication therapy, using Kaplan-Meier analysis. The incidence was 32/2451 (1.31%) in patients with successful eradication and 11/639 (1.72%) in patients with failure of eradication (log-rank test, $P = 0.43$).

with gastric or gastroduodenal ulcer, while successful eradication decreased the incidence of gastric cancer significantly in patients with duodenal ulcer (Figures 1 and 2).

DISCUSSION

This was a prospective, multicenter, cohort study in patients with *H. pylori*-positive peptic ulcer, which was designed to evaluate whether *H. pylori* eradication therapy decreased the incidence of gastric cancer in Yamagata Prefecture, a region in which gastric cancer is especially common. Since continuous follow-up is often difficult in clinical observation studies, the data from the present study were reconciled with those of the Yamagata Prefecture Cancer Registry to avoid overlooking gastric cancer. This was a unique feature of the present study.

During the follow-up of 4133 patients with peptic ulcer (mean age: 52.9 years) for a mean of 5.6 years, the incidence of gastric cancer in patients who received *H. pylori* eradication therapy was decreased by about 40% compared with that in patients who did not receive eradication therapy, although the difference between the groups was not statistically significant. Longer follow-up period tended to be associated with better prevention of gastric cancer, albeit not to a significant extent. Although there was no significant difference in incidence of gastric cancer according to the result of eradication therapy (success/failure) in those patients who received this treatment, successful eradication therapy did decrease significantly the incidence of gastric cancer in patients with duodenal ulcer.

There are four limitations to the interpretation of the results of the present study: (1) it was not a randomized controlled trial, and the number of patients not receiving eradication therapy was small; (2) the eradication rate was only 80%; (3) the follow-up period was not sufficiently long; and (4) the mean age of participants was high, at 53 years.

Factors (1) and (2) are limitations of the present study, in which randomization of patients was impossible

Figure 2 Proportion free of gastric cancer in patients with gastric or gastroduodenal ulcer (A) and duodenal ulcer (B) in the eradication group was compared according to results of eradication therapy, using Kaplan-Meier analysis. A: The incidence of gastric cancer was 29/1572 (1.85%) in patients with successful eradication and 8/413 (1.94%) in patients with failure of eradication (log-rank test, $P = 0.92$); B: The incidence of gastric cancer was 2/845 (0.24%) in patients with successful eradication and 3/216 (1.39%) in patients with failure of eradication (log-rank test, $P = 0.03$).

for ethical reasons, and secondary *H. pylori* eradication therapy was not covered by the NHI system. In addition to the four factors noted above, since the decrease in incidence of gastric cancer by *H. pylori* eradication was smaller than expected, and the numbers of patients did not reach those targeted, especially in the non-eradication group, the study did not have the statistical power required to detect a significant difference in the incidence of gastric cancer between patients who received eradication therapy and conventional antacid therapy.

The finding that the efficacy of *H. pylori* eradication in preventing gastric cancer tended to be better among patients with a longer follow-up period suggests that the length of follow-up in this study may have been insufficient. In a study of patients who underwent resection of gastric cancer, cancer in other locations was not detected upon preoperative evaluation^[15]. Although all patients evaluated in the present study underwent endoscopy and biopsy prior to registration, if required, the possibility cannot be ruled out that some patients had undetectable gastric cancer before registration. Gastric cancer lesions detected during the early phase after eradication therapy may in many cases have been present before therapy. More accurate determination of the efficacy of eradication therapy in preventing gastric cancer will require that patients be followed up for a long period of time. Since follow-up endoscopy cannot be continued for many years, it is important that our data be reconciled with those of the Yamagata Prefecture Cancer Registry to continue follow-up of the participants.

As pointed out by Wong *et al.*^[12], the precancerous state may represent the point of no return at which development of gastric cancer can no longer be prevented by *H. pylori* eradication. The participants in the present study were patients with peptic ulcer with a mean age of 53 years, and many patients with gastric ulcer also have atrophic gastritis or intestinal metaplasia. Among the registered patients, duodenal ulcer was more common in those < 50 years of age, while gastric ulcer

was common in patients > 50 years of age. The risk of gastric cancer was higher in patients with gastric or gastroduodenal ulcer than in those with duodenal ulcer, and a significant decrease in the incidence of gastric cancer according to successful *H. pylori* eradication was observed only in patients who underwent *H. pylori* eradication for the treatment of duodenal ulcer. Since *H. pylori* infection is usually established during childhood, it appears likely that antral gastritis and duodenal ulcer are common among young patients with a relatively short history of *H. pylori* infection, and that eradication of *H. pylori* may decrease the occurrence of gastric cancer. However, patients with a longer history of *H. pylori* infection often have corpus gastritis, and eradication therapy does not prevent gastric cancer to a significant extent. The results of an experiment in Mongolian gerbils has shown that eradication of *H. pylori* is more effective in preventing gastric cancer in animals with a shorter duration of *H. pylori* infection^[7]. These findings suggest the importance of the timing and target of *H. pylori* eradication therapy in preventing gastric cancer.

In a randomized clinical study on the effects of eradication of *H. pylori* after endoscopic mucosal resection of early gastric cancer, Fukase *et al.*^[14] have reported a significant decrease in the incidence of secondary gastric carcinoma during a 3-year follow-up period. The significant prevention of secondary gastric cancer by *H. pylori* eradication was considered to be caused by the following: (1) the risk of development of gastric cancer in patients following endoscopic mucosal resection for early gastric cancer is about 10-fold higher than in patients with *H. pylori*-positive peptic ulcer; (2) patients underwent accurate endoscopy several times before and after treatment for cancer; and (3) the number of cases of gastric cancer that were overlooked at the time of registration was therefore considered smaller than in other surveys.

Prior to initiation of the present study, there was concern regarding the possibility of a decrease in visits for endoscopy after symptomatic improvement, which could have resulted in an increase in advanced gastric

cancer. Although the investigators fully explained to subjects the risk of development of gastric cancer after *H pylori* eradication therapy and the importance of follow-up endoscopy, > 15% of them did not undergo examination to confirm the results of *H pylori* eradication therapy. The percentage of patients who received follow-up endoscopy as specified was significantly lower among those who received *H pylori* eradication therapy compared with conventional antacid therapy. Although this may have biased the rate of detection of gastric cancer, we attempted to decrease bias by reconciling our data with those of the Yamagata Prefecture Cancer Registry. Of the 56 cases of gastric cancer detected in the present study, 11 were detected as advanced gastric cancer. Cases of advanced gastric cancer mainly consisted of diffuse-type cancer and those with a mixture of intestinal and diffuse cancer cells. Careful observation is thus needed for the development of gastric carcinoma, especially diffuse-type gastric cancer, which may progress rapidly and is often difficult to detect.

Although it has been reported that gastric cancer does not develop in patients with duodenal ulcer^[3,8,9], gastric cancer developed in six patients with duodenal ulcer in the present study, including five aged ≥ 60 years and one 51-year-old patient. Since continuous infection with *H pylori* may result in the development of corpus gastritis in patients with antral gastritis associated with duodenal ulcer, middle-aged and elderly patients with duodenal ulcer often have gastritis in the corpus, and should thus be considered at high risk for development of gastric cancer, even after successful *H pylori* eradication therapy, especially in regions with a high incidence of gastric cancer.

In conclusion, *H pylori* eradication therapy for patients with peptic ulcer with a mean age of 52.9 years did not significantly decrease the incidence of gastric cancer during a mean follow-up period of 5.6 years. Although our results did not rule out a role for *H pylori* eradication therapy in preventing gastric cancer, the number of patients evaluated, duration of observation, and rate of eradication of *H pylori* were insufficient to obtain a significant difference in the incidence of gastric cancer between the groups with and without eradication therapy, and the mean age of patients was high. Further studies to clarify the efficacy of *H pylori* eradication in preventing gastric cancer will require eradication of *H pylori* as early as possible and careful and prolonged follow-up of patients.

ACKNOWLEDGMENTS

We acknowledge the cooperation with the study group of the 82 participating institutions and the registration of clinical data by 130 investigators.

COMMENTS

Background

Yamagata Prefecture in Japan has the second highest incidence of gastric

cancer in the world. *Helicobacter pylori* (*H pylori*) plays an important role in the development of gastric cancer. It is thus of crucial importance to determine whether *H pylori* eradication therapy in this geographical area is effective in primary prevention of gastric cancer.

Research frontiers

Although it has been demonstrated that *H pylori* is a definite carcinogen in humans, previous studies that have examined the efficacy of eradication therapy in preventing gastric cancer have yielded inconsistent findings. In the present study, the authors found that eradication therapy in patients with peptic ulcer with a high mean age of 53 years did not significantly decrease the incidence of gastric cancer, at least over the mean 5.6-year follow-up period.

Innovations and breakthroughs

Single-center prospective studies and retrospective studies have reported significant prevention of gastric cancer by eradication therapy, while one randomized clinical trial has revealed no overall effects, but significant prevention of gastric cancer in patients without precancerous lesions. The present multicenter, prospective cohort study, conducted in an area where the incidence of gastric cancer is especially high, revealed no overall efficacy of *H pylori* eradication for preventing gastric cancer in patients with peptic ulcer. In contrast, it demonstrated that eradication was associated with a significant decrease of gastric cancer in patients with duodenal ulcer, which is known to be more prevalent in younger individuals.

Applications

Given the overall lack of efficacy of eradication therapy for peptic ulcer in preventing gastric cancer, the findings highlight the importance of longer and careful follow-up after eradication therapy. Furthermore, the significant efficacy of treatment observed in younger patients suggests the need to eradicate *H pylori* as early as possible.

Terminology

Conventional antacid therapy: a conventional method of treatment, covered by the National Health Insurance (NHI) as determined by the Ministry of Health, Labor, and Welfare of Japan, which consists of treatment with antacids including proton-pump inhibitors and histamine- H_2 blockers given over 6-8 wk.

Peer review

The innovative content, as well as readability, reflects the advanced level of clinical research in gastroenterology both at home and abroad.

Abstract

AIM: To compare small sphincterotomy combined with endoscopic papillary large balloon dilation (SES + ELBD) and endoscopic sphincterotomy (EST) for large bile duct stones.

METHODS: We compared prospectively SES + ELBD (group A, $n = 27$) with conventional EST (group B, $n = 28$) for the treatment of large bile duct stones (≥ 15 mm). When the stone could not be removed with a normal basket, mechanical lithotripsy was performed. We compared the rates of complete stone removal with one session and application of mechanical lithotripsy.

RESULTS: No significant differences were observed in the mean largest stone size (A: 20.8 mm, B: 21.3 mm), bile duct diameter (A: 21.4 mm, B: 20.5 mm), number of stones (A: 2.2, B: 2.3), or procedure time (A: 18 min, B: 19 min) between the two groups. The rates of complete stone removal with one session was 85% in group A and 86% in group B ($P = 0.473$). Mechanical lithotripsy was required for stone removal in nine of 27 patients (33%) in group A and nine of 28 patients (32%, $P = 0.527$) in group B.

INTRODUCTION

The basic principle of common bile duct stone removal involves destruction or dilation of the bile duct orifice, which allows easy removal of the stone. Endoscopic sphincterotomy (EST) is accepted as the standard management for stone removal from the bile duct, but it is associated with serious complications such as hemorrhage, pancreatitis, perforation, and recurrent infection of the bile duct, which cause permanent functional loss of the sphincter of Oddi^[1-4]. Endoscopic papillary balloon dilation (EPBD) was introduced by Staritz *et al*^[5] and has been accepted widely as an alternative to EST^[6-10]. It has similar outcomes for common bile duct stone removal compared to EST, and has the advantages over EST of preserving papillary sphincter function and causing minimal complications such as hemorrhage and perforation^[11-19]. Despite these advantages, EPBD is associated with more severe and frequent occurrence of pancreatitis^[20-22]. In addition, EPBD has some technical difficulties for removing large stones because the biliary opening is not enlarged to the same degree as with EST^[23].

To overcome these limitations, Ersoz *et al*^[24]

introduced EBD with conventional EST for the removal of large (≥ 15 mm) bile duct stones that are difficult to remove by EBD alone. They have reported that EBD with conventional EST is more effective for the retrieval of large stones and shortens the procedure time. Recently, this technique has been modified slightly to endoscopic papillary large balloon dilatation (ELBD) with small incision EST, and many studies have reported on the outcome of stone removal and complication rate^[25-27]. However, these studies on the efficacy of ELBD with SES have concentrated on small stones, of which the majority are ≤ 1 cm^[25,26]. Therefore, the effectiveness of SES with ELBD for large stone removal (≥ 15 mm) has not been established.

We conducted a prospective randomized study to compare the efficacy and safety of SES + ELBD with conventional EST for the treatment of large (≥ 15 mm) common bile duct stones.

MATERIALS AND METHODS

Patients

From June 2006 to December 2008, 55 patients were enrolled, and all patients were diagnosed as having common bile duct stones by endoscopic retrograde cholangiography (ERCP) or magnetic resonance imaging (MRI). In all patients, the stone was at least 15 mm in maximum diameter. The exclusion criteria for this study were the following: (1) bleeding tendency with INR > 1.5 ; (2) platelet count $< 50\,000/\text{mL}$; (3) anticoagulation therapy within 72 h of the procedure; (4) bilio-colic fistula; (5) stone size > 50 mm; (6) acute cholecystitis; (7) acute pancreatitis; (8) cholangitis; (9) intrahepatic duct stones; (10) pancreatobiliary malignancy; and (11) surgical history involving the biliary tree (not including the gall bladder) or gastrointestinal tract, such as the stomach or small bowel, which can alter the papillary location. Patients chosen for our study protocol were divided randomly into two groups according to the order of the procedure. Twenty-seven patients underwent SES + ELBD (group A) and 28 patients underwent conventional EST (group B). This study was approved by the institutional review board of our hospital, and all patients provide written informed consent before entering the study.

Methods

Management such as pharyngeal anesthesia and premedication before the procedure was carried out in the same manner as for general endoscopy, and ERCP was performed with a side-viewing endoscope (TJF240; Olympus, Tokyo, Japan). After the bile duct stones were visualized following cholangiography, the stone was removed according to each protocol. In group A, we made an incision to the mid-portion of the papilla with a pull-type sphincterotome (Figure 1A) and then inserted a CRE balloon (15, 16.5, or 18 mm; Boston Scientific, Natick, MA, USA) over a guidewire. Balloon dilation was performed using wire-guided hydrostatic balloon catheters placed across the papilla. The balloon was inflated with dilute contrast media until the waistline was

obliterated under fluoroscopic monitoring (Figure 1B). Initially, we performed dilation with a 15-mm-diameter balloon, and if the balloon was not large enough to remove the stones, we repeated it with a larger balloon in the order 15 mm \rightarrow 16.5 mm \rightarrow 18 mm. When the papillary orifice was dilated after balloon dilation (Figure 1C), the stones were retrieved using a Dormia basket (WebTM extraction basket; Wilson-Cook Medical, Winston-Salem, NC, USA) (Figure 1D) or retrieval balloon catheter (double lumen retrieval balloon catheter; Boston Scientific). When the stones were not extracted from the biliary tract with initial basket trapping, mechanical lithotripsy (BML-4Q; Olympus) was performed to fragment the stones. In group B, EST was performed with a pull-type sphincterotome (KD-6Q; Olympus) as the standard method, which was accomplished by extending the incision up to the major horizontal fold of the papillary orifice. After EST, the stones were removed in the same way as in group A. If the stones could not be removed completely in one session, we performed another stone removal session in each group. Complete stone removal was documented with a final cholangiogram. The procedure time was measured as the time between selective cannulation and complete stone removal in the cases of successful stone removal in the first session. The maximum procedure time for the first session was limited to 40 min if the stone was difficult to remove in one session.

Measurements

Stone size and number and bile duct size were documented on the cholangiogram during ERCP. Stone size was assessed by comparing the largest diameter of the stone with the diameter of the TJF240 endoscope, as measured on the cholangiogram. The primary endpoint was the success rate for complete removal of stones within the initial ERCP session. The secondary outcomes included the time for the procedure of these initial-success cases, frequency of mechanical lithotripsy, and associated complications such as bleeding, pancreatitis, cholangitis, and perforation. To observe the complications, blood samples involving a complete blood count, liver function test, amylase, and lipase concentrations were taken before the procedure and 1 and 2 d after ERCP. Post-ERCP pancreatitis was defined as persistent abdominal pain of more than 24 h duration, associated with serum amylase more than three times the upper limit of normal. Bleeding complication was deemed a decrease in hemoglobin concentration of > 2 mg/dL or clinical signs of bleeding after the procedure, such as melena or hematemesis. Cholangitis was defined as a fever accompanied by leukocytosis and right upper quadrant pain after the procedure. All complications were classified and graded according to the consensus guidelines with some modification^[28]. After the stones were removed, ductal clearance was confirmed with a cholangiogram during the procedure.

Statistical analysis

Statistical analysis was performed using the statistical

Figure 1 Endoscopic view. A: A small sphincterotomy using a pull-type sphincterotome; B: Endoscopic papillary balloon dilation with a large balloon after small endoscopic sphincterotomy; C: Dilated orifice after small EST + ELBD; D: Stone removal through the dilated orifice of the major papilla.

Table 1 Baseline characteristics of the patients

	Group A (n = 27)	Group B (n = 28)
Gender (M/F)	10/15	11/14
Mean age (yr) ¹	70.3 ± 8.7	69.8 ± 9.2
Mean diameter of stone (mm) ¹	20.8 ± 4.1	21.3 ± 5.2
Mean No. of stones ¹	2.2 ± 1.3	2.3 ± 1.2
Mean diameter of bile duct (mm) ¹	21.4 ± 6.3	20.5 ± 5.7
Periampullary diverticulum (%)	9 (33.3)	10 (35.7)
Previous cholecystectomy (%)	9 (33.3)	7 (25)
Distal CBD tapering (%)	11 (41)	10 (36)

¹mean ± SD; CBD: Common bile duct.

SPSS for Windows version 12.0 (Chicago, IL, USA). Data are presented as the mean ± SD or median with range. Categorical parameters were compared using the χ^2 or Fisher's exact test, and continuous variables were compared with Student's *t* test. $P < 0.05$ was considered statistically significant.

RESULTS

The gender ratio was similar in the two groups. The mean age was 70.3 years in group A and 69.8 in group B. The mean size of the stones was 20.8 mm (range 15-38.3 mm) in group A and 21.3 mm (range 15-48 mm) in group B. The mean number of stones was 2.2 in group A and 2.3 in group B. The maximal bile duct diameter did not differ significantly between the two groups. A peri-ampullary diverticulum was observed in nine patients in group A and 10 in group B. Sixteen

(29%) patients had a history of cholecystectomy. A tapered common bile duct was observed in 11 (41%) patients in group A and 10 (36%) in group B (Table 1).

Overall, complete removal of bile duct stones in the first session was achieved in 46 (84%) patients, while nine required additional sessions. The causes of failure in the first session were incomplete stone capture with the mechanical lithotripsy basket as a result of a large stone (two cases each in groups A and B), stone impaction (one case in group A), procedure-induced bleeding (one case in group B), and incomplete retrieval because of multiple stones (one case each in groups A and B). The stone clearance rate in the first session between the two groups did not differ significantly, and was 84% in both groups ($P = 0.473$). Mechanical lithotripsy was used for nine (33%) patients in group A and nine (32%) in group B ($P = 0.527$). The mean procedure time was compared in the cases involving successful removal of the stone in the initial session and did not differ statistically between the two groups. All stones were removed completely in all patients within three sessions (group A: 1.27 ± 0.53 sessions, group B: 1.31 ± 0.71 sessions, $P = 0.714$). The number of sessions of mechanical lithotripsy and mean procedure times did not differ significantly between the two groups (Table 2).

We also divided each group into subgroups according to the stone size (2 cm) and compared the stone removal rate and application of mechanical lithotripsy. The complete stone removal rate for each subgroup in the first session was similar in both groups: 85.7% (group A) and 86.6% (group B) in the subgroups with stones <

Table 2 Results of endoscopic stone removal after small EST + ELBD *vs* EST (stone size ≥ 15 mm)

	Group A (<i>n</i> = 27)	Group B (<i>n</i> = 28)	<i>P</i> value
Stone removal in the first session (%)	23 (85)	23 (86)	0.473
Mechanical lithotripsy (%)	9 (33)	9 (32)	0.527
Mean procedure time (min) ^{1,2}	18 \pm 12	19 \pm 13	0.917
Mean therapeutic session ¹	1.27 \pm 0.53	1.31 \pm 0.71	0.714

¹mean \pm SD; ²Calculated from initial success cases (*n* = 23 in both groups). Overall success rate of the first session: 84%.

Table 4 Comparison of stone removal in the first session and application of mechanical lithotripsy

	Group A (<i>n</i> = 11)	Group B (<i>n</i> = 10)	<i>P</i> value
Stone removal in the first session (%)	9 (81.8)	7 (70)	0.525
Mechanical lithotripsy (%)	6 (54.5)	6 (60)	0.801

2 cm in maximum diameter and 84.6% (group A) and 76.9% (group B) in the subgroups with stones ≥ 2 cm in maximum diameter. The rate of mechanical lithotripsy increased significantly with stone size irrespective of the group (*P* < 0.05 in each group, Table 3). Finally, we compared the stone removal rate in the first session and the need for mechanical lithotripsy in the cases with a tapered distal bile duct between the two groups. A tapered bile duct was deemed as one in which a portion of the distal common bile duct was narrowed with a steady curve on the cholangiogram. The stone removal rate was higher in group A (81.8%) than in group B (70%), but not significantly. In addition, the mechanical lithotripsy rate was similar between the two groups (Table 4).

Complications according to the consensus guidelines were not observed in either group, and we could not compare the complication rate between the two groups. Although mild amylase elevation less than three times the upper limit of normal was observed in four patients in group A (15%) and three in group B (11%), no instances of post-ERCP pancreatitis and cholangitis according to the consensus guidelines occurred in either group. We did not perform prophylactic pancreatic duct stenting during the procedure in any case. A small amount of bleeding was seen in four patients in group A (15%) and two in group B (7%). No procedure-related perforation was observed. Nine cases in which complete ductal clearance was not achieved in the first session underwent a second session on the next day or within a few days, and any additional protective procedure, such as biliary plastic stenting, was not performed until the next session.

DISCUSSION

EST is the most frequently used endoscopic technique for the clearance of stones from the bile duct. Its success rate exceeds 90%, and it has been accepted as the best nonsurgical treatment for common bile duct stones^[29-33]. However, EST is still associated with an 8%-12% rate

Table 3 Comparison of overall application of mechanical lithotripsy according to the size of the stone in each group

	Group A (<i>n</i> = 27)		Group B (<i>n</i> = 28)	
	< 2 cm (<i>n</i> = 14)	≥ 2 cm (<i>n</i> = 13)	< 2 cm (<i>n</i> = 15)	≥ 2 cm (<i>n</i> = 13)
Stone removal in the first session (%)	12 (85.7) ^a	11 (84.6) ^b	13 (86.6) ^c	10 (76.9) ^d
Mechanical lithotripsy (%)	2 (14.3) ^e	7 (53.8) ^f	2 (13.3) ^g	7 (53.8) ^h

Overall application of mechanical lithotripsy: 17/50 (34%). *P* value: a *vs* b, not significant; c *vs* d, not significant; e *vs* f, 0.018; g *vs* h, 0.008.

of acute complications, such as bleeding, perforation, cholangitis, and post-procedure pancreatitis^[11,25,34-37]. In addition, it permanently destroys the biliary sphincter, which can lead to chronic complications, such as duodenal biliary reflux, bacterial contamination, and chronic inflammation of the biliary system^[11].

EBD was introduced by Staritz *et al*^[5] in 1983 as an alternative method for the removal of bile duct stones. The main advantage of this technique is that it does not involve cutting the biliary sphincter, therefore preserving its function. However, major limitations of EBD exist, including difficulty in removing large stones and a high incidence of pancreatitis. Since balloon dilation does not enlarge the sphincter of Oddi to the same extent as EST, large stone removal with EBD is difficult, and mechanical lithotripsy is required more often than with EST^[11,21]. As a result, there is a need to modify the EBD technique to remove large bile duct stones and reduce the risk of pancreatitis. Similarly, EST is not a good method if the stones are too large to remove. Stone fragmentation procedures such as mechanical lithotripsy are required in this situation, regardless of the approach method. Ersoz *et al*^[24] first reported the use of EST followed by papillary balloon dilation. They reported an 83% success rate in the first session with a 7% rate of mechanical lithotripsy in 58 patients in whom endoscopic removal of bile duct stones using standard EST and balloon/basket extraction had failed. Recently, multiple published series have shown that the overall first session success rates of stone removal with EBD following EST ranged from 80% to 100%^[24,25,27,38], and these success rates were similar to those of EST. Although some recent studies have reported that the stone clearance rate for the initial session of EBD following EST is high, the outcome for large stone removal by ELBD following EST remains controversial. Since previous data from ELBD studies have included various sizes of stones, especially small stones < 1 cm, and comparison studies between SES + ELBD and conventional EST for large stone (≥ 15 mm) removal are not sufficient^[25,26,39]. Therefore, we could not clarify the effectiveness of ELBD following EST for large stone removal.

In our present study, we compared SES + ELBD to conventional EST in terms of usefulness and safety for the treatment of large stones. We also evaluated the number of applications of mechanical lithotripsy and compared this with previous studies, which reported

that EST + ELBD reduced the use of mechanical lithotripsy^[24,25,39]. The number of patients enrolled in our study was limited by the stone size and exclusion criteria. However, these criteria enabled us to compare the outcomes between the two groups more objectively.

Our findings showed that the initial success rate for the clearance of common bile duct stones was same in both groups and it was not significantly different. A previous series of EST + ELBD gave first session success rates of 70%-99% and mechanical lithotripsy rates of 1%-11%^[24-27,39]. In contrast, we had a 33% mechanical lithotripsy rate in group A and a 32% rate in group B. Compared to previous reports, the frequency of mechanical lithotripsy was markedly higher^[24-27,39], which might be attributable to the large stones (≥ 15 mm).

Previous studies likely reported lower rates of mechanical lithotripsy, because of smaller stones^[25,26,39], or a wider sphincterotomy^[24,40]. Of course, the frequency of mechanical lithotripsy might be related to various factors, such as the extent of EST, size of the stone and balloon, and shape of the stone and common bile duct. Removing large stones (≥ 15 mm) in patients with a tapered common bile duct without stone fragmentation might be difficult, despite orifice dilation using large balloon dilation. A retrospective pilot study of 50 patients revealed that patients that required mechanical lithotripsy were more often characterized by large stones combined with a tapered distal common bile duct rather than either of these features alone^[41].

Other recent studies have revealed that SES + ELBD reduced the frequency of mechanical lithotripsy and gave better results for the removal of stones^[25,27,39].

However, in our study, mechanical lithotripsy was not reduced with SES + ELBD, and no difference in the frequency of mechanical lithotripsy was observed between the two groups. We needed a stone fragmentation method such as mechanical lithotripsy, although we used a large balloon (maximum, 18 mm) to dilate the orifice; the larger stone size was associated with more frequent mechanical lithotripsy. The CRE balloon had a length of 8 cm, of which approximately half was positioned in the distal bile duct. Considering this point, we speculate that part of the terminal and distal bile duct could be dilated simultaneously using balloon dilation, and if the stone was small enough to pass through the dilated bile duct, it could be removed more easily. To remove large stones, however, some EST and large balloon dilation may help to dilate the sphincter of Oddi orifice, to allow the passage of large stones. Large balloon dilation alone cannot stretch the wall of the distal bile duct to the degree necessary for the effective removal of large stones. Hence, the configuration and wall lumen tension of the terminal bile duct may be more important factors for the removal of large stones than the size of the balloon and dilation of the bile duct. Therefore, if a stone is too large to remove *via* the dilated terminal bile duct and sphincter of Oddi, stone fragmentation using mechanical lithotripsy, for example, might be inevitable.

Complications according to the consensus guidelines did not occur in our study, which may be related to the

small number of patients enrolled. No procedure-related pancreatitis occurred. Only amylase elevation less than three times the upper limit of normal was observed in seven patients (four in group A and three in group B). Perforation did not occur in any patient.

A small amount of bleeding was observed in six patients in our study. Of these, stone removal was postponed to the next session for one patient in group B, but this case did not meet the criteria for bleeding complications according to the consensus guidelines^[28]. Other bleeding complications were easily controlled using argon-plasma coagulation, epinephrine spray, or compression by the balloon. Ersoz *et al*^[24] have reported a 9% bleeding rate in their EST + ELBD group, especially in patients with a tapered distal bile duct. With the larger balloon, the higher rate of bleeding could have been attributable to the moderate degree of EST. In addition, they performed major EST in their study. In the SES + ELBD group, the reported rate of bleeding ranged from 0% to 4.5%, and all of the cases were relatively mild^[25,39,40].

In conclusion, SES + ELBD did not show significant benefits compared to conventional EST and reducing the rate of mechanical lithotripsy, especially for the removal of large (≥ 15 mm) bile duct stones. Regarding the occurrence of complications, SES + ELBD showed a similar level of safety compared to conventional EST. Hence, SES + ELBD is a good alternative to conventional EST for the removal of large stones, especially for the unskilled endoscopist. However, a large-scale study of patients is required to clarify the difference in the efficacy of the two procedures.

COMMENTS

Background

Many recent studies on small sphincterotomy combined with endoscopic papillary large balloon dilation (SES + ELBD) have reported on the outcome of stone removal and the complication rate. As previous studies concentrated on the efficacy of small bile duct stone removal, the effectiveness of ELBD with SES for large stone removal (≥ 15 mm) has not been established.

Innovations and breakthroughs

Other recent studies have revealed that SES + ELBD reduced the frequency of mechanical lithotripsy and gave better results for the removal of stones. However, the present study found that SES + ELBD did not reduce the need for mechanical lithotripsy in removing large (≥ 15 mm) bile duct stones. Large balloon dilation alone cannot stretch the wall of the distal bile duct to the degree necessary for the effective removal of large stones. To remove large stones, the configuration and wall lumen tension of the terminal bile duct may be more important factors than the size of the balloon and dilation of the bile duct. Therefore, if a stone is too large to remove *via* the dilated terminal bile duct, stone fragmentation might be inevitable.

Applications

For the removal of large common bile duct stones, SES + ELBD is a good alternative to conventional endoscopic sphincterotomy (EST), especially for the unskilled endoscopist. However, a large-scale study is required to clarify differences in the efficacy of the two procedures.

Terminology

Endoscopic papillary balloon dilation (EPBD), an alternative method with similar outcomes compared to EST, is associated with frequent, severe pancreatitis. SES + ELBD is a modified EPBD technique.

Peer review

In this study, the numbers of the patients are too small to compare infrequent complications like bleeding or pancreatitis. However, it may be difficult to enroll many more patients with large bile duct stones.

between the two groups. During a follow-up period ranging from 1.0 to 122.7 mo (median, 10.9 mo), S-PAC and L-PAC patients had a similar prognosis after resection ($P = 0.4805$). Among the S-PAC patients group, patients with higher albumin level (> 3.5 g/dL) had more favorable survival than those with lower albumin levels, which was the only favorable predictive prognostic factor. Meanwhile, early-staged (stage I, II) S-PAC patients tended to have a more favorable outcome than late-stage (stage III, IV) S-PAC patients, but this was not statistically significant.

CONCLUSION: S-PAC patients should not be regarded as early PAC. Only higher albumin level (> 3.5 g/dL) and early stage disease (stage I, II) were the favorable prognosis factors for S-PAC patients.

Abstract

AIM: To investigate the differences in clinicopathological features between patients with pancreatic cancer greater or less than 2 cm situated over the pancreatic head and the prognostic factors for survival of patients with pancreatic cancer < 2 cm over the pancreatic head.

METHODS: From 1983 to 2006, 159 patients with histologically proven pancreatic adenocarcinoma (PAC) at the pancreatic head undergoing curative resection at the Department of Surgery, Chang Gung Memorial Hospital, Taipei, Taiwan were reviewed, comprising 123 cases of large (L)-PAC (tumor > 2 cm) and 36 cases of small (S)-PAC (tumor ≤ 2 cm). We compared the clinicopathological characteristics and prognosis of L-PAC and S-PAC patients. The clinicopathological characteristics of S-PAC were investigated to clarify the prognosis predictive factors of S-PAC.

RESULTS: One hundred and fifty-nine PAC patients, aged 16-93 years (median, 59.0 years) with a tumor at the pancreatic head undergoing intentional curative resection were investigated. The S-PAC and L-PAC patients had similar demographic data, clinical features, and tumor markers (a similar positive rate of carcinoembryonic antigen and carbohydrate antigen 19-9). There were also similar rates of lymph node metastasis, portal vein invasion, stage distribution, tumor differentiation, positive resection margin, surgical morbidity and mortality observed

Key words: Prognostic factor; Pancreas; Pancreatic head area; Pancreatic cancer

Chiang KC, Yeh CN, Lee WC, Jan YY, Hwang TL. Prognostic analysis of patients with pancreatic head adenocarcinoma less than 2 cm undergoing resection. *World J Gastroenterol* 2009; 15(34): 4305-4310 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4305.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4305>

INTRODUCTION

Pancreatic adenocarcinoma (PAC), one of the most lethal malignant cancers, ranks fifth in mortality related to cancer worldwide with the 5-year survival after resection ranging from 10% to 29%^[1-3]. Thirty-two thousand new PAC cases have been found in America each year^[4].

Surgery remains the only curative treatment of PAC and detection of PAC with small size (≤ 2 cm) (S-PAC) seems to be essential to improve the outcome, which is demonstrated in some reports^[5-7]. The 5-year survival rate varied from 19% to 41% for PAC patients undergoing pancreatectomy with the highest survival in patients with small tumors confined to the pancreas.

But the controversial question is “Dose PAC with tumor diameters of 2 cm or less necessarily indicate early-stage disease or good prognosis?” Recent data have shown the different opinions about this issue^[8,9], which warrants further studies addressing this topic.

To collect an adequate number of resected cases of S-PAC was difficult due to limitations of diagnostic equipment, explaining why most of the previous studies were multi-institutional^[7,10,11]. Recent advances in diagnosis have made it possible to detect PAC earlier and to increase the number of resected cases; consequently evaluation of S-PAC cases in one center becomes feasible, which could provide more accurate information.

We retrospectively reviewed 159 PAC cases with pancreatic head cancer undergoing pancreaticoduodenectomy from 1983 to 2006. Among them, 36 cases were diagnosed with S-PAC, and the remainder were PAC with tumor diameter > 2 cm, classified as large PAC (L-PAC). We compared the clinicopathological features and surgical outcomes between S-PAC and L-PAC to find the favorable prognostic factors.

MATERIALS AND METHODS

From 1983 to 2006, 159 patients with histopathologically proven PAC located at the pancreatic head undergoing intentional curative resection at the Department of Surgery, Chang-Gung Memorial Hospital, Taipei, Taiwan were reviewed. Curative resection was defined as a negative resection margin observed during histopathological examination. The 159 PAC patients comprised 96 men and 63 women with a median age of 64.0 years (range, 16-93 years). Among them, 36 patients (22.6%) had a tumor size \leq 2 cm classified as S-PAC and 123 PAC patients had tumor size > 2 cm (L-PAC). Tumor size was defined by histopathological examination. Surgical mortality was defined as death occurring within 1 mo after surgery. Laboratory tests were conducted on the day before surgery. Serum carbohydrate antigen 19-9 (CA 19-9) and carcinoembryonic antigen (CEA) were measured by radioimmunoassay. The tumors were preoperatively evaluated by abdominal ultrasonography, endoscopic retrograde cholangiopancreatography, percutaneous transhepatic cholangiography, computed tomography, magnetic resonance image with cholangiopancreatography, and angiography, as appropriate. Tumor stage was defined according to the pathological tumor node metastasis (pTNM system) classification proposed by the UICC. Stages I and II were classified as early-stage, and stages III and IV as advanced stage PAC. Adjuvant chemotherapy was systemic administration of either 5-fluorouracil-based or gemcitabine-based regimen due to either the positive section margin or lymph node metastasis. Adjuvant radiotherapy was conducted by intra-operative radiotherapy, external beam radiotherapy and/or brachytherapy due to either a positive section margin or local recurrence.

Statistical analysis

All data are presented as percentage of patients or mean

with standard deviation. Numerical data were compared by independent two-sample *t*-tests. Nominal data were compared by Pearson chi-square test, or multiple forward stepwise logistic regression when appropriate. Survival was calculated and plots constructed according to the Kaplan-Meier method. Sixteen clinicopathological variables were selected for survival analysis, including demographic data, clinical features, laboratory data, operative findings, and pathological features. The log-rank test was performed for a univariate analysis for prognosis by using log-rank test and multivariate analysis was conducted with Cox's proportional hazard model. All statistical analyses were performed using the SPSS computer software package (Version 10.0, Chicago, IL, USA). A value of $P < 0.05$ was considered significant.

RESULTS

Clinicopathological features of L-PAC and S-PAC patients

The S-PAC group contained 22 men and 14 women, with a mean age of 61.9 ± 8.2 years. In the L-PAC group, there were 74 men and 49 women, with a mean age of 62.8 ± 10.5 years. Both groups had a similar age distribution, gender ratio, and laboratory data. In terms of symptoms and physical examination, both groups possessed a higher positive rate (> 80%) for non-specific symptoms and signs irrespective of the tumor size. Regarding tumor markers (CEA and CA 19-9), L-PAC and S-PAC groups had similar positive rates (35.9% and 75%, and 29.6% and 69%, respectively). In the light of lymph node metastasis and portal vein invasion, the two groups had similar positive rates. Even in the S-PAC groups, lymph node metastasis and portal vein invasion rates reached 63.9% and 11.1%, respectively. Both groups had almost the same curative resection rate. Portal vein invasion and retroperitoneal extension of the tumor explained the reasons for the positive margin. Both groups also had similar distributions of tumor differentiation and stage.

Morbidity and mortality rates between L-PAC and S-PAC groups

Surgical morbidity and mortality rates for the L-PAC group were 26.8% and 4.1%, respectively, similar to those of the S-PAC group which were 30.6% and 2.8%, respectively (Table 1). Almost the same percentage of patients received post-operative chemotherapy and radiation in the two groups, mainly for lymph node metastasis and positive margin.

Survival analysis between L-PAC and S-PAC

All of the 159 PAC patients undergoing resection were followed regularly until death with the duration of follow-up ranging from 1.1 to 213.5 mo (median, 16.4 mo). The 1-, 3- and 5-year survival rates of the 159 cases were 51.3%, 23.1% and 12.5%, respectively (Figure 1). The 3- and 5-year survival rates of the S-PAC and L-PAC patients were 26.4% and 6.6%, and 22.1% and 14.7%, respectively

Table 1 Clinicopathological features of 159 pancreatic head adenocarcinoma patients with tumor size smaller and larger than 2 cm *n* (%)

	S-PAC (<i>n</i> = 36)	L-PAC (<i>n</i> = 123)	<i>P</i>

(Figure 2). The S-PAC patients had a similar overall survival rate to the L-PAC patients ($P = 0.48$) (Figure 2).

Prognosis predictive factors of S-PAC patients

S-PAC and L-PAC groups had the same prognosis in this study, which meant tumor size did not influence the outcome of this disease. So, we were interested in which factors could affect the prognosis of S-PAC patients. We chose 16 clinicopathological characteristics including demographic data, clinical biochemical laboratory values, tumor markers, operative procedure, tumor invasion, tumor differentiation, tumor stage, post-operative chemotherapy and radiation to determine which one could be the prognostic predictive factor (Table 2). Only the albumin level had a significant impact on survival of S-PAC patients ($P = 0.002$). The early stage S-PAC patients (Stage I, II) tended to have a favorable outcome compared with late stage S-PAC patients (Stage III, IV), but this difference did not reach statistical significance ($P = 0.0931$). Age, gender, operative procedures, biochemical data, tumor invasion, resection margin, and tumor differentiation did not associate with favorable prognosis.

DISCUSSION

PAC is one of most lethal human malignancies

**Figure 1** The overall survival rates of 159 pancreatic head adenocarcinoma patients.**Figure 2** The overall survival rates of S-PAC and L-PAC patients.

producing the fourth highest cancer-related mortality in the western world and the fifth highest cancer-related mortality rate worldwide^[4]. The overall 5-year survival rate of PAC has been reported to be around 1%-4%, which was attributed to its aggressive growth behavior, early local spread, early metastasis, and resistance to radiation and most systemic chemotherapies^[4]. Surgery remains the cornerstone of treatment. After resection, the 5-year survival rate can reach 10%-29%^[1-3].

For most malignancies, a smaller tumor size is usually deemed as a good indicator of early stage, and should be diagnosed and treated as soon as possible to improve the outcome. Some reports have demonstrated that tumor size was one of most important determinants of resectability and prognosis for pancreas cancer^[12-14]. Previously, Satake *et al*^[15] stated that PAC with tumor size < 40 mm represented a better prognosis. However, according to our report, even PAC with tumor size < 20 mm did not necessarily mean early stage disease and should not be treated by surgery alone^[7,9,16,17]. The reported 5-year survival for S-PAC patients ranges from 8% to 59% and is only 6.6% in our series^[3,7,9,16,18,19].

Several reasons could be found to explain this dismal outcome. S-PAC patients (tumor size < 2 cm) had similar clinicopathological features including positive clinical symptoms, tumor differentiation pattern and positive

lymph node invasion rate to L-PAC patients (Table 1). Contrary to previous reports^[9,20], a well-differentiated type of adenocarcinoma is more frequently seen in PAC tumors with tumor size < 2 cm, but in our study, tumor size had no impact on tumor differentiation. S-PAC and L-PAC possessed the same distribution in terms of tumor differentiation. Jung *et al*^[20] also indicated that pancreas tumor size < 2 cm would tend to be symptomless, however, in our study, we could not find this difference. Both groups had a very low negative rate of symptoms. Contrary to Shimada's report^[8], we showed the incidence of lymph node metastasis was similar between S-PAC and L-PAC (as high as 63.9%), demonstrating that S-PAC with tumor size < 20 mm did not necessarily mean early stage disease. Such findings showed that PAC was attributed to its aggressive growth

behavior, early local spread and early metastasis no matter what its size.

CEA and CA 19-9 are widely used to screen malignancies in the general population. An 80% CA19-9 positive rate in pancreas cancer and high levels of CA19-9 associated with more advanced disease were reported^[21-23]. Jung *et al*^[20] reported that CA19-9 and CEA in patients with PAC tumor size > 6 cm would be higher than in smaller cancers. Steinberg revealed that CEA and CA 19-9 would not increase in patients with pancreas cancer < 2 cm^[24]. But in our study, we found the sensitivity of CEA and CA 19-9 for S-PAC and L-PAC patients were 29.6% and 69%, and 35.9% and 75%, respectively. Tumor marker values did increase in the S-PAC group and both groups had similar positive rates of CEA and CA 19-9.

Regarding prognostic analysis for S-PAC patients, only albumin level could be a favorable prognostic factor for S-PAC statistically ($P = 0.0002$). Early stage S-PAC (Stage I, II) tended to have a better prognosis than late stage S-PAC (Stage III, IV), but this was not statistically significant ($P = 0.0931$). In our study, most non-curative resection cases were due to portal vein invasion and retroperitoneum tumor extension. However, curative resection or not did not influence the final survival of S-PAC and tumor differentiation of S-PAC did not have any influence on survival either. Lymph node metastasis, poorly differentiated tumors, and positive margins were usually regarded as poor prognostic factors for pancreas cancer^[13,25,26]. In this study, we did not find these as unfavorable factors for prognosis. Limited case numbers should be the main cause. In terms of these issues, we need more time to collect more cases to answer these questions. Detection of PAC with small size (≤ 2 cm) (S-PAC) still warrants more efforts to improve the outcome.

In conclusion, S-PAC and L-PAC had similar clinicopathological characteristics. They expressed similar tumor biology, such as lymph node metastasis, portal vein invasion and tumor differentiation. So both groups had the same survival rate, explaining why S-PAC should not be deemed as an early stage disease and treated by surgery alone. For S-PAC groups, only albumin level could be a prognostic predictor. Early stage S-PAC tended to have a more favorable prognosis than late stage S-PAC, although this did not reach statistical significance.

COMMENTS

Background

Pancreatic cancer is a devastating cancer. Previously, cancer size has been deemed as an important prognostic factor for pancreatic cancer. However, growing evidence recently demonstrated the controversial conclusion against the previous viewpoint. Herein, the authors collected data from pancreatic cancer patients with cancer on the pancreatic head and they compared the clinicopathologic characteristics and survival between small pancreatic adenocarcinoma (S-PAC) and large (L)-PAC groups. In addition, they also tried to find out the prognostic factor for S-PAC patients.

Research frontiers

The tumor biology, including differentiation, lymph node metastasis, portal vein invasion and so on is similar between S-PAC and L-PAC patients, which would give rise to further studies of whether there are any different gene mutations in terms of the size of pancreatic cancer.

Innovations and breakthroughs

In this report, albumin level is the only prognostic factor for survival of S-PAC patients. Traditionally, lymph node metastasis and portal vein invasion are deemed as important prognostic factors for pancreatic cancer. Although such findings were not shown in their report, they considered these could be blamed partly on the limited number of cases.

Applications

Through the findings of their report, S-PAC should not be regarded as a early pancreatic cancer. Aggressive management such as post-operative chemotherapy and radiation are justified.

Peer review

This is an interesting clinical report. However, due to the poor prognosis of S-PAC patients and thus the small number of cases who survived for 5 years, we have to be careful in making extended conclusions from the data.

Abstract

AIM: To determine which baseline factors of chronic hepatitis B patients are predictive of virological response to Peginterferon α -2b therapy.

METHODS: A total of 21 HBeAg-positive chronic hepatitis B (CHB) patients treated with Peginterferon α -2b were recruited. They were treated with Peginterferon α -2b (0.5-1.0 μ g/kg per week) for 24 wk and followed up for 24 wk. Clinical and laboratory data of the patients were determined at pretreatment and at week 12, at 24 during treatment, and at week 48 during follow up.

RESULTS: Ten patients achieved a virological response at the end of treatment. Their baseline serum alanine aminotransferase (ALT), thyroid-stimulating hormone (TSH), and total thyroxin (TT4) levels were significantly different from those who failed treatment. The positive predictive values (PPV) and negative predictive values (NPV) of ALT, TSH, and TT4 were 75% and 89 %, 75% and 89 %, and 75% and 75%, respectively. Moreover, combinations of the baseline ALT and TT4, ALT and TSH, TT4 and TSH levels had much higher PPV and NPV (86% and 88%, 89% and 100%, 83% and 100%, respectively).

INTRODUCTION

Chronic hepatitis B virus (HBV) infection is a worldwide health problem. More than 400 million people are chronically infected with HBV and are at risk of developing liver cirrhosis and hepatocellular carcinoma. Each year more than one million people die from HBV-related liver diseases^[1-4].

At present, the two main categories of antiviral drugs for chronic hepatitis B are interferon (including Peginterferon) and nucleoside/nucleotide analogs. Many studies have shown that an elevated serum ALT level is associated with virological response and HBeAg seroconversion in CHB patients^[5-8]. Besides higher serum ALT level, some studies also showed that higher aspartate aminotransferase (AST) level, increased histological activity in biopsy specimens, female sex, and lower serum HBV DNA levels are associated with a higher probability of HBeAg seroconversion in CHB patients treated with interferon-based therapies^[9-13]. It is also reported that the HBV genotype is an important predictor of response to interferon-based therapies^[14-17].

Recently, serum HBeAg levels have been used as

outcome predictors of sustained virological response to Peginterferon α -2a in HBeAg-positive CHB patients and showed high negative predictive values (NPVs) at week 24 of therapy^[18]. Another study showed that early serum HBsAg drops also had high predictive values of sustained virological response to Peginterferon α -2a in HBeAg-negative chronic hepatitis B patients both at week 12 and 24^[19].

However, the predictive values of other factors, especially the baseline factors for virological response to Peginterferon α -2b therapy are not clear. Therefore, in this study, we aimed to determine how well the baseline factors predicted the virological response to Peginterferon α -2b therapy in HBeAg-positive CHB patients.

MATERIALS AND METHODS

Ethics

The study was approved by the Investigation and Ethics Committee for Human Research at the Peking University First Hospital (Beijing, China). All patients provided informed written consent.

Patients and study design

Twenty-one consecutive HBeAg-positive chronic hepatitis B patients were evaluated. Patients were treated with Peginterferon α -2b at a dose of 0.5-1.0 μ g/kg per week for 24 wk. Clinical and laboratory data of the patients were determined before treatment, at week 12, and 24 during treatment. Thereafter they were scheduled for follow-up visits every 12 wk. End of treatment (EOT) response was defined as more than 2 log₁₀ IU/mL reduction in HBV DNA levels at the EOT. Non-response was defined as less than 2 log₁₀ IU/mL reduction in HBV DNA levels at the EOT.

Measurement of serologic markers of HBV

HBsAg, antibody to HBsAg, HBeAg, antibody to HBeAg and anti-HBc were measured using a microparticle enzyme immunoassay (Abbott Laboratories, North Chicago, IL). The HBV genotype was determined using the INNO LiPA HBV genotyping assay. Serum HBV DNA was measured using the TaqMan polymerase chain reaction assay [COBAS TaqMan, Roche Molecular System (lower limit of detection, 20 IU/mL)].

Measurement of biochemical markers

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were measured using a Hitachi Model 7600 Series Automatic Analyzer (Hitachi). Thyroid-stimulating hormone (TSH), total triiodothyronine (TT3), and total thyroxine (TT4) levels were measured using a Centaur Automated Chemiluminescence System (Bayer).

Statistical analysis

Quantitative variables were expressed as the median with interquartile ranges (IQR), and categorical variables

as frequencies. Comparisons between groups of quantitative and qualitative variables were performed using the Mann-Whitney *U* test and the Fisher's exact test, respectively. The accuracy of serum factors to predict virological response was assessed using the receiver operating characteristic curve. The cutoff value was chosen according to the receiver operating characteristic curve when the sensitivity and specificity were both relatively high for the selective baseline factor. All tests were two-sided and used a significance level of 0.05. Data handling and analysis were performed with SPSS software for windows, version 13.0 (SPSS Inc., Chicago, IL).

RESULTS

Baseline characteristics of patients

The baseline characteristics of the 21 HBeAg-positive CHB patients are shown in Table 1. The median age was 25 years (range, 20-39), and 81% of them were male (17/21). The median value of serum HBV DNA levels was 8.2 log₁₀ IU/mL (IQR, 7.5-8.7 log₁₀ IU/mL). The distribution of HBV genotype was: B, 24%; C, 76%. The median values of serum ALT, AST, TSH, TT3, and TT4 level were 147 IU/L (IQR, 123-201 IU/L), 65 IU/L (IQR, 51-97 IU/L), 2.06 mIU/L (IQR, 1.41-3.10 mIU/L), 2.22 nmol/L (IQR, 2.04-3.03 nmol/L), and 111.4 nmol/L (IQR, 96.8-140.6 nmol/L) respectively. The baseline TT3 and TT4 values of one patient were not assayed at pretreatment. Serological tests were negative for hepatitis C virus, hepatitis D virus, and human immunodeficiency virus in all patients.

Virological response

Of the 21 patients, ten (48%) showed an EOT response, and eleven (52%) were non-responders. Four patients (19%) obtained HBeAg seroconversion at the end of treatment (week 24). However, two of the four HBeAg seroconversion patients lost anti-Hbe, while another six patients achieved HBeAg seroconversion at week 48. The median value of serum HBV DNA levels were 2.7 log₁₀ IU/mL (IQR, 1.9-4.0 log₁₀ IU/mL) and 3.1 log₁₀ IU/mL (IQR, 1.8-6.6 log₁₀ IU/mL) in responders at week 24 and 48 respectively. In non-responders, The median value of serum HBV DNA levels were 7.4 log₁₀ IU/mL (IQR, 6.8-7.9 log₁₀ IU/mL) and 7.6 log₁₀ IU/mL (IQR, 7.1-8.7 log₁₀ IU/mL) at week 24 and 48 respectively. The baseline ALT and TT4 level were significantly higher in responders than in non-responders (both *P* < 0.05, Table 1). However, the baseline TSH level was significantly lower in responders than in non-responders (*P* < 0.05, Table 1). The baseline age was similar between responders and non-responders.

Predictability

To determine how well the baseline ALT, TSH and TT4 levels predicted virological response to Peginterferon α -2b therapy, we performed receiver operating characteristic curves for each parameter. The areas under the curves of

Table 1 Baseline characteristics of patients

Characteristic	All patients (n = 21)	Responders (n = 10)	Non-responders (n = 11)	P value
Median age, range (yr)	25 (20-39)	25 (20-38)	25 (20-39)	0.749
Gender, male (%)	81	70	91	0.311
HBV genotype (%B, C)	24, 76	10, 90	36, 64	0.311
Median HBV DNA levels, range [log (IU/mL)]	8.2 (7.5-8.7)	7.7 (7.2-8.4)	8.4 (8.1-8.8)	0.090
Median ALT level, range (IU/L)	147 (123-201)	184 (146-247)	124 (112-148)	0.011 ^a
Median AST level, range (IU/L)	65 (51-97)	90 (57-132)	64 (45-73)	0.072
Median TSH levels, range (mIU/L)	2.06 (1.41-3.10)	1.82 (1.14-2.08)	2.55 (1.68-4.11)	0.035 ^c
Median TT3 levels, range (nmol/L)	2.22 (2.04-3.03)	2.85 (2.02-3.85)	2.20 (2.02-2.54)	0.305
Median TT4 levels, range (nmol/L)	111.4 (96.8-140.6)	132.7 (109.0-168.5)	107.8 (88.4-117.3)	0.037 ^c

Data are expressed as the median (IQR) and as percentages. HBV: Hepatitis B virus; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; TSH: Thyroid-stimulating hormone. ^a $P < 0.05$ differences of baseline serum ALT level between responders and non-responders; ^c $P < 0.05$ differences of baseline serum TSH level between responders and non-responders; ^c $P < 0.05$ differences of baseline serum TT4 level between responders and non-responders.

Table 2 Predictive value of single and combined baseline factors

Parameters	Responders	Non-responders	Predictive value (%)
ALT \geq 140	9	3	PPV = 75
ALT < 140	1	8	NPV = 89
TSH < 2.4	9	3	PPV = 75
TSH \geq 2.4	1	8	NPV = 89
TT4 \geq 120	6	2	PPV = 75
TT4 < 120	3	9	NPV = 75
ALT \geq 140, TT4 \geq 120	6	1	PPV = 86
ALT < 140, TT4 < 120	1	7	NPV = 88
ALT \geq 140, TSH < 2.4	8	1	PPV = 89
ALT < 140, TSH \geq 2.4	0	6	NPV = 100
TT4 \geq 120, TSH < 2.4	5	1	PPV = 83
TT4 < 120, TSH \geq 2.4	0	7	NPV = 100

Data are expressed as numbers of instances. PPV: Positive predictive values; NPV: Negative predictive values.

ALT, TSH, and TT4 were 0.827 ($P = 0.011$), 0.773 ($P = 0.035$), and 0.778 ($P = 0.037$), respectively. Accordingly, we chose cutoff values of 140 IU/L, 2.4 mIU/L, and 120 nmol/L for ALT, TSH, and TT4, respectively. Correspondingly, their positive predictive values (PPV) and negative predictive values (NPV) were 75% and 89 %, 75% and 89 %, and 75% and 75% (Table 2). We further performed the combination of the baseline ALT and TT4, ALT and TSH, and TT4 and TSH to predict the virological response. We found that their PPV and NPV were 86% and 88%, 89% and 100%, and 83% and 100%, respectively (Table 2).

DISCUSSION

Nowadays, more and more doctors are taking the initiative in individualized treatment for chronic hepatitis B patients. With the purpose of taking individualized treatment, it is important to evaluate the baseline status of each patient at the start of treatment and to then decide which antiviral drug is the best choice. For those patients who are not likely to benefit from Peginterferon α -2b therapy, an early switch to nucleoside/nucleotide analogs is essential.

Recently, a study showed that HBeAg levels had high negative predictive values (NPVs) at week 24 of

sustained virological response to Peginterferon α -2a in HBeAg-positive CHB patients^[18]. While in HBeAg-negative CHB patients, early serum HBsAg drops also had high predictive values of sustained virological response to Peginterferon α -2a at week 12 and 24^[19].

In our study, 21 HBeAg-positive CHB patients were treated with Peginterferon α -2b for 24 wk and followed up for 24 wk. We found that baseline serum ALT, TSH, and TT4 levels, and especially the combination of these factors, had high predictive values of virological response to Peginterferon α -2b therapy.

To identify the baseline predictors of virological response, we performed univariate analysis and receiver operating characteristic curves for baseline serum ALT, TSH, and TT4 levels, and found that the cutoff value of 140 IU/L of baseline serum ALT level had a relatively high predictive value of virological response. The cutoff values for TSH and TT4 were 2.4 (mIU/L) and 120 (nmol/L), respectively. Moreover, we found that combinations of these factors could further improve the PPV and NPV scores.

Some studies have shown that the rates of HBeAg loss and seroconversion were correlated with the baseline level of ALT. In patients with a higher baseline level of ALT, the rates of HBeAg loss and seroconversion during lamivudine therapy were also significantly higher at the end of year three^[7]. A previous study showed that CHB patients with normal ALT levels respond very poorly to interferon α -2a therapy. However, the response was significantly better in patients with elevated ALT levels^[13]. In HBeAg-negative CHB patients treated with Peginterferon α -2a, with or without lamivudine, a high baseline ALT level was identified as a significant predictor of virological response at weeks 24 post-treatment^[8].

Besides high baseline serum ALT level, we also found that higher TT4 level and lower baseline serum TSH level were associated with better outcome of Peginterferon α -2b therapy in HBeAg-positive CHB patients.

Although no study exploring the predictive value of virological response for baseline serum TT4 in chronic hepatitis B patients has been reported, several studies have demonstrated a reciprocal relationship between the endocrine and immune systems. Recently a study showed that triiodothyronine and thyroxine concentrations were

positively associated with markers of inflammation, natural killer-like T cells, activated monocytes derived interleukin-6 (IL-6), higher expression of IL-2 receptor on CD3+ T-lymphocytes, and percentage expression of memory T-lymphocytes, memory T-helper lymphocytes and memory T-cytotoxic lymphocytes within normal physiological ranges^[20]. This is supported by previous findings that thyroid hormone was involved in primary and secondary lymphopoiesis, and blastogenic responses to T and B cell mitogens were also enhanced following thyroxine administration^[21,22]. Other studies showed that thyroxine did not induce resting T lymphocyte proliferation but increased mitogen ConA-induced stimulation after three days of culture, in a dose-dependent manner. Thyroxine substitutive treatment restored the euthyroid status and reversed the impairment of T-cell activation induced by chronic stress in mice^[23,24]. Interestingly, the age-dependent immunological deterioration in old mice could be recovered by thyroxine treatment^[25]. These results indicated that thyroxine could enhance the immune response. Thus, this may be the reason why the responders who had higher baseline TT4 level achieved virological response more easily during Peginterferon α -2b therapy in our study.

Another major finding was the lower baseline TSH level of responders was also associated with higher virological response rate. This could be caused by the negative feedback mechanism due to their higher baseline serum TT4 level.

In conclusion, the identification and application of baseline factors to predict virological response of chronic hepatitis B patients before antiviral therapy is important. Using this method, we can identify patients who will most likely benefit from Peginterferon α -2b therapy before treatment. However, because of the small cohort of patients enrolled in our study, large-scale studies are needed to further confirm our results and to identify simpler and more appropriate factors that have high predictive values of virological response in chronic hepatitis B patients.

COMMENTS

Background

Early prediction of virological response for chronic hepatitis B patients treated with antiviral drugs is important. Some factors such as HBsAg and HBeAg reduction have been found to have high predictive values of sustained virological response in chronic hepatitis B patients treated with Peginterferon α -2a. However, the predictive values of other factors, especially the baseline factors for virological response to Peginterferon α -2b therapy, are not clear.

Research frontiers

Many studies have shown that an elevated serum alanine aminotransferase (ALT) level was associated with virological response and HBeAg seroconversion in CHB patients. Recent studies showed a reciprocal relationship between the endocrine and immune system. In this study, the authors showed that baseline serum ALT, thyroid-stimulating hormone (TSH), and total thyroxine (TT4) levels, and especially combinations of these factors, have high predictive values of virological response to Peginterferon α -2b in HBeAg-positive CHB patients.

Innovations and breakthroughs

The present study demonstrated that baseline serum ALT, TSH, and TT4 levels, and especially combinations of these factors, have high predictive values of virological response to Peginterferon α -2b in HBeAg-positive chronic hepatitis B (CHB) patients before treatment.

Applications

This study might represent a future strategy for identifying chronic hepatitis B patients who will most likely benefit from Peginterferon α -2b therapy before treatment.

Terminology

ALT is an enzyme that is normally present in liver and heart cells. ALT is released into blood when the liver or heart is damaged. TSH is a peptide hormone synthesized and secreted by thyrotrope cells in the anterior pituitary gland which regulates the endocrine function of the thyroid gland. Thyroxine (T4) is a form of thyroid hormone which is the major hormone secreted by the follicular cells of the thyroid gland.

Peer review

This study is of interest as it describes the relationship of virological response to Peginterferon α -2b therapy and serum parameters at pretreatment, although this was obtained in a very small cohort of patients.

Abstract

AIM: To investigate the expression of thymidylate synthase (TS) and glutathione-s-transferase π (GST- π) in esophageal squamous cell carcinoma and their association with the clinicopathologic characteristics.

METHODS: Immunohistochemical methods were used to detect the expression of TS and GST- π in surgically resected formalin-fixed, paraffin-embedded esophageal squamous cell carcinoma (ESCC) tissue sections from 102 patients (median age, 58 years) and in 28 normal esophageal mucosa (NEM) samples. The relationship between TS and GST- π expression and clinicopathologic factors was examined.

RESULTS: The expression of TS and GST- π was not statistically significantly associated with age of the patients, tumor size, lymph node metastasis, depth of invasion or tumor stage. TS staining was positive in 17.86% of normal esophageal mucosa and in 42.16% of ESCC samples ($P < 0.05$). The expression level of TS

was not only significantly lower in well-differentiated (21.88%) than in poorly-differentiated carcinomas (51.43%, $P < 0.05$), but was also significantly higher in samples from male patients (46.51%) than from female patients (18.75%, $P < 0.05$). GST- π was positively stained in 78.57% of normal esophageal mucosa and in 53.92% of ESCC samples ($P < 0.05$). The expression level of GST- π was also significantly higher in well-differentiated carcinomas (65.63%) than in poorly-differentiated carcinomas (35.00%, $P < 0.05$).

CONCLUSION: The expression of TS and of GST- π may be used as molecular markers for the characterization of ESCC. Poorly-differentiated cells showed increased expression of TS and reduced expression of GST- π .

INTRODUCTION

Nearly 50% of patients with the diagnosis of esophageal cancer present with overt metastatic disease, and chemotherapy is the mainstay of palliation in this setting. With the increasing use of chemotherapy as an adjunct to surgical management, systemic chemotherapy will ultimately be used to treat the majority of patients with esophageal cancer. The combination of 5-fluorouracil

(5-FU) and cisplatin is widely used in the treatment of esophageal cancer. Alternatively, taxane or irinotecan is applied in combination with either 5-FU or cisplatin^[1]. The response to cisplatin and 5-FU has been low, ranging from 35% to 40%^[2]. Therefore, there is great interest in identifying additional biochemical markers that might be predictive of chemotherapy response and resistance. As Ilson *et al.*^[1] stated: “future strategies in the treatment of esophageal carcinoma will undoubtedly be based on advances in the understanding of the molecular biology of the disease”.

Thymidylate synthase (TS) is a key enzyme for DNA and RNA synthesis. The anticancer activity of 5-FU is based on this molecular target. Glutathione-S-transferase π (GST- π) actively binds to platinum and allows it to be removed from the cytosol^[3]. Several studies have suggested that the expression of TS and GST- π could be associated with chemotherapy resistance and prognosis in esophageal cancer and gastric cancer patients^[3-6]. To our knowledge, the significance of TS and GST- π expression in esophageal squamous cell carcinoma (SCC) has not been reported to date in a Chinese population.

The current study was conducted (1) to investigate the expression characteristics of TS and GST- π in esophageal SCC (ESCC) in a Chinese population, and (2) to study the association between TS, GST- π and the clinical characteristics of the patients.

Immunohistochemical analysis has been used to assess the expression of molecular markers in malignant tumors. TS or GST- π has been shown to predict chemotherapy response and resistance in several cancers^[7-12].

MATERIALS AND METHODS

Patients and specimens

In this study, we determined the expression of TS and GST- π in surgically resected formalin-fixed, paraffin-embedded ESCC tissue sections from 102 patients and in 28 normal esophageal mucosa samples using immunohistochemical methods. The patients (86 males and 16 females) with ESCC underwent surgical resection at the Department of Thoracic Surgery, People's Hospital of Taizhou (Taizhou Medical School, Yangzhou & Nantong University), between August 2005 and September 2007. All patients had undergone a subtotal or total esophagectomy and radical lymph node dissection.

Histopathological specimens were fixed in 10% buffered formalin, routinely processed, and embedded in paraffin. All specimens were obtained from patients who had not received chemo- or radiotherapy prior to surgical resection. All hematoxylin and eosin stained sections were reviewed and reexamined by pathologists. The grade of tumor differentiation was determined according to the classification of the World Health Organization^[13], and staged according to the TNM classification^[14].

The patients were 35-76 years of age with a median age of 58.0 years. The location of the tumors was as

follows: upper intra-thoracic esophagus in 11 cases (10.7%); middle intra-thoracic esophagus in 55 cases (53.9%); lower intra-thoracic esophagus in 36 cases (35.2%). Histological degree of differentiation was well-differentiated in 32 cases (31.4%), moderately-differentiated in 50 cases (49.1%) and poorly-differentiated in 20 cases (19.6%). Five cases were Stage I, 47 cases were Stage II, 33 cases were Stage III and 17 cases were Stage IV. NEM samples were taken from 28 patients from an area more than 5 cm from the cancerous tissue, as control non-tumor samples.

Antibodies

The following antibodies were used in this study: mouse monoclonal antibody, anti-human TS and GST- π , the PV-9000 test kit (Zhongshan Goldenbridge Biotechnology Co., LTD, Beijing, China) was also used.

Immunohistochemical staining

The specimens with adjacent non-cancerous esophageal mucosa were cut into 4-5- μ m thick sections and mounted onto slides, deparaffinized with xylene, and rehydrated with graded concentrations of ethanol. Endogenous peroxidase activity was blocked by incubating with 3% hydrogen peroxide (H₂O₂) in deionized water for 10 min. The slides were washed three times with TBS buffer (10 mmol/L Tris-HCl, 100 mmol/L NaCl, pH 7.5) for 2 min. Before application of the TS primary antibody, an antigen retrieval technique was used (10 mmol/L sodium citrate solution, pH 6.0 in a rice cooker, at 640 W for 30 min). After three washes with TBS, an aliquot of 100 μ L of primary antibody was then applied to each section and incubated at 4°C overnight. It is not necessary to perform an antigen retrieval technique for GST- π . After washing 3 times with TBS and following the directions in the kit manual, agent one and then agent two (including the kit) were applied for 20 min at RT. Finally, the sections were washed 3 times with TBS, and the immunoreactions were visualized with 0.0067% diaminobenzidine as the substrate with 0.03% H₂O₂ in 100 mmol/L Tris-HCl buffer for 3 min. The sections were lightly counterstained in Harris hematoxylin solution for microscopic examination. Simultaneously, each section was incubated with TBS instead of the primary antibody as an internal negative control.

The immunostained specimens were analysed by two independent pathologists. Cytoplasm and/or nuclear staining (brown reaction product) was regarded as a positive result. Five fields in each tumor and non-tumor section were evaluated at medium power ($\times 200$) to determine the proportion of tumor cells and the staining intensity of the cytoplasm and/or nuclei in each section. The percentage of positive tumor cells was assigned to one of the following categories: 0 (0%-4%), 1 (5%-24%), 2 (25%-49%), 3 (50%-74%), or 4 (75%-100%). The intensity of immunostaining was determined as 0 (negative), 1+ (weak), and 2+ (strong). Additionally, an immunoreactive score was calculated by multiplying the percentage of positive cells and the staining intensity. The

Figure 1 Expression of thymidylate synthase (TS) and glutathione-s-transferase π (GST- π) in normal esophageal mucosa and esophageal squamous cell carcinoma. A and E: Negative control for TS and GST- π in normal esophageal mucosa, positive staining can not be detected (using TBS as primary antibody) ($\times 100$); B and F: Positive staining was located in the cytoplasm in normal mucosa ($\times 200$); C and G: Poorly-differentiated SCC, note the diffuse strong TS immunostaining in esophageal SCC ($\times 200$), for GST- π , positive staining was shown in the cytoplasm ($\times 200$); D and H: Moderately-differentiated SCC, TS positive staining is in the cytoplasm ($\times 200$); Well-differentiated SCC, diffuse strong GST- π immunostaining can be seen in esophageal SCC ($\times 200$).

average score in each tumor and non-tumor section was calculated, and the expression was considered positive when the score was $> 2^{[15]}$. To confirm the reproducibility of the results, all sections were scored twice, the highest score between the 2 observers are thus reported.

Statistical analysis

The correlations between the expression of TS, GST- π and clinicopathological factors were determined using the χ^2 or Fisher test (SPSS 15.0 software package) at the 5% level.

RESULTS

Expression pattern of TS in normal esophageal mucosa and in ESCC

Without specific primary antibody to TS, no staining was observed in esophageal specimens (Figure 1A). The staining of TS was mainly concentrated in the cytoplasm of

cells, occasionally, the nuclei were also stained (Figure 1B). The expression rates of TS in normal esophageal mucosa and in ESCC were 17.86% (5/28) and 42.16% (43/102), respectively. This suggested that the expression level of TS in ESCC was significantly higher than that in normal esophageal mucosa ($\chi^2 = 5.50$, $P = 0.018$).

TS staining and clinicopathological factors

The correlations between the expression of TS and the clinicopathologic features of ESCC are summarized in Table 1. The expression of TS was not significantly associated with age of the patients, tumor size, lymph node metastasis, depth of invasion or tumor stage. The expression of TS was significantly higher in poorly- and moderately-differentiated ESCC (Figure 1C) than in well-differentiated ESCC (Figure 1D) ($\chi^2 = 7.866$, $P < 0.01$). Female patients had tumors with low TS expression (18.75%) more frequently than male patients (46.51%) ($\chi^2 = 4.264$, $P < 0.05$).

Expression pattern of GST- π in normal esophageal mucosa and in ESCC

Without specific primary antibody to GST- π , no staining was observed in esophageal specimens (Figure 1E). While the staining of GST- π was mainly concentrated in the cytoplasm, occasionally, the nuclei of cells were also stained (Figure 1F). The positive expression rates of GST- π in normal esophageal mucosa and in ESCC were 78.57% (22/28) and 53.92% (55/102), respectively. This showed that the expression level of GST- π in normal esophageal mucosa was significantly higher than that in ESCC ($\chi^2 = 5.528$, $P < 0.05$).

GST- π staining and clinicopathological factors

The correlations between the positive expression rates of GST- π and the clinicopathologic features of ESCC are summarized in Table 2. The positive expression rates of GST- π were not significantly associated with the sex or age of the patients, tumor size, lymph node metastasis, depth of invasion or tumor stage. However, positive expression was significantly higher in well-differentiated ESCC (Figure 1H) than in poorly-differentiated ESCC (Figure 1G) ($\chi^2 = 4.645$, $P < 0.05$).

DISCUSSION

The present study was designed to evaluate the expression characteristics of TS and GST- π in ESCC, and to assess the relationship between TS, GST- π and clinical characteristics. Chemotherapy with cisplatin/5-FU is accepted as a standard treatment in squamous cell and adenocarcinoma of the esophagus. TS is the enzyme targeted by 5-FU, and this may be a potential marker of chemotherapy response, whereas an increase in expression of TS may indicate resistance to 5-FU^[16].

Assessment of the probability of chemotherapy resistance using immunohistochemistry methods detecting TS and GST- π expression may allow for the selection of a more effective chemotherapeutic regimen in several cancer patients^[8-12].

TS plays an important role in folate metabolism. Using the methyltetrahydrofolic acid as a substrate, TS catalyses the methylation of deoxyuridylic acid, transferring it into deoxythymidylic acid, which is an important nucleotide in the synthesis and reparation of DNA^[17]. This study showed that the expression of TS in ESCC was higher than that in normal tissue, and that the expression in moderately- and poorly-differentiated ESCC was higher than that in well-differentiated ESCC. This study also revealed that there is a potential to select patients according to whether TS expression is correlated with chemosensitivity to 5-FU. Some studies have indicated that esophageal cancer in patients with low expression of TS is more sensitive to chemotherapy than those with high expression^[3,4].

In the current study, the expression level of TS was observed to be associated with gender. The expression level of TS was significantly higher in males than in females, contrary to the findings reported by Dong^[4]. More studies are needed to investigate the significance of this difference, if any, to the outcome of patients.

In our study, the proportion of male to female patients was 5.4 to 1, this was similar to that of Joshi (6.07 to 1)^[3]. If we can verify that the expression of TS is higher in male than female patients, then this result may help us to understand why esophageal squamous cell carcinoma is related to gender.

GST is a group of isozymes with the function of detoxification and combining proteins. In humans, GST

contains α , μ , π , σ and θ , 5 family constellations and 13 different enzymes. The constellations are encoded by GSTA, GSTM, GSTP, GSTS, GSTT, respectively, and the relationship between GST- π and tumors has attracted much attention^[18]. GST- π not only affects cisplatin by shifting it away from the cells, but it can also release oxygen free radicals, a mechanism which reduces radiation damage^[2]. The expression of GST- π was higher in normal esophageal mucosa than in ESCC, and was higher in well-differentiated tumors compared to poorly-differentiated tumors. These results suggest that the loss of GST- π expression in esophageal epithelium may be an early pre-cancerous sign. The expression of GST- π had no significant association with gender, age, location of the tumor, lymph node metastasis or T stage, consistent with a previous report^[19]. Recently, a study in gastric cancer indicated that the expression of GST- π may be associated with the efficacy of cisplatin^[6].

In conclusion, the present results indicate that expression of TS and GST- π in ESCC in a Chinese population may add to understanding tumor characteristics and to predict response to chemotherapy. It is possible to predict chemotherapy response and resistance by detecting these biological markers. Thus, we are planning to investigate the relationship between expression of TS, GST- π , the curative effect of chemotherapy, and survival rate in patients with ESCC in a future study.

COMMENTS

Background

Esophageal cancer is a serious threat to human health, and nearly 50% of patients with a diagnosis of esophageal cancer present with overt metastatic disease. Chemotherapy has played a crucial role in the treatment of esophageal cancer. The combination of 5-fluorouracil and cisplatin is widely used in these patients. The response to these two drugs has been low. Therefore, it is important to know which drugs may induce a response in these patients.

Research frontiers

Thymidylate synthase (TS) is a key enzyme for DNA and RNA synthesis. The anticancer activity of 5-FU is based on this molecular target. Glutathione-S-transferase π (GST- π) actively binds to platinum and allows it to be removed from the cytosol. In this study, we demonstrated that the expression of TS and GST- π was related to clinicopathological factors of esophageal cancer.

Innovations and breakthroughs

Recently, a number of studies have suggested that the expression of TS and GST- π is associated with chemotherapy resistance and prognosis in esophageal cancer and gastric cancer patients. However, the study of TS and GST- π in esophageal squamous cell carcinoma (ESCC) has not been reported in a Chinese population. Their study showed that the expression features of TS and GST- π were obviously different in normal esophageal mucosa and ESCC. Furthermore, the expression level of TS and GST- π is related to clinicopathological factors of ESCC in a Chinese population.

Applications

By understanding the anti-cancer molecular target of 5-FU and platinum and their relationships with TS and GST- π , this study indicated that it may be possible to predict response and resistance to chemotherapy by detecting TS and GST- π in patients with ESCC.

Terminology

The expression level of TS in ESCC was higher than in normal esophageal mucosa. In contrast, GST- π in normal esophageal mucosa was higher than that in ESCC. These enzymes can be used as diagnostic molecular markers for ESCC. The results demonstrated that tumor tissues were poorly differentiated when the expression of TS was increased and the expression of GST- π was reduced.

Peer review

This is well written article, describing the correlation between expression of TS and GST- π with clinicopathological features in patients with ESCC.

Abstract

AIM: To investigate acute nonvariceal bleeding in the upper gastrointestinal (GI) tract and evaluate the effects of endoscopic hemoclippping.

METHODS: Sixty-eight cases of acute nonvariceal bleeding in the upper GI tract were given endoscopic treatment with hemoclip application. Clinical data, endoscopic findings, and the effects of the therapy were evaluated.

RESULTS: The 68 cases (male:female = 42:26, age from 9 to 70 years, average 54.4) presented with hematemesis in 26 cases (38.2%), melena in nine cases (13.3%), and both in 33 cases (48.5%). The causes of the bleeding included gastric ulcer (29 cases), duodenal ulcer (11 cases), Dieulafoy's lesion (11 cases), Mallory-Weiss syndrome (six cases), post-operative (three cases), post-polypectomy bleeding (five cases), and post-sphincterotomy bleeding (three cases); 42 cases had active bleeding. The mean number of hemoclips applied was four. Permanent hemostasis was obtained by hemoclip application in 59 cases; 6 cases required emergent surgery (three cases had peptic ulcers, one had Dieulafoy's lesion, and two were caused by sphincterotomy); three patients died (two had Dieulafoy's lesion and one was caused by sphincterotomy); and one had recurrent bleeding with Dieulafoy's lesion 10 mo later, but in a different location.

CONCLUSION: Endoscopic hemoclip application was

INTRODUCTION

Bleeding in the upper gastrointestinal (GI) tract is very common. The majority of patients benefit from conservative treatments; however, for those who have active bleeding, or have a high risk of recurrence of bleeding, it is still a serious problem for both endoscopists and surgeons^[1]. At present, endoscopic therapy has been recommended as the first choice for the treatment of acute upper GI bleeding^[2]. Effective methods for the control of bleeding in the upper GI tract include local injection (epinephrine or ethanol), thermal coagulation (laser; heater probe), and mechanical methods (hemoclips; elastic bands)^[3,4]. Among these methods, hemoclips can achieve immediate hemostasis^[5] by obstructing the vessel and have the special advantage of lack of additional tissue damage^[6]. During January 2000 to January 2007, 68 patients were given endoscopic hemoclippping treatment for nonvariceal bleeding in the upper GI tract. In this retrospective study, clinical data and endoscopic findings are described, and the outcomes of the therapy are also evaluated.

MATERIALS AND METHODS

During January 2000 to January 2007, a total of 632 patients had emergent endoscopy for bleeding in the upper GI tract in our hospital, and 155 patients were given endoscopic therapy. Among them, 68 cases

with nonvariceal bleeding were given endoscopic hemoclip application. Written informed consent was obtained from all the patients or their relatives before the treatment. The 68 cases had ages ranging from 9 to 70 years (average 54.4, male:female = 42:26). The presenting manifestations were hematemesis in 26 cases (38.2%), melena in nine cases (13.3%), and both in 33 cases (48.5%). Some of the patients had basal disease, including cardiovascular disease (myocardial infarction, congestive heart failure, or significant cardiac arrhythmia) in eight cases (11.8%), liver cirrhosis in two cases (2.94%) and respiratory disease (chronic obstructive pulmonary disease) in six cases (8.82%). Twenty-eight cases were in a state of shock, and 44 cases were given blood transfusions of more than 400 mL; the systolic blood pressures of 12 cases were still less than 90 mmHg when they were given the endoscopic treatment. The electrocardiogram, blood pressure, and oxygen saturation were monitored for those who were in a severe condition.

The type of hemoclip applied was MD 850 (Olympus Corp.) with a rotatable clip application device (HX-5L, Olympus Corp.). After finding the bleeding point, we exposed the clip from the sheath, rotated it to a desired axis, and opened the clip to the maximum width. The clip was then pressed against the lesion and deployed. If needed, the procedure was repeated. The mean number of hemoclips applied was four. All of the patients were given physical care after endoscopic therapy, such as monitoring vital signs, fasting, intravenous fluid, intravenous administration of Histamine-2 receptor antagonists or proton pump inhibitors, hemostatic agents, and some were given blood transfusions.

RESULTS

The causes of the nonvariceal bleeding in the upper GI tract can be listed as followings: gastric ulcer in 29 cases, duodenal ulcer in 11 cases, Dieulafoy's lesion in 11 cases, Mallory-Weiss syndrome in six cases, post-operative in three cases, post-polypectomy bleeding in five cases, and post-sphincterotomy bleeding in three cases.

Hemostasis was defined as endoscopic cessation of bleeding for at least one minute after hemoclip application. Clinically, hemostasis was defined as no decrease in hemoglobin concentration, and correction of shock by blood transfusion and intravenous fluid. Hemostasis was obtained by hemoclip placement in 59 cases. Six patients underwent emergent surgery, in which three cases had peptic ulcers (two located in the posterior wall of the gastric body and one duodenal ulcer located in the posterior wall near the lesser curvature), one case had Dieulafoy's lesion, and two cases were caused by sphincterotomy. Three patients died due to cardiovascular failure and liver cirrhosis (two had Dieulafoy's lesion and one was caused by sphincterotomy). To evaluate the long-term outcomes of the treatment, the patients were followed-up for 30 d. All 59 cases achieved permanent hemostasis, and one of them had recurrent bleeding because of

Dieulafoy's lesion 10 mo later, but in a different location (initially in the proximal one third of the stomach and later in the duodena). The patient underwent endoscopic hemoclip application again, and also achieved a satisfactory result.

DISCUSSION

Despite the development of pharmacology and endoscopic therapy, nonvariceal bleeding in the upper GI tract remains a serious problem, especially for those who have active bleeding. It is associated with an approximately 20% rebleeding rate and its mortality ranges from 10% to 36%^[7-9]. The etiology of acute nonvariceal bleeding in the upper GI tract has changed little in the past 20 years, peptic ulcers (including gastric ulcer and duodenal ulcer) are still the most common causes of acute hemorrhage in the upper GI tract^[10]. In our group, it accounted for 58.8% of bleeding episodes. After endoscopic therapy, acid suppression is essential for those who have bleeding caused by peptic ulcer disease. In a low pH environment, platelets can lose their function, and blood clots might be dissolved by pepsin, resulting in further bleeding. Among the 40 bleeding peptic ulcers, 92.5% achieved permanent hemostasis, only three cases underwent emergent surgery.

Tears at the gastroesophageal junction (Mallory-Weiss syndrome) account for 5% to 15% of all cases of nonvariceal bleeding in the upper GI tract^[11]. These lesions are usually associated with repeated nausea and vomiting. For nonbleeding cases, conservative treatments are usually sufficient. In our group, six cases with active bleeding were given hemoclip application and all had excellent outcomes. Compared with other endoscopic treatments, such as sclerotherapy, epinephrine injection, and heater probe, the hemoclip is a safer choice, without adverse effects^[12].

Dieulafoy's lesion, an important cause of potentially life-threatening GI bleeding, was first described in 1896 and is a submucosal artery protruding from a minute defective mucosa surrounded by normal tissue^[13,14]. Its histopathologic description is "a caliber-persistent artery" in the submucosal tissue^[14]. It was regarded as a rare disease in the past because the caliber-persistent artery often retracts after bleeding^[9], but with the development of technology and familiarity with this disease, it is now estimated to represent about 5% the etiology of acute upper-GI bleeding^[9]. Endoscopic therapy is now considered the first-line method of achieving hemostasis, and hemoclip application has achieved satisfactory results with no reported ulcerative complications^[10]. It can cause occlusion of the bleeding vessel, which results of immediate local hemostasis and prevent delayed recanalization and recurrent bleeding^[5]. In most cases, the hemoclip can replace surgery as the first choice therapy for patients with Dieulafoy's lesion. However, because the lesions are often located in the proximal stomach, usually along the lesser curvature, it might be technically difficulty to apply a hemoclip. In our group, one case underwent emergent surgery and

two cases were dead due to cardiovascular failure.

Upper GI bleeding caused by endoscopic treatment, such as resection of polyps, mucosal resection, and sphincterotomy, is becoming more and more frequent in clinics due to the increased endoscopic treatments. In our group, five cases were caused by resection of polyps by endoscopy and three cases were caused by sphincterotomy by endoscopy. Among them, two cases underwent emergent surgery and one case died from GI bleeding. These three cases were all caused

by sphincterotomy. In most cases, hemoclippping can achieve satisfactory results; however, it is difficult to accomplish hemostasis through endoscopy in upper GI bleeding caused by sphincterotomy, even for experienced endoscopists, so if necessary, emergent surgery might be a better choice.

Patients who have active bleeding or have a high risk of recurrence of bleeding require effective hemostasis^[15]. At present, endoscopic therapy has been recommended as the first choice for the treatment of acute nonvariceal upper GI bleeding^[2]. Some endoscopic therapies, such as heat probe coagulation, injection of epinephrine, or sclerotic agency, have been proved to be effective for achieving hemostasis, but they might cause tissue injury at the same time, causing necrosis or even perforation^[16,17].

As a mechanical method of hemostasis, the hemoclip application was first introduced in 1975^[18,19]. Due to its simplicity, low cost, easy availability, repetition, minimal damage to the localized field, and reduced risk of adverse effects, hemoclips have been widely used for the treatment of nonvariceal bleeding in the upper GI tract, such as bleeding peptic ulcer^[20,21], Dieulafoy's lesion bleeding^[22,23] (Figures 1 and 2), Mallory-Weiss syndrome^[24,25] (Figure 3), post-polypectomy bleeding^[26], and post-sphincterotomy bleeding^[27]. It is suggested that

hemoclips are particularly helpful when active bleeding is encountered and/or there is a specific point of bleeding^[28]. In these cases, hemoclip application is fast and very effective in controlling bleeding. Theoretically^[6], clips can provide immediate hemostasis comparable with surgery by ligation of the bleeding vessel, with minimal injury to the adjacent tissue. DiMaio *et al*^[10] reported that Hemoclip application has excellent results for initial (97.6%) and permanent hemostasis (95.1%). An experimental study^[29] showed that only this mechanical method was effective for control of bleeding from vessels greater than 2 mm in diameter. Cipolletta *et al*^[30] also thought that clipping was superior to a standard therapy such as injection epinephrine, with significantly less further bleeding, fewer units of blood transfused, a shorter hospital stay, and limited damage to surrounding tissue. However, Gevers *et al*^[31] and Lin *et al*^[32] produced different results.

These inconsistent results in randomized controlled trials suggest that some other factors, such as age, the reasons and the locations of the lesions, shock, presence of multiple comorbidities, could all be associated with the failure of endoscopic hemoclips for bleeding^[33]. For example, some lesions are located in difficult-to-reach sites, which make it hard to apply the clips to the bleeding spot with a perpendicular angle^[34]. The tissue of an ulcer is very brittle, the clip can easily fall off if located on it, so the clip must be located on the normal tissue across the ulcer. If the ulcer is very large and beyond the width of the clip, we can not achieve hemostasis using a hemoclip. However, the experience of endoscopists appears to play a major role in successful clip application. In some cases, it is difficult to deploy hemoclips to the lesion with active bleeding, and only experienced endoscopists can accomplish this task. Thus, hemoclippping is more operator-dependent than other therapies, with some endoscopists achieving excellent results and others having less success. This could explain why the results have great variation in the hemoclip group. The devices themselves might also affect the final results. At present, a number of design improvements have been made to achieve better results. For example, the clip device can be rotated to a desired axis, which makes it easier to adjust the clip position before deployment. The installation of the clips is easier than before, which can save time, because in many cases, more than one clip is needed to achieve hemostasis. Of course, the results will be better if the device could deploy multiple clips at the same time and larger, stronger clips are designed to control the bleeding from large vessels. In summary, endoscopic hemoclip application is an effective and safe method for control nonvariceal bleeding in the upper GI tract with satisfactory outcomes, but the clip and the application device require further improvements.

COMMENTS

Background

Endoscopic hemoclippping has been proved to be effective for achieving hemostasis for nonvariceal gastrointestinal (GI) hemorrhage. However, the

efficacy for different causes of acute nonvariceal upper GI hemorrhage has been rarely reported. The aim of this study was to assess retrospectively the efficacy of endoscopic hemoclippping for different causes of acute nonvariceal upper GI hemorrhage, such as bleeding peptic ulcers, Dieulafoy's lesion bleeding, Mallory-Weiss syndrome, post-polypectomy bleeding, and post-sphincterotomy bleeding. The authors also wanted to determine the factors associated with failure of endoscopic hemoclippping to achieve hemostasis.

Research frontiers

The hemoclip has been widely used for the treatment of nonvariceal bleeding in the upper GI tract. The research hotspots is how to improve the success of hemostasis by endoscopic hemoclip application.

Innovations and breakthroughs

Many studies on the use of a hemoclip for the treatment of nonvariceal bleeding in the upper GI tract have been reported recently, but the results are inconsistent. In this article, The authors analyzed the common causes of acute nonvariceal bleeding in the upper GI tract, evaluated the efficiency of endoscopic hemoclippping for different causes of hemorrhage, and analyzed the factors associated with the failure of endoscopic hemoclippping to achieve hemostasis.

Applications

The study results suggest that endoscopic hemoclip application is an effective and safe method for controlling nonvariceal bleeding in the upper GI tract, with satisfactory outcomes and no adverse effects. Many factors, such as age, the causes and the locations of the lesions, shock, presence of multiple comorbidities, the devices and the experience of endoscopist might all be associated with the failure of endoscopic hemoclip to achieve hemostasis; and the clip and application device need to be further improved.

Peer review

It's a good idea to publish this clinical experience. This study is short (68 cases) but it's interesting to read it especially by endoscopists and it encourages other physicians to publish their experiences.

Abstract

Cytomegalovirus (CMV) infection of the gastrointestinal (GI) tract has been reported in both immunocompetent and, more frequently, in immunocompromised patients. We describe a case of a 19-year-old male who developed CMV infection of the terminal ileum while receiving immunosuppression for lupus nephritis. This was a distinctly unusual site of infection which clinically mimicked Crohn's ileitis. We note that reports of terminal ileal CMV infection have been infrequent. Despite a complicated hospital course, ganciclovir therapy was effective in resolving his symptoms and normalizing his ileal mucosa. This report highlights the importance of accurate histological diagnosis and clinical follow-up of lupus patients with GI symptoms undergoing intense immunosuppression.

INTRODUCTION

Cytomegalovirus (CMV) infection of the gastrointestinal (GI) tract has been reported in both immunocompetent and, more frequently, in immunocompromised patients^[1,2]. Sometimes the presentation of this infection can mimic other illnesses, making accurate diagnosis difficult. As the therapy for this infection can be very toxic, and discontinuation of therapeutic immunosuppression can cause worsening of the underlying pathology, accurate diagnosis is essential. The case presented here illustrates the difficulty in making an accurate diagnosis, while highlighting the fascinating mimicry which CMV can display.

CASE REPORT

A 19-year-old white male presented with a 3-wk history of increasing malaise, weakness, fever, and arthralgia. He had no significant past medical history or family medical history and was on no medications. Outpatient workup revealed elevated acute serum Lyme and Ehrlichia titers for which he received oral doxycycline. Two weeks later, he presented with fever, arthralgia and a malar rash, along with mild diffuse abdominal pain and diarrhea. Physical examination demonstrated hypertension (blood pressure 150/90 mmHg), lower extremity edema, and mild diffuse abdominal tenderness. A complete blood count and comprehensive chemistry profile revealed pancytopenia (white blood cells 3000/mm³, hematocrit 25% and platelets 100 000/mm³), elevated transaminases (aspartate transaminase 250 IU/L and alanine transaminase 271 IU/L), albumin 2 g/dL, nephrotic range proteinuria (5 g/d) and a urinalysis with red blood cells and red cell casts, consistent with glomerular hematuria. His creatinine was 0.8 mg/dL with an estimated glomerular filtration rate of 130 mL/min. Serologic examination was significant for depressed complement components C3 and C4, a high titer antinuclear antibody 1:320, a positive anti-double stranded DNA antibody, erythrocyte sedimentation rate of 65 with negativity for c-ANCA (antineutrophil cytoplasmic antibody) and p-ANCA. A bone marrow biopsy was non diagnostic. Renal biopsy revealed features of World Health Organization class IV and class V lupus nephritis. He was treated with pulsed methylprednisolone 1 g daily for 3 d along with 1.2 g (0.7 g/m²) cyclophosphamide by intravenous infusion.

Figure 1 Abdominal gastrointestinal series X-ray revealing the typical string sign.

He continued on prednisone 80 mg/d orally. His immediate course was complicated by a transient psychotic reaction which required rapid tapering of the steroids. Subsequently his blood counts, liver function and clinical symptoms improved, and he was discharged home with close outpatient follow-up.

Approximately one month after receiving cyclophosphamide, he developed fever, severe debilitating watery diarrhea with abdominal pain, and presented to the emergency room in acute renal failure (creatinine 2.0 mg/dL). The renal dysfunction resolved completely after the administration of intravenous saline, but the GI symptoms persisted. Urinalysis demonstrated persistent hematuria and proteinuria. Routine stool studies, including cultures, occult blood and *Clostridium difficile* toxin were negative. The diarrhea was intractable with a large stool osmolar gap, hypoalbuminemia of 1.4 g/dL, and depressed cyanocobalamin levels, consistent with malabsorption and protein-losing enteropathy. Abdominal computed tomography (CT) demonstrated edema of the small intestinal wall, particularly in the ileum. A small bowel barium study clearly demonstrated a “string sign” with long narrowed segments of distal jejunum and ileum consistent with Crohn’s jejuno-ileitis (Figure 1). At the time, the differential diagnosis also included lupus vasculitis of the GI tract, ileal tuberculosis, actinomycosis, lymphoma, amoebiasis, or viral infection. Stool acid-fast bacilli and amoebic serologies were negative. An initial colonoscopy showed an inflammatory stricture with friable, erythematous and edematous mucosa at the terminal ileum, 2 cm proximal to the ileocecal junction through which the scope could not be passed.

Multiple biopsies were obtained but were not diagnostic. A CT angiogram, performed to rule out lupus vasculitis demonstrated a normal mesenteric vasculature. A subsequent colonoscopy one week later demonstrated persistently inflamed and denuded mucosa with a persistent terminal ileal stricture. Terminal ileal biopsies clearly revealed intranuclear basophilic inclusions consistent with CMV infection which was confirmed by immunocytochemical staining (Figure 2). No evidence of granulomas or vasculitis was seen on histology. Based on this finding alone, further immunosuppression was

Figure 2 Hematoxylin and eosin staining of ileal tissue revealing cytomegalovirus inclusions, cytomegaly and intranuclear inclusions.

deferred, and the patient was started on intravenous ganciclovir 5 mg/kg twice daily. His subsequent hospital course was complicated by continued diarrhea, protein-losing enteropathy, severe malnutrition requiring total parenteral nutrition, fungal sepsis, and subclavian deep venous thrombosis. Ganciclovir was continued for 4 wk. Ultimately he recovered fully. His abdominal symptoms resolved, and he was able to tolerate an oral diet before discharge.

A repeat colonoscopy 4 mo later found resolution of the stricture, with no inclusion bodies seen on repeat biopsy. After this confirmation, cyclophosphamide and glucocorticoid therapies for lupus nephritis were resumed, with oral ganciclovir prophylaxis. There were no further infectious sequelae. He has had no further complications on follow-up and was switched to mycophenolate mofetil maintenance therapy. Currently he has normal renal function, no proteinuria or hematuria and continued quiescent lupus serology.

DISCUSSION

CMV is a double-stranded DNA virus and a member of the herpesviridae family.

During primary infection, T-cells are vital in controlling the viral replication, but do not eliminate the virus completely. This leads to a latent infection. Acute CMV infection in immunocompetent hosts can manifest with transient nonspecific symptoms, or as a systemic disease with significant organ involvement^[3]. It is estimated that 50%-80% of the adult population is seropositive for the virus^[4]. In immunocompromised hosts, re-activation or re-infection can lead to overt disease e.g., pneumonitis, hepatitis, pancreatitis, colitis, encephalitis, retinitis, or pericarditis leading to substantial morbidity and mortality. Transplant recipients and HIV infected patients with CMV enteritis had a mortality rate as high as 44% in one study^[5].

Immunosuppressive therapies for lupus have well documented infectious risks. Cyclophosphamide is a potent alkylating agent that impairs T-cell immunity at even low to moderate doses. In contrast to cancer chemotherapeutic doses, the doses given for lupus nephritis do not usually result in profound effects.

However, leukopenia and opportunistic infections can sometimes supervene. Data on the incidence of CMV disease with the cyclophosphamide induction protocol for lupus are scarce. The Euro-Lupus Nephritis Trial documented 3 cases out of 45 lupus nephritis patients on intravenous cyclophosphamide^[6].

The protean manifestations of lupus, together with the numerous possible complications of therapy, present unique problems for the treating physician. Lupus vasculitis has been reported to mimic Crohn's ileitis^[7]. The perplexing question in this case was whether the patient's symptoms represented this rare manifestation of GI lupus vasculitis, versus the coexistence of systemic lupus erythematosus (SLE) and Crohn's disease, an infectious complication of immunosuppression, or a fourth, less likely, possibility that the patient's CMV infection was the etiology of his abdominal pain at the time of his initial presentation with SLE, and thus predated his immunosuppression. The transient leukopenia and elevated transaminases on initial presentation, though not unusual for active systemic lupus, could have been the result of primary CMV infection in this spontaneously immunocompromised host.

The acute onset of CMV disease has been described in up to 46% of patients with connective tissue disease undergoing immunosuppressive therapy^[8]. It has also been noted that patients with connective tissue diseases treated with immunosuppression are at high risk for reactivation of latent CMV disease^[9]. Any part of the GI tract may be affected by CMV. Colitis is the most common manifestation of gastrointestinal CMV and can occur either alone or with other systemic involvement. CMV infection of the small bowel, though reported, is distinctly rare, especially in apparently immunocompetent hosts, and only involves 4.3% of CMV infections of the GI tract^[3,10]. CMV enteritis presents most commonly with fever, abdominal pain, diarrhea, or hemorrhage. The virus directly infects the bowel causing mucosal erosions or ulcerations. In severe cases, tissue necrosis and bowel wall perforation can occur^[1]. Histology of the affected mucosa shows a nonspecific inflammatory reaction and giant cells with ovoid nuclei containing basophilic "Cowdry" inclusion bodies. Mesenchymal cells are infected most frequently (97%) followed by endothelial cells (35%), smooth muscle cells (6%) and epithelial cells (3%). Mucosal ulcers are seen in more than half the cases^[10,11]. CMV ileitis in lupus patients is rare, but has been reported to cause ileal perforation^[12]. Though one case found CT evidence of bowel wall thickening^[7], we found no cases described in association with the radiographic "string sign". As mentioned, it is also possible that the initial presentation of abdominal pain and diarrhea in this case, prior to the diagnosis of lupus nephritis, may have actually been manifestations of CMV enteritis. Such infections have been reported to coincide with the immune dysregulation associated with SLE^[13,14].

Interestingly, there have even been reports suggesting that CMV disease itself may induce autoimmune abnormalities^[15]. There are a few case reports of acute CMV infection with elevated CMV antibody titers at

the time of diagnosis of SLE leading to speculation about a possible role in precipitating lupus activity^[16]. There have also been isolated case reports of SLE and Crohn's disease manifesting simultaneously in the same patient^[17], an association which could be attributed to the immunological basis of both diseases. CMV ileitis masquerading as Crohn's disease has also been reported, with documented mucosal and CT findings consistent with that diagnosis^[3]. However, the appearance of a radiographic "string sign" has never been described.

In this case, the persistently low complements and the ileal "string sign", in light of reports of lupus vasculitis of the GI tract mimicking Crohn's disease^[18], led to a therapeutic quandary. Specifically, it was uncertain whether the patient required intensification of his immunosuppression regimen for presumed vasculitis, or whether discontinuation of immunosuppression and concurrent antibiotic therapy was indicated. Given the well-documented infectious risks of therapies in both lupus and Crohn's disease, it was decided, despite decreasing complements and continued intractable diarrhea, to defer further immunosuppression pending definitive diagnosis of the underlying ileal pathology. This decision may have saved the patient from potentially catastrophic enhancement of his immunosuppression.

It is instructive to clinicians to be made aware of a rare complication of this common infection in an increasing number of potentially at-risk patients. A negative routine workup in a lupus nephritis patient with acute abdominal pain and diarrhea should provoke a high index of suspicion for occult CMV infection of the GI tract. Such symptoms may also result from mesenteric lupus vasculitis or from a manifestation of inflammatory bowel disease. Since morbidity increases with delay in initiation of effective therapy in all cases, early diagnosis and definitive treatment is vital for a favorable outcome. This case also raises the question in lupus patients as to whether CMV antigenemia and/or polymerase chain reaction for CMV DNA should be done routinely before initiating immunosuppression. The question whether empiric antiviral prophylaxis should be given to CMV seropositive patients remains unanswered.

abdominal wall repair: A case report. *World J Gastroenterol* 2009; 15(34): 4331-4333 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4331.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4331>

Abstract

Permacol® mesh has shown promise when used in abdominal wall repair, especially in the presence of a contaminated surgical field. This biomaterial, derived from porcine dermis collagen, has proposed advantages over synthetic materials due to increased biocompatibility and reduced foreign body reaction within human tissues. However, we present a case report describing a patient who displayed rejection to a Permacol® mesh when used in the repair of abdominal wound dehiscence following an emergency laparotomy. Review of the English language literature using PubMed and Medline, showed only two previously published cases of explanation of Permacol® due to sepsis or wound breakdown. The authors believe this is the first case of severe foreign body reaction leading to rejection of Permacol®. Both animal and human studies show conflicting evidence of biocompatibility. There are several reports of successful use of Permacol® to repair complex incisional herniae or abdominal walls in the presence of significant contamination. It appears from the literature that Permacol® is a promising material, but as we have demonstrated, it has the potential to evoke a foreign body reaction and rejection in certain subjects.

Wotton FT, Akoh JA. Rejection of Permacol® mesh used in

INTRODUCTION

Abdominal wall closure in the presence of overt sepsis is associated with a high failure rate. Biological prostheses are often used to reduce the risk of sepsis and ensure a trouble-free recovery. This is a case report of an experience involving the use of Permacol® mesh in abdominal wound dehiscence following an emergency laparotomy for caecal perforation. This patient later exhibited a severe foreign body reaction to the implant requiring its removal. Below, we outline an overview of the case followed by a review of the literature (using PubMed and Medline keywords: Permacol; porcine dermis collagen, abdominal wall repair; hernia repair), and resulting conclusions.

CASE REPORT

This case describes a 72-year-old man who was admitted as an emergency with acute abdominal pain and vomiting. On examination he had a distended rigid abdomen with reduced bowel sounds. He underwent an emergency laparotomy and right hemicolectomy for a perforated caecum, with localised abscess and generalised peritonitis. The wound was closed with “0” loop Polydioxanone (PDS) single layer with staples to the skin. Postoperatively he was admitted to the High Dependency Unit (HDU) but discharged to the ward the next day as he was making good progress. He developed a wound infection, manifested as discharge, on the 7th postoperative day. Some skin staples were removed to allow wound drainage and a vacuum assisted closure (VAC) dressing was applied on the 14th postoperative day. Two days after this, he was taken back to theatre to deal with a full thickness dehiscence of the abdominal wound. Following a thorough lavage, a Permacol® mesh was used to close the abdominal wound, partly as a bridge prosthesis as the fascial edges could not be approximated. This second operation was complicated by superficial wound dehiscence of the wound seven days later. A VAC dressing was reapplied

and the patient was discharged into the community. After sometime, the infection was controlled and there was pink granulation tissue formation in the wound. However, there was no demonstrable wound contraction or attempt at skin cover. He had application of silver nitrate to areas of over-granulation without significant response. Four months later, he underwent an elective exploration of the wound. At the time of surgery there was macroscopic evidence of rejection of the Permacol® mesh with nodular foreign body reaction and no attempt at wound healing at the level of the skin. The Permacol® mesh was excised and replaced with a Surgipro® mesh, with an uneventful postoperative period. Review of the wound 11 wk post-exchange of Permacol® with Surgipro® revealed evidence of wound healing in the superior section, although there remained an area (about 3 cm × 2 cm) of non-healing in the inferior section with the suspicion of a small piece of Permacol® remaining in the wound. An elective excision of abdominal wound sinus was carried out. Histology revealed features of acute and chronic inflammation superficially and granulomatous inflammation in the deep layer consistent with a “stitch granuloma”.

DISCUSSION

Permacol® (Tissue Science Laboratory, Covington, USA) is a biomaterial that has been used across a variety of surgical specialties since the 1980s, for urological, plastic, and gynaecological procedures^[1,2]. It was reported to have encouraging results when used in the form of a mesh for the repair of abdominal wall defects, and parastomal and inguinal hernias^[3]. Permacol® is derived from porcine skin and undergoes the removal of cellular components and genetic material before cross-linking the remaining extracellular matrix. The aim of this process is to produce a material that induces minimal foreign body reaction in tissues and is resistant to biodegradation by native collagenases. This is in contrast to Surgipro® (Cook Surgical, USA) which comprises monofilament fibres of polypropylene polymers to form a strong non-absorbable mesh, inducing a fibrous reaction which is the mainstay for the current repair of abdominal wall herniae and fascial defects^[3].

The proposed advantages of using a biomaterial over non-biomaterials are reduced infection; reduced risk of adhesion and fistula formation; and less rejection and erosion^[2,3]. Also, it is claimed that Permacol® is more suitable for use in contaminated surgical fields, where the risk of infection with a non-absorbable prosthesis is high^[2,4]. Permacol® initially takes on a structural role before becoming vascularized, followed by the incorporation of host cells, leading to remodeled tissue similar to that of the host. However, it has been proposed that there is a higher associated risk of hernia recurrence with biomaterials when compared to synthetic materials^[2,4].

This is an unusual case of extensive tissue reaction leading to rejection of a bioprosthesis (Permacol®). Animal studies (in a rat model) have demonstrated only a

minor chronic inflammatory response, limited evidence of collagen deposition or vascular ingrowth, and no foreign body reaction^[5,6]. However, Petter-Puchner *et al*^[7] who studied tissue responses to porcine cross-linked collagen implants in 10 rats at 17 d and three months showed extensive signs of foreign body inflammatory reaction, with three rats requiring euthanasia due to the migration of implants transcutaneously, and concluded that porcine dermal collagen shows suboptimal biocompatibility. Human studies revealed conflicting evidence of biocompatibility, lack of fibroblast penetration into the graft due to cross-linking of the porcine collagen matrix, absent acute polymorph cellular reaction, and occasional chronic foreign body reaction^[8-10]. Although the prosthesis had to be removed in this case, several studies have reported the successful use of Permacol® in abdominal wall or hernia repair^[2,11]. Hsu *et al*^[11] successfully used Permacol® in the reconstruction of incisional hernias or open abdomens in 28 patients with none requiring the prosthesis to be removed.

The decision to use Permacol® in this case is supported by others^[12,13] who described successful repair of complicated incisional herniae involving contaminated or uncontaminated surgical fields, with no post operative complications, wound infections or recurrence of herniae. Furthermore, Jehle *et al*^[14] described a case of complete wound dehiscence post elective panproctocolectomy where Permacol® was used to reconstruct the abdominal wall defect, and combined it with topical negative pressure dressing to achieve wound healing at five months. In another case where an emergency Hartmann's procedure for a sigmoid stercoral perforation was complicated by wound dehiscence and polyglactin absorbable mesh reconstruction of the abdominal wall resulted in an enterocutaneous fistula, resection and abdominal wall closure was achieved with Permacol® mesh.

Permacol® was used to repair complex abdominal wall defects in nine patients with incisional hernias following the removal of infected mesh, excision of abdominal wall tumour, wound infections and strangulated hernia repair. Despite the contaminated surgical field, five out of the nine patients had no complications due to infection. Two reported cases of explantation of Permacol® involved a patient who developed an abdominal wall abscess seven months after surgery^[15]. A paediatric renal transplant patient required Permacol® insertion as an adjunct to abdominal wall closure following transplantation, but suffered skin dehiscence 23 d postoperatively^[16].

In conclusion, our report provides the third reported case of Permacol® removal but for a very different reason-rejection. There was no sign of infection but the wound would not heal. Histology showed a mixture of acute and chronic inflammation, and foreign body inflammation. We believe this is the first documented case of Permacol® rejection in humans. Review of the literature has revealed the proposed biocompatibility of Permacol®, which is substantiated by the reported successes of its use in the repair of

incisional hernia and abdominal wall repair, including those with a contaminated surgical field. Most common complications include seromas, wound dehiscence or infection with only two reported cases in the literature where Permacol® was required to be removed. It would appear that Permacol® is a promising biomaterial but, as we have reported, it has the potential to induce severe foreign body reaction or rejection in certain subjects.

Abstract

A 33-year-old woman who presented with epigastric discomfort and diarrhea underwent an abdominal ultrasound (US). This investigation and subsequent contrast-enhanced computed tomography, magnetic resonance imaging and endoscopic US with fine needle aspiration (FNA) revealed a 40 mm well-circumscribed mass in the uncinate process of the pancreas. Findings were suggestive of a mucinous or solid-cystic pseudopapillary tumor of the pancreas, although other lesions such as a non-functioning neuroendocrine tumor could not be ruled out. FNA samples were negative for malignant cells, but of limited value due to poor cellularity. It was decided to surgically remove the tumor because malignancy could not be discounted. Multiple intraoperative biopsies were suggestive of mesenchymal tumor and consequently a conservative resection (uncinectomy) was performed. The postoperative course was uneventful. The definitive diagnosis was ganglioneuroma. Immunocytochemistry showed positive staining with vimentin, S-100 protein, neurofilament and neuron-specific enolase. Ganglioneuroma is a rare benign tumor that can also present as a pancreatic tumor. Uncinectomy is feasible, safe and a good surgical technique for the treatment of non-malignant tumors located in the uncinate process of the pancreas.

INTRODUCTION

Ganglioneuroma is a rare benign soft tissue tumor that arises from sympathetic nerve fibers. It is most frequently discovered during childhood or in young adults. The two most common presentations are in the mediastinum and retroperitoneum^[1,2]. Although often difficult and not always possible, a preoperative diagnosis can be obtained by fine-needle aspiration (FNA)^[1-3]. Clinical features, FNA and histological findings have been accurately described^[3]. Adequate treatment consists of radical resection of the whole tumor and definitive diagnosis is obtained after surgical removal by morphologic examination of the complete specimen.

Most solid pancreatic masses are malignant and extended radical surgery is usually the standard of care. Conservative surgery of the pancreas has been advocated mostly for benign or premalignant lesions, most of which are cystic or neuroendocrine tumors (NETs)^[4,5]. Uncinectomy is a relatively novel surgical technique recently described for the treatment of non-malignant lesions^[6].

We present the case of a young woman who had an apparent solid-cystic pancreatic mass in the uncinate process of the head of the pancreas and who was treated by conservative resection (uncinectomy), with a definitive diagnosis of ganglioneuroma. Informed consent for writing this article has been obtained from the patient.

Figure 1 A hypodense and non-infiltrative tumor is occupying the uncinate process of the pancreas (1); It is in close contact with the superior mesenteric vein (2) and superior mesenteric artery (3).

Figure 2 Hypointense-T1 and heterogeneous tumor that does not present any modifications following IV contrast administration with Gadolinium.

CASE REPORT

A 33-year-old woman was diagnosed with a well-circumscribed pancreatic mass measuring 40 mm in diameter in the head of the pancreas. The mass was discovered during the course of an abdominal ultrasound performed while the patient was being assessed for epigastric pain and diarrhea. The physical examination did not reveal any relevant findings. Serum analysis showed a discrete hypochromic microcytic anemia only. On initial abdominal ultrasound (US), the lesion appeared to have a solid consistency. An abdominal contrast-enhanced computed tomography (CT), contrast-enhanced magnetic resonance imaging (MRI) and endoscopic ultrasound (EUS) with FNA biopsy were all carried out to complete the patient's assessment. Tumoral (CA 19.9, CEA) and hormonal markers were normal. Following the guidelines of our centre, the study protocol for pancreatic nodules was followed.

CT (Figure 1)

This examination showed the presence of a hypodense, non-infiltrative tumor measuring 36 mm × 22 mm × 36 mm in both arterial and portal phases, with the appearance of having internal walls, located in the head of the pancreas and occupying the uncinate process in close contact with the superior mesenteric artery and vein, celiac trunk and hepatic artery. These findings were suggestive of a cystic or solid-cystic pseudopapillary tumor of the pancreas.

MRI (Figure 2)

This examination showed a hypointense-T1 lesion that did not present any modifications following IV contrast administration (Gadolinium) that would be suggestive of a mucinous pancreatic tumor.

EUS

This examination showed a 42 mm × 21 mm well-defined, non-infiltrative and heterogeneous mass in the uncinate process of the pancreas, in contact with the portal-mesenteric axis. There were no pathologic lymph nodes and the remaining pancreas looked normal. The

pancreatic duct was not dilated. Repeated direct FNA showed a tumor of extremely hard consistency, which made it difficult to obtain good quality samples. The ones obtained were negative for malignant cells, but of limited cellularity.

Although the diagnosis was not clear, it was decided to surgically remove the tumor because of a suspected solid-cystic pseudopapillary tumor or a non-functioning NET. Informed consent for conducting the protocol study and posterior operation was obtained from the patient. The operation was carried out through a right subcostal incision extended slightly to the left. During the exploration a well-delineated, non-infiltrative mass that occupied the uncinate process of the head of the pancreas was found. The mass was attached to the portal and superior mesenteric veins and to the superior mesenteric artery. Intraoperative multiple tumor biopsies (three tru-cut) showed fibrous tissue with some histiocytic cells suggestive of mesenchymal tumor. Intraoperative excisional biopsy of the intraaortic-cava, portal and hepatic lymph nodes showed no malignancy. Inferior pancreato-duodenal vessels were preserved. A complete resection of the uncinate process with preservation of the duodenum and the head of the pancreas was then performed (Figure 3A). Harmonic scalpel (Ethicon Endo-Surgery, Johnson & Johnson, Cincinnati, OH, USA) was used for cutting the pancreatic parenchyma. Cholecystectomy was carried out and a posterior cholangiography showed no leaking in the bile or in the pancreatic ducts. TachoSil® (Nycomed Pharma S.A.) sealant was applied, wrapping the head of the pancreas to prevent the formation of a pancreatic fistula (Figure 3B). An aspirative drain was established from the bed of the pancreatic resection site. The postoperative course was uneventful, and the patient was discharged on the sixth day.

The definitive diagnosis was a ganglioneuroma (Figures 4-6). The immunocytochemistry study showed positive staining with vimentin, S-100 protein, neurofilament and neuron-specific enolase (Figure 6).

DISCUSSION

Ganglioneuromas are very rare soft tissue tumors composed of gangliocytes and mature stroma^[1,3,7]. They usually

Figure 3 Appearance of surgical field with specimen resected. A: Uncinate process resected. Duodenum (D), neck of the pancreas (NP) and rest of the head of the pancreas (HP) are preserved. Superior mesenteric vein (SMV) is separated from uncinate process that is removed in the picture. Portal (PV) and splenic vein (SV) are also dissected. Inferior pancreaticoduodenal vessels (IPDv) are preserved; B: TachoSil® sealant is applied over the surface of the surgical bed for prevention of pancreatic fistula.

Figure 4 Macroscopic appearance of the surgical specimen. A: Nodular lesion with well-demarcated margins with normal residual pancreatic tissue adjoining; B: The tumor is well-circumscribed and firm. The inner surface is tan without evidence of necrosis or hemorrhage.

Figure 5 Microscopic images of the tumor (HE, × 10). A: The lesion is composed of a proliferation of spindle-shaped cells in a whorled or fascicular pattern [Schwann cells (SC) and nerve fibers]. The cells have elongated and wavy nuclei with eosinophilic cytoplasm; B: Scattered mature ganglion cells (GC) are another of the histopathologic components of the tumor.

consist of benign masses that produce symptoms caused by their growth and location. Ganglioneuromas are usually asymptomatic and are often discovered casually during the course of explorations when looking for other diseases. Although the most frequent presentations are in the mediastinum and in the retroperitoneum^[1-3], ganglioneuromas can also be found at any other location of the body such as in the neck or pelvis. In our review of the literature we have not been able to find any previous description of

a pancreatic localization. Diagnostic imaging is very difficult because ganglioneuromas present as a non-specific solid mass. MRI seems to be the most accurate diagnostic imaging method although not a definitive one^[7]. Unlike in other tumors, FNA is not always definitive, but its usefulness has been proven in some cases. A definitive diagnosis can only be reached after morphological examination of the removed specimen. Adequate treatment of ganglioneuromas is total surgical removal.

Figure 6 Representative immunocytochemistry samples of the typical ganglioneuroma ($\times 20$). A: S100 protein stain showing mostly Schwann cells and ganglion cells; B, C: Epithelial membrane antigen (EMA) and neurofilament (NF) stain showing the nerve fibers, highlighting the perineural cells and the axons of the nerve fibers; D: Ganglion cells are positive for neuronal-specific enolase (NSE).

Retroperitoneal ganglioneuromas usually present as sarcomatous soft tissue tumors. In the case we present here, the macroscopic appearance of the tumor was that of a pancreatic mass with limits that extended into the pancreas as confirmed by all the imaging studies performed. Although it can be hypothesized that these tumors usually originate from peripancreatic nerve fibers, they invade pancreatic tissue, as it is impossible to find a plane between the tumor and the pancreatic parenchyma. In fact, in this case the morphological macroscopic study showed that the mass was completely attached to the pancreas in a continuous manner (Figure 4A). The only way to obtain a definitive diagnosis and to provide total certainty of no malignancy was total excision of the tumor. A differential diagnosis, taking into account tumor characteristics and preoperative imaging results, was done to differentiate between mucinous cystadenoma, non-functioning NET and solid-cystic papillary tumor, all of which could have the potential to become malignant. NETs can also present as cystic lesions although this occurrence is rare^[8]. Somatostatin receptor scintigraphy with octreoscan has been recommended as the best imaging technique in NETs, being able to visualize more than 70% of these type of tumors^[9]. In our case, we decided not to perform this exploration because the decision for radical resection was proposed independently of this result. We preferred to carry out multiple tru-cut biopsies intraoperatively, prior to deciding what type of pancreatic resection to perform. Biopsy results were suggestive of a benign soft tissue tumor, although some malignant entities such as pseudoinflam-

matory tumor or primary malignant fibrous histiocytoma could not be completely ruled out before the tumor was removed in its entirety. Local resection without standard lymphadenectomy was performed.

Further knowledge gained over the last few years regarding the anatomy of the pancreas has helped to develop the concept of conservative surgery. Conservative surgery has gained popularity among surgeons and not only for lesions located in the left pancreas^[10]. Preserving the duodeno-pancreatic region is an issue for tumors that are also nested in the head of the pancreas. Resection of the uncinate process is an alternative to pancreato-duodenectomy (PD) for the treatment of non-malignant or pre-malignant lesions located in this area. Sharma *et al*^[6] described the technique used to perform an uncinectomy for the treatment of intraductal papillary mucinous neoplasms. Some other procedures such as resection of the head of the pancreas with preservation of the duodenum, median or central pancreatectomy, or enucleation, can be carried out depending on the type and precise location of the lesion. When these procedures have to be carried out, it is mandatory to obtain adequate preoperative or intraoperative confirmation of the benign nature of the samples. The postoperative course and long term sequelae are much better for conservative surgery than for PD.

As with enucleation, the main concern when performing an uncinectomy is the risk of leakage into the main pancreatic duct. To minimize the risk of this severe complication, direct intraoperative US exploration is highly recommended during resection. Nevertheless, in

many cases the pancreatic duct is narrow and is hard to identify. Intraoperative cholangiography and retrograde contrast back filling of the pancreatic duct can be an option for assessing the integrity of both the biliary and pancreatic ducts.

In conclusion, ganglioneuroma is a rare benign tumor that can also present as a pancreatic tumor. When a favorable location permits it, conservative resection of the pancreas is the treatment of choice. Uncinectomy is feasible, safe and a good surgical technique for the treatment of non-malignant tumors located in the uncinate process of the pancreas.

Novel *ABCB11* mutations in a Thai infant with progressive familial intrahepatic cholestasis. *World J Gastroenterol* 2009; 15(34): 4339-4342 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4339.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4339>

INTRODUCTION

Progressive familial intrahepatic cholestasis (PFIC) refers to a heterogeneous group of autosomal recessive liver disorders of childhood in which cholestasis of hepatocellular origin often presents in the neonatal period or first year of life, and leads to death from liver failure at ages ranging from infancy to adolescence^[1,2]. Three types of PFIC have been found; each is related to mutations in hepatocellular transport system genes involved in bile formation^[1-3]. PFIC type 1 (Byler disease) is caused by mutations in *ATP8B1* (chromosome 18q21-22), which encodes familial intrahepatic cholestasis 1 (FIC1). PFIC type 2 is caused by mutations in *ABCB11* (chromosome 2q24), which encodes bile salt export pump (BSEP). Mutations in *ABCB4* (chromosome 7q21), which encodes multidrug resistance protein 3 (MDR3), which is responsible for biliary secretion of phospholipids, cause PFIC type 3. In PFIC types 1 and 2, low or normal serum γ -glutamyltransferase (GGT) levels are found, whereas GGT levels are high in PFIC type 3^[1,2].

The diagnosis of PFIC can be difficult, especially where genetic testing is not readily available, as in Thailand. We report here a Thai infant diagnosed with PFIC type 2.

CASE REPORT

A 2-mo-old female infant presented with a 1-mo history of icteric sclerae associated with pale yellowish stools. She was a normal full-term infant (birth weight 2700 g). Hypothyroidism had been diagnosed at age 1 mo [free

Abstract

Progressive familial intrahepatic cholestasis (PFIC) type 2 is caused by mutations in *ABCB11*, which encodes bile salt export pump (BSEP). We report a Thai female infant who presented with progressive cholestatic jaundice since 1 mo of age, with normal serum γ -glutamyltransferase. Immunohistochemical staining of the liver did not demonstrate BSEP along the canaliculi, while multidrug resistance protein 3 was expressed adequately. Novel mutations in *ABCB11*, a four-nucleotide deletion in exon 3, c.90_93delGAAA, and a single-nucleotide insertion in exon 5, c.249_250insT, were identified, with confirmation in her parents. These mutations were predicted to lead to synthesis of truncated forms of BSEP. Immunostaining and mutation analysis thus established the diagnosis of PFIC type 2.

ALP: Alkaline phosphatase; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; Alb: Albumin; TB: Total bilirubin; DB: Direct bilirubin; Chol: Cholesterol; BW: Body weight; Ht: Height. Units and expected ranges for test-result values are given in parentheses. ¹Normal values for female children < 1 year, 185-555; 1-2 years, 185-520; 3 years, 185-425 U/L^[17]; ²Normal values for children 1-2 mo, 12-123; 2-4 mo, 8-90; 4 mo-10 years, 5-32 U/L^[18].

T4 0.94 ng/dL, thyroid stimulating hormone (TSH) 20.5 mIU/L], and thyroxine therapy begun. Growth and development were otherwise normal. No family history of liver disease was elicited. She had mildly icteric sclerae and hepatomegaly without splenomegaly or ascites. All other physical-examination findings were normal.

Conjugated-bilirubin and transaminase values were elevated but albumin, cholesterol, and GGT values were within expected ranges (Table 1). Prolonged coagulogram values were corrected by intravenous vitamin K administration. No IgM-class antibodies against cytomegalovirus were found, and VDRL testing was non-reactive. Plasma amino acid analysis found only mildly elevated methionine levels, interpreted as a nonspecific consequence of liver disease. Urine-reducing substances were absent. Other laboratory investigation results were normal, including free T4 and TSH, complete blood count, electrolytes, glucose, urea nitrogen, creatinine, ammonia and alpha-fetoprotein levels. Ultrasonography revealed a normal liver and bile duct. DISIDA scanning showed good hepatic function with demonstrable intraduodenal tracer at 3 h. Microscopy of a liver-biopsy specimen found changes interpreted as neonatal hepatitis. Ursodeoxycholic acid (UDCA) and fat-soluble vitamins were given.

Cholestasis persisted (Table 1), with development of severe pruritus and hepatosplenomegaly. On repeat liver biopsy aged 10 mo, hepatocellular swelling with multinucleation was found, as was canalicular and hepatocellular cholestasis (Figure 1A). Mild portal lymphocytic infiltration and fibrosis were also observed (Figure 1B). BSEP was not detected along the canaliculi on immunostaining (Figure 1C and D), while the homologous transport protein MDR3 was expressed adequately, which demonstrated that tissue fixation was adequate and permitted the inference that lack of BSEP expression was BSEP-specific. As these results were compatible with PFIC type 2, *ABCB11*, which encodes BSEP, was sequenced after parental consent was obtained.

Treatment with UDCA and fat-soluble vitamins was continued. At the time of writing, the patient is 30 mo old, with persistent jaundice and growth delay [Table 1; body weight 11.5 kg (P25) and height 80 cm (< P3)]. Serum alpha-fetoprotein concentrations are normal and sonographic monitoring has found no focal changes. She awaits liver transplantation.

Mutation analysis

ABCB11 was analyzed by direct sequencing of PCR products obtained from genomic DNA extracted from peripheral blood leukocytes. All exons, together with the adjacent parts of the intronic sequences, were amplified by PCR with intronic oligonucleotide primers as reported previously^[4]. The amplicons were gel-purified, extracted with QIAquick spin columns (Qiagen, Hilden, Germany), and used as templates for the sequencing reaction with Big Dye Terminator kit v3.1 (Applied Biosystems, Foster City, CA) according to the manufacturer's protocol. The products were analyzed on a Genetic Analyzer 3130 (Applied Biosystems).

Two suspected sequence disturbances were predicted from the dual sequence readings at 20 bp from the potential mutation start site in both directions. The presence of both mutations was verified by molecular cloning into a plasmid vector pCR4.1-TOPO (Invitrogen, Carlsbad, CA), and sequencing the cloned wild-type and the mutated allele separately. In addition, the presence of suspected mutations was also examined by direct sequencing of appropriate amplicons obtained from the proband's parents. Two different heterozygous *ABCB11* mutations were found in the patient: a four-nucleotide deletion in exon 3 (protein coding exon 2), c.90_93delGAAA, inherited from the patient's mother, and a single-nucleotide insertion in exon 5 (protein coding exon 4), c.249_250insT, inherited from the patient's father (Figure 2). Both mutations are predicted to cause reading frame shift and premature termination of DNA translation, respectively p.Lys30AsnfsX31 and p.Gly84TrpfsX9, and therefore are considered to be pathogenic.

DISCUSSION

To the best of our knowledge, this is the first case report of PFIC type 2 in Thailand. The patient had a typical clinical presentation of PFIC type 2 with cholestasis of onset in early infancy, with development of hepatomegaly and severe pruritus^[1,2]. In PFIC type 2 serum bile acid concentrations are high, biliary bile-salt concentrations are very low, and GGT and cholesterol values are normal^[2,5]. While serum bile-acid and biliary bile-salt concentrations could not be determined, as such studies are unavailable in Thailand, her severe pruritus

Figure 1 Liver, second biopsy (10 mo). Hepatocellular swelling and multinucleation, with intralobular cholestasis (A), accompanying mild portal-tract lymphocytic infiltration and fibrosis (B). On immunostaining, bile salt export pump (BSEP) expression was not detected (C); canaliculi in control liver stained normally for BSEP (D). [Hematoxylin/eosin, A and B; rabbit anti-BSEP polyclonal antibody (generous gift of Dr B Stieger)/hematoxylin, C and D; original magnification, all images, × 200].

Figure 2 Mutations c.90_93delGAAA and c.249_250insT detected in exon 3 and 5 of *ABCB11*. FW: Forward reading (coding strand sequence); RC: Reversed and complemented reading (reversed and complemented sequence of the complementary strand).

indicated hypercholanemia. This feature and our patient’s GGT and cholesterol values were compatible with PFIC type 2. Although hypothyroidism in this patient might have caused cholestasis by delayed emptying of the biliary tract, and by changes in bile composition and

excretion rate^[6], normalization of free T4 and TSH levels after thyroxine therapy argued against this possibility. Since hypoglycemia was not present and initial growth was unremarkable, hypopituitarism was not pursued.

While PFIC type 1 has initial clinical and laboratory findings similar to those of PFIC type 2, histological features may differ. In PFIC type 1, bland canalicular cholestasis with variable fibrosis is found. In PFIC type 2, variable features include canalicular cholestasis and a neonatal hepatitis pattern, with hepatocellular swelling and giant cell transformation^[1,2]. Lobular and portal inflammation and fibrosis are more pronounced in PFIC type 2 than type 1^[2]. Immunostaining is a useful diagnostic tool for PFIC type 2 since most patients with *ABCB11* mutations and hepatobiliary disease of onset in infancy have no canalicular BSEP expression^[7]. At initial liver biopsy (2 mo) changes of neonatal hepatitis were found. At follow-up biopsy, these changes persisted, and BSEP was not detected along the canaliculi. The clinicopathological picture, felt to be compatible with PFIC type 2, thus prompted *ABCB11* analysis.

BSEP is an ATP-dependent transporter located on the canalicular membrane of hepatocytes^[8,9]. It is a major exporter of primary bile salts from hepatocyte cytoplasm into the bile-canalculus lumen, and works against an extreme concentration gradient^[2,9]. Mutations in *ABCB11* that lead to failure of BSEP expression, or to expression of functionally defective BSEP, in turn lead to accumulation of bile salts inside hepatocytes, with ongoing severe hepatocellular damage and diminished bile flow.

To date, more than 100 mutations in *ABCB11* have been identified^[7,10-14]; however, genotype-phenotype correlations are not wholly clear. Severe phenotypes are often associated with mutations that lead to premature protein truncation or failure of protein production. Insertion, deletion, nonsense, and splicing mutations result in damaging effects, and patients who have clinical PFIC associated with such mutations exhibit little or no BSEP expression in hepatocyte canaliculi^[2,7]. Missense mutations are also common. These can affect protein processing and trafficking or disrupt functional domains and protein structure^[2,7,15]. Detectable BSEP expression does not exclude functional BSEP deficiency^[2,7].

E297G and D482G are the two most common mutations in persons of European descent, and account for approximately 58% of BSEP mutations in European studies^[7]. In Asian patients, few reports of mutations in PFIC type 2 exist^[12-14]. Goto *et al*^[14] have reported four mutations in *ABCB11*, predicted to yield V330X, R487H, R575X and E636G, in two Japanese PFIC patients. Chen *et al*^[13] have reported seven BSEP mutations (M183V, V284L, R303K, R487H, W493X, G1004D and 1145delC) in four PFIC patients of Chinese descent; none of these mutations has been described in Caucasian patients. To the best of our knowledge, the mutations identified in our patient are novel. These mutations are predicted to lead to synthesis of truncated forms of BSEP.

Patients with PFIC type 2 are at risk for hepatobiliary malignancy^[7,16]. Hepatocellular carcinoma or cholangiocarcinoma developed in 19 of 128 patients (15%)^[7] and those who had two protein-truncating mutations were at particular risk^[7]. Close surveillance of BSEP-deficient patients who retain their native liver is therefore essential.

In conclusion, we report a Thai infant with clinical features of normal-GGT PFIC. Her liver did not express immunohistochemically demonstrable BSEP. Novel mutations in *ABCB11* were identified in the infant, with confirmation in her parents. These mutations were predicted to lead to synthesis of truncated forms of BSEP. Immunostaining and mutation analysis thus established the diagnosis of PFIC type 2.

Abstract

Squamous cell carcinoma of the pancreas has been sparsely described since the 1940s, and generally has a poor prognosis. Herein, we present a case of primary squamous cell carcinoma of the pancreas with liver metastasis, both confirmed by endoscopic ultrasound-guided fine needle aspiration (EUS-FNA). To the best of our knowledge, this is the first case report in literature utilizing EUS-FNA for a cell-type specific diagnosis of primary pancreatic squamous cell carcinoma with a liver metastasis.

INTRODUCTION

Primary squamous cell carcinoma is rare among all pancreatic neoplasms, constituting less than 1% of cases. Herein, we present a case of primary squamous cell carcinoma of the pancreas with liver metastasis, both confirmed by endoscopic ultrasound-guided fine needle aspiration (EUS-FNA).

CASE REPORT

A 76-year-old American African female was referred with a few weeks history of dull epigastric pain with radiation to the back, and weight loss of 10 pounds. Initial physical examination revealed only minimal tenderness over the epigastrium, and blood tests were all normal including serum lipase (29 IU/L, reference: 10-50 IU/L) and CA 19-9 (2 IU/mL, reference: 0-37 IU/mL). Upper endoscopy showed mild gastritis. Subsequent computed tomography (CT) of the thorax and abdomen revealed a 5 cm partial cystic mass in the tail of the pancreas and a 1 cm subtle hypodense non-enhanced lesion in the left lobe of the liver, with normal chest and mediastinum. CT-guided biopsy of the liver mass was performed, however, preliminary histology only revealed atypical cells. Endoscopic ultrasound (EUS) was performed for clarification of the pathology. A complex cystic mass with a large solid component was seen in the tail of the pancreas measuring up to 68 mm. Another 14 mm × 18 mm ill-defined, almost isoechoic lesion was also noted in the left lobe of the liver (Figure 1). Transgastric EUS-FNA, using a 25-gauge needle, of both the liver and tail of pancreas lesions was carried out, which revealed squamous cell carcinoma in both sites, although on-site interpretation was difficult due to the unusual cell type (Figure 2).

DISCUSSION

Squamous cell carcinoma of the pancreas has been

Figure 1 Endoscopic ultrasound image of the heterogenous, nearly isoechoic lesion in the left lobe of the liver (A) and the complex cystic mass in the tail of pancreas (B).

rarely described since the 1940s, and generally has a poor prognosis^[1]. It is hypothesized that squamous metaplasia of pancreatic ductal epithelium after chronic inflammation (e.g. chronic pancreatitis), could be one of the possible oncogenic mechanisms^[2]. A subset of pancreatic adenocarcinoma, adenosquamous carcinoma is occasionally found in surgical specimens after Whipple's operation. In one series, dual differentiation towards both adenocarcinoma and squamous cell carcinoma was seen in 25 pancreatic cancer patients^[3]. However, pure squamous cell carcinoma of the pancreas is extremely rare, and is often mistaken as either benign squamous cells from upper gastrointestinal contamination when it is well-differentiated, or metastasis from other sites (e.g. lung and upper aerodigestive tract) when it is obviously malignant. A MEDLINE search only identified 14 case reports in the English literature so far^[4-17], and all diagnoses were based on surgical specimens. Hypervascularity on contrast CT has been reported as a characteristic finding, but was not seen in this case^[15].

Since the introduction of EUS-FNA for investigating pancreatic cancer in the 1990s^[18], it has now become the standard procedure for pancreatic lesions. Cytopathological confirmation can be obtained with EUS-FNA, so as to avoid unnecessary pancreatic resection^[19]. From our knowledge, this is the first case report in the literature utilizing EUS-FNA for a cell-type specific diagnosis of primary pancreatic squamous cell carcinoma with a liver metastasis. The distinction of well-differentiated squamous cell carcinoma from benign disease such as lymphoepithelial cysts (LEC) of the

Figure 2 Fine-needle aspiration specimen. A: Liver mass (HE, × 100); B: Pancreatic mass (HE, × 100). The cell block shows atypical squamous cells consistent with keratinizing squamous cell carcinoma. C: Liver mass (ThinPrep, × 400). Squamous cell contamination from the esophagus as evidenced by the presence of bacteria and fungal organisms.

pancreas may be difficult. LEC is an infrequent benign condition and EUS-FNA typically shows squamous cells, lymphocytes, notched crystals and keratin debris^[20-22]. Because cystic degeneration can occur in pancreatic cancers, as in our case^[23], differentiation between benign and malignant squamous cell lesions could be difficult. If there is a solid component, it should be targeted during EUS-FNA rather than the cyst. In general, dense orangeophilic keratin debris, atypical parakeratosis, and nuclear atypia including hyperchromasia and nuclear membrane irregularities help us to differentiate cancer from reactive squamous metaplastic cells^[24]. A glandular component should also be sought when noting atypical squamous carcinoma cells, as adenosquamous carcinoma is more common than the pure squamous cell type^[3]. Squamous cell contaminants could also contribute to diagnostic uncertainty; although transgastric and

transduodenal routes for EUS-FNA should not produce many of these cells, however, they appear to have been noted in our case (Figure 2C)^[25]. In this patient, diagnosis of primary squamous cell carcinoma of the pancreas with liver metastasis was confirmed, as EUS-FNA obtained the same type of cancer cells from both pancreatic and liver lesions, and CT and upper endoscopy did not identify other possible primary squamous cell malignancy.

Abstract

In light of the growing epidemics of nonalcoholic fatty liver disease (NAFLD), identification and validation of the novel biochemical surrogate markers for nonalcoholic steatohepatitis (NASH) are paramount to reduce the necessity for liver biopsy. The availability of such markers has tremendous potential to radically alter the management strategies of NAFLD patients and to monitor the disease activity. Although current biomarkers do not entirely fulfill the many requirements for the identification of patients with NASH, they should not discourage our quest, but remind us that we need to cognize the challenges ahead.

Yilmaz Y, Dolar E. Biomarkers for noninvasive biochemical diagnosis of nonalcoholic steatohepatitis: Tools or decorations? *World J Gastroenterol* 2009; 15(34): 4346-4347 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4346.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4346>

TO THE EDITOR

In light of the dramatic increase in the prevalence of nonalcoholic fatty liver disease (NAFLD), noninvasive, simple, reproducible, and reliable biomarkers that can allow identifying patients with nonalcoholic steatohepatitis (NASH) among NAFLD patients are greatly needed^[1]. The availability of such biomarkers has tremendous potential to radically alter the diagnostic and monitoring strategies through the reduction in the need for liver biopsy^[2].

To be introduced in the clinical practice, the ideal biomarker for NASH must fulfill many requirements, such as ease of interpretation by clinicians, accurateness, reproducibility obtained in a standardized fashion, as well as high sensitivity and specificity. This latter point is both important and dependent on the design of study.

The recent report by Uslusoy *et al*^[3] published in the *World Journal of Gastroenterology* has provided evidence that certain noninvasive markers for liver injury, including aminotransferase levels and AST/ALT ratio, do not entirely reflect the histological aspects of liver biopsy in patients with NASH. Based on their results, the authors concluded that aminotransferase levels and AST/ALT ratio do not seem to be reliable predictors for NASH. Although numerous non-invasive biomarkers are available, all patients with fatty liver should undergo liver biopsy^[3]. It is feasible, however, that this radical conclusion may be too far to reach given the important caveats of this study. Firstly, the authors limited their analysis to aminotransferase levels. It has been previously shown, in this regard, that serum levels of caspase-cleaved cytokeratin 18 may be a potential biochemical marker for NASH in NAFLD patients with normal aminotransferase levels^[4]. Secondly, the statistical analysis of data, demonstrating the lack of an association of aminotransferase levels and AST/ALT ratio with NASH, is likely to be underpowered as the study enrolled too few participants to identify such differences. Underpowered studies are overly prone to making false-negative conclusions, or committing what epidemiologists call type II errors^[5]. Finally, appropriate use of biomarker results requires use of a Bayesian approach^[6], i.e. integrating pretest probabilities with biomarker test results (expressed as sensitivity and specificity) to estimate the posttest probability of disease.

Prerequisites for the clinical use of biomarkers for NASH include the elucidation of specific indications, the standardization of analytical methods, the characterization of analytical features, the assessment of performance characteristics, the incremental yield of different markers for given clinical indications, and the demonstration of cost-effectiveness. Although the development of NASH biomarkers fulfilling these features is challenging, it should not discourage our quest, but remind us that we need to cognize the challenges ahead. Technological advances will likely facilitate the use of multimarker profiling^[7] to identify patients with NASH in the near future.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (World J Gastroenterol ISSN 1007-9327, DOI: 10.3748) is a weekly, peer-reviewed, online, open-access (OA) journal supported by an editorial board of 1126 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in *WJG* will include the following. (1) Editorial: to introduce and comment on major advances in rapidly developing areas and their importance. (2) Frontier: to review recent developments and comment on current research status in important fields, and propose directions for future research. (3) Topic Highlight: this column consists of three formats, including: (a) 10 invited review articles on a hot topic; (b) a commentary on common issues associated with this hot topic; and (c) a commentary on the 10 individual articles. (4) Observation: to update the development of old and new questions, highlight unsolved problems, and provide strategies for their resolution. (5) Guidelines for Basic Research: as suggested by the title. (6) Guidelines for Clinical Practice: to provide guidelines for clinical diagnosis and treatment. (7) Review: to review systemically the most representative progress and unsolved problems, comment on current research status, and make suggestions for future work. (8) Original Article: to report original and innovative findings. (9) Brief Articles: to report briefly on novel and innovative findings. (10) Case Report: To report a rare or typical case. (11) Letters to the Editor: to discuss and reply to contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest. (12) Book Reviews: to introduce and comment on quality monographs. (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities on basic research and clinical practice

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgments,

References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press and Baishideng, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine, and we encourage all potential contributors to register with it. However, in the event that other registers become available, you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the corresponding author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://wjg.wjgnet.com/wjg>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to submission@wjgnet.com, or by telephone: +86-10-85381892. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be

provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039, Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/...; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS AND DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^aP < 0.05$, $^bP < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^cP < 0.05$ and $^dP < 0.01$ are used. A third series of *P* values can be expressed as $^eP < 0.05$ and $^fP < 0.01$. Other notes in tables or under illustrations should be expressed as 1F , 2F , 3F ; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at <http://www.wjgnet.com/wjg/help/14.doc>.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. The author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, and responses to the reviewers by courier (such as EMS/DHL).

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No.62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

Telephone: +86-10-59080039

Fax: +86-10-85381893

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Language evaluation

The language of a manuscript will be graded before it is sent for revision.

- (1) Grade A: priority publishing;
- (2) Grade B: minor language polishing;
- (3) Grade C: a great deal of language polishing needed;
- (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/wjg/help/10.doc>.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/wjg/help/9.doc>.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put online. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

INTRODUCTION

World Journal of Gastroenterology is an international, open-access, peer-reviewed, and multi-disciplinary weekly journal that serves gastroenterologists and hepatologists. The biggest advantage of the open access model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the values of the readers, the authors and the society.

Maximization of the value of the readers can be comprehended in two ways. First, the journal publishes articles that can be directly read or downloaded free of charge at any time, which attracts more readers. Second, the readers can apply the knowledge in clinical practice without delay after reading and understanding the information in their fields. In addition, the readers are encouraged to propose new ideas based on those of the authors, or to provide viewpoints that are different from those of the authors. Such discussions or debates among different schools of thought will definitely boost advancements and developments in the fields. Maximization of the value of the authors refers to the fact that these journals provide a platform that promotes the speed of propagation and communication to a maximum extent. This is also what the authors really need. Maximization of the value of the society refers to the maximal extent of the social influences and impacts produced by the high quality original articles published in the journal. This is also the main purpose of many journals around the world.

Abstract

5-aminosalicylic acid (5-ASA) compounds are a highly effective treatment for ulcerative colitis (UC). While UC patient compliance in clinical studies is over 90%, only 40% of patients in every day life take their prescribed therapy. Adherence to medication has been emphasized recently by a Cochrane meta-analysis that has suggested that future trials of 5-ASA in UC should look at patient compliance rather than drug efficacy. Better compliance can be obtained by reducing the number of tablets and times of administration. Given that the 5-ASA formulations have different delivery systems that split the active moiety in various regions of the intestine, it is particularly important that an adequate dose of the drug arrives at the inflamed part of the colon. 5-ASA Multi matrix (MMx) is a novel, high strength (1.2 g), oral formulation designed for once-daily dosing. It releases the active moiety throughout the colon. Different studies with this compound have shown that it is as effective as 5-ASA enema in the treatment of mild-to-moderate, left-sided UC, and is comparable to a pH-dependent, delayed release 5-ASA (Asacol®), even if given once daily. Recently, the effectiveness in the acute phase of UC has been confirmed also in maintenance. In conclusion, at present, 5-ASA MMx seems theoretically the best agent for maintaining patient compliance, and consequently, treatment effectiveness.

Prantera C, Rizzi M. 5-ASA in ulcerative colitis: Improving treatment compliance. *World J Gastroenterol* 2009; 15(35): 4353-4355 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4353.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4353>

INTRODUCTION

Ulcerative colitis (UC) is a chronic inflammatory bowel disease that involves the rectum and can extend to the colon in a caudal-cranial direction. The worldwide incidence is 0.5-24 new cases per 100 000 individuals, and prevalence is 100-200 cases per 100 000. From 60% to 80% of patients have distal and left-sided colitis^[1].

After the first introduction of sulfasalazine (Salazopyrin), composed of sulphapyridine (SP) and 5-ASA, for treating UC, the discovery that the active moiety is 5-ASA has prompted the industry to develop 5-ASA compounds with different delivery systems, because the SP molecule has been associated with important adverse effects^[2].

The delivery systems that have been designed for conveying 5-ASA to the colon include various pH-dependent polymers, microgranules encapsulated into ethyl cellulose, or azo-bound derivatives. None of these is as effective as the topical formulations for inducing remission in distal forms of UC^[3].

However, patients do not easily accept local therapy. The low compliance with topical administration is a determinant factor of late relapse^[4].

NEW SYSTEM FOR DELIVERING 5-ASA

5-ASA Multi matrix (MMx) 1.2-g tablets is a novel formulation of mesalamine that is characterized by a patented polymeric lipophilic and hydrophilic matrix enclosed within a gastro-resistant, pH-dependent coating^[5,6]. This coating permits the delay of 5-ASA release until the tablet is exposed to a pH of 7 (normally in the terminal ileum), while the interaction of lipophilic and hydrophilic excipients with intestinal fluids makes the release of 5-ASA slow and gradual throughout the entire colon^[7]. This system allows the delivery of a larger amount of 5-ASA to the colonic lumen than is possible with other mesalamine formulations. Moreover, another

advantage may be a longer residence of 5-ASA in the colon, as shown by a scintigraphic study that demonstrated that MMx was still detectable in the sigmoid colon 24 h after ingestion^[8].

Do these characteristics really confer a benefit over the other 5-ASA compounds? The first step was to discover whether MMx was comparable to 5-ASA enema, which is considered the gold standard therapy for treating left-sided UC.

5-ASA MMx IN ACTIVE UC

In an Italian study, 79 patients were randomized to receive oral MMx 3.6 g/d with a bedtime placebo enema, or oral placebo tablets with a bedtime enema of mesalamine 4 g/100 mL. At 8 wk, clinical remission rate was 60% in the MMx arm *vs* 50% in the enema arm; endoscopic and histological remission rates were 45% and 15% *vs* 37% and 8%, respectively. Compliance rate for the MMx group was 97% overall compared with 87.5% in the mesalamine enema group. The remission rate in the enema group declined after 4 wk because the patients in remission spontaneously reduced administration^[5].

A further explorative study was a phase II, multicenter, randomized, double-blind, dose-ranging small trial in patients with mild-to-moderate UC^[7]. Thirty-eight patients were randomized to once-daily dosing of MMx mesalamine at a dose of 1.2, 2.4 or 4.8 g, for 8 wk. Six patients achieved complete remission at 8 wk: 4 (30.8%) in the 2.4 g/d group, 2 (18.2%) in the 4.8 g/d group, and none in the 1.2 g/d group. The difference in remission rates between the groups was not statistically significant given the small sample size. In general, MMx was well-tolerated among the three groups. Within the limitation of the small sample size, the data suggest that MMx mesalamine at 2.4 g/d or 4.8 g/d is an effective once-daily treatment for mild-to-moderate UC.

The following two large phase III studies showed that MMx given once or twice daily at 2.4-4.8 g was effective for induction of remission, and endoscopic and symptomatic improvement in patients with mild-to-moderate UC at 8 wk^[9,10].

The first was a randomized, double-blind, placebo-controlled multicenter trial of 280 patients with mild-to-moderate UC^[9]. Patients received MMx 2.4 g/d (twice daily) or 4.8 g/d (once daily), or placebo for 8 wk. Clinical and endoscopic remission rates at week 8 were higher in the MMx 2.4 g twice daily (34.1%) and 4.8 g once daily (29.2%) than in the placebo (12.9%) group ($P < 0.001$). Clinical improvement rates were 55.7% and 59.6% *vs* 25.9%, respectively ($P < 0.001$). Endoscopic improvement rates were 61.4% and 69.7% *vs* 35.5%, respectively ($P < 0.01$).

In the second randomized, double-blind, double-dummy, placebo-controlled multicenter trial, 343 patients with mild-to-moderate UC received MMx 2.4 g once daily, MMx 4.8 g once daily, pH release mesalamine (Asacol[®]) 2.4 g (800 mg three times daily), or placebo for 8 wk^[10]. Clinical and endoscopic remissions at 8 wk were

higher in patients receiving MMx 2.4 g/d (40.5%, $P = 0.01$) or MMx 4.8 g/d (41.2%, $P = 0.007$) than placebo, while the differences between MMx and Asacol[®] (32.6%) and between Asacol[®] and placebo (22.1%) were not statistically significant.

STUDIES WITH 5-ASA MMx IN MAINTENANCE OF UC REMISSION

The 459 patients, who achieved remission in the previous two studies, were enrolled in a randomized, multicenter, open label trial^[11]. The aim was to evaluate the safety and efficacy of 2.4 g/d MMx once or twice daily as 12 mo maintenance therapy in patients with UC. One hundred and seventy-four of 459 patients (37.9%) experienced 384 adverse events, the majority of which were mild or moderate in intensity. Most serious adverse events were of a gastrointestinal nature. At month 12, 88.9% of patients in the once-daily treatment group and 93.2% in the twice-daily group maintained clinical remission.

The first placebo-controlled trial that reported the efficacy of MMx in maintenance therapy was a multicenter study^[12]. Three hundred and thirty-one European patients with UC were randomized to receive MMx 2.4 g/d once daily, or Asacol[®] 2.4 g/d twice daily, administered in a double-dummy fashion for 12 mo. All patients were in remission with at least one documented relapse in the previous year. The data from this study indicate that MMx 2.4 g/d once daily and Asacol[®] 2.4 g/d twice daily are similarly tolerated and effective in the maintenance of remission of left-sided UC. Overall, 68.0% of patients in the MMx group and 65.9% in the Asacol[®] group, were in clinical remission at 12 mo. Clinical and endoscopic remission was maintained in 60.9% and 61.7% in the MMx and Asacol[®] groups, respectively, at 12 mo. The proportion of patients in remission was not distributed equally: Polish and Ukrainian showed a higher proportion of patients in remission than did Italian centers (country effect, $P < 0.001$). This variation may reflect differences in practice between the national health services in each study country. Poland and Ukraine reported quite high remission rates in all study populations, with 77.8%-96.7% of patients maintaining remission at 12 mo.

In contrast, patients from the Italian centers showed consistently lower remission rates 56.2% (MMx group) and 54.6% (Asacol[®] group) at 12 mo, which is consistent with the currently available literature. A possible explanation for this discrepancy is that 66.5% of the Italian population were taking at baseline an adequate maintenance dose of 5-ASA (≥ 1.6 g/d). In contrast, only 49.0% and 36.1% of patients in Poland and Ukraine were using comparable maintenance therapy. It is therefore possible that investigators in Poland and Ukraine included patients with milder UC, who were in remission without adequate therapy.

Examining only the Italian population, including

the diary card data, a significant difference was detected between the MMx and Asacol[®] groups, in the intention-to-treat ($P = 0.026$) and per-protocol ($P = 0.010$) population. This study, however, was not able to test if the compliance with once-daily administration of MMx improved the efficacy, given that it was designed to distribute medication in a double-dummy fashion. In this study, 5-ASA therapy was well tolerated. Indeed, the adverse-effect profile reported in was similar to those reported in other long-term studies of 5-ASA. The majority of AEs were mild or moderate in severity^[12].

5-ASA compounds are very effective drugs for treating UC, and they are of particular value in maintenance therapy. However, long-term reduced compliance interferes with their effectiveness. A recent study has reported that local therapy, taking too many tablets, or inconvenient dosing regimens are the reasons for non-compliance, especially in maintenance therapy^[4,13,14]. In fact, patients with UC in remission who are not compliant with 5-ASA therapy have a fivefold greater risk of relapse than compliant patients^[4].

Patient adherence to medication has been emphasized recently in a Cochrane meta-analysis that suggests that future trials of ASA in UC should explore patient compliance rather than drug efficacy^[15]. This is the main reason why the doctor should tailor therapy for the individual patient by reducing the number of tablets at the effective dose to as few as possible, and by stressing to him/her the importance of following the drug's instructions. On the other side, the industry should improve patient compliance by reducing the number of tablets to be taken, and the frequency of daily dosage. 5-ASA MMx has been designed to reach these goals to make use of some properties of the drug: i.e., its long-term residence in the colon, the higher 5-ASA content in each tablet, and a delivery system that splits the active moiety along the entire colon.

CONCLUSION

5-ASA MMx has been shown to be at least as effective as the most employed 5-ASA compound Asacol[®], for inducing and maintaining remission of UC. 5-ASA MMx has three useful characteristics that should add to this formulation some advantage over the other 5-ASA compounds: (1) the 1.2-g content of each tablet decreases the number of tablets to be taken; (2) the long residence in the colon allows once-daily dosing; and (3) delivery of 5-ASA to the entire inflamed colon should produce efficacy comparable to that of a combination of tablets and enema.

Abstract

It is now widely recognized that chronic hepatitis C (CHC) is associated with insulin resistance (IR) and type 2 diabetes, so can be considered a metabolic disease. IR is most strongly associated with hepatitis C virus (HCV) genotype 1, in contrast to hepatic steatosis, which is associated with genotype 3 infection. Apart from the well-described complications of diabetes, IR in CHC predicts faster progression to fibrosis and cirrhosis that may culminate in liver failure and hepatocellular carcinoma. More recently, it has been recognized that IR in CHC predicts a poor response to antiviral therapy. The molecular mechanisms for the association between IR and HCV infection are not well defined. This review will elaborate on the clinical associations between CHC and IR and summarize current knowledge regarding the molecular mechanisms that potentially mediate HCV-associated IR.

INTRODUCTION

Infection with the hepatitis C virus (HCV) is a leading cause of chronic liver disease, with over 3% of the world's population (180 million people) infected and 130 million at risk of cirrhosis^[1]. The majority of infected individuals (60%-80%) develop chronic hepatitis C (CHC), which is associated with progressive liver fibrosis and a 3%-9% risk of cirrhosis after 20 years as shown in community-based studies^[2]. CHC is also associated with significant morbidity and mortality, accounting for 50%-76% of all liver cancer cases worldwide, and two thirds of liver transplants in the developed world^[1].

It is now widely recognized that CHC is associated with insulin resistance (IR) and type 2 diabetes (T2DM), so can be considered a metabolic disease. Apart from the well-described complications of diabetes, IR in CHC predicts faster progression to fibrosis and cirrhosis that may culminate in liver failure and hepatocellular carcinoma (HCC). More recently, it has been recognized that IR in CHC predicts a poor response to antiviral therapy. The molecular mechanisms for the association between IR and HCV infection are not well defined. This review will elaborate on the clinical associations between CHC and IR and summarize current knowledge regarding the molecular mechanisms that potentially mediate HCV-associated IR.

INSULIN SIGNALING AND IR

Insulin is an anabolic hormone secreted by pancreatic β -cells that is required for the maintenance of glucose homeostasis. It inhibits hepatic glucose production and increases peripheral glucose uptake and glycogen synthesis. The principal signaling pathway (Figure 1) involves sequential activation of the insulin receptor, insulin receptor substrates (IRS), phosphatidylinositol-3-kinase (PI3K), Akt and protein kinase C isoforms ζ and λ ^[3,4]. Akt is phosphorylated initially at serine 473 by phosphoinositide-dependent kinase (PDK)2 and

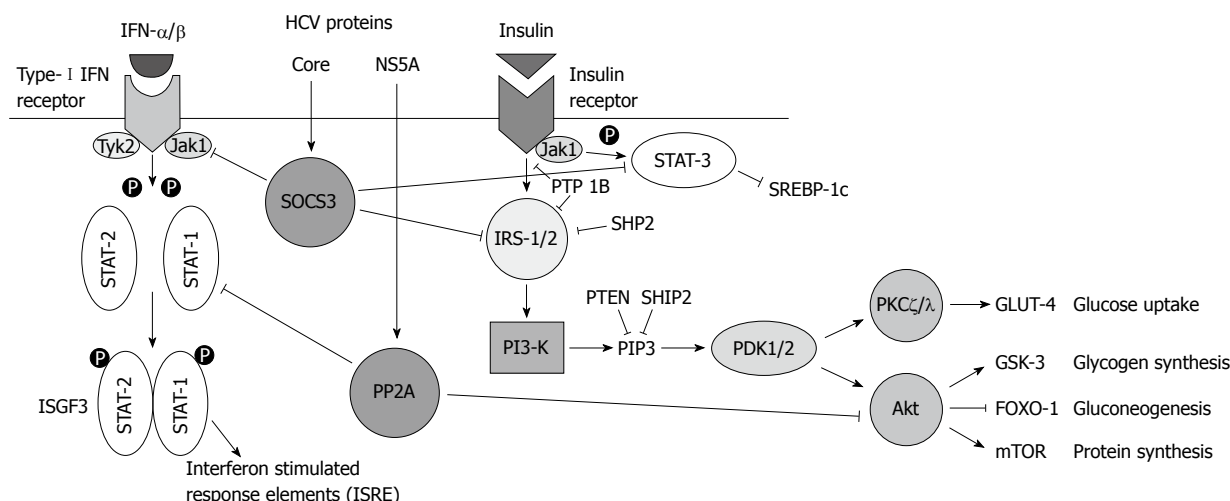

Figure 1 Hepatitis C virus core and NS5A proteins may inhibit insulin and interferon signaling.

subsequently at threonine 308 by PDK1. Activated Akt promotes storage of excess glucose as glycogen by phosphorylating glycogen synthase kinase and suppresses gluconeogenesis by inhibiting phosphoenol-pyruvate carboxykinase and glucose-6 phosphatase. In striated muscle and adipose tissue, activated Akt promotes translocation of the glucose transporter GLUT4 to the plasma membrane, promoting glucose uptake^[5].

Insulin promotes lipid synthesis *via* sterol regulatory element-binding protein 1c and fatty acid synthase, although importantly the pathways are probably different from those mediating insulin-stimulated glucose homeostasis^[5]. With regard to protein, insulin promotes cell survival and protein synthesis, mediated by the mammalian target of rapamycin (mTOR) pathway^[3].

Insulin resistance plays a fundamental role in the pathogenesis of T2DM. It results from defects at any level of the ligand-receptor-response pathway, including well-characterized defects at the level of the insulin receptor or IRS molecules, although these account for only a small minority of cases of IR in clinical practice^[3,4]. These defects can result from either reduced levels of signaling proteins, or modulation of their activity by phosphorylation. For example, IRS-1 is activated by phosphorylation of tyrosine residues, but inhibited by phosphorylation of key serine residues including Ser307, Ser318, Ser636 and Ser639^[6]. Negative feedback loops down-regulate the pathway in response to chronic glucose supply, including inhibition of PI3K by phosphatase and tensin homolog.

Two IRS proteins are important in human liver: IRS-1 and IRS-2^[7]. They appear to have complementary but overlapping roles in that IRS-1 knockout mice exhibit growth retardation and IR, while IRS-2 knockouts develop T2DM due to β -cell failure and hepatic IR. While both knockouts are insulin-resistant, IRS-1 knockout mice have reduced peripheral glucose uptake, while IRS-2 knockouts have a more complex phenotype, with both peripheral and central IR^[8]. This has led to the traditional view that IRS-2 is more important for insulin signaling and glucose homeostasis

in the liver^[9]. However, recent evidence suggests that IRS-1 may be more important for glucose homeostasis, while IRS-2 is more important for lipid metabolism^[10]. Therefore, changes affecting either IRS could contribute to HCV-induced hepatic IR.

The roles of mTOR in insulin signaling are multiple and complex. Early studies showed that insulin signaling *via* Akt caused phosphorylation and activation of mTOR^[11]. However it is now known that mTOR is present in at least two different mTOR complexes and plays multiple roles in insulin signaling, as reviewed recently^[12,13]. The mTOR-raptor complex 1 (mTORC1) appears to mediate the downstream effects of insulin on cell growth and proliferation^[12] and also provides negative feedback of insulin signaling by phosphorylating IRS-1 at inhibitory serine residues 636 and 639^[14]. In contrast, mTOR associates with rictor to form a second complex mTORC2^[12], the elusive “PDK2” that phosphorylates Akt at serine 473 in response to insulin^[15]. mTORC2 is much less sensitive to rapamycin inhibition than mTORC1^[12].

CLINICAL ASSOCIATIONS OF HCV AND IR

CHC and T2DM

It is now over 10 years since an association between HCV and diabetes was first described by Allison *et al*^[16] who noted that people with cirrhosis and HCV had T2DM more commonly than those with cirrhosis from other causes. A subsequent study of cirrhotic patients confirmed that T2DM was present in 21% of patients with cirrhosis due to CHC but was present in only 12% of patients with cirrhosis and chronic hepatitis B (CHB)^[17]. In the latter report, T2DM was particularly associated with HCV genotype 2a^[17].

Significantly, subsequent case control studies have confirmed that T2DM is associated with CHC even in the absence of cirrhosis^[18-20]. Most recently, a large cross-sectional study of over 9000 individuals in the USA found that in persons over 40 years of age, those with HCV infection were over three times more likely to

have T2DM than those without^[21]. Of relevance, there was no association between CHC and type 1 diabetes, and no association of hepatitis B virus infection with T2DM, suggesting a virus-specific association of HCV with T2DM. Interestingly, the association of T2DM was with HCV genotype 1b. In a subsequent large cohort study, it was noted that HCV-associated T2DM mainly occurred in patients with other risk factors for diabetes, such as older age and a high body mass index^[22]. Thus, among patients classified as “high risk” for T2DM, CHC increased diabetes risk more than 11-fold after 9 years^[22], although further studies are required to firmly establish causality.

CHC and IR

Insulin resistance is present in > 90% of individuals before the onset of frank T2DM. While the euglycemic hyperinsulinemic clamp^[23] is the “gold standard” for measuring glucose utilization and insulin sensitivity or resistance, a common clinical approximation is obtained using the homeostasis model of IR (HOMA-IR), calculated by the following equation: $\text{HOMA-IR} = \text{fasting glucose (mmol/L)} \times \text{fasting insulin (}\mu\text{U/mL)} / 22.5$ ^[24,25]. Typically, a HOMA-IR value > 2 is used to signify significant IR^[26].

In 2003, Hui *et al*^[27] first reported that IR is increased in patients infected with HCV, particularly genotype 1 and that this may form the basis for the earlier observations regarding the association with T2DM. Subsequent studies have confirmed this association, including for genotype 4^[28] and possibly also genotype 2a^[29]. Since liver fibrosis irrespective of etiology can of itself cause hyperinsulinemia, it is important to exclude patients with advanced fibrosis in any assessment of the relationship between HCV and IR. This was undertaken in the study by Hui *et al*^[27], who demonstrated that even patients with minimal fibrosis (F0 or F1) had a mean HOMA-IR of 2.4 compared to 1.9 for matched uninfected controls ($P = 0.002$).

Studies have shown that in people with HCV and IR who respond to treatment there is a reduction in HOMA-IR^[26]. This improvement in insulin sensitivity is maintained for people with a sustained virological response (SVR)^[26,30], and results in a reduced risk of subsequent diabetes^[30,31]. However other groups have shown that the apparent reduction in diabetes risk may actually reflect the lower baseline risk of diabetes in patients who respond to interferon treatment, rather than an effect of treatment *per se*^[32]. It is also worth noting that not all patients with CHC develop IR, suggesting a complex interaction between virus and host factors that is only partially understood.

In contrast to the specific association of IR with CHC, IR is not associated with CHB. A recent study found that in patients with CHB the HOMA-IR reflected their overall metabolic profile, but was not increased in people with CHB compared with matched healthy controls^[33]. Another recent prospective study comparing patients with CHB and CHC confirmed

that IR is a specific feature of hepatitis C genotype 1 and 4 infection, but not CHB; it was present in 35% of patients with CHC compared with only 5% with CHB^[28].

Complications of HCV-induced IR

As well as predisposing to T2DM, the presence of IR in CHC predicts non-response to antiviral therapy^[26], both for genotype 1^[26,34-36] and genotypes 2 and 3 infection^[37]. Central obesity, which can be associated with IR, has also been shown to predict non-response^[38]. Furthermore, HCV-infected patients who respond to antiviral therapy show improved insulin sensitivity^[39]. Similarly, improvements in CHC-induced steatosis have been observed following SVR^[40]. Interestingly, IR has been associated in several studies with elevated HCV viral loads^[28,41,42]. One possible mechanism involves p21-activated kinase 1, which suppresses HCV replication and is stimulated by PI3K/Akt signaling, *via* mTOR^[43]. HCV-associated IR could decrease PI3K/Akt signaling and thus favor viral replication, although the mechanism by which HCV induces IR is unclear.

The interactions between HCV, IR, steatosis and hepatic fibrosis are complex and genotype specific. In CHC due to genotype 1, IR is associated with hepatic steatosis. In this setting, IR is either virus-mediated or due to host metabolic factors such as visceral obesity^[44]. A similar association has been shown for genotype 4^[45]. In contrast, steatosis in HCV genotype 3 infection is predominantly a direct effect of the virus, occurring in the absence of other metabolic risk factors^[46,47]. It should be noted however, that in people with genotype 3 CHC and obesity, a proportion of the hepatic steatosis will be secondary to their metabolic dysregulation. In patients infected with HCV, steatosis and IR are predictive factors for the later progression to hepatic fibrosis and cirrhosis^[28,48-51]; the latter predisposes to HCC. Likewise, diabetes mellitus itself has recently been shown to increase the risk of HCC^[52]. While CHC-induced steatosis has been reported as a risk factor for hepatic fibrosis^[53], subsequent studies suggest that IR is most important in this relationship, both for genotypes 1 and 3^[46,48].

MECHANISMS OF HCV-INDUCED IR

Inflammation and IR

Chronic inflammation plays a significant role in IR associated with metabolic liver disease, due to increased levels of interleukin (IL)-1, tumor necrosis factor (TNF)- α , IL-6 and leptin, and reduced levels of adiponectin^[54]. Diet-induced IR in the context of obesity partly involves the inflammatory mediator I κ B kinase β (IKK β)^[55]. Inflammatory cytokines such as IL-1, TNF- α and free fatty acids stimulate IKK β . This induces proteasomal degradation of I κ B, allowing nuclear translocation of the downstream effector molecule NF κ B to stimulate secretion of IL-6^[56]. IKK β also induces IR by inhibitory phosphorylation of the insulin signaling molecule IRS-1 at serine 312^[57]. High doses

of aspirin and other salicylates inhibit IKK β and can reduce IR in both rats and humans^[58-60]. IR can similarly occur in other inflammatory conditions associated with elevated TNF- α , including inflammatory bowel disease^[61], rheumatoid arthritis^[62] and psoriasis^[63].

Based on these well-described associations, it was initially proposed that IR in CHC may arise as a non-specific consequence of hepatic inflammation, possibly mediated by IKK β . In support of this hypothesis, expression of HCV core protein in transgenic mice (genotype 1b) induces hepatic IR^[64]. When fed a high-fat diet, these mice develop frank diabetes and hepatic steatosis that is associated with elevated circulating levels of TNF- α . The IR is reversed by administering antibodies against TNF- α , but the mechanism of this effect has not been well defined.

Early human studies were conflicting but more recent studies have shown that HCV-induced IR is NOT due to alterations in serum inflammatory cytokines or adipokines^[65]. Rather, IR in CHC seems to be due to direct virus-specific effects on insulin signaling. Thus, initial studies noted increased serum levels of TNF- α in subjects with CHC^[66-68] or showed a correlation with IR^[69] but did not adequately correct for potential confounders. A later well-controlled study compared 154 HCV-infected non-diabetic males with 75 matched uninfected controls^[65]. In that study, as expected, serum levels of TNF- α and IL-6 were higher in HCV-infected patients than controls but levels did not correlate with IR^[65]. Serum levels of the adipocytokines leptin and adiponectin were likewise independently associated with IR (adiponectin inversely), but not with HCV infection itself. The authors therefore concluded that these adipocytokines could not account for the increased IR seen in HCV-infected subjects^[65].

Direct effects of HCV in modulating insulin signaling HCV core protein

Although it was initially suggested that IR associated with CHC may be due to chronic inflammation, it is now known that HCV can induce IR directly, through specific viral effects^[70]. Much of the published literature in this area has focused on the HCV core protein, which has been proposed to cause IR in hepatocytes by reducing the level or activity of molecules involved in insulin signaling, particularly IRS-1 and IRS-2. However, there is considerable disagreement concerning which of these molecules is more important, and whether altered signaling results from changes in IRS expression, degradation, or altered activity^[64,71-75].

For example, one study found reduced activation (reduced tyrosine phosphorylation) of IRS-1 in liver biopsies from HCV-infected patients and reduced association of IRS-1 with its downstream effector PI3K but increased expression of IRS-1 protein^[71]. In contrast, another report demonstrated reduced expression of both IRS-1 and IRS-2 in patient samples and in livers from transgenic mice expressing HCV core protein^[73]. It was proposed that core protein stimulated increased

levels of the molecule suppressor of cytokine signaling (SOCS) 3, leading to ubiquitination and proteasomal degradation of IRS-1 and IRS-2^[73] (Figure 1). This is consistent with data showing IR in mice following over-expression of SOCS1 or SOCS3^[76]. In support of their hypothesis, the same group found that in patients who responded to antiviral therapy hepatic levels of both IRS-1 and IRS-2 were increased, along with improved clinical insulin sensitivity^[39]. One clinical study showed higher levels of SOCS3 in peripheral lymphocytes from people infected with HCV genotype 1 rather than genotype 2 and found that the level of SOCS3 was the best predictor of response to interferon therapy^[77]. In a similar study from the same group, polymorphisms in the SOCS3 gene were shown to correlate with clinical response to interferon^[78]. SOCS3 mRNA levels were higher in obese subjects with CHC than lean subjects and may contribute to their reduced response to IFN- α treatment^[79].

The effects of HCV genotype on insulin signaling are less well understood but are important given the clinical association of genotypes 1 and 4 with IR^[27,28]. One study compared the effects of over-expressing genotype 1b and 3a core proteins in the Huh7 hepatoma cell line^[75]. No difference in SOCS3 expression was detected, but cells expressing genotype 3a core contained higher levels of SOCS7 than cells expressing genotype 1b core, as well as reduced levels of IRS-1^[75]. In contrast, cells expressing genotype 1b core had a smaller reduction in the amount of IRS-1, but increased phosphorylation of IRS-1 at inhibitory serine residues (636/639), as well as increased mTOR activity^[75]. The authors therefore speculated that IR in the context of HCV genotype 1 infection is due to core-induced induction of the TORC1 mTOR/raptor complex, resulting in reduced IRS-1 signaling^[75]. A different group has shown reduced insulin signaling in core-expressing cells, due to JNK-mediated inhibitory phosphorylation of IRS-1 at serine 312^[72]. Although intriguing, the relevance of IRS-1 serine phosphorylation to clinical HCV-induced IR has yet to be confirmed.

PA28 γ is an inducer of late proteasome activity that may play a role in HCV-induced IR as it is essential for the development of IR in HCV core transgenic mice^[74]. Core transgenic mice display reduced insulin sensitivity, reduced activation (tyrosine phosphorylation) of IRS-1 and reduced expression (mRNA and protein) of IRS-2; factors which are restored to normal following knockout of the PA28 γ gene^[74]. TNF- α expression was increased in the livers of core transgenic mice and in human hepatoma cell lines expressing core protein, but knocking out or silencing PA28 γ returned TNF- α expression to normal^[74]. PA28 γ has also been shown to play a critical role in the development of steatosis and HCC^[80], and may provide a useful link between the different pathways affected by HCV.

HCV NS5A

Another molecule that may play a role in HCV-induced

IR is protein phosphatase 2A (PP2A). PP2A can affect several cell pathways and is upregulated in HCV infection, possibly due to increased endoplasmic reticulum (ER) stress^[81] or directly by the HCV non-structural protein NS5A^[82] (Figure 1). PP2A has been shown to mediate HCV-associated IR by dephosphorylating and thus inactivating Akt^[83]. In that study, PP2A levels were increased in HCV protein-expressing cell lines, the livers of transgenic mice expressing HCV proteins and in liver biopsies from HCV-infected patients. Impaired insulin signaling was demonstrated in each model, with reduced insulin-stimulated phosphorylation of Akt^[83]. However, the authors were unable to show a correlation between reduced Akt signaling and IR in HCV-infected patients, as measured by HOMA-IR^[83]. Interestingly, PP2A has been shown to inhibit interferon signaling and this has been proposed as another potential link between IR and reduced clinical response to interferon treatment in HCV-infected patients^[84].

Peroxisome proliferator activated receptor (PPAR)- α and PPAR- γ

PPARs are nuclear receptors that modulate lipid and glucose metabolism, as reviewed recently^[85]. PPARs form heterodimeric complexes with the retinoid X receptor (RXR) and bind to PPAR response elements (PPRE) on PPAR regulated genes, inhibiting their expression. Binding of PPAR ligands, including unsaturated fatty acids, eicosanoids, oxidised low density lipoprotein (LDL) and very LDL, causes dissociation of the PPAR-RXR complex, derepression and increased gene expression^[85]. In this way PPARs react to lipid excess by stimulating differentiation of adipocytes, oxidation of fatty acids and glucose metabolism.

PPAR- α is the major PPAR isoform present in liver and is also found in brown fat and heart. It regulates cell energy by stimulating oxidation of fatty acids in mitochondria and peroxisomes^[85]. Along with PPAR- δ , it stimulates expression of human adipose differentiation-related protein, thus promoting storage of cellular lipid in lipid droplets^[86]. PPAR- γ is the dominant isoform in adipose tissue, colon, myeloid cells and placenta, where it stimulates adipocyte differentiation and lipid storage^[85].

As well as their effects on lipid metabolism, PPARs may also play a role in HCV-induced IR^[87]. Liver biopsies from patients with CHC show reduced levels of PPAR- γ and PPAR- α mRNA^[88,89]. In an *in vitro* model of HCV-induced hepatic IR, cells expressing genotype 3 core protein, but not genotype 1b, had reduced levels of PPAR γ mRNA^[89]. In a follow-up study, treatment of genotype 3a core-expressing cells with the PPAR- γ agonist rosiglitazone improved insulin signaling^[75]. Interestingly, PPAR- α is required for HCV core-induced steatosis in transgenic mice^[90], suggesting overlapping mechanisms for IR and steatosis in people with CHC.

Oxidative stress and IR

Oxidative stress may contribute to IR in HCV-infected people, as well as to steatosis. *In vitro* studies demonstrate

increased mitochondrial reactive oxygen stress in hepatoma cells over-expressing core protein^[91] and in HCV core transgenic mice^[91,92]. Further, in HCV-infected patient serum, thioredoxin, a marker for oxidative stress, has been shown to correlate with clinical IR, independent of obesity^[93]. However the interactions between oxidative stress, IR, metabolic syndrome and steatosis are complex, with each potentially influencing the other. A recent study showed that in patients infected with HCV genotype non-3, HOMA-IR ($P < 0.01$), fibrosis ($P < 0.01$) and oxidative stress ($P < 0.05$) were independently associated with steatosis, whereas steatosis was independently associated with oxidative stress ($P < 0.03$) and HOMA-IR ($P < 0.02$)^[94]. The authors concluded that in genotype non-3 infection "oxidative stress and IR contribute to steatosis, which in turn exacerbates both IR and oxidative stress and accelerates the progression of fibrosis"^[94].

Treatment of IR in people infected with HCV

It has been shown that response to interferon-based treatment can be improved by diet-induced weight loss, which improves insulin sensitivity^[95]. Given the association between IR and poor treatment response in CHC, clinical trials of insulin-sensitizing drugs have been proposed to improve treatment response^[29]. Since the mechanisms of HCV-induced IR are not well understood it is not clear whether it is better to use thiazolidinediones that target PPAR- γ , or metformin, which activates AMP-activated protein kinase^[96] and may also stimulate the insulin receptor to signal *via* IRS-2^[97].

A recent pilot study adding the PPAR- γ agonist pioglitazone (15 mg) to pegylated interferon alpha and ribavirin was undertaken in patients with HCV-induced IR who had previously failed standard treatment^[98]. Although most of the treated patients showed improvement in their HOMA-IR on pioglitazone, none had a satisfactory virological response after 12 wk and the trial was terminated. A recent case report suggests that reducing IR prior to antiviral therapy, by pre-treating with insulin sensitizing drugs, may improve outcomes^[99]. The authors administered a high dose of pioglitazone (45 mg) to a patient with genotype 3a CHC who had previously failed antiviral treatment. After 5 mo of pioglitazone, the patient's HOMA-IR reduced from 4.8 to 1.3 and subsequent treatment with pegylated interferon and ribavirin for 48 wk produced a SVR^[99]. It is not clear whether this outcome was due to the higher dose of pioglitazone, the sequential treatment approach or the patient's genotype 3 infection^[100]. Several similar studies are underway to address these issues and their results are eagerly awaited.

CONCLUSION

There is increasing evidence that CHC is a metabolic disease, strongly associated with IR and T2DM. Insulin resistance is most strongly associated with HCV genotype 1, in contrast to hepatic steatosis which is associated with genotype 3 infection. Although the precise mechanisms of HCV-associated IR are unclear, several

possibilities have been suggested and the mechanisms may be multi-factorial, including both virus and host factors. Early studies in transgenic mice suggested IR may result from chronic inflammation and elevated TNF- α , but subsequent human studies have suggested a virus-specific effect. HCV core protein has the most evidence to support its role in IR, with likely effects on insulin signaling at the level of IRS. Core-induced increases in SOCS3 or SOCS7 expression may cause IRS destruction, probably requiring PA28 γ , but other proposed alternatives include feedback inhibition of IRS-1 by activated mTOR or JNK. Insulin resistance may also result from core-induced alterations in PPAR- α and PPAR- γ , especially in genotype 3 infection. PP2A can cause IR and in CHC its activity may be increased, either in response to ER stress or to the HCV non-structural protein NS5A, which interacts with many cellular pathways.

Since IR in CHC is associated with a reduced response to antiviral treatment, clinical trials are underway to determine whether reducing IR improves treatment outcomes. Preliminary data from pilot studies of PPAR- γ agonists have been disappointing, but case reports suggest that more aggressive treatment may be successful, particularly if IR is reduced prior to commencing antiviral therapy. Trials of other insulin-sensitizing drugs including metformin are also in progress and their results are eagerly awaited. Since the underlying mechanisms of HCV-induced IR are still not clear, ongoing research is essential to guide a more rational, targeted approach to therapy.

Abstract

Malignant gastroduodenal obstruction can occur in up to 20% of patients with primary pancreatic, gastric or duodenal carcinomas. Presenting symptoms include nausea, vomiting, abdominal distention, pain and decreased oral intake which can lead to dehydration, malnutrition, and poor quality of life. Endoscopic stent placement has become the primary therapeutic modality because it is safe, minimally invasive, and a cost-effective option for palliation. Stents can be successfully deployed in the majority of patients. Stent placement appears to lead to a shorter time to symptomatic improvement, shorter time to resumption of an oral diet, and shorter hospital stays as compared with surgical options. Recurrence of the obstructive symptoms resulting from stent occlusion, due to tumor ingrowth or overgrowth, can be successfully treated with repeat endoscopic stent placement in the majority of the cases. Both endoscopic stenting and surgical bypass are considered palliative treatments and, to date, no improvement in survival with either modality has been demonstrated. A tailored therapeutic approach, taking into consideration patient preferences and involving a multidisciplinary team including the therapeutic endoscopist, surgeon, medical oncologist, radiation therapist, and interventional radiologist, should be considered in all cases.

Key words: Malignant gastric outlet obstruction;

INTRODUCTION

Malignant gastroduodenal obstruction can occur in up to 20% of patients with primary pancreatic, gastric or duodenal carcinomas, with pancreatic cancer being the most common cause^[1]. Obstruction is a late occurrence in patients with advanced disease. Presenting symptoms include nausea, vomiting, abdominal distention, pain and poor oral intake which can lead to dehydration, malnutrition, and poor quality of life.

Traditionally, malignant gastric outlet obstruction has been treated surgically, usually by creating a gastrojejunostomy. More recently, the use of endoscopically placed self-expandable metal stents (SEMS) has become a routine practice^[2].

Radiologists were the first to offer an alternative to surgery by demonstrating the feasibility of stent placement using a peroral or percutaneous approach under fluoroscopic guidance^[3-5], but this approach never gained popularity due to its invasiveness and limited success rate^[4]. Technological advances have led to the development of self-expandable metallic stents that can pass through the operating channel of a therapeutic endoscope, allowing for endoscopic placement with fluoroscopic guidance, first described by Truong *et al*^[6] in 1992. Endoscopic treatment has become more successful as this approach has increased in popularity.

TECHNICAL CONSIDERATIONS

There are limitations in the ability to successfully place metal stents, including the inability to pass the guidewire

Table 1 Outcomes and complications of endoscopic stent placement

Author, yr	No. of patients	Stent used	Technical success (%)	Clinical outcome (%)	Complications, early/late
Cho <i>et al</i> ^[13] , 2009	75	Hanaro and Niti-S, covered and uncovered	98	87	3 (1 pneumonia, 1 perforation, 1 stent kinking)/35 (23 ingrowth, 2 overgrowth, 8 migration, 2 food impactions)
Nassif <i>et al</i> ^[9] , 2003	63	Wallstent (36), Choostent (32)	95	92	9 (1 perforation, 8 stent dysfunction)/18 (1 perforation, 13 obstruction, 4 migration)
Maetani <i>et al</i> ^[20] , 2009	60	Uncovered (31) and covered (29) Ultraflex	100	90.3 (uncovered), 86.2 (covered)	2 (mild pancreatitis)/10 (4 obstructions, 2 migrations, 2 stent fractures, 1 perforation, 1 bleed)
Kim <i>et al</i> ^[14] , 2007	53	NiTi-S Pyloric	100	81.1	5 (tumor ingrowth)/12 (9 tumor ingrowth, 1 tumor overgrowth, 2 migration)
Phillips <i>et al</i> ^[21] , 2008	46	Wallstent (40), Alimaxx (4), Bard (2)	100	91	5 (2 stent migration, 2 delayed-onset obstructive symptoms, 1 stent fracture)/2 (1 duodenal perforation, 1 aortoenteric fistula)
Lopes <i>et al</i> ^[16] , 2008	44	Choostent (14 uncovered, 1 covered), Hanarostent (21 uncovered, 1 covered), uncovered Wallstent (21)	100	Not measured	6 (1 perforation, 1 migration, 3 obstructions, 1 hemorrhage)/11 (8 obstructions, 2 migrations, 1 fistula)
Mosler <i>et al</i> ^[8] , 2005	36	Gianturco Z-stent, Ultraflex, Endocoil, enteral Wallstent	92	75	3 (2 stent migrations, 1 impaction)/13 (5 migrations, 4 tumor ingrowth, 2 erosion/perforation, 2 impactions)

through severely narrowed stenoses, anatomic difficulties such as a dilated stomach which may lead to significant looping, or complicated post-surgical anatomy that limits passing of the endoscope or the guidewire to the site of obstruction^[7]. It may be useful to obtain imaging of the obstructed area, such as performing an upper GI barium study, to try to assess the patient's anatomy, the stricture length, and degree of obstruction, if possible.

After administering conscious sedation, the area of stenosis is reached using a therapeutic upper endoscope. If the length of the stenosis is not known, then this can be determined by advancing the endoscope through the stenotic area or, if the stricture is not traversable, then it can be measured fluoroscopically. A guidewire is then advanced through the working channel of the endoscope and passed at least 20 cm distal to the obstructing area. The stent length should be at least 3-4 cm longer than the stenosis to allow for an adequate stent margin after placement. Next, the SEMS delivery system is passed over the guidewire through the working channel of the endoscope and aligned so that the ends of the undeployed stent overlies both ends of the stenosis equally. Once the alignment is correct, the stent is then deployed distal end first, followed by the proximal end. Next, the stent placement and luminal patency are confirmed endoscopically and fluoroscopically.

Patients with malignant gastric outlet obstruction often have coexistent biliary obstruction, which may present before or after the symptoms of gastric outlet obstruction. Placement of a metal biliary stent should be considered prior to duodenal stenting in patients with existent or impending biliary obstruction. Once the duodenal stent is in place, access to the biliary tree becomes extremely limited and a percutaneous transhepatic approach is usually required^[7].

confirmed presence of an unresectable malignancy or malignant recurrence at an anastomotic surgical site causing symptomatic gastric outlet or duodenal obstruction, a single stenotic region, and an expected short survival period (usually less than six months). The presence of free perforation with signs of peritonitis and tension pneumoperitoneum are contraindications to endoscopic stent placement^[7]. The desired outcomes after placement of a SEMS include relief of obstructive symptoms, return to a normal diet with improved nutritional status and improvement in the patient's quality of life. No studies have shown any evidence of survival benefit associated with the relief of malignant obstruction.

Efficacy of endoscopic stent placement in most studies is defined by two measures: technical and clinical success. Technical success is defined by accurate stent placement with adequate expansion of the stent and evidence of luminal patency post-procedure, usually evaluated by performing a water-soluble or barium contrast study. Clinical success is determined by resolution of the patient's obstructive symptoms and the ability to resume a regular diet after stent placement and maintain adequate oral intake during follow-up. The results of the studies evaluating the use of SEMS in malignant gastric outlet obstruction are summarized in Table 1.

The reported technical success rates for endoscopically placed SEMS range from 92%-100%. Mosler *et al*^[8] reviewed outcomes in 36 patients who had undergone SEMS placement for malignant gastric outlet or proximal small bowel obstruction over a 13-year period. Initial stent placement was successful in 33/36 patients (92%); two patients had immediate stent migration and one stent impacted into the duodenal wall. The authors felt that their technical success rate was not as high as more recent studies since their retrospective review extended from January 1991 to March 2003 and a variety of SEMS types were used during the earlier years that were not specifically designed for enteral use, leading to a higher rate of

EFFICACY AND OUTCOMES

Indications for the placement of a SEMS include the

early complications. Nassif *et al*^[9] also reported a high technical success rate with 60/63 patients (95%) obtaining immediate radiographic evidence of luminal patency. It is mentioned that three patients required hydrostatic stent dilation during the initial procedure for insufficient expansion, however it is unclear if these three patients were included in the unsuccessful category. In the other studies with 100% technical success, this was determined based on achieving the technical goals in one endoscopic session, whether that required placement of several overlapping stents due to a long stricture site, adjustment of a migrated stent by realignment using forceps or complete removal with new stent placement, or using hydrostatic dilation to ensure adequate expansion^[10-16].

The use of fluoroscopic and endoscopic guidance allows for adequate stent and stenosis visualization to ensure proper stent placement during the procedure and improve technical success overall. However, in the study by Kaw *et al*^[17], successful stent placement was achieved in 32/33 patients (96.9%) due to complete obstruction distal to a previous surgical site with recurrence at the anastomosis and inability to pass the guidewire through the stricture in one patient. Complete obstruction remains a major limitation to endoscopic stent placement and surgical intervention is then required if possible.

Not surprisingly, clinical success rates are usually lower than the technical success, with reports ranging from 79%-91%, depending on the definition of success^[17,18]. Mosler *et al*^[8] defined clinical success as improvement in obstructive symptoms (i.e. nausea, vomiting, abdominal distention, and reflux), which occurred in 29/32 patients (90.6%), with no symptomatic improvement in three patients. Kim *et al*^[10] also used symptomatic improvement as the measure of clinical success in their assessment of outcomes after SEMS placement in 53 patients with gastric outlet obstruction due solely to gastric cancer, in which they reported a success rate of 81.8%.

Adler *et al*^[11] and Lindsay *et al*^[12] specifically studied clinical success, defined as the ability to resume a regular diet after SEMS placement. Adler *et al*^[11] reported the results of endoscopic treatment for malignant gastric outlet obstruction in 36 patients and found an improvement in 31/36 (86%), which was statistically significant ($P < 0.0001$), with 61% being able to consume a solid or soft diet without symptoms of obstruction. Importantly, 58% noted improvement in < 1 d with 86% showing improvement in 3 d or less. Lindsay *et al*^[12] reported an 80% clinical success rate in patients deemed unsuitable for surgical intervention, with a median survival of 7 wk, as 32/40 patients were able to resume a solid or soft diet after stent insertion.

Also looking at the clinical success rate, van Hooft *et al*^[19] reported symptomatic improvement in 51 patients with malignant gastric outlet obstruction followed prospectively at three tertiary referral centers. In this study, clinical improvement was determined by the change in the Gastric Outlet Obstruction scoring system before treatment compared with the score after endoscopic placement of the Wallflex enteral stent. There was a 98% (50/51 patients) technical success

rate and an 84% (43/51 patients) clinical success rate, with a statistically significant ($P < 0.001$) improvement in obstruction symptoms after treatment, as well as improvement in overall performance status ($P = 0.002$). Forty-six patients (90%) were able to resume oral intake within one day of stent placement. This study did not, however, find an improvement in global quality of life.

Masci *et al*^[18] prospectively assessed the duration of symptomatic improvement in a cohort of 38 patients with malignant upper gastrointestinal obstruction treated with endoscopic stent placement. At 30 d, follow-up was available for 34 patients and 79.4% of these patients were able to tolerate a solid or soft diet. At 90 d, 11 patients remained alive and 90.9% remained on a solid or soft diet. At 180 d, only five patients were alive, however all of them were eating a solid or soft diet. Telford *et al*^[15] reported a median duration of oral intake of 146 d after SEMS placement, which increased to 219 d with repeat stenting for recurrent obstruction, in patients with a median survival of 97 d. These articles not only highlight the duration of stent patency but the short survival period in these patients.

Kim *et al*^[14] and Cho *et al*^[13] evaluated clinical factors that contribute to longer durations of stent patency. Kim *et al*^[14] found that patients who received chemotherapy after stent placement were noted to have significantly prolonged stent patency. Cho *et al*^[13] reported similar findings, however they included the use of covered stents, in addition to chemotherapy after stent placement, as a significant prognostic factor contributing to stent patency.

COMPLICATIONS

Complication rates range from 11%-43% and can be reported as immediate, which occur within 24 h after placement of the SEMS, early or late^[9,18]. Each study determines the time frame that differentiates early from late complications, which can vary anywhere from < 96 h to within two weeks to be considered an early complication^[16,18]. Immediate and early complications include problems with sedation, stent obstruction, stent malposition, perforation, aspiration, and bleeding. Late complications include stent obstruction, bleeding, perforation, stent migration, and fistula formation^[7] (Table 1).

In the study by Cho *et al*^[13], 2/75 (2.6%) patients experienced immediate complications (1 aspiration pneumonia and 1 bowel perforation, which was successfully treated with surgical gastrojejunostomy) and 1 patient had a recurrence of obstructive symptoms due to tumor ingrowth within 1 wk of stent placement (1.3%), which was treated with repeat stenting. Late complications in this study included stent migration in 8/75 patients (6 treated with repeat stenting, 1 treated with palliative gastrojejunostomy, and 1 was asymptomatic so received no further treatment) and recurrence of obstructive symptoms in 25/75 (33.3%) due to tumor ingrowth in 23 and tumor overgrowth in 2 (14 treated with repeat stenting, 1 with palliative radiotherapy, no further intervention in the other 10 patients either due to mild

symptoms, poor condition or patient preference).

In the study by Kim *et al*^[10], restenosis occurring at less than 4 wk after stent placement was found in 5/43 patients (11.6%), which was successfully treated with placement of covered stents in the new stenotic area. Stent-related problems requiring treatment occurred in 17 patients (32.1%) during the follow-up period (mean 145 d, range 4-718 d). Two patients (3.8%) had recurrence of symptoms due to distal stent migration (both successfully treated with placement of a second stent overlapping the first), stent overgrowth occurred in one patient (1.9%) at 331 d after deployment, tumor ingrowth occurred in 14 patients (26.4%) at a mean of 78.4 d after stent placement. In this study the mean survival was 145 d and the median stent patency time was 187 d.

Ten early complications were reported in the study by Nassif *et al*^[9]. Eight patients (12.7%) had a primary duodenal stent dysfunction (treated with insertion of a second stent or with hydrostatic dilation), 1 patient who had previously undergone duodenal dilation for papillary cannulation experienced a duodenal perforation 24 h after stent placement (successfully treated with surgical bypass), and one patient developed mild post-endoscopic retrograde cholangiopancreatography (ERCP) acute pancreatitis after undergoing biliary stenting (which resolved with medical management). Eighteen patients (28%) experienced late complications in this study, with the majority due to stent obstruction secondary to tumor ingrowth (in 12 patients) or due to impaction of the proximal end of the stent into the duodenal bulb (in 1 patient). These were treated with repeat stenting (in 9 patients), surgical bypass (in two patients) and conservative management (in two patients). Stent migration occurred in four patients (6.3%); two patients were treated with repeat stenting and the other two patients were asymptomatic and required no further intervention. There was one case of peritonitis due to duodenal wall perforation that occurred 1 mo after stent placement in a patient who was being treated with chemotherapy and radiation for duodenal invasion by a Hodgkin's lymphoma, which was treated with surgical bypass.

Lopes *et al*^[16] assessed complications associated with endoscopic stenting for palliative treatment of malignant esophageal, gastroduodenal, and colonic obstruction. In their study population of 153 patients, 44 patients underwent duodenal stent placement, 84% for neoplastic obstruction and 16% for extrinsic compression. In this group of patients there were 6 (12%) procedure-related complications, including 1 perforation, 1 stent migration, 3 obstructions and 1 hemorrhage, which were all successfully treated endoscopically. The group of patients with gastroduodenal obstruction had a higher procedure-related complication rate than the esophageal (8.8%) or colonic (7.5%) stenting groups, primarily due to early obstruction. Eleven (22%) late complications were reported, including 8 due to obstruction from tumor ingrowth or overgrowth, 2 due to migration and 1 fistula, which were all treated with endoscopic placement of new stents; however one patient with late stent migration was treated with supportive care only.

More recently, Maetani *et al*^[20] compared the outcomes, complication rate and reintervention rate in patients who received uncovered (31 patients) *vs* covered (29 patients) stents for malignant gastric outlet obstruction. There was a 100% technical success rate in both groups and no significant difference in clinical success. In each group, there was one patient who experienced mild pancreatitis within 1 wk of stent placement, which was managed medically in both instances. In the uncovered stent group, late complications included one stent fracture, which did not require any additional intervention; one stent obstruction due to hyperplasia, which required repeat stent placement for treatment; one case of bleeding, which ceased spontaneously; and 1 fatal perforation that occurred during chemoradiation therapy 39 d after stent placement. In the covered stent group, late complications included 1 stent fracture that occurred after ERCP for management of biliary stent dysfunction, 3 stent obstructions (2 due to tumor overgrowth, 1 due to hyperplasia), and 2 stent migrations; all were treated with repeat endoscopic stent placement. This study concluded that reintervention is more commonly required after covered stent placement for management of complications.

Looking at the long term results and complications of enteral stent placement for unresectable cancer, Phillips *et al*^[21] reviewed the outcomes of 46 patients with malignant gastric outlet obstruction. All patients had successful stent placement and 42 patients (91%) showed clinical improvement. There were 5 early complications (defined as occurring in ≤ 30 d) including stent migration in 2 patients, both treated with endoscopic removal of the initial stent and stent replacement; 2 patients with delayed-onset obstructive symptoms with patent SEMS, both treated with percutaneous endoscopic gastrojejunostomy placement; and 1 patient with stent fracture, treated with stent removal and endoscopic dilation. Late complications consisted of 1 patient with a duodenal perforation, treated with emergent surgical repair, and 1 patient who developed an aortoenteric fistula from stent erosion in the setting of a previous pancreaticoduodenectomy, which was treated with an endovascular aortic stent followed by definitive repair. There were 4 patients who developed stent obstruction and recurrence of obstructive symptoms due to local tumor ingrowth. In this study, unlike most others, this was not included as a procedural complication as it was due to progression of the underlying primary disease and not a result of the intervention.

TYPES OF STENTS

Studies have evaluated the use of different stent designs, covered and uncovered, to try to determine which stent is best for different patient populations. Since recurrent obstruction due to tumor ingrowth with uncovered stents is common^[22-24] and the migration rate of covered stents used for malignant gastric outlet obstruction was found to be unacceptably high (21% and 26% in two small studies^[25,26]), Kim *et al*^[27] examined the rate of stent restenosis in 49 patients with malignant gastric outlet

obstruction in an effort to identify characteristics that would predict early restenosis. In all patients, uncovered stents were used and there was a 100% technical success. The patients were then divided into two cohorts, one with early restenosis and the other without early restenosis, for retrospective comparison with regard to host-related factors (i.e. age and gender) and lesion-related factors (i.e. primary illness, stenosis site and length). The only statistically significant difference between these groups was the site of stenosis, with early restenosis occurring more frequently at the post-operative anastomotic sites ($P < 0.05$, 95% CI 0.003-0.005). The median follow-up period was 17 wk (range 2-64 wk), median patient survival was 10 wk, while the median stent patency time was 8 wk. Placement of an additional uncovered stent, placement of a covered stent inside an occluded uncovered stent, and use of laser therapy have all been used to treat stent restenosis^[28-30]. A study by Jung *et al.*^[31] reported a decrease in stent migration rate and a decrease in recurrent obstruction caused by tumor ingrowth with coaxial placement of uncovered and covered expandable stents, however, the use of this technique with all patients is cost-prohibitive.

ENDOSCOPY WITH STENT PLACEMENT VS SURGICAL GASTROENTEROSTOMY

Multiple retrospective studies have compared the outcomes of surgical bypass and endoscopic stent placement for the palliative treatment of malignant gastric outlet obstruction. Early studies showed significant morbidity, including delayed gastric emptying post-operatively for up to 31 d, and a mortality of up to 18%, associated with gastrojejunostomy^[32]. More recently, Maetani *et al.*^[33] retrospectively reviewed the outcomes of 20 patients who underwent palliative enteral stenting compared with 19 matched patients who underwent surgical gastrojejunostomy and found that the only statistically significant difference between the groups was an earlier return to an oral diet in the endoscopically treated group at 1 d compared with 9 d in the surgical group ($P < 0.0001$). Otherwise, there was no difference with regard to patient survival, complication rates, technical or clinical success rates, and possibility of discharge. There was a difference in the length of hospital stay (15 d in the endoscopically treated group *vs* 30 d in the surgical group), however, due to the small study population, this difference was not statistically significant. In 2005, Maetani *et al.*^[34] reported another slightly larger comparative study, limited to patients with gastric outlet obstruction due to gastric cancer, and reported similar results with a significant difference in time to resumption of an oral diet as well as a shorter procedure time in the endoscopically treated groups, but no significant difference in the other measured outcomes (possibility of discharge, median post-operative hospital stays, survival periods, complication rates).

In a study by Mittal *et al.*^[35], 16 patients who had open gastrojejunostomy, 14 patients who had laparoscopic

gastrojejunostomy, and 16 patients who underwent endoscopic stenting were all matched for age, sex, ASA grade and level of obstruction in order to compare treatment outcomes, including time to starting free oral fluids and a light diet, length of hospital stay and patient survival. They found that oral intake could be tolerated in 6 d in the open gastrojejunostomy group, in 4 d in the laparoscopic gastrojejunostomy group, and on the same day following endoscopic stenting ($P < 0.001$). In addition they found a higher rate of complications in both surgical groups compared with the endoscopically treated group ($P = 0.016$). There were no differences in the total length of stay between the groups, which was attributed to a delay in referral for endoscopic stenting, however the length of stay after procedure was significantly less in the endoscopic stenting group at 2 d compared with 7 d in the laparoscopic gastrojejunostomy group and 10 d in the open gastrojejunostomy group ($P < 0.001$). Interestingly, survival was noted to be shortest in the endoscopically treated group, which was likely due to patient selection as patients with more advanced disease are referred for the least invasive treatment. In addition to confirming similar findings regarding outcomes in endoscopically *vs* surgically treated patients, this study highlights the lack of difference between open and laparoscopic gastrojejunostomy, the latter of which was previously felt to be superior.

In a prospective, randomized trial of 18 patients referred for treatment of malignant antro-pyloric strictures, patients were randomly assigned into two treatment groups consisting of endoscopic stenting or gastroenterostomy and were followed for 3 mo. Endoscopic treatment was found to have a significantly shorter operative time, with an earlier restoration of oral intake and shorter hospital stay, consistent with previously reported outcomes. There were no differences noted between the groups with regards to delayed gastric emptying, morbidity, mortality, and clinical outcomes at the 3-mo follow-up^[36]. Jeurnink *et al.*^[37] reviewed the outcomes of 95 patients who underwent gastrojejunostomy (42 patients) or endoscopic stent placement (53 patients), including resumption of an oral diet, persistent and recurrent obstructive symptoms, re-interventions, complications, hospital stay and survival. As with previous studies, there was a significantly shorter hospital stay ($P < 0.001$) and shorter time to resuming an oral diet ($P = 0.01$) with endoscopic treatment. This study, however, also found a significantly shorter time to late major complications ($P = 0.004$), shorter time to recurrent obstructive symptoms ($P = 0.002$), and shorter time to re-intervention ($P = 0.004$) in the patients who underwent endoscopic treatment. This study points out that there are benefits and limitations with each treatment option.

The one indisputable difference between these treatment options is cost. In 2001, Yim *et al.*^[38] compared the costs of palliative treatment with endoscopic enteral stenting *vs* gastrojejunostomy in patients with malignant gastric outlet obstruction due to pancreatic cancer and found the cost of endoscopic treatment was \$9921 *vs* \$28173 for surgical bypass. Adler *et al.*^[11] also conducted a cost analysis, including procedural and hospitalization

costs, comparing 10 patients who underwent endoscopic stenting with 10 patients who had surgical bypass for the treatment of malignant gastric outlet obstruction and found the median cost of endoscopic treatment was \$5970 compared to \$13445 in the surgical group ($P < 0.0001$). Mittal *et al*^[35] included a cost comparison in their study comparing three treatment groups and, as expected, found the surgical treatment options to be more expensive than endoscopic treatment with the cost of open gastrojejunostomy to be NZ\$13256, laparoscopic gastrojejunostomy to be NZ\$10938, and endoscopic stenting costing NZ\$5736. It has been consistently shown in these studies that surgical intervention is more costly than endoscopic treatment strategies.

CONCLUSION

In summary, endoscopic placement of SEMS is a safe, minimally invasive, and cost-effective option for palliation of malignant gastric outlet obstruction. SEMS can be successfully deployed in the majority of patients. Stent placement appears to lead to a shorter time to symptomatic improvement, shorter time to resumption of an oral diet, and shorter hospital stays as compared with surgical options. There is, however, a potential for the development of recurrence of the obstructive symptoms, most often due to stent obstruction from tumor ingrowth or overgrowth, which can, in the majority of cases, be successfully treated with repeat endoscopic stent placement. Both endoscopic stenting and surgical bypass are considered palliative treatments and, to date, no improvement in survival with either modality has been demonstrated. A tailored therapeutic approach, taking into consideration patient preferences and involving a multidisciplinary team including the therapeutic endoscopist, surgeon, medical oncologist, radiation therapist, and interventional radiologist, should be considered in all cases.

INTRODUCTION

Numerous cutaneous disorders have been associated with underlining malignancies of the gastrointestinal (GI) tract. In some cases the skin can be directly infiltrated by cancer cells that represent metastatic spread from a GI malignancy (e.g. a Sister Mary Joseph nodule). In other cases, the skin lesions are related to the underlying presence of malignancy, but they do not contain malignant cells and are referred to as paraneoplastic dermatological syndromes^[1]. Some of them, such as Muir-Torre, Peutz-Jeghers, and Cronkhite-Canada syndromes, are inherited and are caused by genetic factors, others however, have unknown etiologies and unpredictable expression and prognosis.

Dermatologists have the advantage of recognizing certain cutaneous signs, which hint at underlying visceral malignancies. From a practical perspective, such cutaneous manifestations might have an important diagnostic value if they are the sole expressions of otherwise asymptomatic carcinomas. The recognition of some typical paraneoplastic dermatologic disorders can lead to prompt diagnosis of the underlying GI malignancy, timely administration of therapy, and ultimately, better prognosis. In this review we will discuss the most common paraneoplastic dermatologic syndromes from the perspective of the practicing gastroenterologist (Table 1).

Abstract

Numerous dermatological disorders have been associated with underlining malignancies of the gastrointestinal (GI) tract. Such cutaneous manifestations might have an important diagnostic value if they are the sole expressions of otherwise asymptomatic carcinomas. The recognition of some typical paraneoplastic dermatologic disorders can lead to the prompt diagnosis of the underlying malignancy, timely administration of therapy, and ultimately, better prognosis. In this review we discuss the most common paraneoplastic dermatological syndromes from the perspective of the practicing gastroenterologist. We also outline a comprehensive practical approach for the evaluation for occult malignancy in patients presenting with cutaneous findings potentially associated with GI cancers.

ACANTHOSIS NIGRICANS

Acanthosis nigricans (AN) is a classic example of a paraneoplastic dermatosis, and its frequent relation with GI tract malignancies was emphasized by Darier at the end of the 19th century^[2]. The disease initiates with symmetric skin hyperpigmentation in the axillary and inguinal folds, submammary region, around the mamilla, umbilical, and ano-genital regions. Later, the skin lesions can infiltrate and become slightly hyperkeratotic pigmented velvety plaques surrounded by acrochordons (Figure 1). The neck region is frequently

Table 1 Relationships between morphologic features of cutaneous paraneoplastic disorders and gastrointestinal malignancy

Dermatologic disorder	Cutaneous manifestations	Localization	Associated gastrointestinal malignancy
Acanthosis nigricans	Pigmented papillomatous plaques	Axillar and inguinal folds, submammary and mamilla region, ano-genital regions	Gastric carcinoma; Colorectal carcinoma
Palmo-plantar keratoderma	Diffuse epidermal thickening with rugose appearance	Palms, fingers and soles	Gastric carcinoma; Hepatic metastases
Acrokeratosis paraneoplastica (Bazex syndrome)	Erythematous psoriasiform plaques	Hands, feet, ears, nose, elbows and knees	Squamous cell carcinoma of oropharynx/esophagus; Adenocarcinoma
Leser-Trélat syndrome	Multiple seborrheic keratoses	Trunk and extremities	Gastric carcinoma; Colorectal carcinoma; Esophageal carcinoma; Pancreatic carcinoma
Muir-Torre syndrome	Sebaceous adenomas; Sebaceous carcinomas; Keratoacanthomas	Head, trunk and extremities	Colorectal carcinoma; Colorectal adenomatous polyps
Paraneoplastic dermatomyositis	Periorbital heliotrope erythema and edema; Gottron papules; Gottron sign	Eyelids, upper cheeks, forehead; Phalangeal joints; Elbows, knees	Colorectal carcinoma; Gastric carcinoma; Hepatocellular carcinoma
Paraneoplastic pemphigus	Erosions; Vesicles and blisters, Erythematous to violaceous patches papules, plaques	Oral cavity; Head, trunk and extremities	Castleman's disease; Sarcoma; Adenocarcinoma; Squamous cell carcinoma
Peutz-Jeghers syndrome	Hyperpigmented macules	Buccal mucosa, gums; Tips of the fingers and toes	Multiple intestinal polyps; Colorectal carcinoma; Pancreatic carcinoma; Gastric carcinoma; Small bowel carcinoma
Cronkhite-Canada syndrome	Hyperpigmented macules; Nail plate separation, discoloration and atrophy; Alopecia	Hands, palms, arms, neck and face; Fingernails and toenails; Scalp	Hamartomatous polyps; Colon carcinoma; Gastric carcinoma
Paraneoplastic hypertrichosis lanuginosa acquisita	Lanugo hairs	Head, trunk and extremities	Colorectal carcinoma; Pancreatic carcinoma

affected in childhood. Similar pigmented papillomatous lesions can be observed on the mucous membranes of the oral cavity, nasal, and laryngeal mucosa, and vulva. The areola of the nipple can also be affected. Nails are brittle and hyperkeratotic, and leukonychia have been reported. Noncicatrical alopecia in the axilla and pubic regions is also possible.

AN can be idiopathic when related to endocrine disorders (obesity, insulin resistance, or overt diabetes mellitus), and only in some cases is it associated with malignancy^[3]. Only 20 cases of oral malignant AN were reported in the English language literature from 1968 to 2002^[4]. In malignancy-associated acanthosis nigricans the lesions are often more extensive and severe than when the cause is benign, and skin irritation can be a prominent and distressing symptom. Moreover, the skin lesions usually appear before the onset of any other GI symptoms^[5]. Malignancy-associated acanthosis nigricans is frequently seen with GI cancers^[6-8].

Anderson *et al*^[8] presented a 66-year-old male patient with poorly differentiated, metastatic gastric adenocarcinoma, who complained of severe pruritus and developed severe AN on the chest and nipples. The patient was treated with 5-fluorouracil, cisplatin and epirubicin chemotherapy resulting in dramatic improvement of the dermatological disorder and quality of life; however, the patient died six months later due to lymphangitic carcinomatosis. The authors assumed that factors affecting epidermal proliferation are involved because of the reduction in papillomatosis and increase in cutaneous pigmentation after chemotherapy administration^[8]. Pentenero *et al*^[4] reported a case of a 53-year-old man with gastric adenocarcinoma who suddenly developed hyperkeratotic, verrucous, slightly pigmented, brownish papules in the axillae and thickened

mucosa with a velvety and papillomatous surface, without hyperpigmentation on the lips, buccal mucosa and palate. Skin biopsies, performed from the buccal mucosa and the axilla, confirmed the diagnosis of AN with mucosal localization^[4].

Palmo-plantar keratoderma or “tripe palms” is a recognized feature of acanthosis nigricans and presents with epidermal thickening with a rugose appearance and broadened rete ridges bounded by deep sulci of the palms and fingers^[4,9] (Figure 2). Breathnach and Wells describe five patients with palmo-plantar keratoderma and acanthosis nigricans associated with gastric adenocarcinoma and in two patients they found squamous cell carcinoma^[9].

The exact pathophysiological mechanism of the paraneoplastic AN has not been well defined, but it could be related to cancer byproducts. Transforming growth factor alpha, structurally related to epidermal growth factor (EGF), has been considered as possible causative agent^[3,4].

The prognosis of the malignancy associated acanthosis nigricans tends to be poor because the underlying malignancy appears to behave aggressively. The average survival time of patients with signs of paraneoplastic AN is two years, although cases in which patients have survived for more than 10 years have been reported. Importantly, older patients with new onset AN usually have associated internal malignancy and therefore targeted investigation should be carried out (see below).

ACROKERATOSIS PARANEOPLASTICA (BAZEX SYNDROME)

The first patient with this entity was described by

Bazex *et al*^[10] in 1965, as “paraneoplastic syndrome with hyperkeratosis of the extremities”. Clinical manifestations include erythematous or livid squamous plaques resembling psoriasis, which are symmetrically distributed in acral regions and affect mainly the hands, feet, ears, nose, elbows and knees^[11]. Skin biopsies usually reveal nonspecific findings, including hyperkeratosis, acanthosis, parakeratosis, vacuolar degeneration, pigment incontinence, and a perivascular infiltrate of lymphocytes and histiocytes and occasionally dyskeratotic keratinocytes^[11].

Bazex syndrome predominates in males over 40 years and is most commonly associated with squamous cell carcinoma (SCC) of the upper bronchial and GI tracts^[11,12]. Adenocarcinomas of the stomach^[13], colon^[14], biliary system and hepatocellular carcinoma^[11], are also described in the literature. In a retrospective study of the primary location of malignancies in 113 patients with Bazex syndrome, Bologna *et al*^[15] reported the following results: oropharynx and larynx (48.6%), lung (17.7%), unknown location (16%), esophagus (10.6%, one of them with an associated pyriform sinus carcinoma), and isolated cases in the prostate, liver, stomach, uterus, vulva, and bone marrow.

LESER-TRÉLAT SYNDROME

Ulysse Trélat (1884) and Edmund Leser (1901)^[16], both surgeons, were the first to propose that multiple seborrheic keratoses could be associated with internal malignancy. Denucé, who was a resident of Trélat, wrote in 1899 that the professor had often stressed the symptom of “Trélat’s nevi” associated with deep tumors of the abdomen and pelvis in his lectures^[17]. The indication of Leser-Trélat or Leser-Trélat syndrome (LTS) is an eruptive appearance of, or at least a sudden increase in, the number or size of multiple seborrheic keratoses in association with an internal malignancy^[18,19]. No evidence of dermatitis or erythroderma precedes the seborrheic keratoses appearance on the skin and pruritus is a leading symptom in about half of the cases^[20]. Seborrheic keratoses associated with malignancy show no clinical or histological differences compared to patients without neoplasia^[21]. The majority of patients with LTS have adenocarcinomas, most commonly of the stomach^[22,23], colon or rectum^[19,21,24-28], and less frequently carcinomas of esophagus^[29], duodenum^[30], pancreas^[31], gallbladder^[32] or hepatocellular carcinoma^[33].

We observed a 66-year-old man who presented with multiple flat, sharply demarcated, yellowish to brown lesions with a verrucous surface located mainly on the trunk arms and thighs, which were clinically very suggestive of seborrheic keratoses (Figure 3). The patient developed fever and night sweats. A barium enema detected a tumor in the rectum. Computed tomography (CT) showed no evidence of distant metastasis. The rectal lesion was removed surgically, and histology showed moderately differentiated rectal adenocarcinoma involving muscularis propria with no evidence of perirectal lymph node involvement. However, three months after

the operation, seven lung metastases were visualized by CT. During courses of 5-fluorouracil, oxaliplatin and capecitabine chemotherapy, the cutaneous lesions markedly diminished but did not completely disappear^[19]. We found 14 other published cases of Leser-Trélat syndrome associated with colorectal adenocarcinoma in the literature from 1972 to 2004^[19].

About two-thirds of patients with LTS can have other paraneoplastic disorders, the most frequent of which is acanthosis nigricans, which accounts for one third of these cases^[34]. Moreover, Andreev *et al*^[35] considered that Leser-Trélat syndrome represents a particular clinical variant of acanthosis nigricans. The pathogenesis of LTS remains unclear. As in malignant acanthosis nigricans, an increased epidermal staining for the transforming growth factor alpha receptor has been observed^[36].

MUIR-TORRE SYNDROME

In 1967 Muir *et al*^[37], and later Torre^[38], reported patients with multiple sebaceous neoplasms and visceral malignancies. Muir-Torre syndrome (MTS) is defined by the development of internal malignancy, most commonly colon cancer, in association with sebaceous adenomas and epitheliomas, sebaceous carcinomas and multiple or early-onset keratoacanthomas^[39]. The syndrome has autosomal dominant inheritance, and is considered as a subtype of hereditary nonpolyposis colorectal cancer syndrome (HNPCCS). Sixty percent of patients with MTS have a strong family history of visceral malignancy and show clinicopathological overlap with HNPCCS^[40]. The pathogenesis includes mutations in the DNA mismatch repair genes (MLH-1 or MSH-2)^[39]. HNPCC and MTS usually result from an inherited defect in one allele of either MLH1 or MSH2^[41]; however, Muir-Torre syndrome more commonly involves a mutation of MSH2, while HNPCC shows a roughly equal prevalence of MLH1 and MSH2^[42].

Sebaceous gland tumors in MTS include sebaceous adenoma, sebaceous carcinoma and keratoacanthoma with sebaceous differentiation^[40]. Sebaceous hyperplasia and ectopic sebaceous glands do not appear to be significant markers of the syndrome. Sebaceous adenoma is believed to be the most specific lesion of Muir-Torre syndrome and these can sometimes show cystic change or keratoacanthoma-like architecture^[42]. Between 24%-30% of patients with MTS have sebaceous carcinomas^[39,43].

Cancers of the GI tract comprise more than 60% of the visceral malignancies in MTS, and colorectal cancer is the predominant neoplasm^[39,44]. Tumors are located predominantly in the proximal colon (cecum to splenic flexure), in contrast to the general populace, whose colorectal tumors are usually distal to the splenic flexure^[44,45]. An association with colorectal adenomatous polyps was observed in 26% of patients with MTS^[45].

Recently, a 54-year-old Japanese man with MTS who developed a sebaceous carcinoma and concurrently adenocarcinoma of the colon was reported^[46]. A novel germline mutation of the *MSH2* gene with duplication of the genomic region involving exon 7 was identified^[46].

Multiple sebaceous tumors or sebaceous tumors

Figure 1 Hyperpigmented papillomatous plaques in left axial of a male patient with acanthosis nigricans.

Figure 2 "Tripe palms" keratoderma on the palms of the same patient.

Figure 3 Multiple eruptive seborrheic keratoses on the trunk of a 66-year-old patient with rectal adenocarcinoma.

occurring before the age of 50 years are strong indicators of Muir-Torre syndrome. Moreover, MTS should be suspected in all cases when sebaceous gland tumors or multiple keratoacanthomas have been diagnosed. Some authors suggest that all patients with sebaceous-gland neoplasms should be screened for MTS in contrast to those with keratoacanthomas because they are less likely to be markers of MTS^[47]. All patients with MTS should undergo a colonoscopy to detect colorectal neoplasms.

PARANEOPLASTIC DERMATOMYOSITIS

The first report of paraneoplastic dermatomyositis (PDM) was by Stertz^[48], who in 1916 observed a patient with proximal muscle weakness, eyelid changes, muscle

Figure 4 Periorbital heliotrope erythema and edema in a patient with paraneoplastic dermatomyositis.

Figure 5 Violaceous plaques with erosions on the trunk of a patient with paraneoplastic pemphigus.

biopsy evidence of myositis, associated with gastric cancer. Dermatomyositis (DM) is a rare idiopathic inflammatory myopathy that presents clinically with proximal muscle weakness and characteristic cutaneous manifestations^[49]. Skin lesions can be classified as pathognomonic, characteristic, and compatible with DM^[50]. The more specific or pathognomonic manifestations of DM are the periorbital heliotrope rash, and erythematous maculopapular lesions covering bony prominences, described by Gottron in 1931 and named after him as Gottron papules and Gottron sign^[49,50]. The "Heliotrope" rash presents as a red to purple-colored confluent, macular erythema involving symmetrically the eyelids, upper cheeks, forehead, and the temples and is often associated with edema of the eyelids and periorbital tissues (Figure 4). Other characteristic skin lesions include: shawl sign (a violaceous erythema disposed in a "shawl" distribution over the neck, upper back, and shoulders), photosensitive poikiloderma, diffuse redness and shininess of the nail folds, "mechanic's hands" hyperkeratosis, cutaneous calcinosis, and scalp erythema^[49,51]. Other contemporary criteria for diagnosis of DM include the appearance of symmetric proximal muscle weakness, an elevation of serum skeletal-muscle enzymes levels, abnormal electromyography, features of inflammatory infiltration in muscle biopsy, autoantibodies against RNA synthetase antigens (Jo-1, PL-7, PL-12, and OJ) or against Mi2 or SRP antigens in patients' sera^[52].

The increased risk for developing cancer in DM patients has been convincingly demonstrated in several studies from Sweden^[53], Australia^[54], and Scotland^[55]. The malignancy can precede, occur concurrently with, or follow the diagnosis of dermatomyositis. In patients with dermatomyositis several predictive factors for the presence of underlying malignancy have been described including: age over 50 years, male gender, the presence of cutaneous necroses and ulcers, increased erythrocyte sedimentation rate and C-reactive protein, and highly elevated or normal serum creatinine kinase^[56-58].

Different types of tumors are observed in dermatomyositis patients. Adenocarcinomas are the most common and, in general, the frequency of each cancer type corresponds to those in the general population. In a study of 750 patients with polymyositis or dermatomyositis in Sweden, Sigurgeirsson *et al*^[53] reported that the colon (including the rectum) and the lungs were the most frequent cancer sites. Hatada *et al*^[59] mentioned that in Japan, gastric cancer was the most frequent malignant disease (25.4%) among patients with dermatomyositis. In South-Eastern Asia, the incidence of nasopharyngeal carcinoma is elevated in the male population with or without dermatomyositis^[60]. In another retrospective study, 12 patients with internal malignancy were described among group of 64 patients with polymyositis and 28 patients with dermatomyositis^[61]. Of those 12 patients, four had GI tract malignancies (two male patients, 74- and 75-year-old respectively had gastric carcinoma; another 51-year-old female had pharyngeal carcinoma and one female had pancreatic cancer)^[61]. From 1941 to 1988 only one case of paraneoplastic dermatomyositis associated with gastric cancer has been reported in Bulgaria^[62]. Since then, twelve additional PDM cases have been documented^[63]. Two of these 12 cases in our retrospective study of patients with PDM, had GI malignancy; a 54-year-old female who had rectal adenocarcinoma and a 64-year-old patient with pancreatic cancer^[59].

Many authors have stressed the importance of early investigation targeted at detecting malignancy in dermatomyositis. A detailed search for malignancy should be carried out during the first three to five years after the disease onset, however the optimal cancer-screening regimen necessary for patients with a recently diagnosed myositis remains uncertain.

PARANEOPLASTIC PEMPHIGUS

Paraneoplastic pemphigus (PNP) is an autoimmune bullous disease characterized by the production of various autoantibodies against plakin proteins in keratinocytes. The disease was described by Anhalt *et al*^[64] in 1990. Patients with paraneoplastic pemphigus have to fulfill at least four of the following five criteria: polymorphic eruption on skin and mucous membranes, histopathological features that include intraepidermal acantholysis and dyskeratosis with vacuolar changes, intraepidermal and/or basal membrane zone deposition of IgG and C3 on direct immunofluorescence (IF), and serum autoantibodies against 250, 230, 210 and 190 kDa

antigens (mainly desmoglein 1 and 3, periplakin and envoplakin) in immunoblotting^[64,65].

The mucosal involvement includes erosions of the oral cavity, conjunctiva, pharynx, anogenital areas and even the GI mucosa^[65,66]. Cutaneous manifestations of PNP are heterogeneous, and include vesicles and blisters, erythematous to violaceous maculae, papules, plaques, and even erythroderma (Figure 5). The morphology of the lesions resembles a variety of dermatological diseases, including pemphigus vulgaris, bullous pemphigoid, erythema multiforme, and lichen planus^[64,66,67].

Paraneoplastic pemphigus cases have been reported more often in patients with a history of lymphomas, chronic lymphocytic leukemia, poorly differentiated sarcoma and Castleman's disease. In a retrospective study of 163 cases with paraneoplastic pemphigus reported between 1990 and 2003 carcinomas were diagnosed in 14 cases; consisting of adenocarcinoma in seven, squamous cell carcinoma in two, multiple basal cell carcinomas in one, and bronchogenic carcinoma also in one patient^[68]. Ostezan *et al*^[69] presented a patient with severe mucocutaneous involvement of PNP associated with hepatocellular carcinoma. However, PNP is not always accompanied by neoplasia^[69], suggesting that other factors such as drugs and inflammatory diseases can trigger autoantibody formation related to PNP in the absence of a neoplasm^[70].

In 2001, Nguyen *et al*^[71] proposed a new term for this disease—"paraneoplastic autoimmune multiorgan syndrome" (PAMS), which, according to them, reflects the presence of target antigens and the pathologic damage frequently occurring in multiple organ systems including lung, kidney, and muscle.

PEUTZ-JEGHERS SYNDROME (HEREDITARY INTESTINAL POLYPOSIS SYNDROME)

Peutz-Jeghers syndrome (PJS) is an autosomal dominant disorder described in 1921 by Peutz, who noted a relationship between the intestinal hamartomatous polyps and mucocutaneous macules in a Dutch family^[72]. The syndrome is caused by mutations in *STK11/LKB1*, serine/threonine kinase 11 genes, located on band 19p13.3^[73].

Cutaneous lesions consist of 1-5 mm diameter hyperpigmented macules, irregularly distributed over the buccal mucosa, gums, hard palate and lips, mainly on the lower lip. Lentigines usually appear during early childhood, and have a tendency to increase in size^[74]. Larger maculae (melanosis) are rarely seen over the back of the hands, the tips of the fingers and toes, and over the palms and soles^[75].

GI tract manifestations include numerous intestinal polyps in the jejunum, ileum and less frequently in the colon, rectum, stomach and duodenum that are typical hamartomas^[75]. Histology reveals pseudo invasion of the epithelial cells, forming benign glands surrounded by smooth muscle. About half of PJS patients die from cancer before the age of 60. The cumulative risk for

developing GI tract associated cancers in patients with PJS aged 15-64 years varies according to the localization from 0.5% for the esophagus, 29% for the stomach, 13% for the small intestine, 36% for the pancreas to 39% for the colon and rectum^[76].

CRONKHITE-CANADA SYNDROME

In 1955 Cronkhite *et al*^[77] described two women with acquired generalized GI polyps with features of hamartomatous polyps and epidermal changes.

Cutaneous lesions in patients with Cronkhite-Canada syndrome (CCS) include hyperpigmented macules ranging from a few millimeters to 10 cm in diameter, localized on the dorsal surface of the hands, palms, arms, neck, face and scalp^[74]. Fingernails and toenails have discoloration, atrophy, nail plate separation and shedding. Alopecia occurs rapidly and in some cases leads to total hair loss^[74,78].

GI lesions in CCS are hamartomatous polyps histologically revealing pseudopolypoid-inflammatory changes. Although considered a benign condition, in 1967, Gomes da Cruz^[79] reported an association of this syndrome with a cancer of the cecum and descending colon. Among 387 cases published in literature by the end of 2002, Cronkhite-Canada syndrome associated with colon cancer has been reported in 31 (8%) cases, and other 19 CCS patients (5%) had concomitant gastric cancer^[80].

Some authors propose phenotypic overlap between the features of CCS, and Peutz-Jegher syndrome, particular in the morphology of cutaneous and intestinal lesions^[81,82]. In contrast to PJS, however, no underlying genetic mechanism has been found so far in Cronkhite-Canada syndrome.

PARANEOPLASTIC HYPERTRICHOSIS LANUGINOSA ACQUISITA

In 1865, Turner reported a woman with breast cancer whose face and body in two or three weeks became covered with a thick crop of short and white downy hair^[83]. Lanugo hairs are long, thin and unpigmented, affecting the face and spreading in a caudal direction on the entire integument. Paraneoplastic hypertrichosis lanuginosa acquisita (PHLA) is predominant in women, and colorectal carcinoma is the most frequently associated malignancy, followed by lung and breast cancer^[84-86]. Patients usually have metastatic disease at the time of diagnosis and a poor prognosis^[86]. PHLA is associated with other paraneoplastic disorders such as acanthosis nigricans (which supports the hypothesis of tumor-produced cytokines stimulation over hair follicles).

EVALUATION OF PATIENTS WITH DERMATOLOGICAL MANIFESTATIONS ASSOCIATED WITH GI MALIGNANCY

The described dermatologic syndromes are not always

associated with malignancy, but in many cases can be idiopathic. Therefore the practicing physician is confronted with the great challenge of carrying out a comprehensive search for underlying cancer in a systematic and cost effective manner. There are no universally accepted algorithms for the scope of the evaluation in such a patient, but, in general, the work-up should be guided by the following principles: (1) Initial thorough medical history and physical examination (including rectal exam in both sexes, pelvic exam in women and prostate exam in men) followed by basic laboratory testing (complete blood count, erythrocyte sedimentation rate, serum chemistry panel, and urinalysis). At that point, targeted evaluation of any specific patient symptoms or laboratory abnormalities should be pursued (e.g. iron deficiency anemia should be investigated with colonoscopy and upper endoscopy); (2) If the patient is asymptomatic or has no risk factors for a particular type of cancer, age-appropriate cancer screening tests should be carried out (e.g. colonoscopy in patients older than 50); and (3) Limited additional testing, such as CT scan of the chest, abdomen, and pelvis, are recommended for patients with significantly increased risk of malignancy (e.g. smoking, positive family history for cancer). The role of screening with serum prostate specific antigen (PSA), CA125, and CA19-9 has not been well determined.

CONCLUSION

A wide variety of dermatologic signs have been associated with GI malignancy. Cutaneous manifestations might develop before the GI neoplasm is recognized and their prompt recognition can significantly aid in the diagnosis. Once one of the cutaneous lesions associated with GI cancer is diagnosed, an evaluation for underlying malignancy should be undertaken. The evaluation for cancer should start with thorough medical history, physical examination, and basic laboratory testing. In asymptomatic patients, age-appropriate cancer screening tests should be carried out. Targeted additional testing, such as CT scans of the chest, abdomen, and pelvis, is recommended for patients with significantly increased risk of malignancy.

Abstract

Squamous cell carcinoma of the rectum is a rare malignancy. It appears to be associated with chronic inflammatory conditions and infections. The clear association seen between Human Papilloma Virus and various squamous cancers has not been firmly established for the squamous cell cancer of the rectum. The presentation is nonspecific and patients tend to present with advanced stage disease. Diagnosis relies on endoscopic examination with biopsy of the lesion. Distinction from squamous cell cancer of the anus can be difficult, but can be facilitated by immunohistochemical staining for cytokeratins. Staging of the cancer with endoscopic ultrasound and computed tomography provides essential information on prognosis and can guide therapy. At present, surgery remains the main therapeutic option; however recent advances have made chemoradiation a valuable therapeutic addition. Squamous cell carcinoma of the rectum is a distinct entity and it is of crucial importance for the practicing Gastroenterologist to be thoroughly familiar with this disease. Compared to adenocarcinoma of the rectum and squamous cell cancer of the anal canal, squamous cell carcinoma of the rectum has different epidemiology, etiology, pathogenesis, and prognosis but, most importantly, requires a different therapeutic approach. This review will examine and summarize the available information regarding this disease from the perspective of the practicing gastroenterologist.

INTRODUCTION

Squamous cell carcinoma of the gastrointestinal (GI) tract is a rare malignancy. When encountered, it usually involves the esophagus or the anal canal. Occasionally it can be associated with a GI tract fistula, lined by squamous mucosa. Squamous cell carcinoma of the rectum is extremely unusual and unlike squamous cell carcinoma of the esophagus and anal canal, little is known about the etiology, prognosis, and optimal treatment. This review will examine and summarize the available information regarding this disease from the perspective of the practicing gastroenterologist.

EPIDEMIOLOGY

Squamous cell carcinoma of the rectum is a rare entity and only case reports and relatively small case series have been published^[1-24] (Table 1). Schmidtman^[25] in 1919 described the first case of squamous cell carcinoma of the large intestine localized to the cecum. It was not until 1933 that the first case involving the rectum was subsequently described by Raiford^[1]. Since that time, 73 cases have been reported in the English language literature. Based on a review of this literature, the incidence of the disease is approximately 0.10 to 0.25 per 1000 colorectal cancers^[22,26-29]. Of all cases of squamous cell carcinoma of the large intestine, the rectum is the most frequent location for the disease, followed by the right colon^[29]. This is likely an underestimation due to reporting bias and histologic variability.

Given the rarity of the disease, strong epidemiological data regarding patient demographics, risk factors, natural history and optimal treatment is lacking. However, there have been several retrospective reviews that have tried to

Table 1 Reported cases of squamous cell carcinoma of the rectum

provide a framework for understanding this disease.

Squamous cell carcinoma of the rectum appears to affect individuals between the ages of 39 to 93 years old, with a mean age of 57 years. The disease tends to occur more frequently in women than in men. A review of available reports shows that 66% of cases occurred in women and 34% in men. Patients often present with advanced disease, Dukes C or Stage III^[8]. This might be due to a reporting bias based on the fact that most of these case reports come from tertiary care centers. There is no geographic or ethnic predilection that has been established for this disease, but it is interesting to note that Mel'nikov *et al*^[30] reported 107 cases of squamous cell cancer of the rectum in Russia in one center alone. The details of the study are unavailable, and it is unclear why this population would have such a seemingly high incidence of this malignancy. One plausible explanation is that some cases of anal squamous cell carcinoma might have been misclassified as originating in the rectum.

While no clear set of risk factors can be established, several associations have been observed. Some case reports have found squamous cell carcinoma in association with inflammatory processes involving the colon and rectum. Several cases have been reported in patients with ulcerative colitis^[27,31-33], while others have been found in association with infections including Schistosomiasis^[3], *Entamoeba histolytica*^[6] and human papilloma virus (HPV)^[16,23]. Adenocarcinoma has also been associated with squamous cell cancer of both the colon and rectum. Multiple studies have described either synchronous^[5,15,34] or metachronous lesions^[7,15,35,36] of adenocarcinoma occurring in the large intestine of patients with squamous cell cancer of the rectum. Additional coexisting diseases have been described including colonic duplication^[37,38], ovarian cancer^[39], prostate cancer^[7], endometrial cancer^[40], and breast cancer^[15].

PATHOGENESIS

With so few cases described, the exact mechanism behind the development of squamous cell cancer of the rectum remains elusive. Over the years, four hypotheses have developed regarding the pathophysiology of the disease. (1) Some suggest that inflammation or irritation, secondary to inflammatory bowel disease^[32,41,42], infection^[3,6,43] or radiation^[39,44], results in squamous metaplasia from which carcinoma develops^[10]; (2) Hicks and others^[45-47] have described the possibility of pluripotent stem cells capable of squamous differentiation. This theory is supported by the fact that squamous carcinoma is often found in the midst of poorly differentiated cells; (3) Michelassi *et al*^[48] have suggested that epithelial damage causes proliferation of uncommitted basal cells into squamous cells, which then undergo malignant transformation; (4) Histological reviews of adenocarcinomas have demonstrated areas of squamous differentiation, suggesting the possibility that these carcinomas may arise out of preexisting adenomas or adenocarcinomas^[6,46].

A clear association between HPV and squamous cell cancer of the anus has been established. Furthermore,

HPV has been associated with many squamous cell cancers including: skin, oral, vaginal, penile, esophageal and anal. The subclasses most commonly associated with virulent disease include HPV-16, 18, 31 and 33^[49]. The studies relating to HPV and squamous cell cancer of the rectum however, are few and varied in the methods of detection and the results obtained. Frizelle *et al*^[15] and Nahas *et al*^[22] evaluated a total of 11 squamous cell carcinoma patients for HPV using in situ hybridization and detected no HPV deoxyribonucleic acid (DNA) in any of the specimens. Audeau *et al*^[43] used immunohistochemistry to evaluate 20 patients with squamous cell cancer, adenosquamous cancer, and squamous metaplasia of the rectum, none of whom had detectable HPV. Polymerase chain reaction (PCR) has been considered the gold standard for detection of HPV. In two studies^[16,23], a total of four patients, have been evaluated *via* this methodology. All of those evaluated *via* PCR were HPV-16 positive. There have been concerns that the use of PCR for detection of HPV may lead to false positive results secondary to cross contamination. Indeed, two out of the above four patients with squamous cell cancer of the rectum evaluated *via* PCR were noted to have a history of cervical dysplasia, a condition known to be associated with HPV^[23]. At present we do not have firm evidence for a cause/effect relationship between infection with HPV and squamous cell cancer of the rectum.

DIAGNOSIS

Patients with squamous cell carcinoma of the rectum present with symptoms similar to those with adenocarcinoma of the rectum. The symptoms most frequently encountered are rectal bleeding, abdominal pain, change in bowel habits and weight loss^[8,43]. Patients usually experience symptoms for several weeks to months^[4,7].

Proctoscopy or colonoscopy with forceps biopsies of any visible abnormalities are the primary modalities for definitive diagnosis of rectal squamous cell carcinoma. The endoscopic appearance can range from a polyp to an ulcerated obstructing mass. Recent advances in endoscopy have been utilized to detect more subtle lesions. An example of this is narrow band imaging (NBI), a new endoscopic technique that highlights mucosa and underlying capillary networks. Fu *et al*^[42] describe the use of this technique in detection of squamous metaplasia in a patient with ulcerative colitis. If the metaplasia-dysplasia-carcinoma pathway is established as for other cancers, then NBI might play an important role in detecting premalignant lesions.

Occasionally, there can be difficulty either in distinguishing squamous cell cancer of the rectum from that of the anus or other small cell, poorly differentiated tumors on biopsy specimens. Immunohistochemistry has proved useful in characterizing these lesions. The most useful cytokeratins are CAM 5.2, AE1/AE3, and 34B12. CAM 5.2 helps to differentiate rectal from anal lesions. It characteristically stains rectal squamous

cell and adenocarcinoma but not anal squamous cell lesions^[22]. The cytokeratins AE1/AE3 stain positively for cells of squamous origin, helping to delineate less well-characterized lesions^[18,50].

In 1979, Williams *et al*^[6] established diagnostic criteria for squamous cell cancer involving the rectum which included: (1) absence of evidence of squamous cell carcinoma of any other part of the body, indicating possible metastasis; (2) careful proctoscopy to exclude proximal extension of anal squamous cell carcinoma; and (3) lack of a fistulous tract lined by squamous cells. The above criteria are required in conjunction with histology consistent with a squamous carcinoma^[51] without glandular differentiation^[52].

Squamous cell carcinoma antigen (SCC Ag) is a tumor marker that has been found to be associated with squamous carcinoma of the anus. Rasheed *et al*^[53], found SCC Ag to be elevated in three out of six patients with squamous cell carcinoma of the rectum. It was noted that after treatment with chemo- and/or radiation therapy, the SCC Ag normalized. In 2001, Comer *et al*^[27] found an elevated SCC Ag along with metastatic disease in a patient previously treated for rectal squamous cell cancer. Retreatment with chemotherapy and radiation resulted in an improvement in SCC Ag levels. Based on these observations, it appears that SCC Ag level is not suitable for initial diagnosis of squamous cell carcinoma of the rectum, but might be helpful to monitor disease response and progression.

Once the diagnosis of squamous cell carcinoma of the rectum has been established, the work-up should focus on staging of the tumor and evaluation for regional and distant metastasis. Trans-rectal endoscopic ultrasound (R-EUS) has become an integral part of the staging process of rectal cancer of all types. Accurate staging helps to determine appropriate surgical treatment (local excision *vs* radical resection) and the need for adjuvant therapy. The stage of the disease as determined by R-EUS is also predictive of patient survival. In squamous cell cancer of the anus, an increase in stage is associated with a decrease in five-year survival^[54]. While there are no large studies to support this for squamous cell cancer of the rectum, a review of available case reports supports a similar trend. R-EUS helps to determine the depth of tumor invasion. Superficial T1 lesions involve one or more of the first three echo layers (superficial mucosa, deep mucosa, and submucosa) of the rectal wall. Extension into the muscularis propria, the 4th echo layer, denotes a T2 lesion. Transmural invasion through the muscularis propria into the perirectal fat characterizes a T3 lesion, and T4 lesions involve invasion of surrounding organs^[55]. In addition to depth of tumor invasion, local nodal involvement can also be assessed. Size, echogenicity, shape and demarcation are felt to be helpful in distinguishing benign from malignant lymph nodes^[56], although this concept has yet to be validated in rectal cancer. Park *et al*^[57] evaluated the accuracy of R-EUS with fine needle aspiration (FNA) in the detection of rectal cancer. They found nodal involvement *via* only R-EUS in 33% of histologically confirmed nodes. When FNA was added

to the endosonographic examination, the accuracy of the test increased to 87%.

R-EUS should be performed in conjunction with computed tomography (CT) for complete staging. Several studies have compared the two modalities with regards to the staging of rectal cancer. The accuracy of R-EUS was superior to CT for evaluation of wall invasion (T staging), with a sensitivity of 67% to 93% *vs* 53% to 83%, respectively. R-EUS also outperformed CT for nodal staging, sensitivity 80% to 87% *vs* 57% to 72%^[55,58,59]. The current consensus is that R-EUS and CT are complimentary. R-EUS provides better tumor and local lymph node evaluation and CT has the advantage of detecting distant metastasis. Endorectal magnetic resonance imaging (MRI) has also been used for evaluation of local disease, allowing a larger area of view than R-EUS. In the limited studies available, endorectal MRI has yet to be shown to be superior to R-EUS^[60].

TREATMENT

The treatment paradigm for squamous cell carcinoma of the rectum primarily involves surgery. Secondary to the perceived aggressiveness and often late stage of presentation, surgery has always been thought to offer the best chance of a cure. Surgical techniques have been adopted from rectal adenocarcinoma treatment, despite the lack of randomized studies indicating the most appropriate therapy.

Surgery

Surgical options often depend upon tumor characteristics, such as size, location, depth of invasion, and local and distant metastasis. Additional considerations dictating surgical technique include the patient's body habitus and comorbidities^[61].

Local excision is appropriate in selected cases of stage T1 (invasion to the mucosa or submucosa) cancers or possibly stage T2 (invasion to the muscularis propria) lesions. There is growing evidence however, that T2 lesions particularly require close follow-up, as recurrence after local excision can be as high as 20%^[61]. In adenocarcinoma, low-risk lesions have been characterized as those that are well differentiated on histology and demonstrate no endovascular or lymphatic involvement^[62,63]. Clearly, this is in conjunction with no evidence of local or metastatic disease on R-EUS, CT or MRI^[61]. In 1985, Lafreniere *et al*^[8] reported a case of a 60-year-old successfully treated with local excision followed by chemotherapy and radiation. The patient was noted to be alive and well two years after the diagnosis.

For more advanced disease, low anterior resection (LAR) or abdominoperineal resection (APR) can be used for treatment, depending upon tumor location. For lesions in the proximal two-thirds of the rectum, LAR can be performed to remove the tumor-containing rectum. Preserving the anus allows for anastomosis of the descending colon with the distal rectum or anus thus maintaining rectal continuity. APR is performed not only for distal rectal lesions, but also for locally advanced

lesions, where disease free margins cannot be assured. APR allows for excision of anus and rectum as well as abdominal exploration for metastatic disease prior to creation of an ostomy. Overall, APR is associated with increased postoperative complications and poor long-term patient satisfaction^[64]. Review of the available case reports shows APRs have been performed more frequently; 2:1 compared to LAR. This is likely due to more advanced disease at diagnosis, which is frequently the case in squamous cell cancer of the rectum. Only seven of the 41 patients with adequately described surgical interventions underwent local resection^[8,12,22,23].

Chemoradiation therapy

Several studies have evaluated the utilization of chemoradiation therapy (CRT) for the treatment of squamous cell carcinoma of the rectum, as the primary therapy or in conjunction with surgery. Secondary to the infrequency in which cases are encountered, a standard protocol has yet to be established.

Several case reports have used CRT as the primary therapeutic intervention, usually in patients who are high-risk surgical candidates. The early studies^[7,13,29] showed suboptimal results with no significant change in mortality or maintenance of bowel continuity. Recently, Rasheed *et al*^[53] and Clark *et al*^[24] in two separate populations, evaluated the success of CRT in the treatment of squamous cell carcinoma of the rectum. Unlike previous cases^[7,13], these treatment regimens used primarily 5-fluorouracil based treatment along with either mitomycin-C or cisplatin. These were the same drug regimens that revolutionized the therapy squamous cell carcinoma of the anus^[65-68]. Around the same time, the benefits of radiotherapy combined with chemotherapy were also established, making CRT the treatment modality of choice for squamous malignancy involving the anus^[69-73]. Surgery was relegated to the role of salvage therapy^[54]. It was following this paradigm that CRT was adopted for treatment of squamous cell cancer of the rectum. Of the 13 patients treated with CRT by Rasheed and Clark, only three ended up with surgical resections. After histological evaluation, only one of the three resected specimens demonstrated residual tumor. The issue of which chemotherapeutic regimen to use in conjunction with radiotherapy, has not been evaluated in patients with squamous cell cancer of the rectum. Extrapolations can be made from trials in patients with anal canal cancer. A recent large prospective randomized study compared mitomycin C with cisplatin in patients with anal cancer^[74]. There was no difference in five-year survival, locoregional recurrence and distant metastasis between the two groups, but the patients receiving cisplatin had a higher rate of conversion to colostomy.

Endoscopy

Up to this point, endoscopy has not been reported as a treatment option for squamous cell cancer of the rectum, probably due to its rarity. Lee *et al*^[75] in 2000 reported a case of squamous cell metaplasia in the rectum successfully treated with argon plasma coagulation

Table 2 TMN classification for squamous cell rectal cancer

Stage	T	N	M
0	Tis	N0	M0
I	T1	N0	M0
	T2	N0	M0
II A	T3	N0	M0
II B	T4	N0	M0
III A	T1-T2	N1	M0
III B	T3-T4	N1	M0
III C	Any T	N2	M0
IV	Any T	Any N	M1

(APC). The metaplasia-dysplasia-carcinoma relationship has not been established for squamous cell cancer of the rectum. If it is found to be similar to that of colon adenocarcinoma, then APC might provide a safe and easy alternative for the treatment of these lesions. Endoscopic mucosal resection (EMR) involves removal of lesions *via* the endoscopic resection of mucosa and submucosa. It has been used in the removal of superficial adenocarcinoma lesions, particularly in poor surgical candidates^[55]. When used in the treatment of adenocarcinoma, EMR shows a low-risk of recurrence and decreased need for surgery in appropriate populations^[54]. This might prove to be transferable technology to the treatment of rectal squamous cell carcinoma.

PROGNOSIS

The process of evaluating tumor spread is based on the TNM classification system used for squamous cell cancer of the anus: T = tumor invasion into the wall, N = nodal involvement, M = metastasis, (Table 2). From this information, the stage of disease can be established which is the most important predictor of prognosis^[76]. Frizelle's^[15] evaluation of 52 patients with squamous cell carcinoma of the colon revealed a prognosis similar to Stage I / II, node negative adenocarcinoma of the colon. However when nodal involvement occurred, squamous cell cancer demonstrated a worse prognosis stage for stage. Its overall prognosis is poor, secondary the tendency of rectal cancer to have local lymph node involvement compared to malignancy in other parts of the colon. This is in addition to the fact that it frequently presents at a late stage. Mixed squamous cell carcinoma and poor differentiation on histology have been found to be poor prognosticators^[15].

The overall five-year survival rate is 32%, with significant variation by stage; Duke B 50%, Duke C 33% and Duke D 0%. With the addition of adjuvant therapy, it is likely these numbers will improve. Studies have shown better outcomes with preoperative CRT. Nahas^[22] showed there was an increase in sphincter preserving surgeries from 67% to 71% when radiation therapy was added preoperatively.

CONCLUSION

Squamous cell carcinoma of the rectum is a rare malignancy. The available information for review is

clouded by a lack of uniformity in diagnosing staging and treating the disease. It is likely we will never be able to fully establish a firm relationship between it and adenocarcinoma of the colon, as found in other diseases, such as ulcerative colitis. Given the significant number of adenomas and adenocarcinomas reported in these patients, close follow-up for the development of colorectal cancer is warranted. It is likely that advances in technology and treatment of other diseases will also aid our success in management of this disease. Advances in CRT will likely supplant surgery as the primary intervention.

Abstract

Nonalcoholic fatty liver disease (NAFLD) remains a leading cause of chronic liver disease. In the context of NAFLD, the presence of nonalcoholic steatohepatitis (NASH) portends an adverse prognosis with greater risk of liver fibrosis and cirrhosis. Although liver biopsy is the keystone of patient management in NAFLD, it is also increasingly clear that such evaluation has its limitations. The availability of biochemical markers of NAFLD and NASH has tremendous potential to radically alter management strategies for these conditions, as well as to monitor disease activity. Our article provides an overview of biomarker discovery and selection in the setting of NAFLD and highlights future directions in the field.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is a leading cause of chronic liver disease and its incidence is rising worldwide^[1-3]. The term NAFLD is used to describe a wide spectrum of fatty liver changes ranging from simple steatosis to nonalcoholic steatohepatitis (NASH)^[4]. Although simple steatosis usually follows a benign course, steatohepatitis is prone to progress to hepatic fibrosis and cirrhosis leading to excess morbidity and mortality^[5,6]. In this context, early identification of patients with NASH prior to the onset of advanced fibrosis would be helpful in guiding aggressive intervention. Liver biopsy remains the gold standard for obtaining an accurate diagnosis of NASH, as well as for differentiating this condition from simple steatosis. Unfortunately, biopsy is a costly and invasive diagnostic procedure, possibly subject to inter- and intra-observer variability^[7,8]. Thus it is becoming increasingly clear that although liver biopsy is the keystone of patient diagnosis and management in the setting of NAFLD, such evaluation has its limitations. Clinicians should therefore use additional tools to aid clinical assessment and to enhance their ability to identify the patient at risk for NASH and liver fibrosis. Biomarker use is one such tool to better identify subjects with NASH in the context of NAFLD, and hopefully to effectively prognosticate patients with this condition.

The development of NASH biomarkers can be theoretically achieved *via* two different strategies: the first strategy can be defined as “knowledge-based” (deductive method based on the current knowledge of NASH pathophysiology), while the second one is more “unbiased” (inductive strategy). The “knowledge-based” approach relies on a direct understanding of the pathophysiological processes that underlie the development of NASH as well as the evolution of its sequelae. It may consist of biochemical assays aiming to assess attractive novel candidate markers informed by the biology of the disease process. For instance, the understanding of the role played by hepatocyte apoptosis^[9] and insulin resistance^[10,11] in the pathobiology of liver injury has enabled the development of promising biomarkers of NASH, such as caspase-cleaved cytokeratin 18 fragments or numerous different adipokines. On the other hand, the “unbiased” approach involves the use of modern techniques including proteomics, metabolomics, and

bioinformatics that have allowed unbiased investigations of numerous putative markers that may be informative with regard to the various stages of NAFLD, including overt NASH and its sequelae^[12].

This article provides an overview of biomarker discovery and selection in the setting of NASH starting with some “knowledge-based” biomarkers. The list of biochemical markers provided in this review is not intended to be exhaustive; rather, a brief summary of some key biomarkers is provided.

BIOMARKERS OF HEPATOCYTE APOPTOSIS

To illustrate the opportunities and challenges related to the use of “knowledge-based” biomarkers of NASH, let us consider as an example biomarkers of hepatocyte apoptosis. Growing evidence has now accrued that hepatocellular apoptosis plays a central role in NAFLD progression^[9]. Interestingly, data from animal and human studies have suggested that apoptosis is prominent in NASH but not in simple steatosis^[13]. Cytokeratin 18 (CK-18) is the major intermediate filament protein in the liver and one of the most prominent substrates of caspases during hepatocyte apoptosis. Apoptotic cell death of hepatocytes is associated with release of caspase-cleaved CK-18 fragments into the bloodstream^[14], and several studies have demonstrated elevation of these molecules in the context of NAFLD. A pilot study by Wieckowska *et al*^[14] was the first to measure the levels of caspase-generated CK-18 fragments in patients with NAFLD. Results showed that caspase-cleaved CK-18 fragments were significantly higher in NAFLD patients than in controls, and that levels of these molecules correlated with the presence of liver fibrosis^[14]. In line with these results, the usefulness of CK-18 fragments for the diagnosis of NAFLD was subsequently confirmed in obese patients^[15], as well as in pediatric populations^[16]. Interestingly, caspase-generated CK-18 fragments released in NAFLD also serve as an indicator of hepatic inflammation. The increased apoptotic rate as a consequence of the hepatic inflammatory response is reflected by elevation of serum CK-18 fragments that may therefore distinguish NASH from simple steatosis^[17]. These results have been further confirmed; even in NAFLD patients with normal aminotransferase levels^[18].

Although CK-18 fragments can be used to identify patients with NASH and these molecules are currently being incorporated into multimarker schemes^[15], their routine use in patients with suspected NAFLD depends on the answers to several questions: Are the sensitivity and specificity of these tests similar to those obtained with liver biopsy? Where is the test being performed (Gastroenterology Department, Physician’s Office, Outpatient Unit)? What discrimination limits should be used? Is the test being performed for diagnosis or for prognosis? Answers to these questions are part of the scientific evaluation process that is critical for assessing

whether the information gained from CK-18 fragments is worth its cost to the healthcare system. Such answers require the performance of large studies to evaluate the relationship of caspase-cleaved CK-18 fragments with histological phenotypes of interest in the liver and, when applicable, the conduction of clinical trials to relate caspase-cleaved CK-18 fragments to disease risk and to therapeutic responses in patients with NAFLD.

BIOMARKERS OF THE METABOLIC SYNDROME

Although the pathogenesis of NAFLD is clearly multifactorial, this condition is currently considered as the hepatic manifestation of the metabolic syndrome. Comprehensive assessments of the role played by insulin resistance in the pathogenesis of NAFLD have also been published recently^[19-21]. The present review will not attempt to replicate these texts. On the other hand, we aim to provide here a concise overview of biomarkers of the metabolic syndrome (leptin, adiponectin, resistin, soluble RAGE) in the setting of NAFLD, including a display of the evidence linking them to NASH.

Leptin is a peptide hormone, mainly produced by adipocytes, that plays a central role in the regulation of body weight^[22]. In human liver, leptin has been shown to attenuate a number of insulin-induced activities ultimately resulting in insulin resistance^[23]. Furthermore, a proinflammatory and profibrogenic activity of leptin has been reported^[24]. Since leptin has been linked to metabolic abnormalities and insulin resistance, its potential role in NAFLD has been the focus of much investigation. Compared with controls, significantly higher levels of leptin have been observed in patients with NAFLD^[25,26] and in those with NASH^[27,28]. However, there are inconsistencies in published literature, with some authors showing an unaltered level of leptin in the setting of NAFLD^[29]. In addition, serum leptin levels showed no correlation with liver fibrosis^[30].

Adiponectin is an adipose tissue-specific protein whose receptors are expressed in several cell types including hepatocytes^[31]. Main functions of this molecule comprise of the downregulation of inflammatory processes, the promotion of lipolysis, and the prevention of lipid accumulation^[32]. Adiponectin is known to exert antifibrogenic and antiestrogenic effects in the liver^[33]. Hypoadiponectinemia has been suggested as contributing to insulin resistance and the metabolic syndrome^[34], and several studies have reported decreased adiponectin levels in patients with liver steatosis as compared with controls^[35-37]. Of note, some authors have also demonstrated that lower adiponectin levels are associated with more extensive necroinflammation in the setting of NAFLD and that they may contribute to the development of NASH^[38,39]. However, controversy surrounds the role of decreased adiponectin level as a reliable laboratory marker of NASH^[40].

Resistin is a 10 kDa protein of 94 amino acids highly expressed in the adipose tissue. It is a major determinant of hepatic insulin resistance induced by high-fat diet in animal models^[41]. Although human data regarding the role of this adipokine in insulin sensitivity and the metabolic syndrome are controversial^[42], preliminary evidence seems to suggest a potential role of this adipokine in the pathogenesis of NAFLD. Pagano *et al*^[43] have initially shown that patients with NAFLD are characterized by higher serum resistin levels in association with the NASH score, an index that takes into account necrosis, inflammation, and fibrosis in liver biopsies. However, no correlation was found between insulin resistance and hepatic steatosis score^[43]. These findings were recently replicated by Jiang *et al*^[44], who showed that serum resistin levels were significantly elevated in patients with NAFLD compared to controls. In contrast, Cho *et al*^[40] failed to show altered levels of this molecule in Korean male patients.

Besides classical adipokines, levels of soluble receptor for advanced glycation endproducts (sRAGE) have been recently linked to insulin resistance and several components of the metabolic syndrome^[45]. Recently, Yilmaz *et al*^[46] have investigated concentrations of sRAGE across the spectrum of NAFLD. Levels of sRAGE were significantly lower in patients with definite NASH and borderline NASH compared to controls. Interestingly, levels of sRAGE were significantly and inversely correlated with serum aminotransferase, indicating that lower concentrations of sRAGE are associated with the most severe forms of NAFLD^[46].

Altogether, our investigations indicate that a flurry of case-control studies relating biomarkers of the metabolic syndrome to NAFLD and NASH have been conducted in the past decade. Most of the available data are on adipokines, and much less is known about soluble RAGE. Of note, most studies to date also have been carried out in groups of people of Caucasian ancestry, and there are few data on African populations or African Americans. Furthermore, matching of cases and controls limits comparisons across sex and age demographics. Finally, the use of different assays across the studies also makes it difficult to define cut-off points. Additional larger studies of more diverse populations, including a full range of potential confounding variables, would be helpful at this juncture.

MISCELLANEOUS “KNOWLEDGE-BASED” BIOMARKERS

By using the “knowledge-based” approach, numerous other potential biomarkers of NAFLD and NASH have been explored in pilot cross-sectional studies. Angiopoietin-like protein 3 (ANGPTL3) is a liver-derived plasma protein that modulates plasma triglyceride clearance^[47], which has been recently investigated in the setting of NAFLD^[48]. Levels of ANGPTL3 have been found to be higher in patients with NASH than in those with simple fatty liver. Nonetheless, no association with

histological staging and pathological characteristics of NAFLD was seen^[48]. Pentraxin 3 (PTX3) is an acute-phase reactant that reflects the tissue inflammatory response^[49]. It has been recently demonstrated that plasma PTX3 levels may differentiate NASH patients from non-NASH subjects, and that higher plasma PTX3 levels are associated with severe stages of hepatic fibrosis^[50]. However, it is unknown whether any of these biochemical markers are involved in the causal chain of NAFLD progression, mediating the effects of other risk factors (e.g. insulin resistance or inflammation) or whether they merely reflect the presence of NAFLD. Additional basic and clinical research will likely shed more light on these issues.

PROTEOMIC APPROACHES

Proteomic approaches to the identification of NASH biomarkers rely principally on the unbiased comparative analysis of protein expression in normal and diseased liver tissues to identify aberrantly expressed proteins that may represent new biomarkers, as well as direct serum protein profiling^[12]. Proteomics methodologies include the isolation, identification, and quantification of proteins in biosamples by adsorption of proteins to activated surfaces (matrix-assisted laser desorption/ionization technology), or *via* peptide ionization procedures and mass spectroscopy. Mass spectrometry can yield a comprehensive profile of peptides and proteins in biosamples without the need for initial protein separation, thereby facilitating biomarker identification with reduced sample requirements and a high throughput^[12].

Only two studies to date have examined the NAFLD proteome. Younossi *et al*^[51] investigated, by means of surface-enhanced laser desorption/ionization time-of-flight mass spectrometry (SELDI-TOF), serum protein profiles of different subtypes of NAFLD and identified twelve significantly different protein peaks across the study groups. Using a similar SELDI-TOF technique, Trak-Smayra *et al*^[52] have searched for serum markers of steatosis and NASH in obese nonalcoholic patient candidates for bariatric surgery. The authors identified two peaks of 7558.4 and 7924.2 *m/z* that may distinguish between NASH patients and controls. Such peaks were identified as being the double charged ions of hemoglobin-alpha and hemoglobin-beta. There were also three peaks, the intensity of which increased significantly according to severity of liver lesions (steatosis and NASH), but no association was seen with either liver function tests or metabolic parameters^[52].

Although further research of the NAFLD/NASH proteome is certainly needed, the global analysis of protein expression represents an important paradigm shift from the traditional single-molecule approach to the evaluation of protein networks. The future availability of rapid, high-throughput analytical platforms are likely to facilitate molecular phenotyping of different subtypes (simple fatty liver, borderline NASH, definitive NASH) in the spectrum of NAFLD.

CONCLUSION

The need to carry out a biopsy to distinguish NASH from simple steatosis has impeded research to develop strategies for interventions to treat steatohepatitis. In this context, the overall expectation of a NASH biomarker is to enhance the ability of the clinician to optimally manage the patient without the use of liver biopsy^[53]. Theoretically, biomarkers may provide a powerful approach in the understanding of the spectrum of NAFLD, with potential applications in several areas including screening, diagnosis, prognosis, and therapeutic monitoring. Advances in proteomics, metabolomics, and bioinformatics have revolutionized unbiased investigations of several biomarkers that may be informative with regard to the various stages of NAFLD, including NASH and its potential sequelae (advanced fibrosis, hepatocellular carcinoma, end-stage liver disease). Obviously, a crucial prerequisite for the clinical use of biomarkers is elucidation of analytical features, standardization of analytical methods, assessment of performance characteristics, and demonstration of cost-effectiveness. A new biomarker of NASH will be of clinical value only if it is reproducibly obtained in a standardized fashion, it is easy to interpret by clinicians, and if it has high sensitivity and high specificity for identifying NASH, and for distinguishing this condition from benign simple fatty liver. Establishing the prognostic utility of a biomarker in the setting of NAFLD to identify patients that may progress to NASH and fibrosis is more challenging because it requires a prospective design, and serial liver biopsies are presently the gold standard. Although there is evidence to suggest that currently available biomarkers (and their combination) have an increasing ability to distinguish “case” (NASH) from “noncase” (not-NASH) in cross-sectional studies, the step ahead in this field is to differentiate by the use of a biochemical marker “those who will develop fibrosis and end-stage liver disease” from “those who will not” in longitudinal investigations. Hopefully, the ongoing research in NASH biomarker development will also mandate a systematic organization of data that may facilitate the online sharing of biomarker metadata among researchers. Over the next years, technological advances will likely facilitate the use of multimarker profiling to replace the gold standard for the diagnosis of NASH, liver biopsy, with a “biomarker biopsy”^[54].

in macrophages. In addition, lansoprazole-induced ferritin protein levels in both cell systems. Moreover, induction of the antioxidant proteins HO-1 and ferritin by lansoprazole was followed by a decrease in NADPH-mediated ROS formation. The radical scavenging properties of lansoprazole were diminished in the presence of the HO inhibitor, chromium mesoporphyrin IX. Induction of *HO-1* gene expression by lansoprazole was not related to oxidative stress or to the activation of the mitogen-activated protein kinase pathway. However, the phosphatidylinositol 3-kinase inhibitor LY294002 showed a concentration-dependent inhibition of HO-1 mRNA and promoter activity.

CONCLUSION: Activation of HO-1 and ferritin may account for the gastric protection of lansoprazole and is dependent on a pathway blocked by LY294002.

Abstract

AIM: To investigate the molecular mechanism and functional consequences of heme oxygenase-1 (HO-1) activation by lansoprazole in endothelial cells and macrophages.

METHODS: Expression of HO-1 mRNA was analyzed by Northern blotting. Western blotting was used to determine the HO-1 and ferritin protein levels. NADPH-dependent reactive oxygen species (ROS) formation was measured with lucigenin-enhanced chemiluminescence. HO-1 promoter activity in mouse fibroblasts, stably transfected with a 15-kb *HO-1* gene that drives expression of the reporter gene luciferase, was assessed using *in vivo* bioluminescence imaging.

RESULTS: Lansoprazole increased HO-1 mRNA levels in endothelial cells and HO-1 protein levels

INTRODUCTION

Peptic ulcer disease remains common worldwide. It is caused most frequently by stress, alcohol, *Helicobacter pylori* (*H. pylori*) infection, or the use of non-steroidal anti-inflammatory drugs (NSAIDs). It is believed that the integrity of the gastric mucosa depends on a delicate balance between aggressive and defensive mechanisms. Although the cellular and molecular bases of gastric mucosal defense are well understood, the mechanisms by which mucosal damage is mediated by aggressive factors

remain largely unclear. The increased production of reactive oxygen species (ROS), termed oxidative stress, is considered to be a major causative factor for mucosal lesions induced by stress^[1], NSAIDs^[2], and *H. pylori*^[3].

Proton pump inhibitors (PPIs) are the drugs of choice for the therapeutic control of gastroesophageal reflux disease, peptic ulcer disease, and eradication of *H. pylori*, and as mucosal protective agents when using NSAIDs. They have been shown to be more effective than other anti-secretory drugs (i.e. H₂ receptor antagonists) in the management of acid-related diseases^[4]. The anti-secretory action is mediated by their irreversible inhibition of H⁺/K⁺-ATPase, the terminal proton pump of parietal cells^[5]. However, emerging evidence suggests that the benefit of PPIs is not only mediated by their potent blockade of the gastric H⁺/K⁺-ATPase, but also by their ability to provide anti-inflammatory, anti-apoptotic, and antioxidative effects^[6,7]. By scavenging ROS and thus protecting the mucosa, these pleiotropic effects of PPIs may be responsible for maintaining the anatomical and functional integrity of the gastric mucosa. In addition to a variety of endogenous factors such as prostaglandins, nitric oxide, and sulfhydryl compounds, which have been proposed to account for the gastroprotective effects of PPIs^[7,8], we previously have shown that PPIs also induce the antioxidant protein heme oxygenase-1 (HO-1) in gastric epithelial and endothelial cells^[9].

The inducible stress protein HO-1 is the rate-limiting enzyme involved in heme breakdown to generate equimolar amounts of biliverdin, free iron, and CO^[10]. Biliverdin is subsequently converted by biliverdin reductase to bilirubin, which is a potent free radical scavenger and acts as a strong endogenous antioxidant^[11]. CO has been recognized as a protective agent in hemorrhagic shock and as a modulator of vascular tone. Moreover, it shows anti-apoptotic and anti-inflammatory activity^[12]. The HO-1-dependent release of free iron leads to the expression of a second antioxidant protein, ferritin^[13]. Ferritin rapidly sequesters free cytosolic iron, thus limiting the formation of oxygen-centered radicals *via* the Fenton reaction. Thereby, ferritin has emerged as a critical and fast-acting endogenous cytoprotectant that plays an important role in cellular antioxidant defense mechanisms^[13].

The activation of the *HO-1* gene is regulated primarily at the level of transcription involving various signaling pathways. In particular, phosphorylation-dependent signaling cascades that bind to the transcription factors regulating the *HO-1* gene seem to play a key role in *HO-1* gene stimulation. In an inducer- and cell-specific fashion, signaling pathways that are implicated in regulating *HO-1* gene expression are those important for proliferation and cell survival. Many studies have focused on the activation of the mitogen-activated protein kinases (MAPKs). Recently, other investigators have demonstrated a link between the phosphatidylinositol 3-kinase (PI3K) cell survival pathway and regulation of the *HO-1* gene. Some reports suggest a role of cAMP-dependent protein kinase A, protein kinase C, cGMP-

dependent PKG, or tyrosine kinases in HO-1 transcriptional regulation^[14].

The aim of this study was to elucidate the mechanism of gastric protection by PPIs beyond their effective acid reduction properties, using lansoprazole as a model compound. We focused on the activation of the antioxidant proteins, HO-1 and ferritin, by lansoprazole in cell systems that lack the actual PPI target, the H⁺/K⁺-ATPase pump. We then further assessed the underlying mechanism of the upregulation of HO-1 by lansoprazole.

MATERIALS AND METHODS

Materials

Fetal bovine serum (FBS), cell culture media, and penicillin and streptomycin were obtained from GIBCO (Eggenstein, Germany). Chemiluminescence Western Blotting Kit and D-luciferin were purchased from GE Healthcare (Freiburg, Germany) and BioSynth (Naperville, IL, USA), respectively. Wortmannin and primary HO-1 antibody were obtained from Axxora (Grünberg, Germany). PeqGOLD TriFast was purchased from Peqlab (Erlangen, Germany). Chromium mesoporphyrin IX (CrMP) was purchased from Frontier Scientific (Carnforth, UK). For HO-1 probes, the template was an *Eco*RI restriction fragment of the human HO-1 cDNA (clone 2/10), which was kindly provided by Dr. Rex Tyrrell (University of Bath, UK)^[15]. The polyclonal antibody against human ferritin and all other chemicals were obtained from Sigma (Taufkirchen, Germany). The stock solutions of lansoprazole (300 mmol/L), ranitidine (300 mmol/L), MAPK inhibitors [SB203580 (22 mmol/L), SB202190 (20 mmol/L), SP 600125 (45 mmol/L), PD 098059 (22.5 mmol/L)], and PI3K inhibitors [LY294002 (20 mmol/L), wortmannin (100 µmol/L)] were all prepared in dimethyl sulfoxide and stored at -20°C in the dark. The stock solution of CrMP (10 mmol/L) was prepared by dissolving 6.5 mg in 50 µL 2 mol/L NaOH, adjusted to 1.0 mL with sterile water, and stored at -20°C in the dark until use or for up to 12 mo.

Cell culture

Human endothelial-like ECV304 cells were obtained from the European Collection of Cell Cultures (Salisbury, UK). ECV304 cells have been used as a convenient model for the study of vascular endothelial cells^[16,17], because they show endothelium-like properties such as producing endothelium specific Weibel-Palade bodies, endothelium-related antigens and angiotensin-converting enzyme, in addition to having human-umbilical-vein-endothelial-cell-like morphology^[18,19]. Cells were grown in M199 medium that contained 10% FBS, streptomycin (100 µg/mL), and penicillin (100 U/mL). Murine bone-marrow-derived macrophages (J774), obtained from the American Type Culture Collection (Manassas, VA, USA), were maintained in Dulbecco's Minimal Essential Medium (DMEM) that contained 10% FBS, streptomycin (100 µg/mL), and penicillin (100 U/mL). Embryonic

mouse fibroblast cells (NIH3T3-HO-1-*luc*), stably transfected with a transgene that contained the full-length (15 kb) mouse HO-1 promoter that drives expression of the reporter gene luciferase, were grown in DMEM that contained 10% FBS, streptomycin (100 µg/mL), and penicillin (100 U/mL). All cells were maintained in a humidified incubator at 37°C and 5% CO₂.

HO-1 mRNA analysis

Sub-confluent endothelial cells in 150-mm culture dishes were incubated for 8 h in the presence of control medium, lansoprazole, or ranitidine. Superoxide dismutase (SOD), as well as PI3K and MAPK inhibitors, was added 20 min before lansoprazole treatment. Total RNA was extracted using Trizol reagent according to manufacturer's instructions (Peqlab). For Northern blotting, samples that contained equal amounts of RNA (20-30 µg) were separated on a 1% denaturing formaldehyde gel and then transferred onto a positively charged nylon membrane by vacuum (500 mbar). The transferred RNA was fixed by baking at 80°C for 30 min. After incubation, membranes were hybridized with a randomly primed ³²P-labeled human HO-1 cDNA probe^[15] overnight at 65°C. Equal loading of RNA was assessed by staining 18S and 28S rRNAs with ethidium bromide and by a second hybridization using a ³²P-labeled β-actin cDNA probe.

Formation of ROS

NADPH-dependent ROS formation was measured by monitoring lucigenin-derived chemiluminescence at 37°C using a Berthold LB96V luminometer according to previously published protocols^[20]. Cells were first cultured in six-well plates. After pretreatment with lansoprazole or ranitidine for 12 h, cells were washed and suspended in PBS and then lucigenin (5 µmol/L) and NADPH (10 µmol/L) were added. CrMP (3 µmol/L) was added 20 min before lansoprazole treatment. Chemiluminescence was measured in relative light units (RLU) every 5 min over a period of 20 min. Data were expressed as the mean of peak values in the 20-min measurement normalized to the maximal light emission (RLU_{max}%) of time-matched NADPH-treated control cells.

HO-1 and ferritin protein analysis

ECV304 cells and macrophages were cultured in 100-mm dishes as described above. After 4-24 h of incubation with control medium or lansoprazole, cells were washed and extracted as described previously^[21]. One hundred micrograms of HO-1 protein or 20 µg ferritin protein were separated by SDS-PAGE. Proteins were then transferred to a nitrocellulose membrane and incubated with a polyclonal antibody to HO-1 or ferritin. Antigen/antibody complexes were visualized using a horseradish peroxidase chemiluminescence system according to the manufacturer's instructions. The densitometric quantitation was performed using Quantity One Basic software (Bio-Rad, USA).

Figure 1 Effect of ranitidine and lansoprazole on HO-1 mRNA induction in endothelial cells after 8 h of incubation. Fold induction from control levels is shown as mean ± SD of three separate experiments. **P* < 0.05 vs control. Treatment with CdCl₂ was used as a positive control. Representative Northern blotting analysis is shown in the upper panel.

In vivo HO-1 promoter activity

NIH3T3-HO-1-*luc* cells, stably transfected with a 15-kb HO-1 gene upstream of the transcription initiation site that drives expression of the reporter gene luciferase, were treated with control medium or lansoprazole. PI3K and MAPK inhibitors were added 20 min before lansoprazole. After 24 h incubation, luciferin (300 µg/mL) was added to the cells. Light emission, used as an index of HO-1 promoter activity in living cells, was collected using the In Vivo Imaging System (IVIS™, Caliper Life Sciences, Alameda, CA, USA), quantitated using LivingImage software (Caliper Life Sciences), and expressed as photons emitted/5 min, as previously described^[22].

Statistical analysis

Results are expressed as mean ± SD. Data were analyzed using ANOVA and by Bonferroni's correction for multiple comparisons. All statistical calculations were performed using GraphPad Prism 3.02. Differences were considered significant at *P* < 0.05. Analyses were based on three to six independent experiments using different cell passages on different days.

RESULTS

Effect of lansoprazole and ranitidine on HO-1 mRNA levels

In endothelial cells, the effects of ranitidine (an H₂ receptor antagonist) and lansoprazole on HO-1 mRNA levels were compared following 8 h incubation with each compound. Compared to untreated control cells, ranitidine treatment did not affect HO-1 mRNA levels at any concentration (Figure 1). In contrast, lansoprazole treatment elevated HO-1 mRNA levels in a concentration-dependent manner with nearly a sixfold induction at 100 µmol/L. This increase in HO-1 mRNA levels was

Figure 2 Effect of lansoprazole on HO-1 protein expression in macrophages (J774 cells) after 12 h of incubation. Fold induction from control levels is shown as mean \pm SD of three to six separate experiments. $^aP < 0.05$ vs control. Representative Western blotting analysis is shown in the upper panel.

comparable to the induction observed following treatment with the positive control CdCl_2 (10 $\mu\text{mol/L}$).

Effect of lansoprazole on HO-1 protein expression in macrophages

When we investigated the effect of lansoprazole (5–100 $\mu\text{mol/L}$) on HO-1 protein expression in J774 macrophages, a cell system contributing positively to the mucosal defense, a significant 1.75–2.2-fold induction in HO-1 protein levels was found following 12 h of incubation with lansoprazole at concentrations of 30, 50 and 100 $\mu\text{mol/L}$ (Figure 2).

Effect of ranitidine and lansoprazole on NADPH-mediated ROS formation

Activated phagocytes represent a major source of ROS production and are therefore used to investigate oxidative stress in cell systems. To analyze the free-radical scavenging effects of the anti-secretory drugs ranitidine and lansoprazole, macrophages were preincubated with these compounds for 12 h. Ranitidine (30 $\mu\text{mol/L}$) did not affect NADPH-mediated ROS formation (Figure 3). In contrast, lansoprazole (30 $\mu\text{mol/L}$) significantly decreased NADPH-mediated ROS production (20%). To examine whether HO-1 accounted for the cell protection mediated by lansoprazole, the selective HO inhibitor CrMP was used. CrMP (3 $\mu\text{mol/L}$) eliminated the antioxidant action of lansoprazole against NADPH-mediated free-radical formation. No change in NADPH-mediated ROS formation was observed in cells treated with CrMP alone.

Effect of lansoprazole on ferritin protein expression in endothelial cells and macrophages

Increased ferritin protein levels were found in tandem with increased HO-1 protein in macrophages in a concentration-dependent manner after 12 h of incubation with lansoprazole (Figure 4A). Ferritin protein expression

Figure 3 Lansoprazole, but not ranitidine, decreased NADPH-dependent ROS formation in macrophages. This effect was reversed in the presence of CrMP. Measurements of lucigenin-enhanced chemiluminescence were performed. $^aP < 0.05$ vs control; $^cP < 0.05$ vs lansoprazole alone. Data are shown as mean \pm SD of three to six separate experiments.

in endothelial cells also increased in a time-dependent manner following exposure to lansoprazole (Figure 4B). The induction of ferritin protein expression occurred at a lansoprazole concentration of 100 $\mu\text{mol/L}$, which significantly induced HO-1 mRNA and protein levels.

Regulation of the lansoprazole-induced HO-1 gene expression: effect of oxidative stress

Since HO-1 is highly induced by oxidative stress, we evaluated the role of superoxide anion in the PPI-mediated upregulation of HO-1 mRNA. Endothelial cells were treated with lansoprazole (30–100 $\mu\text{mol/L}$) in the presence of SOD for 8 h (Figure 5). Preincubation with SOD (15 U/mL) did not change the basal or lansoprazole-mediated increases in HO-1 mRNA levels. These results indicate that superoxide anion is not involved in the regulation of HO-1 expression by lansoprazole.

Effect of MAPK inhibitors on the lansoprazole-induced HO-1 gene activation

Induction of HO-1 mRNA in endothelial cells after treatment with lansoprazole for 8 h was not influenced by pretreatment with the ERK inhibitor PD098059 (10 $\mu\text{mol/L}$) or the JNK inhibitor SP600125 (10 $\mu\text{mol/L}$) (Figure 6A and B). At a concentration of 10 $\mu\text{mol/L}$, the p38 inhibitor SB203580 had no effect on HO-1 mRNA induction by lansoprazole (50 $\mu\text{mol/L}$). Higher concentrations of the inhibitor decreased HO-1 mRNA levels in comparison to that following treatment with 50 $\mu\text{mol/L}$ lansoprazole alone (Figure 6C). Thus, to further explore the role of p38 MAPK on PPI-mediated HO-1 gene activation, we treated endothelial cells with a second p38 MAPK inhibitor (α and β subunit), SB202190 (0.1–10 $\mu\text{mol/L}$). SB202190 did not affect the induction of HO-1 mRNA by lansoprazole (Figure 6C). Moreover, when we investigated the effect of both p38 MAPK inhibitors on HO-1 promoter activity using NIH3T3-HO-1-*luc* cells, incubation with 30 $\mu\text{mol/L}$ lansoprazole alone for 24 h significantly increased HO-1 promoter

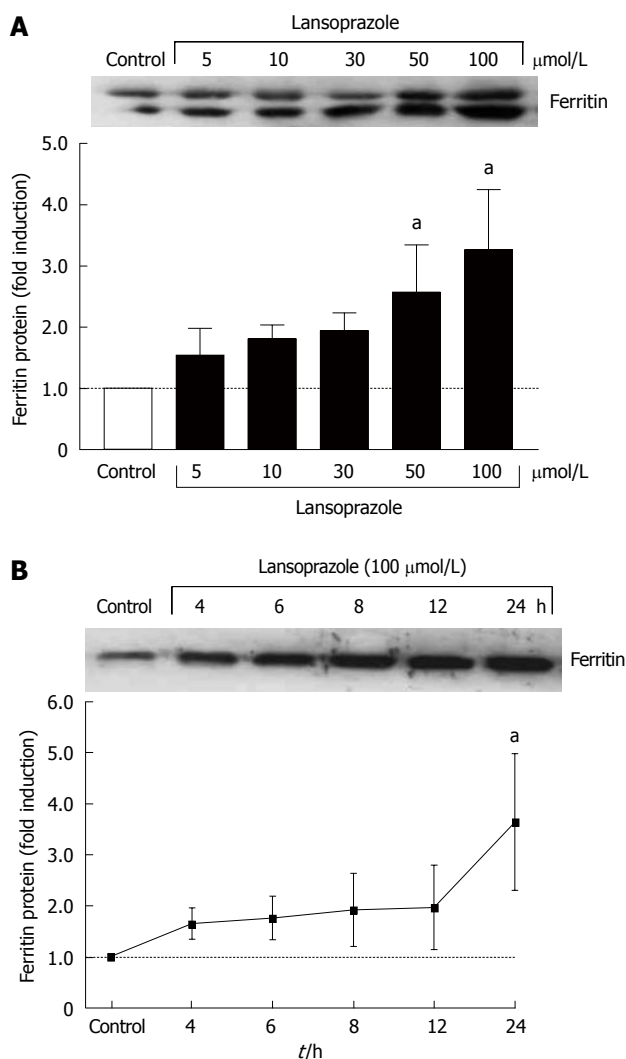

Figure 4 Lansoprazole increased ferritin protein expression in a concentration- and time-dependent manner in macrophages (A) and endothelial cells (B). Data are shown as mean \pm SD of three to six separate experiments. $^aP < 0.05$ vs control. A representative Western blotting analysis is shown in the upper panel.

activity by 1.7-fold compared with untreated control levels (data not shown). Neither p38 inhibitor diminished HO-1 promoter activation by lansoprazole (Table 1). All MAPK inhibitors alone did not affect HO-1 mRNA levels or HO-1 promoter activity.

Involvement of the PI3K pathway in the regulation of HO-1 induction by lansoprazole

Preincubation of endothelial cells with the PI3K inhibitor LY294002 (5-50 μmol/L) diminished the lansoprazole-induced (50 μmol/L) increase in HO-1 mRNA expression in a concentration-dependent manner (Figure 7A and C). Similar effects were observed in NIH3T3-HO-1-*luc* cells (Figure 8A and C). The lansoprazole-mediated (30 μmol/L) promoter activation was abolished by up to 50% in the presence of LY294002 (5-25 μmol/L) (Figure 8C). Preincubation with the fungal metabolite wortmannin (0.01 and 0.1 μmol/L) did not affect the lansoprazole-mediated increase in HO-1 mRNA and HO-1 promoter activity levels (Figure 7B and C, Figure 8B and C).

Figure 5 Effect of SOD on lansoprazole-induced HO-1 mRNA expression. After pretreatment with SOD for 20 min, endothelial cells were incubated with lansoprazole for 8 h. Fold induction compared to control is shown as mean \pm SD of three separate experiments. $^aP < 0.05$ vs control. A representative Northern blotting analysis is shown in the upper panel.

Table 1 Effect of p38 inhibitors SB203580 and SB202190 on lansoprazole-induced HO-1 promoter activity in NIH3T3-HO-1-*luc* cells (mean \pm SD, %)

Treatment	HO-1 promoter activity
Lansoprazole (30 μmol/L)	100.0 \pm 8.4
Lansoprazole (30 μmol/L) + SB203580 (10 μmol/L)	109.2 \pm 9.0
Lansoprazole (30 μmol/L) + SB203580 (20 μmol/L)	108.8 \pm 12.6
Lansoprazole (30 μmol/L) + SB203580 (30 μmol/L)	101.8 \pm 14.4
Lansoprazole (30 μmol/L) + SB202190 (0.1 μmol/L)	91.0 \pm 3.7
Lansoprazole (30 μmol/L) + SB202190 (1.0 μmol/L)	112.4 \pm 15.1

Change from HO-1 promoter activity measured in cells treated with 30 μmol/L lansoprazole.

Both PI3K inhibitors alone did not affect HO-1 promoter activity or transcriptional levels under identical experimental conditions.

DISCUSSION

Since ROS and inflammation are important causative factors for the development of mucosal damage, the pleiotropic effects of PPIs are of particular clinical interest for the control of gastroduodenal ulcers. Thus, investigation of the molecular mechanism of PPI-mediated gastric protection is required.

In this study, we used endothelial cells and macrophages, which play important roles in mucosal defense, to evaluate the effects of PPIs on the HO-1/ferritin system. The blood flow through the endothelial cells that innervate the mucosa is crucial for supplying nutrients, limiting damage, and facilitating repair. Macrophages play key roles in the mucosal immune system, sensing and in response to foreign materials^[23].

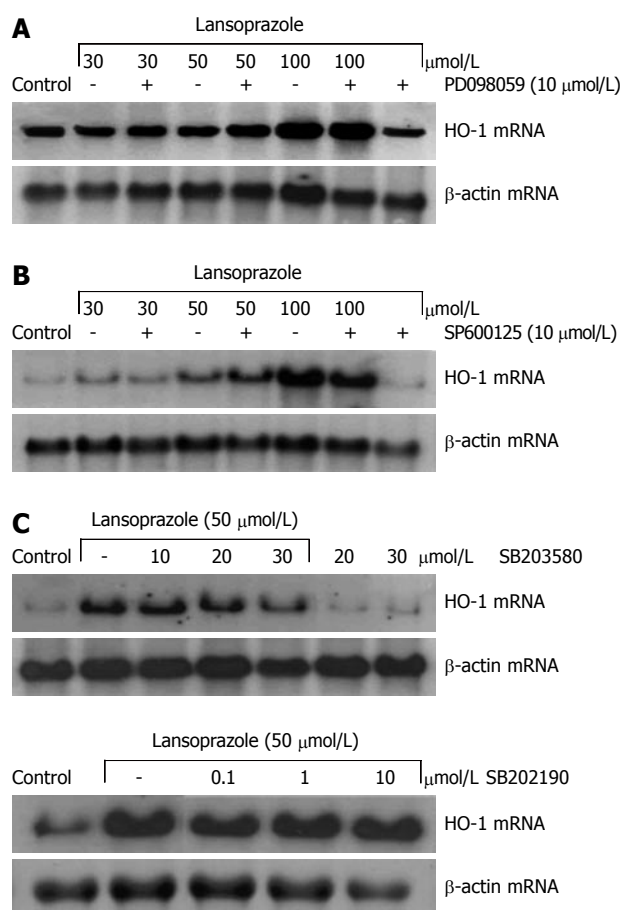

Figure 6 Effect of different MAPK inhibitors on lansoprazole-induced HO-1 mRNA expression. After pretreatment with ERK inhibitor PD098059 (A), JNK inhibitor SP600125 (B), or p38 inhibitors SB203580 and SB202190 (C) for 20 min, endothelial cells were incubated with lansoprazole for 8 h. The Northern blotting analysis shown is representative of three to six independent experiments.

Neither cell type expresses H^+/K^+ -ATPase, therefore, the observed induction of HO-1 and ferritin by PPIs is assumed to be independent of their antiseecretory properties. We have shown previously that PPIs induce HO-1 mRNA, protein and enzymatic activity in gastric epithelial cells and endothelial cells^[9]. In this study, we provided further evidence that activation of the *HO-1* gene by PPIs might account for their beneficial effects in the treatment of peptic ulcer disease. We demonstrated that the H_2 receptor antagonist ranitidine, in contrast to lansoprazole, failed to increase HO-1 mRNA levels. Moreover, lansoprazole also significantly upregulated HO-1 protein levels as a consequence of elevated HO-1 mRNA levels in J774 cells (data not shown). Macrophage-derived ROS production promotes the killing of microorganisms on one hand, but on the other hand, contributes to oxidative stress in inflammatory sites and alters basic cell functions such as adhesion and proliferation^[24,25]. In acute inflammatory illnesses, HO-1 mRNA levels are significantly elevated, which suggests that monocytes exert potent anti-inflammatory effects *via* HO-1 activation, and thereby regulate the production of pro-inflammatory cytokines to protect organs and cells from irreversible damage^[26].

Figure 7 Effect of PI3K inhibitors LY294002 and wortmannin on lansoprazole-induced HO-1 mRNA expression. After pretreatment with PI3K inhibitors for 20 min, endothelial cells were incubated with lansoprazole for 8 h. Representative Northern blotting analysis is shown (A and B). Results are expressed as mean \pm SD of three to six separate experiments compared to lansoprazole (control = gene expression of cells stimulated with 50 μ mol/L lansoprazole = 100%) (C). ^a $P < 0.05$ vs lansoprazole alone.

Thus, upregulation of HO-1 expression by lansoprazole in macrophages could be beneficial in the management of mucosal inflammation.

In addition, we demonstrated that lansoprazole performed free-radical scavenging in macrophages. The protection against NADPH-mediated ROS production by lansoprazole occurred after 12 h of incubation and after washout of lansoprazole. Moreover, the inhibition of the antioxidant effect of lansoprazole in the presence of the HO inhibitor CrMP^[27] demonstrates that HO-1 and its enzymatic products are indeed of functional relevance for the antioxidant effects of lansoprazole.

All experiments in this study have been performed with lansoprazole, but studies using omeprazole have shown similar effects on HO-1 mRNA and HO-1 and ferritin protein expression, as well as on the reduction of ROS (data not shown). Taken together, these data indicate that the induction of HO-1 might be responsible, at least in part, for the antioxidative action of PPIs and their advantage over H_2 -antagonists in the therapy of ulcer disease and NSAID-related mucosal damage.

Our data support other work that has shown that

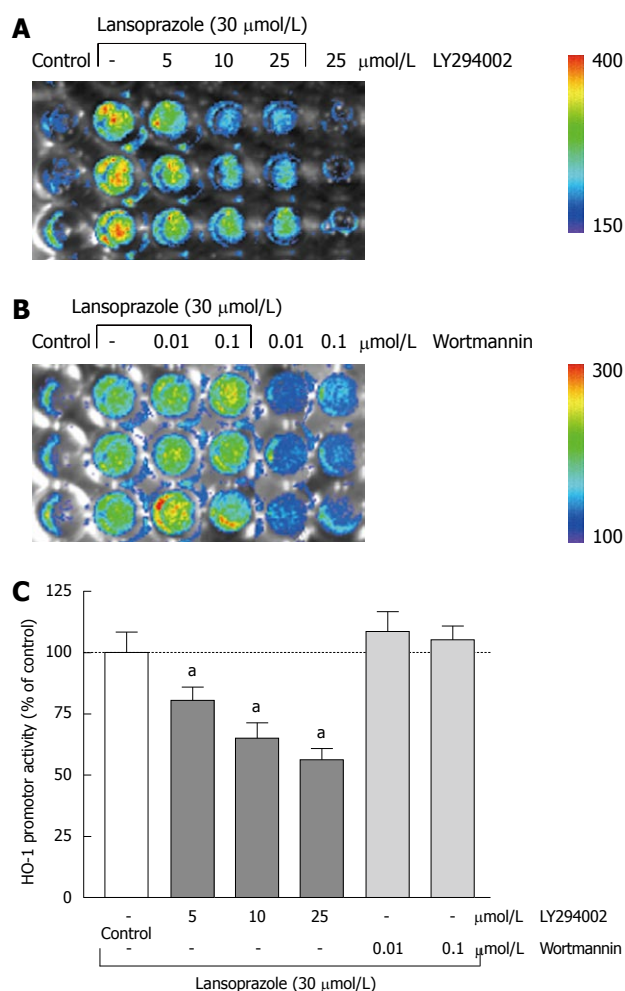

Figure 8 Effect of PI3K-inhibitors LY294002 and wortmannin on lansoprazole-induced HO-1 promoter activity in stable transfected cell lines. Representative images of three to six separate experiments are shown (A and B). Light emission (shown by the rainbow bars: blue, least intense; red, most intense) was measured in NIH3T3-HO-1-luc cells with the IVIS. Results are expressed as mean \pm SD of three to six separate experiments compared to lansoprazole (control = HO-1 promoter activity of cells stimulated with 30 $\mu\text{mol/L}$ lansoprazole = 100%) (C). ^a $P < 0.05$ vs lansoprazole alone.

HO-1 might be a mediator of gastroprotective pathways. Immunohistochemical studies have demonstrated that HO-1 is expressed constitutively in normal gastric and colonic mucosa and its upregulation occurs in these tissues during inflammation or the healing phase of gastric ulcers^[28,29].

In the present study, significant HO-1 induction following treatment with lansoprazole in endothelial cells and macrophages, as well as antioxidant protection occurred at a concentration of 30 $\mu\text{mol/L}$. Plasma concentrations after oral administration of lansoprazole (30 mg/d) ranged from 2.2 to 5.6 $\mu\text{mol/L}$ ^[30]. Depending on the dose (30-90 mg/d) and the route of administration, higher plasma concentration levels (e.g. 15-21 $\mu\text{mol/L}$) may be attainable^[31,32]. These concentrations approximate the concentrations found to be effective at increasing the level of HO-1 expression in the present study. Furthermore, Blandizzi and co-workers have suggested that the ED₅₀ of lansoprazole needed to provide gastroprotection is 2-4 times higher compared to that needed for

inhibition of acid secretion^[7].

The anti-inflammatory and antiproliferative actions of the HO-1 product CO, as well as the potent antioxidant effect of bilirubin, are thought to contribute to the overall protective effect of HO-1^[12]. CO has also been shown to provide vasodilatory activities through the activation of soluble guanylyl cyclase^[33]. Omeprazole and lansoprazole induce relaxation of isolated human arteries^[34] at the same concentration range (30-300 $\mu\text{mol/L}$ lansoprazole) that we have found to be effective in the induction of HO-1. Although Naseri and co-workers have suggested the regulation of intracellular Ca^{2+} as an underlying mechanism, it might also be possible that the generation of CO by HO-1 activity contributes to the vasodilatory effect of PPIs.

The third direct product of heme metabolism, free Fe^{2+} , leads to the induction of a multimeric iron-chelating protein, ferritin^[35]. In the present study, the ferritin protein induction by lansoprazole occurred in a concentration- and time-dependent manner in macrophages and endothelial cells. The activation of ferritin protein synthesis was obtained after long incubations (12-24 h) and at concentrations that have also been shown to result in HO-1 mRNA and protein increase, which suggests ferritin induction as a functional consequence of elevated HO-1 activity.

Besides induction through its physiological substrate heme, HO-1 gene expression can also be stimulated by a variety of stress inducers including, but not limited to, heavy metals, ultraviolet irradiation, endotoxin, and oxidants such as hydrogen peroxide^[14]. In contrast, antioxidants such as α -tocopherol and allopurinol prevent the upregulation of HO-1^[36]. Thus, we investigated the role of ROS in PPI-mediated HO-1 induction. Pretreatment with the antioxidant enzyme SOD did not affect lansoprazole-mediated HO-1 induction, precluding a mediator role of superoxide.

Recently, it has been shown by Yeo and co-workers that PPIs influence MAPK-dependent pathways^[37]. However, in the present study, the ERK inhibitor PD098059 and the JNK inhibitor SP600125 had no inhibitory effect on lansoprazole-induced HO-1 mRNA. All inhibitors have been used in concentrations previously shown to be effective in the inhibition of the final kinase of the respective MAPK cascade^[38,39]. The p38 kinase inhibitor (α - and β -subunit) SB203580, at a concentration of 30 $\mu\text{mol/L}$, impaired the lansoprazole-mediated HO-1 mRNA induction. SB 203580 has been shown to inhibit its established targets, the α - and β -subunit of p38 with IC₅₀ values of 50 and 500 nmol/L, respectively. Yet, other kinases like lymphocyte-specific protein tyrosine kinase, glycogen synthase kinase-3 β (GSK3 β) and Akt1 (protein kinase B α) were also inhibited by SB 203580, with IC₅₀ values that were 100 \pm 500-fold higher than that for p38^[40]. As SB203580 interacts with other kinases at higher concentrations, we determined the effect of a second p38 inhibitor, SB202190, on HO-1 mRNA induction by lansoprazole. SB202190 was without effect on the lansoprazole-mediated increase in HO-1 mRNA. In agreement with

this, both p38 inhibitors have been without effect on lansoprazole-induced HO-1 promoter activity in NIH3T3-HO-1-*luc*-cells, which indicates that MAPK activation is not involved in PPI-mediated HO-1 induction.

The PI3K inhibitor LY294002 diminished the increase of HO-1 mRNA level and HO-1 promoter activity induced by lansoprazole in a concentration-dependent manner. Surprisingly, a second PI3K inhibitor, wortmannin, did not affect HO-1 expression. Although both PI3K inhibitors have been shown to block the phosphorylation of PI3K completely at the concentrations used in our study^[41,42], the potency to interact with other kinases is different. An inhibitory effect by LY294002 but not by wortmannin on HO-1 induction has already been described by other groups, which suggests that PI3K is not involved in *HO-1* gene activation in these particular cases^[43,44]. LY294002 is also known to block casein kinase 2 (CK2) and GSK3 β by up to 50% at a concentration of 50 $\mu\text{mol/L}$ ^[40]. Moreover, the phosphorylation of PI3K downstream kinase p70^{s6k} is inhibited almost completely at a concentration of 10–25 $\mu\text{mol/L}$ LY294002, whereas the inhibition of Akt phosphorylation requires LY294002 doses of up to 150–200 $\mu\text{mol/L}$ ^[45]. Therefore, a different influence of special PI3K downstream kinases or an involvement of CK2 or GSK3 β on the PPI-mediated *HO-1* gene activation is conceivable. Indeed there is evidence that CK2 might exert a significant influence on *HO-1* gene activation by the phorbol 12-myristate 13-acetate^[46]. Further studies are needed to clarify the influence of GSK3 β , CK2 and PI3K downstream kinases on HO-1 induction by PPIs.

In summary, we demonstrated that lansoprazole is a potent inducer of the antioxidant proteins HO-1 and ferritin. The induction of HO-1 by lansoprazole is independent of oxidative stress, and involves a signaling pathway that is blocked by LY294002. The activation of the HO-1/ferritin pathway occurs in endothelial cells and macrophages; cells relevant to the mucosal microcirculation and the mucosal immune system. Neither cells express H⁺/K⁺-ATPase, therefore, the observed induction of HO-1 and ferritin by lansoprazole can be assumed to occur independently of the antiseecretory effect. It is plausible that HO-1 and its enzymatic products are responsible for, or contribute to, the gastric protection seen with lansoprazole and other PPIs.

ACKNOWLEDGMENTS

We thank Hendrik J Vreman, PhD (Department of Pediatrics, Stanford University School of Medicine, Stanford, CA, USA) for valuable discussions and for critically reviewing the manuscript, and Petra Schwartz for her excellent technical assistance.

COMMENTS

Background

Proton pump inhibitors (PPIs) irreversibly inhibit the gastric proton pump

in parietal cells and are therefore potent antiseecretory drugs. However, comparisons with other acid-reducing agents suggest that the gastroprotective effect of PPIs cannot be explained solely by their antisecretory action. Recent studies have revealed anti-apoptotic, anti-inflammatory, and free-radical scavenging properties of PPIs. The inducible stress protein, heme oxygenase-1 (HO-1), catalyzes the degradation of heme. As a result of the antioxidative, anti-inflammatory, and vasodilatory effects of its products, bilirubin and CO, HO-1 is believed to be a mediator of cytoprotective pathways.

Research frontiers

The pathogenesis of gastric ulcer disease is generally characterized by a decrease in mucosal defense and an increase in aggressive mechanisms. Although the cellular and molecular basis of the gastric mucosal defense are well understood, the mechanisms of mucosal damage mediated by aggressive factors remain largely unclear. The increased production of reactive oxygen species (ROS), termed oxidative stress, is considered to play a crucial role in the development of mucosal damage.

Innovations and breakthroughs

The induction of the antioxidant proteins HO-1 and ferritin by PPIs occurs independently of their antisecretory effects. It is plausible that HO-1 and its enzymatic products are responsible for, or at least contribute to, the gastric protection observed with PPI treatment. There is evidence that PPIs activate the *HO-1* gene through a phosphatidylinositol 3-kinase (PI3K)-dependent pathway.

Applications

The present results suggest that the cytoprotective effects of PPIs can be ascribed to a reduction of oxidative stress via induction of the HO-1/ferritin system in endothelial cells and macrophages. PPIs might be beneficial for cardiac patients and patients on daily pain medication by enhancing gastric mucosal protection and reducing the risk of gastrointestinal bleeding caused by chronic use of aspirin and other NSAIDs. Moreover, PPI-dependent HO-1 induction in endothelial cells of the systemic circulation might exert vascular-protective actions.

Terminology

HO-1 is also known as heat shock protein 32. The enzyme catalyzes the degradation of heme and leads to the accumulation of free iron, CO, and bilirubin. HO-1 is the inducible of two isoforms of the enzyme. PI3K catalyzes the production of the plasma membrane lipid phosphatidylinositol-3,4,5-trisphosphate. Signaling pathways downstream of PI3K affect cell growth, survival and movement.

Peer review

The manuscript investigated molecular mechanism(s) for lansoprazole-induced gastric protection. The authors used endothelial cells and macrophages as models for cytoprotection and showed that lansoprazole induced HO-1 and ferritin and thereby decreased ROS formation in those cell systems. This *HO-1* gene activation involved the PI3K pathway. The authors' hypothesis that lansoprazole upregulates HO-1 and thereby protects gastric mucosa is provocative.

Abstract

AIM: To assess each layer of the optical coherence tomography (OCT) image of the esophageal wall with reference to the histological structure.

METHODS: Resected specimens of fresh pig esophagus was used as a model for the esophageal wall. We injected cyanoacrylate adhesive into the specimens to create a marker, and scanned them using a miniature OCT probe. The localization of these markers was assessed in the OCT images. Then we compared the OCT-imaged morphology with the corresponding histological section, guided by the cyanoacrylate adhesive markers. We prepared a second set of experiments using nylon sutures as markers.

RESULTS: The OCT image of the esophageal specimen has a clear five-layered morphology. First, it consisted of a relatively less reflective layer; second, a more reflective layer; third, a less reflective layer; fourth, a more reflective layer; and fifth, a less reflective layer. Comparing the OCT images with marked histological sections showed that the first layer corresponded to stratified squamous epithelium; the second to lamina propria; the third to muscularis mucosa; fourth, submucosa; and fifth, muscularis

INTRODUCTION

The recent widespread use of endoscopy has enabled us to detect early stage superficial esophageal squamous cell carcinoma (SESCC). Endoscopic resection can be performed for these SESCO with the advantage of it being a minimally invasive treatment for patients^[1-5]. According to a draft of subclassifications of SESCO that was formulated by the Japanese Society for Esophageal Disease^[6], the depth of invasion of SESCO is defined as follows: epithelial layer (T1a-EP), proper mucosal layer (T1a-LPM), muscularis mucosa (T1a-MM), upper third of the submucosal layer (SM1), middle third of the submucosal layer (SM2), lower third of the submucosal layer (SM3). Based on this subclassification, endoscopic resection is indicated only for “T1a-EP” or “T1a-LPM” cancers because their frequency of lymph node metastasis is extremely rare. On the other hand, it was reported that

lymph node metastasis was observed in 8% of “T1a-MM” cancers and 13% of “SM1” cancers^[7], and that endoscopic resection may be insufficient as a radical therapy for these “T1a-MM” or “SM1” cancers^[6-10]. Therefore, an accurate diagnosis of depth of cancer invasion is important in the decision for an appropriate treatment for the SESCC patients, especially for the patients with “T1a-MM” or “SM1” cancers. Until now, endoscopic ultrasonography (EUS) has been the standard examination for the assessment of depth of cancer invasion in SESCC. However, its accuracy for diagnosing “T1a-MM” and “SM1” cancers is inadequate^[11].

A new imaging modality, optical coherence tomography (OCT)^[12] is a non-invasive optical imaging technology that provides high resolution, cross-sectional images of biological tissue in real time. OCT is analogous to B-scan ultrasonography (US); however, it measures reflected infrared light rather than acoustical waves. The resolution of OCT imaging (10-20 μm) is 5 to 25 times higher than that of high frequency US. Therefore, OCT is a currently available clinical device with the highest resolution for intraluminal tomographic imaging^[13].

Several *in vivo* and *in vitro* studies have reported the feasibility of OCT imaging in the GI tract^[14-28]. For the normal esophageal wall, it was reported that the OCT image was delineated as a layered morphology. However, there are few studies concerning the histological interpretation with regard to the layered morphology of the OCT image and these studies differ in their interpretation.

The aim of this study was to ascertain which layer of the OCT image corresponded to each component of the esophageal wall.

MATERIALS AND METHODS

We employed an OCT system developed by Light Lab Imaging (Boston, USA) and HOYA (Tokyo, Japan) (Figure 1). The OCT images were obtained using a superluminescent diode light source with a center wavelength of 1300 nm, a bandwidth of 50 nm, and power output 10 mW, resulting in a 10-20 μm axial image resolution. The lateral or transverse resolution was determined by the diffraction limit of the OCT endoscopic catheter. The spot diameter that resulted from the diffraction of the light was selected to be comparable to the axial OCT resolution while maintaining an appropriate depth of focus. By scanning the interrogating beam across the tissue surface, a series of tomograms were obtained and constructed into a two-dimensional image.

We used a 1.5 mm diameter prototype OCT probe which could be inserted through the accessory port of an endoscope and provide a 360-degree radial scan. Since the OCT beam is invisible, the position of the beam on samples was monitored using a coincident, visible-light, guiding beam (670 nm). OCT images were typically displayed in gray-scale. That is, the image could be configured to represent highly reflective signals as white, and low reflective signals as black.

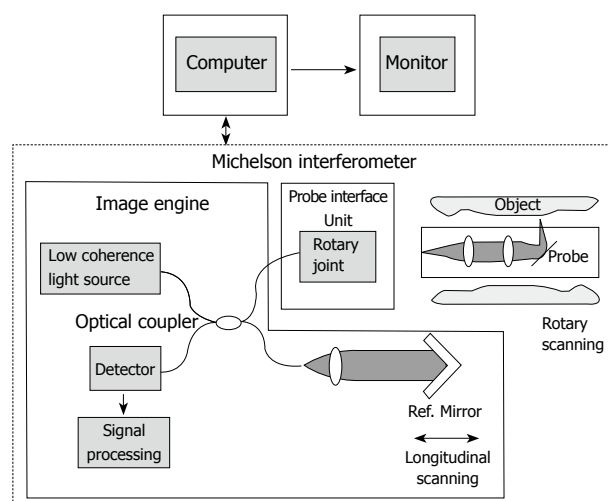

Figure 1 Schema of the OCT system (Light Lab Imaging, Boston, USA, and HOYA, Tokyo, Japan) used in the present study. Near infrared light is generated from the light source, and then is split evenly. One beam is directed to the tissue sample and the other to a reference mirror. The light is reflected from both the sample and mirror. The reflected light beams are recombined in a beam splitter.

Figure 2 OCT image of a fresh pig esophageal wall specimen. OCT image of the esophageal wall delineated a five-layered morphology (arrows) consisting of a relatively less reflective layer (the first layer), a more reflective layer (the second layer), a less reflective layer (the third layer), a more reflective layer (the fourth layer), and a less reflective layer (the fifth layer). The white bar represents 1 mm.

We assessed the layered morphology of OCT images of the esophageal wall, referring to previous studies for the identification of the layered morphology of the GI tract wall with EUS^[29,30]. We employed fresh pig esophageal wall as tissue specimens, because the histological structure of the pig esophageal wall is similar to that of humans. The tissue specimens were used within two hours, because the inherent optical property of the specimens may change with time. Excess blood and mucus were carefully removed by washing with saline. Specimens were then stretched and pinned onto a rubber plate with the luminal surfaces exposed. The position for the OCT imaging was marked on the specimen using two needles pinned through the specimen about 2 mm apart. To create a marker for identifying the layered morphology of the OCT image, we injected a small amount of cyanoacrylate adhesive

Figure 3 OCT image and corresponding histological sections of esophageal wall specimen injected with cyanoacrylate adhesive into the first layer. A: OCT image of the esophageal wall specimen injected with cyanoacrylate adhesive into the first layer (relatively less reflective layer). The injection location of cyanoacrylate adhesives into the first layer is clearly recognized. B: Corresponding histological section. The cyanoacrylate adhesive is observed in the stratified squamous epithelium (HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm. EP: Stratified squamous epithelium; LP: Lamina propria; MM: Muscularis mucosa; SM: Submucosa; MP: Muscularis propria; AD: Adventitious tissue.

Figure 4 OCT image and corresponding histological sections of esophageal wall specimen injected with cyanoacrylate adhesive into the second layer. A: OCT image of the esophageal wall specimen injected with cyanoacrylate adhesive into the second layer (more reflective layer). The injection location of cyanoacrylate adhesive into the 2nd layer is clearly recognized. B: Corresponding histological section. The cyanoacrylate adhesive is observed in the lamina propria (HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

with a needle (24 G, diameter 400 μm) into the tissue specimen between the two needles. After the injection, we scanned the position between the two needles with the OCT probe.

The specimens were subjected to routine histological processing. Briefly, the specimens were immersed in 10% buffered formalin for 48 h and processed for standard paraffin embedding. Five-micron-thick sections were cut at the marked position and stained with Hematoxylin-Eosin (HE) and Elastica-Masson (EM). Finally, the layered morphology of OCT images was compared with that of each marked histological section.

We performed another experiment using nylon sutures as a marker instead of injecting cyanoacrylate adhesive. Thin nylon sutures (surgical suture with a needle: diameter 70 μm approximately) were passed through each layer of the specimens to create a marker on each layer imaged by OCT.

RESULTS

The OCT image of normal esophageal wall

Figure 2 shows an OCT image of the normal pig esophagus specimen. In the OCT image, the five-layered morphology of the esophageal wall is clearly delineated. The layers were arranged outward as follows: a relatively less reflective layer (the first layer), a more reflective layer (the second layer), a less reflective layer (the third layer), a more reflective layer (the fourth layer), and a less reflective layer (the fifth layer).

Comparison of the OCT image with histology using cyanoacrylate adhesive as a marker

Figures 3-7 show OCT images and corresponding histology of the normal pig esophageal wall injected with cyanoacrylate adhesive. The OCT image after injection with cyanoacrylate adhesive into the first layer and corresponding histology are shown in Figure 3. The position injected with cyanoacrylate adhesive was recognized as a non-reflective spot. The non-reflective spot was observed in the first layer of the OCT image. In the corresponding histological section, the cyanoacrylate adhesive was observed in stratified squamous epithelium. Therefore, we confirmed that the first (relatively less reflective) layer of the OCT image corresponded to stratified squamous epithelium. The second (more reflective) layer corresponded to lamina propria (Figure 4), the third (less reflective) layer corresponded to muscularis mucosa (Figure 5), the fourth (more reflective) layer corresponded to submucosa (Figure 6), and the fifth (less reflective) layer corresponded to muscularis propria with deeper structures of the esophageal wall (Figure 7).

Comparison of the OCT image with histology using thin nylon suture as a marker

Figures 8-12 show OCT images and corresponding histology using thin nylon sutures as markers. In Figure 8, the thin nylon suture was recognized as a more reflective dot in the first layer of the OCT image. In the corresponding histological section, the fragment of

Figure 5 OCT image and corresponding histological sections of esophageal wall specimen injected with cyanoacrylate adhesive into the third layer. A: OCT image of esophageal wall injected with cyanoacrylate adhesive into the third layer (less reflective layer). The injection location of cyanoacrylate adhesive into the third layer is clearly recognized. B: Corresponding histological section. The cyanoacrylate adhesive is observed in the muscularis mucosa (HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

Figure 6 OCT image and corresponding histological sections of esophageal wall specimen injected with cyanoacrylate adhesive into the fourth layer. A: OCT image of esophageal wall specimen injected with cyanoacrylate adhesive into the fourth layer (more reflective layer). The injection location of cyanoacrylate adhesive into the fourth layer is clearly recognized. B: Corresponding histological section. The cyanoacrylate adhesive is observed in submucosa (HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

Figure 7 OCT image and corresponding histological sections of esophageal wall specimen injected with cyanoacrylate adhesive into the fifth layer. A: OCT image of esophageal wall specimen injected with cyanoacrylate adhesive into the fifth layer (less reflective layer). The large white arrow indicates the injection location for cyanoacrylate adhesive. B: Corresponding histological section. The cyanoacrylate adhesive is observed in the muscularis propria (HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

thin nylon suture was observed in stratified squamous epithelium. Therefore, we confirmed that the first (less reflective) layer of the OCT image corresponded to stratified squamous epithelium. The second (more reflective) layer corresponded to the lamina propria (Figure 9), the third (less reflective) layer corresponded to the muscularis mucosa (Figure 10), the fourth (more reflective) layer corresponded to the submucosa (Figure 11), and the fifth (less reflective) layer corresponded to the muscularis propria with deeper structures of the esophageal wall (Figure 12).

Figure 13 presents a schema of the OCT image of the normal esophageal wall with a delineated five-layered morphology, consisting of relatively less reflective stratified squamous epithelium, more reflective

lamina propria, less reflective muscularis mucosa, more reflective submucosa, and less reflective muscularis propria with deeper structures of the esophageal wall.

DISCUSSION

We have shown that OCT can clearly delineate the five-layered morphology of the normal pig esophageal wall *in vitro*. In addition, we confirmed that the layered morphology imaged by OCT matches the histological structure of the esophageal wall.

Sergeev *et al.*^[14] were the first to report that they obtained OCT images of the human esophageal wall and stomach. Also, several studies demonstrated the utility of OCT for the diagnosis of Barrett's esophagus

Figure 8 OCT image and corresponding histological sections of esophageal wall specimen with a thin nylon suture in the first layer. A: OCT image of esophageal wall specimen with a thin nylon suture in the first layer (relatively less reflective layer). The marker of the thin nylon suture (large white arrow) is recognized in the 1st layer. B: Corresponding histological section. The fragment of nylon suture is observed in the stratified squamous epithelium. (HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

(HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

Figure 10 OCT image and corresponding histological sections of esophageal wall specimen with a thin nylon suture in the third layer. A: OCT image of esophageal wall specimen with a thin nylon suture in the third layer (more reflective layer). The marker of thin nylon suture (large white arrow) is recognized in the third layer. B: Corresponding histological section. The fragment of thin nylon suture is observed in the muscularis mucosa. (HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

Figure 11 OCT image and corresponding histological sections of esophageal wall specimen with a thin nylon suture in the fourth layer. A: OCT image of esophageal wall specimen with a thin nylon suture in the fourth layer (more reflective layer). The marker of thin nylon suture (large white arrow) is recognized in the fourth layer. B: Corresponding histological section. The fragment of nylon suture is observed in the submucosa. (HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

(BE) because the high resolution of OCT images could distinguish BE from stratified squamous epithelium or gastric mucosa^[15-22].

In the normal squamous stratified epithelium of the

human esophageal wall, several studies demonstrated *in vivo* that the OCT image of the esophageal wall was delineated as a five-layered morphology, and that the muscularis mucosa was delineated as a less reflective

Figure 12 OCT image and corresponding histological sections of esophageal wall specimen with a thin nylon suture in the fifth layer. A: OCT image of esophageal wall specimen with a thin nylon suture in the fifth layer (more reflective layer). The marker of thin nylon suture (indicated within white circle) is recognized in the fifth layer. B: Corresponding histological section. The fragment of nylon suture is observed in the muscularis propria. (HE, original magnification $\times 4$). C: Corresponding histological section (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

Figure 13 A schema of the correspondence between the OCT image of normal esophagus and histology. The OCT image of normal esophageal wall delineates a five-layered morphology, consisting of relatively less reflective stratified squamous epithelium (the first layer), more reflective lamina propria (the second layer), less reflective muscularis mucosa (the third layer), more reflective submucosa (the fourth layer), and less reflective muscularis propria with deeper structures of esophageal wall (the fifth layer). (EM, original magnification $\times 4$). The white and black bars represent 1 mm.

layer^[14-17,23]. However, Sivak *et al*^[24] reported that the esophageal wall was observed as an eight-layered morphology, and that the muscularis mucosa appeared to be a relatively thick triple layer (two more reflective layers separated by one of less reflectivity). Das *et al*^[25] reported that muscularis mucosa was delineated as a more reflective multilayered structure. Jäckle *et al*^[23] attempted to interpret *in vivo* OCT images compared with the histological structure using vessels or glands in the biopsy or mucosectomy specimens of the esophageal wall as markers, resulting in the association of the main structures of *in vitro* OCT images with epithelium, lamina propria and muscularis mucosa. However, it has proved difficult to determine all the layers of the esophageal wall visualized by OCT using only biopsy and mucosectomy specimens. Therefore, correlation of the layered morphology of the *in vivo* OCT image with the histological structure of esophageal wall has not been sufficiently clarified.

On the other hand, *in vitro* studies of surgically resected specimens or autopsies can compare OCT images of the esophageal wall with full thickness sections. Cilesiz *et al*^[26] reported that OCT images of esophageal wall were observed to closely agree with *in vivo* data. But, even for *in vitro* studies, the interpretation of OCT images of esophageal wall is still under discussion. Tearney *et al*^[27] suggested that muscularis mucosa was more reflective than stratified squamous epithelium. Other studies reported that stratified squamous epithelium presented as a more reflective layer than lamina propria^[18,28]. In these studies, the layered morphology of the OCT image was interpreted without a definitive marker for orientation of the histological structure of the esophageal wall.

Considering the above-mentioned matters, we used fresh pig esophageal wall specimens and histologically

assessed the layered morphology imaged by OCT using both cyanoacrylate adhesives and nylon sutures as markers. Under these conditions, we demonstrated that the OCT image of the normal esophageal wall clearly delineated the five-layered morphology, and that the layered morphology consisted of relatively less reflective stratified squamous epithelium, more reflective lamina propria, less reflective muscularis mucosa, more reflective submucosa, and less reflective muscularis propria with deeper structures of esophageal wall.

The mechanism by which OCT images delineate five-layered morphology may be explained by the difference of reflectivity of light through the esophageal tissues, which have different optical properties. Generally, the structure of epithelium, muscularis mucosa, and muscularis propria is uniform and orderly consisting of only epithelial cells or smooth muscle fibers. In this study, OCT images delineated them as less reflective layers because the light passes through them with less obstruction. In contrast, lamina propria and submucosa consist of various mixed components such as connective tissue, vessels, lymph follicles, and glands. The OCT images of these were delineated as more reflective layers due to obstruction of the passage of light.

Concerning the diagnosis for depth of invasion of SESCC, Murata *et al*^[11] reported that accuracy assessed by EUS was 81% for both “T1a-EP” and “T1a-LPM” cancers, but that the accuracy for both “T1a-MM” and “SM1” cancers was only 60%, suggesting that it was hard to make a diagnosis for the “T1a-MM” and “SM1” cancers by EUS. In our study, OCT clearly imaged the muscularis mucosa which is a boundary line between “T1a-MM” and “SM1” cancer. Therefore, OCT may provide us with the opportunity to select more appropriate treatment for SESCC patients than

does EUS. Das *et al*^[25] reported that the resolution of the OCT image was superior to that of high-frequency EUS; however, the depth of penetration with OCT was limited to mucosa and submucosa when compared with the high-frequency EUS. Further investigation is necessary to evaluate the feasibility of diagnosing the depth of invasion in SESCC.

In conclusion, we have demonstrated that the OCT image of the normal esophageal wall clearly delineates a five-layered structure, and we have identified the layered morphology which consists of relatively less reflective stratified squamous epithelium, more reflective lamina propria, less reflective muscularis mucosa, more reflective submucosa, and less reflective muscularis propria with deeper structures of the esophageal wall.

COMMENTS

Background

In the normal esophageal wall, it has been reported that the optical coherence tomography (OCT) image is delineated as a layered morphology. But there are few studies concerning the histological interpretation of the layered morphology of the OCT image and these studies differ in their interpretation.

Research frontiers

To ascertain which layer of the OCT image corresponded to each component of the esophageal wall.

Innovations and breakthroughs

Comparing the OCT images with marked histological sections showed that the first layer corresponded to stratified squamous epithelium; the second to lamina propria; the third to muscularis mucosa; fourth, submucosa; and fifth, muscularis propria with deeper structures of the esophageal wall.

Applications

OCT images may contribute to the accurate diagnosis of the depth of cancer invasion, and thus help when choosing therapeutic options for superficial esophageal squamous cell carcinoma (SESCC).

Peer review

The authors demonstrated that the OCT image of the normal esophageal wall clearly delineates a five-layered structure, and identified the layered morphology consisting of relatively less reflective stratified squamous epithelium, more reflective lamina propria, less reflective muscularis mucosa, more reflective submucosa, and less reflective muscularis propria with deeper structures of the esophageal wall. Therefore, OCT images may contribute to the accurate diagnosis for the depth of cancer invasion, when choosing therapeutic options for SESCC.

Abstract

AIM: To investigate the effect of paeonol on controlling the proliferation of colorectal cancer cell line HT-29 and to discuss its possible mechanism.

METHODS: The inhibitory effect of paeonol on proliferation of HT-29 cells was detected by MTT assay. The results of apoptosis were measured by flow cytometry. Immunocytochemical staining was performed to detect the expression of cyclooxygenase-2 (COX-2) and protein p27 in HT-29 cells treated with paeonol at different concentrations. Reverse transcription-polymerase chain reaction (RT-PCR) was used for mRNA analysis.

RESULTS: From the data of both MTT and flow cytometry, we observed that cell proliferation was inhibited by different concentrations of paeonol. By immunocytochemical staining, we found that HT-29 cells treated with paeonol (0.024-1.504 mmol/L) reflected reduced expression of COX-2 and increased expression of p27 in a dose-dependent manner. RT-PCR showed that paeonol down-regulated COX-2 and up-regulated p27 in a dose- and time-dependent manner in HT-29 cells.

CONCLUSION: One of the apoptotic mechanisms of paeonol is down-regulation of COX-2. p27 is up-regulated simultaneously and plays an important part in controlling cell proliferation and is a crucial factor in the Fas/FasL apoptosis pathway.

INTRODUCTION

It has been confirmed that inhibition of expression of cyclooxygenase-2 (COX-2) has antitumor activity against gastrointestinal carcinoma^[1]. Selective COX-2 inhibitor celecoxib can prevent and reduce the incidence of colorectal cancer to some extent^[2]. However, a recent study has shown that cardiovascular toxicity is caused when selective COX-2 inhibitors are used in the long term^[3]. Consequently, it is considerable importance that a more effective and less toxic selective COX-2 inhibitor, which can be used for the treatment of colorectal carcinoma, is found.

Paeonol is a herb that is the main active component of peony bark. It has been shown to have many pharmacological activities, such as antifebrile, analgesic, antipyretic, anti-atherosclerotic, anti-platelet and antioxidative activity^[4,5]. It has also been demonstrated that paeonol has antitumor effects in animal experiments^[6]. Our recent study on apoptosis after addition of paeonol in human colorectal carcinoma cell line HT-29 shows that paeonol has antitumor activity, by regulating the expression of Fas, Bcl-2, Bax and p53 and finally causing apoptosis^[7,8]. However, the pathway of paeonol-induced apoptosis is still confusing, which emphasizes the necessity of identifying its antitumor mechanism.

In the present study, the expression of COX-2 and p27 was detected and compared, and one of the antitumor mechanisms of paeonol was explored.

MATERIALS AND METHODS

Materials

Human colorectal carcinoma cell line HT-29 was purchased from the Cancer Research Institute of the

Wuhan University in China. Paeonol (Tianzhen Pharmaceutical Company of Ningbo, China), 5 mg/mL, RPMI 1640 (Hyclone Company, USA), calf serum, DABC immunoassay kit (Beijing Zhongshan Company, China), mouse anti-p27, rabbit anti-COX-2, GAPDH, anti-mouse and anti-rabbit secondary antibodies (Santa Cruz Biotechnology, Santa Cruz, CA, USA) were purchased as indicated.

Methods

MTT assay^[9]: Cell proliferation was measured using the MTT assay. Cells were plated in triplicate at 5×10^3 cells/well in 96-well plates, and treated with increasing concentrations of paeonol for culture of 24, 48, 72 and 96 h. Twenty microliters of 5 mg/mL MTT (Amresco, OH, USA) was added to each well and the cells were cultured at 37°C for an additional 4 h. The resulting formazan crystals were solubilized by the addition of 150 μ L DMSO to each well. The optical density at 570 nm was measured and the percentage cell viability was calculated using the following formula: percentage cell viability = (absorbance of experimental well - absorbance of blank)/(absorbance of untreated control well - absorbance of blank) \times 100% (Figure 1).

Immunocytochemistry: HT-29 cells (5×10^5 - 7×10^5) were seeded into 24-well plates and treated with paeonol at a concentration of 0, 0.094, 0.376 or 1.504 mmol/L for 48 h, in triplicate, and then cells were trypsinized, and rinsed with PBS. Immunocytochemical staining was carried out using the DABC immunoassay kit according to the manufacturer's instructions. Immunostaining was observed by immunofluorescence microscopy. Positive staining for COX-2 was located mainly in the cytosol, and p27 in the nucleus. Immunocytochemical staining was classified as follows^[10]: number of positive cells < 10% was deemed as negative (-), 10%-25% as (+), 25%-50% as (++), and > 50% as (+++).

Flow cytometry: HT-29 cells (5 - 7×10^5) were seeded in six-well plates. Paeonol at 0, 0.094, 0.376 or 1.504 mmol/L was added to each well, in triplicate. Cells were incubated for another 48 h. Cells (5×10^6 /L) were collected and detected by flow cytometry.

RNA preparation and reverse transcription-polymerase chain reaction (RT-PCR): Total RNA was isolated using the Trizol reagent (Invitrogen, CA, USA) and 1 μ g RNA was used as a template for the synthesis of cDNA using the RversetAid First Strand cDNA Aynthesis Kit (Fermentas, ME, USA) according to the manufacturer's instructions. PCR analysis was performed in a final volume of 25 μ L using PCR Master Mix (Fermentas). COX-2-specific primer sequences (forward: 5'-TTCAAATGAGATTGTGGGAAAATTGCT-3'; reverse: 5'-AFATCATCTCTGCCTGAGTATCTT-3'); p27-specific primer sequences (forward: 5'-CGTGCAGTGTCTAACGG-3'; reverse: 5'-CGGATCAGTCTTTGGGTC-3'); GAPDH-specific sequences (forward: 5'-ACGGATTGTGGTCGTATTGGG-3'; reverse: 5'-TC

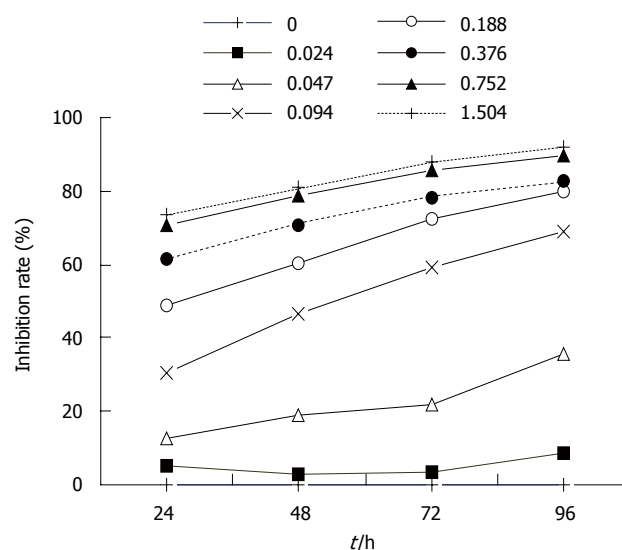

Figure 1 Effect of different concentrations (0-1.504 mmol/L) of paeonol on proliferation of HT-29 cells. The inhibition of cell proliferation showed a dose- as well as time-dependent increase.

CTGGAAGATGGTGTGATGGG-5') were designed using the Primer Premier 3 (Applied Biosystems, CA, USA). PCR products were separated in 1.5% agarose gels, stained with ethidium bromide and photographed.

Statistical analysis

Statistics were calculated with the SPSS version 11.5 (SPSS Inc., Chicago, IL, USA). All determinations were repeated in triplicate. Data are presented as means \pm SD. Significance for comparison of samples was determined by Student's *t* test and χ^2 test. $P < 0.05$ were considered to be statistically significant throughout the study.

RESULTS

Inhibition of cell proliferation by paeonol in a dose- and time-dependent manner

HT29 cells were treated with paeonol at different concentrations for 0, 24, 48 and 96 h, and the rate of inhibition was determined by MTT assay. We observed that growth of HT-29 cells was suppressed in a dose- and time-dependent manner (Figure 1).

Effects of paeonol on cell apoptosis

In order to confirm the results obtained from the MTT assay and to elucidate the mechanisms of action of paeonol, we analyzed apoptosis using DABC immunocytochemistry (Figure 2A and B) and flow cytometry (Figure 3). HT-29 cells were treated with 0, 0.094, 0.376 or 1.504 mmol/L paeonol and examined after 48 h. Paeonol lowered the proportion of COX-2-positive cells, while increasing the level of p27, in a dose-dependent fashion (Tables 1 and 2).

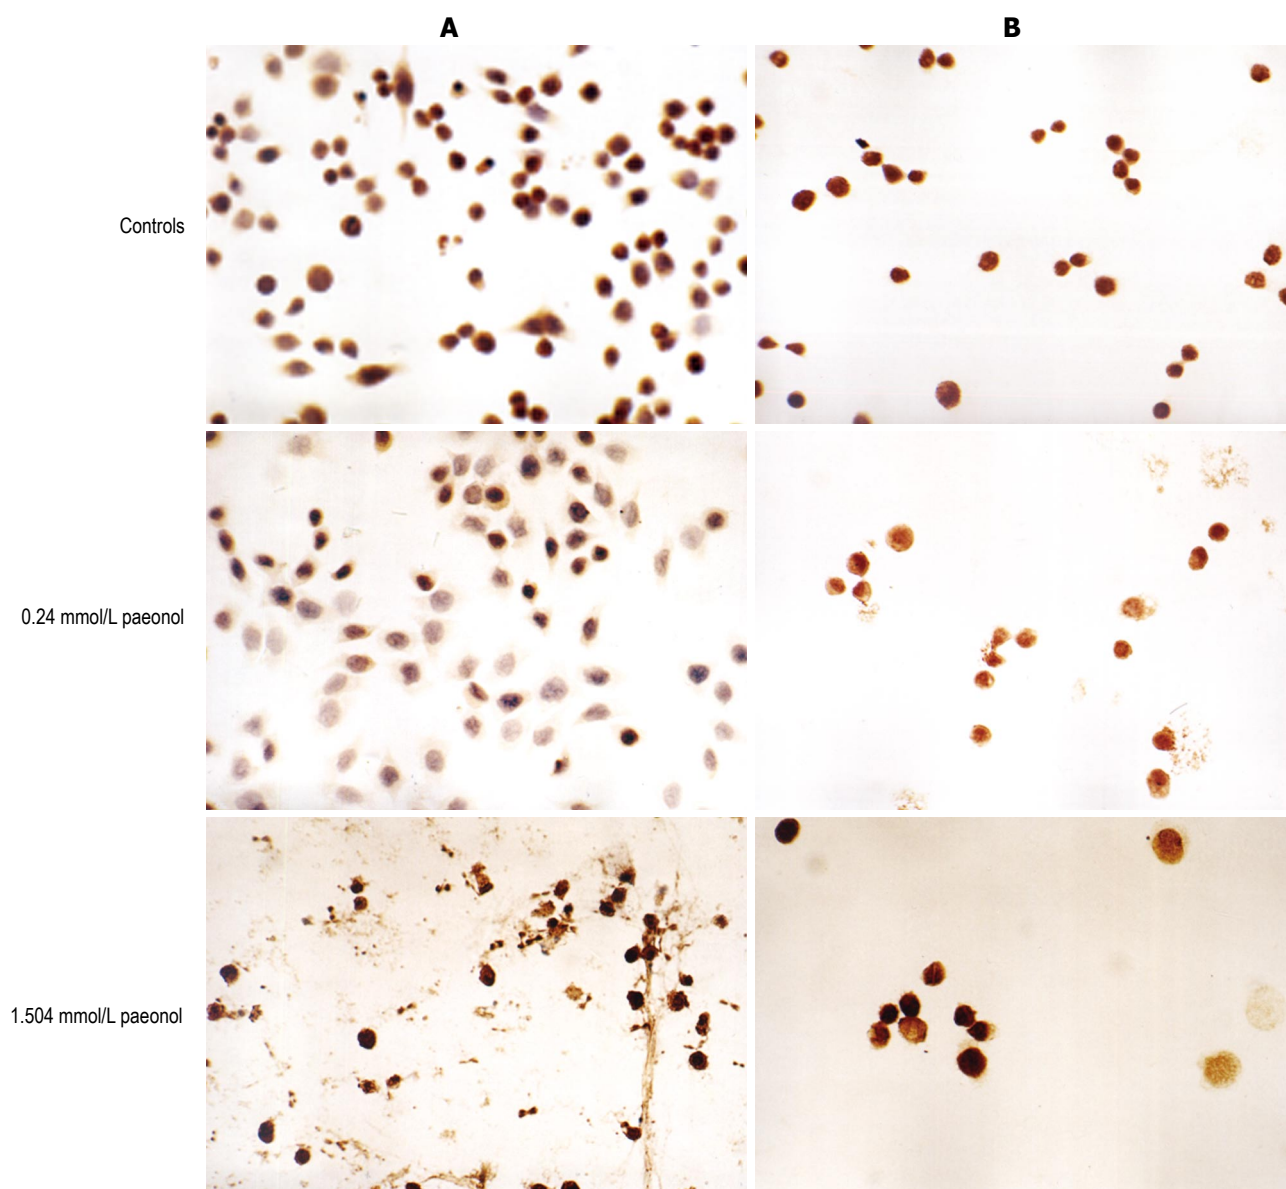

Cell cycle distribution was assessed by flow cytometry. As shown in Figure 2B, the rate of apoptosis increased significantly as higher concentrations of paeonol were used, which reached 34.5% when paeonol was

Table 1 Expression of COX-2 protein in HT-29 cells after treatment with paeonol

Paeonol concentration (mmol/L)	Staining intensity	Positivity rate (%)
0	+++	98.21 ± 0.835
0.094	+++	95.82 ± 0.751 ^a
0.376	++	47.39 ± 0.831 ^a
1.504	+	23.60 ± 1.390 ^a

^a*P* < 0.05 vs untreated control cells.**Table 2** Rate of apoptosis, cell cycle and expression of p27 after treatment with paeonol

0	-	0.46	2.3	61.3	20.3	18.4
0.094	+	18.18 ^b	7.6 ^b	28.7 ^b	55.8 ^b	16.1
0.376	++	46.70 ^b	16.1 ^b	50.7 ^b	35.8 ^b	13.5 ^b
1.504	+++	86.86 ^b	34.5 ^b	38.0 ^b	45.6 ^b	16.4

^b*P* < 0.01 vs untreated control cells.**Figure 2** Expression of COX-2 (A) and p27 (B) in HT-29 cells induced by paeonol (× 400).

1.054 mmol/L. Paeonol caused S-phase arrest and thus inhibited transition to the G₀ and G₂/M phases in a dose-dependent manner (*P* < 0.01) (Table 2).

The results suggested that apoptosis was the main mechanism by which paeonol inhibited the proliferation of HT-29 cells, and COX-2 and p27 were involved in the changes.

Dose- and time-dependent effect of paeonol on COX-2 and p27

It has already been reported that COX-2 plays a critical role in controlling the growth as well as apoptosis in carcinogenesis. To elucidate the interaction between COX-2 and paeonol, HT-29 cells were exposed to 0, 0.094, 0.376 or 1.504 mmol/L paeonol for 48 h, and

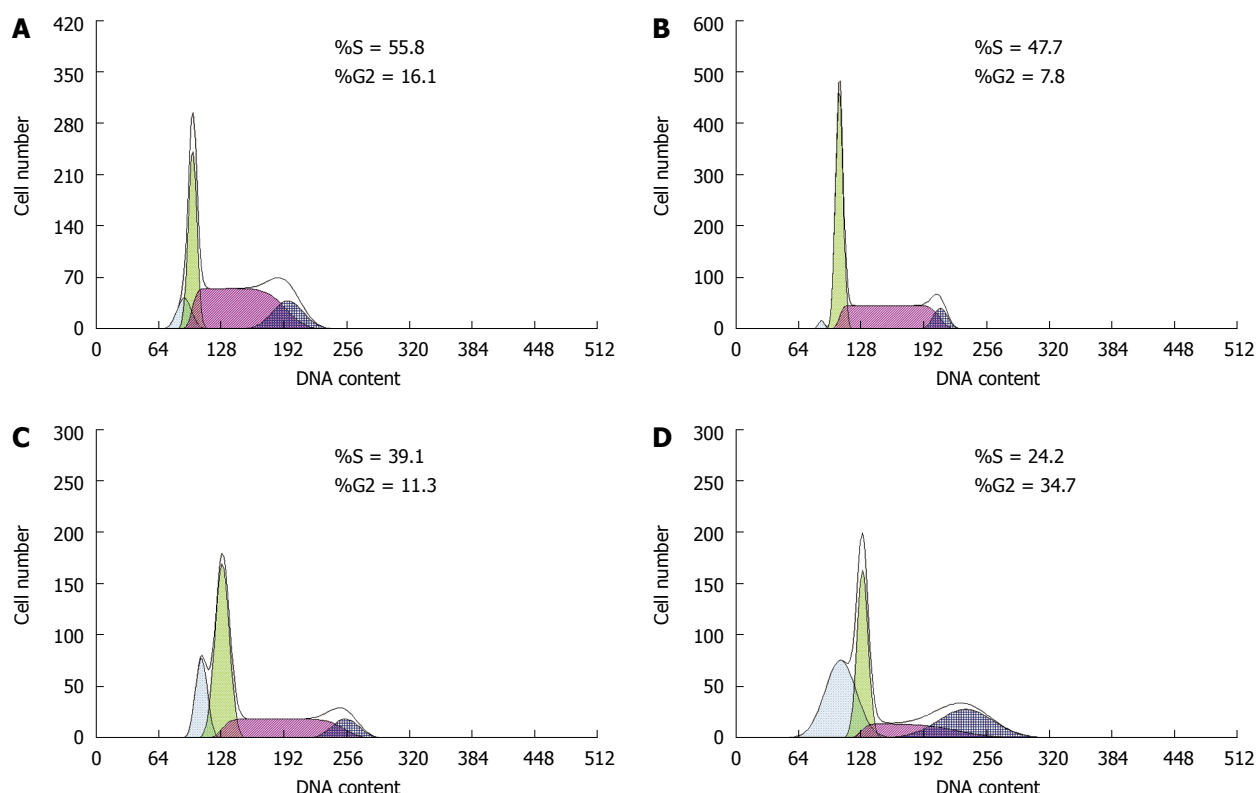

Figure 3 Flow cytometry detects apoptosis of HT-29 cells induced by paeonol. A: Controls; B: 0.094 mmol/L paeonol; C: 0.376 mmol/L paeonol; D: 1.504 mmol/L paeonol.

Figure 4 Changes in COX-2 and p27 induced by paeonol. After exposure to different concentrations for 24 and 48 h, HT-29 cells were observed to have a dose-dependent decrease in COX-2, but an increase in p27. GAPDH acted as an internal control.

expression of COX-2 and p27 was detected, as shown in Figure 4. We observed that the level of COX-2 mRNA from cells treated with 0.094 mmol/L paeonol was lower than in the controls. Treatment with 1.504 mmol/L paeonol caused a further decrease in COX-2 expression, which indicated a dose-dependent decrease in COX-2 expression.

p27, which also plays a critical role in apoptosis, showed increased mRNA expression as the concentration of paeonol was increased (Figure 4), which indicated a dose- and time-dependent response.

DISCUSSION

COX-2 is an key inducible enzyme that regulates prostaglandin E2 (PGE2) synthesis^[11]. It has a low expression level in normal tissue, while its expression in

multiple malignant cancer cells is exceedingly high^[12,13]. By promoting the proliferation of cancer cells and suppressing the expression of certain angiogenesis genes, PGE2 contributes to reducing apoptosis and increasing tumor invasiveness^[14,15]. We found in the present study that paeonol had an inhibitory effect on the expression of COX-2 in HT-29 cells, which was dose- as well as time-dependent. The results show that one of the possible pharmacological effects of paeonol is inhibiting the expression of COX-2.

p27 is an anti-oncogene which is one of the cyclin-dependent kinase inhibitors, and it belongs to the p21 family. It inhibits cell proliferation by blocking the cell cycle^[16,17]. We discovered in the present study that paeonol promoted the expression of p27 in HT-29 cells in a dose-dependent manner ($P < 0.01$). The cell cycle was blocked in S phase, and the percentages of G₀/G₁ and G₂/M cells decreased significantly after paeonol treatment. From the cytometry figures, we observed that there was an obvious apoptosis peak after adding paeonol to HT-29 cells at a concentration of 1.504 mmol/L, and the rate of apoptosis was higher than that in the controls. This shows that paeonol can cause apoptosis by promoting the expression of p27, which blocks the cell cycle in S phase and interferes with DNA synthesis.

We also discovered that not only does paeonol down-regulate the expression of COX-2, but it also promotes the expression of p27 at the same time, which suggests that they are on the same apoptotic pathway. It has been reported that COX-2 is one of the upstream factors that controls Bcl-2 expression^[18]. It has already

been demonstrated in our previous study that paeonol can decrease the expression of Bcl-2 and increase the expression of Fas and caspase-8 in HT-29 cells, and we drew the conclusion that Fas/FasL is a central pathway that leads to paeonol-induced apoptosis^[19]. In the present study, we found that COX-2 and p27 were correlated negatively after paeonol treatment, and consequently, we deduced that COX-2 and p27 may cooperate in controlling the proliferation of colorectal carcinoma cells. That is, when activated, COX-2 inhibits expression of p27 and promotes cell proliferation. Another inference we can make from this study is that p27 plays an important part in the control of Fas/FasL apoptosis and promotes apoptosis when its expression is up-regulated.

To identify the apoptotic mechanism of paeonol more clearly, further investigations are needed. We expect that paeonol may replace nonsteroidal anti-inflammatory drugs or selective COX-2 inhibitors because of their toxic effects, and form a new strategy for the therapy of colorectal carcinoma.

COMMENTS

Background

Paeonol has been shown to have many pharmacological activities, which include an antitumor effect in animal experiments. The authors' previous work on the expression of apoptosis and apoptosis-related genes after treating human colorectal cell line HT-29 with paeonol has shown that paeonol has antitumor activity, by regulating the expression of apoptosis genes Fas, Bcl-2, Bax and p53, and inducing apoptosis. However, until now, the mechanism of action of paeonol has remained unclear. In the present study, the mechanism of the antitumor effect of paeonol was explored, and the expression of cyclooxygenase-2 (COX-2) and protein p27 was detected and discussed.

Research frontiers

Colorectal carcinoma is common all around the world and has a high incidence among all the carcinomas. In research on paeonol, the hot topics are to identify the mechanism of its antitumor action, and to establish the possible pathways by which paeonol induces apoptosis in the HT-29 cell line.

Innovations and breakthroughs

The authors discovered that p27 also played some role in regulating COX-2, which indicates that p27 may play a part in the control of the Fas/FasL apoptosis pathway and promote apoptosis when it is up-regulated.

Applications

The authors expect that paeonol may replace nonsteroidal anti-inflammatory drugs or selective COX-2 inhibitors because of their toxic effects and form a new therapeutic strategy for colorectal carcinoma.

Peer review

This study determined the changes in expression pattern of COX-2 and p27 following paeonol treatment of HT-29 cells. The results showed that there was a significant decrease in COX-2 expression that was associated with an increase in p27 activity in a dose-dependent manner. The authors also conducted flow cytometry analysis to differentiate the growth phases after paeonol administration.

Abstract

AIM: To assess the use of capecitabine-based therapy and associated complication rates in patients with gastroesophageal cancer (GEC) in a real-world treatment setting.

METHODS: Patients with claims between 2004 and 2005 were identified from the Thomson Reuters MarketScan® databases. Capecitabine regimens were compared with 5-fluorouracil (5-FU) and other chemotherapy regimens, and were stratified by treatment setting.

RESULTS: We identified 1013 patients with GEC: approximately half had treatment initiated with a 5-FU regimen, whereas 11% had therapy initiated with a capecitabine regimen. The mean capecitabine dose overall was 2382 ± 1118 mg/d, and capecitabine was used as monotherapy more often than in combination. Overall, 5-FU regimens were the most common treatment option in neoadjuvant and adjuvant settings, while other non-capecitabine regimens were used more widely in first- and second-line settings. The overall unadjusted complication rate for capecitabine regimens was about half of that seen with 5-FU regimens. In multivariate analyses, capecitabine recipients had a 51% (95% CI: 26%-81%) lower risk of developing any complication than 5-FU recipients did. The risk of developing bone marrow, constitutional, gastrointestinal tract, infectious, or skin complications was lower

with capecitabine therapy than with 5-FU.

CONCLUSION: Capecitabine appeared to have a favorable side effect profile compared with 5-FU, which indicates that it may be a treatment option for GEC.

INTRODUCTION

Gastroesophageal cancer (GEC), which includes cancers that originate in the esophagus, gastroesophageal junction and stomach, is common in many countries. For example, gastric cancer is, by some estimates, the fourth most common cancer in the world, and esophageal cancer is eighth^[1]. The incidence of GEC shows a marked geographic variation, with high-prevalence areas including Asia, Southern and Eastern Africa, and South America^[2,3].

GEC is relatively uncommon in the United States compared with colorectal, lung, breast, and prostate cancers; however, the incidence of esophageal cancer (both squamous cell and adenocarcinoma) appears to be increasing^[4-6]. It is estimated that in 2008, 37 970 cases of GEC will have been diagnosed and 25 160 deaths will have been attributed to these cancers^[4].

A patient's outcome depends on cancer stage at diagnosis; approximately 50% of patients with gastric or esophageal cancer have advanced disease (at least extending beyond the locoregional confines) at diagnosis^[2,3]. The disease is highly metastatic; as a result, 70%-80% of resected specimens will have metastasized to the regional lymph nodes at the time of resection. The disease is associated with a poor prognosis: overall 5-year survival has been estimated at < 10%^[7].

Patients with resectable disease are candidates for adjuvant chemotherapy. 5-fluorouracil (5-FU) plus leucovorin and radiotherapy significantly improve median overall survival compared with surgery alone in patients with resected adenoma of the stomach or gastroesophageal junction (36 mo *vs* 27 mo; $P = 0.005$)^[8]. Regimens that may be considered for preoperative use or as definitive chemoradiation therapy for localized esophageal carcinoma include fluoropyrimidine-cisplatin, taxane-based, and oxaliplatin, and irinotecan-based regimens^[2].

Chemotherapy should also be considered for patients with metastatic disease. A meta-analysis of randomized trials in a total of 390 patients with advanced gastric cancer showed a greater 1-year survival rate and improved quality of life with chemotherapy than with supportive care^[9]. In this analysis, the 1-year survival rate achieved with supportive care was 8%, compared with 20% with chemotherapy ($P = 0.05$), and 30% of the patients in the chemotherapy group attained a 6-mo symptom-free period, *vs* 12% in the supportive care group ($P < 0.01$).

Chemotherapy options for advanced gastric or esophageal cancer include 5-FU/leucovorin, fluoropyrimidine-, cisplatin-, oxaliplatin-, and irinotecan-based combinations, and taxane-based regimens^[2].

Another treatment option currently being investigated in patients with GEC is the fluoropyrimidine capecitabine. Capecitabine has been used widely to treat patients with colorectal and breast cancer, and has a well-established safety profile. Capecitabine is administered orally, therefore, there is no requirement for intravenous access, and the associated complications and morbidity seen with IV 5-FU are absent.

Two recent phase III trials have suggested that survival with capecitabine-based regimens compares favorably with that with 5-FU-based regimens as first-line therapy for GEC^[10,11]. The REAL-2 study randomized 1002 patients with advanced GEC to receive first-line triple therapy with epirubicin and cisplatin plus either 5-FU (ECF) or capecitabine (ECX), or triple therapy with epirubicin and oxaliplatin plus either 5-FU (EOF) or capecitabine (EOX). The primary endpoint was non-inferiority in overall survival for the regimens that contained capecitabine as compared with 5-FU, and oxaliplatin as compared with cisplatin. Capecitabine-containing regimens demonstrated non-inferiority in overall survival compared with 5-FU-containing regimens. Median survival times in the ECF, ECX, EOF, and EOX groups were 9.9, 9.9, 9.3, and 11.2 mo, respectively.

In the other phase III trial, Kang and colleagues compared first-line doublet therapy with capecitabine/cisplatin *vs* 5-FU/cisplatin in 316 patients with advanced gastric cancer. The primary endpoint was non-inferiority in progression-free survival (PFS) between the two regimens. Non-inferiority was reached, with the capecitabine regimen achieving a median PFS of 5.6 mo *vs* 5.0 mo with the 5-FU regimen (unadjusted HR 0.81; 95% CI, 0.63-1.04; $P < 0.001$ *vs* non-inferiority margin of 1.25).

The current study was undertaken to assess the

usage of capecitabine-based therapies and associated complication rates in patients with GEC in a real-world treatment setting. Capecitabine is currently not approved by the US FDA for this indication.

MATERIALS AND METHODS

Data source

This retrospective analysis used claims data from the Thomson Reuters Healthcare MarketScan[®] Commercial Claims and Encounters and Medicare Supplemental and Coordination of Benefits databases to determine treatment patterns in patients with GEC. These databases contain data from 25 million individuals of all ages who are covered in the United States under employer- and government-funded (Medicare) health insurance plans, including a variety of fee-for-service and capitated provider reimbursement schemes. The MarketScan databases capture information on inpatient and outpatient health care claims, as well as outpatient pharmacy-dispensed drug claims. In compliance with the Health Insurance Portability and Accountability Act (HIPAA), patient data included in the analysis were statistically de-identified and therefore exempt from Institutional Review Board approval.

Patient selection

Patients included in the current analysis were required to have had at least three claims with a primary or secondary diagnosis of stomach or esophageal cancer [*International Classification of Diseases, Ninth Revision* (ICD-9) diagnosis codes 150 or 151] between January 1, 2000 and December 31, 2005. Because predominant treatments change over time and this study sought to compare current chemotherapy regimens, only patients with at least one claim for an identifiable chemotherapy agent between 2004 and 2005 were retained.

Patients were required to have been enrolled in the plan for at least 6 mo before the first chemotherapy administration (index date) in 2004 or 2005, and for at least 30 d after index. Patients with index dates between January 1, 2004 and February 14, 2004 were required to have had no claims for chemotherapy for at least 45 d before the index date.

Availability of data for both medical and pharmacy coverage was also required. Patients with only a chemotherapy diagnosis or revenue codes were excluded. Patients were followed from diagnosis until death, disenrollment, or study end (December 31, 2005).

Patient characteristics

Patient-level demographic variables measured as of the index date included age, geographic region, area of residence (urban *vs* rural), payer type (commercial *vs* Medicare), and length of follow-up (mo).

Clinical variables evaluated during the 6-mo pre-index period included: total direct health care costs; the Charlson Comorbidity Index (CCI); the Chronic Disease Score (CDS); select comorbidities (anemia, anxiety or depression, cerebrovascular disease, congestive heart failure, chronic

obstructive pulmonary disease, diabetes, hypertension, or hypercalcemia); and pre-index treatments (radiotherapy, surgery). Other variables included the year of first cancer diagnosis (between 2000 and 2005), year of first chemotherapy (between 2000 and 2005), and the presence of metastases at any point during the pre-index period.

Treatment episodes

A treatment episode-level analysis file was created, which contained all chemotherapy treatments identified from the claims database. A treatment episode was defined as the time from treatment initiation until the addition of a new agent not seen in the first 30 d, or until a gap of ≥ 45 d in treatment. Neoadjuvant treatment regimens ended on the date of surgery. Patients could contribute more than one treatment episode to the study if they received multiple chemotherapy regimens during the 2004-2005 study period.

Each chemotherapy episode was categorized according to treatment regimen and setting. Treatment regimens of interest included capecitabine monotherapy; capecitabine in combination with a platinum agent; capecitabine in combination with a platinum and a non-platinum agent; capecitabine in combination with a non-platinum agent; 5-FU monotherapy; 5-FU in combination with a platinum agent; 5-FU in combination with a platinum and a non-platinum agent; 5-FU in combination with a non-platinum agent; and other chemotherapy. Treatment settings included neoadjuvant (90 d before surgery), adjuvant (within 90 d after surgery), first line (> 90 d after surgery), and second line (any subsequent treatment regimens).

Complications of chemotherapy

Complications of chemotherapy were identified at the treatment episode level, using diagnosis codes, procedure codes, or pharmacological treatment specific to adverse events (Table 1). Adverse events were grouped into six categories: bone marrow complications (anemia, neutropenia, secondary thrombocytopenia); constitutional symptoms (asthenia, cough, fever, headache, insomnia, night sweats); gastrointestinal tract symptoms (constipation, diarrhea, esophagitis, gastritis, mucositis, nausea and vomiting, weight loss); infection (including central-line infection); skin complications (alopecia, dermatitis); and “other” (central-line thrombosis, pneumothorax). The complication rate was standardized per 1000 person-months on treatment. Person-month accumulation was based on time to event for treatment episodes with a complication event, and treatment episode length for those without an event.

Statistical analysis

Descriptive analyses of patient demographics, clinical characteristics, complication rates, and treatment characteristics were performed for each individual treatment regimen. Categorical variables were summarized in frequency tables. Continuous and other numeric variables were summarized by presenting the number of

observations, mean, and standard deviation.

Multivariate analyses were performed to adjust for differences in patient demographic and clinical factors that confounded the complication rates from the descriptive analysis. Cox proportional hazard models were used to estimate time to first complication event for each of the six complication categories described above. Covariates employed in the models included patients' age, sex, region, cancer type, presence or absence of metastases during each treatment episode, treatment setting, cancer diagnosis year, pre-index anemia status, pre-index CCI score, and pre-index surgery status.

Complications that occurred in patients treated with capecitabine were compared to those occurring in patients who received 5-FU regimens (i.e. capecitabine monotherapy was compared with 5-FU monotherapy;

Marketscan Commercial and Medicare Databases: 2000-2005. CAP: Capecitabine. ¹One patient may receive multiple regimens; therefore, the sum of patients in each episode will exceed the total number of study-eligible patients; ²Demographics measured on the date the first study-eligible chemotherapy was administered; ³Clinical characteristics measured in the 6 mo before the first study-eligible chemotherapy, unless otherwise specified; ⁴Measured using all available data prior to episode onset; ⁵Mean per month over 6 mo pre-index.

capecitabine combination regimens were compared with 5-FU combination regimens; and “any capecitabine” regimens were compared with “any 5-FU” regimens).

RESULTS

Demographic and clinical characteristics

A total of 1013 patients with GEC were identified from the database and met the inclusion criteria for this analysis. These patients had 1349 treatment episodes during 2004 and 2005. Their characteristics are summarized in Table 2. There were more females than males in the selected population (73.6% of total patients), and the average age was 62.6 (\pm 11.8) years (most patients were in the 50-64-year age group). Patients were followed-up on average for 9.9 (\pm 6.9) mo after the initiation of the index chemotherapy.

Approximately two-thirds of patients were classified as having non-metastatic disease at the time of index treatment. Patients had high comorbidity scores at baseline (mean CCI score 5.2 ± 3.0 ; mean CDS 4.6 ± 3.5). Hypertension was the most common comorbidity and occurred in 30.6% of patients during the 6-mo pre-index period. Other common comorbidities included anemia, diabetes, and coronary artery disease.

Radiotherapy was used in 40.5% of patients in the 6-mo pre-index period, and 23.6% of patients underwent surgery.

Treatment patterns

Comparison of index treatment patterns: Approximately half of all patients included in the current analysis received a 5-FU regimen as their index treatment (540 of 1013; 53.3%) (Table 2). 5-FU combination therapy was initiated in 33.9% of patients, and 25.3% received 5-FU monotherapy. In comparison, 16.4% of patients had therapy initiated with a capecitabine regimen (166 of 1013); 10.4% received capecitabine monotherapy, and

7.5% received capecitabine combination therapy.

Patients who received capecitabine as index treatment were on average 1.5 ± 0.4 years older than those who were treated with 5-FU-based regimens (mean age: 63.0 ± 12.3 years *vs* 61.7 ± 11.9 years). Aggregate measures of comorbidity and chronic disease were similar between patients given 5-FU- and capecitabine-based regimens (Table 2). Patients who received capecitabine-based therapy were followed for about 1 mo less than those given 5-FU-based regimens (mean follow-up 9.1 ± 6.4 mo *vs* 10.3 ± 6.9 mo).

Comparison of treatment patterns by drug regimen and treatment setting:

Combined data for all treatment episodes (index and subsequent treatments) showed that 5-FU regimens remained the most widely used treatments (53.3% of patients) and 5-FU monotherapy was the most popular 5-FU regimen (25.4% of patients) (Figure 1 and Table 3). Overall, 16.4% of patients received capecitabine across all treatment settings: capecitabine monotherapy was the preferred regimen, given to 10.4% of patients (1.9% received a capecitabine-platinum combination; 3.1% received a capecitabine-platinum-non-platinum combination; and 3.2% received a capecitabine-non-platinum combination). Overall, 51.7% of patients received other chemotherapy regimens.

First-line treatment was the most common treatment setting in the selected population (73.3%), followed by second-line therapy (34.9%), adjuvant therapy (21.0%), and neoadjuvant therapy (8.3%) (Table 3). Patients could have more than one treatment episode; therefore, the sum of the percentage of patients receiving each treatment exceeded 100%.

5-FU was used widely in the neoadjuvant and adjuvant settings (in 60.7% and 65.7% of patients, respectively) (Figure 2 and Table 3). Capecitabine was used infrequently in the neoadjuvant setting (4.8% of patients), but was used more often in the adjuvant setting (11.3% of patients).

Table 3 Distribution of patients by chemotherapy regimen and treatment setting¹ *n* (%)

Chemotherapy regimen	Neoadjuvant (<i>n</i> = 84)	Adjuvant (<i>n</i> = 213)	First-line (<i>n</i> = 743)	Second-line (<i>n</i> = 354)	Any setting (<i>n</i> = 1013)

**Figure 1** Chemotherapy treatment patterns across all settings in patients with GEC (*n* = 1013).

Other chemotherapy regimens were used in 38.1% and 25.4% of patients in these respective treatment settings.

In the first-line setting, 42.9% and 12.1% of patients, respectively, were treated with 5-FU or capecitabine regimens. Although still a popular choice, 5-FU was used less often in the second-line setting than in other settings (in 39.3% of patients), and other chemotherapy regimens became the most popular choice (used in 61.6% of patients). The second-line treatment setting was the most popular choice for capecitabine-based therapies (given to 20.3% of patients). Capecitabine monotherapy was used in 11.9% of patients in this setting; cisplatin plus a

**Figure 2** Distribution of chemotherapy by treatment setting.

non-platinum compound was used in 5.4% of patients (Table 3).

Capecitabine dosage regimens: The mean overall capecitabine dose was 2382 (\pm 1118) mg/d; a lower dose was used in combination regimens than in monotherapy [mean overall dose: 2349 (\pm 1052) *vs* 2410 (\pm 1175) mg/d, respectively].

Complication rates: Capecitabine compared favorably with 5-FU in terms of crude (unadjusted) complication rates (Table 4). The unadjusted complication rate (per 1000 person-months) for capecitabine-based regimens was half that for 5-FU-based regimens (387 *vs* 806 per 1000 person-months). Patients who received

Figure 3 Adjusted complication hazard ratio: 5-FU vs capecitabine regimens. A: 5-FU monotherapy compared with capecitabine monotherapy; B: 5-FU combination compared with capecitabine combination; C: Any 5-FU regimen compared with any capecitabine regimen. Complications were determined per 1000 person-months.

capecitabine monotherapy were 56% less likely to have a complication during treatment than patients given 5-FU monotherapy (336 *vs* 764 per 1000 person-months), and patients who received capecitabine combination therapy were 45% less likely to have a complication during treatment than those given 5-FU combination therapy (460 *vs* 835 per 1000 person-months).

Complication rates were lower with capecitabine regimens than with 5-FU across four individual categories: bone marrow (151 *vs* 307; 51% lower); constitutional symptoms (183 *vs* 293; 37% lower); gastrointestinal tract (224 *vs* 529; 58% lower); and infection (131 *vs* 238; 45% lower). Skin complications were rare in both comparison cohorts.

Relative risk of complications: The results of multivariate analyses supported the findings of the crude rate calculations (Figure 3). Cox proportional hazard models showed that, overall, 5-FU therapy was associated with a significantly higher risk for any complication than capecitabine (adjusted HR: 1.51, 95% CI: 1.26-1.81) (Figure 3). Specifically, the higher risk of developing a complication associated with 5-FU therapy was observed for bone marrow events (HR: 1.84, 95% CI: 1.42-2.37), constitutional symptoms (HR: 1.28, 95% CI: 1.01-1.63), and gastrointestinal tract events (HR: 1.56, 95% CI: 1.27-1.93). No difference was detected in the risk for infection or "other" complications, possibly because of the low number of reported events (skin: 1 *vs* 0; "other": 19 *vs* 22, for capecitabine and 5-FU regimens, respectively).

The risk of complication with 5-FU monotherapy was markedly higher than with capecitabine monotherapy for bone marrow (HR: 1.68, 95% CI: 1.11-2.53), constitutional symptoms (HR: 1.85, 95% CI: 1.23-2.79), and gastrointestinal tract complications (HR: 1.52, 95% CI: 1.10-2.09). The overall risk for any complication also differed significantly between the two monotherapy treatment groups (HR: 1.39, 95% CI: 1.07-1.81) (Figure 3).

Similar to monotherapy, the difference in overall

risk of any complication was significantly higher with 5-FU combination regimens than with capecitabine combination regimens (HR: 1.55, 95% CI: 1.21-1.99). The risk of bone marrow complications was 76% higher (HR: 1.76, 95% CI: 1.27-2.44), and the risk of developing a gastrointestinal tract event was higher (HR: 1.50, 95% CI: 1.13-2.01) with 5-FU than with capecitabine combination regimens (Figure 3).

DISCUSSION

Of the 1013 patients with GEC identified in this retrospective database analysis, approximately 50% had treatment initiated with a 5-FU regimen, whereas only 11% had therapy initiated with a capecitabine regimen. The mean capecitabine dose overall was 2382 (SD \pm 1118) mg/d, and capecitabine was used as monotherapy more often than in combination. Overall, 5-FU regimens were the most common treatment option in the neoadjuvant and adjuvant settings, whereas other non-capecitabine regimens were used more widely in the first- and second-line settings.

The retrospective analysis of complication rates with capecitabine and 5-FU therapies indicates that capecitabine-based therapy may be a better tolerated treatment option than 5-FU in patients with GEC. The overall unadjusted complication rate for capecitabine regimens was about half of that seen with 5-FU regimens: in multivariate analyses, capecitabine recipients had a 51% lower risk of developing any complication than 5-FU recipients did. Lower complication rates were observed in bone marrow, constitutional, gastrointestinal tract, infection, and skin complications. Overall, patients who received capecitabine therapy (monotherapy or combination) were 38% less likely than their 5-FU counterparts to have a complication associated with therapy.

The two recent phase 3 trials of first-line capecitabine in GEC that were described earlier^[10,11] have demonstrated non-inferiority in survival parameters for capecitabine-

vs 5-FU-based regimens, as well as similar tolerability between the regimens. Although the incidence of grade 3/4 neutropenia was higher with the ECX regimen compared with ECF (51.1% *vs* 41.7%), in the study by Cunningham and colleagues, the incidence of these events was similar or slightly lower with the capecitabine regimen EOX *vs* EOF (27.6% *vs* 29.9%)^[10], and capecitabine/cisplatin *vs* 5-FU/cisplatin (16% *vs* 19%) in the study by Kang and colleagues^[11]. Other common treatment-related grade 3/4 adverse events in the latter study were vomiting (7% *vs* 8%) and stomatitis (2% *vs* 6%) with capecitabine/cisplatin *vs* 5-FU/cisplatin, respectively. Thus, the clinical efficacy of capecitabine demonstrated in the two phase three studies, combined with the lower complication rate observed in the current retrospective analysis, support capecitabine use for the treatment of patients with GEC. Capecitabine therapy also has the advantage of convenient oral administration, which eliminates the need for intravenous access and associated complications.

The treatment patterns observed in our analysis correspond with standard recommended treatment protocols for GEC: 5-FU-based regimens were used in about 50% of patients and other non-capecitabine chemotherapy regimens were also a common choice. Although not approved for this indication, there was considerable use of capecitabine for the treatment of GEC in the study period between 2004 and 2005. Overall, 16% of patients received a capecitabine-based regimen. Monotherapy was the preferred capecitabine regimen, and was given to 10% of patients overall across all treatment settings (1.9% received capecitabine plus a platinum agent; 3.1% received a capecitabine-platinum-non-platinum combination; 3.2% received a capecitabine-non-platinum combination). Capecitabine was most likely used in the second-line setting, and least likely used as neoadjuvant therapy.

In interpreting our findings, several limitations of the analysis should be considered. Although the current study was based on a large, diverse sample of patients with GEC, it was not a random population sample, and may not represent the United States population as a whole. Moreover, diagnostic information is recorded by physicians and hospitals to support their claims for reimbursement for particular services, but additional clinical information is limited. We relied exclusively on billing and coding by health care providers to identify cancer type, treatment setting, treatment regimen, treatment episode, and complication events. As such, particular conditions common among patients undergoing chemotherapy may not have been recorded on a claim unless deemed clinically relevant. In addition, clinical measures were not used to confirm the presence of complications. We also presumed that the use of known treatment for a complication was evidence of its existence. However, as prophylaxis is often used for specific events, the frequency of complications reported in the current study may have been overstated. Alternatively, the frequency of complications may have been understated because patients may have experienced complications that did not result in the generation of a

health care claim for reimbursement. For example, hand-foot syndrome was recorded using the ICD-9 code 693, which includes dermatitis caused by substances taken internally. To ensure that hand-foot syndrome was not being miscoded, we conducted a sensitivity analysis using all ICD-9 codes indicative of an inflammatory dermatologic reaction (codes 690-698), but rates still remained low. Cases of hand-foot syndrome may not have been clinically significant to warrant coding. Finally, a key problem that often plagues observational studies is the lack of randomization in assigning individuals to either treatment or control groups. Given this concern, the estimation of the effects of treatment may have been biased by the existence of confounding factors. The current study used multivariate models to adjust for these pretreatment differences. Given the strength of the selection bias observed in the current study, it may be desirable for future studies to incorporate a propensity model approach in combination with multivariate adjustment.

In conclusion, in the United States, 5-FU-based regimens represented approximately 50% of the regimens used to treat patients with GEC between 2004 and 2005, which reflects current treatment recommendations for this indication. Capecitabine-containing regimens represented 16% of all regimens used for this indication during this time period, and were used most frequently in the second-line setting. Capecitabine appeared to have a favorable side-effect profile compared with 5-FU and, thus, could be a useful treatment option for patients with GEC.

COMMENTS

Background

Capecitabine is an oral cytotoxic agent with comparable efficacy to and a better safety profile than intravenous 5-fluorouracil (5-FU), as seen in clinical trials of gastroesophageal cancer (GEC). This study compared the occurrence of select adverse events (AEs) in patients treated with capecitabine and 5-FU in a real-world setting.

Research frontiers

Although two recent phase III trials have suggested that survival with capecitabine-based regimens compares favorably with that with 5-FU-based regimens as first-line therapy for GEC (REAL-2 study and Kang *et al* study), data are lacking for the use of capecitabine in patients with GEC in a real-world treatment setting. This study was undertaken to assess the usage of capecitabine-based therapy and associated complication rates in patients with GEC in a real-world treatment setting.

Innovations and breakthroughs

The complication rate of a capecitabine regimen was nearly half that of 5-FU (387/1000 *vs* 806/1000 person-months). These findings held when comparing monotherapy (336/1000 *vs* 764/1000 person-months) and combination (460/1000 *vs* 835/1000 person-months) regimens. After adjusting for differences in demographic and clinical profile, patients on capecitabine monotherapy had significantly lower risk for any complication compared with patients on 5-FU alone (HR: 1.39, 95% CI: 1.07-1.81). Patients on a capecitabine combination regimen had significantly lower risk of complication compared with patients on a 5-FU combination regimen (HR: 1.55, 95% CI: 1.21-1.99).

Applications

Capecitabine is currently not approved by the US FDA for treatment of GEC. Consistent with trial data, in this real-world setting, capecitabine alone and in combination with other agents had lower rates of AEs than 5-FU did. These findings support that, in the treatment of GEC, capecitabine regimens produce a similarly favorable safety profile in the real-world setting as in controlled

clinical trials.

Terminology

Charlson Comorbidity Index (CCI): The CCI predicts the 1-year mortality for a patient who may have comorbid conditions, such as heart disease, diabetes, or cancer (a total of 17 conditions). Each condition is assigned a score of 1, 2, 3 or 6 depending on the associated risk of dying from this condition. Scores for individual comorbidities are added and the sum is used as a predictor for mortality. The CCI aids in directing how aggressively a condition should be treated (e.g. although a patient may have cancer, additional comorbidities may be severe enough that the costs and risks of treatment may outweigh the short-term benefit from treatment of the cancer). Chronic Disease Score (CDS): The CDS is a risk-adjustment measure based on age, sex, and history of dispensed drugs.

Peer review

It is useful to publish the practice of the utilization of these drugs. This was a retrospective study and although there are biases related to the data collection and lack of control related to the selection of patients for different treatments, these limitations are recognized and the study makes an important contribution to our knowledge of the potential of capecitabine in the treatment of GEC.

Abstract

AIM: To evaluate the effectiveness of a rapid and easy fingertip whole blood point-of-care test for celiac disease (CD) case finding and diet monitoring.

METHODS: Three hundred individuals, 206 females (68.7%) and 94 males (31.3%), were submitted to a rapid and easy immunoglobulin-A-class fingertip whole blood point-of-care test in the doctor's office in order to make immediate clinical decisions: 13 healthy controls, 6 with CD suspicion, 46 treated celiacs, 84 relatives of the celiac patients, 69 patients with dyspepsia, 64 with irritable bowel syndrome (IBS), 8 with Crohn's disease and 9 with other causes of diarrhea.

RESULTS: Upper gastrointestinal endoscopy with duodenal biopsies was performed in patients with CD suspicion and in individuals with positive test outcome: in 83.3% (5/6) of the patients with CD suspicion, in 100% of the patients that admitted gluten-free diet transgressions (6/6), in 3.8% of first-degree relatives (3/79) and in 2.9% of patients with dyspepsia (2/69). In all these individuals duodenal biopsies confirmed CD (Marsh's histological classification). The studied test showed good correlation with serologic antibodies, endoscopic and histological findings.

INTRODUCTION

Celiac disease (CD) is a multifactorial disorder that occurs in genetically susceptible individuals. CD is considered an immune-mediated enteropathy caused by a permanent intolerance of the small bowel mucosa to gluten, and affects approximately 1% of the world population^[1]. In our geographic area the estimated prevalence is 1/475^[2]. Individuals with CD can be asymptomatic or can present a variety of gastrointestinal symptoms or extra-intestinal manifestations and often the diagnoses of dyspepsia or irritable bowel syndrome (IBS) are suggested^[3]. The diagnosis of CD is based on serologic and histopathologic findings. Antiendomysial (EMA) and anti-tissue transglutaminase antibodies, class IgA, are considered highly specific serological markers for CD. Biopsies of the proximal small bowel in positive individuals for these antibodies confirm the diagnosis of CD^[1].

As CD is a disorder that can be ruled out in the differential diagnosis of several gastrointestinal diseases, non-invasive tests are recommended as a first-step to screening patients before small intestinal biopsy to confirm CD^[1,4]. Also, gluten-triggered tissue autoantibodies can be determined to aid in monitoring the diet and for case findings of CD in at-risk groups such as relatives^[5] and in patients with other autoimmune

Table 1 Demographic data of all the studied individuals¹

Group	Number	Female	Male	Median age	Range	Positivity
Healthy control	13	6	7	40.0	7-75	0

diseases^[6-8].

The conventional tests, EMA determined by indirect immunofluorescence and anti-tTG performed by ELISA, require sera samples, are laborious and time-consuming, need special laboratorial centers, are expensive and the results are available only after a time lag. So, a rapid test, with a result which can be available immediately, will help the physicians to make decisions at their own offices^[9].

The aim of this study was to evaluate the effectiveness of a rapid and easy immunoglobulin-A-class whole blood point-of-care test for celiac autoantibody detection in patients routinely seen in the clinic, to enable immediate clinical decisions.

MATERIALS AND METHODS

Patients

The patients were tested at the Gastroenterology and Endoscopy Services, Pontifical Catholic University of Paraná, and also tested on site in the author's office, Curitiba city, State of Paraná, South of Brazil. The study was approved by the Research Ethic Committee of the institution. All the participants gave informed consent.

A total of 300 consecutive Caucasoid individuals born in southern Brazil were studied, 206 females (68.7%) and 94 males (31.3%) divided by groups: 13 controls not relatives of the celiac patients; 6 with CD suspicion; 46 treated celiacs, 40 with and 6 without compliance to a gluten-free diet (GFD); 85 relatives of the celiac patients, 79 first- and 6 second-degree relatives; 69 patients with clinical diagnosis of dyspepsia; 64 with irritable bowel syndrome; 8 patients with Crohn's disease; 9 with other causes of diarrhea (4 lactose intolerance, 2 collagenous colitis, 1 diarrhea/possible gastroenteritis, 1 severe psoriasis, 1 AIDS). Table 1 shows the demographic data of the studied groups.

Methods

The diagnosis of CD was based on serologic tests and on the findings of a small intestinal mucosal biopsy. Because some tests are operator-dependent, the same professional (RMN) performed all the serologic tests: Antiendomysial antibodies (IgA EmA) by indirect

immunofluorescence assay using human umbilical cord as substrate, according to Volta *et al*^[10], sera considered positive if fluorescence was observed at a dilution of 1/2.5 or higher; serum IgA anti-tissue transglutaminase antibodies (anti-tTG) titres measured by an enzyme-linked immunosorbent assay (ELISA) using a commercial kit (INOVA Diagnostics Inc., USA), based on the method described by Dieterich *et al*^[11], results higher than 20 U were considered positive.

Upper gastrointestinal endoscopy was done by the same physician (APBR) with attention to the classical endoscopic markers of CD: erosions, scalloping of folds, decrease and atrophy of duodenal folds, mosaic patterns^[12,13]. The histological analysis was performed by the same pathologist (LRK), familiar with the spectrum of mucosal changes in CD, using Marsh's classification^[14] in Hematoxylin-Eosin stained fragments. These were, briefly, type I (infiltrative) with increased number of intraepithelial lymphocytes; type II (hyperplastic) with increased number of these cells and crypt hyperplasia; type III (destructive) with villous atrophy, A: partial, B: subtotal and C: total; type IV (hypoplastic) with flat atrophic mucosa. The number of intraepithelial lymphocytes (IEL) was counted according to Ferguson and Murray^[15]; 24% was considered normal for the Brazilian population, according to previous study^[16].

All the individuals (patients and relatives) were submitted to a rapid test for celiac-specific immunoglobulin A class tissue transglutaminase antibody detection performed from fresh fingertip whole blood sample (*Biocard Celiac-Test*TM, ANI Biotech, Vantaa, Finland). The basic concept is to liberate the individual's own tTG from the red blood cells by hemolysing an anticoagulated whole blood sample. When tTG-specific antibodies are present in the sera they recognize and form complexes with the liberated self-tTG. The complexes can be detected by binding tTG to a solid surface coated with tTG-capturing proteins. The bound antigen-antibody complexes can be seen in a color reaction with the help of labeled anti-human IgA solution^[9]. According to the manufacturer, 5 min (not longer than 10 min) is the time till the interpretation of the results. However, a positive test result may appear within 1 to 2 min. The test result is positive when both

the control line and the line in the test field can be seen; in negative cases only the control line forms^[9]. The result was interpreted immediately on site at the Endoscopy Room or in the doctor's office by the same physicians (APBR and LMSK).

The patients previously diagnosed as having CD were invited to an interview with their same physician to monitor diet, answering a questionnaire concerning the adherence to a GFD^[17]. The first-degree relatives of the patients were invited to participate in the study by phone call^[5].

Patients with clinical complaints suggestive of CD were submitted to the point-of-care test and to intestinal biopsy plus IgA EmA determination for comparison^[18].

The patients with dyspepsia, defined as persistent or recurrent pain or discomfort in the upper abdomen, were submitted to upper gastrointestinal endoscopy and biopsies by routine procedures. The mucosa of the bulb and the second portion of the duodenum was carefully studied^[12,13] and, if the previous test was positive, or if there were any changes, 5 to 7 fragments were obtained for histologic evaluation and Marsh's classification^[14]. In these cases IgA EmA test was also performed for correlation.

The diagnosis of IBS was based in Roma III criteria^[19]. Crohn's disease was diagnosed by clinical, endoscopic, imaging and histologic findings^[20]. The final diagnosis of the other cases were based on recommended tests^[3,8].

RESULTS

Table 1 shows the positivity of the Biocard Celiac-Test™ with the corresponding percentages.

The test was negative in the controls, in CD patients with strict adherence to a GFD, in the second-degree

relatives, in IBS, in Crohn's disease and diarrhea of different etiologies. Positive tests were detected in 83.3% of patients with suspicion of CD, in 100% of the patients that admitted diet transgressions, in 3.8% of the first-degree relatives and in 2.9% of patients with dyspepsia.

Considering only the female gender, the positivity of the studied test was 75.0% (3/4) for patients with CD suspicion, 66.7% (4/6) for patients with GFD transgressions, 5.3% (3/56) for first-degree relatives, and 4.3% (2/46) for patients with dyspepsia.

One female (HK) was negative for the rapid test, but positive for IgA EmA. Biopsy confirmed CD. IgA anti-tTG was determined in the sera of the patient (HB) with Biocard test positive and IgA EmA negative, with a resulting antibody level of 193 U, and CD confirmed by duodenal biopsy. IgA EmA was also determined in all the individuals with Biocard test positive ($n = 16$); 2 were negative (12.5%) for these antibodies (Table 2).

Duodenal biopsy was performed in 15 of the 16 individuals with positive Biocard test and recommended for one first-degree relative. Lesions characterized as Marsh III-C were seen in 11 cases or 73.3% (5 CD suspicion, 4 with GFD transgressions, 1 first-degree relative and 1 with and 1 without dyspepsia); Marsh III-A were detected in 2 patients with GFD transgressions and in 1 patient with dyspepsia (20.0%); Marsh type I was seen in one young first-degree relative (6.7%) (mother and aunt with CD). The number of IEL was increased in all the positive individuals (100%). Table 2 shows the demographic data of these individuals in relation to the positivity of IgA EmA and the endoscopic and histological evaluations.

DISCUSSION

CD has become more common than in the past, and can

be diagnosed at any age^[1]. However, it frequently remains undetected for long periods of time, because of failure by health care professionals to recognize the disorder, probably due to the variable clinical presentation or failure to perform appropriate diagnostic tests^[21].

In the present study, there was a young adult preponderance in all groups, indicating that it is important to exclude CD in the differential diagnosis of gastrointestinal complaints in this age group. However, we must remember that this affliction occurs also in patients of more than 60 years (as is shown here in the case of a male, 62 years, with recent-onset diarrhea)^[22].

The female preponderance, also reported by several authors in different countries, alerted us to investigate carefully women with digestive or systemic symptoms^[8,23]. When we considered only female gender, we observed that the percentage of CD case findings was higher than the total number of positive individuals in first-degree relatives and in patients with dyspepsia.

In this investigation, in the CD-suspicion group, the point-of-care test was positive in 83.3% (5/6) patients, similar to the report of Korponay-Szabó *et al*^[24]. It is possible that a patient can have only one CD-specific test positive, as was the case of the female patient with Biocard test negative and IgA EmA positive, or the male 62-year-old with this test positive, anti-tTG increased (193 U) and IgA EmA negative (Table 2). These cases demonstrate that more than one test is recommended if CD is suspected^[4].

Patients with CD should be evaluated at regular intervals by a health care team, including a physician and a dietician, but there are no clear guidelines as to the optimal means to monitor adherence to a GFD. Dietary compliance as assessed by interview is the best marker of CD due to low cost, non-invasiveness and strong correlation with serological tests and intestinal damage^[17]. Repeat serologic testing after 6 mo or more on a GFD can be helpful. The disappearance or decline of CD-specific serum antibodies during a diet is a further indication of dietary adherence and antibody testing is therefore recommended in dietary monitoring of CD (sensitivity varies from 29% to 100%)^[24]. However, antibody tests might not reveal slight dietary transgressions^[25]. In the present experience, the Biocard test recognized the disappearance of anti-tTG antibodies in all the patients with a GFD compliance and was positive in 14% (6/43) of the patients who admitted transgressions: they were young patients (median age 24 years), confirming the reports that adolescents had difficulties adhering strictly to the diet^[26-28]. The positivity of the test presumes major dietary transgressions^[25]. Notably, repeat biopsies are no longer required, but in the patients with positive tests the biopsy was performed for correlation (Table 2).

Dietary compliance varies a great deal in CD around the world. The compliance is related to the physician's recommendations but also to the collaboration of the families. It is important to know about the adherence to a GFD due to the probability of nutritional imbalances in children and adolescents^[28]. So, an easy test at

the office or at home can be very useful to detect transgressions because positivity rate correlates with dietary lapses^[24].

The prevalence of CD in first-degree relatives of patients with CD undergoing intestinal biopsy varies from 5.5%^[29] to 22.5%^[30]. In a previous study with 115 Brazilian relatives, we reported 15.6% CD prevalence^[5], with female preponderance, and in the present study there was 3.8% of test positivity (Table 2)^[31]. All were female: 1 sister and 1 daughter of the same family; 1 mother. This mother currently presents severe dyspeptic complaints. Her positivity for the point-of-care test occurred 7 years after the first IgA EmA negative determination, showing that the relatives need to be re-evaluated periodically^[32]. In some individuals, only more subtle changes of crypt lengthening with an increase in IEL, or simply an increase in IEL, are present. So, it is important that the slides be viewed by an experienced pathologist familiar with the spectrum of mucosal changes in CD. The example is the patient LGS (Table 2) with positive serologic tests, normal endoscopy and duodenal mucosa with preserved architecture, but with an increased number of IEL^[15,16].

In this investigation, there was no positivity in second-degree relatives. However, this was a small group. In a previous study with more Brazilian relatives we reported 5.9% of positivity^[32].

Although dyspepsia may be part of the clinical spectrum in CD patients, there are scarce data about its prevalence in silent CD^[33]. Duodenal biopsy undertaken during routine upper GI endoscopy in adults has been gradually incorporated into clinical practice, and is a useful tool for the diagnosis of CD in high-risk groups such as those with anemia and/or chronic diarrhea.

In this study there was 2.9% of test positivity in dyspepsia patients, both young female patients without diarrhea (Table 1). The correlations with IgA EmA and intestinal biopsy were 100% (Table 2). This result is similar to the findings of Riestra *et al*^[33] in Spain (2.2% also in women); Ozaslan *et al*^[21] in Turkey (1.5% in women). In another Brazilian region, Lima *et al*^[34] reported 1.4% positivity in women. In summary, CD should be kept in mind as a cause of dyspepsia during clinical assessments^[35]. Serological screening can be recommended for patients with refractory dyspepsia, especially females^[35]. A GFD may still bring symptomatic relief for dyspeptic symptoms in CD^[36].

Diarrhea is part of the clinical spectrum of IBS; the habitual tests are normal and the nutritional state is not compromised. There is a female prevalence probably related to hormones^[37-39]. In the present study 46 of 64 diarrhea patients were female (71.8%), median age 46.8 years, similar to previous reports^[40]. Even when CD was suspected in IBS, none of our patients were positive for anti-tTG point-of-care test (Table 1).

Patients with Crohn's disease can present chronic diarrhea as the only manifestation. At the beginning of the evaluation, differential diagnosis with CD can be pertinent, mainly in children and adolescents. In this study 62.5% (5/8) were female, mean age 35.6 years,

almost the same characteristics of the women with CD^[20,40]. None of the patients with Crohn's disease were positive for the point-of-care test (Table 1).

In the differential diagnosis of chronic diarrhea, a serological test to suggest or rule out CD is pertinent, especially in the doctor's office, to guide subsequent investigations. In 9 patients of this investigation, who were point-of-care test negative, the final diagnosis confirmed that the patients were not celiac patients^[3,41,42].

In a cost-effectiveness analysis in our geographic area, south of Brazil, the cost of IgA EmA or anti-tTG is 8 times the cost of the studied test, another reason to use this screening. The same conclusions were reported by Crovella *et al.*^[42] in another Brazilian area (Recife, Northeast).

To conclude, in this study the results of the point-of-care test showed good correlation with positivity of IgA EmA antibodies, endoscopic and histological findings (Table 2). As the test is quick, economical, easy to perform and as reliable as the conventional serological tests in CD case finding and in diet monitoring, it can be performed on site in the physician's office and in primary care^[24,43].

COMMENTS

Background

A rapid test, with a result which can be available immediately, will help the physicians to make decisions at their own offices for celiac disease.

Research frontiers

The literature only shows data in Finland populations and the authors emphasize the importance of the tissue transglutaminase antibody detection test in other geographic areas.

Applications

Due to low cost, the point-of-care test is important for celiac disease screening in developing countries.

Peer review

Overall this was a very good paper that demonstrate the value of TTG assay for diagnosis of celiac disease.

Abstract

AIM: To assess sustained virological response (SVR) rates in a predominantly hepatitis C virus (HCV) genotype 4 infected population.

METHODS: Between 2003-2007, 240 patients who were treated for chronic hepatitis C infection at our center were included. Epidemiological data, viral genotypes, and treatment outcomes were evaluated in all treated patients. Patients with chronic renal failure, previous non-responders, and those who relapsed after previous treatment were excluded from the study. Among all patients, 57% were treated with PEG-interferon (IFN) α -2a and 43% patients were treated with PEG-IFN α -2b; both groups received a standard dose of ribavirin.

RESULTS: 89.6% of patients completed the treatment with an overall SVR rate of 58%. The SVR rate was 54% in genotype 1, 44% in genotype 2, 73% in genotype 3, and 59% in genotype 4 patients. There was no statistical difference in the SVR rate between patients treated with PEG-IFN α -2a and PEG-IFN α -2b (61.5% vs 53%). Patients younger than 40 years had higher SVR rates than older patients (75% vs 51%, $P = 0.001$). SVR was also statistically significantly higher when the HCV RNA load (pretreatment) was below 800.000 (64% vs 50%, $P = 0.023$), in patients with a body mass index (BMI) less than 28 (65% vs 49%, $P = 0.01$), and in patients who completed the treatment duration (64% vs 8%, $P \leq 0.00001$).

CONCLUSION: The SVR rate in our study is higher than in previous studies. Compliance with the standard duration of treatment, higher ribavirin dose, younger age, lower BMI, and low pretreatment RNA levels were associated with a higher virological response.

INTRODUCTION

Chronic infection with the hepatitis C virus (HCV) affects about 170 million individuals worldwide. The natural history of chronic hepatitis C has been difficult to clearly define because of the long course of the disease; however multiple studies suggest that 20%-30% of infected patients eventually develop cirrhosis and its complications^[1]. Regardless of the mode of transmission, chronic hepatitis follows acute hepatitis C in 50%-85% of infected patients^[2]. Genotypes 1-4 account for nearly 90% of HCV-infected cases and genotype 4 is the most prevalent genotype in the Middle East, including Saudi Arabia. Genotype 1 is the next common, while genotypes 2, 3 and 5 are the least prevalent^[3-5]. Treatment of chronic HCV is aimed at slowing disease progression, preventing complications of cirrhosis, reducing the risk of hepatocellular carcinoma (HCC), and treating extrahepatic complications^[6]. The most effective therapy is the combination of PEGylated interferon (IFN) plus ribavirin. The benefit is mostly achieved in patients with HCV genotype 2 and 3 infections^[7]. Most of the published literature on management of HCV involves genotypes 1, 2 and 3. The data on treating hepatitis in the Middle East, in which genotype 4 predominates, is

limited. A recent study assessing sustained virological response (SVR) in Saudi Arabia revealed an SVR rate of around 48% in patients infected with HCV genotype 4; however, only PEG-IFN α -2a (PEGASYS) was used and they also included patients who were considered difficult to treat^[8]. Limitations of other studies include small number of patients, use of conventional interferons, and the lack of viral genotype data^[9]. Therefore, the objectives of this study were to (1) assess the SVR rates in treatment naïve patients; (2) compare the outcome of treatment using both PEG-IFN α -2b and PEG-IFN α -2a; and (3) define the predictors of SVR.

MATERIALS AND METHODS

A retrospective chart review of 400 patients treated at our center between January 2003 and January 2007 was conducted. All HCV treatment naïve patients with a positive PCR were included. Exclusion criteria included (1) pediatric patients; (2) chronic renal failure patients; (3) previous non-responders and those who had a relapse following prior treatment; (4) post renal transplant patients; and (5) patients with cirrhosis and signs of portal hypertension.

Biochemical assessments, including ALT (normal value: 0-58 IU/L), AST (normal value: 0-36 IU/L), γ -glutamyltransferase (GGT), alkaline phosphatase (ALP), bilirubin, albumin, and coagulation profile, were done according to our laboratory standards.

Serum HCV RNA was extracted using an automated extraction system. HCV detection and quantification were performed using the COBAS Ampliprep™/COBAS TaqMan™ HCV test (Roche diagnostics) utilizing different sets of primers and probes, which target a conserved region of the 5' untranslated region of the genome. The main processes of this procedure include: (1) specimen preparation to isolate HCV RNA; (2) reverse transcription of the target RNA to generate complementary DNA (cDNA) and (3) simultaneous PCR amplification of target cDNA and detection of cleaved dual-labeled oligonucleotide detection probe specific to the target. This assay detects and quantifies HCV genotype (1-6) with a detection limit that ranges from 15 to 69 000 000 IU/mL. Prior to treatment, the HCV genotype was assayed using INNO-LiPA HCVII (Innogenetics, Ghent, Belgium).

After reviewing the patients' data, 240 patients fulfilling the inclusion criteria were selected for the study. Epidemiological data and treatment records were reviewed. Liver biopsy is not done routinely in our center unless there is suspicion of underlying cirrhosis or a concomitant liver disease. For data entry, patients were divided according to their gender, viral load (HCV RNA below *vs* above 800 000 IU/mL), age (younger *vs* older than 40), treatment (PEG-IFN α -2a *vs* PEG-IFN α -2b), liver enzyme pattern (normal *vs* abnormal), and body mass index (BMI) (below *vs* above 28) (Table 1).

Patients received either PEG-IFN α -2a (40 Kd; PEGASYS, F. Hoffmann-La Roche, Basel, Switzerland) at a dose of 180 mg/wk or PEG-IFN α -2b (12 Kd;

PEGINTRON, Schering-Plough LTD, Singapore) at a dose of 1.5 mg/kg, and a standard dose of 1200 mg ribavirin with no weight related adjustments. While on treatment, patients were followed monthly or more frequently if required. Complete blood count (CBC) and liver enzymes were checked at each visit. To maintain the starting dose of PEGylated interferon and ribavirin, erythropoietin and granulocyte-colony stimulating factor (G-CSF) were given as early as possible to overcome any potential treatment-induced anemia or neutropenia. Patients with genotype 2 and 3 were treated for 24 wk, while patients with genotypes 1, 4 and 5 were treated for 48 wk. Viral loads were repeated at 12 wk to assess those who achieved an early virological response (EVR), at the end of treatment to assess the end of treatment virological response (ETVR), and six mo later to confirm an SVR. This study was approved by the Research Ethics Committee of our hospital.

Statistical analysis

Data were collected using a specialized data collection

Figure 1 Response rates among the different genotypes. SVR: Sustained virological response.

Table 2 Overall treatment outcomes

Treatment outcome	Frequency (%)
SVR	139 (58)
Relapse	17 (7)
Primary non responder	61 (25)
Intolerant	23 (10)
Total	240 (100)

form, then introduced into a Microsoft Excel worksheet and finally transferred to the statistical package for social sciences version 15.0 (SPSS, Chicago, IL, USA). Analyses used included descriptive statistics as well as a Student's *t*-test. $P < 0.05$ was considered statistically significant.

RESULTS

Eighty-two (34%) patients were genotype 4, while 46 (19.2%), nine (3.8%), 15 (6.3%), and one (0.4%) had genotypes 1, 2, 3 and 5, respectively. The genotype could not be identified in five (2.1%) patients, while the genotype data was missing in 82 (34.2%) patients (Figure 1).

Two hundred and fifteen (89.6%) patients completed the treatment, while 25 (10.4%) patients could not complete the treatment because of significant side effects. In the entire cohort ($n = 240$), end of treatment Virological response (ETVR) was achieved in 160 (66.7%). 139 (58%) patients achieved SVR, while 101 (42%) did not respond or had a relapse after achieving ETVR (Table 2).

One hundred and twenty five (52.1%) had side effects, while 115 (47.9%) did not report any treatment related side effects. None of the patients required a blood transfusion for anemia. One hundred and thirty eight (57.5%) patients were treated with PEG-IFN α -2a while 102 (42.5%) patients received PEG-IFN α -2b. Among those who were treated with PEGylated IFN α -2a, the SVR was 61.5% and for those who were treated with PEG-IFN α -2b it was 53%, this did not reach statistical significance.

Younger patients achieved statistically significantly higher SVR rates compared to older patients. This observation is in agreement with other studies and we

believe that this is because younger patients, in addition to tolerating full treatment doses, have a less advanced fibrosis stage compared to older patients (75% *vs* 51%, $P = 0.001$).

Other statistically significant predictors of achieving a SVR in the present study include compliance to a full treatment duration (64% *vs* 8%, $P < 0.00001$), a BMI lower than 28 (65% *vs* 49%, $P = 0.01$), and a pretreatment HCV RNA load below 800 000 IU/mL (64% *vs* 50%, $P = 0.023$). SVR rates were similar in relation to patient's gender, liver enzyme pattern, and the type of drug used (Table 3).

DISCUSSION

Most of the data on HCV management originates from western populations in which genotypes 1, 2, and 3 predominate. There is less data from populations

where the prevalence of HCV is much higher and in which HCV genotype 4 predominates. Initial studies with conventional interferon and ribavirin resulted in lower SVR rates, giving the impression that genotype 4 is difficult to treat^[10]. One of the first trials on the treatment of HCV using PEGylated interferon in our region was conducted by Alfaleh *et al*^[11]. In their study, 48 wk of PEG-IFN α -2b and ribavirin combination therapy resulted in an SVR rate of around 43%. One of the possible explanations for this relatively low SVR is the use of an 800 mg fixed dose of ribavirin daily. More recently Al Ashgar *et al*^[8] published their results in which 335 patients treated with PEG-IFN α -2a and ribavirin achieved an SVR rate of around 48%. In this study, they adjusted the ribavirin dose according to the body weight. They also included renal failure patients, patients who failed previous interferon based treatment, and patients with concomitant HBV or HIV.

Other studies originating from our region, using a combination therapy of PEG-IFN α -2b and ribavirin, resulted in SVR rates of 43% to 68%^[9,11-14].

In the present study, only treatment naïve patients were included. 58% of the patients achieved an SVR (64% excluding the patients that didn't complete the treatment). The following exclusion criteria were used to achieve a more homogenous study population: previously failed interferon based treatment, renal failure patients, and patients with a concomitant HBV/HIV.

In the present study, both PEG-IFN α -2a and PEG-IFN α -2b were used, with comparable results. A fixed dose of ribavirin was also given to the whole study population with no weight-based adjustment. This approach is considered to be an effective method for improving the outcome^[9], and likely contributed to the higher SVR rate in our study compared to previous studies on genotype 4 infected patients. SVR was achieved by 64% of patients in whom the treatment duration was completed, while only 2% of patients who did not complete the treatment achieved SVR. This confirms the importance of compliance in achieving SVR, as suggested by other studies^[15].

Duration of Treatment with PEG-IFN and ribavirin is individualized according to initial treatment response, genotype, and pretreatment viral load. Patients with HCV genotype 1 and 4 require treatment for 48 wk and those with genotypes 2 or 3 seem to be adequately treated in 24 wk^[16,17]. Some investigators tried treatment durations of 16 wk for HCV genotypes 2 and 3 infected patients who had a rapid virological response at four wk, with variable results. In one study, SVR was lower in patients treated for 16 wk than in patients treated for 24 wk, and the rate of relapse was significantly greater in the 16-wk group^[18]. Other studies show that extending the treatment duration from 48 wk to 72 wk in genotype 1 patients with slow virological response to PEG-IFN and ribavirin significantly improves SVR rates^[19]. The current practice worldwide is to treat HCV genotype 4 patients for 48 wk. However, recent data suggests treating chronic HCV genotype 4 patients for 24 and 36 wk might be sufficient when viral loads are undetectable

at four and 12 wk, respectively^[14]. Whether extending the treatment to 72 wk in genotype 4 patients with a slow response will increase the SVR rate is yet to be determined.

Factors that are thought to be associated with a favorable outcome include genotype 2 and 3, mild hepatitis, minimal fibrosis, absence of obesity, and female gender^[20]. Genotype 1, serum HCV RNA concentrations over 800 000 IU/mL, advanced duration of infection, histologically advanced liver disease, increased bodyweight, relapse or no response to previous treatment, presence of cirrhosis, African-American ethnicity, and advanced age were among the factors that are thought to be associated with a less favorable outcome^[21].

In the present study, patients with genotype 4 were treated for 48 wk and achieved an SVR of 64% in the patients who completed the treatment duration. Younger patients, low pretreatment viral load, lower BMI, and compliance with the standard duration of treatment were associated with a higher SVR. This study supports the view that treatment results of genotype 4 HCV naïve patients are more favorable than has been previously suggested when higher doses of ribavirin are used.

COMMENTS

Background

Chronic hepatitis C virus (HCV) infection is a major health problem and it is the main indication for orthotopic liver transplantation among adults. PEGylated interferon (IFN) and ribavirin combination therapy is the standard treatment, but data regarding sustained virological response (SVR) in our predominantly HCV genotype 4 infected population is limited.

Research frontiers

HCV genotype 4 is the most frequent cause of chronic hepatitis C in the Middle East and North Africa. In Saudi Arabia, disease prevalence is estimated at 2.5%. Initial studies suggested that genotype 4 was difficult to treat and was associated with a low SVR.

Innovations and breakthroughs

The use of PEGylated interferon and ribavirin resulted in a higher SVR rate in patients infected with genotype 4 when higher doses of ribavirin are given. In the study, patients were given a fixed high dose of ribavirin, and it is believed that this contributed to the higher SVR rates in the study compared to previous studies. Additionally, it is shown that younger patients, patients with lower body mass index, and patients with low viral loads had a better treatment outcome.

Applications

This study supports the view that treatment results of genotype 4 HCV naïve patients are more favorable than has been previously suggested when higher doses of ribavirin are used.

Peer review

The article concerns a very topical problem-interferon therapy effectiveness in HCV-patients. The content of the article will be interesting, not only for gastroenterologists, but also for practical medicine.

Published online: September 21, 2009

RESULTS: The sensitivity, specificity, PPV, NPV, and accuracy of CT were 61.5%, 84.9%, 50%, 90% and 80.3%, respectively. For PET, the percentages were 46.2%, 100%, 100%, 88.3%, and 89.4%. Additionally, there were 8 false positive CT cases (8/53, 15.1%) and zero false positive PET cases. Of the 13 metastatic PANs, there were 5 false negative CT scans (38.5%) and 7 (53.9%) false negative PET scans.

CONCLUSION: For detecting PAN metastasis, CT is more sensitive than PET, while PET is more specific.

Paraaortic lymph node metastasis in patients with intra-abdominal malignancies: CT vs PET. *World J Gastroenterol* 2009; 15(35): 4434-4438 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4434.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4434>

Abstract

AIM: To compare the diagnostic accuracy of computed tomography (CT) and positron emission tomography (PET) for the preoperative detection of paraaortic lymph node (PAN) metastasis in patients with intra-abdominal malignancies.

METHODS: Sixty-six patients with intra-abdominal malignancies who underwent both CT and PET before lymphadenectomy were included in this study. Histopathologically, 13 patients had metastatic PAN, while 53 had non-metastatic PAN. The CT criteria for metastasis were: short diameter of > 8 mm, lobular or irregular shape, and/or combined ancillary findings, including necrosis, conglomeration, vessel encasement, and infiltration. The PET criterion was positive fluorodeoxyglucose (FDG) uptake. The sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of both modalities were compared with the pathologic findings, and the false positive and false negative cases with both CT and PET were analyzed.

INTRODUCTION

Paraaortic lymph node (PAN) metastasis is considered an important prognostic factor in several abdominal and pelvic malignancies, such as stomach cancer, colorectal cancer, cholangiocarcinoma, and cervical cancer^[1-4]. While it is very important to evaluate PAN metastasis in preoperative evaluations, the correct diagnosis is not always definitively determined. Because of this, sampling and pathologic confirmation of the paraaortic nodes should be carried out before starting a radical operation, which is why many surgeons, including those in our hospital, perform paraaortic node dissection before radical surgery^[5-8]. Although lymphadenectomy followed by histologic examination of the lymph nodes is still the gold standard for determining metastasis, doctors must be careful in using this technique because of the perioperative risks and postoperative complications of

PAN dissection^[3,9,10]. All of this makes preoperative, noninvasive imaging diagnosis of PAN metastasis very important^[11,12].

For preoperative evaluation of abdominal malignancies, computed tomography (CT) has usually been used as the first-line examination. However, many investigators have reported CT to have low sensitivity and low specificity when used for lymph node (LN) diagnosis. Nowadays, positron emission tomography (PET) with fluorodeoxyglucose (FDG) has been recognized as a useful diagnostic technique in clinical oncology, not only for primary tumor evaluation, but also for detection of metastasis (including nodal metastasis)^[13]. However, FDG-PET has also been reported to have low sensitivity for the detection of LN metastasis^[14], and FDG-PET cannot determine the anatomical location of small lesions, such as lymph nodes^[15]. To our knowledge, however, there has been limited study comparing CT with PET in evaluating PAN metastasis^[16,17].

The purpose of our study is to compare the diagnostic accuracy of CT and FDG-PET in the preoperative detection of PAN metastasis in patients with an intra-abdominal malignancy. We also analyze the false positive and false negative cases of both CT and PET scans and suggest clinical guidelines for using CT and PET results.

MATERIALS AND METHODS

Patients

The protocol for this study was approved by the Institutional Review Board at our institution and informed consent was not required. Our pathologic database was retrospectively searched from September 2002 to July 2006 for all patients who underwent paraaortic lymphadenectomy before or during a surgical resection operation. A total of 305 patients were selected from the database, and, among these, 113 had underlying intra-abdominal malignancies (excluding lymphoma). Finally, 66 patients (39 women and 27 men, age range 28-78 years, mean age 56 years) who underwent both CT and PET no \leq 1 mo before a lymph node biopsy were chosen for the study. The underlying malignancies were as follows: hepatobiliary cancer ($n = 11$), pancreatic cancer ($n = 10$), colorectal cancer ($n = 20$), gastric cancer ($n = 3$), cervical cancer ($n = 7$) and tubo-ovarian cancer ($n = 15$).

Imaging procedures

For CT, all patients underwent single-section spiral CT (HiSpeed CT/I, GE Medical Systems, Milwaukee, WI) or multi-detector CT scanning (four detector row; Lightspeed Plus, GE Medical Systems, Milwaukee, WI or sixteen-detector row; Sensation 16, Siemens, Erlangen, Germany) according to an established protocol. A 60% iodinated contrast material [Iopromide (Ultravist); Schering, Berlin, diatrizoate meglumine (Hypaque) or iohexol (Omnipaque 300); Nycomed Amersham, Princeton, NJ] was administered intravenously at a rate

of 2-4 mL/s by using an automatic power injector with a volume of 2 mL/kg, up to a maximum volume of 150 mL. Portal venous phase CT scans were obtained 70 s after initiating the contrast material injection, and the abdomen and pelvis, from the level of the hepatic dome to the ischial tuberosities, were scanned with a pitch of 1.0-1.5 and a reconstruction thickness of 3.0-5.0 mm. The transverse images were reconstructed with a soft-tissue algorithm.

For PET, patients fasted at least 4 h before intravenous injection of 18F-FDG, and scanning began 60 min later. Images from the neck to the proximal thigh were obtained either on an Advance PET scanner (GE advance, GE Medical Systems, Milwaukee, WI), with a spatial resolution of 5 mm in the center of the field of view, or an Allegro PET scanner (Allegro, Philips-ADAC medical systems, Cleveland, OH), with a spatial resolution of 5.3 mm in the center of the field of view. For the Advance scanner, approximately 370 MBq of 18F-FDG were intravenously injected, and the emission scan was acquired for 5 min per bed position in the 2-dimensional mode. The Allegro acquired data in the 3-dimensional mode after administration of 5.18 MBq (0.14 mCi)/kg of 18F-FDG. Transmission scans (3 min per bed position) to correct for non-uniform attenuation were obtained using point sources of 68Ge for the Advance or 137Cs for the Allegro. Transmission scans were interleaved with the multiple emission scans for the Allegro. The images were reconstructed using an iterative reconstruction algorithm: that is, either the ordered-subset expectation maximization for the Advance or the low-action maximal-likelihood algorithm for the Allegro.

Imaging analysis

All imaging analysis was performed on a picture archiving and communication system (PACS) workstation (Centricity 1.0; GE Medical Systems). Two radiologists independently evaluated preoperative CT images in the 66 patients without knowledge of the final pathologic diagnoses. They considered the following criteria as the primary findings for a metastatic PAN: short diameter > 8 mm, lobular or irregular shape, and/or combined ancillary findings including necrosis, conglomeration, vessel encasement, and infiltration (Figure 1). Reviewers characterized the PAN as metastatic or non-metastatic. When discrepancies were detected, interpretations were achieved via consensus. Two experienced nuclear medicine physicians also interpreted the preoperative PET images, where the criterion was positive FDG uptake. When discrepancies were detected, interpretations were determined via consensus. The sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and accuracy of CT and PET for the detection of metastatic PAN were then calculated.

As a second portion of our study, a third radiologist analyzed the cases of false diagnosis for both CT and PET scans. She also evaluated the relationship between primary tumors and PAN in terms of the FDG uptake of the primary tumors on PET.

Figure 1 Typical case of metastatic paraaortic lymph node (PAN) on both computed tomography (CT) and positron emission tomography (PET). A 52-year-old woman with ovarian cancer underwent CT and PET. (A) Axial CT scan shows enlarged (short diameter was 16 mm) and conglomerated PAN (arrow) and (B) coronal view of PET image shows positive FDG uptake in this PAN (arrow).

RESULTS

In our 66 patients, we found 13 patients with metastatic paraaortic nodes and 53 patients with non-metastatic ones according to the pathologic results.

The sensitivity, specificity, PPV, NPV, and accuracy of CT for detecting PAN metastasis were 61.5% (8/13), 84.9% (45/53), 50% (8/16), 90% (45/50), and 80.3% (53/66), respectively. For PET, the results were 46.2% (6/13), 100% (53/53), 100% (6/6), 88.3% (53/60), and 89.4% (59/66), respectively. From these numbers, we can conclude that CT was more sensitive while PET was more specific, and the overall accuracy was slightly higher with PET.

With CT, 8 (15.1%) of the 53 non-metastatic nodes were false positively diagnosed (Figure 2). One of these cases showed central necrosis. There were no false positives using PET, as all 53 showed no FDG uptake.

For the 13 metastatic nodes, 5 cases (38.5%) on CT, 7 cases (53.9%) on PET, and 4 cases (30.8%) on both CT and PET were false negatively diagnosed. Among the false negative CT cases, only one (1/5, 20%) showed positive FDG uptake on PET. Among the false negative PET cases, 3 (3/7, 42.9%) were diagnosed as malignant nodes on CT (Figure 3).

In terms of the relationship between a primary tumor and PAN on FDG uptake, six of the seven false negative metastatic PAN cases showed high FDG uptake on the primary tumor. Only one patient with primary stomach cancer with ovarian metastasis showed negative FDG uptake on both the metastatic PAN and the primary

Figure 2 False positive metastatic PAN on CT. A 38-year-old man with colon cancer underwent CT and PET. (A) Coronal CT scan shows multiple enlarged (short diameter was 8 mm in the largest one) PAN (arrow), but (B) coronal view of PET image shows negative fluorodeoxyglucose uptake in these lymph nodes. This patient had underlying inflammatory bowel disease of ulcerative colitis.

Figure 3 False negative metastatic PAN on PET. A 72-year-old woman with common bile duct cancer underwent CT and PET. (A) Axial CT scan shows enlarged (short diameter was 12 mm) PAN (arrow) with surrounding fat infiltration, but (B) coronal view of PET image shows negative FDG uptake in this lymph node. Pathology was confirmed as metastatic lymph node.

tumor. A total of 3 cases (3/66, 4.5%) showed no FDG uptake on the primary tumor, and one of these (1/3, 33%) showed negative FDG uptake on the metastatic PAN.

DISCUSSION

Our study shows that CT is more sensitive than PET, while PET is more specific than CT for the diagnosis of metastatic PAN in patients with abdominal malignancies.

PET has generally been considered a sensitive tool for detecting distant metastasis^[13,18,19]. In daily practice, PET detects some lesions that are difficult to detect by CT, such as mesenteric or pelvic nodes between bowel loops. However, when considering only PAN, CT

showed more sensitivity than PET in our study.

PET is a functional imaging modality based on the increased glucose metabolism of physiologic or pathologic conditions. Because of this, PET has a limitation associated with metabolism: the primary tumor must have a strong avidity for ^{18}F -FDG, which may or may not be the case, depending on the histopathologic type of the tumor^[14,20]. Low metabolic activity can cause a false negative PET scan^[13], while a non-tumorous hypermetabolic condition, such as a systemic inflammation or an infection, can lead to false positive uptake^[13]. The usefulness of PET imaging is also limited in patients with uncontrolled diabetes mellitus ($> 150 \text{ mg/dL}$)^[14].

In our study, PET (53.9%) showed higher false negative rates than CT (38.5%) in metastatic PAN. One false negative metastatic PAN case (14.3%) also showed no FDG uptake on the primary tumor. The FDG activity of the primary tumor may reflect that of the metastatic PAN, meaning more careful attention is required to diagnose PAN if the primary tumor shows no FDG uptake.

Among the 7 false negative PET cases, 3 (42.9%) were diagnosed as metastatic PAN using CT because they showed necrosis or conglomeration, even though the short diameter was $< 8 \text{ mm}$. This means that CT may be helpful in the characterization of false negative PET cases.

CT also showed higher false positive rates than PET in our study. Many studies discuss the criteria for the detection of metastatic lymph nodes on CT, with size as the most frequently used parameter^[14,19,21-24]. However, this places a major limitation on CT, as it will be unable to detect small, metastatic lymph nodes and might misrepresent large, reactive lymph nodes^[13,19]. All of the false positive cases in our study showed no FDG uptake, which suggests that FDG-PET may be very useful for increasing the specificity of CT.

Integrated PET-CT has been introduced into clinical practice, providing shorter total imaging time and a reduction in the number of ambiguous lesions^[25,26]. Moreover, some researchers have reported that PET-CT improves diagnostic accuracy when compared with PET alone in abdominal and pelvic cancer^[27]. Recent studies report the sensitivity, specificity, and accuracy of PET-CT for lymph node metastasis as 28.6%-51.7%, 92.9%-99.8%, and 75.0%-99.8%, respectively^[15,17,28], but this still shows the lower sensitivity and higher specificity of PET-CT. While the role of CT in PET-CT is usually limited to anatomic localization and attenuation correction^[25], the results of our study suggest that CT is useful not only for anatomic localization, but also for a reduction in the false negative rate of PET. Previous studies have also reported that dedicated CT scans do additional work in some cases, such detecting as stomach cancer, liver cancer and mucinous primary or metastatic tumors^[19,26,29]. Moreover, there are some reports about integrated PET/contrast-enhanced CT as an accurate modality for assessing colorectal cancer in recent studies^[30,31]. However, the usefulness of integrated PET/

contrast-enhanced CT in other malignancies is still being debating and additional study of this topic is needed.

There are some limitations to our study. First, the diagnoses were variable with intra-abdominal malignancy (including hepatobiliary cancer, gastrointestinal cancer and gynecologic cancer) except lymphoma. Tumor characteristics on PET and lymphatic drainage pattern can be different between these malignancies. The second limitation is that we evaluated the data not on a per-node basis, but on a per-case basis. This is a limitation of retrospective study, and further evaluation with prospective study is needed.

In conclusion, CT is more sensitive than PET for detecting PAN metastasis, but PET is more specific. PET is useful for ruling out enlarged reactive lymph nodes and reducing the false positive rate of CT scans alone. To reduce the false negative rate of PET, CT can be helpful by showing necrosis or other ancillary findings of PAN. These results all suggest that the two modalities are complementary to each other in the diagnosis of PAN metastasis.

COMMENTS

Background

Paraaortic lymph node (PAN) metastasis is considered an important prognostic factor in several abdominal and pelvic malignancies. However, the correct diagnosis is not always definitively determined. Pathologic confirmation before starting a radical operation has perioperative risks and postoperative complications. Therefore, preoperative, noninvasive imaging diagnosis of PAN metastasis is very important.

Research frontiers

For preoperative evaluation of abdominal malignancies, computed tomography (CT) has usually been used as the first-line examination. Positron emission tomography (PET) with fluorodeoxyglucose (FDG) has been recognized as a useful diagnostic technique in clinical oncology. However, there has been limited study comparing CT with PET in evaluating PAN metastasis. The aim of our study is to compare the diagnostic accuracy of CT and FDG-PET in the preoperative detection of PAN metastasis in patients with an intra-abdominal malignancy.

Innovations and breakthroughs

CT is more sensitive than PET for detecting PAN metastasis, but PET is more specific. PET is useful for ruling out enlarged reactive lymph nodes and reducing the false positive rate of CT scans alone. To reduce the false negative rate of PET, CT can be helpful by showing necrosis or other ancillary findings of PAN.

Applications

CT and PET are complementary to each other in the diagnosis of PAN metastasis in patients with an intra-abdominal malignancy.

Peer review

Preoperative evaluation of paraaortic lymph node metastasis is very important in intra-abdominal malignancy. The results of this study are interesting as a preliminary result. It may be a first step to confirm the results of a prospective study in the future.

Abstract

AIM: To investigate the effect of Chai-Qin-Cheng-Qi Decoction (CQCQD) on cefotaxime (CTX) concentration in pancreas of rats with acute necrotizing pancreatitis (ANP).

METHODS: Sixty healthy male Sprague-Dawley rats were divided randomly into an ANP group (ANP model + CTX, $n = 20$), treatment group (ANP model + CTX + CQCQD, $n = 20$) and control group (normal rats + CTX, $n = 20$). ANP models were induced by retrograde intraductal injection of 3.5% sodium taurocholate (1 mL/kg), and the control group was injected intraductally with normal saline. All rats were injected intraperitoneally with 0.42 g/kg CTX (at 12-h intervals for a continuous 72 h) at 6 h after intraductal injection. Meanwhile, the treatment group received CQCQD (20 mL/kg) intragastrically at 8-h intervals, and the ANP and control group were treated intragastrically with normal saline. At 15 min after the last CTX injection, blood and pancreas samples were collected for the determination of CTX concentration using validated high-performance liquid chromatography. Pathological changes and wet-to-dry-weight (W/D) ratio of pancreatic tissue were examined.

RESULTS: Serum CTX concentrations in three groups were not significantly different. Pancreatic CTX

concentration and penetration ratio were lower in ANP group *vs* control group ($4.4 \pm 0.6 \mu\text{g/mL}$ *vs* $18.6 \pm 1.7 \mu\text{g/mL}$, $P = 0.000$; 5% *vs* 19%, $P = 0.000$), but significantly higher in treatment group *vs* ANP group ($6.4 \pm 1.7 \mu\text{g/mL}$ *vs* $4.4 \pm 0.6 \mu\text{g/mL}$, $P = 0.020$; 7% *vs* 5%, $P = 0.048$). The histological scores and W/D ratio were significantly decreased in treatment group *vs* ANP and control group.

CONCLUSION: CQCQD might have a promotive effect on CTX concentration in pancreatic tissues of rats with ANP.

Effects of Chai-Qin-Cheng-Qi Decoction on cefotaxime in rats with acute necrotizing pancreatitis. *World J Gastroenterol* 2009; 15(35): 4439-4443 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4439.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4439>

INTRODUCTION

Acute necrotizing pancreatitis (ANP) accounts for approximately 20% of patients with acute pancreatitis. When complicated by infection, pancreatic necrosis becomes a major contributor to late mortality^[1-3]. Early broad-spectrum antibiotics in the initial stage of disease appear to be associated with significantly decreased mortality and therefore improve outcome^[4]. The choice of the antibiotics must be driven by the flora as well as penetration in the pancreatic tissue^[5-7]. Cefotaxime (CTX), a semisynthetic broad-spectrum cephalosporin antibiotic, has an active penetrability and sustains an effective antibacterial concentration in human pancreatic tissue^[8-10].

An important criterion in determining the most appropriate antibiotic treatment for pancreatitis is antibiotic tissue concentration in the pancreas, which varies during the progression of ANP and is mainly

influenced by the changes in pancreatic tissue morphology and capillary blood flow. Previous studies have shown that the improvement of microcirculation and local infusion of the pancreas by regional arterial infusion can improve antibiotic concentrations in pancreatic tissue and reduce the pancreatic infection rate and mortality^[11,12].

Chai-Qin-Cheng-Qi Decoction (CQCQD) is modified from Da-Cheng-Qi Decoction (*Cortex Magnoliae Officinalis*, *Fructus Aurantii Immaturus*, *Radix et Rhizoma Rhei* and *Natrii Sulfas*), which is a well-known and popular traditional Chinese medicine that is used as a purgative in China and East Asia. In recent decades, CQCQD has been used widely for pancreatitis^[13]. Generally, CQCQD plays a multi-target and comprehensive role in ANP, but the exact therapeutic mechanism is still unclear.

In the present study, we performed validated high-pressure liquid chromatography (HPLC) to determinate the changes in CTX concentration and penetration ratio in pancreatic tissue of rats with ANP after oral administration of CQCQD. Our hypothesis was that CQCQD would increase CTX concentration and penetration rate in pancreatic tissue of ANP rats.

MATERIALS AND METHODS

Animals

Sixty healthy male Sprague-Dawley rats weighting 250-300 g were purchased from the Experimental Animal Center of West China Center of Medical Sciences of Sichuan University [SCXK (Chuan-11-2006)]. The animals were kept at constant room temperature with a 12-h light-dark cycle, free access to water and standard laboratory chow, and adjusted to laboratory conditions for 1 wk with a 12-h fast but free access to drinking water before the experiments. Animal experiments and performance of this study were approved by the Animal Care Committee of Sichuan University.

Preparation of CQCQD

CQCQD is composed of Chaihu (*Radix Bupleuri*) 15 g, Huangqin (*Radix Scutellariae*) 15 g, Houpo (*Cortex Magnoliae Officinalis*) 15 g, Zhishi (*Fructus Aurantii Immaturus*) 15 g, Yinchén (*Herba Artemisiae Capillaris*) 15 g, Zhizi (*Fructus Gardeniae*) 20 g, Dahuang (*Radix et Rhizoma Rhei*) 15 g, and Mangxiao (*Natrii Sulfas*) 10 g. All high-quality medicinal herbs were provided, prepared to decoction, vaporized and dried into lyophilized powder of CQCQD by Herbal Pharmacy of West China Hospital, Sichuan University, China. The lyophilized powder was stored at 4°C and freshly dissolved in drinking water (a raw herbal concentration of 2 g/mL) prior to use.

Main reagents

CTX sodium for injection (Claforan®) was a product of NCP Create Pharma Co., Ltd., China. Sodium taurocholate powder was purchased from Sigma (T-0750; St. Louis, MO, USA). All other reagents were of the highest purity available.

Animal grouping and administration

Rats were randomized divided into an ANP group (ANP model + CTX, $n = 20$), treatment group (ANP model + CTX + CQCQD, $n = 20$) and control group (normal rats + CTX, $n = 20$). After anesthesia with intraperitoneal injection of 40 mg/kg sodium pentobarbital, ANP models were induced by retrograde intraductal injection of 3.5% sodium taurocholate (1 mL/kg) using a micropump, within 5 min. Rats in the control group were administered with the same volume of normal saline. Six hours after retrograde injection, all animals were injected intraperitoneally with 0.42 g/kg CTX at 12-h intervals for a continuous 72 h; at the same time, rats in the treatment group were treated intragastrically with 20 mL/kg CQCQD at 8-h intervals, and the ANP group was given the same volume of normal saline as the positive control.

Sample collecting

Fifteen minutes after the last CTX injection, blood samples were collected *via* the inferior vena cava and centrifuged at 3600 r/min for 5 min at 4°C. The serum was kept at -70°C. Pancreatic tissues were removed quickly and stored immediately in liquid nitrogen at -70°C. Histopathological examination was also performed.

HPLC analysis

Prior to HPLC, pancreatic tissues were thawed and centrifuged at 2500 r/min for 5 min. HPLC was performed as follows: 100 μ L samples were mixed with 100 μ L water and 50 μ L internal standard, and then mixed with 500 μ L methanol. After centrifugation at 13000 r/min for 15 min at 16°C, the filtrate was evaporated under an air stream in a 40°C water bath. The residue was dissolved in 200 μ L mobile phase with methanol/0.05 mol/L phosphate buffer (18/82: v/v), and 50 μ L of the solution was injected into the HPLC system. The chromatographic separation was performed on a YMC-Pack ODS-A C18 column (5 μ m, 150 mm \times 4.6 mm). The flow rate was 0.8 mL/min. The retention time of CTX and the internal standard was 14.32 and 8.97 min, respectively. The detection was set at a wavelength of 254 nm.

Histopathological examination and wet-to-dry-weight (W/D) ratio

Pancreatic edema, inflammatory infiltration, hemorrhage and acinar cell necrosis were evaluated and scored according to the criteria shown in Table 1^[14]. For each pathological section, 10 visual fields under a high-power microscope [hematoxylin and eosin (HE) stain, $\times 400$] were selected randomly and scored by one single investigator (Xiang DK). The mean score of 10 visual fields from one pathological section was calculated as the pathological score.

We weighed the freshly collected pancreas samples in the wet state and incubated them at 210°C for 12 h, and the wet weight and dry weights were measured. The W/D ratio was used to represent water content in the pancreas.

Figure 1 Histopathological changes in pancreatic tissues in three groups (HE stain). A: Control group (× 200); B: ANP rats without CQCQD treatment (× 400); C: ANP rats with CQCQD treatment (× 200).

Statistical analysis

Data were expressed as mean ± SD or percentage. *P* value was calculated using ANOVA test for multiple comparisons. *P* < 0.05 was considered statistically significant.

RESULTS

CTX concentration in serum and pancreatic tissue, and CTX penetration ratio

CTX concentration in serum (*C*_s, μg/mL) and pancreatic tissue (*C*_p, μg/g), as well as CTX penetration ratio (*C*_p/*C*_s × 100%, %) are shown in Table 2. Three groups had no significant differences in serum CTX concentration (*P* >

Table 2 CTX concentrations in serum and pancreatic tissue, and penetration ratio (<i>C</i> _p / <i>C</i> _s × 100%) in three groups (mean ± SD)				
Group	<i>n</i>	<i>C</i> _s (μg/mL)	<i>C</i> _p (μg/g)	Penetration ratio (%)
Control group	20	98.9 ± 2.4	18.6 ± 1.7	19
ANP group	20	96.8 ± 2.2	4.4 ± 0.6 ^b	5 ^b
Treatment group	20	97.4 ± 3.0	6.4 ± 1.7 ^{a,b}	7 ^{a,b}

^a*P* < 0.05 *vs* ANP group; ^b*P* < 0.001 *vs* control group. CTX: Cefotaxime.

0.05). CTX concentration in pancreatic tissue (*P* < 0.001) and CTX penetration ratio (*P* < 0.001) were significantly lower in the ANP group versus the control group. Compared with the ANP group, the treatment group had a significantly higher CTX concentration in pancreatic tissue (*P* < 0.05) and CTX penetration ratio (*P* < 0.05).

Histopathological changes and histological scores

Histopathological changes in pancreatic tissues are shown in Figure 1. Comparison between the treatment and ANP groups indicated that scores for edema and inflammatory infiltration were significantly lower in the former (*P* < 0.001), although the differences in scores for hemorrhage and necrosis were not significant. Compared with the control group, pathological scores were significantly higher in the ANP and treatment groups (*P* < 0.001) (Figure 2).

W/D ratio

W/D ratio was higher in the ANP group than the control group (7.1 ± 1.7 *vs* 1.45 ± 0.1, *P* < 0.001). Although significantly higher than that in the control group (4.5 ± 1.5 *vs* 1.45 ± 0.1, *P* < 0.001), W/D ratio in the treatment group was significantly lower than that in the ANP group (4.5 ± 1.5 *vs* 7.1 ± 1.7, *P* < 0.01) (Figure 3).

DISCUSSION

Previous studies have reported that pancreatic perfusion decreases the progression of pancreatic necrosis^[15,16]. Early antibiotic therapy may be favorable for infection of the pancreas with enteric microorganisms in the course of

Figure 2 Histological scores of pancreatic tissues in three groups ($n = 20$, mean \pm SD). ^b $P < 0.001$ vs control group, ^d $P < 0.001$ vs ANP group.

ANP^[17,18]. Based on pharmacokinetic and bacteriological studies of the efficacy of different antibiotics in ANP, a consensus has emerged that antibiotics in ANP must not only cover the spectrum of bacteria usually found in necrotic pancreatic tissue (including anaerobes), but also penetrate into the pancreas with a sustainable anti-bactericidal concentration. The pancreatic concentration of antibiotic is determined by the pathophysiological condition of the pancreas, alkaline pH, high ion concentration, enzymatic and hormonal regulation, pathological changes, and infection^[19]. Promoters of pancreatic perfusion and microcirculation might enhance the therapeutic effects against infection by increasing antibiotic tissue concentrations.

HPLC analysis showed that CTX concentration in healthy rats was as high as 98.9 ± 2.4 $\mu\text{g/mL}$ in serum, but reduced to 18.6 ± 1.7 $\mu\text{g/mL}$ in pancreatic tissue (CTX penetration ratio in normal rats was 19%). These results indicate that the distribution of antibiotics is restricted by the existence of a blood-pancreatic juice barrier^[20]. Furthermore, the significantly reduced CTX concentration in pancreatic tissue and penetration ratio were detected in the ANP group more than in the control group ($P < 0.001$), as found by other investigators^[11]. The results also showed significant higher pancreatic tissue concentration and penetration ratio of CTX in the treatment group, which confirmed our hypothesis that CQCQD treatment could improve antibiotic concentration and penetration ratio in pancreatic tissue of rats with ANP.

Meanwhile, pathological scoring confirmed that CQCQD improved the severity of interstitial edema, inflammatory infiltration, hemorrhage and acinar cell necrosis. The significantly reduced W/D ratio of pancreatic tissue in the treatment group confirmed that CQCQD alleviated the severity of parenchymal edema.

Although we found a promotive effect of CQCQD on CTX tissue concentration in rats with ANP, the exact mechanism remains unclear. Some previous studies have demonstrated that prescriptions composed of Dahuang, Mangxiao, Zhishi and Houpo increase the blood flow of most abdominal organs during peritonitis, reduce inflammatory exudate and lesions, inhibit the "waterfall effect" of cytokines, and therefore protect the target organ^[21-23]. We speculate that the mechanism of action of CQCQD on antibiotics pancreatic concentrations in ANP rats

may be related to promotion of pancreatic microcirculation, increasing local perfusion and blood flow of the pancreas, improving pancreatic tissue edema, and reducing anti-inflammatory responses^[24-29].

There are some methodological aspects that should be taken into consideration when interpreting the results. (1) The ANP model was induced by intraductal retrograde injection of sodium taurocholate, which could closely mimic the etiology, pathogenesis and pathology of severe human pancreatitis, and is therefore the current standard and perfect modeling method with good reproducibility and comparability^[30,31]; (2) The first CTX injection was at 6 h after induction of ANP, because it represented early antibiotic therapy in the initial stage of the disease, and the protocols for CTX administration were adopted from previous studies in small rodents^[17], as well as from our clinical protocol; (3) Seventy-two hours after modeling was chosen as the measurement time-point when pancreatic necrosis was fully developed and when stable concentrations of CTX and CQCQD would be available in the blood.

In summary, the results of the present study validate the hypothesis that CQCQD increases pancreatic tissue concentration and penetration ratio of CTX in rats with ANP, through the possible mechanism of eliminating pancreatic inflammation and edema. Thus, the study might form the basis of advanced studies on the associated therapeutic mechanisms of Chinese medicine in ANP.

COMMENTS

Background

Infection in pancreatic necrosis is still regarded as the most serious complication of acute necrotizing pancreatitis (ANP), with a morbidity of 16%-47%, which has not substantially changed during the past two decades, despite of strenuous efforts and rapid progress in treatment. Early broad-spectrum antibiotics in the initial stage of the disease appear to decrease significantly mortality and improve outcome. Based on pharmacokinetic and bacteriological studies of the efficacy of different antibiotics, antibiotics used in patient with ANP must not only cover the spectrum of bacteria usually found in necrotic pancreatic tissue (including anaerobes), but also penetrate into the pancreas with a sustainable anti-bactericidal concentration.

Research frontiers

Pancreatic perfusion and microcirculation are decreased in ANP, therefore, intravenous antibiotics might not reach an effective anti-bactericidal concentration in the pancreas. Promoters of pancreatic perfusion and microcirculation might

enhance the therapeutic effects against infection by increasing antibiotic tissue concentrations.

Innovations and breakthroughs

The therapeutic mechanisms of Chinese medicines are characterized by multiple targets and complicated networks. The innovations and breakthroughs of the present study are the linkage between antibiotic tissue concentration and Chai-Qin-Cheng-Qi Decoction (CQCQD), which may explain the therapeutic mechanisms of Chinese medicine prescribed for ANP. The study methods and results might provide the basis for advanced studies in this field.

Terminology

Acute pancreatitis is an acute inflammatory process of the pancreas that frequently involves peripancreatic tissues, and at times, remote organ systems. Pancreatic necrosis is defined as one or more areas of nonviable pancreatic parenchyma, and is associated usually with peripancreatic fat necrosis.

Peer review

In this pilot study, the authors explored the effect of CQCQD on cefotaxime concentration in pancreatic tissue of rats with ANP, using validated high-performance liquid chromatography. The results indicated that CQCQD has a promotive effect on cefotaxime concentration in pancreatic tissues of rats with ANP. The study might elucidate the associated therapeutic mechanisms of Traditional Chinese Medicine in ANP.

INTRODUCTION

Radiotherapy for locally advanced pancreatic cancer is technically difficult and potentially deleterious, because of the proximity of adjacent vital organs. Although intensity-modulated radiotherapy recently has proven its efficacy in sparing vital organs from irradiation, digestive toxicity remains an important limiting factor^[1]. Helical tomotherapy (HT) is a new irradiation modality that combines intensity-modulated fan-beam radiotherapy with megavoltage computed tomography imaging for patient positioning^[2]. Its availability recently has opened new fields of exploration for pancreatic radiotherapy as a result of its ability to tailor very well-defined dose distributions around the target areas.

To the best of our knowledge, this report is the first to explore the use of HT and its potential for sparing vital organs in two patients with locally advanced pancreatic cancer.

CASE REPORT

Patient 1 was a 59-year-old man whose pancreatic cancer was discovered fortuitously in September 2007 at a follow-up examination for previous prostatic cancer. Clinical examination was normal. Computed tomography (CT) showed a mass in the head of the pancreas, which measured 33 mm in the greatest dimension, with portal vein thrombosis. Endosonography demonstrated infiltration of the superior mesenteric vein, which reached the superior mesenteric artery. Histological examination confirmed an adenocarcinoma. Patient 2 was a 62-year-old woman who presented in April 2008 with abdominal pain and weight loss. There was no abnormality at clinical examination. The CT scan showed diffuse dilatation of the duct of Wirsung, with an irregular mass in the pancreatic isthmus. Endosonography revealed a mass in the isthmus, which measured 25 mm in the greatest dimension, with tumor extension to posterior peripancreatic fat tissue and massive splenic artery encasement. Histological examination confirmed a papillary mucinous adenocarcinoma. For both patients, laboratory tests

Abstract

Radiotherapy for locally advanced pancreatic cancer is technically difficult and frequently associated with high-grade digestive toxicity. Helical tomotherapy (HT) is a new irradiation modality that combines megavoltage computed tomography imaging for patient positioning with intensity-modulated fan-beam radiotherapy. Its recent availability opens new fields of exploration for pancreatic radiotherapy as a result of its ability to tailor very well-defined dose distributions around the target volumes. Here, we report the use of HT in two patients with locally advanced pancreatic cancer. Doses to the bowel, kidneys and liver were reduced significantly, which allowed for excellent treatment tolerance without any high-grade adverse effects in either patient.

Chargari C, Campana F, Beuzeboc P, Zefkili S, Kirova YM. Preliminary experience of helical tomotherapy for locally advanced pancreatic cancer. *World J Gastroenterol* 2009;

revealed no biological abnormality and no elevation of tumor markers. No lymph node or distant metastases were observed at initial staging.

The patients were treated with induction chemotherapy of gemcitabine (1000 mg/m² on day 1 every week) and oxaliplatin (100 mg/m² on day 1 every 2 wk). In patient 1, assessment after six cycles showed no local or metastatic evolution. In patient 2, assessment after five cycles showed partial regression of the pancreatic mass, which measured 18 mm in the greatest dimension, and no metastatic extent. Patient 1 and 2 were referred for preoperative and exclusive chemoradiation, respectively.

In patient 1, HT delivered 45 Gy to the whole pancreas, and 50.4 Gy to the tumoral mass, using 6-MV photons, at 1.8 Gy per daily fraction, for a total duration of 39 d. In patient 2, HT delivered 45 Gy to the whole pancreas, and 66 Gy to the tumoral mass, using 6-MV photons, at 2 Gy per daily fraction, for a total duration of 64 d. For both patients, capecitabine was given at 3000 mg/m² per day in two divided doses, 5 d/wk, concurrently with radiotherapy. Chemoradiation was marked by grade 1 nausea in both patients. No other acute toxicity was observed. For patient 1, abdominal pain disappeared after completion of chemoradiation. However, he developed early hepatic metastases and was given palliative chemotherapy with gemcitabine and oxaliplatin, followed by erlotinib for progressive disease. Patient 1 maintained a complete local response that was still present at 18 mo follow-up. Patient 2 remains disease-free at 6 mo follow-up.

DISCUSSION

Conventional radiotherapy for pancreatic cancer can involve some parts of the duodenum, stomach, small intestine, and kidneys, which results in frequent severe acute gastrointestinal toxicity when chemotherapeutic agents are administered concurrently with radiotherapy. This can lead to frequent treatment disruption and limits the delivery of a sufficient radiation dose. Moreover, high-grade toxicity compromises quality of life, which is an important endpoint in patients with poor prognosis^[3]. Since gemcitabine and oxaliplatin have improved the outcome of patients with locally advanced or metastatic disease, by improving survival with clinical benefits, every effort should be made to avoid additional radiation-induced digestive toxicity that might potentially compromise the delivery of subsequent chemotherapy^[4].

For both of our patients who were at risk for high-grade toxicity, HT provided a potential tool to decrease the risk of gastrointestinal toxicity^[5]. As a result of isodose conformation, radiation doses to the bowel, right kidney and liver were reduced significantly, which allowed for excellent treatment tolerance without any high-grade adverse effects in either patient. It is reasonable to

Figure 1 Distribution of isodoses with HT treatment planning in patient 1 (A) and patient 2 (B), in axial and coronal representation. The different doses are represented with different colors. Red color represents the target volume dose.

assume that HT may have spared structures that normally would not have been spared with more conventional 3D conformal radiotherapy (Figure 1). However, very low doses are distributed to larger volumes. While the problem of radiation-induced malignancy in such patients with poor prognosis should not be considered to be of primary importance, further assessment of HT remains necessary.

The present report highlights the potential of HT to reduce the dose of radiation delivered to vital organs, thus improving tolerance to irradiation.

Abstract

A 67-year-old man with celiac disease developed recurrent diarrhea, profound weakness and weight loss, with evidence of marked protein depletion. His clinical course was refractory to a strict gluten-free diet and steroid therapy. Postmortem studies led to definition of unrecognized collagenous sprue that caused ulceration and small intestinal perforation. Although PCR showed identical monoclonal T-cell populations in antemortem duodenal biopsies and postmortem jejunum, careful pathological evaluation demonstrated no frank lymphoma. Rarely, overt or even cryptic T-cell lymphoma may complicate collagenous sprue, however, small intestinal ulcers and perforation may also develop independently. The dramatic findings here may reflect an underlying or early molecular event in the eventual clinical appearance of overt T-cell lymphoma.

INTRODUCTION

Collagenous sprue was initially observed to complicate the clinical course of celiac disease^[1]. The disorder is characterized by a pathologically distinctive lesion with the appearance of a patchy or diffusely thickened sub-epithelial collagen band in flattened small intestine. Most patients with extensive collagenous sprue have a progressive and deteriorating clinical disorder marked by severe pan-malabsorption of multiple nutrients, profound weight loss, and evidence of marked protein loss that fails to respond to a gluten-free diet^[2]. Etiology and pathogenesis of collagenous sprue remain obscure, although inherited and other factors may play a role^[2]. A number of treatment regimens, including steroids, have been reported anecdotally to show benefit^[3,4].

Although only limited information on the natural history, pathogenesis and clinical outcome of collagenous mucosal disorders of the small and large intestine are available, occasionally, lymphoma may complicate collagenous sprue^[5-8] and collagenous colitis^[9]. In some of these, the lymphoma was already extensive and advanced^[5-7], but in another, synchronous development of collagenous sprue and lymphoma occurred, which suggested to the authors that collagenous sprue may represent a noninvasive component of the lymphomatous process^[8]. Collagenous enterocolitis has also been noted in a patient with localized colon cancer, with complete reversion to normal following resection of the malignant lesion^[10]. It was hypothesized that intestinal sub-epithelial collagen deposition with concomitant malignancy represents a paraneoplastic morphologic marker that may be completely reversible^[10].

CASE REPORT

In November 2006, a 67-year-old man was evaluated initially in his community hospital for progressive fatigue, diarrhea and weight loss of 15 kg over 6-8 mo. Physical examination revealed bilateral lower limb edema. Initial laboratory studies were normal except for hypoalbuminemia (serum albumin, 13 g/L; normal, 35-50) and elevated tissue transglutaminase (tTG) antibody of 35 U (normal, < 20). Endoscopy of his upper and lower gastrointestinal tract appeared normal, but duodenal biopsies showed typical changes of untreated celiac disease, with crypt hyperplastic villous atrophy. A gluten-free diet was started but his

Figure 1 Antemortem biopsy from duodenum showed features of untreated celiac disease, despite a gluten-free diet. Although later postmortem PCR of this biopsy documented a monoclonal population of T cells, frank lymphoma was not detected.

Figure 2 Postmortem small bowel section showed diffuse mucosal involvement with collagenous sprue. Note eosin-stained sub-epithelial band. Trichrome staining was also positive (HE, $\times 20$).

Figure 3 Autopsy showed ileum with a focal jejunal ulcer and perforation. A: Low-power photomicrograph showed jejunal ulceration with perforation in an area of collagenous sprue in postmortem material; B: High-power photomicrograph showed perforated collagenous sprue.

clinical course became complicated by progressive dyspnea that required hospital re-admission. Computed tomography (CT) scanning showed bilateral pulmonary emboli and pleural effusions with prominent mesenteric lymph nodes. He was started on anticoagulation and was maintained on coumadin for the next year. By February 2007, his fatigue resolved and exercise tolerance improved. His diarrhea resolved completely and his weight increased and normalized. Peripheral edema resolved and his serum albumin increased to 35 g/L. A repeat CT scan showed resolution of chest findings. Mesenteric lymph nodes were not enlarged.

In November 2007, diarrhea and weight loss recurred in spite of strict adherence to a gluten-free diet. Over the next month, recurrent edema also developed in his lower extremities up to his waist. Physical examination now revealed generalized wasting, brawny induration with hyperpigmentation of his lower extremities, bilateral ichthyosis, especially over the anterior tibial surfaces, and pitting edema. Laboratory investigations, including hemogram, were normal except for hypoproteinemia (35 g/L; normal, 62–82 g/L) and hypoalbuminemia (11 g/L; normal, 34–50 g/L). Serum carotene was reduced to $< 0.5 \mu\text{mol/L}$ (normal, 1.1–3.7 $\mu\text{mol/L}$), while serum tTG assay was normal (9.1 U), with a normal serum IgA (1.12 g/L; normal, 0.70–4.00 g/L). Endoscopy was normal except for scalloping of proximal duodenal mucosal folds. Biopsies showed crypt hyperplastic villous atrophy,

despite a gluten-free diet (Figure 1). Fresh biopsy material was submitted for PCR, but analysis failed. Endoscopic biopsies of stomach and colon were normal with no intra-epithelial lymphocytosis. A barium study of the small intestine showed dilation of small bowel loops but no discrete lesion, abnormal loop separation or stricture. Gluten-free diet was continued but his weight fell further by 5 kg. A contrast CT scan of the chest, abdomen and pelvis showed no new findings, although a left common femoral vein thrombus was seen. Mesenteric lymph nodes were normal. Oral budesonide 3 mg/d was prescribed^[11].

He deteriorated suddenly over 2 d with abdominal pain, worsening weakness and continued weight loss. He was readmitted to his community hospital and parenteral nutritional support was initiated. In hospital, he deteriorated rapidly with fluctuations in consciousness and died 3 d later. Autopsy showed extensive collagenous sprue (Figure 2) in the jejunum and ileum with a focal jejunal ulcer and perforation (Figure 3). Careful review failed to show lymphoma. Immunohistochemical studies (BCCA Lymphoma Referral Laboratory, Vancouver, BC, Canada) showed CD3-positive T-cells that expressed CD2 and CD7, but failed to express CD4, CD8 and CD5. CD3-positive T cells showed intracytoplasmic rather than membrane labeling. Immunostaining for CD56 was negative and cells were negative for Epstein-Barr virus by an EBER ISH stain. Stains for cytotoxic markers TIA-1, perforin and granzyme B showed that the majority of cells were negative. PCR of the previous antemortem duodenal

biopsies, along with a postmortem section of jejunum, showed an identical monoclonal T-cell band.

DISCUSSION

This report documents collagenous sprue in a patient with recurrent diarrhea and profound weight loss, with severe protein depletion despite a gluten-free diet and steroid therapy. Collagenous sprue appeared to complicate preexistent celiac disease that initially had responded clinically to administration of a gluten-free diet, similar to the original description of this disorder^[1]. Here, however, symptoms redeveloped despite a strict gluten-free diet and oral budesonide^[11]. This appeared to be related to collagenous sprue complicated by ulceration and perforation of the distal small bowel. Even though an identical monoclonal T-cell population was defined molecularly by PCR in antemortem duodenal biopsies and postmortem jejunal sections, careful pathological review failed to reveal any neoplastic lymphoid cells. It is likely that this very unusual complication of ulceration and perforation of the small intestine reflects a stage of development of cryptic T-cell lymphoma^[5], which may precede the appearance of frank pathologically defined lymphoma. Rarely, ulceration and free perforation of the small intestine may complicate celiac disease as the initial manifestation^[12]. However, the sequence of events here in collagenous sprue with ulceration and perforation has not been described previously and provides an additional dimension to our understanding of the natural history and clinical outcome of this very unusual small intestinal disorder.

While development of small intestinal ulceration and perforation clearly led to our patient's demise, it may not be an entirely surprising event in the clinical course of collagenous sprue. A number of factors may play a role. First, mucosal thickness in collagenous sprue appears to be reduced markedly so that complication of a focal ulcer with free perforation might more readily occur. Second, lymphoma has been noted previously to be responsible for free perforation of the small intestine in celiac disease^[12], and a superimposed lymphoma in collagenous sprue could occur that might present with free perforation. Finally, the collagenized layer in the small intestine may be more susceptible or more prone to perforation. Indeed, in collagenous colitis, free and spontaneous perforation of the colon has been described^[13], along with a propensity for instrument-induced colon fractures and perforation^[14]. Since there is evidence that the collagen deposited in the small and large bowel in these disorders is similar^[2], and has been hypothesized to affect the integrity of the intestinal wall^[14], this outcome with ulceration and

perforation of the small bowel during the clinical course of collagenous sprue may occur more frequently than is appreciated at present.

Abstract

The anti-tumor necrosis factor (TNF) α medications demonstrate efficacy in the induction of remission and its maintenance in numerous chronic inflammatory conditions. With the increasing number of patients receiving anti-TNF α agents, however, less common adverse reactions will occur. Cutaneous eruptions complicating treatment with an anti-TNF α agent are not uncommon, occurring in around 20% of patients. Adalimumab, a fully humanized antibody against TNF α , may be expected to cause minimal immune-mediated skin reactions compared to the chimeric monoclonal antibody, infliximab. We, however, report a case of Stevens-Johnson syndrome that required hospitalization and cessation of adalimumab in a patient with Crohn's disease (CD). In this case report, a 29-year-old male with colonic and perianal CD with associated erythema nodosum and large joint arthropathy developed severe mucositis, peripheral rash and desquamation, fevers and respiratory symptoms concomitant with a second dose of 40 mg adalimumab after a 2 mo break from adalimumab therapy. Skin biopsies of the abdominal wall confirmed erythema multiforme and the patient was on no other drugs and infective etiologies were excluded. The patient responded rapidly to IV hydrocortisone and was able to be commenced on infliximab without recurrence of the Stevens-Johnson syndrome. Desquamating skin reactions have now been described in three of the TNF α antagonists

(infliximab, etanercept and adalimumab). These reactions can be serious and prescribers need to be aware of the potential mucocutaneous side effects of these agents, especially as Stevens-Johnson syndrome is associated with significant morbidity and mortality.

INTRODUCTION

Managing chronic diseases is one of the greatest challenges for medicine and the community today as poor management results in increased resource utilization and financial costs. The anti-tumor necrosis factor (TNF) α medications, infliximab and adalimumab have demonstrated efficacy in the induction of remission, and the long-term maintenance of remission, in numerous chronic inflammatory conditions including rheumatoid arthritis (RA)^[1], ankylosing spondylitis^[2], psoriatic arthritis and severe chronic psoriasis^[3,4]. The use of biological anti-TNF α medications in the inflammatory bowel diseases (IBD), Crohn's disease (CD) and ulcerative colitis (UC) is also well accepted^[5-9]. The IBDs are life-long, chronic, conditions and many patients suffer severe attacks that require hospitalization. There are many drug combinations that can be used to manage these patients, but many patients are either resistant or intolerant to the non-biological therapies available. In view of the effectiveness of anti-TNF α medications, and the long-term nature of the diseases they treat, the number of patients receiving these

medications continues to increase.

As a fully humanized antibody against TNF α , adalimumab may potentially cause less immune-mediated skin reactions in comparison to infliximab. The risk, however, is still present and we report here the first case in the literature of the immune-mediated skin reaction Stevens-Johnson syndrome (SJS), that can be attributed to the use of adalimumab.

CASE REPORT

We report here a 29-year-old male diagnosed in 2005 with ileocolonic and fistulising perianal CD associated with the extra-intestinal complications of erythema nodosum, pustular psoriasis and large joint arthropathy. In August 2007, despite the use of azathioprine (AZA) 125 mg/d, antibiotics and 5-aminosalicylic acids, he had a Crohn's Disease Activity Index (CDAI) of greater than 300, indicating moderately severe disease activity. Endoscopy confirmed severe ulcerating inflammation of the colon and the terminal ileum. In September 2007, he was commenced on routine induction therapy with adalimumab, 160 mg at week 0, 80 mg week 2 followed by 40 mg every other week (eow) administered subcutaneously (sc). Tuberculosis had been excluded by Quantiferon gold testing and chest X-ray, while his hepatitis B and C serology were confirmed to be negative prior to commencing adalimumab treatment. Complete resolution of his colitis and healing of his perianal fistulae occurred by 12 wk. He was continued on maintenance adalimumab therapy at 40 mg (sc eow) and AZA.

In December 2007, 16 wk after commencing the adalimumab therapy, he was admitted to a district hospital for suspected cellulitis of his left leg and treated by a general physician with intravenous antibiotics. His adalimumab was withheld and AZA ceased due to concerns about infection. After 10 d on antibiotic therapy he developed a severe mucositis, peripheral rash and fever. He was transferred to the Centre for Inflammatory Bowel Diseases, Fremantle Hospital, which is a specialist IBD unit in a tertiary institution that services the southern metropolitan region of Perth, Australia. At that time his C-reactive protein was 151 mg/L (normal < 10 mg/L), Hb 90 g/L (normal 135-180 g/L), platelet $521 \times 10^9/L$ (normal $150-400 \times 10^9/L$) and WBC $7.9 \times 10^9/L$ (normal $4.00-11.00 \times 10^9/L$). His blood cultures were clear as was his CXR. The suspected cellulitis was diagnosed as erythema nodosum and the mucositis, peripheral rash and fever were considered to be an adverse reaction to the antibiotic combination he had received. He was commenced on prednisone for the drug reaction and his severe mucositis slowly improved while the erythema nodosum resolved over the following months on a weaning dose of oral prednisolone. Due to patient concerns that his symptoms may have been exacerbated by the adalimumab, this was not recommenced at that time.

In March 2008, due to the recommencement of draining from the perianal fistulae, symptoms consistent

Figure 1 Mucosal lesions. A: Lip involvement with target-lesion on left upper lip progressing to a bullae (black arrow); B: Tongue desquamation demonstrated as white plaques (white arrows).

Figure 2 Chest X-Ray. Patchy bilateral alveolar infiltrates consistent with bronchial pneumonia.

with flaring of the colonic inflammation and reactivation of the erythema nodosum, the patient was recommenced on 40 mg adalimumab eow. A week after the first dose the patient felt that his abdominal symptoms had resolved quite significantly, the erythema nodosum had improved and there was no pain and minimal discharge from the perianal fistula. A day after receiving the second dose of 40 mg adalimumab, however, the patient became systemically unwell with fever. He developed a severe mucositis (Figure 1) and a peripheral rash with desquamation on his abdomen. He also suffered reactivation of the erythema nodosum on his legs that was confirmed to be erythema nodosum on skin biopsy.

The patient was also dyspnoeic and on chest X-ray patchy opacification was observed of both mid and upper

Figure 3 Histology of skin biopsies. The epidermis shows mild irregular acanthosis with a small amount of overlying compact keratin (thin arrow). There is superficial dermal oedema associated with vacuolar change of the basal layer of the epidermis (thick arrow). Within the dermis is a mixed inflammatory cell infiltrate. The findings are consistent with erythema multiforme. A: 25 × magnification; B: Insert at 100 × magnification.

zones consistent with bronchopneumonia (Figure 2). CT scan of the thorax confirmed widespread bronchopneumonia tending to confluence in the right upper lobe. The patient was taking no other medications concurrent with the adalimumab and the adalimumab was ceased. Blood and sputum culture were negative and bacterial aetiologies and other infective causes were excluded including tuberculosis, mycoplasma pneumoniae, viral infections (HSV 1 and 2, CMV, EBV, HIV, HBV, and HCV) and rickettsia. His antinuclear antibody (ANA) remained negative throughout. Skin biopsies taken from the anterior abdominal wall rash were consistent with erythema multiforme (Figure 3). Due to the combination of mucositis membrane erosions, target lesions and epidermal necrosis with skin detachment consistent with erythema multiforme, a diagnosis of SJS was made. The chest findings also supported this diagnosis, as pulmonary infiltrates are present in 1/3 of patients with SJS. Oral doxycycline was commenced in combination with intravenous hydrocortisone with a rapid improvement in his systemic symptoms and resolution of his fever and chest X-ray infiltrates. He was transferred onto oral prednisone and his mucocutaneous symptoms resolved over the course of 3-4 wk. Due to continuing symptoms from his perianal and colonic CD, the patient was commenced on an induction regime of infliximab therapy with resolution of his CD symptoms and without reactivation of the SJS.

DISCUSSION

Cutaneous reactions in patients treated with TNF α antagonists are relatively common, but make up a heterogeneous group. Recently the rate of new onset cutaneous eruptions in patients treated with infliximab for CD has been documented at 20%^[10], and in a prospectively analysed series of RA patients treated with TNF α antagonists, 35/150 (23.3%) of patients developed cutaneous reactions. Eczema and psoriasis made up the majority of these (45.7%), with infections the cause of over a third (37.1%)^[11]. There have been 3 reported cases of an interface dermatitis, with histological characteristics suggesting erythema multiforme, in patients treated with infliximab for RA. One of these subjects also developed a similar cutaneous reaction, confirmed on histology, after treatment with etanercept^[12].

With an increasing number of patients receiving an anti-TNF α agent less common adverse reactions are bound to occur, and the physician must be aware of these potential problems. There is a spectrum of severe cutaneous adverse drug reactions that may represent variants of the same disease process, and include SJS and toxic epidermal necrolysis (TEN) that are on a spectrum of disease severity. They are both characterised by varying degrees of disruption of the dermoepidermal junction. Clinically, each presents with a pattern characterised by the triad of mucous membrane erosions, target lesions and epidermal necrosis with skin detachment. A mortality rate of between 1%-5% is associated with SJS and TEN may be as high as 40%^[13]. Erythema multiforme, erythema multiforme major and atypical erythema multiforme major, are cutaneous reactions that do not involve the mucous membranes, and are primarily observed post-infection, with the majority secondary to the herpes simplex virus, rather than as a drug reaction. The distinction, however, is often difficult to make and drugs are still implicated in up to 50% of cases of erythema multiforme.

Apart from the case reported here, there has been only 1 case in the literature of adalimumab-implicated desquamating skin reactions. This occurred in a 63-year old woman with RA after her sixth injection of adalimumab. This patient developed a papulopustular rash on the palms and soles of her feet followed by desquamation. The patient remained systemically well despite the cutaneous reaction and as there was no mucous membrane involvement she was diagnosed as having erythema multiforme, but no skin biopsy was performed. Therapy with adalimumab was discontinued and the symptoms rapidly improved without specific therapy^[14]. Our case, however, was a more severe reaction with mucous membrane, skin and lung involvement that were histologically and clinically consistent with SJS. This is of particular significance due to the potentially life threatening nature of SJS. The patient was only taking one medication at the time of his second presentation and the SJS resolved on cessation of the adalimumab and treatment with hydrocortisone.

The SJS can, thus, with some confidence be attributed to the use of the TNF α antagonist, adalimumab.

Desquamating skin reactions have now been described in 3 of the TNF α antagonists (infliximab, etanercept and adalimumab). Some of these reactions can be very serious and prescribers need to be aware of the potential for the mucocutaneous adverse effects from the use of these agents, particularly due to the significant morbidity and mortality that are associated with SJS and TEN.

Hairy cell leukemia presenting as multiple discrete hepatic lesions. *World J Gastroenterol* 2009; 15(35): 4453-4456 Available from: URL: <http://www.wjgnet.com/1007-9327/15/4453.asp> DOI: <http://dx.doi.org/10.3748/wjg.15.4453>

INTRODUCTION

Metastases of an unknown primary site are found in about 5% of all cancer patients^[1-3]. The recent advances in molecular technology, including gene expression profiling, raise the expectation for improved diagnosis of cancer of unknown primary (CUP). This is needed to identify subsets of patients who could potentially respond to therapy. The liver is involved in about a third of patients with CUP^[3]. In about 50% of these patients, the primary tumor is carcinoma of the lung, colon, rectum, or pancreas. Other primary tumor sites are the liver, breast, skin (melanoma), stomach *etc.* Here we describe a patient with discrete hepatic masses which proved to be hairy cell leukemia. This is in contrast to the regular liver involvement by hairy cell leukemia, which is in the form of diffuse infiltration. Since treatment of this tumor is very effective, its diagnosis should not be missed.

Abstract

The involvement of hairy cell leukemia in the liver is in the form of portal and sinusoidal cellular infiltration. Here we describe the first case of hepatic hairy cell leukemia presenting as multiple discrete lesions, which was treated successfully. We suggest that in the investigation of discrete hepatic lesions in cases of cancer of unknown primary, hairy cell leukemia should be considered. The excellent response of hairy cell leukemia to therapy highlights the need for such a consideration.

CASE REPORT

A 61-year-old male patient presented to the outpatient clinic in 2005 with complaints of paresthesia in his hands. Abdominal imaging studies, which he underwent previously, detected focal liver lesions. In 1996, an abdominal ultrasound carried out for epigastric pain, revealed two focal hepatic lesions presumed to be hemangiomas. This was verified by a red blood cell (RBC) scan. In 2000, an abdominal computed tomography (CT) study showed ten hepatic lesions of different sizes, however, no further investigation was performed. In 2003, the patient had an inferior wall myocardial infarction. His blood count showed a hemoglobin level of 132 g/L, white blood cell count of $6.7 \times 10^9/L$ and a platelet count of $188 \times 10^9/L$. In 2005, a routine blood count showed hemoglobin of 111 g/L. A repeat ultrasound (US) detected multiple hepatic lesions, and an abdominal CT scan showed that the hepatic lesions had grown since the previous (2000) study. Another RBC scan

Figure 1 Axial fused PET-CT scans of the upper abdomen before (Right-2005) and after (Left-2009) treatment. Right- An FDG-avid lesion is seen in the left lobe of the liver (arrow). Left-The lesion is smaller with decreased intensity of FDG uptake (arrow).

Figure 2 Histological findings. A, B: Liver core needle biopsy; C, D: Bone marrow biopsy. A: Infiltration by small to medium-sized tumor cells is seen. In the left lower part of the picture, normal residual liver parenchyma is seen (HE, $\times 200$); B: Immunohistochemical stain for TRAcP is positive in tumor cells ($\times 200$); C: Hairy leukemic cells are seen in the bone marrow (HE, $\times 400$); D: The immunohistochemical stain for TRAcP is positive in hairy cells.

again showed only two hemangiomas. Finally, a positron emission CT (PET-CT) scan showed uptake of fluorodeoxyglucose (FDG) in several hepatic lesions (Figure 1B), and a decision was made to biopsy one of the lesions. On histopathological examination, the cells of the lesion were different from the known primary and metastatic tumors of the liver, and all the immunohistochemical stains performed were negative. A neuroendocrine tumor was considered the most

likely morphological diagnosis, despite negative staining for the neuroendocrine antigens, synaptophysin and chromogranin A (Figure 2A).

The patient was referred to our clinic for further evaluation. He denied any weight loss, diarrhea or flushing. On physical examination he appeared well. No lymphadenopathy was noted, his abdomen was not tender, and no signs of an enlarged liver or spleen were found. His laboratory results showed pancytopenia

with a hemoglobin level of 110 g/L, white blood cells of 3.5×10^9 /L, and a platelet count of 120×10^9 /L. All liver function tests were normal, albumin level was 40 g/L. Blood levels of adreno-cortico-trophic hormone (ACTH) and beta-human chorionic gonadotropin (hCG) were normal, urine levels of vanilmandelic acid (VMA) and 5-hydroxyindoleacetic acid (5HIAA) were also in the normal range. An octreotide scan showed increased uptake in the liver. A bone marrow biopsy was performed, which was compatible with hairy cell leukemia with positive stains for CD-20 and Tartaric Acid Resistant Acid Phosphatase (TRAcP) (Figure 2C and D). A repeat examination of the hepatic specimen showed positive staining for CD-20 and TRAcP (Figure 2B).

The patient was started on cladribine (2-chlorodeoxyadenosine-2CDA) with a diagnosis of hairy cell leukemia with hepatic involvement. No side effects were noted. Three months after treatment, a gradual rise in his blood count was seen. A follow-up CT scan showed that the hepatic lesions had not changed in size. His paresthesia had resolved.

Two years after treatment with 2CDA his blood counts had increased, his hemoglobin level was 148 g/L, white blood cell count was 6.2×10^9 /L, and platelet count was 189×10^9 /L. Repeat CT and an abdominal magnetic resonance imaging (MRI) scan showed that the lesions were similar in size to those shown on the previous CT. A repeat PET-CT scan about three years after treatment demonstrated that only one lesion in his left hepatic lobe still showed uptake of FDG, no uptake was observed in the other lesions (Figure 1A).

PET-CT and pathological findings

PET-CT scan with F^{18} -FDG: The first PET-CT scan of 2005 (Figure 1B), shows multiple hypodense lesions of different sizes in the liver; some of the lesions show increased uptake of F^{18} -FDG. The post-treatment PET-CT scan of 2009 (Figure 1A), shows significant improvement. All the previously hypermetabolic lesions are smaller, and all foci of increased uptake, with the exception of one, disappeared. This latter lesion, although reduced in size, still shows increased F^{18} -FDG uptake but with lower intensity. These dynamic changes are consistent with involvement of the underlying disease. According to CT from the PET-CT scan of 2009, the lesions which did not show increased F^{18} -FDG uptake either in 2005 or in 2009 did not change in size. This suggests that they are of a different nature i.e. hemangioma. This was proven by a labeled red blood cell nuclide scan.

Pathological findings: The submitted liver core needle biopsy was fixed in formalin (neutral 10%, pH 7.4) and embedded in paraffin wax. Sections 4 microns thick were cut and stained with hematoxylin and eosin (HE). The histological sections showed liver tissue infiltrated by diffuse aggregates of small/medium-sized uniform tumor cells, with bland oval nuclei, clear cytoplasm with no well defined cytoplasmic borders. No cellular atypia or mitotic figures were demonstrated (Figure 2A). For immunophenotyping, we used the standard avidin-

biotin method on the paraffin sections. The slides were immunostained in the automated system ES Ventana (Ventana Medical Systems, Inc). Immunohistochemical staining showed that the cells were positive for vimentin (V9, ZYMED Laboratories, South San Francisco, CA, USA) and negative for α -smooth muscle actin/SMA (1A4, DAKO, Glostrup, Denmark), desmin (ZC 18, ZYMED Laboratories) (muscle origin), S-100 (S-100, DAKO, Glostrup, Denmark), chromogranin (Chromogranin A, DAKO, Glostrup, Denmark), synaptophysin (Synaptophysin, Z66, ZYMED Laboratories) and CD56 (T199, DAKO, Glostrup, Denmark) (neuroendocrine origin), MNF116 (MNF116, DAKO, Glostrup, Denmark), CAM 5.2 (Zym 5.2, ZYMED Laboratories), CK7 (OTVL, BioGenex, San Ramon, CA, USA), CK20 (IT-Ks20.8, BioGenex, San Ramon, CA, USA), CEA (ZC23, ZYMED Laboratories) (epithelial origin), CD31 (JC70A, DAKO, Glostrup, Denmark), CD34 (QBEnd/10, CellMarque, Rocklin, CA, USA), (vascular origin), and α -fetoprotein (α -1 DAKO, Glostrup, Denmark), and HEPA (OCH1ES, DAKO, Glostrup, Denmark), (liver origin). The Ki67 proliferation antigen was positive in about 10% of cells. Despite the fact that the tumor cells were negative for almost all the basic non-hematological immunostains, it was decided that the morphological differential diagnosis was either a neuroendocrine tumor or a glomus tumor. One month later a bone marrow trephine biopsy was performed. The bone marrow was infiltrated by sheets of tumor cells with morphological features of hairy cell leukemia (Figure 2C). The immunohistochemical stains for CD20 (L26 DAKO, Glostrup, Denmark), and TRAcP (ZY-9C5, ZYMED Laboratories), were positive and confirmed the diagnosis of hairy cell leukemia (Figure 2D). In a revision of the liver biopsy, it became clear that the tumor cells were morphologically similar to the hairy cells in the bone marrow. The immunohistochemical stains for CD20 and TRAcP were also positive and confirmed the diagnosis of hairy cell leukemia of the liver presenting as a tumoral mass (Figure 2B).

DISCUSSION

The pathological diagnosis of cancer of unknown primary requires a careful evaluation of the morphology as well as the immunohistochemistry of the affected tissue^[4]. Discrete hepatic lesions formed by infiltration of hairy cell leukemia cells were not described until last year. Hairy cell leukemia (HCL) is a rare chronic lymphoproliferative disorder usually characterized by an indolent course. The hairy cells are B cells found in the blood circulation that consist of oval nuclei and abundant cytoplasm with characteristic micro-filamentous ("hairy") projections. Patients usually present with cytopenia and splenomegaly due to infiltration of the cells into the bone marrow and spleen^[5].

Hepatomegaly can be seen in up to a third of patients^[6]. Histologically, liver involvement has been described in the form of portal and sinusoidal infiltration. Some lesions in the liver have been described as angiomatous with tumor cells and blood cells filling the sinusoids^[7].

Clinical features of liver involvement may include in addition to hepatomegaly, jaundice and increased levels of aminotransferases and alkaline phosphatase^[7]. The mechanism of production of nodular hepatic lesions in some cases of hairy cell leukemia is unknown. It is also unclear whether there is a difference in the course and prognosis of the disease in subjects with hairy cell leukemia and hepatic diffuse *vs* nodular involvement.

The introduction of purine-nucleoside analogues such as cladribine for the treatment of hairy cell leukemia has dramatically changed the prognosis in affected subjects^[8]. In a recent long-term follow-up study of 233 patients, Else *et al*^[9] found that overall, the complete response rate was 80%, and median relapse-free survival was 16 years. The outcome of patients with recurrent disease has improved with the monoclonal antibody anti-CD20, rituximab^[9,10].

Recently, Al-Za'abi *et al*^[11] have reported a case of HCL presenting as a solitary liver mass 20 years after the initial presentation with splenic involvement. These clinical features enabled correct diagnosis of the hepatic mass. No details regarding the treatment and course of the patient's disease were provided. To the best of our knowledge, our case is the first of a patient with HCL presenting with multiple discrete hepatic lesions. These lesions were present prior to the appearance of pancytopenia, which is the consequence of extensive bone marrow involvement. The patient responded to standard treatment, as seen by the disappearance of pancytopenia, and by the marked decrease in FDG uptake by the hepatic lesions.

This report highlights the need to consider the possibility of hairy cell leukemia in the investigation of discrete hepatic lesions in cases of cancer of unknown primary. The excellent response to therapy of this tumor further emphasizes the need for correct diagnosis.

Abstract

An iliopsoas hematoma can occur either spontaneously or secondary to trauma or bleeding tendency due to hemophilia and anticoagulant therapy. Although liver cirrhosis is commonly associated with coagulopathy, iliopsoas hematoma is very rare. We herein, present a case of bilateral iliopsoas hematoma in a patient with alcoholic cirrhosis, and review the literature on muscle hematoma associated with cirrhosis. A 56-year-old man with alcoholic cirrhosis was admitted in a state of shock with anemia. The cause of anemia could not be detected, and the patient was treated conservatively. The site of bleeding was not detected with either gastroduodenal endoscopy or upper abdominal computed tomography, the latter of which did not include the iliopsoas muscle. He died on the 10th day of admission and bilateral iliopsoas hematomas were found on autopsy. An iron stain was positive in the iliopsoas muscle. Eight cases of muscle hematoma associated with cirrhosis, including the present case, were found in a review of the literature. Four of these cases involved the rectus abdominis muscle, 3 involved the iliopsoas muscle and 1 involved combined muscles. Alcoholic cirrhosis accounted for 75% of the cases. One case (12.5%) was associated with virus-related cirrhosis, and another with combined virus- and alcohol-related cirrhosis. The mortality rate was 75% despite early diagnosis and low risk scores for cirrhosis. Muscle hematoma in patients with cirrhosis is

INTRODUCTION

Liver cirrhosis is commonly associated with coagulopathies, including thrombocytopenia and hypoprothrombinemia, which often cause easy bruising and bleeding^[1]. Sudden bleeding from gastrointestinal varices due to portal hypertension is also an established risk of liver cirrhosis. Muscle hematoma usually occurs either traumatically or spontaneously in patients with hemophilia^[2] and in patients receiving anticoagulant therapy^[3]. However, it is rare in cirrhosis.

We herein, report a case of spontaneous bilateral iliopsoas hematoma in a patient with alcoholic liver cirrhosis. We also include a review of the literature on muscle hematoma associated with cirrhosis. The mortality rate of this condition is extremely high in comparison to that of muscle hematomas in patients with hemophilia or under anticoagulant treatment. These findings characterize muscle hematoma as a clinically important complication of cirrhosis.

CASE REPORT

A 56-year-old man visited a clinic complaining of severe fatigue. He was found to be in a state of shock with

Figure 1 Bilateral iliopsoas hematoma (arrows) observed at autopsy.

severe anemia and was transferred immediately to our hospital. He had ingested 1.5 L of beer every day for 36 years and alcoholic cirrhosis had been diagnosed.

On arrival, a medical history was impossible to obtain because of his decreased level of consciousness. His body temperature was 35.0°C, his systolic blood pressure was 80 mmHg, and his pulse rate was weak but regular at 62 beats per minute. The abdomen was symmetrical and bowel sounds were weak. On palpation, there was neither rigidity nor tenderness, and no mass was palpable. The psoas position was not observed, and neurological examinations revealed only asterixis. Bilateral leg edema was noted.

The laboratory test results were as follows: white blood cell count, 3300/mm³; hemoglobin, 50 g/L; platelets, 45000/mm³; albumin, 21 g/L; total bilirubin, 6.4 mg/dL; aspartate aminotransferase/alanine aminotransferase, 58/16 U/L; alkaline phosphatase, 202 U/L; blood urea nitrogen, 32 mg/dL; serum creatinine, 2.1 mg/dL; creatine kinase, 202 U/L; prothrombin time-International Normalized Ratio, 1.48; activated partial thromboplastin time, 31.6 s. Stool samples were positive for occult blood.

A chest X-ray showed cardiomegaly and massive bilateral pleural effusion. Abdominal ultrasonography revealed a dull edge and irregular margins of the liver consistent with cirrhosis. Upper abdominal enhanced computed tomography (CT) also confirmed liver cirrhosis with splenomegaly and massive ascites but did not include the iliopsoas muscle. A gastroduodenal endoscopy did not disclose any hemorrhagic diseases. Further examinations were not performed due to the general deterioration of his condition.

Treatment, including the transfusion of red blood cell concentrate, branched-chain amino acids, and albumin as well as the administration of dopamine hydrochloride and diuretics, was initiated. On the 5th day of admission, imipenem/cilastatin sodium (1 g/d) and gamma globulin (2.5 g/d) were empirically administered for a high fever. On the 8th day, the patient received fresh frozen plasma (FFP) and antithrombin III to treat disseminated intravascular coagulation. Wide ecchymosis appeared on both sides of the patient's back on the 9th day and he died on the 10th day.

Autopsy findings revealed bilateral iliopsoas

hematoma (Figure 1) with liver cirrhosis. The source of bleeding could not be detected inside the iliopsoas muscles, and there was no evidence of either a neoplasm or an arterial anomaly. Other causes of anemia including bone marrow disorders were not detected. A histological examination with iron staining was positive in the iliopsoas muscle. The appearance of this type of staining depends on the age of hemorrhage, and indicated that the bleeding started around the day of admission in this case.

DISCUSSION

Intramuscular hematoma is classified as either spontaneous or traumatic. Causes of the former include hemorrhagic diseases, neoplasm, and arterial diseases. Iliopsoas and rectus abdominis muscle hematomas are well known as major and well documented complications of hemophilia and anticoagulant therapy^[2-5]. Although decreased levels of coagulant factors and thrombocytopenia are often observed in liver cirrhosis, intramuscular hemorrhage is very rare^[6].
