Minor allele frequencies (MAF), genotype counts (GT; 11 = homozygous for minor allele; 12 = heterozygous for common allele; 22 = homozygote for common allele), allelic test *P* values (<sup>a</sup>*P*<sub>CCA</sub> < 0.05), and odds ratios (OR, shown for the minor allele) with 95% confidence intervals (CI) are depicted for both the CD and UC case-control population.

consistent with Hardy-Weinberg equilibrium (Table 3). For each of the variants studied, the risk of carrying the variant was compared between the CD, UC and healthy controls groups. The genotype and minor allele frequencies are presented in Table 3.

As expected, none of the studied individuals were carriers of all three *NOD2* risk alleles. However, two CD patients were determined as compound heterozygotes. The combined allele carriership in the group of patients with CD was much higher than in controls (41.1% vs 16.9%) and resulted in significant association ( $P = 2 \times 10^{-4}$ , OR = 3.48, 95% CI: 1.81-6.72) whereas no significant difference was observed between UC patients and controls. The PAR% in CD patients was 29.5% for possession of one or more *NOD2* variant alleles at any of the three sites.

In the allelic single marker analysis of the *NOD2* variants, a significant association was detected only between CD and Leu1007insC. For this variant, both the allelic and genotypic tests revealed *P*-values < 10<sup>-4</sup> (OR<sub>allele</sub> = 5.54, 95% CI: 2.85-10.75; OR<sub>carriership</sub> = 6.12, 95% CI: 2.88-13.15), resulting from the increased minor allele frequency (MAF) in cases (21.4%) vs controls (4.7%). In the UC group, the risk allele frequency of 4.1% was almost identical with the frequency detected in the controls. The frequencies of the other two *NOD2* variants: Arg702Trp and Gly908Arg were low in both controls and IBD pa-

tients groups and were not statistically significant.

The allele frequencies distribution for the *IL23R* and *ATG16L1* disease associated variants were almost identical between cases and controls and did not demonstrate significant differences.

## DISCUSSION

This is the first report on the prevalence of the previously defined *NOD2*, *ATG16L1* and *IL23R* disease associated variants in an IBD case-control sample from Lithuania. Baltic countries still observe low IBD incidence rates, especially for CD in their populations. In Estonia (1993-1998) the incidence rate of CD was reported to be 1.4 per 100 000 inhabitants<sup>[16]</sup>; and in Lithuania (2006) - 2.0 per 100 000 inhabitants<sup>[9,10]</sup>. Therefore, analysis of the genetic contribution to disease susceptibility in this region was of great interest.

Since 2001, following the identification of *NOD2* as the first gene conferring susceptibility to CD<sup>[3-5]</sup> a significant number of studies have replicated the association of the Arg702Trp, Gly908Arg and Leu1007insC variants with the development of CD in populations of Caucasian origin from Europe and North America<sup>[17]</sup>. However, significant heterogeneity in the frequencies of these variants has been observed not only between ethnically divergent populations<sup>[18,19]</sup>, but also within Europe<sup>[17]</sup>.

Our study results add to this pattern. The carriage of at least one *NOD2* variant was highest in the CD patients group (41.1%) compared to the control group (16.9%) and resulted in the OR = 3.48 (95% CI: 1.81-6.72). These data are in concordance with previously reported rates of 30%-50% in CD and 7%-20% in controls from other European regions<sup>[17]</sup>. The Leu1007insC variant was responsible for the major contribution of *NOD2* to disease susceptibility in the Lithuanian CD population (MAF = 21.4%, OR = 5.54, 95% CI: 2.89-10.75). These data are consistent with previous reports from Central Europe and North America (MAF = 6.6%-16%)<sup>[17]</sup> and contrast markedly with studies performed in Northern Europe, where carriage rates of Leu1007insC and other *NOD2* variants are relatively low, i.e. the carriage of at least one *NOD2* variant varies from 2.8% to 22%<sup>[20,21]</sup>. However, we were not able to confirm the association between Arg702Trp, Gly908Arg and IBD susceptibility in our study group. These findings are in contrast with previous reports from Southern and Central European populations, where a positive association between Arg702Trp, Gly908Arg and CD was detected. The reported allele frequency rates in these European countries vary from 6.7% to 12.5% for Arg-702Trp, from 3.3% to 6.1% for Gly908Arg, respectively, in CD patients and from 3.5% to 6.9% and from 0.6% to 3.0%, respectively, in controls<sup>[17]</sup>.

Moreover, the PAR%, an indication of the contribution of a mutation to the disease in a specific area, was 29.5% in the present study and contrasts with the other Northern European populations reporting lowest PAR% (range: 1.88%-11%)<sup>[20,21]</sup>. The PAR% measured in the Central European populations and North America was around 30%<sup>[3,5,17]</sup>. Therefore, the results of our study indicate that CD in Lithuania has a strong genetic background that is related partially to *NOD2* susceptibility variants. Interestingly, the relatively high carriership frequency of any of the three *NOD2* alleles in the healthy controls (16.9%) in our study is in contrast with data of low CD incidence in Lithuania<sup>[9]</sup>. This indicates the importance of environmental factors (e.g. diet, lifestyle) in disease development.

The first two genome wide association studies identified genetic alterations within *IL23R*<sup>[6]</sup> a component of the adaptive immune system - and *ATG16L1*<sup>[7]</sup> - a protein involved in autophagic processes - to be associated with IBD and CD. These findings broadened the understanding of the different pathways that are involved in IBD susceptibility and/or pathogenesis. In addition, the *IL23R* and *ATG16L1* findings were confirmed in large independent Caucasian samples<sup>[22-34]</sup>. A study in Japan<sup>[35]</sup> failed to replicate these results, supporting the previously reported distinct ethnic difference of the genetic background of CD. Upon analysis of the Lithuanian IBD population we were not able to confirm any of these findings. We were just able to observe trends for possible associations with *ATG16L1* risk allele. The frequencies and contributable risk of the *ATG16L1* G allele reported in our study (55% CD and 48% controls, OR: 1.32) were similar to the published studies performed in Germany (59% CD and 52% controls, OR: 1.35)<sup>[22]</sup>, UK

(57% CD and 51% controls, OR: 1.30)<sup>[23]</sup>, Hungary (58% CD and 50% controls, OR: 1.39)<sup>[26]</sup> and pooled study of German, Dutch and Hungarian cohorts (57% CD and 51% controls, OR: 1.32)<sup>[24]</sup>. The allele frequency distribution of the protective *IL23R* variant in our control samples (5.9%) was similar to previous reports in Caucasian populations (approx. 6%), whereas the allele frequencies in our both IBD cases groups were higher (3.6% CD and 4.5% UC) compared to the results of other studies (1.87%-2.85% CD and 1.9%-2.68% UC)<sup>[26-34]</sup>.

It must be noted that our relatively small study population was underpowered to demonstrate such weak to moderate disease associations. The panel had a power of 80% to detect an odds ratio of 1.8 or higher at the 5% significance level, assuming a frequency of the disease-associated allele of at least 30% in the controls. Therefore, larger-sized case-control panels will be needed in order to further evaluate the importance of the herein tested loci.

In summary, our study provides clear evidence that the *NOD2* Leu1007insC variant increases susceptibility to CD in the Lithuanian study population, whereas associations of *IL23R* and *ATG16L1* variants with any of the distinct IBD subtypes need to be further evaluated in larger North-Eastern European IBD sample collections.

## ACKNOWLEDGMENTS

The authors wish to thank all patients, families and physicians for their cooperation. We also thank the technical staff at the Institute for Clinical Molecular Biology (Kiel, Germany) for their expert help. The popgen biobank received infrastructure support through the DFG excellence cluster "Inflammation at Interfaces".

## COMMENTS

### Background

Numerous genome-wide and linkage studies have identified and replicated significant association between inflammatory bowel disease (IBD) development and polymorphisms of genes attributed to recognition of bacterial products (*CARD15*), adaptive immune responses (*IL23R*), and autophagosome pathways (*ATG16L1*). However, there has been reported a heterogeneity in allele frequencies of genetic factors involved in the pathogenesis of IBD in different European populations. The genetic association with IBD susceptibility has never been investigated in Lithuania previously.

### Research frontiers

The research was performed to obtain data about the frequency of *NOD2*, *IL23R* and *ATG16L1* genetic variants in a case-control study group for IBD from Lithuania.

### Innovations and breakthroughs

The results of the authors' study indicate that Crohn's disease (CD) in Lithuania has a strong genetic background that relates partially to *NOD2* susceptibility variants, especially Leu1007insC. The relatively high carriership frequency of any of the three *NOD2* alleles in the healthy controls (16.9%) in this study is in contrast with the data of low CD incidence in Lithuania. This indicates the importance of environmental factors (e.g. diet, lifestyle) in disease development.

### Applications

This is one of the first studies investigating the genetic association with IBD in a North-Eastern European country. The results of this study confirm that the heterogeneity of variants might be observed within Europe and will further help to understand the role of interplay between genetic and environmental factors in the development of complex diseases. Future studies in larger study groups

and further analysis of the biological functions of the identified variants are required to understand their role in determining the risk of CD and ulcerative colitis in ethnically divergent populations.

### Terminology

*NOD2* is a member of the NACHT-LRR receptor (NLR) protein family, which is known to be involved in recognition of microbial structures. *ATG16L1* encodes a protein which is part of a larger family of proteins that are required for the intracellular degradation system - autophagy process. *IL23R* encodes a protein which is a subunit of the receptor for IL23A/IL23 and participates in JAK-STAT3 signaling pathway.

### Peer review

The authors concluded that the *NOD2* Leu1007insC variant increases susceptibility to CD in the Lithuanian study population, whereas associations of *IL23R* and *ATG16L1* variants with any of the distinct IBD subtypes need to be further evaluated in larger Eastern European IBD sample collections. The study was conducted with good design and convincing analysis, and the manuscript has been well written and solid conclusions have been drawn.

C-reactive protein (CRP) of each patient were performed 7 d before the scintigraphic images. The leukocytes were labeled according to the International Society of Radiolabeled Blood Elements (ISORBE) consensus protocol and the scintigraphic images, including single photon emission computed tomography, were obtained 30 min and 2 h after injection of the radiolabeled leukocytes.

**RESULTS:** The labeling yield of the leukocytes with the lipophilic complex  $^{99m}\text{Tc}$ -HMPAO was  $55.0\% \pm 10\%$ . Six of the 20 patients (30%) presented congruent results for the three parameters investigated (CDAI, Scintigraphic Index and CRP). On the other hand, 14 patients (70%) did not show congruent results. There was no significant correlation between the indices analyzed according to the Spearman test ( $P > 0.05$ ,  $n = 20$ ).

**CONCLUSION:** The results suggest that  $^{99m}\text{Tc}$ -HMPAO-labeled leukocyte scintigraphy could be important for determining inflammatory activity in CD even in the absence of clinical symptoms.

### Abstract

**AIM:** To evaluate inflammatory activity in patients with Crohn's disease (CD) using technetium-99m-hexamethylpropyleneamine oxime ( $^{99m}\text{Tc}$ -HMPAO) granulocyte scintigraphy.

**METHODS:** Twenty patients (7 male and 13 female) with CD and five healthy volunteers were selected for  $^{99m}\text{Tc}$ -HMPAO granulocyte scintigraphy. The Crohn's Disease Activity Index (CDAI), blood tests and

## INTRODUCTION

Crohn's disease (CD) is characterized by chronic intestinal inflammation of unknown etiology that can affect any segment of the digestive tract from the mouth to the rectum<sup>[1]</sup>. The diagnosis of this disease is based on clinical manifestations, radiological, endoscopic, surgical and anatomical pathological observations. However, none of these findings is considered pathognomonic of the disease<sup>[2-4]</sup>.

The initial clinical symptoms of CD may be subtle, variable, nonspecific and easily overlooked. Recurrent episodes of inflammation in the gastrointestinal tract are typical. This inflammation underlies many of the symptoms and signs of the disease, thus its detection and monitoring are of the utmost importance in clinical management<sup>[5]</sup>. The follow-up of patients in clinical remission is based currently on the calculate of clinical activity indexes, including the Crohn's Disease Activity Index (CDAI) that is based on clinical and laboratory parameters, and measures CD activity as a sum of points<sup>[6]</sup>. CDAI < 150 is characteristic of remission of the disease. Values between 150 and 250 are associated with mild inflammatory activity. Inflammatory activity is considered moderate when the values lie between 250 and 350, and CDAI > 350 characterizes intense activity<sup>[7]</sup>. Another parameter used in the CD is the Vienna Classification that considers data constant such as age (A), location (L) and behavior (B) of the disease. It has as its aim phenotype standardization to evolutionary studies and works involving genetic, biological and environment factors<sup>[3]</sup>.

Gastrointestinal inflammation is not directly observable by patients or physicians, therefore, many methods have been developed to quantify the severity and extent of this inflammation. Therefore, a simple, rapid, sensitive, specific, inexpensive, noninvasive method to detect and monitor intestinal inflammation in CD is needed. According to Annovazzi *et al*<sup>[6]</sup>, if relapse or subclinical inflammation can be predicted in CD, it is likely to change the approach to treatment<sup>[6]</sup>. In this case, the use of a functional imaging method such as technetium-99m-hexamethylpropyleneamine oxime (99mTc-HMPAO) granulocyte scintigraphy could be more important to elucidate the location of the inflammatory site in the bowel. Scintigraphic images are based on functional alterations of the tissue, which permit an early diagnosis of the inflammation and infection when the anatomical alterations are not visible<sup>[4,8]</sup>. Among the scintigraphic methods used in the identification of the inflammatory and infectious foci, the use of radiolabeled leukocytes has been employed as a specialized technique that explores the natural migratory behavior of the white blood cells<sup>[9]</sup>.

Arndt *et al*<sup>[10]</sup> have demonstrated that 99mTc-HMPAO-labeled leukocyte scintigraphy is better than the Van Hees activity index and laboratory parameters for the evaluation of the inflammatory activity of intestinal diseases. Other authors have reported that autologous radiolabeled leukocyte scintigraphy can be utilized in

the monitoring of patients to evaluate the efficiency of therapy, differentiation between fibrotic and inflammatory stenosis, and the recurrence of the disease after surgery<sup>[11,12]</sup>. Among the treatment options for CD, the following stand out: aminosalicylates, corticosteroids, immunomodulators and biological therapy for control of inflammatory activity<sup>[2]</sup>.

The aim of the present study was to evaluate the presence of the inflammatory activity in patients with CD, who were subjected to usual treatment using 99mTc-HMPAO-labeled leukocyte scintigraphy.

## MATERIALS AND METHODS

### Materials

HMPAO (Ceretek) was supplied by Amersham Health (UK). Technetium-99m was obtained from a molybdenum generator (IPEN/Brazil). All other chemicals and reagents used were of analytical grade.

### Subjects

Twenty patients (mean age 38.7 years, 7 male and 13 female) with previous diagnosis of CD were selected at the Gastroenterology Alfa Institute of the Clinical Hospital at Federal University of Minas Gerais in the period between September 2007 and June 2008. The diagnoses were based on the patient's clinical history and physical examination, as well as the results of radiological and endoscopic examinations. The patients were being treated with corticosteroids, aminosalicylates, antibiotics, immunomodulators and biological therapy (Table 1). Informed consent was obtained from all patients admitted to the study. This study was approved by the Ethical Committee at Federal University of Minas Gerais. Seven days before 99mTc-HMPAO-labeled leukocyte scintigraphy, patients were subjected to determination of complete hemography, erythrocyte sedimentation rate and C-reactive protein (CRP) level. The CRP reference value was considered < 8 mg/L. In this same period, all patients filled in the card to calculate CDAI<sup>[6]</sup>. Five healthy volunteers were invited to participate in this study as controls.

### Cell labeling with 99mTc-HMPAO

The labeling of leukocytes with 99mTc-HMPAO was performed in accordance with the method described by Martin-Comin *et al*<sup>[13]</sup>. Briefly, blood samples (45 mL) were withdrawn from patients and healthy volunteers with a syringe that contained 6.0 mL anticoagulant [citric acid-citrate-dextrose (ACD)]. The leukocyte-rich pellet was obtained according to the established protocol of the International Society of Radiolabeled Blood Elements (ISORBE)<sup>[14]</sup>. The leukocyte-rich pellet was gently resuspended in 0.5 mL cell-free plasma using a polypropylene Pasteur pipette. The HMPAO was labeled with a solution of sodium pertechnetate ( $\text{Na}^{99\text{m}}\text{TcO}_4$ ) with 1480 MBq of activity. After labeling, the radiochemical purity of the 99mTc-HMPAO was determined by partition between 0.9% saline and chloroform<sup>[15]</sup>. Freshly prepared 99mTc-

CD: Crohn's disease; CDAI: Crohn's Disease Activity Index; SI: Scintigraphic index; CRP: C-reactive protein.

HMPAO (0.7 mL, approximate 600 MBq) was added to the leukocyte-rich pellet. This preparation was incubated at 37°C for 15 min. Aliquots of 4 mL of cell-free plasma were added to the test tube. The tube was centrifuged (150 g) for 5 min. The plasma supernatant that contained unbound <sup>99m</sup>Tc-HMPAO was removed, and the <sup>99m</sup>Tc-HMPAO-labeled leukocyte pellet was suspended in 4.0 mL cell-free plasma. The labeling yield was calculated from: Labeling yield = {[cpm (precipitate)]/[cpm (precipitate) + cpm (supernatant)]} × 100; cpm = counts per minute or disintegrations per minute.

### Scintigraphic imaging

Images were obtained at 30 min and 2 h after injecting patients and healthy volunteers with the labeled leukocytes (mean activity approximate 273 MBq). Abdominal scans were obtained in the anterior and caudal views (patients sat on the camera bed with the detector head positioned below the bed) using a wide field gamma camera (Orbiter, Siemens, Germany and Millennium MG, General Electric Company, Milwaukee, WI, USA)<sup>[16]</sup>. The time of each image was approximately 10 min or one million counts<sup>[17]</sup>.

The single photon emission computed tomography (SPECT) study was performed just after completing the 30-min and 2-h planar images<sup>[16]</sup>. SPECT was acquired using the following parameters: a matrix size of 64 × 64, 360° circular rotation, and a 5° step angle with a 20-s time frame.

### Scintigraphic index (SI)

SI was calculated according to the method of Ybern *et al.*<sup>[18]</sup>. Briefly, regions of interest (ROIs) were outlined over the liver, spleen, iliac crest and abnormal accumulations when present (Figure 1). The processing program of the gamma camera furnished the number of counts/area proportional

to the radioactivity and the average value of the activity per pixel present in each region. The abdomen was divided into five zones: right, top, left, bottom and center, which corresponded approximately to the ascending colon, transverse colon, descending colon, sigmoid colon/rectum and small bowel. The SI was calculated in all scans in the anterior view:  $SI = (\sum A_i) + B$ . "A<sub>i</sub>" represents the degree of activity of the accumulations in each zone (1 = activity less than bone activity; 2 = activity greater than bone activity; 3 = activity greater than liver activity; 4 = activity greater than spleen activity). "B" indicates the number of zone with abnormal accumulations of labeled leukocytes (1 = one or more accumulations in one zone; 2 = accumulations in two or three zones; 3 = abnormal accumulations in four or five zones). SI > 2 was considered as active disease<sup>[18]</sup>.

### Statistical analysis

CDAI, SI and CRP were compared using the Spearman's rank correlation.

## RESULTS

The radiochemical purity of the lipophilic complex <sup>99m</sup>Tc-HMPAO presented a mean labeling percentage of the order of 85.0% ± 9.0% for the 25 samples. The mean yield for labeling of the autologous leukocytes with the lipophilic complex <sup>99m</sup>Tc-HMPAO was 55.0% ± 10.0%.

Six of the 20 patients (30%) presented congruent results for the three parameters investigated (CDAI, SI and CRP), which were two patients (I.M.F.; G.E.S.F.) with inflammatory activity and four (J.A.N.; F.R.F.; R.M.M.; A.B.O.) with disease in remission. On the other hand, 14 patients (70%) did not show congruent results for CDAI, SI and CRP (Table 1). Twelve patients showed results that were congruent with the Vienna Classification

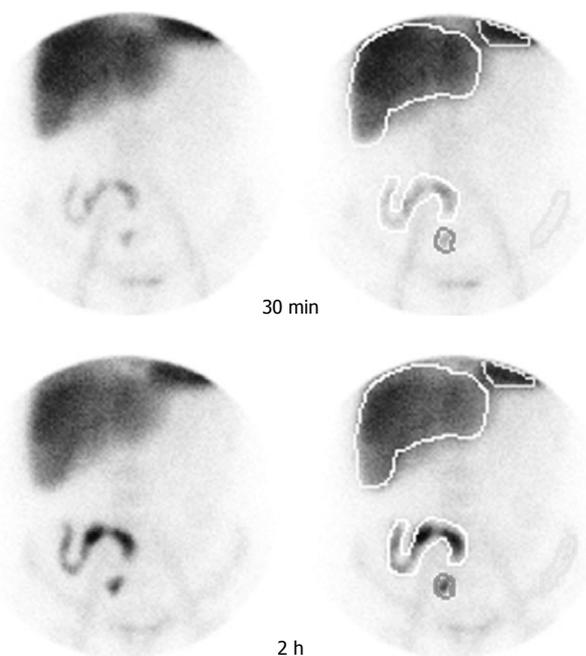

Figure 1 Regions of interest (ROIs).

(Table 1) and technetium-99m-HMPAO-labeled leukocyte scintigraphy with regard to disease location. Besides, there was no correlation for both parameters that were described above in five patients; since scintigraphy images showed positive areas while these regions were not included in the Vienna Classification. In three other patients, the scintigraphy results did not show radioactivity uptake in the intestinal segments.

The images from a healthy volunteer in the anterior and caudal projections at 30 min and 2 h after injection of 99mTc-HMPAO-labeled leukocytes are presented in Figure 2. Intense accumulation in the liver and the spleen could be seen at 30 min post-injection, as well as accumulation in the bone marrow. Because it was a control case, there was no abnormal accumulation in the digestive tract.

Accumulation of 99mTc-HMPAO-labeled leukocytes in the region of the terminal ileum, which suggested the presence of an inflammatory process at this location (anterior view), is shown in Figure 3A. At 2 h, uptake of labeled leukocytes increased, which showed the concentration of radiotracer in the indicated region. No pathological accumulation of 99mTc-HMPAO-labeled leukocytes could be seen in the caudal view, which indicated that there was no inflammation in the sigmoid and/or rectum.

The presence of inflammatory foci in the terminal ileum, descending colon, sigmoid and rectum, revealed by the intense accumulation of radiolabeled leukocytes, is shown in Figure 3B. Regions of the sigmoid and rectum affected by inflammation can be seen in the caudal projection. An increase in the radioactivity with time can also be seen.

According to the Spearman test, there was no significant correlation between the CDAI, SI and CRP in any of the investigated cases (Table 2).

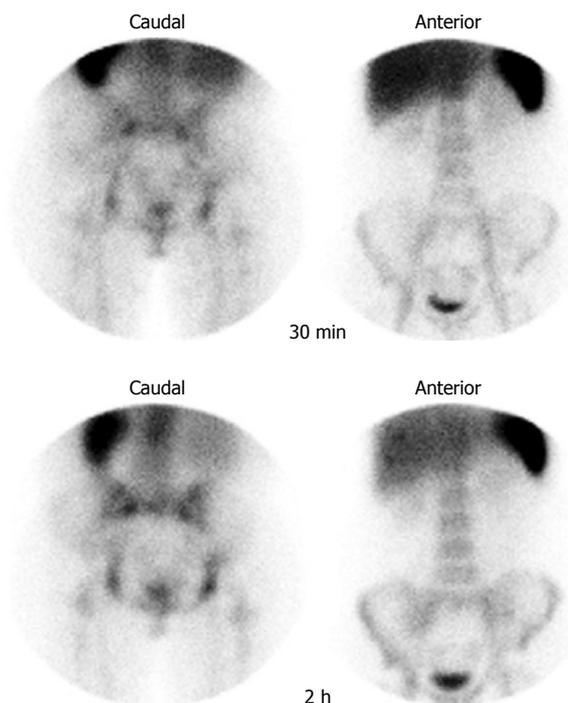

Figure 2 Images of a healthy volunteer (control) in the anterior and caudal projections at 30 min and at 2 h after injection of radiolabeled leukocytes.

	Table 2 Spearman's rank correlation ( <i>n</i> = 20)		
	Spearman's rank	Correlation coefficient ( <i>ρ</i> )	
		<i>t</i>	<i>P</i>
CDAI and SI	0.1835	0.7918	0.4388
CDAI and CRP	0.3373	1.5204	0.1457
SI and CRP	0.2783	1.2293	0.2347

## DISCUSSION

The radiochemical purity of the lipophilic complex (HMPAO) labeled with technetium-99m was 85.0% ± 9.0%. The data suggest that 85% of the technetium-99m atoms were bound to HMPAO molecules. This result is in agreement with other data described in the literature<sup>[15]</sup>. On the other hand, the labeling yield for leukocytes was 55.0% ± 10%. Labeling yields of 46% and 65.5% have been reported previously<sup>[19,20]</sup>. Thus, the value obtained in the present work is supported by published data, which suggests that the manipulation process utilized in the preparation of the radiolabeled cells was adequate.

99mTc-HMPAO granulocyte scintigraphy of a healthy volunteer (Figure 2) showed uptake of radiolabeled leukocytes by the liver, spleen and bone marrow, which reflected physiological retention of labeled white blood cells<sup>[11]</sup>.

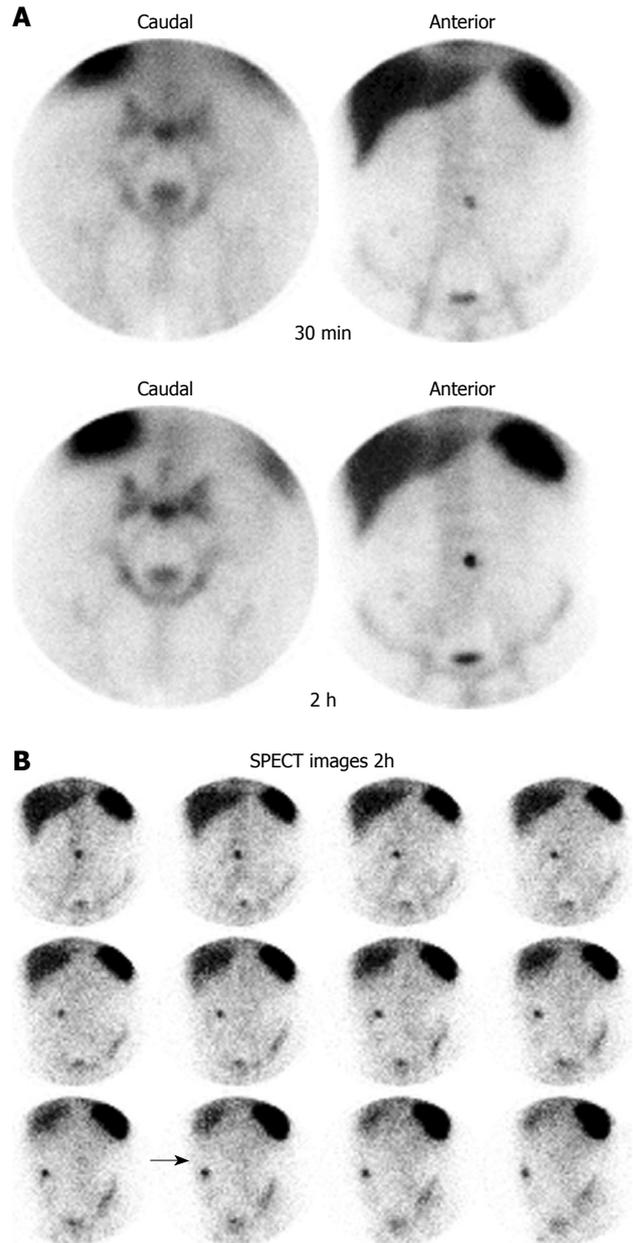

The scintigraphic images were based on physiological alterations such as an increase in blood flow, vasodilatation, increased permeability and cellular leakage, which permit the precocious detection of inflammatory foci. These findings support the use of 99mTc-HMPAO granulocyte scintigraphy as an important examination for

**Figure 3** Images obtained 30 min and 2 h post-injection of  $^{99m}\text{Tc}$ -HMPAO-labeled leukocytes in the caudal and anterior views. A: The arrows indicate the region of the intestine affected by the inflammation (L.M.T., female, 54 years); B: The arrows indicate  $^{99m}\text{Tc}$ -HMPAO-labeled leukocyte uptake in the terminal ileum, descending colon and rectum-sigmoid (L.D., female, 24 years). The black arrows indicate terminal ileum; the arrowhead indicates descending colon; the white arrow indicates rectum-sigmoid.

diagnostic screening of inflammatory diseases<sup>[4]</sup>. Cardoso *et al*<sup>[9]</sup> have observed sensitivity, specificity and accuracy values of > 87.5% in studies performed in patients highly suspected of having inflammatory bowel disease.

The data obtained in the present study showed that, in 70% of investigated cases, the results did not show correspondence with CDAI, CRP and SI (Table 1). It

**Figure 4**  $^{99m}\text{Tc}$ -HMPAO granulocyte scintigraphy of patient J.A.N., male, 44 years. A: Images obtained at 30 min and at 2 h after injection of the radiolabeled leukocytes, in the caudal and anterior projections; B: SPECT images 2 h after injection of the radiolabeled leukocytes. The arrow indicates the fistula region of the patient's abdomen.

is known that CDAI is quite subjective and is based on a group of signs and clinical symptoms associated with erythrocyte sedimentation rate. This method was able to indicate inflammatory activity in four patients, while the SI and CRP indicated inflammatory activity in 13 and nine patients, respectively. Therefore, it is reasonable to suppose that the intestines of patients may have inflammatory foci that attract radiolabeled leukocytes in the specific case of CD, which results in a positive SI, although the signs and symptoms may still be absent.

As example of this observation, the patient L.M.T. (female, 54 years, Figure 3A) showed retention of radiolabeled leukocytes in the terminal ileum. On the other hand, the CDAI index (59.3) indicated disease remission

and the CRP value (7.3 mg/L) suggested the absence of inflammatory activity. This patient was receiving treatment with prednisone and azathioprine, but inflammatory activity was present, which justified the uptake of  $^{99m}\text{Tc}$ -HMPAO-labeled leukocytes in the region, however, the patient was asymptomatic.

A case that deserves special attention is the pathological accumulation of radiolabeled leukocytes in the terminal ileum, descending colon, sigmoid and rectum, which resulted in an SI of 8 (disease activity) as illustrated in Figure 3B (patient L.D., female, 24 years). Before performing  $^{99m}\text{Tc}$ -HMPAO-labeled leukocyte scintigraphy, it was known that the CD in this patient was located only in the region of the terminal ileum, with absence of clinical signs, and the patient was receiving immunomodulator treatment. Seven days before  $^{99m}\text{Tc}$ -HMPAO granulocyte scintigraphy, CRP level was elevated (34.1 mg/L). Despite all the segments that were identified by scintigraphy, the disease was considered to be in remission according to the CDAI (47.1). Thus, this result showed the importance of  $^{99m}\text{Tc}$ -HMPAO-labeled leukocyte scintigraphy as a early diagnosis method for identifying affected regions not previously known. In addition, the therapeutic response should be also evaluated using this method, since the dose of immunomodulator administered to the patient probably was not sufficient to control the disease<sup>[11,12]</sup>.

$^{99m}\text{Tc}$ -HMPAO-labeled leukocyte scintigraphy performed in the patient J.A.N. (male, 44 years; Figure 4A) showed uptake of radiolabeled leukocytes in the central region of the abdomen, which indicated the presence of enterocutaneous fistula. On the other hand, the results did not show uptake of  $^{99m}\text{Tc}$ -HMPAO-labeled leukocytes in segments of the intestine. SPECT showed that this radioactive uptake in the planar images corresponded to the external surface of the patient's enterocutaneous fistula (Figure 4B). According to Arndt *et al.*<sup>[10]</sup>, the capture of leukocytes in areas outside the intestinal segments, such as abscesses and fistulas, should be analyzed separately, but not considered for the calculation of SI<sup>[10]</sup>. In our opinion, this uptake should be considered for SI calculation, because a fistula is a clinical feature that is suggestive of inflammatory activity and possible complications of CD.

The data obtained in the present work show that  $^{99m}\text{Tc}$ -HMPAO-labeled leukocyte scintigraphy of the intestine could be useful for the evaluation of CD inflammatory activity, even in the absence of clinical signs and symptoms (disease remission). A functional method (scintigraphy) was compared with subjective (CDAI) and nonspecific (CRP) tests. Therefore, further studies will be necessary to prove the real utility of radiolabeled leukocytes to diagnosis and monitor patients with CD. Thus, it will be interesting to compare the scintigraphic method with another examination such as CT enterography.

scintigraphy was able to identify inflammatory activity in patients with Crohn's disease (CD) even in the absence of signs and clinical symptoms.

### Research frontier

Scintigraphic images are based on functional alterations of the tissues, and permit the early diagnosis of inflammatory bowel disease, when the anatomical alterations are not visible.

### Innovations and breakthroughs

In the authors' clinical routine, the Crohn's disease activity index is used normally to evaluate the presence of inflammatory activity in patients. However, this index is subjective and sometimes is not able to detect the presence of inflammatory activity in subclinical disease. Thus,  $^{99m}\text{Tc}$ -HMPAO granulocyte scintigraphy could contribute to follow-up of these patients.

### Applications

The results obtained suggest that  $^{99m}\text{Tc}$ -HMPAO-labeled leukocyte scintigraphy could be used to monitor inflammatory bowel disease and evaluate the efficiency of therapy.

### Terminology

Scintigraphic images are obtained using compounds or cells labeled with radioactive isotopes such as technetium-99m, iodine-131 and gallium-67. CD is a chronic intestinal inflammation of unknown etiology that can affect any segments of the digestive tract.

### Peer review

The number of patients is small and therefore their positive experience with the technique may decrease with time and number of patients. The figures are of high quality and indicate the expertise of the authors.

### Abstract

**AIM:** To determine the effects of genetic variants associated with gallstone formation and capsaicin (a pungent component of chili pepper) metabolism on the risk of gallbladder cancer (GBC).

**METHODS:** A total of 57 patients with GBC, 119

patients with gallstones, and 70 controls were enrolled in this study. DNA was extracted from their blood or paraffin block sample using standard commercial kits. The statuses of the genetic variants were assayed using Taqman® SNP Genotyping Assays or Custom Taqman® SNP Genotyping Assays.

**RESULTS:** The non-ancestral T/T genotype of apolipoprotein B rs693 polymorphism was associated with a decreased risk of GBC (OR: 0.14, 95% CI: 0.03-0.63). The T/T genotype of cholesteryl ester transfer protein (CETP) rs708272 polymorphism was associated with an increased risk of GBC (OR: 5.04, 95% CI: 1.43-17.8).

**CONCLUSION:** Genetic variants involved in gallstone formation such as the apolipoprotein B rs693 and CETP rs708272 polymorphisms may be related to the risk of developing GBC in Chilean women.

## INTRODUCTION

There is a prominent worldwide geographical and racial variability in the incidence of gallbladder cancer (GBC), which correlates with the prevalence of cholelithiasis<sup>[1]</sup>. High incidences of GBC are observed in specific countries and in confined areas. For example, the incidence of GBC is very high in northern Indian cities (5-7 per 100 000 women) and low (0-0.7 per 100 000 women) in southern India, possibly reflecting the different ethnic origins of these populations<sup>[2]</sup>. The evidence suggests that the incidence of GBC is associated with the presence of both geographically-specific environmental factors and environmental factor-related genetic factors.

Recent studies have shown that the incidence rate for GBC is higher in Chile than in other countries<sup>[3-5]</sup>. According to a previous epidemiological study, the consumption of high levels of red chili pepper has been identified as an important risk factor for GBC in Chilean women who carry gallstones (GS)<sup>[6]</sup>. However, the pathogenic mechanism by which GBC occurs *via* chili pepper consumption in the presence of GS remains uncertain.

Although GS is the main cause of GBC, not all patients with GS develop GBC. While the standard mortality rates for GBC between 1985 and 2002 remained unchanged at 11.3 per 100 000 (0.0113%) in Chile<sup>[7]</sup>, 38.8% of adult women and 14.9% of adult men, which are staggeringly high rates, were GS carriers between 1972 and 1995<sup>[8]</sup>. Red chili pepper is a widely consumed spice among the Chilean population. Therefore, the development of GBC in Chilean women cannot be completely explained by the presence of GS and chili pepper consumption alone.

In some but not all studies, lipid metabolism-related gene variants have been associated with GS formation. Apolipoprotein (apo) B, apo E, and cholesteryl ester transfer protein (CETP) polymorphisms have been associated with increased risk for cholelithiasis<sup>[9-11]</sup>. On the other hand, capsaicin (8-methyl-N-vanillyl-6-nonenamide) is the active ingredient that makes chili peppers pungent. Although previous findings regarding the potential genotoxicity of capsaicin are inconsistent<sup>[12-15]</sup>, it is possible that GBC can be caused by high consumption of red chili pepper that contains capsaicin. Therefore, genes involved in the metabolism of capsaicin, such as cytochrome P450 (CYP) 2E1, CYP2C9, and CYP3A4, may be related to increased risk for GBC<sup>[16-18]</sup>. However, no study has examined the association between the risk of GBC in Chile and the genetic variants involved in GS formation and capsaicin metabolism.

We hypothesized that individuals with a genotype promoting greater lipid metabolism/capsaicin metabolism would be more prevalent among the GS and GBC patients than among healthy subjects. We conducted a hospital-based case-control study in a Chilean population with special reference to polymorphism-polymorphism combination.

## MATERIALS AND METHODS

### Study subjects

A total of 57 female patients with GBC who had been diagnosed by histological examination of tissue at Sótero del Río Hospital in Santiago, Chile, between January 2007 and February 2008 were enrolled in this case-control study. A total of 119 female patients with GS who were diagnosed by an ultrasonic diagnostic method were also enrolled in the study. Seventy controls, who were patients with hernia or varicose veins of the legs who had no history of GS or any cancer and who were diagnosed by an ultrasonic diagnostic method, were selected randomly at the same hospital over the same period.

All patients gave their written informed consent, and our study protocol was approved by the Ethics Committee at Sótero del Río Hospital.

### DNA extraction and storage

Samples collected in the hospital were sent to Niigata University, Japan, for DNA extraction and genotyping assay. Genomic DNA was extracted from the blood or paraffin block samples using standard commercial kits for blood samples (DNA Extractor WB-rapid, WAKO Pure Chemicals Industries, Ltd., Osaka, Japan) and for paraffin block samples (Dexpat, Takara Bio Co. Ltd., Tokyo, Japan). The extracted DNA samples were stored in a freezer at -80°C until genetic polymorphism analyses were performed.

### Genotyping assay

The statuses of the genetic variants of apo B rs693, apo E rs7412, rs429358, CETP rs708272, CYP2C9 rs1057910, CYP2C9 rs1799853, and CYP3A4 rs12721627 were assayed using TaqMan<sup>®</sup> SNP Genotyping Assays purchased from Applied Biosystems (Foster City, CA, USA). The assay IDs were C\_7615420\_20 for rs693, C\_904973\_10 for rs7412, C\_3084793\_20 for rs429358, C\_9615318\_10 for rs708272, C\_27104892\_10 for rs1057910, C\_25625805\_10 for rs1799853, and C\_30634207\_10 for rs12721627. Genotyping for the presence of CYP2E1 polymorphisms (rs2031920, rs6413432) was performed using the Custom Taqman<sup>®</sup> SNP Genotyping Assays purchased from Applied Biosystems. The reaction components for a single 10 µL reaction (using a 96-well plate) included sample genomic DNA, TaqMan<sup>®</sup> Genotyping Master Mix (Applied Biosystems), SNP Genotyping Assay-Mix (Applied Biosystems), DNase free water was used. The thermal cycler (PE 9700, Applied Biosystems) conditions were as follows: 95°C for 10 min, followed by 40 cycles of 92°C for 15 s and 60°C for 1 min. After the PCR reaction, the plate read-out and allele discrimination were analyzed using a multiplex real-time QPCR system (Mx3000P, Stratagene Japan, Tokyo).

For quality control, all genotyping assays were reconfirmed according to the PCR-restriction fragment length polymorphism method and the replicates were 100% concordant.

Food intake was grouped into the following 5 categories, and a sequence number was assigned to each category: (0) never; (1) 1-3 times/mo or less; (2) 1-3 times/wk; (3) 4-6 times/wk; and (4) everyday. Data on height, weight, and food intake was collected from 70 controls, 119 GS patients, and 26 GBC patients. Data were evaluated by one-way analysis of variance (ANOVA) followed by Scheffe's multiple comparison test. GS: Gallstone; GBC: Gallbladder cancer; BMI: Body mass index; NS: No significant difference.

### Measurement of dietary intake

An interviewer-administrated food-frequency questionnaire was used in the present study. Our subjects were asked to report the frequencies of their long-term intake of red chili pepper, vegetables, fruits, beef, pork, chicken, fish, milk, butter, cheese, and fried foods. Food intake was grouped into the following 5 categories, and a sequence number was assigned to each category: (0) never; (1) 1-3 times/mo or less; (2) 1-3 times/wk; (3) 4-6 times/wk; and (4) every day. Each dietary intake assessment was made according to the score obtained from each subject.

### Statistical evaluation

Statistical analyses were performed using SAS software (Release 6.12, SAS Institute Inc., Cary, NC, USA) and STATA software (SE 8.0, STATA Corporation, TX, USA). Fisher's exact probability test was used to assess the association between the genotypes or alleles and GBC risk. The age-adjusted odds ratios (ORs) and 95% confidence intervals (95% CI) were calculated from logistic regression coefficients. Data on demographic characteristics and food intake frequencies were evaluated by one-way analysis of variance (ANOVA) followed by Scheffe's multiple comparison test. *P* values of less than 0.05 were considered to indicate statistical significance. The genotypic distribution of the polymorphisms in the controls was compared with that expected based on Hardy-Weinberg equilibrium (HWE) by the  $\chi^2$  (Pearson) test. When the *P* values exceeded 0.05, we estimated that the sample was under the HWE.

## RESULTS

Table 1 shows the demographic characteristics and food intake frequencies of our subjects. The GBC patients had the highest mean age among the three groups, showing significant differences from the other two groups. No significant differences were found in the height, weight, or body mass index (BMI) among the three groups.

Significantly higher consumption of red chili pepper was observed in the GBC patients compared with the controls (*P* < 0.01) and the GS patients (*P* < 0.05). This difference in the consumption of red chili pepper between the GBC and GS patients was in agreement with the result of a previous study<sup>[6]</sup>. In the GBC patients, the consumption of pork, fish, fried foods, and cheese were significantly higher than in the controls and the GS patients. Overall, higher consumption of the foods we asked about was observed in the GBC patients.

Table 2 shows the GBC risk associated with the apo B rs693 polymorphism. The genotype distributions were consistent with HWE in the controls (*P* = 0.44). The frequency of the T/T genotype was significantly lower in the GBC patients than in the controls; the age-adjusted OR for the GBC risk was 0.14 (95% CI: 0.03-0.63, *P* = 0.0099). The T allele was associated with a decreased risk of GBC (OR: 0.49, 95% CI: 0.29-0.84, *P* = 0.010). Based on these results, we designated the C allele that is presumed to increase the risk of GBC as the "at-risk" allele. No significant differences in the genotypic and allelic distribution were detected between the controls and the GS patients.

Table 3 shows the risk of GBC associated with the CETP rs708272 polymorphism. In the GBC patients, the frequencies of the C/C, C/T and T/T genotypes were 28.1%, 40.3% and 31.6%, respectively. The frequencies of the C/C, C/T, and T/T genotypes in the controls were 25.7%, 57.2% and 17.1%, respectively, and in the patients with GS they were 35.3%, 47.9% and 16.8%, respectively. The distribution of the genotypes of the rs708272 polymorphism agreed with HWE in the controls (*P* = 0.20). The frequency of the T/T genotype was significantly higher in the GBC patients than in the GS patients (*P* = 0.012), though no significant differences were found between the controls and the GS patients, or between the controls and the GBC patients. Based on these results, we designated the T allele that is presumed to increase the risk of GBC as the "at-risk" allele.

NS: No significant difference;  $P_{HWE}$ : P for Hardy-Weinberg equilibrium test.

The apo E and capsaicin metabolism-related gene variants were not associated with either GBC or cholelithiasis risk.

Table 4 shows the risk of GBC associated with the combined “at-risk” genotypes of the apo B rs693 and CETP rs708272 polymorphisms. The frequencies of the combined “at-risk” genotypes of the C/C genotype of the apo B rs693 polymorphism and the T/T genotype of the CETP rs708272 polymorphism were 4.3% in the controls, 6.7% in the GS patients, and 19.3% in the GBC patients. Compared with all remaining combinations combined, the frequency of the C/C plus T/T genotypes was significantly higher in the GBC patients than in the controls; the age-adjusted OR for the GBC risk was 4.75 (95% CI: 1.16 -19.4,  $P = 0.030$ ).

## DISCUSSION

In this hospital-based case-control study, the T allele carriers of the apo B rs693 polymorphism were associated with a decreased risk of GBC. In contrast, the T/T genotype of the CETP rs708272 polymorphism was associated with an increased risk of GBC. However, the capsaicin metabolism-related gene variants were not associated with GBC risk.

Singh *et al*<sup>[19]</sup> found that the frequency of the C allele of the apoB rs693 polymorphism was significantly higher in GBC patients than in GS patients or healthy subjects. Their data also showed that the C/T and T/T genotypes are associated with a lower risk for GBC compared with the C/C genotype (ORs: 0.28 and 0.34, 95% CI: 0.17-0.46, and 0.13-0.89, respectively). They suggested that the apo B rs693 polymorphism confers susceptibility to GBC under specific environmental conditions. Our results were

CETP: Cholesteryl ester transfer protein.

in agreement with their findings, showing an association between the T allele and the lower risk of GBC. Since apo B is a key protein in lipid metabolism<sup>[20]</sup>, the apo B variant may be related to a higher incidence of GS and subsequently GBC. Generally, the T/T genotype has been reported to have significantly higher serum total cholesterol, low density lipoprotein cholesterol (LDL), and apo B levels compared with the C/C genotype<sup>[21,22]</sup>. Therefore the T/T genotype or the T allele appears to relate to a higher risk of GS or GBC. However, our findings showed that the T allele may work as a preventive factor for GBC. The inverse association between the T/T genotype of the apo B polymorphism and the GBC risk may be explained by structural changes of apo B as proposed by Boekholdt *et al*<sup>[23]</sup>. Their hypothesis about the inverse association between the T/T genotype and ischemic heart disease (IHD) is as follows: the apo B variant causes hypercholesterolemia, modifies LDL to become a less atherogenic particle, and causes IHD. We could not clarify by what mechanism the T allele decreases the risk of GBC, and the mechanism research will be the topic of our next trial.

Some genetic variants may exert population-specific effects that are independent of the other genetic profiles of the individual and of environmental exposures, while other population-specific effects may be generated under differential gene-gene interactions in different populations, differential gene-environment interactions, or both<sup>[24]</sup>.

As reported by some researchers, GS which is a main risk factor for GBC, has been associated with both decreased levels of high-density lipoprotein (HDL) cholesterol and increased levels of LDL cholesterol and triglyceride<sup>[25-27]</sup>. CETP has a central role in the metabolism of HDL and therefore might relate to the susceptibility to

**Table 4** Effects of the combined genotypes of the apo B rs693 and CETP rs708272 polymorphisms on the risk of gallbladder cancer

Others: All remaining combinations combined.

cholelithiasis<sup>[28]</sup>. The CETP variant has been reported to be associated with higher plasma CETP levels and lower HDL cholesterol levels<sup>[29]</sup>. For this reason, we examined the association between the genotypic frequencies of the CETP variant and GBC risk. No significant difference in the CETP variant was found between the controls and the patients with GS or between the patients with GS and those with GBC. However, the frequency of the T/T genotype of CETP rs708272 polymorphism was significantly higher in the GBC patients than in the patients with GS (OR = 5.04,  $P = 0.012$ ). Hassanzadeh *et al*<sup>[30]</sup> reported that the C allele is associated with higher HDL cholesterol levels and lower CETP activity. Since the C allele is the major allele in GS patients<sup>[31]</sup>, the frequency of the C allele or that of the C/C genotype may have been higher in the GS patients than in the GBC patients. Obesity is one of the risk factors for GBC, and an association between obesity and low HDL cholesterol level has been found<sup>[32,33]</sup>. Since the CETP variant has been associated with lower HDL cholesterol levels<sup>[29]</sup>, the risk of progression from cholelithiasis to GBC may be increased by obesity through an abnormality in the lipid metabolism of HDL cholesterol. However, the difference in the frequency of the T/T genotype may be caused by the small sample size of the controls and the GBC patients in our study, because the 95% CI was quite broad, ranging from 1.43 through 17.8. Further study in which the numbers of cases and controls are increased is needed to demonstrate our finding more clearly.

We also examined the combined effects of the apo B rs693 and CETP rs708272 polymorphisms on the risk of GBC. As shown in Table 4, the frequency of the combined C/C genotype of the apo B rs 693 polymorphism and the T/T genotype of the CETP rs708272 polymorphism was significantly higher in the GBC patients (19.3%) than in the controls (4.3%,  $P = 0.030$ ). The OR for the “at-risk” T/T genotype of the rs708272 polymorphism alone was 5.04 (95% CI: 1.43-17.8), and that for the combined “at-risk” genotype of the C/C and T/T was 4.75 (95% CI: 1.16-19.4); their 95% CIs were widely overlapping. Thus, the T/T genotype of the CETP polymorphism appeared to be a

good candidate gene for the genetic factor independently.

The other genetic variants involved in GS formation that we evaluated in this study did not reach conventional levels of statistical significance. As patients with hernia or varicose veins of the legs who had no history of GS or cancer were used as controls in this study, the association may be attenuated. Since both disease incidences might affect the genotype distribution, healthy subjects having no GS or cancer may be needed to detect significant differences between the controls and cases.

The genotypic and allelic frequencies in the capsaicin metabolism-related gene polymorphisms were not significantly different among the three groups. Previous studies indicated that pure capsaicin was a non-mutagenic substance when tested using the Ames test<sup>[12,13]</sup>, but other studies showed that capsaicin and chili extract both acted as tumor promoters, carcinogens, and potential mutagens<sup>[14,15]</sup>. Capsaicin is catalyzed by CYP 2E1, CYP2C9, and CYP3A4 to reactive species<sup>[16-18]</sup>. On the basis of this evidence, we examined the effects of the CYP2E1, CYP2C9, and CYP3A4 variants on the GBC risk. No significant differences in the genotypic and allelic frequencies were found between the three groups. Some other constituents of the chili pepper, e.g., aflatoxin contamination, may be associated with the GBC risk rather than capsaicin itself.

Identification of the high-risk group characterized in terms of genetic measures is important for GBC screening studies. The high-risk group also should be a target of chemoprevention and treatment trials. In addition to genetic association studies of apo B, CETP, CYP2C9 and CYP3A4, further genetic association studies of inflammatory (cyclooxygenase and ATP-binding cassette half-transporters, interleukin-1 beta) genes are needed to help illuminate the complex landscape of GBC risk and genetic variations. We also anticipate that in future genetic association studies of GBC, new approaches will facilitate the evaluation of haplotype effects, either for selected polymorphisms that are physically close to each other or for multiple genes in the overall gallbladder carcinogenesis pathway.

This study had the following limitation. Our sample size was small, and the GBC patients had a bias in age distribution with respect to the controls and the GS patients. Thus, our results may have reduced statistical power to detect a possible association between genetic variants and GBC risk, or they may have failed to reflect precisely the genetic risk factors for the development of GBC. Nonetheless, our finding of the apo B rs693 polymorphism was in agreement with the result of the Indian study<sup>[19]</sup>. To the best of our knowledge, the present study is the first to demonstrate that the T/T genotype of the CETP rs708272 polymorphism was associated with an increased risk of GBC. An additional study including a greater number of controls and cases is required to clarify the association between these genetic factors and the GBC risk.

In conclusion, the C/C genotype of the apo B rs693 polymorphism and the T/T genotype of the CETP

rs708272 polymorphism were associated with increased risk of GBC in Chilean women. While our findings require further confirmation, they provide evidence that the apo B and CETP genes are associated with a higher risk of GBC in Chilean women.

## COMMENTS

### Background

Gallbladder cancer (GBC) is the most common type of biliary tract cancer which results from a complex interplay of genetic and environmental risk factors, like other common multifactorial diseases such as cardiovascular disease, diabetes mellitus and autoimmune disease. Whether genetic variants involved in gallstone formation and capsaicin metabolism affect the risk of GBC in Chilean women is unknown.

### Research frontiers

In this study, the frequency of the cholesteryl ester transfer protein (CETP) rs708272 T/T genotype was significantly higher in the GBC patients than in the gallstone patients. This is the first analysis of the association between genetic predisposition and GBC risk in Chilean women.

### Innovations and breakthroughs

Variants of gallstone formation-related genes such as apolipoprotein B and CETP were associated with an increased risk of GBC in Chilean women. However, capsaicin metabolism-related gene variants were not associated with GBC risk. To clarify the role of genetic predisposition in the development of GBC, we may have to pay more attention to other genes such as inflammatory genes.

### Applications

The apolipoprotein B rs693 T/T and CETP rs708272 T/T genotypes can be used as biomarkers for selecting patients from the group of individuals at high risk for GBC in Chile. Identifying such susceptibility polymorphisms may lead to the development of tests that allow more focused follow-ups of high-risk groups.

### Terminology

CETP is a protein that facilitates the exchange of cholesteryl esters for triglycerides between high-density lipoproteins (HDL) and triglyceride-rich lipoproteins. Therefore, CETP has a central role in the metabolism of both of these types of lipoproteins. Although the C/C genotype was associated with higher plasma CETP and lower HDL cholesterol levels, there is no consistent result regarding the role of the C/C genotype in the development of gallstones.

### Peer review

This study provided some useful data on genetic predisposition and risk of GBC. Methods used in this study are generally reliable, the results are reasonable and convincing. The manuscript is also well written. Authors also pointed out the shortcoming of this study-small sample size.

### Abstract

**AIM:** To determine the association of hepatitis B virus (HBV) genotypes with probable cirrhosis and fatty liver in community-based populations.

**METHODS:** A multi-stage cluster probability sampling method was applied to recruit 10167 subjects aged between 6 and 72 years from our epidemiological bases in Eastern China. After excluding the subjects co-infected with hepatitis C or hepatitis D viruses, the hepatitis B surface antigen (HBsAg)-positive subjects were examined for HBV genotype, serum viral load, alanine aminotransferase (ALT), hepatitis B e antigen (HBeAg) status, and ultrasonographic changes. Logistic regression models were used to determine the factors associated with probable cirrhosis and fatty liver.

**RESULTS:** Of 634 HBsAg-positive subjects with HBV genotype determined, 82 had probable cirrhosis (ultrasonographic score  $\geq 5$ ), 42 had ultrasonographic fatty liver. Probable cirrhosis was only found in the HBeAg-negative subjects, and more frequently found in the subjects with genotype C than in those with genotype B (14.8% vs 8.0%,  $P = 0.018$ ). In HBeAg-negative subjects, high viral load was frequently associated with abnormal ALT level, while ALT abnormality was more frequent in those with probable cirrhosis than those without (19.5% vs 7.8%,  $P = 0.001$ ). Univariate analysis showed that age, sex, HBV genotypes, and viral load were not significantly associated with ultrasonographic fatty liver, whereas ALT abnormality was significantly related to ultrasonographic fatty liver (OR = 4.54, 95% CI: 2.11-9.75,  $P < 0.001$ ). Multivariate analysis demonstrated that HBV genotype C, age ( $\geq 45$  years), male sex, and ALT abnormality were independently associated with probable cirrhosis (AOR = 2.30, 95% CI: 1.26-4.19; AOR = 1.81, 95% CI: 1.10-2.99; AOR = 1.74, 95% CI: 1.03-2.95; AOR = 2.98, 95% CI: 1.48-5.99, respectively).

**CONCLUSION:** A crude prevalence of probable cirrhosis is 12.9% in the community-based HBV-infected subjects. HBV genotype C is independently associated with probable cirrhosis in the HBeAg-negative subjects.

## INTRODUCTION

Hepatitis B virus (HBV) infection is a serious public health problem. Approximately 2 billion people have been exposed to HBV, and more than 300 million are chronically infected with HBV. Chronic HBV infection is the most important risk factor of liver cirrhosis and hepatocellular carcinoma (HCC) in HBV endemic areas<sup>[1]</sup>. Liver fibrosis, which is the natural wound healing process to necroinflammation frequently caused by chronic HBV infection, is the essential pathogenic process that leads to cirrhosis. Metabolic syndrome is also an independent risk factor of liver cirrhosis in the patients with chronic hepatitis B<sup>[2]</sup>. Subclinical liver cirrhosis diagnosed by ultrasonography is significantly associated with the risk for HCC<sup>[3]</sup>.

HBV genotypes have distinct geographical distributions, and have been shown to differ with regard to clinical outcome and prognosis<sup>[4]</sup>. Genotypes B and C are endemic in most parts of Asia<sup>[5]</sup>. Genotype C is associated with HCC in the aged<sup>[6,7]</sup>. Genotype B is associated with HCC in the young, relapse of HCC, and acute hepatitis B in adults<sup>[8-10]</sup>. However, the relationship between HBV genotypes and liver cirrhosis remains controversial. Some studies suggested that genotype C had a higher risk of cirrhosis, whereas other studies indicated that the progression to cirrhosis did not differ among genotypes B- and C-related chronic liver diseases<sup>[11-13]</sup>. In addition, the association between HBV genotypes and subclinical cirrhosis has not been evaluated in community-based studies in the HBV endemic areas.

Our objective was to determine the prevalence of probable liver cirrhosis in community-based subjects who were seropositive for hepatitis B surface antigen (HBsAg), and to evaluate the viral and demographic factors contributing to subclinical cirrhosis.

## MATERIALS AND METHODS

### *Study population and epidemiological survey*

The study was carried out at our epidemiological bases in Eastern China, from February to July 2009. A multistage cluster probability sampling method was applied to select the study population. A total of 10167 residents aged between 6 and 72 years were involved in this study. The participants were interviewed by the trained research assistants using a standard questionnaire requesting information about sociodemographic characteristics. Fasting blood samples (4 mL) were collected with vacuum blood collection tube (BD Diagnostics, Plymouth, UK) without anticoagulant. The serum was separated by centrifugation at 4°C at the Centers for Disease Control and Prevention, transported on dry ice and stored at -40°C in the Department of Epidemiology, Second Military Medical University. Informed consent in writing was obtained from each participant or guardian. Each resident who agreed to participate in the study completed a questionnaire and provided blood samples. The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki, and was approved by the Institutional Review Board of this university.

### *Examination of HBV serological markers, serum viral load, and serum alanine aminotransferase level*

All participants received HBsAg examination. Those positive for HBsAg were examined for hepatitis B e antigen (HBeAg), serum viral load, and alanine aminotransferase (ALT). HBsAg was examined using enzyme linked immunosorbent assay (Kehua, Shanghai, China) according to the manufacturer's instructions. Serological testing for HBeAg, antibody to hepatitis C virus (HCV), and antibody to hepatitis D virus (HDV), liver function tests, and  $\alpha$ -fetoprotein examination were performed as previously described<sup>[9]</sup>. Upper limit of normal ALT was 45 U/L. Viral load was measured in the LightCycler™ 480 (Roche, Basel, Switzerland) using quantitative HBV PCR fluorescence diagnostic kits (Fosun Diagnostics, Shanghai, China). The kit has a certified lower limit of detection of 500 copies/mL, which was standardized using the Abbott reagents (Abbott Laboratories, North Chicago, IL).

### *HBV genotyping*

HBV DNA was extracted from 200  $\mu$ L HBsAg-positive serum using High Pure Viral Nucleic Acid Kits (Roche Diagnostics, Mannheim, Germany) according to the manufacturer's instruction. HBV genotype was determined using a multiplex PCR assay<sup>[9,14]</sup>. HBV genotypes of samples with low level of HBV DNA were identified by nested multiplex PCR. Outer primers were 5'-TTTGCGGGTCACCATATTCTTGG-3' and 5'-CGA ACCACTGAACAAATGGCACTAG-3'. An Autorisierter Thermocycler (Eppendorf AG, Hamburg, Germany) was programmed to initially denature the samples for 3 min at 95°C, followed by 35 cycles consisting of 94°C for 60 s, 58°C for 60 s, 72°C for 60 s, followed by a final elongation step at 72°C for 10 min. The products (2  $\mu$ L) were used as templates for multiplex PCR<sup>[14]</sup>.

### Ultrasonographic examination of liver cirrhosis and fatty liver

With the use of a Philips iU22 scanner (Philips Medical Systems, Best, the Netherlands) equipped with a 2-4 MHz variable convex probe or Toshiba systems (SSA-340; Toshiba, Tokyo, Japan) with a 3.75 MHz convex probe, probable liver cirrhosis and fatty liver were determined. Each subject was examined by two independent operators who were blinded to the clinical details. Discrepancies were resolved by consensus. The ultrasonographic scoring system consisting of liver surface, parenchyma, vascular structure, and splenic size was used to describe the existence and the severity of cirrhosis. The scores ranged from 4 for a normal liver to 11 for advanced cirrhosis<sup>[15]</sup>. A score of 8 or more was used as the cutoff point for ultrasonographic cirrhosis. The subjects with the score from 5 to 7 were diagnosed as having cirrhosis-like ultrasonographic abnormality. A score of 5 or more was defined as probable cirrhosis. The subject with an ultrasonographic steatosis score of 2 or more was diagnosed as having fatty liver<sup>[16]</sup>.

### Statistical analysis

$\chi^2$  test was used to determine the differences in categorical variables, such as HBeAg positivity and the percentage of HBV genotypes. Continuous variables, like serum viral load and ALT level with skewed distribution, were adjusted to normal distribution by transformation into logarithmic function, and then tested by Student's *t* test. Univariate and multivariate regression analyses were performed to obtain the odds ratio (OR) and adjusted odds ratio (AOR) of factors for the risk of probable liver cirrhosis or ultrasonographic fatty liver and their 95% confidence intervals (CI). All statistical tests were two-sided, and performed using the Statistical Program for Social Sciences (SPSS15.0 for Windows, SPSS, Chicago, IL). A *P* value of < 0.05 was considered as statistically significant.

## RESULTS

Of the 10167 participants, 793 were HBsAg positive; 745 of the 793 subjects were free of antibodies to HCV or HDV; and 634 of 745 subjects had HBV genotyped. Ten of the 634 subjects (8 with genotype C, one with genotype D, and one with genotype B) were diagnosed as having ultrasonographic cirrhosis (score 8 or higher), while 72 had cirrhosis-like ultrasonographic abnormalities (scores 5-7). Of the 634 subjects, one was diagnosed as having HCC. A crude prevalence of probable cirrhosis (ultrasonographic cirrhosis and cirrhosis-like ultrasonographic abnormalities) was 12.9%. Table 1 shows the demographic and viral characteristics and liver abnormalities of the 634 subjects. There were no significant differences in proportions of age, sex, ALT level, HBeAg positivity, and fatty liver between the subjects infected with genotype B and those with genotype C. Compared with genotype C, HBV genotype B was more frequently seen in those with a high viral load ( $\log_{10}$  copies/mL  $\geq 4$ ). Of the 634 subjects, 39 were positive for HBeAg. The HBeAg-positive subjects were significantly younger than the HBeAg-negative

Probable cirrhosis <sup>4</sup>	16 (8.0)	61 (14.8)	5 (20.8)	0.018

<sup>1</sup>23 cases for genotype mixture, 1 case for genotype D; <sup>2</sup>Genotype C *vs* genotype B; <sup>3</sup>mean ± SD; <sup>4</sup>Ultrasonographic cirrhosis and cirrhosis-like ultrasonographic abnormalities (ultrasonographic score  $\geq 5$ ). ALT: Alanine aminotransferase; HBeAg: Hepatitis B e antigen; HBV: Hepatitis B virus.

subjects ( $25.4 \pm 11.2$  years *vs*  $42.7 \pm 12.4$  years, *P* < 0.001). The subjects with probable cirrhosis were significantly older than those without probable cirrhosis ( $45.3 \pm 10.5$  years *vs*  $41.1 \pm 13.3$  years, *P* = 0.001). Probable cirrhosis was only found in the HBeAg-negative subjects, and more frequently in the subjects with genotype C than in those with genotype B (14.8% *vs* 8.0%, *P* = 0.018). Serum viral load was significantly higher in the HBeAg-negative subjects with abnormal ALT levels than in the HBeAg-negative subjects with normal ALT levels ( $4.54 \pm 2.16 \log_{10}$  copies/mL *vs*  $3.31 \pm 1.36 \log_{10}$  copies/mL; *P* < 0.001). However, this association was not found in the HBeAg-positive subjects. Serum ALT level was significantly higher in the subjects with high viral load ( $\geq 1 \times 10^4$  copies/mL) than in those with low viral load ( $< 1 \times 10^4$  copies/mL) ( $33.9 \pm 2.4$  U/L *vs*  $22.4 \pm 1.9$  U/L, *P* < 0.001). Serum ALT level was significantly higher in the subjects with ultrasonographic cirrhosis (score  $\geq 8$ ) than in the HBeAg-negative subjects with ultrasonographic score less than 7 ( $41.1 \pm 1.6$  U/L *vs*  $24.1 \pm 2.0$  U/L, *P* = 0.026). ALT abnormality was more frequent in HBeAg-negative subjects with probable cirrhosis than those without probable cirrhosis (19.5% *vs* 7.8%, *P* = 0.001).

Table 2 shows the factors associated with probable liver cirrhosis in the HBeAg-negative subjects by univariate and multivariate regression analyses. Age ( $\geq 45$  years *vs* < 45 years), sex (male *vs* female), HBV DNA ( $\geq 4 \log_{10}$  copies/mL *vs* <  $4 \log_{10}$  copies/mL), ALT ( $> 45$  U/L *vs*  $\leq 45$  U/L), and HBV genotypes (genotype C *vs* genotype B) were included in the models. It was found that age ( $\geq 45$  years), male sex, genotype C, and ALT abnormality were independently associated with

**Table 2** Univariate and multivariate regression analyses for the risk factors of probable liver cirrhosis in the 595 HBeAg negative subjects infected with HBV

Variables	Controls (n = 513)	Cases (n = 82)	OR (95% CI)	AOR (95% CI)

probable cirrhosis (AOR = 1.81, 95% CI: 1.10-2.99; AOR = 1.74, 95% CI: 1.03-2.95; AOR = 2.30, 95% CI: 1.26-4.19; AOR = 2.98, 95% CI: 1.48-5.99, respectively).

Forty-two (6.6%) of the 634 subjects had ultrasonographic fatty liver, including 11 with abnormal ALT levels. Ultrasonographic fatty liver was not found in the subjects with probable cirrhosis. In the subjects with high viral load (log<sub>10</sub> copies/mL ≥ 4), ultrasonographic fatty liver was more frequently found in those with genotype B than in those with genotype C (12.5% *vs* 0.0%, *P* = 0.005). Univariate analysis showed that age, sex, HBV genotypes, and viral load were not significantly associated with ultrasonographic fatty liver, whereas ALT abnormality was significantly associated with ultrasonographic fatty liver (OR = 4.54, 95% CI: 2.11-9.75, *P* < 0.001).

## DISCUSSION

This large epidemiological study for the first time described the prevalence of probable liver cirrhosis in community-based, HBV-infected subjects who were free of HCV or HDV infection. About 13% of HBV-infected subjects had probable cirrhosis. The subjects with probable cirrhosis were significantly older than the subjects without cirrhosis. Probable cirrhosis was only found in the HBeAg-negative subjects. The HBeAg-positive subjects were significantly younger than the HBeAg-negative subjects. These results indicate that age is an important determinant for the development of probable liver cirrhosis. High viral load and ALT abnormality are associated with liver fibrosis in the HBeAg-negative patients<sup>[17]</sup>. We further demonstrated that high viral load was associated with increased serum ALT levels in the HBeAg-negative subjects and high ALT levels were frequently found in the subjects with probable cirrhosis, indicating that continuing HBV replication and hepatocyte damage contribute to the development of liver cirrhosis.

Importantly, the occurrence of probable liver cirrhosis

was significantly higher in the subjects with genotype C than in those with genotype B. Multivariate analysis indicated that genotype C was significantly associated with an increased risk of probable liver cirrhosis. This was probably related to the prolonged immune clearance and delayed HBeAg seroconversion<sup>[18,19]</sup>. Although genotype B is associated with acute hepatitis<sup>[10]</sup>, it tends to be self-limiting and short-living. However, genotype C was associated with the longer duration of liver damage in the HBeAg-negative subjects<sup>[12,20]</sup>, which may be the main reason for the development of liver cirrhosis. In addition, genotype C-specific viral mutations are associated with probable cirrhosis<sup>[11,21,22]</sup>. Our recent meta-analysis has shown that PreS deletion, C1653T, T1753V, and A1762T/G1764A are increasingly more prevalent as chronic HBV infection progressed from the asymptomatic HBsAg carrier to cirrhosis or HCC<sup>[23]</sup>. Further studies are needed to probe into the different mutation patterns between genotypes B and C and their roles in the development of liver cirrhosis.

Since metabolic syndrome increased the risk of liver cirrhosis in the patients infected with HBV<sup>[2]</sup>, we evaluated the prevalence and possible risk factors of ultrasonographic fatty liver in the 634 HBV-infected subjects. Interestingly, ultrasonographic fatty liver was not found in those with probable cirrhosis, while ultrasonographic fatty liver was more frequently found in those with genotype B than in those with genotype C at high viral load levels. This suggests that ultrasonographic fatty liver is unlikely to be a late event during the development of probable cirrhosis.

In conclusion, this study found that HBV genotype C, age (≥ 45 years), ALT abnormality, and male sex are independently associated with an increased risk of probable cirrhosis. Ultrasonographic fatty liver is not found in the subjects with probable cirrhosis. Although cirrhosis-like ultrasonographic abnormalities are not clinical liver cirrhosis, it is an early event during the development of clinical cirrhosis. Genotype C HBV-infected male residents at the age of 45 years or older should be routinely examined for active hepatitis and early cirrhosis. Early intervention to the HBV-infected subjects with high risks of cirrhosis might be effective for decreasing the overall mortality from liver cirrhosis and subsequent HCC.

## ACKNOWLEDGMENTS

We thank Dr. Hong-Xia Ni and Dr. Ting Fang, Municipal Center for Disease Control and Prevention of Ningbo, for their great help in field study; Dr. Lei Han, Dr. Wen-Ying Lu, Dr. Yi-Fang Han, Dr. Xiao-Jie Tan, and Dr. Wen-Jun Chang, Department of Epidemiology, Second Military Medical University for their technical assistance.

## COMMENTS

### Background

Chronic hepatitis B virus (HBV) infection is the most important risk factor of liver cirrhosis and hepatocellular carcinoma (HCC) in HBV endemic areas. Metabolic syndrome has been found to be an independent risk factor of liver cirrhosis in the

patients with chronic hepatitis B. The relationship between HBV genotypes and liver cirrhosis remains controversial. Furthermore, the association between HBV genotypes and subclinical cirrhosis has not been evaluated in community-based population.

### Research frontiers

HBV genotypes have distinct geographical distributions and differ with regard to clinical outcome, prognosis, and response to interferon treatment. The role of genotype B and C, the two major HBV genotypes endemic in East Asia, in the development of liver cirrhosis has not been unequivocally addressed. In this study, the authors demonstrate that infection with HBV genotype C is closely associated with subclinical cirrhosis in the community-based subjects with increasing age.

### Innovations and breakthroughs

Recent reports have highlighted the importance of HBV genotypes, alanine aminotransferase (ALT), age, and sex in hepatocarcinogenesis and the development of clinical liver cirrhosis. Metabolic syndrome has been found to be independently associated with liver cirrhosis in the patients with chronic hepatitis B. This is the first study to report that HBV genotype C, age ( $\geq 45$  years), male sex, and ALT abnormality are independently associated with probable cirrhosis in community-based HBV-infected subjects, especially with the subclinical liver cirrhosis. Furthermore, this study suggested that fatty liver may not be associated with probable liver cirrhosis.

### Applications

This study suggests that genotype C HBV-infected male residents at the age of 45 years or older should be routinely examined for active hepatitis and early cirrhosis. Early intervention to the HBV-infected subjects with high risks of cirrhosis might be effective for decreasing the overall mortality from liver cirrhosis and subsequent HCC.

### Terminology

Probable cirrhosis is referred to ultrasonographic cirrhosis (ultrasonographic score  $\geq 8$ ) and cirrhosis-like ultrasonographic abnormalities (ultrasonographic score from 5 to 7). Probable cirrhosis is not histologically confirmed liver cirrhosis. Ultrasonography is an imaging examination which is widely accepted by the community-based HBV-infected subjects without apparent clinical manifestations.

### Peer review

The results of this study provide sufficient experimental evidences or data from which scientific conclusions can be drawn. The discussion is well organized and an overall theoretical analysis is given.

### Abstract

**AIM:** To investigate the *in vivo* hepatoprotective effects and mechanisms of *Gentiana manshurica* Kitagawa (GM) in acetaminophen (APAP)-induced liver injury in mice.

**METHODS:** GM (200, 150 or 50 mg/kg body weight) or N-acetyl-L-cysteine (NAC; 300 mg/kg body weight) was administered orally with a single dose 2 h prior to APAP (300 mg/kg body weight) injection in mice.

**RESULTS:** APAP treatment significantly depleted hepatic glutathione (GSH), increased serum aspartate aminotransferase (AST), alanine aminotransferase (ALT) and malonyldialdehyde (MDA) and 4-hydroxynonenal levels, and decreased hepatic activity of glutathione peroxidase (GSH-px) and superoxide dismutase (SOD). However, the pretreatment of GM significantly alleviated APAP-induced oxidative stress by increasing

GSH content, decreasing serum ALT, AST and MDA, and retaining the activity of GSH-px and SOD in the liver. Furthermore, GM pretreatment can inhibit caspase-3 activation and phosphorylation of c-Jun-NH<sub>2</sub>-terminal protein kinase 2 (JNK1/2) and extracellular signal-regulated kinase (ERK). GM also remarkably attenuated hepatocyte apoptosis confirmed by the terminal deoxynucleotidyl transferase mediated dUTP nick end-labeling method.

**CONCLUSION:** Hepatoprotective effects of GM against APAP-induced acute toxicity are mediated either by preventing the decline of hepatic antioxidant status or its direct anti-apoptosis capacity. These results support that GM is a potent hepatoprotective agent.

### INTRODUCTION

Acetaminophen (APAP) is a widely used analgesic and antipyretic drug. It is safe at therapeutic doses, however,

when taken at high doses, APAP can precipitate severe liver injury that may develop into a liver failure<sup>[1,2]</sup>. Overdoses of APAP lead to the generation of high amounts of the toxic metabolite N-acetyl-quinoneimine (NAPQI) by the cytochrome P-450 isoenzyme mixed-function oxidase system, which is immediately conjugated with glutathione (GSH), forming the nontoxic metabolites cysteine and mercapturic acid conjugates. Although a number of P450 enzymes can metabolize APAP, the most relevant isoenzyme is CYP2E1<sup>[3]</sup>. There is an alternative view that oxidative stress plays a role in hepatotoxicity. Oxidative stress in APAP hepatotoxicity is characterized by several features, including lipid peroxidation, mitochondrial damage and ATP depletion in proteins<sup>[4]</sup>. NAPQI reacts with GSH spontaneously or catalyzed by glutathione-S-transferases to form a GSH-adduct. Thus, GSH depletion and formation of protein adducts are key mechanisms of APAP-induced cell death<sup>[5-7]</sup>.

Many antioxidant agents have been studied in experimental and clinical studies to reduce or prevent APAP-induced hepatotoxicity. The most popular antioxidant for APAP hepatotoxicity is N-acetyl-L-cysteine (NAC)<sup>[8]</sup>. Protection by NAC is believed to be attributable to its ability to regenerate GSH stores because of its capacity to provide cysteine residues<sup>[9]</sup>.

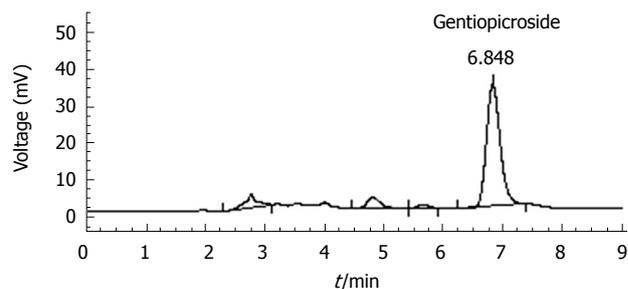

In recent years, plant-derived natural products have received considerable attention due to their diverse pharmacological properties. A growing interest has been observed in the analysis of these natural entities for their potential benefits to human health on hepatoprotective effects. *Gentiana manshurica* Kitagawa (GM) is distributed in northeastern China and reputed “Dongbei longdan”, which is one of the most common herbal medicines used by Chinese people suffering from chronic liver diseases. As an iridoid containing plant, GM has various pharmacological activities. Previous phytochemical studies reported that GM includes loganic acid, 6-O-β-d-glucopyranosylgentiopicroside, swertiamarin, gentiopicroside, sweroside and 2-(o,m-dihydroxybenzyl)-sweroside<sup>[10]</sup>. It was reported that gentiopicroside involves down-regulation of NR2B receptors in the anterior cingulate cortex to persistent inflammatory pain<sup>[11]</sup>. Animal experiments have revealed adaptogenic<sup>[12]</sup> and anti-inflammatory<sup>[13]</sup> activities. GM has also been used traditionally as a folk remedy for healing wound<sup>[14,15]</sup>. However, no research has been conducted about its hepatoprotective patterns.

Since a high dose APAP-induced hepatotoxicity resulted from the generation of free radicals during its metabolism at liver, the possible protection by GM was evaluated and the results are presented in this paper.

## MATERIALS AND METHODS

### Chemicals

APAP and NAC were purchased from Sigma Chemicals (St. Louis, MO, USA). Detection kit for GSH and malondialdehyde (MDA), glutathione peroxidase (GSH-px) and superoxide dismutase (SOD) were purchased

**Figure 1** HPLC chromatograms of *Gentiana manshurica* Kitagawa (GM). Column: Diamonsil C18 (250 mm × 4.6 mm); Flow rate: 1 mL/min; Mobile phase: Methanol and H<sub>2</sub>O (35:65).

from Nanjing Jiancheng Bioengineering Institute (Nanjing, China). All other chemicals used were of analytical grade.

### Preparation of GM

The rhizomes and roots GM were purchased from Yanbian Puhe, China in March 2006 and authenticated by Prof. Hui-Zi Lv of College of Pharmacy, Yanbian University. The rhizomes and roots of GM (1 kg) were extracted three times with methanol (10 L) and boiled under reflux for 4 h at 40°C, and then the percolated was concentrated in a rotary vacuum evaporator followed by lyophilization. The yield (w/w) of extract was about 22.35%. The freeze-dried extract was used in both chemical analysis and pharmacological studies. GM extract was analyzed on HPLC to confirm the presence of gentiopicroside (Figure 1). The content of gentiopicroside was 2.48% in GM extract. The extract was pre-solubilized in distilled saline for the *in vivo* studies.

### Animals and treatment

Male Kunming mice (20-22 g) were provided by Yanbian University Laboratory Animal Center, fed with a standard chow diet and given tap water *ad libitum*. Animals were housed in plastic cages and maintained at 22 ± 2°C and 50%-60% relative humidity, with a 12-h light-dark cycle throughout the experiment. Animal experiments were performed under the latest edition of “Guiding Principles in the Use of Animals in Toxicology” adopted by the Society of Toxicology (USA).

The mice were fasted overnight (16 h) prior to administration of a single intraperitoneal dose (300 mg/kg) of APAP dissolved in sterile phosphate buffered saline (PBS, pH 7.4) warmed to 40°C<sup>[16]</sup>. Animals were divided into 7 groups of ten animals each. Animals of group 1 received vehicle only and served as normal and group 2 treated intraperitoneally with a single dose of APAP (300 mg/kg) was kept as control. Groups 3, 4 and 5 were administered orally with GM extract (50, 100 or 200 mg/kg) 2 h before APAP injection, and served as GM *per se*. Group 6 was treated with NAC (300 mg/kg) 2 h before APAP injection, and served as positive control. Group 7 received only GM extract (200 mg/kg) 2 h after saline injection, instead of APAP injection. Animals were sacrificed and blood was collected from the carotid artery 12 h after administration of APAP. Serum was then separated by

centrifugation at 4°C, 3000 r/min for 30 min. The liver was removed immediately from each mouse, and kept at -80°C until analyzed.

### Blood biochemistry

Blood was collected at 12 h after APAP administration. Serum levels of AST and ALT were detected using an Autodry Chemistry Analyzer (SPOTCHEM™ SP4410, Arkray, Japan).

### GSH, SOD, GSH-px activities and hepatic lipid peroxidation assay

The removed liver tissue was homogenized in 9 volumes of cold buffer (0.01 mol/L Tris-HCl, 0.0001 mol/L EDTA-2Na, 0.01 mol/L sucrose, and 0.8% saline, pH 7.4) on ice. The homogenate was centrifuged at 4°C (3000 r/min, 15 min) and the supernatant was used for the determination of GSH and MDA, GSH-px and SOD following the manufacturer's instructions. Briefly, the MDA was detected using the thiobarbituric acid reactive substances (TBARS) methods; 4-hydroxynonenal (4-HNE) was detected as a fluorimetric derivative<sup>[17]</sup>; the GSH activity was detected through yellow tetramethyl-benzidine and oxidised GSH produced by the combination of GSH and dithio-nitrobenzene; SOD activity was examined through nitroblue tetrazolium coloration; and GSH-px activity was determined through detecting selenium cysteine, the active centre of GSH-px. Protein content was determined with a Bio-Rad Protein Assay Kit (Bio-Rad, USA).

### Histopathological analysis

Liver samples obtained at different time points after the APAP injection were fixed in 10% phosphate-buffered formalin and embedded in paraffin. Sections were stained with hematoxylin and eosin for histopathological analysis. The sections were examined under light microscopy and graded for the presence and intensity of lesions using a scale from 0 to 5 (0 = no lesions; 1 = minimal lesions involving a single or few necrotic cells; 2 = mild lesions, 10%-25% necrotic cells or mild diffuse degenerative changes; 3 = moderate lesions, 25%-40% necrotic or degenerative cells; 4 = marked lesions, 40%-50% necrotic or degenerative cells; and 5 = severe lesions, more than 50% necrotic or degenerative cells)<sup>[18,19]</sup>.

### Transferase-mediated dUTP nick end-labeling (TUNEL) assay

Apoptotic cells were detected by the terminal deoxynucleotidyl TUNEL method using an *in situ* cell detection kit (Roche, Mannheim, Germany) for the detection and quantification of apoptosis at a single-cell level. Staining of tissue sections was performed according to the manufacturer's protocol, as follows. Paraffin-embedded sections were dewaxed in xylene and rehydrated by passing through a graded series of ethanol solutions, ending with phosphate-buffered saline. Sections were permeabilized with proteinase K (20 µg/mL in 10 mmol/L Tris-HCl,

pH 7.4-8.0) at 37°C for 15 min. After washing, sections were stained with fluorescent anti-TdT. Sections were viewed and photographed using standard fluorescent microscopic techniques.

### Western blotting analysis

The total protein extracts were made by pulverization in a grinder with liquid nitrogen, then using a ratio of 1 mL lysis buffer (150 mmol/L NaCl, 1.0% NP-40, 0.5% NaVO<sub>4</sub>, 0.1% SDS, 50 mmol/L Tris, pH 7.5) containing 1 mmol/L PMSF for each 100 mg powdered liver sample. Liver lysates (40 µg) were electroblotted onto a PVDF membrane following separation on 8%-12% SDS-polyacrylamide gel electrophoresis. Blotted membranes were blocked with 5% skim milk in incubation buffer at room temperature, followed by incubation overnight at 4°C with 1:1000 dilution of caspase-3, JNK, ERK (Santa Cruz biotechnology, CA, USA) and phospho-JNK, phospho-ERK (Cell Signaling Technology, MA, USA) primary antibody. Bound antibody was detected with horseradish peroxidase-conjugated secondary antibody (Santa Cruz Biotechnology, CA, USA) and immunodetected proteins were visualized using WEST-ZOL™ (plus) Western blotting detection system (iNtRON Biotechnology, Gyeonggi, Korea). Loading accuracy was evaluated by membrane rehybridization with monoclonal antibodies against  $\alpha$ -tubulin (Sigma, St. Louis, MO, USA). Densities of the immunoreactive bands were analyzed with the Image Master 1D Elite software (Amersham Pharmacia Biotech, Piscataway, NJ, USA).

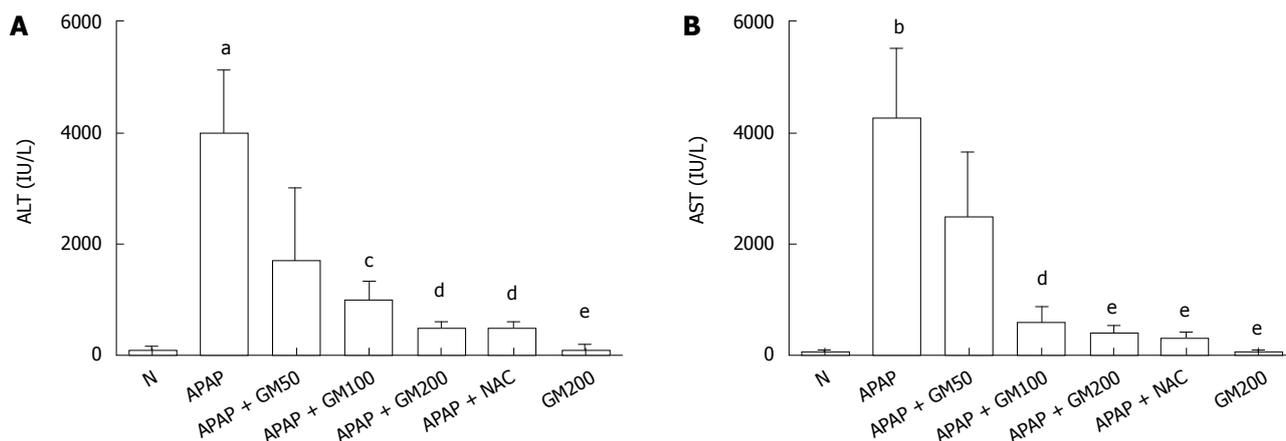

### Statistical analysis

All values were expressed as mean  $\pm$  SD. All other results, except pathological findings, were evaluated by one-way ANOVA and Tukey's multiple comparison tests. Liver histopathological examination data were analyzed by the Kruskal-Wallis nonparametric test, followed by a Mann-Whitney test. Statistically significant differences between groups were defined as *P* values less than 0.05. Calculations were performed with the GraphPad Prism program (Graphpad Software, Inc, San Diego, USA).

## RESULTS

### Effects of GM on serum AST and ALT levels

Serum activities of ALT and AST are shown in Figure 2. A single dose of APAP significantly elevated the serum ALT (*P* < 0.05) and AST (*P* < 0.01) activities when compared with the normal animals. Pretreatment with GM 2 h prior to APAP administration lowered markedly both serum ALT and AST levels. Serum ALT levels were significantly decreased to 43%, 26%, 13% or 13% in GM groups (200, 100 and 50 mg/kg) or NAC group (300 mg/kg) compared with APAP alone group, respectively. Serum AST levels were significantly decreased to 58%, 14%, 10% or 8% in GM groups (200, 100 and 50 mg/kg) or NAC group (300 mg/kg) compared with APAP alone group, respectively.

**Figure 2** Protective effects of GM on serum biochemical parameters after acetaminophen (APAP) administration. Mice were intraperitoneally injected with APAP (300 mg/kg body weight). GM (200, 100 or 50 mg/kg body weight) was orally administered at 2 h before APAP injection. All data are presented as mean  $\pm$  SD,  $n = 10$ /group. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ , significantly different when compared with normal controls. <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$ , <sup>e</sup> $P < 0.001$  significantly different when compared with APAP alone group.

### Effects of GM on GSH, SOD, GSH-px activities, MDA and 4-HNE contents

Twelve hours after APAP administration, GSH, GSH-px and SOD concentrations were significantly decreased to 44% ( $P < 0.05$ ), 35% ( $P < 0.05$ ) and 55% ( $P < 0.05$ ) respectively in APAP group compared with the normal group. However, pretreatment with a high dose of GM (200 mg/kg) significantly alleviated subsequent APAP-induced GSH depletion to  $1561 \pm 186$  ( $P < 0.05$ ). SOD ( $P < 0.01$ ) and GSH-px activities ( $P < 0.05$ ) were significantly enhanced in GM 200 mg/kg plus APAP treated group. MDA levels increased by 252% in mice treated with APAP, indicating that APAP administration significantly increased lipid peroxidation in liver ( $P < 0.01$ ). Briefly, in mice receiving GM (200 or 100 mg/kg) plus APAP, the MDA levels were significantly reduced to 42% ( $P < 0.01$ ) or 43% ( $P < 0.01$ ) as compared with the APAP treated mice. In mice receiving GM (200 mg/kg) plus APAP, the 4-HNE levels were significantly reduced to 59% ( $P < 0.05$ ) compared with the APAP treated mice (Figure 3).

### Effects of GM on histopathology

Histopathological analysis of the APAP alone treated animal showed severe centrilobular necrosis, fatty infiltration and lymphocytes infiltration (data not shown), which were significantly less in the GM plus APAP treated groups with mild sinusoidal congestion, less inflammatory cell infiltration, and well preserved hepatocytes with less area of necrosis (Table 1 and Figure 4).

### GM protects against APAP-induced hepatocyte apoptosis in mice via inhibiting caspase-3 and JNK/ERK MAPK pathway

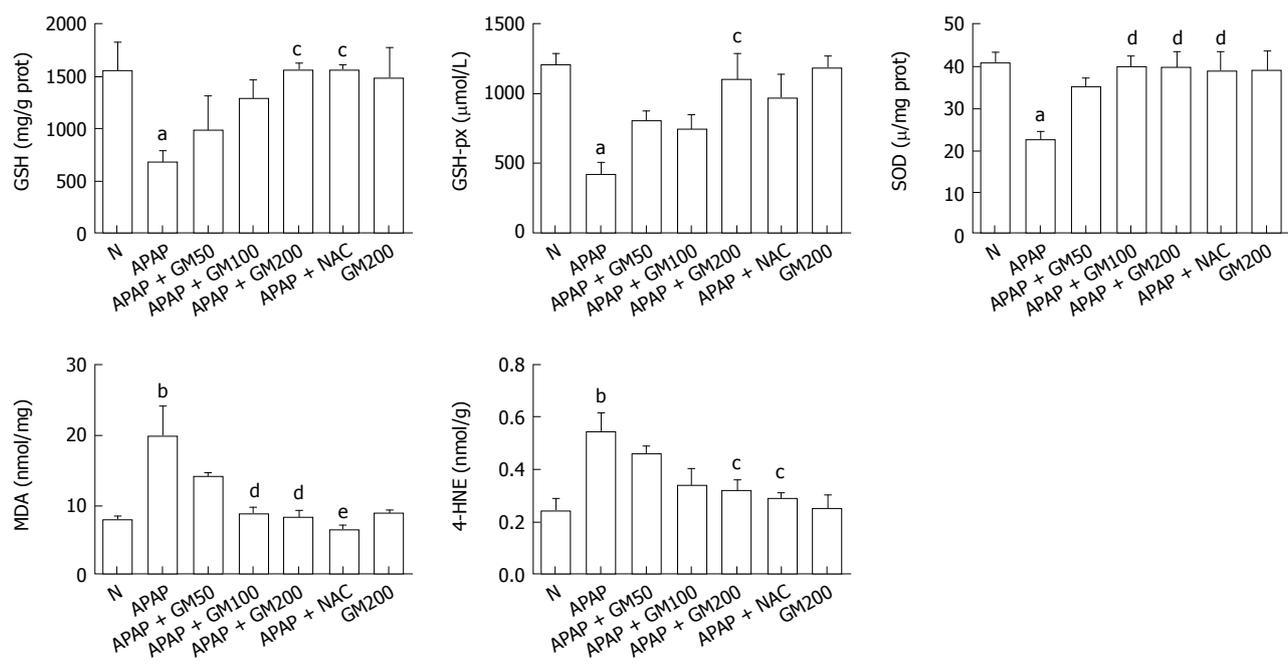

Apoptotic hepatocytes were detected by TUNEL staining. A large number of TUNEL-positive hepatocytes were seen in the livers of APAP-treated mice 12 h after injection, however, a few TUNEL-positive hepatocytes were found in livers from animals pretreated with GM (Figure 4). The protease activity of caspase-3 was measured in APAP-induced liver injury mice treated with

and without GM. Caspase-3 was proteolytically processed to the active p17 fragment 12 h after APAP treatment in mice (Figure 5). However, GM significantly inhibited caspase-3 activity. It has recently been reported that c-Jun-NH2-terminal protein kinase 2 (JNK1/2) plays a critical role in mediating APAP hepatotoxicity in mice<sup>[20]</sup>. JNK1/2 activation is an early key signal in mediating mitochondria-mediated lethal cell injury triggered by toxicants in hepatocytes<sup>[21]</sup>. Therefore, we investigated whether APAP-induced JNK activation was attenuated by GM. Our data revealed that phosphorylated JNK and phosphorylated ERK, significantly increased after treatment with APAP when oxidative stress in the liver had been significantly enhanced as described above, while the JNK and ERK total protein level were almost normal 12 h after APAP treatment (Figure 5). After administered with various doses of GM 2 h via APAP injection, phosphorylated JNK and phosphorylated ERK levels were declined (Figure 5). These data are consistent with our hypothesis that GM inhibits JNK/ERK MAPK signaling pathway.

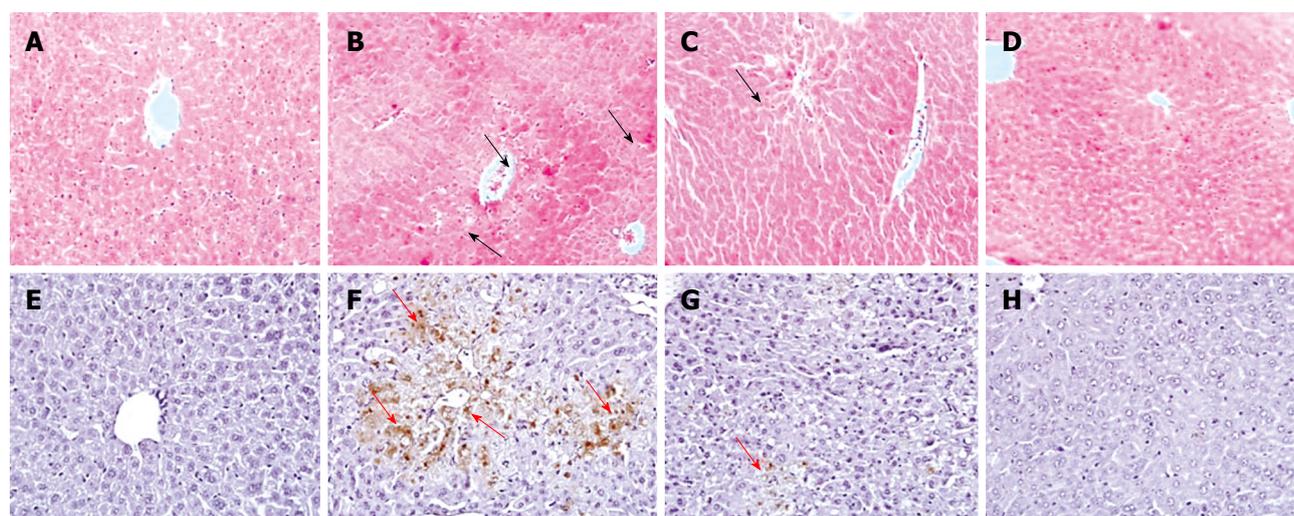

## DISCUSSION

Progress has been achieved in research of the chemical constituents and pharmacological activities of genus *Gentiana*. It is reported that gentianine from *Gentiana Macrophylla* Radix, one of *Gentiana* species, might express anti-inflammatory activities at least partly through preventing the immune cells, including macrophages, from producing TNF- $\alpha$  and IL-6, pro-inflammatory cytokines in male *Sprague Dawley* rats treated with LPS<sup>[22]</sup>. Hepatoprotective effects of *Gentiana olivieri* Griseb, flowering herbs on subacute administration were studied using *in vivo* models in rats, and the remarkable hepatoprotective activity of *Gentiana olivieri* might be due to the potent antioxidant activity of iso-orientin<sup>[23]</sup>. However, this is the first study to report the hepatoprotective effects of GM against APAP-related liver toxicity.

APAP is a safe and effective analgesic when used at therapeutic doses, an overdose of APAP, however, can

**Figure 3** Protective effects of pretreatment with GM against APAP-induced glutathione (GSH) depletion, malonyldialdehyde (MDA) levels, 4-hydroxynonenal (4-HNE) levels and superoxide dismutase (SOD), glutathione peroxidase (GSH-px) activity in liver of mice. APAP was given intraperitoneally with a single dose of 300 mg/kg. GM was given orally with a single dose of 200, 100 or 50 mg/kg. All data are presented as mean ± SD, n = 10/group. <sup>a</sup>P < 0.05, <sup>b</sup>P < 0.01, significantly different when compared with normal controls. <sup>c</sup>P < 0.05, <sup>d</sup>P < 0.01, <sup>e</sup>P < 0.001 significantly different when compared with APAP alone group.

**Figure 4** Liver histopathology and transferase-mediated dUTP nick end-labeling (TUNEL) assay. APAP was given intraperitoneally with a single dose of 300 mg/kg. GM was given orally with a single dose of 200 mg/kg. A and E: Normal group; B and F: APAP group; C and G: APAP plus GM 200 mg/kg; D and H: Only GM 200 mg/kg. Upper panels stand for HE staining and the lower panels for TUNEL assay. The regions by black arrows in the upper figures indicate the hepatocyte necrosis or hepatocyte degeneration; the regions by red arrows in the lower figures indicate the TUNEL-positive apoptotic cells (× 100 magnification).

induce severe hepatotoxicity in experimental animals and in human<sup>[24,25]</sup>. Liver injury induced by APAP is commonly used for the screening of hepatoprotective drugs<sup>[16]</sup>. NAC is used currently in clinical treatment for APAP overdose. Hereby, we used NAC as positive control, to compare with GM on hepatoprotective effects.

Administration of a single high dose of APAP significantly ( $P < 0.01$ ) elevated the serum transaminase activities compared with the normal controls (Figure 2). The significantly decreased serum transaminases activities in the GM administered groups prior to APAP demonstrated

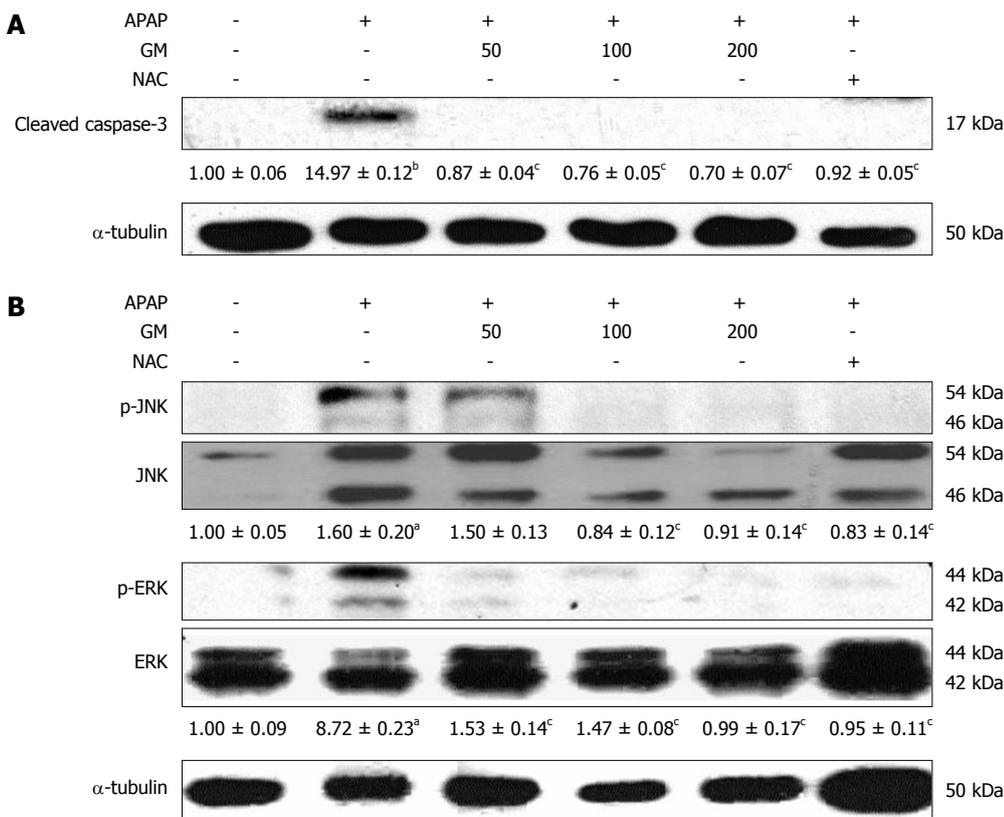

its hepatoprotective effects. Thus, a single dose of methanol extract of GM could render a complete protection.

Cytochrome P-450 enzymes are the major catalysts involved in the metabolism of drugs. APAP is mainly metabolized by cytochrome P-450 to form an electrophilic metabolite, N-acetyl-p-benzoquinonimine, which is primarily inactivated by conjugation with GSH<sup>[26,27]</sup>. A large number of the metabolites produced by APAP are found to generate superoxide anion and other free radicals in the biological systems<sup>[28]</sup>. However, at a higher dose of APAP, intermediate metabolites accumulate and cause

**Table 1** Effects of GM on hepatic damage induced by APAP in mice

Treatment	Dose (mg/kg)	Histopathological scores						Average
		0	1	2	3	4	5	
Saline + Saline	-	10	0	0	0	0	0	0.0

APAP was given intraperitoneally with a single dose of 300 mg/kg. GM was given orally with a single dose of 200, 100 or 50 mg/kg. Livers were graded from 0 to 5 as described in Materials and Methods. Each value is the number of animals with grading changes. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 significantly different when compared with APAP alone group. GM: *Gentiana manshurica* Kitagawa; APAP: Acetaminophen.

**Figure 5** Western blotting analysis of caspase-3 and JNK/ERK MAPK. GM (200, 100 or 50 mg/kg), NAC (300 mg/kg) or saline was orally administered 2 h before APAP injection. Active form of caspase-3, phospho-JNK and phospho-ERK were detected by Western blot. The active form of caspase-3 levels corresponding to each immunoreactive band were digitized and expressed as a percentage of the α-tubulin levels. Densitometric scanning data of phospho-JNK and phospho-ERK levels were expressed as the ratio of JNK or ERK, respectively. The ratio of the normal group was set to 1.00. Data of three independent experiments are expressed as mean ± SD. <sup>a</sup>*P* < 0.01, <sup>b</sup>*P* < 0.001, significantly different when compared with the normal group. <sup>c</sup>*P* < 0.001 significantly different when compared with APAP alone group.

liver damage. Depletion of GSH beyond certain critical level can lead to oxidative stress and development of overt hepatotoxicity<sup>[29]</sup>.

The decreased hepatic antioxidant status is related to oxidative stress and elevation of lipid peroxidation that lead to the leakage of hepatic enzymes to serum in APAP alone treated animals. To determine whether GM could inhibit APAP-induced GSH depletion, we measured the hepatic GSH levels. Our results showed that co-treatment with GM and APAP inhibited APAP-induced GSH depletion (Figure 3). NAC reduced APAP hepatic toxicity

by increasing hepatic GSH levels. The increasing GSH levels had no significant differences between the group pretreated with GM (200 mg/kg) and NAC. The elevated hepatic reduced GSH level could partially explain the hepatoprotective mechanism of GM. Reduced GSH can function as a reductant in the metabolism of hydrogen peroxide and various organic peroxides. The GSH-px present in the cells can catalyze this reaction<sup>[30]</sup>. It is reported that depletion of GSH below a threshold value was associated with a significant conversion of xanthine dehydrogenase to reversible xanthine oxidase, a superoxide

radical generation reaction catalyzing enzyme. Therefore, the enhanced hepatic GSH-px and SOD activities in the GM plus APAP treated group further support its hepatoprotective effects (Figure 3). MDA and HNE are major end-products of oxidation of polyunsaturated fatty acids, and are frequently measured as indicators of lipid peroxidation and oxidative stress *in vivo*. Thereby, the elevated antioxidant status in the liver of GM plus APAP treated group is related to the decreased MDA level and 4-HNE level, could maintain the membrane integrity and prevented lipid peroxidation and was comparable to NAC (Figure 3). The histopathological analysis of liver section indicates a moderate centrilobular necrosis, fatty infiltration and lymphocytic infiltration in the GM plus APAP treated animals with respect to the APAP alone treated animals (Table 1 and Figure 4).

APAP was believed to induce apoptosis based on the observation that APAP treatment results in the activation of caspase-3. In this study, pretreatment with GM prior to APAP inhibited caspase-3 cleavage (Figure 5). Thus, the active form of caspase-3 was not observed in GM or NAC pretreated groups. Microscopic observation on TUNEL-stained sections demonstrated that GM significantly decreased the TUNEL-positive apoptotic hepatocytes. Furthermore, it was reported that p38 MAPK, JNK, and ERK were activated by APAP<sup>[31]</sup>. JNK2 plays a protective role against APAP-induced liver injury in mice, in part, by modulating hepatocellular regeneration and repair, which further suggests the use of JNK inhibitors as a potential treatment for APAP-induced liver injury<sup>[32]</sup>. In both cultured hepatocytes and *in vivo* livers, treatment with APAP induced a sustained activation of JNK as reflected in increased phospho-c-jun levels<sup>[33]</sup>. A number of studies have suggested that oxidative stress leads to JNK activation, either through redox alteration of the sequestration of JNK or through inhibition of JNK phosphatase<sup>[34,35]</sup>. Our data showed that phospho-JNK1/2 expression was greatly increased 12 h after APAP administration (Figure 5). Coinciding with the expression of phospho-JNK1/2, APAP also increased the level of phospho-ERK1/2. However, GM pretreatment can effectively inhibit phosphorylation of ERK1/2 (Figure 5). These data suggest that GM inhibits the JNK/ERK signaling pathway at a more proximal regulatory step, resulting in inhibition of its downstream effector mechanisms.

In conclusion, in this study, GM can significantly prevent the APAP-induced acute hepatotoxicity by enhancing the hepatic antioxidant activity, and inhibiting the caspase-3 cleavage and JNK/ERK MAPK activation. GM exerts some effects which resemble those of an antidote of acetaminophen such as NAC. However, further detailed studies are required to confirm its clinical application.

## COMMENTS

### Background

Acetaminophen (APAP) is a widely used analgesic and antipyretic drug that is safe at therapeutic doses, however, when taken at high doses, APAP can precipitate severe liver injury that can develop into a liver failure. Overdoses of APAP lead to the generation of high amounts of the toxic metabolite N-acetyl-

quinoneimine (NAPQI). NAPQI reacts with glutathione (GSH) spontaneously or catalyzed by glutathione-S-transferases to form a GSH-adduct. Thus, GSH depletion and formation of protein adducts are key mechanisms of APAP-induced cell death.

### Research frontiers

In recent years, plant-derived natural products have received considerable attention due to their diverse pharmacological properties. Further studies on hepatoprotective effect of these natural entities and its possible mechanism are important for understanding the mechanism of APAP-induced liver injury.

### Innovations and breakthroughs

The authors investigated the effects of *Gentiana manshurica* Kitagawa (GM) on APAP-induced liver injury in mice and whether GM prevents APAP-induced hepatocyte apoptosis *in vivo*. The present study concluded that GM can significantly prevent the APAP-induced acute hepatotoxicity by enhancing the hepatic antioxidant activity, and inhibiting the caspase-3 cleavage and JNK/ERK MAPK activation, and GM exerts some effects which resemble those of an antidote of acetaminophen such as NAC.

### Applications

The results provide significant evidence illustrating the key feature of recovery from APAP-induced acute liver injury.

### Peer review

This is an interesting paper that, although descriptive, points out to the potential hepatoprotective effect of a herbal compound (*Gentiana manshurica* Kitagawa: GM) on the acetaminophen-induced acute hepatotoxicity. Results are clear and manuscript is well written.

### Abstract

Herein we describe an early colonic carcinoma which developed in a colonic interposition 14 years after surgery for esophageal cancer, which was successfully treated by endoscopic submucosal dissection (ESD). An 80-year-old man underwent colonic interposition between the upper esophagus and stomach after surgery for an early esophageal squamous cell carcinoma in 1994. He received a surveillance endoscopy, and a laterally-spreading tumor of granular type, approximately 20 mm in size, was identified in the colonic interposition. An endoscopic biopsy revealed moderately differentiated adenocarcinoma histologically, however, we diagnosed the lesion as an intramucosal carcinoma based on the endoscopic findings. The lesion was safely and completely removed *en bloc* by ESD using a bipolar knife. Histologically, the lesion was an intramucosal moderately differentiated adenocarcinoma in a tubular adenoma.

### INTRODUCTION

Although rarely reported, adenoma and adenocarcinoma can occur as a late complication in colon segments used to replace the esophagus. Herein, we describe an early colonic carcinoma which developed in a colonic interposition 14 years after surgery for esophageal cancer, which was successfully treated by endoscopic submucosal dissection (ESD).

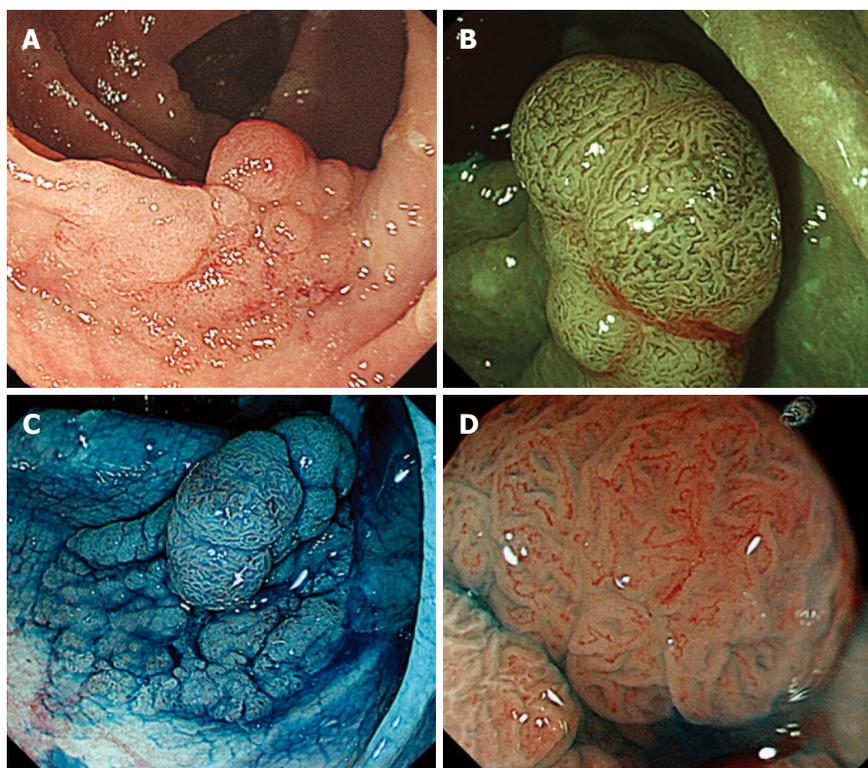

### CASE REPORT

An 80-year-old man underwent colonic interposition between the upper esophagus and stomach after surgery for an early esophageal squamous cell carcinoma (T1, N0, M0, stage I according to the TNM classification) in 1994. He received an esophagogastroduodenoscopy for surveillance and a laterally-spreading tumor of granular type (LST-G), approximately 20 mm in size, was identified in the colonic interposition. On conventional view, a

ESD: Endoscopic submucosal dissection; NI: No information.

**Figure 1** A laterally-spreading tumor of granular type (LST-G) in the colonic interposition was shown at colonoscopy. Narrow-band imaging with magnification revealed a capillary pattern type II. Magnifying chromoendoscopy using 0.4% indigo carmine revealed a type IV pit pattern. A: Conventional view; B: Narrow-band imaging with magnification; C: Chromoendoscopy with 0.4% indigo carmine; D: Magnifying chromoendoscopy using 0.4% indigo carmine dye spraying.

**Figure 2** Histologically, the resected specimen showed an intramucosal adenocarcinoma in a tubular adenoma. Cross sectional view (HE, magnification  $\times 5$ ).

large, reddish nodule was detected in the lesion. With magnifying narrow-band imaging (NBI) observation, the lesion revealed a capillary pattern type II according to Sano's classification<sup>[1]</sup>, and a type IV pit pattern according to Kudo's classification was detected under magnifying chromoendoscopy using 0.4% Indigo carmine dye

spraying<sup>[2]</sup>. An endoscopic biopsy was taken from the large nodule and a histological diagnosis of moderately differentiated adenocarcinoma was established, however, we diagnosed the lesion as an intramucosal carcinoma based on the above endoscopic findings (Figure 1). Thus, the lesion was considered a good candidate for endoscopic

resection. The lesion was safely and completely removed *en bloc* by ESD using a bipolar knife (B-knife® XEMEX Co. Ltd. Tokyo, Japan)<sup>[3,4]</sup>. Histologically, the lesion was an intramucosal moderately differentiated adenocarcinoma in a tubular adenoma. Lateral and vertical margins of the specimen were negative. There was no lymphatic and venous invasion (Figure 2). The patient was hospitalized for 6 d after ESD to confirm the absence of complications such as delayed perforation, and was then discharged.

## DISCUSSION

Despite the fact that many interposition grafts are performed for malignant esophageal disease, to the best of our knowledge, there have only been 10 reported cases, including four adenomatous polyps and six adenocarcinomas, arising in a colonic interposition (Table 1)<sup>[5-13]</sup>. Because the sizes of the adenomatous polyps in the reported cases were small, they were treated with polypectomy. Reoperation or chemoradiotherapy was performed in patients with cancers. Therefore, this is the first case of an early adenocarcinoma in a colonic interposition resected by ESD.

We performed ESD instead of endoscopic mucosal resection (EMR) in this case, as the lesion was not well-elevated even after submucosal injection of glycerol. This phenomenon is the so-called “non-lifting sign positive” as determined by Uno *et al.*<sup>[14]</sup>. As our endoscopic diagnosis of an intramucosal carcinoma was established with magnifying NBI and chromoendoscopy, submucosal benign fibrosis rather than desmoplastic reaction created by invasive cancer was considered to cause the non-lifting sign positive. EMR for the lesion with the non-lifting sign positive may result in incomplete resection or unfavorable complications such as colonic perforation. During ESD, hyaluronic acid was additionally injected into the submucosal layer and a transparent hood was attached to the tip of the scope for better submucosal dissection<sup>[15]</sup>. To reduce deep burn to the muscle layer, we used a bipolar knife instead of a monopolar knife. To reduce operating time, we used a bipolar snare to remove the lesion after adequate dissection. These efforts enabled us to completely and safely remove the lesion *en bloc* without complication. Furthermore, the patient's colonic interposition was reconstructed using the subcutaneous route, and thus the risk of mediastinitis even if perforation occurred was lower than that if reconstructed substantially.

Despite the fact that many interposition grafts are performed for malignant esophageal disease, few reports of adenocarcinoma arising in a colonic interposition have been reported. It is commonly thought that patients who have esophageal malignancy carry a dismal prognosis, and few of these patients will survive long enough to develop colonic adenocarcinoma. However, with recent progress in chemotherapy, many patients have long-term survival. Almost all case reports presenting with adenoma or adenocarcinoma arise five or more years after colonic interposition surgery, and there are only two case reports where adenoma or adenocarcinoma in the

colonic interposition has arisen 1 or 2 years after surgery (Table 1). In our case, adenocarcinoma in a tubular adenoma was detected 14 years postoperatively. Colonoscopic screening is usually performed before colonic interposition. However, Heresbach *et al.*<sup>[16]</sup> reported an overall miss rate of 23.4% in the colonoscopic detection of neoplasia including both adenomas and colorectal cancers. Therefore, we recommend upper endoscopic screening within 1 year of colonic interposition and periodic surveillance, as lesions may be detected early and removed safely by endoscopy.

### Abstract

Actinomycosis is an uncommon chronic infectious disease. Common sites of involvement include the cervicofacial, thoracic and abdominopelvic regions. In abdominopelvic actinomycosis, the ileocecal region, including the appendix, is the most commonly involved site. In some reports, limited appendiceal actinomycosis has revealed a thickened appendiceal wall with peri-appendiceal inflammation as acute appendicitis or perforated appendicitis. We experienced pathologically confirmed intraluminal limited appendiceal actinomycosis without peri-appendiceal infiltration. Here, we report the computed tomography and ultrasound findings.

### INTRODUCTION

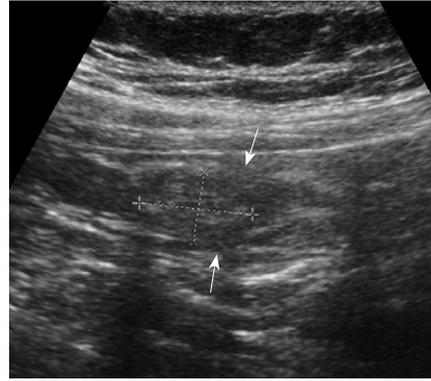

Actinomycosis is a chronic progressive suppurative disease caused by *Actinomyces israelii*, and is characterized by the formation of multiple abscesses, draining sinus, abundant granulation, and dense fibrous tissue<sup>[1]</sup>. Several reports have described the radiological findings of abdominopelvic actinomycosis. The infiltrative mass with unusual aggressiveness is the one of important radiological findings<sup>[1-3]</sup>. Also, some reports of appendiceal actinomycosis have described wall thickening and peri-appendiceal inflammation, with contrast enhancement<sup>[4,5]</sup>. We experienced pathologically confirmed appendiceal actinomycosis that presented as a small intraluminal mass without peri-appendiceal infiltration. Here, we report the computed tomography (CT) and ultrasound (US) findings.

### CASE REPORT

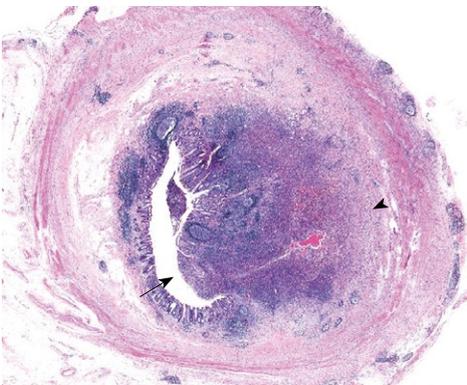

A 50-year-old woman was found incidentally to have a small appendiceal mass during routine screening. Past clinical history, physical examination, and laboratory examination were all unremarkable. Contrast-enhanced abdominal CT showed a well-defined small mass at the origin of the appendix. The length of the mass on CT

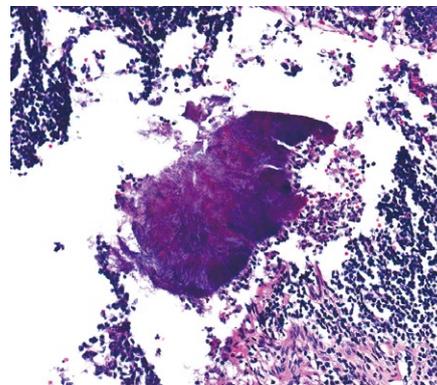

**Figure 1** Contrast-enhanced CT revealed a well-defined solid mass with strong enhancement in the base of the appendix (arrow). Peri-appendiceal infiltration was not seen.

**Figure 2** US showed a heterogeneous, hyperechoic, intraluminal mass at the base of the appendix, without peri-appendiceal infiltration. We also noted focal defects at the echogenic inner mucosal layer (arrows).

**Figure 3** Microscopy of appendiceal actinomycosis. An abscess composed of chronic and acute inflammatory cells was observed in a mass-like lesion (arrow), from the mucosal surface to the superficial submucosa (arrowhead) (HE,  $\times 10$ ).

**Figure 4** Higher magnification showed a typical sulfur granule surrounded by neutrophils in the clefted abscess center (HE,  $\times 200$ ).

images was 2 cm. This mass showed dense enhancement of 100 HU at the arterial phase and 125 HU at the portal phase. Infiltration around the meso-appendix and peri-appendiceal area was not demonstrated by CT, nor was regional lymph node enlargement detected (Figure 1). Positron emission tomography (PET) with [F18]-2-fluoro-2-deoxy-D-glucose (FDG) showed a high metabolic rate, with a maximum standardized uptake value (SUV) of 3.64.

US images obtained with a 9.4-MHz linear probe showed a well-defined intraluminal mass with heterogeneous echogenicity in the base of the appendix. The diameter of the mass was 1.6 cm. Peri-appendiceal infiltration was not demonstrated by US. US revealed focal defects at the echogenic inner mucosal layer. However, relatively well preserved mural echogenicity was noted (Figure 2).

From these findings, appendiceal neoplasms of mucosal origin, such as mucinous adenocarcinoma and carcinoid, were diagnosed, and a laparoscopic partial cecectomy was performed. Surgical findings revealed an intraluminally growing small mass with no sign of macroscopic serosal invasion. Also, there was no sign of infiltration or invasion of the meso-appendix and other surrounding organs.

Gross pathology revealed an ill-defined, yellowish

white, protruding mass lesion, which originated from the basal portion of the appendix. Adjacent appendiceal and cecal wall showed edema, and the serosal surface was relatively clear. Upon microscopy, the appendix showed a localized, mass-like abscess formation of the appendiceal wall (Figure 3). With higher magnification, a typical sulfur granule surrounded by neutrophils was found (Figure 4), which was confirmed as appendiceal actinomycosis. At the submucosa, the outer portion of the abscess showed evidence of organization, with vascularized granulation tissue and fibrosis in addition to chronic inflammatory cell infiltration.

## DISCUSSION

Actinomycosis has a worldwide distribution and is found with equal frequency in urban and rural dwellers. In humans, *Actinomyces israelii* is the most common cause of the disease. These organisms are indigenous in the oral cavity, gastrointestinal tract, and genital tract, with opportunistic infection occurring when the mucosal barrier is broken, which leads to multiple abscess formation, fistula, or mass lesions<sup>[6,7]</sup>. Actinomycosis commonly occurs in three distinct forms that may occasionally overlap; most clinical disease is cervicofacial (55%), with only 20% occurring in the abdominopelvic

form and 15% in the thoracic form<sup>[8]</sup>. Although the clinical features depend on which organs are involved, common symptoms and signs include fever and leukocytosis<sup>[3,6]</sup>.

Abdominopelvic actinomycosis is associated with abdominal surgery (such as appendectomy), bowel perforation, or trauma<sup>[9]</sup>. In addition, the presence of a long-standing intrauterine device (IUD) is a reported risk factor in young women<sup>[10]</sup>. Although the pathogenesis of abdominopelvic actinomycosis is not well understood, the appendix is the most commonly involved intra-abdominal organ, the colon, stomach, liver, gallbladder, pancreas, small intestine, pelvis, and abdominal wall may also be involved<sup>[6]</sup>. However, development of abdominopelvic actinomycosis after acute appendicitis has decreased because of early diagnosis, a lower incidence of perforated appendicitis, and improved antibiotic therapy<sup>[8]</sup>.

As a result of its resemblance to other diseases such as appendicitis, diverticulitis, colon carcinoma, Crohn's disease, ulcerative colitis, and tubo-ovarian abscess, the diagnosis of abdominopelvic actinomycosis is difficult<sup>[11]</sup>. A definite diagnosis is generally based on histological identification of actinomycotic granules or culture of the *Actinomyces* species, or both. High-dose intravenous penicillin injection is the treatment of choice and has a favorable response<sup>[11]</sup>. Therefore, early diagnosis is important to minimize morbidity of the disease and prevent unnecessary surgery.

Direct spread into adjacent tissue is the most common primary route of propagation after penetration of the organism through the mucosal barrier. Therefore, infiltration has been well described as an important radiological characteristic<sup>[1,3]</sup>. CT is an important imaging modality for suggesting the diagnosis and determining the anatomical location and extent of the disease, as well as monitoring the effectiveness of treatment<sup>[2,3,6]</sup>. Important CT features are an infiltrative mass (predominantly cystic or solid) adjacent to the other involved organs or anatomical structures, and the main CT feature when the gastrointestinal tract is involved is bowel wall thickening<sup>[1-3]</sup>. After infusion of contrast material, dense contrast enhancement in the mass or involved bowel has been reported, which may be caused by abundant granulation and dense fibrous tissue<sup>[1,3,10]</sup>. Although these findings are nonspecific, actinomycosis should be included in the differential diagnosis, especially in patients with abdominal pain, fever, leukocytosis, or

long-term IUD use<sup>[6,9]</sup>. CT features of abdominopelvic actinomycosis closely resemble complicated gastrointestinal malignancy or other chronic inflammatory disease (such as intestinal tuberculosis or Crohn's disease). However, because of the size of the bacterium, it usually does not spread via the lymphatic system; therefore, regional lymphadenopathy is uncommon or develops late<sup>[8,9]</sup>.

In our case, appendiceal actinomycosis showed dense contrast enhancement, especially at the portal phase, and vascularized granulation tissue with fibrosis in the submucosa. There was no sign of regional lymphadenopathy. However, appendiceal actinomycosis presented as an intraluminal limited mass without peri-appendiceal infiltration, which is an unusual finding. A review of the literature about abdominopelvic actinomycosis did not reveal any similar cases.

### Abstract

Cerebral lipiodol embolism (CLE) is an extremely rare complication of transcatheter arterial chemoembolization for hepatocellular carcinoma (HCC). The authors present a case of CLE that occurred after the second hepatic arterial chemoembolization for HCC, and attempt to introduce several plausible mechanisms of CLE, after reporting the clinical and radiological findings and reviewing the medical literature.

### INTRODUCTION

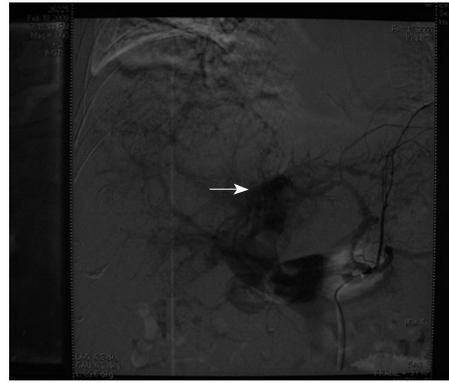

Transcatheter arterial chemoembolization (TACE) is utilized worldwide in the treatment of patients with unresectable hepatocellular carcinoma (HCC). The documented complications of TACE include post-embolization syndrome, septicemia, acute hepatic failure, liver infarction or abscess, intrahepatic biloma, embolization of extrahepatic organs, pseudoaneurysm formation, cholecystitis, tumor rupture, splenic infarction, gastritis, duodenitis, gastroduodenal ulceration, variceal bleeding, and iatrogenic dissection<sup>[1-5]</sup>. Cerebral lipiodol embolism (CLE) is a rare complication of TACE. The authors report a case of CLE that occurred after the second TACE, and present its clinical and imaging findings, as well as a review of the literature.

### CASE REPORT

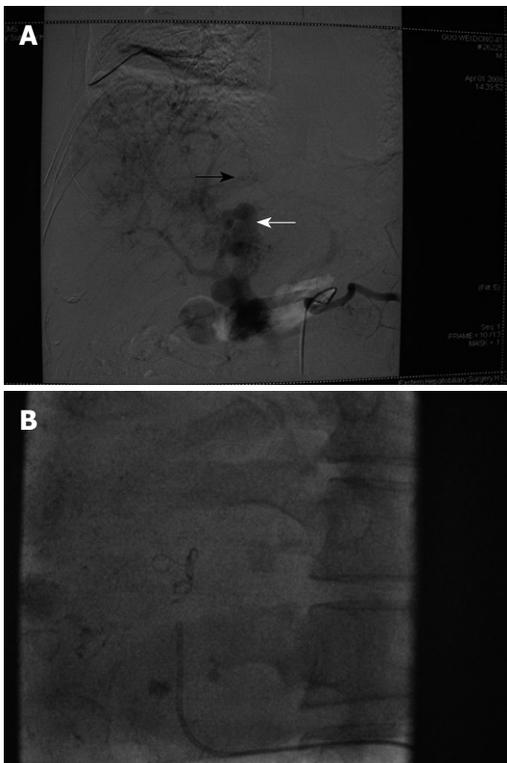

A 41-year-old man with multiple HCC accompanied by portal vein invasion (Figures 1 and 2) underwent a second course of TACE via the proper hepatic artery by using a mixture of 30 mL lipiodol, 10 mg hydroxyl camptothecin and 40 mg pirarubicin, as well as gelatin sponge particles (1400-2000  $\mu\text{m}$ ) and coils (5 mm  $\times$  8 mm) (Figure 3). The tumor marker test showed 136.9  $\mu\text{g/L}$  alpha fetoprotein (AFP), 0.7  $\mu\text{g/L}$  carcinoembryonic antigen (CEA), and of 28.2  $\mu\text{g/mL}$  carbohydrate antigen 19-9 (CA19-9). The liver function was ranked A in Child-Pugh classification. During the procedure, the patient experienced cough, visual loss, headache and motor weakness of the left upper limb and left lower limb. Upon physical examination, blood pressure was 158/93 mmHg, and pulse rate, respiratory rate and body temperature were normal. The muscle strength of the left upper limb was III+, while the left lower limb was IV+. No neurological pathological reflex was observed. The peripheral oxygen saturation was 94%, and with a nasal catheter, the arterial oxygen saturation was elevated and maintained higher than 97%. The patient was given neurotrophins, cerebrovascular dilators and supportive therapy immediately. Functional exercise was added in the following days.

**Figure 1** Computed tomography (CT) scan obtained before the first Transcatheter arterial chemoembolization (TACE) procedure. Portal vein was shown during the arterial period, which suggested that the tumor embolus invaded the portal vein (arrow).

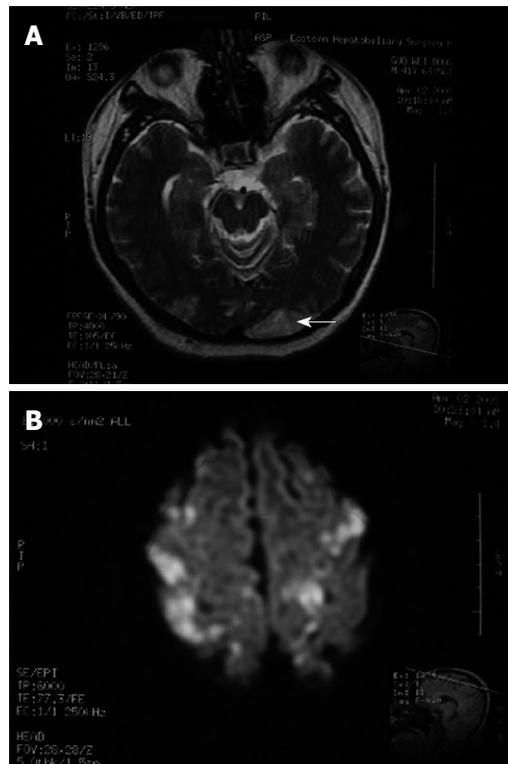

**Figure 2** First TACE procedure. Arterial-portal fistula (arrow).

**Figure 3** Second TACE procedure. A: Hepatic arteriovenous fistula (black arrow), arterial-portal fistula (white arrow); B: Coils (5-8 mm).

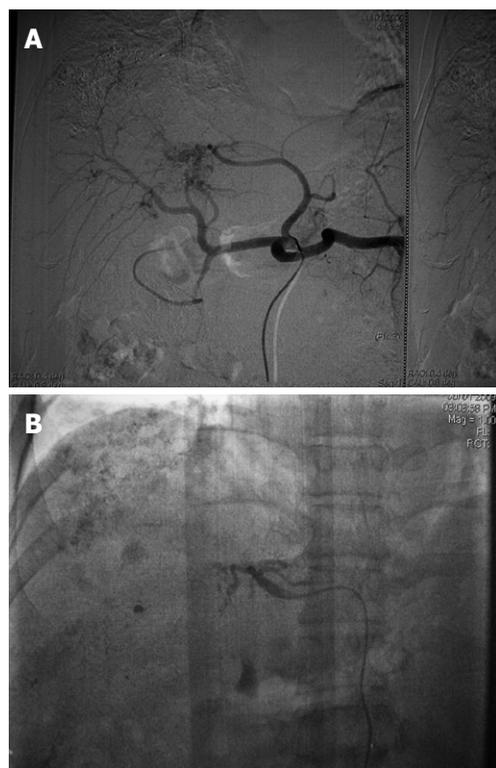

The laboratory data after TACE revealed a white blood cell count of  $13.51 \times 10^9/L$  (normal:  $4 \times 10^9$  to  $10 \times 10^9/L$ ), platelet count of  $83 \times 10^9/L$  (normal:  $100 \times 10^9$  to  $300 \times 10^9/L$ ), total bilirubin of  $28.6 \mu\text{mol/L}$ , direct bilirubin of  $11.0 \mu\text{mol/L}$ , alanine aminotransferase of  $187.4 \text{ U/L}$ , aspartate aminotransferase of  $429.7 \text{ U/L}$ , and normal renal function. Consultation with a neurologist suggested a diagnosis of cerebral embolism induced by the introduction of iodized oil. Magnetic resonance imaging (MRI) was performed 19 h after the TACE procedure, which revealed multiple abnormal signals that indicated ischemic foci of the centrum semiovale, and both parietal and occipital lobes (Figure 4). On the 10th day, with the

**Figure 4** Cranial magnetic resonance imaging (MRI) obtained after the second TACE procedure. A: cerebral lipiodol embolism (arrow); B: cerebral lipiodol embolism (multiple high signals).

appearance of melena, erythrocyte suspension and plasma were transfused along with hemostatic agents. Melena disappeared 2 d later. Vision and muscle strength of the affected extremities also improved gradually. Six weeks after CLE, the patient completely recovered without any neurological sequelae.

Two months after the second TACE procedure, the patient came back for follow-up. The tumor markers were tested: AFP  $11.0 \mu\text{g/L}$ , CEA  $0.8 \mu\text{g/L}$ , CA-19-9  $12.5 \text{ U/mL}$ , and digital subtraction angiography (DSA) revealed that an arterial-portal fistula was still present but improved, meanwhile, hepatic arteriovenous fistula was not seen. Therefore, we performed a third course of TACE. A mixture of 8 mL lipiodol, 10 mg hydroxyl

**Figure 5** Third TACE procedure. A: Hepatic arteriovenous fistula was not seen, and the arterial-portal fistula was still present but improved; B: Lipiodol and gelatin sponge were injected through the left gastric artery and the arterial-portal fistula was embolized.

camptothecin and 40 mg pirarubicin, as well as gelatin sponge particles (760-1000 μm) was injected through the right hepatic artery, left hepatic artery and left gastric artery (Figure 5). The patient did not have any respiratory or neurological complaints and was discharged 2 d later, and was confirmed to be in good condition until the present follow-up.

## DISCUSSION

CLE is an extremely rare complication of the invasive procedure TACE<sup>[1-3,5]</sup>. Only 11 papers have reported 16 cases of lipiodol-associated embolic brain damage following TACE. In China, the first case report of CLE was by Li *et al*<sup>[6]</sup> in 2001, while the first overseas was by Yoo *et al*<sup>[1]</sup> in 2004.

The symptoms of CLE are nonspecific, including visual loss, headache, motor weakness, and change of mental status. These symptoms vary in severity according to the site of iodized oil deposition. In addition, if the lipiodol enters the lungs as well, the patient complains of chest pain and dyspnea<sup>[7]</sup>. Actually, among the twelve prior cases presented, 10 were confirmed with pulmonary embolism after initial diagnosis of respiratory manifestations. Most CLE occurs during or immediately after TACE and is identified initially by one or more symptoms mentioned above, however, a delayed type of CLE also has been reported<sup>[8]</sup>. Although some of the patients who suffered from CLE after TACE die, despite

positive interventions, most of them recover completely without any neurological sequelae<sup>[5]</sup> (Table 1). In our case, the patient developed CLE during the TACE procedure, and after 6 wk of supportive therapy, he recovered, leaving no neurological symptoms.

The radiological findings of CLE on computed tomography (CT) and MRI in the previously reported

cases are similar. The site of lipiodol deposition includes the basal ganglia, thalamus, gray-white matter junction, and both parietal and frontal cortices. Cranial CT/MRI taken after the neurological symptoms disappeared is usually clear, which infers that the lipiodol in the brain could have been cleared entirely<sup>[5,8]</sup>. In our case, the sites of iodized oil deposition were mainly on the centrum semiovale, and both parietal and occipital lobes.

Ten papers covering 12 cases (the present case included) have described in detail the clinical and radiological data of CLE following TACE, and have been selected to make an analysis (Table 1) (in fact, 12 papers in total were searched, and because Zhao *et al*<sup>[9]</sup> and Li *et al*<sup>[10]</sup> provided no detailed information, their two cases were excluded). In six TACE procedures that were complicated by CLE, lipiodol was infused through extra-hepatic collateral arteries, and mostly the inferior phrenic arteries. In all 12 cases, only eight of them described the tumor sites, all of which involved the right liver lobes. This implies that invasion of the diaphragm is probably common in patients with CLE after TACE, although it was confirmed only in three cases<sup>[2,5,11]</sup>.

Six authors have analyzed the mechanisms of CLE following TACE treatment of HCC. Wu *et al*<sup>[3]</sup> have shown that the most probable cause of lipiodol-induced brain embolism after TACE is a combination of a right-to-left shunt and the dose-dependent effect of the drug<sup>[3,12]</sup>. The communication between the systemic and pulmonary vessels might develop via adhesive pleurae or tumor invasion of the diaphragm, thus a right-left shunt is formed. When injecting iodized oil via the inferior phrenic artery, some oil droplets might enter the brain, thus bypassing the right-left shunt. Combined with an increased dose of lipiodol during the second course of TACE, the patient has a greater risk of CLE<sup>[3]</sup>. Wu *et al*<sup>[11]</sup> have added that an intra-pulmonary arteriovenous shunt might appear during the pulmonary lipiodol embolism because of increasing pulmonary artery pressure or hypoxia<sup>[1,11]</sup>. Cui *et al*<sup>[13]</sup> have observed that the contrast medium injected into the hepatic artery enters the pulmonary veins directly during angiography in patients with CLE after TACE. This phenomenon supports the mechanism of intra-pulmonary arteriovenous shunting suggested by Wu *et al*<sup>[3]</sup>. Choi *et al*<sup>[7]</sup> have performed echocardiography and DSA to exclude intra-cardiac and intra-tumoral shunts, to support the mechanism that the communication between the inferior phrenic artery and pulmonary vessels occurs via adherent pleura, and tumor recurrence causes the lipiodol-induced brain embolism after TACE. Li *et al*<sup>[6]</sup> and Matsumoto *et al*<sup>[5]</sup> have made similar speculation.

Yoo *et al*<sup>[1]</sup> have presented three cases of CLE following TACE; all of which had evidence of pulmonary involvement but without a demonstrable intra-cardiac shunt. Yoo *et al*<sup>[1]</sup> have speculated that since it has been verified that fat globules < 7  $\mu\text{m}$  in diameter can pass directly through the pulmonary arteriolar network (i.e. trans-pulmonary shunt) and cause cerebral injury<sup>[14]</sup>, the presence of an intra-cardiac right-to-left shunt might not be necessary<sup>[1]</sup>.

In another case reported by Wu *et al*<sup>[8]</sup>, pulmonary and cerebral embolism occurred 34 and 69 h, respectively, after TACE treatment of HCC. Wu *et al*<sup>[8]</sup> have concluded that the rapid-flow, tumor-feeding artery washes out the iodized oil, which leads to embolic damage of the lungs. Then, the lipiodol that is deposited in the lungs is washed out again and enters the systemic circulation, thus causing embolism of the brain.

In the present case, the most probable mechanism of pulmonary and cerebral embolism is attributed to a hepatic venous-arterial shunt and an intra-pulmonary or intra-cardiac shunt. Lipiodol entered the pulmonary circulation through a hepatic arteriovenous fistula (Figure 3), which caused pulmonary embolism that increased pulmonary artery pressure, and produced a temporary pulmonary arteriovenous fistula. Lipiodol entered the brain through this temporary fistula. In addition, the use of a large dose of lipiodol also promotes CLE.

It is well known that CLE after TACE might be associated with intra-cardiac shunt, intra-pulmonary shunt and infusion of large doses of lipiodol<sup>[7]</sup>. Intra-cardiac right-to-left shunt can occur in some congenital heart diseases, such as patent foramen ovale. Research has revealed that among 1100 non-selected autopsies, 386 cases showed patent foramen ovale and 83% of them were < 0.2 cm in diameter<sup>[15]</sup>. The small foramen ovale, being often undetectable on routine echocardiography, might allow transient right-to-left shunting when the right heart pressure increases following oil trapping in the lungs<sup>[3]</sup>. Pulmonary arteriovenous shunts usually are associated with congenital pulmonary vascular malformations, acute or chronic pulmonary diseases, pulmonary tumors and advanced liver diseases<sup>[3,16]</sup>. The communication that can develop between the inferior phrenic artery and the pulmonary vessels also suggests a possible route for right-to-left shunting<sup>[4]</sup> (Table 1). Large dose of lipiodol infusion might increase the risk of extra-hepatic embolism. Some authors have suggested that a lipiodol dose less than 15 or 20 mL can prevent ectopic embolism<sup>[17,18]</sup>. However, in most prior cases of CLE, including the one described in this study, the HCCs were single large or multiple tumors (Table 1). As a result, limiting the dose of lipiodol to < 20 or 15 mL routinely might not be reasonable, especially when there is insufficient evidence to confirm that a large dose of lipiodol is a determinant factor for CLE following TACE. Three previous cases have revealed that CLE also occurs when the lipiodol dose is < 15 mL<sup>[1,3,5]</sup>. Therefore, all procedures must be individualized.

It is not necessary to search routinely for shunts prior to TACE, especially when right-to-left shunting is often undetectable in routine examination, as in chest or abdominal CT, DSA, and echocardiography<sup>[7]</sup>. In the present case, the patient was subjected to echocardiography and no positive evidence of right-to-left shunting was revealed. The patient had a history of bleeding gastroesophageal varices, therefore, transesophageal echocardiography was not performed. Direct evidence of a shunt has not yet been reported in previous studies (Table 1). Kim *et al*<sup>[19]</sup> have presented one case of CLE

following TACE during which the presence of a right-to-left shunt (was demonstrated by the presence of microbubbles in the left middle cerebral artery and left atrium, while trans-cranial Doppler and transesophageal echocardiography were performed during the intravenous injection of agitated saline.

The mechanism of CLE following TACE has not yet been elucidated. Intracardiac or intrapulmonary right-to-left shunts and infusion of large doses of lipiodol might contribute to the increased risk of CLE following TACE. An individualized plan of therapy, including lipiodol dose determination, shunting detection, as well as selecting vessels for the lipiodol infusion prior to TACE is of great importance to achieve an efficient overall result<sup>[11]</sup>.

## Meetings

### Events Calendar 2010

January 25-26  
 Tamilnadu, India  
 International Conference on Medical  
 Negligence and Litigation in Medical  
 Practice

January 25-29  
 Waikoloa, HI, United States  
 Selected Topics in Internal Medicine

January 26-27  
 Dubai, United Arab Emirates  
 2nd Middle East Gastroenterology  
 Conference

January 28-30  
 Hong Kong, China  
 The 1st International Congress on  
 Abdominal Obesity

February 11-13  
 Fort Lauderdale, FL, United States  
 21th Annual International Colorectal  
 Disease Symposium

February 26-28  
 Carolina, United States  
 First Symposium of GI Oncology at  
 The Caribbean

March 04-06  
 Bethesda, MD, United States  
 8th International Symposium on  
 Targeted Anticancer Therapies

March 05-07  
 Peshawar, Pakistan  
 26th Pakistan Society of  
 Gastroenterology & Endoscopy  
 Meeting

March 09-12  
 Brussels, Belgium  
 30th International Symposium on  
 Intensive Care and Emergency  
 Medicine

March 12-14  
 Bhubaneswar, India  
 18th Annual Meeting of Indian  
 National Association for Study of  
 the Liver

March 23-26  
 Cairo, Egypt  
 14th Pan Arab Conference on  
 Diabetes PACD14

March 25-28  
 Beijing, China  
 The 20th Conference of the Asian

Pacific Association for the Study of  
 the Liver

March 27-28  
 San Diego, California, United States  
 25th Annual New Treatments in  
 Chronic Liver Disease

April 07-09  
 Dubai, United Arab Emirates  
 The 6th Emirates Gastroenterology  
 and Hepatology Conference, EGH  
 2010

April 14-17  
 Landover, Maryland, United States  
 12th World Congress of Endoscopic  
 Surgery

April 14-18  
 Vienna, Austria  
 The International Liver Congress™  
 2010

April 28-May 01  
 Dubrovnik, Croatia

 Case-Based Approach to the  
 Management of Inflammatory Bowel  
 Disease

December 02-04  
 San Francisco, CA, United States  
 The Medical Management of HIV/  
 AIDS

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board

members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systemically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Article: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce Consensus and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

## Instructions to authors

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/1007-9327/Instructions-toAuthprs.asp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com), or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

## MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

### Title page

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. [montgomery.bissell@ucsf.edu](mailto:montgomery.bissell@ucsf.edu)

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

### Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g.  $6.92 \pm 3.86$  vs  $3.61 \pm 1.67$ ,  $P < 0.001$ ; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>; Writing requirements of abstract at: <http://www.wjgnet.com/1007-9327/links/Abstract.doc>.

### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the

main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### Books

#### Personal author(s)

- 10 **Sherlock S**, Dooley J. Diseases of the liver and biliary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

#### Chapter in a book (list all authors)

- 11 **Lam SK**. Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

#### Author(s) and editor(s)

- 12 **Breedlove GK**, Schorfheide AM. Adolescent pregnancy. 2nd ed. Wiczorek RR, editor. White Plains (NY): March of Dimes Education Services, 2001: 20-34

#### Conference proceedings

- 13 **Harnden P**, Joffe JK, Jones WG, editors. Germ cell tumours V. Proceedings of the 5th Germ cell tumours Conference; 2001 Sep 13-15; Leeds, UK. New York: Springer, 2002: 30-56

#### Conference paper

- 14 **Christensen S**, Oppacher F. An analysis of Koza's computational effort statistic for genetic programming. In: Foster JA, Lutton E, Miller J, Ryan C, Tettamanzi AG, editors. Genetic programming. EuroGP 2002: Proceedings of the 5th European Conference on Genetic Programming; 2002 Apr 3-5; Kinsdale, Ireland. Berlin: Springer, 2002: 182-191

### Electronic journal (list all authors)

- 15 Morse SS. Factors in the emergence of infectious diseases. *Emerg Infect Dis* serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

### Patent (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

### Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as  $\nu$  (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6  $24.5 \mu\text{g/L}$ ; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub>, not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

### Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

### Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr-A*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E coli*, etc.

## RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

### Editorial Office

#### World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)

<http://www.wjgnet.com>

Telephone: +86-10-5908-0039

Fax: +86-10-85381893

### Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

### Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/1007-9327/news/10.doc>.

### Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/1007-9327/news/12.doc>.

### Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

### Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

### Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

## Contents

Weekly Volume 16 Number 4 January 28, 2010

### EDITORIAL

- 403 Probiotics and gut health: A special focus on liver diseases  
*Gratz SW, Mykkanen H, El-Nezami HS*
- 411 Endoscope-guided pneumatic dilation for treatment of esophageal achalasia  
*Chuah SK, Wu KL, Hu TH, Tai WC, Changchien CS*

### REVIEW

- 418 Present and future possibilities for early diagnosis of hepatocellular carcinoma  
*Stefaniuk P, Cianciara J, Wiercinska-Drapalo A*
- 425 Colonoscopic perforation: Incidence, risk factors, management and outcome  
*Lohsirivat V*

### ORIGINAL ARTICLE

- 431 Hospitalized prevalence and 5-year mortality for IBD: Record linkage study  
*Button LA, Roberts SE, Goldacre MJ, Akbari A, Rodgers SE, Williams JG*
- 439 Clinical course of subepithelial lesions detected on upper gastrointestinal endoscopy  
*Lim YJ, Son HJ, Lee JS, Byun YH, Suh HJ, Rhee PL, Kim JJ, Rhee JC*
- 445 Two stomach-originated *Lactobacillus* strains improve *Helicobacter pylori* infected murine gastritis  
*Cui Y, Wang CL, Liu XW, Wang XH, Chen LL, Zhao X, Fu N, Lu FG*

### BRIEF ARTICLE

- 453 Diagnostic utility of IgG and IgM immunohistochemistry in autoimmune liver disease  
*Moreira RK, Revetta F, Koehler E, Washington MK*
- 458 Patient interest in video recording of colonoscopy: A survey  
*Raghavendra M, Rex DK*
- 462 Gender influence on defecographic abnormalities in patients with posterior pelvic floor disorders  
*Savoie-Collet C, Savoie G, Koning E, Leroi AM, Dacher JN*
- 467 Impact of endoscopy-based research on quality of life in healthy volunteers  
*Link A, Treiber G, Peters B, Wex T, Malfertheiner P*
- 474 Clinical relevance of *Helicobacter pylori* *babA2* and *babA2/B* in Costa Rica and Japan  
*Con SA, Takeuchi H, Nishioka M, Morimoto N, Sugiura T, Yasuda N, Con-Wong R*

- 479 Lymphoid tyrosine phosphatase R620W variant and inflammatory bowel disease in Tunisia  
*Sfar I, Ben Aleya W, Moulhi L, Aouadi H, Ben Rhomdhane T, Makhlouf M, Ayed-Jendoubi S, Gargaoui H, Najjar T, Ben Abdallah T, Ayed K, Gorgi Y*
- 484 Shape of Barrett's epithelium is associated with prevalence of erosive esophagitis  
*Akiyama T, Inamori M, Iida H, Endo H, Hosono K, Sakamoto Y, Fujita K, Yoneda M, Takahashi H, Koide T, Tokoro C, Goto A, Abe Y, Shimamura T, Kobayashi N, Kubota K, Saito S, Nakajima A*

**AIM AND SCOPE**

*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

### Abstract

Probiotic bacteria have well-established beneficial effects in the management of diarrhoeal diseases. Newer evidence suggests that probiotics have the potential to reduce the risk of developing inflammatory bowel diseases and intestinal bacterial overgrowth after gut surgery. In liver health, the main benefits of probiotics might occur through preventing the production and/or uptake of lipopolysaccharides in the gut, and therefore reducing levels of low-grade inflammation. Specific immune stimulation by probiotics through processes involving dendritic cells might also be beneficial to the host immunological status and help prevent pathogen translocation. Hepatic fat metabolism also seems to be influenced by the presence of commensal bacteria, and potentially by probiotics; although the mechanisms by which probiotic might act on the liver are still unclear. However, this might be of major importance in the future because low-grade inflammation, hepatic fat infiltration, and hepatitis might become more prevalent as a result of high fat intake and the increased prevalence of obesity.

### INTRODUCTION

Probiotics have been well defined and long used in human and animal health and nutrition. Many of the probiotic strains used today have been isolated from the human gut flora, and it is therefore more a reintroduction of organisms rather than a novel concept. The beneficial effects of probiotics and, especially, the clinical use of probiotics in the management of specific diarrhoeal diseases, including Rotavirus diarrhoea, Traveller's diarrhoea and others are well accepted<sup>[1]</sup>. These effects are mainly based on colonisation resistance or the influence of probiotics on microflora balance. When discussing probiotics, it must be remembered that the intestinal microflora, resident in the large intestine, will always outnumber the probiotics that can be administered. Furthermore, probiotic processes will always be confounded by the diversity of the human microbiota and its variability in the face of varied human diets and genetic backgrounds<sup>[2]</sup>.

Within the human gut, we have to separate processes occurring in the distal small intestine from those happening in the colon. The small intestine harbours relatively low numbers of resident intestinal bacteria,

but at the same time contains the major part of the gut associated lymphoid tissue (GALT), which samples intestinal microbes<sup>[3]</sup>. Hence modulation of systemic immune and allergic phenomena might be primarily mediated by the GALT of the small bowel. Supplementing qualitatively and quantitatively optimised microbes to this part of the gut might stimulate Treg cell development and consequent immunomodulation<sup>[1]</sup>. Within the large intestine, bacterial intervention might cause modulation of the microbial fermentation activity and direct action on the colonic epithelium to alter (suppress) innate immunity. These processes might explain the impact of probiotics on inflammatory and functional bowel disorders.

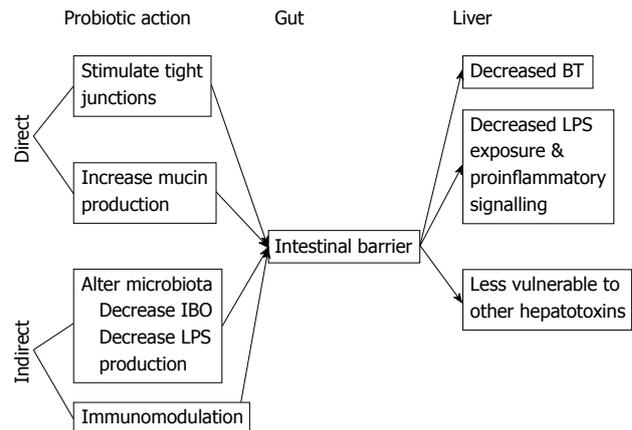

The research field of probiotics is very heavily reviewed, using different clinical and microbiological angles to elucidate the topic. The aim of this review is to summarise the most recent trends in probiotic research, focusing on the clinical use of probiotics and their effects on the healthy and diseased gut and liver.

The direct and indirect actions of probiotics on intestinal cells and their consequences on liver (summarised in Figure 1) will be discussed in this review.

## GUT HEALTH

### Probiotics and intestinal barrier function

The intestinal barrier is seen as the first line of defence against pathogens and food allergens entering the intestinal tract, and probiotics have been intensely studied for their involvement in maintaining this barrier. In colonic epithelia, probiotics are suggested to stimulate mucin production, and therefore enhance the self protecting properties of the intestinal epithelium<sup>[4]</sup>. Furthermore, tight junctional proteins, important for the physical tightness of the epithelial cell layer, are found to be enhanced by probiotics<sup>[5,6]</sup> and the disruption of tight junctions by pathogens can be counteracted<sup>[7]</sup>. Besides these effects on the physical barrier function, evidence is mounting that both commensal microflora and specific probiotic supplementations specifically enhance the immunological barrier function of the small intestinal mucosa<sup>[8]</sup>. For this cross talk between bacteria and the immune system, bacteria derived products including metabolites, cell wall components and DNA, can be sensed by enterocytes and immune competent cells<sup>[9]</sup>. Commensals, unlike pathogens, are efficiently killed by intestinal macrophages, therefore avoiding an inflammatory response in the mucosa<sup>[10]</sup>. At the same time, dendritic cells can sample commensals, incorporate them, and transport them to mesenteric lymph nodes. Here, commensal-loaded dendritic cells induce a local immune response with the activation of specific B-cells to produce secretory IgA against these commensals<sup>[8,10]</sup>. This appears to be a paradox, but this specific and local immune stimulation by commensals and probiotics can actually be considered non-inflammatory in the mucosal environment and the host systemics<sup>[8]</sup>. Therefore GALT,

**Figure 1 Potential mechanisms of action by which probiotics can promote GI health and the consequences for the liver.** Probiotics and surface-layer proteins competitively exclude microbial pathogens from mucosal surfaces. Tight junction proteins, such as zona occludins-1 and claudin1, remain intact and thereby prevent both uptake of intact macromolecules and translocation of viable organisms (BT) to mesenteric lymph nodes, and ultimately to the liver. Through a cascade of signalling events, probiotics enhance production and secretion of anti-inflammatory cytokines, including interleukin-10 and transforming growth factor- $\beta$ , by a subset of immune cells, referred to as T regulatory cells. Innate immune responses to probiotics include increased mucin and trefoil factor production by goblet cells and enhanced production of antibacterial defensins by Paneth cells and intestinal epithelia. Probiotics might alter the intestinal microbiota and hence limit intestinal bacteria overgrowth (IBO) and the production of lipopolysaccharides (LPS).

and specifically the mesenteric lymph nodes, can be considered another layer of intestinal barrier function<sup>[3,10]</sup>.

### Probiotics and inflammatory bowel diseases (IBD)

The pathogenesis of IBD [ulcerative colitis (UC) and Crohn's disease] remains unknown, but the intestinal microflora appears to play an important role. Changes in microflora composition have been observed in UC patients, with increased pro-inflammatory bacteria, including Enterobacteriaceae, increased *Bacteroides fragilis* within the mucosal microflora<sup>[11]</sup>, and decreased protective bacteria, including lactobacilli and bifidobacteria<sup>[12]</sup>. Probiotic treatment has the potential to decrease the severity of symptoms in IBD *via* interaction with gut epithelium<sup>[13]</sup>. Proposed mechanisms include changes in short chain fatty acids (SCFA) production patterns, reduction in pro-inflammatory cytokine secretion, improving Th1/Th2 ratios, and eliminating pathogens. For example, the production of reuterin has been shown *in vitro* to reduce growth of pathogens, including *Escherichia coli* (*E. coli*), *Salmonella enterica*, *Shigella sonnei*, and *Vibrio cholera*. Adhesion of probiotics to enterocytes and enhancement of barrier function (secretion of B-defensins and mucus, TJ proteins) have also been shown for specific strains *in vitro*. However, it is unclear whether this strengthening of the intestinal barrier function would also occur in the large intestine, the area most affected by intestinal disease. Some evidence from a mouse model of colitis [interleukin (IL)-10 deficient mice] suggests that probiotic lactobacilli and the VSL#3 mix reduced

bacterial translocation (BT) and intestinal permeability in the colon<sup>[14,15]</sup>. Mechanistic effects can also be observed with non-viable probiotics and culture supernatants *in vitro* and in animals, which might be a safer therapeutic for patients with impaired intestinal barrier and increased risk of sepsis. Bacteria-free culture supernatant from *Lactobacillus plantarum* was shown to inhibit inflammatory pathways important for intestinal inflammation, such as nuclear factor (NF)- $\kappa$ B binding activity and protease activity, in a young adult mouse colon cell line and in macrophages<sup>[16]</sup>. This might provide a novel and safe strategy for treatment of IBD, if results can be repeated *in vivo*.

### **Probiotics and irritable bowel syndrome (IBS)**

IBS includes a range of symptoms, such as abdominal pain, altered bowel habits, bloating and flatulence in the absence of structural abnormalities in the intestine. As no curative treatment is available for IBS, therapy is palliative and supportive, targeting special symptoms, and is notoriously unsatisfactory. Studies have observed alterations in intestinal microflora in patients and increased symptoms following enteric infections, therefore probiotics might be a useful tool to improve symptoms. A meta analysis of probiotic treatment and IBS<sup>[17]</sup> included 20 trials with 23 probiotic treatments. This study showed that probiotics were associated with improved global IBS symptoms [risk ratio (RR) = 0.77] and with decreased abdominal pain (RR = 0.78). Due to the large variety in probiotic strains used, no analysis on strain type was possible. Probiotics used included *B. infantis*, lactobacilli (*L. acidophilus*, *L. plantarum*, *L. reuteri*, *L. rhamosus*), *Saccharomyces boulardii*, *Streptococcus faecium*, VSL#3 (mix of eight), and other mixes. In a recent systematic review, Brenner *et al*<sup>[18]</sup> claimed that 16 randomized controlled human trials met their inclusion criteria, of which 11 had suboptimal study design. They concluded that only one study using a specific strain of *B. infantis* 35624 efficiently improved IBS symptoms. Probiotics might offer a treatment possibility for IBS symptoms, but more controlled studies are needed to identify the ideal strain, dose, and duration of treatment.

### **Probiotics after gut surgery**

Morbidly obese patients can undergo Roux-en Y gastric bypass surgery (one type of bariatric surgery) for effective and enduring weight loss. This procedure uses restriction in stomach size and intestinal malabsorption as measures for achieving substantial weight loss. Problems that occur postoperatively are alteration of microflora with bacterial overgrowth (BO) in the blind sac of the intestine, intestinal pain, and possibly impaired vitamin B<sub>12</sub> status (due to lack of intrinsic factor production from the stomach). This study<sup>[19]</sup> used probiotic treatment (6 mo, commercial product of unspecified lactobacilli) in 44 post operational patients. BO (measured with hydrogen breath test) improved only after 6 mo, but not earlier. Vitamin B<sub>12</sub> status improved, gastrointestinal

symptoms remained unchanged, but post operational weight loss was significantly increased in the probiotic group. The authors speculated that increased weight loss might be due to changes in microflora towards extracting fewer calories from the diet, although this was not studied.

Probiotics/symbiotics have also been used to prevent postoperative infections in patients undergoing abdominal surgery (biliary cancer, liver transplantation, and pancreaticoduodenectomy). Major infections were pneumonia, urinary tract infection, wound infection, intra-abdominal abscess, and cholangitis. A recent meta analysis<sup>[20]</sup> found that probiotics reduced overall infections [odds ratio (OR) = 0.26], length of antibiotic treatment need (OR = -4.01), reduced length of postoperative hospital stays (OR = -2.7), but did not change overall mortality (OR = 0.98). Overall the use of probiotics is very promising, although data are very variable (type of surgery, type of infection, and type of probiotic treatment). However, bacteremia might be a potential hazard in these vulnerable patients. The appropriate therapeutic route, length of therapy, time of administration, dosage, and kind of probiotic remain controversial and no uniform preventative strategy can be suggested on based of the current literature.

## **LIVER HEALTH**

There is a longstanding practice of using lactulose in the treatment of hepatic encephalopathy, which suggests involvement of gut microflora in the management of chronic liver disease. Loguercio *et al*<sup>[21]</sup> use the phrase "gut liver axis" and suggest that the microflora might affect the liver and be cofactor in aetiology of chronic liver damage. This could happen *via* modulating chronic damage by ethanol or by contributing to complications such as encephalopathy (production of ammonia, ethanol, acetaldehyde, phenols, endotoxin, and benzodiazepines)<sup>[21]</sup>. Probiotic actions most relevant to liver disease are modification of intestinal barrier function and prevention of BT. Gram-negative BO, increased permeability, and impaired immunity all contribute to increased BT, and there is a strong correlation between the rate of BT and the severity of cirrhosis. Probiotics might alter gut flora towards protective organisms and increase barrier function<sup>[22]</sup>.

### **Probiotics and non alcoholic fatty liver disease (NAFLD)**

NAFLD is the most common form of liver disease in the US; its incidence is rising together with rising problems of obesity and Type II diabetes. NAFLD includes a spectrum of pathologies. Steatosis (fatty liver), is clinically asymptomatic, but might predispose the liver to other insults, such as lipopolysaccharides (LPS) or hepatotoxins, that might lead to cirrhosis. Non-alcoholic steatohepatitis (NASH) is an intermediate state where lobular inflammation occurs. Cirrhosis is the most severe form, responsible for most liver specific morbidity and mortality<sup>[23]</sup>.

Histopathological changes are very similar to alcoholic liver disease, and there might be a common pathway of development. Data suggest a “multi hit” hypothesis, where initial hits such as obesity and sub-clinical insulin resistance might promote the development of steatosis<sup>[23]</sup>. This enhances the fatty liver’s vulnerability to subsequent insult (e.g. ethanol and LPS) that increase the production of pro-inflammatory cytokines [e.g. tumor necrosis factor (TNF)- $\alpha$ ]. This aggravates insulin resistance and leads to oxidative stress (increased production of reactive oxygen by hepatocytes and liver macrophages) and organelle dysfunctions, which kill hepatocytes and promote accumulation of inflammatory cells in the liver and the development of NASH<sup>[24]</sup>. Following years of chronic inflammation this might develop into fibrogenic response and cirrhosis.

The contribution of microflora in the development of NAFLD is mainly based on increased hepatic oxidative stress by increased production of ethanol and LPS in the intestinal lumen, and subsequent release of inflammatory cytokines in intestinal epithelia and liver macrophages. Both processes then lead to injury of the intestinal epithelium and disrupted intestinal barrier function, which in turn increases hepatic exposure to intestine-derived toxins. This hypothesis is further supported by evidence that intestinal BO exacerbates fatty liver disease in rodents and humans, and that obese patients with NASH have increased prevalence of BO. Furthermore, obese subjects are known to have decreased intestinal motility and are therefore more prone to BO. A recent clinical trial confirms that patients with NASH have increased intestinal permeability and small intestinal BO<sup>[25]</sup>.

From this data, an obvious way to control the development of NAFLD seems to be a manipulation of the gut microflora, mainly by the reduction of BO. This can be achieved by antibiotic treatment, which has been used successfully, but is controversial due to its unspecific impairment of all microflora and its severe side effects<sup>[23]</sup>. Probiotic therapy, on the other hand, has been suggested to counteract the development of NAFLD on various different levels. Competitive inhibition of pathogens by probiotics might alter their inflammatory effects in intestinal BO, which is associated with NAFLD. Furthermore, improved intestinal epithelium function and decreased BT and endotoxemia following probiotic treatment have been observed in experimental animals and humans<sup>[26]</sup>. In a series of feeding studies in mice, Cani *et al.*<sup>[27]</sup> claimed that high-fat feeding changes the intestinal microflora composition (less bifidobacteria), which led to increased LPS levels in plasma, pro-inflammatory cytokines and increased intestinal permeability. All these effects could be counteracted by prebiotic treatment and increasing bifidobacteria species (summarized in<sup>[27]</sup>). This would indicate a direct effect of intestinal bacteria on low-grade inflammation, insulin insensitivity, and fat deposition in the liver.

Other research suggests a direct decrease in pro-inflammatory cytokines e.g. TNF- $\alpha$  *via* downregulation of

NF- $\kappa$ B activity by probiotic treatments<sup>[14,28-30]</sup>. In a study in ob/ob mice, probiotics (VSL#3) and TNF- $\alpha$  antibodies were used to treat NAFLD. Both treatments improved liver function, reduced hepatic fatty acid content, and both interfered with NF- $\kappa$ B signalling and reduced hepatic fatty acid  $\beta$ -oxidation close to levels in lean mice. The authors suggest that this effect might result from improved hepatic insulin resistance<sup>[28]</sup>. Another study, using the same probiotic in normal mice, measured hepatic natural killer T (NKT)-cell depletion in high-fat fed animals<sup>[31]</sup>. NKT are unconventional T cells that express both T cell and Killer cell receptors. They regulate hepatic inflammatory process by balancing production of pro- and anti-inflammatory cytokines. Alterations of NKT function might lead to overproduction of TNF- $\alpha$ , causing inflammation in insulin resistance. High-fat diet induced the depletion of NKT from the liver, leading to insulin resistance and steatosis. Probiotics significantly improved all these symptoms and the effect resulted from TNF- $\alpha$  signalling and led to improved insulin signalling<sup>[31]</sup>. There is some suggestive evidence that probiotics might have efficacy in NAFLD in humans, but more controlled trials are needed<sup>[30]</sup>.

#### **Probiotics and alcoholic liver disease**

In alcoholic liver disease, bowel liver interactions are well described, and relationships include increased gut permeability, endotoxemia, and TNF- $\alpha$  production<sup>[32]</sup>. In rats, *Lactobacillus* GG has been shown to reduce alcohol induced gut leakiness and steatohepatitis<sup>[33]</sup>. The same group also found that the mucosa associated microflora were altered in rats on a high alcohol feed, and this dysbiosis could be counteracted by *Lactobacillus* GG or oat supplementation<sup>[34]</sup>. Furthermore, alcoholics have altered microflora with decreased numbers of bifidobacteria and lactobacilli. A recent pilot study<sup>[32]</sup> compared control subjects with alcoholics in a clinic, either on standard treatment for alcoholic disease (Vitamin B<sub>1</sub> & B<sub>6</sub> supplements and diazepam,  $n = 34$ ) or on standard treatment + probiotics ( $0.9 \times 10^8$  CFU *B. bifidum* and  $0.9 \times 10^9$  CFU *L. plantarum*,  $n = 32$ ) for five consecutive days. No placebo was included in the control group. They found that lactobacilli, bifidobacteria, and enterococci were reduced in alcoholics and the numbers were restored in the probiotic treatment group. *E. coli* levels were not altered. Liver function parameters [alanine aminotransferase (ALT) and aspartate aminotransferase] were significantly improved by probiotics compared to standard treatment, but remained below levels found in healthy controls. Other liver enzymes (GGT and LDH) were not significantly altered. In the subgroup of alcoholics with well-defined hepatitis, standard treatment only altered total bilirubin, but probiotics improved all the liver parameters mentioned above. The authors concluded that bifidobacteria to play an important role in steatohepatitis of alcoholic and non alcoholic causes, including obesity<sup>[35]</sup>. In a double blind placebo

controlled (sucrose capsule) intervention Lata *et al*<sup>[36]</sup> studied the effect of probiotic *E. coli* Nissle in cirrhotic patients ( $n = 39$ , 34 with alcoholic cirrhosis). They found an improvement of intestinal colonization in faeces, and a restoration of “physiological microflora” in faeces (more patients with normal microflora containing lactobacilli and bifidobacteria, less patients with potentially pathogenic bacteria). They also showed trends towards a reduced endotoxin level in blood ( $P = 0.07$ ) and a reduced Child-Pugh score ( $P = 0.07$ ), which is a measure for severity of overall liver disease. Improved liver function by probiotics has already been published<sup>[5]</sup>, but the mechanism remains unclear. They assume that microflora reduce the toxic load of liver, e.g. reduced endotoxin, which stimulates pro-inflammatory cytokines (TNF- $\alpha$ , IL-1, 6)<sup>[22]</sup>.

### Probiotics to cure/alleviate cirrhosis?

In cirrhosis there are many conditions that alter microflora and the function of the intestinal epithelium, as recently reviewed in detail<sup>[37]</sup>. BT is caused by BO, increased permeability, and altered host defence. BT and microflora imbalance are strongly correlated with the severity of cirrhosis<sup>[38]</sup>. In a rat model of acute liver injury (using either D-galactosamine or endotoxin), probiotic lactobacilli and bifidobacteria attenuated liver injury (ALT and bilirubin), reduced BT, and normalized hepatic TNF- $\alpha$  and glutathione levels compared to liver injury controls<sup>[39,40]</sup>.

Lactobacilli might counteract BT by (1) promoting growth of anaerobes and Gram-positive bacteria while inhibiting gram-negative bacteria, or (2) increasing SCFA while decreasing pH, inducing growth factors and proliferation of microflora, and inhibiting adherence and invasion of pathogens. Patients with liver cirrhosis have imbalanced intestinal microflora with increased aerobes (enterobacter and enterococci) and anaerobes (clostridia), and decreased bifidobacteria counts in stool. In a probiotic intervention trial in cirrhotic patients<sup>[38]</sup> (mainly caused by hepatitis virus B and C; HBV and HCV) patients received two different probiotic capsules [bifidobacteria + *L. acidophilus* + *Enterococcus* or *Bacillus subtilis* (*B. subtilis*) + *Enterococcus faecium* (*E. faecium*)], two capsules per day for 14 d. In both probiotic groups, bifidobacteria counts increased with treatment, while faecal pH and ammonia levels in faeces and blood decreased. Additionally, *B. subtilis* + *E. faecium* decreased clostridia counts and endotoxin levels in the blood of cirrhotic patients.

Flora imbalance in cirrhotics might be caused by decreased gut motility, diminished excretion of secretory IgA, lysozyme, mucus, acids, increased pH, shortage of bile acids, and excessive alcohol intake. Elevated blood ammonia is a crucial factor in hepatic encephalopathy aetiology.

Loguercio *et al*<sup>[21]</sup> conducted a pilot study in patients suffering from hepatitis of various causes (HCV, alcoholism, and NASH). The patients received a probiotic

mix (*Lactobacillus acidophilus*, *L. bifidus*, *L. rhamnosus*, *L. plantarum*, *L. salivarius*, *L. bulgaricus*, *L. lactis*, *L. casei*, *L. breve* + fructo-oligosaccharides + vitamins). Interestingly, the authors reported no effect of probiotics in HCV patients. In NASH patients some liver function parameters (ALT and  $\gamma$ -glutamyltransferase) improved, TNF- $\alpha$  decreased and plasma malondialdehyde decreased in some patients with probiotic treatment. The strongest effect of probiotics was seen in patients with alcoholic liver cirrhosis, where all parameters of liver function improved, as did TNF- $\alpha$  and malondialdehyde.

From these studies in humans, it appears that the microflora is an important cofactor in the aetiology of chronic liver disease, and that probiotics might have a therapeutic role.

### Probiotics to bind toxins and carcinogens

Some experimental evidence suggests that probiotics could be used to bind and immobilise toxic compounds within the gut lumen. Through this process, the negative effects of dietary toxins could be reduced and gut and liver health improved. *In vitro*, *L. rhamnosus* GG is able to bind mycotoxins known to interfere with intestinal mucosal barrier. In Caco-2 cells, the negative effects of mycotoxins on cell differentiation and intestinal integrity can be attenuated with *L. rhamnosus* GG<sup>[41,42]</sup>. In rats, genotoxic effects of food carcinogens, such as heterocyclic amines, on the colonocytes and hepatocytes were counteracted by the use of different probiotics<sup>[43,44]</sup>. Probiotics have also been shown to attenuate hepatotoxic effects of aflatoxin, a well known liver carcinogen, in rats<sup>[45]</sup> and to reduce biomarkers of liver cancer risk in a human intervention trial<sup>[46]</sup>.

### Safety considerations of probiotics

Generally recognized as safe (GRAS) status is defined by the Food and Drug Administration for food adjuncts that might not meet the usual requirements for safety assessment but have been used extensively without demonstrable harm. Probiotics are claimed to be GRAS as they comprise organisms identical to those in human gut and vaginal flora, although strain dependence needs to be considered and GRAS should only be granted to one specific probiotic preparation used in one specific food product<sup>[47]</sup>. Previous probiotic studies stress the safety of probiotic preparations and their ability to reduce BT of pathogenic bacteria to host organs and tissues. Probiotic BT from the intestine is difficult to induce in healthy animals, and therefore hard to study. From animal studies, NOAEL (no observed adverse effect levels) can be determined and ADI (acceptable daily intake) extrapolated for humans. These calculations suggest that up to  $10^{14}$  cfu/d of lactobacilli and bifidobacteria, a dose way beyond the usual intake of  $10^9$ - $10^{11}$  cfu/d, are acceptable for human consumption. In healthy humans, probiotic BT occurs occasionally. but detrimental effects are rare. Salminen *et al*<sup>[48]</sup> assessed the frequency of lactobacillus bacteraemia in the Finnish population

following the increased consumption of probiotic products in the years 1995-2000 and found no trends towards increased lactobacillus bacteraemia over this period. A recent meta analysis summarised the safety of probiotics in pregnancy and concluded no effect of lactobacillus and bifidobacterium species on incidence of caesarean section, birth weight, or gestational age<sup>[49]</sup>. In immunocompromised individuals however, this might be different. Cannon *et al.*<sup>[50]</sup> summarised over 200 clinical cases of lactobacillus infections and found association with endocarditis and bacteraemia. *L. casei* and *rhamnosus* were most common, and the overall mortality rate was nearly 30%. They also reported that the main underlying conditions were cancer, diabetes, antibiotic therapy, organ transplantation, and abscesses. Salminen *et al.*<sup>[51]</sup> investigated the severity and outcome of lactobacillus bacteraemia in 89 patients, and report mortality of 26% 1 mo after illness onset, but only in patients with severe underlying comorbidities.

### Future of probiotic research

Most recent developments in probiotic and prebiotic research use a new systems biology approach to assess the complex relationship between the microflora, probiotic modulations, and the impact on host metabolism in multiple compartments. A major finding is the impact of microflora modulation on host energy metabolism, especially lipid metabolism in the liver where marked decreases in plasma lipoproteins and hepatic glutamine and glycogen levels are observed<sup>[52]</sup>. This group uses a germ free mouse model colonized with human baby flora, to study the effects of a probiotic intervention (*L. paracasei* or *L. rhamnosus*) on gut flora composition, SCFA in caecal content, plasma, urine, faecal and liver metabolomics, and bile acids in ileal flushes.

The integration of multicompartiment metabolic data using hierarchical principal component analysis showed that probiotic lactobacilli induce changes in hepatic influx and efflux of fatty acids, increased enterohepatic recycling of bile acids and dietary fats, lowered plasma LP, and stimulated glycolysis. Probiotic intervention also changed the proteolytic activity and bacterial metabolism of AA and SCFA in the gut<sup>[53]</sup>. In a mouse model of high-fat feeding and NAFLD, an association was shown between the metabolism of choline by microbiota and the host. The author suggested a contribution of microflora to the development of the NAFLD phenotype<sup>[54]</sup>. This complex analytical and statistical methodology allows investigation of the impact of microflora and probiotics on various body compartments simultaneously and might, in the future, lead to a better understanding of the influence of probiotics on the host. Similarly, the complex metabolic relationships between the microflora and the host have also been studied in human cohorts and this approach might be used to gain further understanding of the relation between changes in the microflora (dysbiosis) and disease<sup>[55]</sup>.

## CONCLUSION

It appears that specific clinical applications of probiotics are safe, effective, and can clearly be recommended. However, the importance of probiotic food items in the “maintenance of health” in healthy individuals as marketed by food industries remains questionable. To date, no generalisation can be made from health effects of one probiotic strain to another one and this remains a serious problem within the probiotic research field and its applications. Multi-dimensional research approaches, studying the microflora composition, its metabolic profile, and the impact on host metabolism appear a promising way forward to further describe and explore these complex relationships within the microflora-host “superorganism”.

### Abstract

Pneumatic dilation (PD) is considered to be the first line nonsurgical therapy for achalasia. The principle of the procedure is to weaken the lower esophageal sphincter by tearing its muscle fibers by generating radial force. The endoscope-guided procedure is done without fluoroscopic control. Clinicians usually use a low-compliance balloon such as Rigiflex dilator to perform endoscope-guided PD for the treatment of esophageal achalasia. It has the advantage of determining mucosal injury during the dilation process, so that a repeat endoscopy is not needed to assess the mucosal tearing. Previous studies have shown that endoscope-guided PD is an efficient and safe nonsurgical therapy with results that compare well with other treatment modalities. Although the results may be promising, long-term follow-up is required in the near future.

### INTRODUCTION

Achalasia occurs at all ages; the mean occurrence is in middle age and affects both sexes and all races equally. The diagnosis is made by examinations such as barium esophagography, and esophageal manometry and endoscopy, after it has been distinguished from secondary achalasia caused by malignancy<sup>[1-5]</sup>. The truth we are facing in dealing with esophageal achalasia is that there is so far no cure for the disease. There are currently three main treatment modalities: pneumatic dilation (PD), surgery and botulinum toxin (BT) injection therapy. All therapeutic approaches are to loosen the lower esophageal sphincter (LES), because LES dysfunction leads to obstruction of the esophagus<sup>[6-20]</sup>. The goals are to relieve symptoms, improve esophageal emptying and avoid megaesophagus<sup>[21]</sup>. Traditional smooth muscle relaxants in the form of nitrates and calcium channel antagonists play little role. Besides, there are many intolerable side effects such as headaches, hypotension, and eventual tachyphylaxis<sup>[22,23]</sup>.

No doubt, PD is considered to be the first line nonsurgical therapy for achalasia. The principle of the procedure is to weaken the LES by tearing its muscle fibers by generating radial force. For many decades, there have been many reports about long-term efficacy of

PD in the treatment of achalasia under the guidance of fluoroscopy<sup>[16-20]</sup>. However, some factors may hinder the practice of PD by some gastroenterologists. Some may have fear of the misplaced risk of perforation, and the overall decreased immediate morbidity from laparoscopic myotomy. It is the responsibility of gastroenterologists to continue the tradition of PD as a generally available technique, or otherwise, myotomy may become the routine available therapy for achalasia.

Another reason may be concern about exposure to the X-rays during the procedure under fluoroscopic guidance<sup>[24-26]</sup>. Some of the highest doses to both patients and medical workers only arise from some other interventional radiology procedures<sup>[12,26]</sup>. Potential high doses during interventional procedures have been reached despite the procedure being carried out on equipment that normally has effective local shielding, so that the dose outside the lead coat is relatively low during fluoroscopy<sup>[12,27]</sup>. However, fluoroscopic-guided PD requires positioning of the balloon, which may need longer time, thus increasing the radiation exposure. Besides, the entire endoscope-guided PD procedure is done under direct visual control. It is easy to determine the mucosal injury during the dilation. Unlike fluoroscopic-guided PD, a repeat endoscopy to assess the mucosal tearing is not needed. The issue of the endoscope-guided PD for the treatment of esophageal achalasia is reviewed and discussed in this paper.

## ENDOSCOPE-GUIDED PD

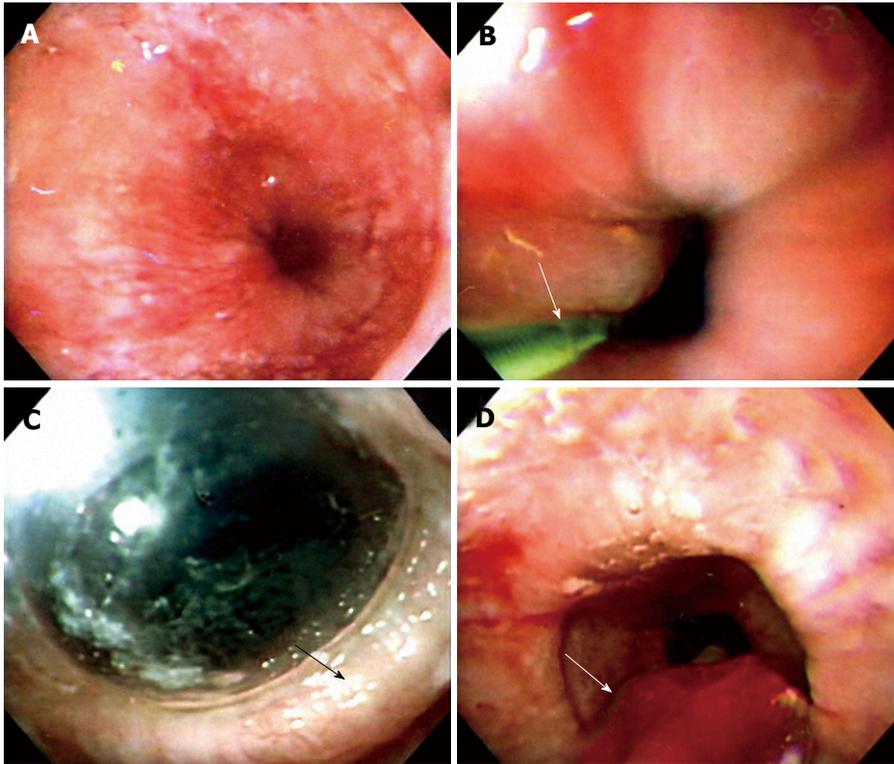

Levine *et al.*<sup>[25]</sup> first proposed a safe and convenient PD technique under endoscopic guidance without the use of fluoroscopy. Since then, this technique has been used by many physicians<sup>[11,12,23,28-35]</sup>. There are many types of pneumatic dilators commercially available. The high-compliance balloons are the Rider-Moeller device and the Brown-McHardy dilator (Narco Scientifics, Piling Division, Fort Washington, PA, USA), Witzel dilator (ABS, par d' Activite Saint Michel, France) while the low-compliance balloons such as Gruntzig-type dilator (Rigiflex dilator; Microvasive, Watertown, MA, USA). Clinicians usually prefer using the low-compliance balloon (Gruntzig-type, Rigiflex dilator), because it has various theoretical advantages over a high-compliance balloon<sup>[34]</sup>. Rigiflex dilator is designed so that it can be inflated to a desired maximum diameter. Further inflation can only result in the increase of the pressure but not the diameter<sup>[35]</sup>. Therefore, the wall tension is increased maximally at the stenotic zone. In contrast, an inflated high-compliance balloon may lead to an increase in the esophageal wall tension more proximal to the stenotic zone more than the stenotic zone itself, which may lead to perforation, by the Laplace law<sup>[36-38]</sup>. Such speculation is supported theoretically by the fact that the most common site of esophageal perforation is proximal to the cardia on the left lateral side of the esophagus in clinical practice<sup>[34,35]</sup>.

## TECHNIQUE OF ENDOSCOPE-GUIDED PD

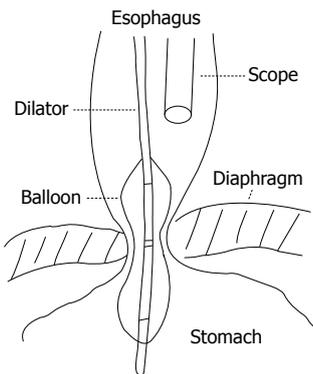

There is so far no clear consensus on the optimal method for performing PD with regard to balloon diameter, and the amount and rate of inflation pressure. It has been shown that the risk of perforation increases with the size of the balloon<sup>[39]</sup>. Mikaeli's<sup>[39]</sup> and Karamanolis' groups<sup>[14]</sup> have reported that graded pneumatic balloon dilatation with a 30-mm diameter and slower rate of balloon inflation is an effective and safe initial method of therapy for achalasia. According to our experience, we recommend that a 3.0-cm dilator with a smaller average inflation pressure of 10-12 psi is sufficient to attain satisfactory clinical remission, at least for oriental populations<sup>[14]</sup>.

Endoscope-guided PD is carried out by choosing a desirable diameter of balloon dilator, under conscious sedation, with informed consent after an overnight fast. Nowadays, the low-compliance Rigiflex dilator is preferred by most doctors. The endoscope is inserted down to the duodenum (Figure 1A). A guide-wire is placed into the duodenum under endoscopic guidance and then the endoscope is removed (Figure 1B). A Regiflex balloon dilator of a desirable diameter, which is marked with a thick colored marker at the mid-section of the balloon, is passed over the guide wire to the stomach. The endoscope is reinserted to serve as a guide to control the position of the balloon in the esophagus. The balloon is withdrawn to the esophagus, until the mark reaches the gastroesophageal junction. The balloon is inflated up to 12 psi and maintained for 60 s, until an ischemic ring at the LES can be seen by the endoscope through the transparent balloon (Figure 1C). The same inflation procedure is repeated once more and held for another 30 s. The balloon is flattened completely and removed together with the endoscope (Figure 1D). Gastrografin ingestion is performed immediately after the dilation to determine possible esophageal perforation. Chest pains and vital signs are monitored closely. Chest X-rays or computer tomography are carried out should severity of the chest pains imply any possibility of rupture.

Studies on the techniques of Rigiflex balloon dilatation of achalasia by positioning the endoscope above the balloon without fluoroscopy have shown results comparable with studies when using fluoroscopy (Figure 2). The advantages are performing this procedure without any extra equipment in a time and cost-effective manner. However, Rai's group<sup>[28]</sup> has introduced a novel technique by the presence of the endoscope across the gastroesophageal junction during the dilation procedure, with good efficacy reported after dilation. However, despite the safety report from Rai's group, the potential danger of increased perforation is a concern of many other clinicians. Some have argued that such a technique is likely to interfere with the application of uniform radial force on the spastic sphincter. The effect of dilation toward the side of the endoscope can be compromising, and lead to a decrease in overall efficacy of the procedure and the possibility of generating an unequal radial force on the sphincter<sup>[40,41]</sup>.

**Figure 1** Technique of endoscope-guided pneumatic dilation (PD). A: A dilated low esophageal lumen with tight gastroesophageal junction under endoscope-guided PD; B: The endoscope is inserted down to the duodenum. A guide-wire (arrow) is placed into the duodenum under endoscopic guidance and the endoscope is removed. A Regiflex balloon dilator, which is marked with a thick colored marker at the mid-section of the balloon, is passed over the guide wire to the stomach; C: The endoscope is reinserted to serve as a guide to control the position of the balloon in the esophagus. The balloon is withdrawn to the esophagus, until the mark reaches the gastroesophageal junction. The balloon is then inflated up to 12 psi and maintained for 60 s, until an ischemic ring (arrow) at the LES is seen by the endoscope through the transparent balloon; D: The balloon is flattened completely and removed together with the endoscope (arrow).

**Figure 2** Almost all endoscope-guided PD are performed by using a low compliance Regiflex balloon dilator by positioning the endoscope above the balloon without fluoroscopy. The advantages are that the procedure can be performed without any extra equipment in a time and cost-effective manner.

## POST-DILATION INVESTIGATIONS

### Assessment by symptom scores vs esophagography

Usually, structured interviews are performed using validated symptom score methods<sup>[10,28,42]</sup> at the initial investigation, 6 wk later, and every year thereafter. Depending on whether dysphagia, regurgitation, and chest pain occur occasionally, daily, or several times during the day, a symptom score can be determined. In the system validated by Eckardt<sup>[42]</sup>, a symptom score of 0-3 was assigned to the degree of weight loss. Thus a completely asymptomatic patient would have a symptom score of 0, whereas a severely affected patient could have a high symptom score. In most of these symptom scoring systems, patients were considered to have reached clinical remission if symptoms had totally disappeared or if they had improved by attaining a certain drop in score. Patients who requested further therapy despite having a certain drop in score were considered treatment failures.

A discrepancy between objective parameters and the subjective symptomatic improvement after PD exists in clinical practice. Radiographic findings do not reliably correlate the symptoms to improved esophageal emptying after PD in some large studies<sup>[43-45]</sup>. However, Vaezi *et al*<sup>[46-49]</sup> have reported that there was a significant association between improvement in patient symptoms and barium height. They believe that radiographic findings can reliably predict clinical remission and have suggested strongly the need for further treatment in those patients with poor esophageal clearance after each dilation, to avoid possible future complications such as sigmoid-type achalasia.

Large-scale, long-term follow-up investigations<sup>[15,50,51]</sup> have reported unfavorable recurrence in patients who have undergone fluoroscopic-guided PD. During the prolonged observation period (median, 13.8 years) in a prospective follow-up investigation study conducted by Eckardt *et al*<sup>[15]</sup>, only 40% of patients treated with a single round of PD remained in remission at 5 years. We used endoscope-guided PD to treat achalasia and attained cumulative remissions of 86.7% in first 2 years, which had dropped to 72.9% after 5 years, but it remained at 61.7% in years 6 and 7, but patients were assessed by clinical symptom scores<sup>[11]</sup>. Bias probably existed when using subjective symptomatic scoring assessment to determine clinical remission. We agree with Vaezi's group who claimed that underscores may occur by only using an objective assessment. However, we believe that esophagography can only offer an additional objective assessment to the response to achalasia treatment, especially in patients who report symptomatic improvement, but the evidence is not strong enough to overthrow the

**Table 1** Cumulative effectiveness of endoscope-guided pneumatic dilators for the treatment of achalasia by using low compliance Regiflex dilators

Author (yr)	n	Study design	Dilator size (cm)	Improvement (%) (excellent/good)	Follow-up (yr) mean (range)	Perforation (%)
Levine <i>et al</i> <sup>[25]</sup> (1987)	62	Retrospective	3.0-3.5	85/88	-	0
Lambroza <i>et al</i> <sup>[24]</sup> (1995)	27	Retrospective	3.0	67	1.8 (0.1-4.8)	0
Dobrucali <i>et al</i> <sup>[28]</sup> (2004)	43	Prospective	3.0-3.5	54/79	2.4 (0.5-5)	0
Rai <i>et al</i> <sup>[29]</sup> (2005)	56	Prospective	3.5	92.9/89.3	2	0
Chuah <i>et al</i> <sup>[11]</sup> (2009)	32	Prospective	3.0	69/91	4.5 (2.5-7)	3.3

traditional assessment of clinical remission by using subjective symptom score assessment<sup>[52]</sup>. Although an additional objective parameter such as esophagography to the subjective symptom scores should be more optimal in assessing clinical remission, further investigations that include larger sample sizes and longer follow-up periods are required for clarification of this issue.

**Manometric studies**

Manometry is an important predictor of treatment failure with balloon dilation, other than younger age (< 40 years), male sex, pulmonary symptoms, and failed response to one or two initial dilations<sup>[15,41,53,54]</sup>. It has been demonstrated previously that post-dilated LES pressure is relevant to better remission. In general, decreases in LES pressure of > 50% after PD, or an absolute end-expiratory LES pressure of < 10 mmHg, are more indicative of clinical success<sup>[15,52,53]</sup>. Therefore, it is suggested strongly that manometry be performed routinely before and after PD. One recent advance in the diagnosis of esophageal achalasia is the use of updated high resolution manometry (HRM) with pressure topography plotting<sup>[55]</sup>. We are optimistic that more promising evidence may emerge on the use of HRM in the near future.

relative safety of endoscope-guided PD compared to fluoroscope-guided PD. However, esophageal perforation is a potential hazard after PD<sup>[60,61]</sup>. Usually, gastrograffin is ingested immediately after each PD to detect extravasation, which implies the presence of perforation. However, on rare occasions, immediate gastrograffin ingestion may not always detect perforation, which can become clinically evident several hours later after delayed presentation (> 24 h)<sup>[62,63]</sup>. Therefore, we must observe the clinical symptoms and signs closely, such as severe chest pain and fever, which imply the potential presence of perforation after PD.

Reflux symptoms after PD are usually mild and transient and should be easily controlled with proton-pump inhibitors<sup>[19]</sup>. However, objective assessment of gastroesophageal reflux after PD has rarely been studied. Other complications are usually minor, and include intramural hematoma, diverticula at the gastric cardia, mucosal tears, prolonged post-procedure chest pain, hematemesis without change in hematocrit, fever and angina.

**EFFECTIVENESS AND POST-DILATION SAFETY OF ENDOSCOPE-GUIDED PNEUMATIC DILATORS FOR ACHALASIA**

Table 1 summarizes studies on the effectiveness of graded endoscope-guided pneumatic dilators for achalasia. Most studies were retrospective except for three prospective, longitudinal cohort studies with a mean follow-up period of 2-4.5 years<sup>[11,24,25,28,29]</sup>. All studies attained an acceptable clinical remission rate of 54%-91%, which was comparable to those reported by using fluoroscopy-guided PD<sup>[52,50,56-59]</sup>. Although the existing mid-term follow-up results are encouraging, further long-term follow-up is required in the near future.

The major adverse event caused by PD is esophageal perforation, with a 2% overall cumulative rate, and may occur in up to as many as 5% of all the reported cases of fluoroscope-guided PD<sup>[32,49,56-59]</sup>. As shown in Table 1, the reported perforation rates was 0%-3.3% for endoscope-guided PD<sup>[11,24,25,28,29]</sup>. This implies the

**LAPAROSCOPIC MYOTOMY VS ENDOSCOPE-GUIDED PD**

Like every other treatment of achalasia, the goal of surgery is to assuage the esophageal obstruction by myotomy of the LES. Minimally invasive laparoscopic myotomy with a variety of fundoplication procedures has evolved to be a primary approach for many surgeons and gastroenterologists in a majority of patients with achalasia<sup>[64-67]</sup>. However, there are only limited systematic reviews and meta-analyses that have compared existing treatment methods for achalasia and all favor surgery to PD<sup>[64,68,69]</sup>. With overall success rates of 47%-82% at 10 years, laparoscopic Heller myotomy with partial fundoplication appears to have evolved into the surgical procedure of choice<sup>[64,65]</sup>. Despite this, the major concern for myotomy is still that it can be complicated by severe acid reflux disease, and the role of fundoplication with myotomy continues to be controversial<sup>[21,69-72]</sup>. Hence, it is generally accepted that myotomy is usually suggested for younger male patients (< 40 years), those with pulmonary symptoms, and those who have failed to respond to one or two initial dilations; older age appears to be associated with favorable outcomes of PD<sup>[70,71]</sup>.

## BT INJECTION THERAPY VS ENDOSCOPE-GUIDED PD

As a result of its wider safety margin and fewer complications, BT injections have been practiced widely in past decades, with excellent immediate responses (success rates of > 90%). Unfortunately, the duration of response for BT injections is relatively discouraging (6-9 mo on average) in most patients, and only half of all patients benefit for > 1 year<sup>[6,10,73]</sup>. The effect of BT injections vanishes with time in elderly patients, which necessitates repeated injections to keep the patients symptom-free. As a result of the number of repeated injections required, this procedure is more expensive than PD by  $\geq 50\%$ . However, it has been reported that the long-term success is highest among elderly patients and in those with an LES pressure that did not exceed the upper normal level before treatment<sup>[6,10,74,75]</sup>. Also, younger patients (< 55 years) with a severe increase in LES pressure do not seem to benefit from BT injections, and PD or minimally invasive myotomy are more advantageous<sup>[10]</sup>. Generally, minimally invasive myotomy is recommended in younger patients.

In short, PD is more efficacious than BT injections for sustained symptomatic relief in patients with achalasia. BT is as good as PD in achieving a short-term improvement in achalasia. It is also effective in patients with tortuous megaesophagus and previous failed PD. However, as mentioned earlier, recurrence is high during 1-year follow-up<sup>[76]</sup>. Furthermore, some surgeons may be concerned that previous BT injections make subsequent minimally invasive myotomy riskier and more difficult<sup>[77]</sup>. Therefore, BT injections are recommended as a suitable alternative only for a minority of older or high-risk patients.

## CONCLUSION

Endoscope-guided PD is an efficient and safe nonsurgical therapy with results comparable to other treatment modalities. Besides, it has the advantage that the entire procedure is done without fluoroscopic control, and the mucosal injury during the dilation can be determined by direct visual observation. Long-term follow-up studies are required in the near future.

### Abstract

Hepatocellular carcinoma (HCC) represents the fifth most common cancer in the world, and the third most frequent oncological cause of death. The incidence of HCC is on the increase. HCC typically develops in patients with chronic liver diseases, and cirrhosis, usually with viral etiology, is the strongest predisposing factor. Nowadays HCC diagnosis is a multistage process including clinical, laboratory, imaging and pathological examinations. The prognosis of HCC is mostly poor, because of detection at an advanced, non-resectable stage. Potentially curative treatment (surgery) is limited and really possible only for cases with small HCC malignancies. For this reason, more effective surveillance strategies should be used to screen for early occurrence of HCC targeted to the population at risk. So far, the generally accepted serological marker is  $\alpha$ -fetoprotein (AFP). Its diagnostic accuracy is unsatisfactory and questionable because of low sensitivity, therefore there is a strong demand by clinicians for new HCC-specific biomarkers. In this review, we will focus on other biomarkers that seem to improve HCC diagnosis, such as AFP-L3, des- $\gamma$ -carboxyprothrombin,  $\alpha$ -L-fucosidase,

$\gamma$ -glutamyl transferase, glypican-3, squamous cell carcinoma antigen, a new generation of immunoglobulin M-immunocomplexes, and very promising gene-expression profiling.

### INTRODUCTION

Hepatocellular carcinoma (HCC) is a major challenge in contemporary medicine. The incidence of HCC is on the increase and it is becoming more and more significant both clinically and epidemiologically. Now HCC represents the fifth most common cancer in the world and the third most frequent cause of mortality amongst oncological patients<sup>[1]</sup>. It is responsible for more than 500 000 deaths with over 600 000 new cases yearly worldwide<sup>[2]</sup>. Incidence rates are different in various countries: highest in South-East Asia and Sub-Saharan Africa (around 120/100 000) and lowest in the USA (1.8/100 000) and Western Europe (3-5/100 000)<sup>[1,2]</sup>. Although Poland belongs to the group of countries with a relatively small incidence rate: lower than 6/100 000 in men and 3/100 000 in women, HCC causes the death of more than 2500 Poles every year and, according to statistically observed trends, the mortality rate will gradually increase<sup>[3]</sup>.

More than 95% of HCC patients present underlying hepatopathy - in particular of viral etiology (Table 1)<sup>[4]</sup>. The majority of the cases (> 85%) have liver cirrhosis, which masks symptoms of cancer progression. The clinical course of HCC is mostly asymptomatic. Suspected focal liver changes are often detected incidentally while monitoring the patient's condition during abdominal ultrasound (US) examination, and often are too large and too advanced for the tumor to be subjected to potentially effective and radical therapy.

In 1999 in "Hepatology", Llovet *et al*<sup>[5]</sup> published the results of an analysis of clinical data of 102 patients with unresectable HCC. They found that 80% of patients with asymptomatic unresectable HCC survived for 1 year, 65% for 2 years, and 50% for 3 years. Only 29% of patients with clinical symptoms who did not have radical therapy survived for 1 year, 16% for 2 years, and 8% for 3 years<sup>[5]</sup>. Despite great medical progress since the times of Llovet's report and huge developments in medicine, patients suffering from HCC presently cannot be offered much more. Because of serious limitations of the surgical and oncological treatment available, it seems necessary to concentrate on the earliest possible diagnosis, particularly sensitive detection of resectable focal liver changes - preferably when tumors are less than 2 cm in diameter<sup>[6]</sup>. For this reason, surveillance with US techniques and serum  $\alpha$ -fetoprotein (AFP) analyses is recommended for all cirrhotic patients and other specific risk groups (Table 2)<sup>[7]</sup> every 6 mo.

## RADIOLOGICAL TECHNIQUES FOR HCC DIAGNOSIS

US is the most popular method for HCC screening. Diagnostic success of US for HCC surveillance depends on many factors, but mostly on the size and character of the focal liver changes, as well as the experience of the sonographer and the technical quality of the US equipment. According to the literature<sup>[8,9]</sup> US sensitivity rises from 70% for lesions of about 1 cm in diameter, towards 90% when the tumor diameter is more than 5 cm. The specificity is variable between 48% and 94%<sup>[8,9]</sup>. HCC does not have a specific morphology on US, whereas smaller lesions, less than 3 cm in diameter, are homogenic and hypoechoic. As they increase and form focal necrosis and microbleeding, they become more and more heterogenic and hyperechoic. This feature together with arterial vascularity are typical of increased malignancy and poor prognosis. Doppler or contrast-enhanced US leading to a better visualization of the relation between organic neoplasms and vascular structures may be used for clear differentiation of those lesions. Because US examination is subjective and non-repetitive, all focal liver lesions suspected on US should be verified using: computer tomography (CT) and/or magnetic resonance imaging (MRI). The use of these methods leads to a much more accurate diagnosis of HCC: sensitivity up to 89% and specificity reaching 99%<sup>[9]</sup>. Unfortunately, the diagnosis seems not to be so precise when

Table 1 HCC risk development factors (%)<sup>[4]</sup>

	Europe	North America	Asia & Africa	Japan
HCV	60-70	50-60	20	70
HBV	10-15	20	70	10-20
ALC	20	20	10	10
Other	10	10	0	0

HCC: Hepatocellular carcinoma; HCV: Hepatitis C virus; HBV: Hepatitis B virus; ALC: Alcohol abuse.

Table 2 HCC specific risk groups (AASLD Practice Guideline 2005)<sup>[7]</sup>

Hepatitis B carriers	Non-hepatitis B carriers
Cirrhotic patients (incidence of HCC: 3%-5%/year)	Hepatitis C (incidence of HCC: 2%-8%/year)
Non-cirrhotic patients with high HBV DNA and hepatitis activity	Alcoholic cirrhosis
Positive family history of HCC	Genetic hemochromatosis
Asian males > 40 years (incidence of HCC: 0.4%-0.6%/year)	Primary biliary cirrhosis and autoimmune hepatitis
Asian females > 50 years (incidence of HCC: 0.2%/year)	$\alpha$ 1-antitrypsin deficiency
Africans > 20 years (incidence of HCC: > 0.2%/year)	Non-alcoholic steatohepatitis

lesions are less than 1 cm in diameter - merely 34%<sup>[10]</sup>.

Many epidemiological studies showed that only 50% of HCC lesions smaller than 1 cm in diameter are discovered during US examination. According to the Barcelona recommendations those lesions should be observed, or, more precisely, screened by US at a minimum of 6 mo intervals. When the tumor is growing and/or becomes larger than 1 cm in diameter on US, CT and/or MRI should be applied. It is recommended that focal liver changes > 1 cm but < 2 cm be subjected to histopathological verification. False negative results have been found in 40% of patients subjected to a targeted liver biopsy<sup>[11]</sup>, therefore exclusion of HCC in this way seems meaningless. If a tumor is > 2 cm in diameter with pathognomic arterial hypervascularity verified by other radiological methods, and there is a high level of total AFP serum concentration (> 400 ng/mL), then HCC can be diagnosed, according to the Barcelona criteria<sup>[12,13]</sup>.

At present more and more doubts have been raised about using AFP as a reliable HCC biomarker. For this reason, American hepatopathologists treat every tumor larger than 1 cm in diameter in cirrhotic liver as HCC, consequently ignoring AFP serology (very frequently false negative)<sup>[14]</sup>.

## HCC SPECIFIC BIOMARKERS

### AFP

AFP was discovered in 1956 by Bergstrand and Czar<sup>[15]</sup>, who used paper for electrophoretic separation of human fetoprotein in serum. The first reports on the usefulness of AFP as a diagnostic marker for HCC were presented

**Table 3** Diagnostic values of AFP as HCC biomarker<sup>[20,21]</sup>

Cut-off value (µg/L)	Sensitivity (%)	Specificity (%)	Ref.
20	55-60	88-90	[21,22]
50	47.0	96.0	[22]
100	31.2	98.8	[21]
200	22.4	99.4	[21]
400	17.1	99.4	[21]

AFP: α-fetoprotein.

in 1964 by Tatarinov and in 1968 by Abelev<sup>[16]</sup>. AFP is a glycoprotein with molecular weight of around 70 kDa, synthesized in the endodermal cells of the yolk sac during early fetal development, and then in embryonic hepatocytes<sup>[17]</sup>. It reaches a maximum serum concentration of 3 g/L in the 12-16th wk of fetal life and during the next 18 mo, AFP values decrease and normalize<sup>[18]</sup>. Its synthesis in adult life is repressed. Pathological elevation is seen in hepatocyte regeneration and hepatocarcinogenesis. Numerous data have proved that significantly higher AFP serum levels accompany various liver diseases (viral hepatitis, liver cirrhosis, liver tumors: primarily HCC and hepatoblastoma, also metastasis in 5%-10% cases), other neoplasms (mainly cancers of the digestive tract: pancreas -24%, stomach -15%, large intestine -3%, and gallbladder). Positive predictive values (PPV) for AFP are paradoxically significantly lower among patients with HCC viral etiology than non-viral (PPV: 70% *vs* 94%,  $P < 0.05$ )<sup>[19]</sup>. It has been confirmed on numerous occasions that AFP serum concentration increases in parallel with HCC tumor size. For this reason AFP has to be considered 'the golden standard' for HCC serum markers. However, the usefulness of AFP testing for the population at risk should be seriously questioned. AFP diagnostic values for this assay are undoubtedly poor. AFP specificity varies from about 76% to 96% and increases with elevated cut-off value. Simultaneous sensitivity decreases much more from about 25% for potentially resectable tumors of less than 3 cm in diameter to about 50% for lesions of > 3 cm in diameter (Table 3)<sup>[20,21]</sup>. 20%-30% AFP sensitivity coincides with cut-off values > 100 µg/L, which means that 70%-80% of the results - of a conventional test used as "a gold standard" for HCC diagnosis - are falsely negative. Based on these data 70%-80% of liver tumors, normally resectable are non-detectable. For this reason only one patient out of 5 receives potentially curative treatment. Unfortunately, the remaining majority unfortunately do not undergo treatment or are subjected to it too late.

Nowadays it is believed that early HCC diagnosis is presently considered feasible in 30%-60% of the cases in developed countries. Tumors smaller than 2 cm in diameter represented < 5% of cases in the 1990s in Europe, whereas now they represent up to 30% of cases in Japan<sup>[6]</sup>. Significantly more effective surveillance strategies in Japan lead to earlier HCC detection and earlier qualification for effectively curative radical surgery, with very good postoperative survival rates<sup>[22]</sup>. According to these assumptions, European and American experts have defined trends and

expected aims of surveillance policies in Western countries in 1980-2020. The applicability of potentially curative treatments have been divided into 3 periods: until 1990: 5%-10% of cases; 1990-2010: 30%-40% of cases; and 2010-2020: 40%-60% of cases<sup>[6]</sup>. Limitations of available therapies constitute a major challenge for diagnostic techniques, which are, most of all, modern visual methods and novel HCC specific biomarkers.

Numerous studies analyzing the chemical structure of AFP have shown that different sugar moieties of the bonds determine their binding capacity to lectin lens culinaris agglutinin (LCA)<sup>[23]</sup>. Taking those facts into consideration, Polish scientists, Breborowicz *et al*<sup>[24]</sup> identified in 1981 3 main glycoforms, namely AFP-L1, AFP-L2, AFP-L3. AFP-L1, the non-LCA-bound fraction, is the major AFP isoform in the serum of nonmalignant hepatopathy patients (chronic hepatitis, cirrhosis). AFP-L2 presents intermediate binding capability with its serum concentration increasing during pregnancy, and it is also present in cases of yolk sac tumors. AFP-L3, as the LCA-bound fraction, is the major glycoform in the serum of HCC patients<sup>[24-26]</sup>. It can be detected in 35% of patients with small HCC (< 3 cm). Some clinical studies have indicated that AFP-L3 can be detected 9-12 mo ahead of changes using visual techniques<sup>[27,28]</sup>. Sensitivities of AFP-L3 in detecting HCC range from 45% for lesions < 2 cm to > 90% for changes > 5 cm in diameter<sup>[20]</sup>. The specificity is more than 95%<sup>[26,29]</sup>. Fucosylation rate can be used in clinical practice (AFP-L3/AFP total). It has been confirmed that the ratio of more than 10% is closely associated with worse liver function and poorer tumor histology with implications such as larger tumor mass, a more invasive/malignant character, and earlier metastatic tendency<sup>[27,28]</sup>. Therefore AFP-L3 could be used as a reliable early HCC biomarker and a valuable indicator of poor prognosis. It is possible to achieve particularly accurate results for HCC screening with the use of AFP-L3 in combination with one of the 3 newly-discovered AFP glycoforms which can also be used as single tests, that is AFP-P4, AFP-P5 (E-PHA), and monosialylated AFP (IEF)<sup>[19]</sup>.

### Des-γ-carboxyprothrombin (DCP)

DCP, also known as PIVKA-II (protein induced by vitamin K absence or antagonist-II), is an abnormal, inactive prothrombin, lacking carboxylation of the 10 glutamic acid residues in the N-terminus, which is the result of an acquired post-translational defect of the prothrombin precursor in HCC cell lines. DCP was discovered in serum of patients during their anticoagulant therapy with a vitamin K antagonist. In 1984 Liebman *et al*<sup>[27]</sup> first described a higher DCP level both in patients with HCC and in cases of HCC recurrence after surgical resection, suggesting the usefulness of DCP as an HCC biomarker. It has been proved that significant concentrations of serum DCP are present in 50%-60% of all HCC patients, but in only 15%-30% of early HCC cases<sup>[31]</sup>. In the analyses of Nakagawa *et al*<sup>[32]</sup> the sensitivity of this test is 48%-62% and the specificity is 81%-98%. The diagnostic value of DCP as a biomarker is

**Table 4** Diagnostic values of HCC serum markers<sup>[34-36]</sup>

Type of test	Sensitivity (%)	Specificity (%)
AFP-L3	61.60 <sup>[34]</sup>	92.00 <sup>[35]</sup>
DCP	72.70 <sup>[34]</sup>	90.00 <sup>[35]</sup>
AFP	67.70 <sup>[34]</sup>	71.00 <sup>[35]</sup>
AFP-L3+DCP	84.80 <sup>[34]</sup>	97.80 <sup>[37]</sup>
AFP-L3+AFP	73.70 <sup>[34]</sup>	86.60 <sup>[35,36]</sup>
DCP+AFP	84.80 <sup>[34]</sup>	90.20 <sup>[35]</sup>
AFP-L3+DCP+AFP	85.90 <sup>[34]</sup>	59.00 <sup>[35]</sup>

DCP: Des- $\gamma$ -carboxyprothrombin.

approximately comparable with AFP. Grazi *et al*<sup>[33]</sup> proved that AFP and DCP are not correlated, so the combination of those markers significantly improves HCC detection: sensitivity 74.2%, specificity 87.2%. Carr *et al*<sup>[34]</sup> reported in 2007 interesting data based on prospective analyses of 99 patients with non-resectable HCC verified using liver biopsy (Table 4)<sup>[34-36]</sup>. Nowadays the best way to diagnose HCC is the use of AFP-L3 with DCP analyzed by immuno-enzymatic higher sensitivity methodology<sup>[33,37]</sup>.

#### **$\alpha$ -L-fucosidase (AFU)**

AFU is a normal lysosomal enzyme which hydrolyzes sugars containing L-fucose. In 1984 Deugnier *et al*<sup>[38]</sup> first reported that AFU is overexpressed in patients with HCC liver changes. It has been proved that the values of AFU serum concentration were not correlated with the tumor size and were frequent in early HCC cases<sup>[23]</sup>. Tangkijvanich *et al*<sup>[39]</sup> indicated that the sensitivity and specificity of AFU were about 80% and 70% respectively, in contrast with 40% and almost 100% for AFP. A simultaneous determination of both markers can improve the sensitivity to 82%<sup>[39]</sup>. This conclusion suggested that AFU could serve as a valuable supplement to AFP in early detection of HCC, similar to another popular serum enzyme -  $\gamma$ -glutamyl transferase.

#### **$\gamma$ -glutamyl transferase (GGT)**

GGT is a glycosylated membrane enzyme which activity is modulated in many physiological and pathological conditions, including differentiation and carcinogenesis<sup>[40]</sup>. It is mainly secreted by the hepatic Kupffer cell and endothelium of the bile duct. GGT is also overexpressed, similar to AFP, by fetal hepatoblasts and HCC cell lines<sup>[23]</sup>. The total serum GGT, a generally accepted cholestatic marker, has poor HCC specificity so can be useful only supplementary to AFP and other newer biomarkers for more effective HCC screening. In 1965, Polish scientists Kokot *et al*<sup>[41]</sup> separated the serum  $\gamma$ -glutamyl transferase into 3 to 4 bands by means of paper electrophoresis<sup>[38]</sup>. Since then, other methods have been used, that is, separation of GGT bands by means of starch gel (Orlowski *et al*<sup>[42]</sup>), cellulose acetate (Hitoi *et al*<sup>[43]</sup>), agarose gel (Hetland *et al*<sup>[44]</sup>), polyacrylamide gel electrophoresis (Kojima *et al*<sup>[45]</sup>, Suzuki *et al*<sup>[46]</sup>, Sawabu *et al*<sup>[47]</sup>, Kew *et al*<sup>[48]</sup>), and polyacrylamide stage gel plate (Xu *et al*<sup>[49]</sup>). Xu reported that they had fractionated 9 to

11 activity bands of GGT, in which GGT II was found in the sera of all patients with hepatoma. The positive rate of GGT was 90% and no correlation was observed with AFP<sup>[49]</sup> and DCP<sup>[50]</sup>. After 10 years of follow-up they reported that GGT II was positive in 90% of cases with HCC and negative in most patients with acute and chronic viral hepatitis, extrahepatic tumors, in pregnant women, and in healthy controls<sup>[51]</sup>.

#### **Glypican-3 (GPC-3)**

GPC-3 is an oncofetal protein being one of the members of heparan sulfate proteoglycans anchored to the plasma membrane through glycosylphosphatidylinositol<sup>[52]</sup>. GPC-3 is normally involved in the regulation of cell proliferation and survival during embryonic development and functions as a tumor suppressor. It has been reported to be downregulated in breast cancer, ovarian cancer and lung adenocarcinoma<sup>[53]</sup> but upregulated in HCC<sup>[54]</sup>. GPC-3 is absent in hepatocytes of healthy subjects and patients with nonmalignant hepatopathy, and can be detected in about 50% of HCC patients and 33% of HCC patients seronegative for both AFP and DCP. The specificity of GPC-3 is 100%<sup>[55]</sup>. Some clinical studies have indicated that the simultaneous determination of GPC-3 and AFP could significantly increase the sensitivity in HCC detection, without a reduction in the specificity<sup>[56]</sup>. More trials have confirmed the diagnostic value of 2 other, newly-discovered membranous proteins: Golgi protein 73 (GP73) and mucin 1 (MUC-1).

GP73 is a resident Golgi protein, shown to be upregulated in hepatocytes of patients with acute hepatitis<sup>[57]</sup> and cirrhosis<sup>[58]</sup> and in the sera of patients with HBV- and HCV-related HCC<sup>[59,60]</sup>. Marrero *et al*<sup>[60]</sup> reported a sensitivity of 69% and a specificity of 75% in HCC versus cirrhotic patients, indicating its superiority in comparison with AFP: sensitivity 30%, specificity 96%.

MUC-1 is a membrane protein expressed in many epithelial cells, but overexpressed in patients with breast cancer<sup>[61]</sup>, inflammatory lung diseases<sup>[62]</sup>, and HCC<sup>[63,64]</sup>. Moriyama *et al*<sup>[63]</sup> demonstrated expression of MUC-1 in HCC cells and in serum of patients with HCV-related HCC. Gad *et al*<sup>[64]</sup> reported specificity of 99%, sensitivity of 87% for combined MUC-1, DCP and AFP in Japanese and Egyptian patients with HCC.

#### **Squamous cell carcinoma antigen (SCCA)**

SCCA represents a family of serine proteases of high molecular weight, also known as serpins. There are 2 homologous genes: *SCCA1* and *SCCA2*, encoding 2 different SCCA isoforms, both expressed in many normal squamous epithelial cells. Increased SCCA levels have been detected in head and neck cancers and other epithelial malignancies, including cervix and lung. Recently Pontisso *et al*<sup>[65]</sup> first reported a high SCCA expression in HCC tissues, which seems very interesting, as liver does not possess squamous epithelial cells. Hepatocytes, however, share a common embryogenic origin. The sensitivity and specificity for SCCA in HCC diagnosis are 84% and 46% respectively. The complementary strengths

(high sensitivity/low specificity) and total AFP (low sensitivity/high specificity) suggest that the combination of the 2 markers should be of more value for screening, and in fact it leads to a diagnostic accuracy of 90%<sup>[66]</sup>.

### **Markers (AFP, SCCA, DCP) in immunocomplexes with immunoglobulins of the IgM class (AFP-IgM IC, SCCA-IgM IC, DCP-IgM IC)**

A new step for HCC testing is represented by forming known antigens (AFP, SCCA, DCP) into immunocomplexes (IC) with immunoglobulins of the IgM class. Monitoring of SCCA-IgM IC, AFP-IgM IC and DCP-IgM IC appears to be a much more advantageous approach for detecting patients with small HCC changes<sup>[67-70]</sup>. Giannelli *et al.*<sup>[67]</sup> confirmed that the combined use of AFP IgM IC, SCCA and SCCA IgM IC in patients displaying low levels of AFP (< 20 IU/mL) identified 25.6% HCC. This study suggests that the use of a combination of all these markers in clinical practice provides a non-invasive and simple test that could increase the accuracy of HCC diagnosis. According to the results of Beneduce *et al.*<sup>[68]</sup>: SCCA IgM IC significantly improves accuracy of HCC testing with sensitivity of 100%, specificity of 70%, PPV of 100%, and negative predictive value of 83%; AFP-IgM IC is a complementary serological marker to free AFP and the combination of these biomarkers may be useful in the diagnosis of liver cancer<sup>[69]</sup>; DCP-IgM IC in HCC patients was not associated with an increase in IgM concentration and was more frequently detected in HCC patients than DCP and AFP, strengthening the diagnostic role of IgM immune complexes in liver cancer<sup>[70]</sup>. The novel generation of HCC biomarkers seems very promising as it introduces new hope in supporting US for more accurate HCC screening.

## **CONCLUSION**

The distinction between early HCC changes and dysplastic nodules among cirrhotic patients is challenging even in expert hands. It frequently proves very difficult to characterize by available radiological and pathological examination. Serum biomarkers such as AFP, AFP-L3, DCP, AFU, GGT, GP-73, MUC-1, SCCA, GPC-3 and a new generation of IgM-immunocomplexes have significant diagnostic limitations, and in fact they are not particularly precise for the early diagnosis of HCC. Simultaneous determination of these markers in various combinations could improve the accuracy in differentiating HCC from nonmalignant hepatopathy, but there still exists the unresolved problem of tiny 'grey' nodules in the 'black and white' diagnostic perspective. The potential of gene-expression profiling as a novel tool to improve diagnostic and prognostic prediction is very exciting. The development and progression of HCC is known to be caused by an accumulation of genetic changes resulting in an expression of cancer-related genes: oncogenes, tumor suppressor genes, genes involved in many regulatory pathways, such as cell cycle control, apoptosis and angiogenesis. Modern technology enables investigators to measure the expression of thousands

of mRNA's simultaneously and therefore may provide comprehensive information for diagnosis and therapy of HCC. Currently there are many defined lists of genes selected for the HCC molecular index such as telomerase reverse transcriptase, topoisomerase II  $\alpha$ , heat shock protein 70, serin/threonine kinase 15), phospholipase A2, insulin-like growth factor 2, connexin 26, chemokine C-X-C motif ligand 12,  $\alpha$ -2-macroglobulin, plasminogen, thrombospondin 1, and platelet-derived growth factor receptor  $\alpha$ <sup>[71,72]</sup>. According to novel advancements in the management of HCC in 2008 by Llovet *et al.*<sup>[73]</sup>, high accuracy rates are presented by a 3-gene set: glypican-3, LYVE1 (lymphatic vessel endothelial hyaluronan receptor-1), and survivin. However, more studies are needed to demonstrate its superiority, and presently this is not the first choice in research on early detection of HCC. Major limiting factors for routine use of molecular technology in a clinical setting at present are the cost and the access to them. Hopefully in the not so distant future the costs will decrease and this technology will become increasingly more popular and automated.

## **ACKNOWLEDGMENTS**

We wish to thank for all the support from all the medical personnel of the Department of Hepatology and Acquired Immunodeficiencies, Warsaw Medical University, Wolska 37, 01-201 Warszawa, Poland.

### Abstract

This review discusses the incidence, risk factors, management and outcome of colonoscopic perforation (CP). The incidence of CP ranges from 0.016% to 0.2% following diagnostic colonoscopies and could be up to 5% following some colonoscopic interventions. The perforations are frequently related to therapeutic colonoscopies and are associated with patients of advanced age or with multiple comorbidities. Management of CP is mainly based on patients' clinical grounds and their underlying colorectal diseases. Current therapeutic approaches include conservative management (bowel rest plus the administration of broad-spectrum antibiotics), endoscopic management, and operative management (open or laparoscopic approach). The applications of each treatment are discussed. Overall outcomes of patients with CP are also addressed.

### INTRODUCTION

Colonoscopic perforation (CP) is widely recognized as one of the most serious complications following lower gastrointestinal endoscopies. Although CP is a rare complication, it is associated with a high rate of morbidity and mortality<sup>[1-5]</sup>. This unpleasant complication could result in operation, stoma formation, intra-abdominal sepsis, prolonged hospital stay, and even death. This article describes an overview of incidence, risk factors, management and outcome of CP.

### INCIDENCE

The incidence of CP could be as low as 0.016% of all diagnostic colonoscopy procedures<sup>[6]</sup> and may be seen in up to 5% of therapeutic colonoscopies<sup>[7,8]</sup>. Meanwhile, the incidence of CP following flexible sigmoidoscopy varies from 0.027% to 0.088%<sup>[1,9-12]</sup>. Interestingly, rectal perforation during colonoscopic retroflexion was reported to be around 0.01%<sup>[13]</sup>. The incidences of CP in some larger series (sample size > 30 000 cases) published from 2000 onwards are shown in Table 1<sup>[2-4,9,14-18]</sup>. The most common site of colonic perforation is the rectosigmoid

Table 1 Incidence of CP, management and outcomes from recent series with sample size &gt; 30 000 cases

CP: Colonoscopic perforation; CPT: Complication; NA: Not available.

colon<sup>[1-4,17,19,20]</sup>. Several factors making this bowel segment vulnerable to being injured include a sharp angulation at either the rectosigmoid junction or the sigmoid-descending colon junction, and the great mobility of the sigmoid colon. A forceful insertion of an endoscope while having a sigmoid loop formation is the leading cause of anti-mesenteric bowel perforation due to an overextension of bowel by the shaft of the endoscope. Additionally, the sigmoid colon is commonly involved with diverticular formation<sup>[17,21]</sup>, and the muscular layer of the bowel wall may be thin or fragile due to previous inflammation (diverticulitis). Pelvic adhesions following previous pelvic operation or infection also contribute to a high incidence of sigmoid perforation<sup>[2,7]</sup>.

## RISK FACTORS

There has been convincing evidence that therapeutic colonoscopies have a significantly higher rate of CP than diagnostic colonoscopies<sup>[15,18,20,22]</sup>. The increased likelihood of CP in therapeutic endoscopy is because the perforation during therapeutic colonoscopy can occur not only through mechanisms that are similar to those seen for diagnostic colonoscopy (mechanical injury or barotrauma), but also through the fact that endoscopic interventions *per se* can cause perforation<sup>[20]</sup>. Several investigators have reported that some endoscopic interventions are associated with an increased CP rate, including polypectomy for polyps larger than 20 mm<sup>[23]</sup>, pneumatic dilatation for Crohn's stricture<sup>[24]</sup>, the use of argon plasma coagulation<sup>[23]</sup>, endoscopic mucosal resection and endoscopic submucosal dissection for colorectal neoplasia<sup>[8,26,27]</sup>.

Patients over 75 years of age also have an approximately 4-6 fold rise in the CP rate as opposed to younger patients<sup>[9,18,20,28]</sup>. Possible explanations for an increased rate of CP in patients with advanced age include the fact that the elderly have a declining colonic wall mechanical strength as recognized in colonic diverticular diseases, and they often have a greater frequency of abnormal colorectal findings which may require endoscopic intervention.

The risk of perforation from colonoscopy is 2-4 times greater than that from flexible sigmoidoscopy<sup>[4,9,20,29]</sup>. Pa-

tients with multiple comorbidities are also at greater risk of this perforation<sup>[9,15]</sup>. These comorbidities include diabetes mellitus, chronic pulmonary disease, congestive heart failure, myocardial infarction, cerebrovascular disease, peripheral vascular disease, renal insufficiency, liver disease and dementia<sup>[30-32]</sup>.

Other risk factors for CP reported in the literature include a history of diverticular disease<sup>[9]</sup> or previous intra-abdominal surgery<sup>[17]</sup>, colonic obstruction as an indication for colonoscopy<sup>[15]</sup>, and female gender<sup>[29]</sup>. The difference in anatomy of the large intestine between males and females was demonstrated by Saunders *et al*<sup>[33]</sup>. They found that women had a greater colonic length and a more mobile transverse colon, thus increasing the difficulty in performing colonoscopy in female patients.

## PRESENTATION AND DIAGNOSIS

The most common clinical feature of CP is the visualization of an extra-intestinal structure during the endoscopic examination<sup>[2]</sup>. However, CP patients could present with symptoms and signs of peritonitis (mainly abdominal pain and tenderness) within several hours after the completion of colonoscopy. Patients with CP from therapeutic colonoscopies tend to have a smaller size of the perforation and have a delay in presentation and diagnosis compared with diagnostic colonoscopies<sup>[3,4,17]</sup>. When perforation is suspected, a plain roentgenogram of the abdomen should be taken to rule out intraperitoneal air. Other sophisticated investigations, such as computed tomography (CT) scanning, and magnetic resonance imaging, are also of great help to identify the free gas<sup>[2]</sup>. Triple-contrast or double-contrast (intravenous and rectal) CT scanning is increasingly used in patients with a clinical suspicion of colonic perforation<sup>[34-36]</sup>, and in those with CP who are eligible for non-operative management<sup>[37]</sup>. Water-soluble contrast enema is seldom performed to detect the perforation, or to confirm a concealed perforation. Practically, patients can be diagnosed and treated for CP on the basis of generalized peritonitis without the radiologic evidence of perforation.

A perforated site is typically a large anti-mesenteric tear of colonic wall if it is caused by the shaft of the endoscope. Furthermore, a smaller perforation can be

found in an injury from the tip of the endoscope, or in those related to endoscopic interventions such as polypectomy. Although perforations usually occur during the colonoscopic examination or within 24 h after the procedure<sup>[1-3]</sup>, delayed perforation of the colon and rectum has been reported<sup>[38,39]</sup>. Physicians should therefore suspect a CP if a patient has fever, abdominal pain or distention following the colonoscopic examination, even if the patient presents with these symptoms several days after the procedure.

It is notable that postpolypectomy coagulation syndrome, also known as postpolypectomy syndrome or transmural burn syndrome, can mimic perforation by presenting with similar symptoms and signs<sup>[40]</sup>. Postpolypectomy syndrome occurs when there is a transmural injury of the bowel wall at the site of excised polyp, caused by an overt electrical current or thermal injury<sup>[41,42]</sup>. Without any obvious perforation, transmural bowel injury as well as serosal irritation results in a localized peritonitis, abdominal pain, fever and leukocytosis. Conventional radiography is often unremarkable in this setting. Meanwhile, CT scan may reveal focal mural thickening and pericolic fluid at the site of recent polypectomy as well as soft-tissue stranding of the pericolic fat, without any evidence of pneumoperitoneum or large hematoma<sup>[43,44]</sup>. Conservative management, as described in the following section, is generally successful with good outcomes<sup>[7,45]</sup>.

## MANAGEMENT

Management of CP remains a controversial issue as it can be effectively managed by both operative and non-operative strategies<sup>[37,46,47]</sup>. Although most patients with CP promptly require open surgery, there is an increasing use of non-operative or laparoscopic approaches in selected patients<sup>[48-53]</sup>. The viable options of CP management are discussed as follows.

### Conservative treatment

Clearly, the choice between conservative and surgical management depends on clinical grounds. Conservative management is reserved for CP patients in good general condition and without any sign of peritonitis. This approach involves intravenous fluids, absolute bowel rest and intravenous administration of broad-spectrum antibiotics. If the conservative treatment is successful, patient's clinical appearance should improve gradually within 24-48 h. If this is not the case, complicated intra-abdominal infections (such as fecal peritonitis or intra-abdominal abscess) should be considered, and thus further investigation and management are imperative. Patients must be prepared to proceed to surgical management if clinical improvement is not maintained or when progressive intra-abdominal sepsis occurs. Overall success rate of conservative treatment for CP varies from 33% to 73%<sup>[14,16,56]</sup>. A small perforation site caused by therapeutic colonoscopy has been shown to have a better success rate with medical treatment<sup>[56]</sup>. Colonic stricture following conservative treatment of a colonoscopic perforation has been reported in the literature<sup>[57]</sup>,

but this can be safely managed by either endoscopic dilatation or surgery.

### Endoscopic closure of the perforation

With recent advances in endoscopic technology (such as better optics, and availability of multichannel endoscopy and intraluminal endoclipping) as well as increasing experience of endoscopic interventions<sup>[58-60]</sup>, many endoscopists have been encouraged to perform the endoscopic closure of CP since the first successful endoscopic repair of CP was reported in 1997<sup>[61]</sup>. However, this approach requires not only high endoscopic skill but also appropriate endoscopic devices. In general, the size of the perforation suitable for endoscopic closure is less than 10 mm, but some reports showed successful endoscopic repairs of the perforation larger than 10 mm<sup>[52,62]</sup>. To overcome the problems of closing large defects, novel endoscopic closure devices have been designed such as detachable endoscopic snares and special metal rings in conjunction with endoscopic clips<sup>[63]</sup>.

Any endoscopic repair should be performed with as little air insufflation as possible because a distended lumen often makes it difficult to close the perforation site. Moreover, an extensive air insufflation not only leads to further fecal spillage into the intraperitoneal space but also causes massive pneumoperitoneum, which can compromise the cardiopulmonary system of CP patients<sup>[62]</sup>. After having endoscopic repair, patients should be given intravenous broad-spectrum antibiotics and a clear liquid diet until bowel movement returns and any evidence of peritonitis disappears. Intensive monitoring and serial abdominal examinations are also essential. A review of 75 reported cases of CP repaired by endoclipping, by Trecca *et al*<sup>[62]</sup> in 2008, showed a success rate of 69%-93%. Early recognition of the perforation, prompt complete endoscopic repair, and good bowel preparation are keys to the success of endoscopic treatment for CP.

### Operative treatment

Surgical management is recommended in those with diffuse peritonitis, those with clinical deterioration under non-surgical treatment, or those with a concomitant colonic pathology that requires surgery, such as colorectal cancer. A wide range of surgical options have been described to manage CP depending on the patient's condition, the size of the perforation, the underlying pathology of the large intestine, the quality of bowel preparation, the time between injury and diagnosis, and the surgeon's preference. Feasible choices of the operation are described as follows.

**Simple closure of the perforation:** This surgical approach is appropriate in the case of small colonic perforation (< 50% of bowel circumference), without significant fecal contamination and concomitant intestinal pathology requiring bowel resection. Oversewing of the perforation has been carried out in 25%-56% of immediate perforations, and the leakage rate following primary repair was extremely low<sup>[1-4,64]</sup>.

**Bowel resection with or without intestinal continuity:**

Bowel resection including the perforation site is required when the perforation site is large, or when primary closure of the perforation could compromise the lumen, or when there is concomitant colon pathology requiring bowel resection, such as severe colonic stricture, large sessile polyp or colorectal cancer. In the absence of significant intra-abdominal contamination, bowel resection and anastomosis can be performed with acceptable morbidity. However, when faced with extensive tissue inflammation or fecal peritonitis, bowel resection without anastomosis should be considered. An extensive study of 165 iatrogenic CP cases by Iqbal *et al*<sup>[2]</sup> in 2008 found that patients being diagnosed with CP within 24 h after the colonoscopic examination were more likely to have minimal peritoneal contamination and, thus, tended to undergo primary repair or resection with anastomosis. Conversely, patients presenting after 24 h were more likely to have feculent contamination and to receive a stoma formation. Furthermore, patients with blunt injuries were more likely to receive a stoma than those with polypectomy and thermal perforations.

Another issue under discussion is the role of laparoscopic surgery for CP<sup>[49,50,62,65,66]</sup>. With advanced laparoscopic techniques such as intracorporeal suturing, laparoscopic repair of CP is becoming widely practiced and acceptable. A small comparative study by Bleier *et al*<sup>[67]</sup> showed that a laparoscopic approach to CP resulted in less postoperative complications, decreased length of hospital stay, and a shorter incision length compared to an open method. However, an inability to laparoscopically localize the perforation site or doubt about the security of the repair should prompt conversion to laparotomy<sup>[50]</sup>.

**OUTCOME**

Patients with CP could have a remarkably high morbidity and mortality rate depending on their existing medical conditions, nature of the perforation, methods of CP management, experience of the care team and hospital setting. The 30-d morbidity and mortality rates are 21%-53% and 0%-26%, respectively<sup>[1-4,16]</sup>. The average length of hospital stay in CP patients is 1-3 wk<sup>[1,3,5,68]</sup>.

Surgical site infection is the most common complication, while cardiopulmonary complications and multiple organ failure are the leading causes of death<sup>[1,2]</sup>. Some investigators have suggested that predisposing factors for poor outcomes of CP patients include a large perforation site, a delayed diagnosis, extensive peritoneal contamination, poor bowel preparation, corticosteroid use, anticoagulants or anti-platelet therapy, prior hospitalization, advanced age of patients, and severe comorbid diseases<sup>[2,3,69,70]</sup>.

**CONCLUSION**

Colonoscopic perforation is a rare complication following lower gastrointestinal endoscopies; however, it is asso-

ciated with a high rate of morbidity and mortality. Special precautions should be taken during therapeutic endoscopy and while performing colonoscopic examination in patients with advanced age or those with several comorbidities. Management of patients with CP should be individualized based on patients' clinical grounds and their underlying diseases, nature of the perforation, and concomitant colorectal pathologies.

### Abstract

**AIM:** To establish the hospitalized prevalence of severe Crohn's disease (CD) and ulcerative colitis (UC) in Wales from 1999 to 2007; and to investigate long-term mortality after hospitalization and associations with social deprivation and other socio-demographic factors.

**METHODS:** Record linkage of administrative inpatient and mortality data for 1467 and 1482 people hospitalised as emergencies for  $\geq 3$  d for CD and UC, respectively. The main outcome measures were hospitalized prevalence, mortality rates and standardized mortality ratios for up to 5 years follow-up after hospitalization.

**RESULTS:** Hospitalized prevalence was 50.1 per 100 000 population for CD and 50.6 for UC. The hospitalized prevalence of CD was significantly higher ( $P < 0.05$ ) in females (57.4) than in males (42.2), and was highest in people aged 16-29 years, but the prevalence of UC was similar in males (51.0) and females (50.1), and increased continuously with age. The hospital-

ized prevalence of CD was slightly higher in the most deprived areas, but there was no association between social deprivation and hospitalized prevalence of UC. Mortality was 6.8% and 14.6% after 1 and 5 years follow-up for CD, and 9.2% and 20.8% after 1 and 5 years for UC. For both CD and UC, there was little discernible association between mortality and social deprivation, distance from hospital, urban/rural residence and geography.

**CONCLUSION:** CD and UC have distinct demographic profiles. The higher prevalence of hospitalized CD in more deprived areas may reflect higher prevalence and higher hospital dependency.

### INTRODUCTION

Inflammatory bowel disease (IBD), comprising mainly Crohn's disease (CD) and ulcerative colitis (UC), can be one of the most severe gastrointestinal disorders with a significant health and economic burden<sup>[1]</sup>. Presenting commonly in adolescence, IBD often results in debilitating morbidity and frequent relapses that impact heavily on

educational, social, professional and family life<sup>[1-3]</sup>.

CD has increased in many countries in the past few decades, with highest prevalence often reported in western regions such as Northern and Western Europe and North America<sup>[3-7]</sup>. In the United Kingdom, the incidence of UC has shown greater stability over time<sup>[6,8]</sup>, while CD has continued to rise in many but not in all regions<sup>[7,9-13]</sup>. Most studies have reported that CD is more common in females than in males<sup>[8,10,11,13-16]</sup>, whereas for UC, higher risks have been reported in females<sup>[3,17,18]</sup> or in males<sup>[2,19]</sup>, as well as similar risks for females and males<sup>[20,21]</sup>.

In the United Kingdom, the prevalence of IBD is not known accurately, although based on regional studies, it is thought to affect approximately 150 000 people<sup>[1]</sup>. Of these, the majority have active IBD, with many having severe IBD that may lead to substantial inpatient stays. Our study focused on severe IBD, which we define as an emergency admission to hospital with a length of stay of  $\geq 3$  d, because we wanted to study people who were acutely ill with severe IBD. Inclusion of all patients admitted to hospital, regardless of length of stay, would have covered a wide spectrum of disease severity, from elective day case investigation of IBD and admissions for elective surgery, to emergency care of patients who were severely ill with IBD.

Little is known about the prevalence of severe IBD in the United Kingdom, how it varies geographically, and its relationship with social deprivation. Mortality following hospitalization for IBD is significant<sup>[22]</sup>, but few studies have been based on long-term follow-up. Additionally, little is known about the effect on mortality of social deprivation and other socio-demographic factors such as area of residence and distance from hospital. These are important aspects of the epidemiology of IBD in the United Kingdom, which are important to understand in planning service provision and treatment.

The main objective of this study was to establish the prevalence of UC and CD that was severe enough to require admission to hospital for  $\geq 3$  d, and to report on subsequent mortality after up to 5 years follow-up. Wales has a population of 3 million, and a mixed urban and rural geography, with areas of significant social deprivation. Further objectives were to assess geographical variation in the hospitalized prevalence and mortality for CD and UC, and to investigate associations with social deprivation and other socio-demographic characteristics, including any association between mortality and distance of patients' residence from hospital and urban or rural residence.

## MATERIALS AND METHODS

For this study, we used hospital inpatient data from the Patient Episode Database for Wales (PEDW), which incorporates medical record linkage to mortality data from the National Health Service Administrative Register<sup>[23]</sup>. PEDW is a comprehensive administrative database that covers all inpatient and day-case admissions to every National Health Service (NHS) hospital in Wales, and has been used as the basis for previously published studies<sup>[24-27]</sup>.

It covers 17 district general or teaching hospitals in eight NHS hospital trusts across 22 health boards, and serves the Welsh population of 3 million. We used record linkage of inpatient and mortality data because this enabled all repeat hospital admissions to be identified for the same patients, and enabled deaths following discharge from hospital to be identified, as well as in-hospital deaths.

The International Classification of Diseases, 10th Edition (ICD-10) codes used were: K50 for CD and K51 for UC. Patients with an emergency hospital admission of three or more consecutive days were classified as severe cases and included in the study. We selected only those admissions for which CD or UC was recorded as the principal diagnosis on the discharge record, and selected only the first admissions for each patient that met the study inclusion criteria during the 8-year study period from 1999 to 2007. We excluded all elective admissions, all day cases and inpatient admissions lasting  $< 3$  d, all admissions subsequent to the first admission, and all admissions for which CD and UC were recorded on the discharge record as secondary diagnoses to other diseases such as colorectal malignancy.

Hospitalized prevalence rates for CD and UC were calculated per 100 000 resident population, using the numbers of severe hospitalized cases as the numerators and the Welsh residential population as the denominators. The direct method and the standard European population were used to standardize the prevalence rates. Mortality rates following hospital admission were calculated using the numbers of deaths (from all causes) as the numerators, and the total number of hospitalized cases, in the same time periods, as the denominators. Mortality rates were expressed as percentages and calculated at 1 and 5 years follow-up from the date of hospital admission.

To establish how mortality among the CD and UC patients compared with that in the general population, we used standardized mortality ratios (SMRs). These were calculated by applying the age- and sex-specific mortality rates in the general Welsh population to the numbers of study patients in the corresponding age- and sex-specific strata, to calculate the expected number of deaths in the study patients, and by comparing the observed deaths with the expected deaths.

Social deprivation scores were assigned to the patients' place of residence on each hospital record by using residential postcodes at the Lower Super Output Area (LSOA) and the Welsh Index of Multiple Deprivation (WIMD) 2005<sup>[28]</sup>. The average population size of the 1896 LSOAs in Wales in 2005 was 1560. The WIMD 2005 was based on seven domains of social deprivation: income, housing, employment, environment, health, access to services, and education. The LSOAs were ranked according to their WIMD 2005 score and grouped into quintiles, with quintile I representing the 20% of least deprived LSOAs and quintile V the 20% of most deprived LSOAs in Wales.

Urban/rural residences were measured using five categories, based on settlement sizes that ranged from  $< 2500$  to  $> 100\,000$  people. Distances from patients'

<sup>1</sup>For geographical details of each health board, see Figure 1. CD: Crohn's disease; UC: Ulcerative colitis; LSOA: Lower Super Output Area.

residential LSOAs (geographical center points) to their hospital of admission were calculated using ArcGIS Geographical Information System (GIS) software and were measured in five categories that ranged from < 3 to > 20 km. Other methods used included logistic regression analysis,  $\chi^2$  tests, and Pearson's correlations.

**RESULTS**

From 1999 to 2007, there were 1467 patients hospitalized for ≥ 3 d following emergency admission for CD (mean ± SD, age: 45.8 ± 20.4 years) and 1482 for UC (mean ± SD, age: 52.0 ± 21.0 years). All the results that follow refer to these patients who meet the definition of severe IBD, although, for brevity, we omitted the repeated use of the term severe.

**Hospitalized prevalence of CD and UC**

The overall hospitalized prevalence rate per 100 000 population was 50.1 for CD and 50.6 for UC (Table 1). Geographically, across the 22 health boards in Wales (Table 1), the prevalence of Crohn's varied from 31.5 per 100 000 (95% CI: 22.6-42.7) to 71.3 (59.3-84.9), whereas for UC, it varied from 38.2 per 100 000 (29.6-48.5) to 89.7 (66.6-118.3).

For UC, there was a significant association between hospitalized prevalence and age ( $P < 0.05$ , Table 2). The hospitalized prevalence of UC increased with age, and was highest for males and females aged > 65 years (103 and 93.4 per 100 000, respectively). There was no significant association between the hospitalized prevalence of CD

and age. The highest age-specific prevalence of CD was in the 16-29 years age group, for both males (61.4) and females (76.0). Overall, the hospitalized prevalence of CD was significantly higher ( $P < 0.05$ ) in females (57.4) than in males (42.2), whereas the hospitalized prevalence of UC was very similar in females (50.1) and males (51.0, Table 2).

Figure 1 shows the geographical distribution of the social deprivation quintiles to the 1896 LSOAs across Wales. The hospitalized prevalence of CD was associated significantly with social deprivation at the LSOA level (Pearson's correlation = 0.07,  $P = 0.004$ ), although the association was not strong. The prevalence of CD tended to be higher in more deprived areas, although there were not quite significant differences between the most and least affluent quintiles (Figure 2). For UC, there was no significant association between prevalence and social deprivation at the LSOA level, or across any of the five social deprivation quintiles (Figure 2).

**Mortality in CD and UC at 1 year**

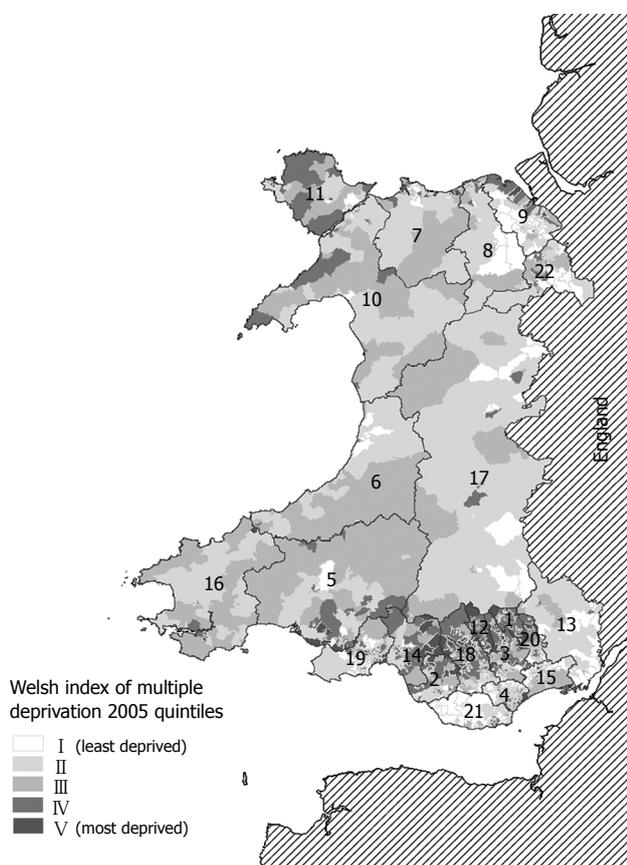

After 1 year follow-up, mortality was 6.8% for CD and 9.2% for UC (Table 3). Corresponding SMRs at 1 year were 5.1 (95% CI: 4.1-6.27; compared with mortality of 1.0 in the general population) for CD and 4.3 (95% CI: 3.6-5.1) for UC.

For CD and UC, mortality at 1 year increased sharply with age, and age-adjusted mortality was similar among males and females (Table 3). Very few deaths occurred among people aged < 45 years. For CD and UC, there was no significant variation in mortality according to social deprivation, urban/rural residence, distance from

**Table 2** Age- and sex-specific hospitalized prevalence rates for severe CD and UC, 1999-2007

		CD			UC		
		Cases	Prevalence (per 100000)	95% CI	Cases	Prevalence (per 100000)	95% CI

	45-64	222	58.9	(51.4-67.2)	189	50.1	(43.3-57.8)
	65+	205	69.4	(60.2-79.6)	276	93.4	(82.7-105)
All Wales		1467	50.1	(47.5-52.7)	1482	50.6	(48.0-53.2)

The ages of three Crohn's patients, two males and one female, was unknown.

**Figure 1** WIMD 2005 quintiles for the 22 health boards and the 1896 geographical LSOAs in Wales. The key to the health board numbering is as follow: 1 Blaenau Gwent; 2 Bridgend; 3 Caerphilly; 4 Cardiff; 5 Carmarthenshire; 6 Ceredigion; 7 Conwy; 8 Denbighshire; 9 Flintshire; 10 Gwynedd; 11 Isle of Anglesey; 12 Merthyr Tydfil; 13 Monmouthshire; 14 Neath Port Talbot; 15 Newport; 16 Pembrokeshire; 17 Powys; 18 Rhondda Cynon Taff; 19 Swansea; 20 Torfaen; 21 The Vale of Glamorgan; 22 Wrexham.

hospital, and whether or not an emergency colectomy was performed (Table 3). Although there was some variation in mortality across the 22 Welsh health boards, there were no significant differences between individual health boards.

**Figure 2** Hospitalized prevalence of severe Crohn's disease and ulcerative colitis according to social deprivation, 1999-2007. I: Least deprived social deprivation quintile; V: Most deprived. Vertical bars represent 95% CI. These prevalence rates are standardised for age group and gender.

**Mortality in CD and UC at 5 years**

Mortality at 5 years was 14.6% for CD and 20.8% for UC (Table 4). SMRs at 5 years were 2.4 (95% CI: 1.9-2.9; compared with mortality of 1.0 in the general population) for CD and 1.9 (95% CI: 1.5-2.2) for UC.

For CD and UC, mortality at 5 years was comparable among females and males, and it increased sharply among older age groups: among men aged > 65 years and women aged > 60 years, mortality was 34% for CD and 49% for UC (Table 4). There were no significant differences in mortality at 5 years according to urban/rural residence, distance travelled to hospital, or whether an emergency colectomy was performed (Table 4). For CD, mortality was significantly higher in the most deprived quintile compared with the second most affluent quintile, although there were no other significant differences in mortality according to social deprivation.

**DISCUSSION**

The main aims of this record linkage study were to

<sup>1</sup>The OR for sex is adjusted for age group. The OR for social deprivation and colectomy was adjusted for age group and sex. The adjusted OR for urban/rural residence and distance from hospital was adjusted for age group, sex and social deprivation.

establish the extent and prognosis of severe CD and UC in Wales, and how they are associated with social deprivation, geography and other socio-demographic aspects. It is thought that IBD affects approximately 150 000 people in the United Kingdom, with corresponding prevalence rates of 55-140 per 100 000 for CD, 160-240 per 100 000 for UC, and approximately 13 300 combined new cases diagnosed each year<sup>[1]</sup>. We found a hospitalized prevalence rate of 50.1 per 100 000 population for severe CD and 50.6 for severe UC. If these prevalence rates for Wales were applied to the whole of the United Kingdom, this would suggest a total of approximately 62 000 people hospitalized with severe IBD over the 9-year study period (30 000 for CD and 32 000 for UC).

The main strength of this study was its size, which covered almost 3000 patients who were hospitalized for IBD in a geographically defined population of nearly 3 million over a 8-year period. Further strengths are that it

was based on systematic record linkage, which enabled long-term mortality follow-up of 5 years, by monitoring deaths that occurred in and following discharge from hospital. The study also used geographical measures of social deprivation to measure social inequality comprehensively on a national scale, as well as other novel prognostic/demographic risk factors, such as distance from home to hospital and urban or rural residences.

We defined severe IBD as emergency hospitalization for IBD, as the principal reason for admission, which lasted ≥ 3 d. This was to distinguish severe illness from relatively minor illness and from day-case investigations. We accept that the definition may also have included some patients who were admitted with long stays for other serious illnesses, for example, myocardial infarction or pneumonia, who also had IBD. However, we sought to minimize this by restricting case selection to people in whom IBD itself was coded as the principal reason for admission.

\**P* < 0.01. <sup>1</sup>The OR for sex was adjusted for age group. The OR for social deprivation and colectomy was adjusted for age group and sex. The adjusted OR for urban/rural residence and distance from hospital was adjusted for age group, sex and social deprivation; <sup>2</sup>Fewer people had 5 years than 1 year follow-up during the 9-year study period, therefore, the number of cases was lower in this Table than in Table 3.

The main limitation of record linkage studies such as this is the lack of detailed information about the history, severity and management of the illness. It was not possible to ascertain the extent of disease from endoscopic evidence or detailed pathology information from our data sources. Our hospitalized prevalence rates referred specifically to CD and UC patients with an inpatient stay of ≥ 3 d following emergency admission. Although length of stay is often affected by factors such as age, comorbidity, and effectiveness of self care and social support, we believe that a length of stay of ≥ 3 d after emergency admission usually indicates severe disease that requires intensive medical or surgical treatment rather than admission for diagnosis or assessment.

For both males and females, we found a continuous rise in the hospitalized prevalence of UC as age increased. For CD, we found highest prevalence among patients aged

16-29 years, with a second peak in prevalence in males aged > 65 years and females aged ≥ 60 years. We also found a higher prevalence of CD in females than in males, but a similar prevalence of UC among males and females, which is consistent with other studies<sup>[8,10,11,13,14,16,19,29]</sup>.

IBD has been linked with higher socioeconomic groups in some studies, particularly for CD<sup>[30,31]</sup>, but also for UC<sup>[31]</sup>, although other studies have reported no association<sup>[32-34]</sup>. Instead, we found slightly higher hospitalized prevalence of CD in more socially deprived locations, although there were not quite significant differences across the social deprivation quintiles. As our study focused on more severe cases, possible reasons for this include higher levels of health-care dependency as well as higher levels of smoking and more comorbidity among patients from more deprived social backgrounds. For UC, we found no significant association between

hospitalized prevalence and social deprivation. The differing demographic profiles between CD and UC, and the stronger evidence of an association between CD and social deprivation suggests that environmental factors play a stronger part in the etiology of CD, but attempts to establish environmental factors have proved inconclusive and sometimes controversial in the past<sup>[31,33-37]</sup>.

Overall mortality was 6.8% at 1 year and 14.6% at 5 years for CD, compared with 9.2% at 1 year and 20.8% at 5 years for UC. At 5 years, mortality was high among older patients (49% and 54% for CD and UC, respectively, among patients aged  $\geq 65$  years). The higher mortality for UC is consistent with other studies<sup>[116,22,38]</sup>, although there is a lack of large studies with long-term follow-up for people hospitalized with IBD. Mortality at 1 year follow-up was five times higher than in the general population for CD and four times higher for UC. At 5 years, mortality was increased two fold for CD and UC. An earlier study has reported SMRs of 3.2 and 2.4 after 3 years follow-up for people hospitalized with severe CD and UC, respectively, in England<sup>[22]</sup>, and further demonstrates that people hospitalized with severe IBD are often at increased risk of mortality, which continues in the long term. Elective colectomy may well be the most effective means of reducing these excess risks of mortality<sup>[22]</sup>.

Although there was some variation in prognosis geographically across health boards, it was not significant for either CD or UC. We also found little discernible association between social deprivation quintiles, distance travelled to hospital and rural versus urban residence, and subsequent mortality at either 1 or 5 years. As IBD often relapses and requires regular monitoring and surveillance, it is possible that patients who live remotely from outpatient clinics and hospital care may have poorer outcomes. Our findings for mortality outcomes do not support such concerns, although recent health service developments in the United Kingdom that encourage greater management and treatment of IBD in primary care may partially offset the distances travelled by patients.

We found that severe CD and UC had quite distinct demographic profiles in Wales. CD and UC also showed slightly differing patterns of association with social deprivation. The higher prevalence of hospitalized CD in more deprived areas may reflect higher smoking rates, more comorbidity and higher levels of hospital dependency, as well as higher prevalence.

## COMMENTS

### Background

The prevalence of Crohn's disease (CD) has increased in many countries in recent decades. Although inflammatory bowel disease (IBD) is thought to affect

about 150 000 people in the United Kingdom, the prevalence of severe IBD is not known. Mortality following hospitalization for IBD is significant but little has been reported on long-term follow-up.

### Research frontiers

This study determined the hospitalized prevalence of severe IBD and subsequent 5-year mortality in Wales, and investigates associations between severe IBD and social deprivation, distance travelled to hospital, and other socio-demographic characteristics.

### Innovations and breakthroughs

This study showed that the hospitalized prevalence of severe CD was slightly higher among the most deprived groups but there was no association between social deprivation and severe ulcerative colitis (UC). Five-year mortality was high for severe CD (14.6%) and UC (20.8%), but there was little association between mortality and social deprivation, distance from hospital, urban/rural residences or geography.

### Applications

The higher hospitalized prevalence of severe CD among the most deprived groups, and differing demographic profiles between CD and UC, suggest that environmental factors play a more significant role in the etiology of CD. The findings of this large population-based study on the prevalence and mortality of IBD are also important for service planning and provision.

### Terminology

Hospitalized prevalence of severe IBD in this study referred to the number of people (per 100 000 population) who were hospitalized as an emergency for  $\geq 3$  d for IBD, as the principal reason for admission, on at least one occasion during the 8-year study period. One and five-year mortality referred to the percentage of these people who died during the subsequent one and five-year follow-up period.

### Peer review

This was a well-conducted, large epidemiological study that provided interesting and novel findings. For example, the findings that distance travelled by patients to hospital did not affect long-term mortality for CD or UC has not been reported previously.

### Abstract

**AIM:** To evaluate the natural history of subepithelial lesions.

**METHODS:** We reviewed the medical records of 104 159 patients who underwent upper gastrointestinal endoscopy at the Center for Health Promotion of Samsung Medical Center between 1996 and 2003. Subepithelial lesions were detected in 795 patients (0.76%); 252 patients were followed using upper gastrointestinal endoscopy for  $82.5 \pm 29.2$  mo (range, 12-160 mo; median, 84 mo; 1st quartile, 60 mo; 3rd quartile, 105 mo). The median interval of follow-up endoscopy was 12 mo (range, 6-105 mo; 1st quartile, 12 mo; 3rd quartile, 24 mo).

**RESULTS:** The mean patient age was 53 years (range, 22-80 years), and the male-to-female ratio was 2.36:1 (177/75). The lesion size at initial measurement averaged 8.9 mm (range, 2-25 mm; median, 8 mm; 1st quartile, 5 mm; 3rd quartile, 10 mm). Of the 252 lesions, 244 (96.8%) were unchanged and 8 (3.2%) were significantly increased in size (from  $12.9 \pm 6.0$  to  $21.2 \pm 12.2$  mm) after a mean interval of  $59.1 \pm 27.5$  mo (range, 12-86 mo). Surgical resection of lesions was performed when the lesions were  $\geq 3$  cm in diameter. Two lesions were diagnosed as gastrointestinal stromal tumors with an intermediate or high risk of malignancy and one lesion was classified as a schwannoma.

**CONCLUSION:** Most small subepithelial lesions do not change as shown by endoscopic examination, and regular follow-up with endoscopy may be considered in small, subepithelial lesions, especially lesions  $< 1$  cm in size.

## INTRODUCTION

Upper endoscopy is commonly performed for the evaluation of symptoms, and for screening and surveillance of neoplasias. Subepithelial masses or bulges covered with normal-appearing mucosa are frequently encountered during endoscopy. Although a previous study has reported that the incidence of gastric subepithelial lesions is approximately 0.3%<sup>[1]</sup>, Kawanowa *et al.*<sup>[2]</sup> reported 50 microscopic gastrointestinal stromal tumors (GISTs) in 100 stomachs entirely resected from patients with gastric cancer. With more widespread use of endoscopy for screening, it is likely that subepithelial lesions will be detected more frequently. The optimal management of incidentally-detected, subepithelial lesions has not been determined.

When clinicians are faced with a subepithelial lesion, they must decide to remove or follow up the lesion. Endosonographic or endoscopic surveillance is common in patients with asymptomatic, subepithelial lesions without signs of malignancy, such as large size, rapid growth, or ulceration, although such an approach has not been formally validated<sup>[3]</sup>. Because little is known about the natural course of subepithelial lesions, the appropriate strategy for management is still controversial. This imposes a tremendous emotional burden on patients who can become preoccupied with the possibility that the tumor is malignant.

The aim of this study was to determine the natural history and provide a basis of surveillance of incidentally-detected, asymptomatic subepithelial lesions.

## MATERIALS AND METHODS

We used computerized medical records and a database of disease codes to study 104 159 patients who underwent upper gastrointestinal endoscopy at the Center for Health Promotion of Samsung Medical Center in Seoul, Korea between March 1996 and March 2003. A computer search over a 7-year period revealed 795 patients (0.76%) with the diagnostic code for submucosal tumors of the esophagus, stomach, or duodenum. Within this group, 252 patients had been followed with upper gastrointestinal endoscopy. Thirty-seven of 61 patients who had lesions > 1 cm in size were further evaluated with endoscopic ultrasonography (EUS). Seven of 8 lesions with a significant increase in size were evaluated using EUS. The duration of follow-up was determined by the last known visit for endoscopic examination at our hospital. All examinations were performed by experienced endoscopists (> 1000 endoscopic examinations each). Endoscopists approximated the size of lesions by using an open biopsy forceps for comparison (6 mm).

### Statistical analysis

Statistical evaluation was performed with SPSS (Statistical Program for the Social Sciences; SPSS, Inc., Chicago, IL, USA). Descriptive statistics were used when appropriate.

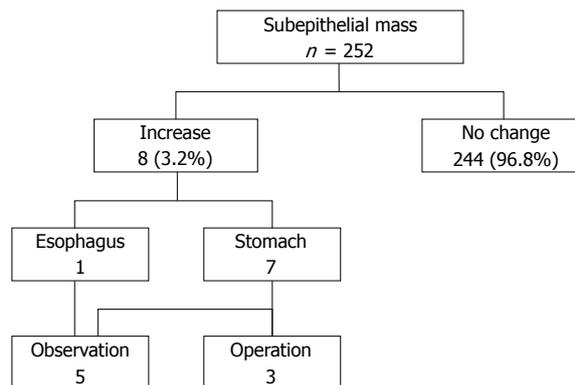

Figure 1 Clinical course of subepithelial masses.

## RESULTS

The mean age of the 252 patients with subepithelial lesions was 53 years (range, 22-80 years), and the male-to-female ratio was 2.36:1 (177/75). The mean lesion size was 8.9 mm (range, 2-25 mm; median, 8 mm; 1st quartile, 5 mm; 3rd quartile, 10 mm). The stomach [130 patients (51.6%)] was the most common site for a subepithelial lesion, followed by the esophagus [104 patients (41.3%)], and duodenum [18 patients (7.1%)].

Biopsies were obtained from 191 of the 252 patients at the time of the initial endoscopy. Endoscopy and biopsy were sufficient for diagnosis in 3 patients. Of these 3 patients, 1 had an esophageal leiomyoma, and 2 had Brunner gland hyperplasia of the duodenum.

Of 252 lesions, 244 (96.8%) were unchanged and 8 (3.2%) significantly increased in size (from  $12.9 \pm 6.0$  to  $21.2 \pm 12.2$  mm) during a mean interval of  $59.1 \pm 27.5$  mo (range, 12-86 mo, Figure 1, Table 1). In these 8 lesions, there was an increase of over 25% and more than 5 mm in diameter at surveillance. Six of the 8 lesions arose from the 4th layer, corresponding to the muscularis propria, and appeared hypoechoic; they were considered to be GISTs. One lesion arose from the 3rd layer and appeared hyperechoic; it was considered to be a lipoma. The other lesion was further evaluated by stomach computed tomography (CT) probably because of the patient's rejection of an EUS examination; however, the lesion was not observed on CT. Surgical resection was performed in 3 lesions  $\geq 3$  cm in size, which were diagnosed as GISTs with an intermediate and a high risk of malignancy, and a schwannoma (Figures 2-4). The 5 patients who did not undergo surgery were followed by means of upper gastrointestinal endoscopy or EUS. No further change was observed in size, shape and EUS finding such as echo pattern or regularity of the outer margin over a period of 1-5 years.

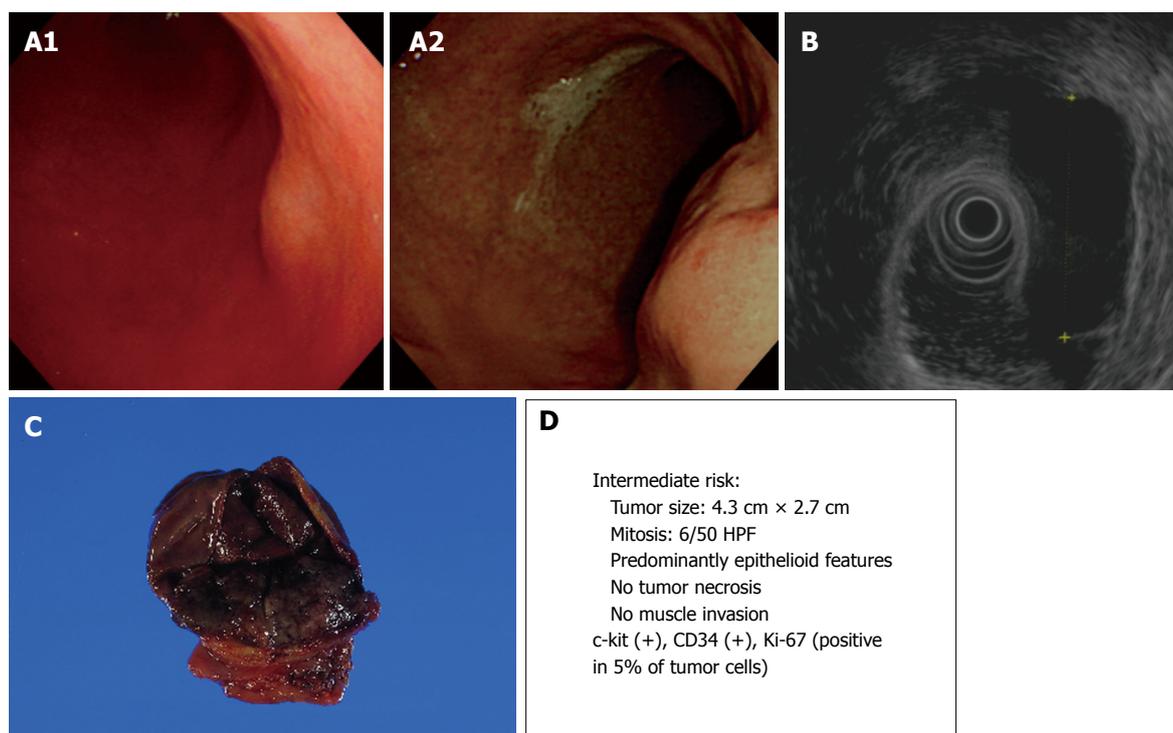

## DISCUSSION

We demonstrated that during a mean period of  $82.5 \pm 29.2$  mo (range, 12-160 mo; median, 84 mo; 1st quartile, 60 mo; 3rd quartile, 105 mo), there was no significant

Table 1 Characteristics of 8 patients with increased subepithelial masses

Patients	Age (yr)	Gender	Location	Initial size (mm)	Increased size (mm)	Follow-up interval (mo)	EUS	Treatment	Surgical gross pathology
1	60	F	Stomach	22	30	40	GIST	Operation	Schwannoma
2	63	M	Stomach	20	30	86	GIST	Observation	
3	65	M	Stomach	15	40	12	GIST	Operation	GIST
4	37	F	Stomach	12	18	36	GIST	Observation

EUS: Endoscopic ultrasound; GIST: Gastrointestinal stromal tumor.

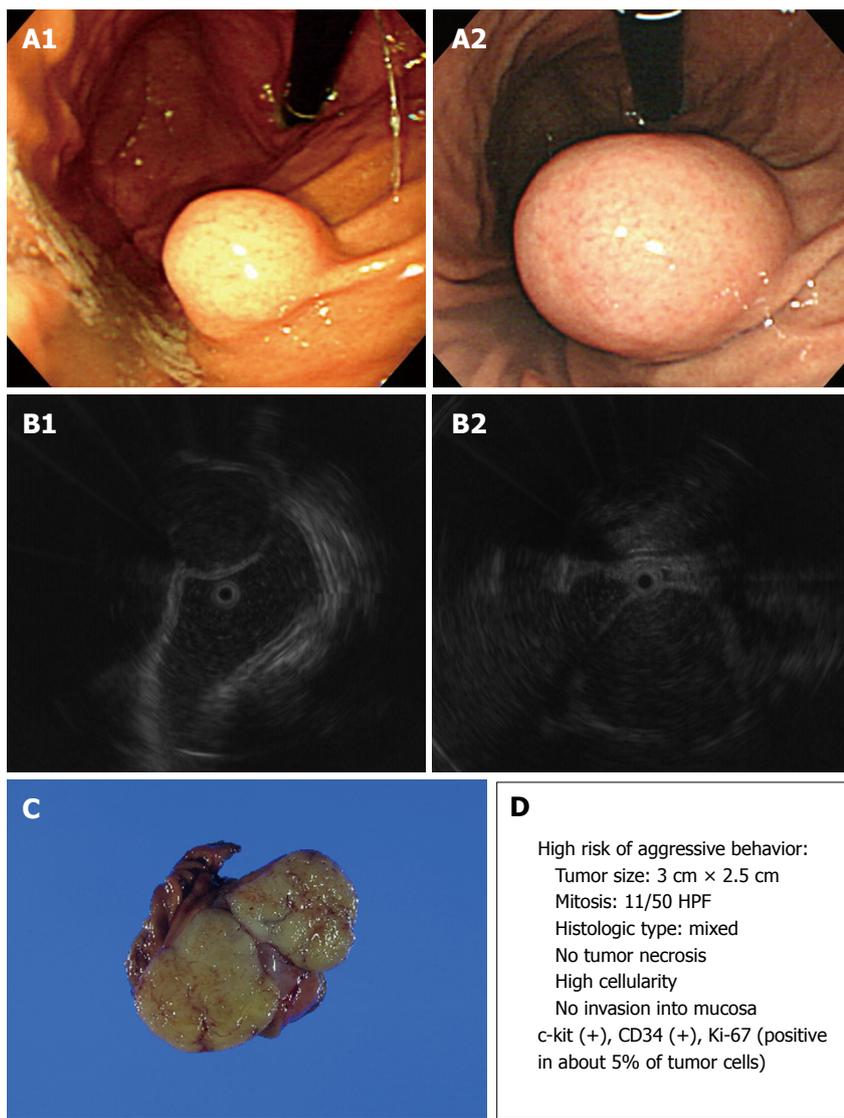

**Figure 2** Endoscopic, endoscopic ultrasonography (EUS), and gross findings of gastrointestinal stromal tumors (GISTs). A: Endoscopic view of a round subepithelial mass with a significant interval change; B: EUS shows an ovoid, homogeneous, hypoechoic mass in the fourth gastric wall layer; C: Gross findings of wedge resection reveal a soft, well-defined mass measuring 4.3 cm × 2.7 cm; D: Malignant potential.

change in the size of small (< 30 mm) subepithelial lesions detected incidentally during upper gastrointestinal endoscopy in 244 of 252 patients (96.8%). Eight lesions (3.2%) were significantly increased in size (from  $12.9 \pm 6.0$  to  $21.2 \pm 12.2$  mm) during a mean interval of  $59.1 \pm 27.5$  mo (range, 12-86 mo), four patients had subepithelial lesions  $\geq 3$  cm in size on follow-up endoscopic examination. Three patients of them underwent tumor resection and were diagnosed with intermediate or high risk GISTs and a schwannoma.

Our findings are consistent with prior studies of subepithelial lesions. Several prior studies have suggested that since most small subepithelial lesions do not exhibit changes that would raise the suspicion of malignant potential, a conservative policy (endoscopic follow-up without pathologic diagnosis) of surveillance is safe. Tio

*et al*<sup>[4]</sup> showed that the size and echo pattern of 21 small (< 3 cm) subepithelial lesions did not change over a period of 1-3 years. Melzer *et al*<sup>[5]</sup> also showed no changes in size or echo pattern in the small subepithelial lesions (< 4 cm) of 24 of 25 patients over a mean period of 19 mo. However, one gastric lesion enlarged from 30 to 38 mm and changed from a hypoechoic to a non-homogeneous pattern. The patient underwent resection of a stromal tumor with high malignant potential. Lee *et al*<sup>[6]</sup> followed patients with 16 esophageal tumors, 9 gastric tumors, and one benign duodenal mesenchymal tumor (< 3 cm) for a mean period of 47.4 mo, and noted no change in 25 of 26 patients during EUS surveys. However, one gastric lesion enlarged from 26 to 34 mm without a change in the echo pattern or regularity of the outer margin. The patient underwent resection of a leiomyoma.

**Figure 3** Endoscopic, EUS, and gross findings of GISTs. A: Endoscopic view of a round subepithelial mass with a significant interval change; B: EUS shows an ovoid, homogeneous, hypoechoic mass in the fourth gastric wall layer; C: Gross findings of wedge resection reveal a soft, well-defined mass measuring 3.0 cm × 2.5 cm; D: Malignant potential.

**D**

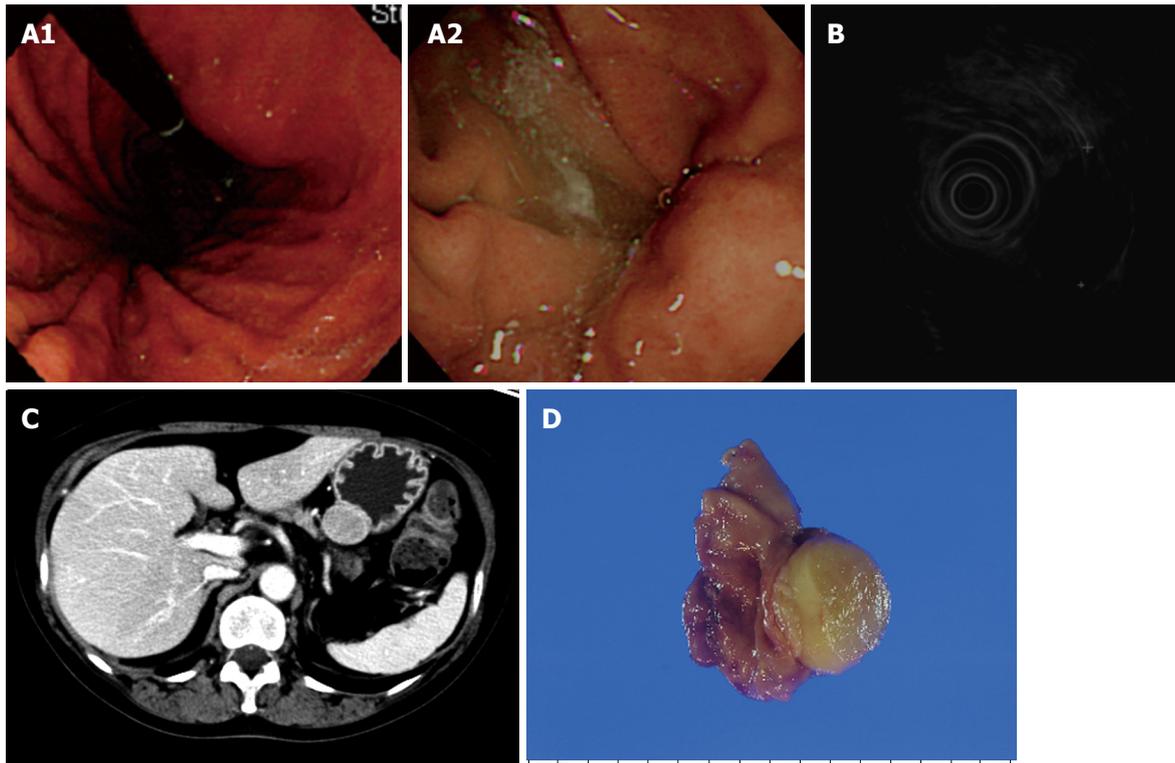

High risk of aggressive behavior:  
 Tumor size: 3 cm × 2.5 cm  
 Mitosis: 11/50 HPF  
 Histologic type: mixed  
 No tumor necrosis  
 High cellularity  
 No invasion into mucosa  
 c-kit (+), CD34 (+), Ki-67 (positive  
 in about 5% of tumor cells)

Imaoka *et al*<sup>[7]</sup> followed 132 gastric subepithelial lesions for 5 years and found that only 2 lesions increased in size. These tumors were diagnosed as GISTs after surgical resection; one patient had liver metastasis. Lachter *et al*<sup>[8]</sup> found that the majority of small (< 17 mm) subepithelial tumors did not change in echogenicity or size during a median period of 5 years. The previous studies have been limited by small sample size and relatively short follow-up.

According to a stepwise approach to subepithelial tumors, EUS is recommended for subepithelial tumors > 1 cm in diameter, and histologic evaluation, such as EUS-guided fine needle aspiration biopsy (EUS-FNAB), is recommended for hypoechoic subepithelial tumors < 3 cm in diameter. Surgery is recommended for subepithelial tumors > 3 cm in diameter<sup>[9]</sup>. Although these procedures are helpful in categorizing a lesion, they cannot absolutely determine the type of lesion or determine if a lesion is benign or malignant<sup>[10,11]</sup>. Clinicians should consider if an invasive method, such as EUS-FNAB, is necessary or available. Furthermore, they should consider individual risk and patient preference.

The optimal management of subepithelial lesions remains controversial because the natural history of subepithelial lesions, such as GISTs, remains incompletely defined. GISTs are the most commonly identified intramural subepithelial tumors in the upper gastrointestinal tract<sup>[11]</sup>. Small GISTs (< 2 cm) have very low malignant potential according to the classification system proposed by the National Institutes of Health Consensus Conference<sup>[12]</sup>. The American Gastroenterological Association recommends periodic endoscopic or endosonographic follow-up or surgical resection for small, hypoechoic, 3rd- and 4th-layer (< 3 cm) masses, which are most likely GISTs<sup>[13]</sup>. Nishida *et al*<sup>[14]</sup> recommended that subepithelial tumors < 2 cm in size and without ulceration or surface depression can be followed with endoscopic examination once or twice per year.

Opinions concerning the duration of follow-up also vary. Brand *et al*<sup>[15]</sup> recommended follow-up for 6 mo after the initial diagnosis for subepithelial lesions with no EUS signs of malignancy. If there is no change during the initial follow-up period, annual follow-up is recommended. Hwang *et al*<sup>[16]</sup> suggested a 1-year follow-up interval

**Figure 4** Endoscopic, EUS, abdominal computed tomography (CT), and gross findings of a schwannoma. A: Endoscopic view of an ovoid subepithelial mass with a significant interval change; B: EUS shows a round, homogeneous, hypoechoic mass in the third gastric wall layer; C: CT scan shows a 2.8 cm × 2.2 cm homogeneous, well-defined, soft tissue mass on the upper body of the stomach; D: Gross findings of wedge resection reveal a 3 cm × 2.5 cm well-demarcated, round, firm, yellow mass.

and suggested that the interval between surveillance examinations be extended if the lesion remains unchanged for 2 consecutive follow-up examinations with EUS. Guidelines in Japan recommend endoscopic examination once or twice per year for subepithelial lesions < 2 cm in size<sup>[14]</sup>.

Our finding must be interpreted in the context of the strength and weakness of this study. The high number of patients and a long follow-up study is its strength. However, there are several limitations in this study. First, there is a lack of accuracy in estimation of size. The open-biopsy forceps technique can underestimate or overestimate the size of submucosal lesion and shows inter-observer variation, but it is convenient to use in clinical practice. In our study, 2 submucosal lesions were estimated as 2 mm in size and we could not exclude the possibility of an under-estimation of the size. Second, we could not analyze all the patients with the diagnostic code for submucosal tumors, because only a proportion of the patients were followed up and analysis was performed only for them.

In conclusion, although the management strategy for small subepithelial lesions is still controversial, regular follow-up with endoscopy or EUS may be considered in small, asymptomatic, subepithelial lesions. Endoscopic surveillance can be an appropriate strategy for lesions < 1 cm. Further prospective, multicenter studies with long-term follow-up would help to validate these surveillance programs.

## COMMENTS

### Background

The natural history of subepithelial lesions has not been clearly elucidated, and the appropriate management strategy for small subepithelial tumors is still controversial.

### Research frontiers

With more widespread use of endoscopy for screening, asymptomatic subepithelial lesions would be detected more frequently. However, the appropriate strategy for management is still controversial. In this study, the authors have determined the natural history and provided a basis for surveillance of incidentally-detected, asymptomatic subepithelial lesions.

### Innovations and breakthroughs

Although several studies pertaining to the natural history of subepithelial lesions, including gastrointestinal tumors, have been published, they have been limited by small sample size and relatively short follow-up. In Korea, many subjects have regular endoscopic examinations because of the high incidence of gastric cancer.

### Applications

The authors have provided the basis for surveillance of incidentally-detected, small subepithelial lesions by means of this study.

### Peer review

Lim *et al* performed a retrospective 3-year follow up study of subepithelial gastrointestinal lesions in 252 patients. This is a high number of patients and a long follow-up, which increases the value of the work.

### Abstract

**AIM:** To investigate the potential anti-*Helicobacter pylori* (*H. pylori*) and anti-inflammation *in vivo* effects of two *Lactobacillus* strains from human stomach.

**METHODS:** Forty *H. pylori* infected Balb/c mice were randomly divided into 4 groups: proton pump inhibitor and antibiotics triple treated group, *Lactobacillus fermenti* (*L. fermenti*) treated group, *Lactobacillus acidophilus* treated group and normal saline control group. Ten uninfected mice were also included as blank control group. The infection of *H. pylori* was detected by rapid urease tests, Giemsa staining and bacterial culture. The colonization of *H. pylori* was assessed in bacterial density score and gastric inflammation was assessed in histological score. The colonization of *L. fermenti* was performed by fluorescent probe.

**RESULTS:** Histopathologic evaluation showed significant release of mucosal inflammation in gastric antrum and gastric body in *Lactobacillus* treated groups and triple treated group. *H. pylori* eradication rate in both *Lactobacillus* treated groups and triple treated group were higher than normal saline control group. *Lactobacillus* treated groups and triple treated group showed significant decrease of *H. pylori* bacterial density.

**CONCLUSION:** Both *Lactobacillus* strains have a significant anti-*H. pylori* activity; *L. fermenti* displays more efficient antagonistic activity *in vivo* against *H. pylori* infection.

Two stomach-originated *Lactobacillus* strains improve *Helicobacter pylori* infected murine gastritis. *World J Gastroenterol* 2010; 16(4): 445-452 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i4/445.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i4.445>

### INTRODUCTION

*Helicobacter pylori* (*H. pylori*) is a spiral-shaped, Gram-negative microaerophilic stomach rod that infects over 50% of the population around the world<sup>[1-3]</sup>, which is considered to be the most important etiological agent of chronic gastritis, peptic ulcer, gastric cancer and mucosa-associated lymphoid tissue<sup>[1,4,5]</sup>. So far, the eradication of

*H. pylori* depends on the combination of antibiotics and acid suppression drugs, with an efficiency of 80%-90%. Unexpectedly, symptoms of 10%-20% patients remain unimproved or reinfected due to the incomplete eradication or antibiotics resistance<sup>[5,6]</sup>. Moreover, the side effect of using multi-antibiotics is obvious, such as antibiotic associated diarrhea, enteric dysbacteriosis, pseudo-membranous colitis, and so on, which lower the curative effect and treatment compliance. Thus attention has been drawn to seek for any alternative method which can eradicate or inhibit *H. pylori* infection efficiently without antibiotics associated side effects.

As mentioned above, over 50% of the population are infected by *H. pylori*, while only a few of them suffer from *H. pylori* associated disease. Some published data showed that when the density of *H. pylori* in gastric antrum drops to less than  $10^5$ , it cannot lead to the formation of gastric and duodenum ulcer<sup>[7,8]</sup>. It is believed that the severity and activity of gastritis is related to the number of bacteria in stomach.

Recently, some reports have suggested that exogenous *lactobacilli* have some inhibitory effects on *H. pylori* infection<sup>[9,10]</sup>, and the colonization of *H. pylori* has a close relationship with the number of *lactobacilli*. It is also reported that *H. pylori* colonization can be inhibited in *lactobacillus* strain *L. salivarius*-fed mice<sup>[11,12]</sup>. Some studies showed that probiotics isolated from dairy products or human feces have suppressive effects on *H. pylori* infection<sup>[9,13]</sup>. Similar results from some clinical trials also support the inhibitory effects of some microbial ecological agents on *H. pylori* associated diseases<sup>[14,15]</sup>.

However, results of clinical trials from some separate groups did not make a definite conclusion. Some studies showed that it is effective to prevent and treat *H. pylori* infected diseases by administering *lactobacillus* or fermented dairy products<sup>[13,16,17]</sup>. Some believe that probiotics have no effect in treating *H. pylori* infected diseases because they are live microbes, and their living environment may change depending on what kinds of food the host takes<sup>[18]</sup>. The possibilities include inappropriate methods to assess the anti-*H. pylori* activity, different strains of probiotics and different origins of strains<sup>[12,19-21]</sup>. Therefore, more detailed studies on more stomach originated probiotic strains will help draw a more definite conclusion.

In the present study, we isolated two stomach originated *lactobacillus* strains, and screened their potential anti-*H. pylori* activity and anti-inflammatory effects on mouse model of *H. pylori*-associated Balb/c gastritis. We found that *lactobacillus* strain *Lactobacillus fermenti* (*L. fermenti*) could adhere to gastric epithelium and displayed antagonistic activity *in vivo* against *H. pylori* infection, thus significantly improving the *H. pylori*-associated Balb/c gastritis in mice.

## MATERIALS AND METHODS

### Bacterial stains and culture conditions

*H. pylori* standard strain SS1 (Sydney strain 1) was kindly

provided by the Infectious Disease Institute of the Chinese Center for Disease Control. The two *lactobacillus* strains *L. fermenti* (CCTCC M 206110) and *Lactobacillus acidophilus* (*L. acidophilus*) (strain LC) were isolated by us from gastric biopsy materials of patients who received endoscopic examination in the Gastroenterology Department of the Second Xiangya Hospital, Hunan, China.

*H. pylori* was resuscitated and inoculated into brain heart infusion broth containing 10% sheep blood, incubated under microaerophilic conditions (5% O<sub>2</sub>, 85% N<sub>2</sub>, 10% CO<sub>2</sub>) at 37°C for 3-5 d. Both *lactobacillus* strains were cultured in Man-Rogosa-Sharpe (MRS) broth, and incubated in anaerobic box at 37°C for 48 h. The concentration of bacteria was regulated to  $1 \times 10^9$  CFU/mL by turbidimetry.

### *H. pylori* infection of Balb/c mice

Sixty specific-pathogen-free 6-8-wk-old Balb/c mice (a male to female ratio of 1:1) were obtained from the Central Animal Facility of Wuhan. They were housed according to relevant Chinese national legislation, fed a commercial diet, and were given water and libitum, except as otherwise stated. *H. pylori* infections by the SS1 strain were induced as follows: freshly prepared aliquots (0.4 mL of  $1 \times 10^9$  CFU/mL) of *H. pylori* SS1 strain in brain heart infusion broth were administered to 50 mice *via* orogastric inoculation 3 times a week (days 1, 3 and 5) at a 1-d interval between inoculations for 2 wk. Accordingly, the other 10 non-infected control animals were inoculated with the same volume of plain brain heart infusion broth. At the end of the 1st and 2nd wk, 5 animals receiving *H. pylori* strain SS1 were sacrificed by carbon dioxide inhalation, and tests were made to confirm whether they were infected with SS1 strain successfully.

The following groups of animals were included in the study: *H. pylori*-infected mice treated by *L. fermenti* (*L. fermenti* group,  $n = 10$ ), *H. pylori*-infected mice treated by *L. acidophilus* (*L. acidophilus* group,  $n = 10$ ), *H. pylori*-infected mice treated by proton pump inhibitor (PPI) and antibiotics (triple group,  $n = 10$ ). The control groups were *H. pylori*-infected mice treated by normal saline solution (NS group,  $n = 10$ ). The non-infected mice (blank control group,  $n = 10$ ) were also included. The quantity of *lactobacillus* was regulated to 0.5 mL of  $1 \times 10^9$  CFU/mL per mouse for *L. fermenti* and *L. acidophilus* groups, and PPI and antibiotics were 0.25 mL of 0.4 mg/mL pantoprazole (Zhongmei East China Pharmaceutical Group Corporation in Hangzhou, 060923), 0.25 mL of 20 mg/mL clarithromycin (Huiren Pharmaceutical Group Corporation in Jiangxi, 0510019), and 0.1 mL of 50 mg/mL ampicillin (North China Pharmaceutical Group Corporation, 060307) per mouse for the triple group. The treatment lasted 10 d, and all animals were sacrificed by carbon dioxide inhalation 4 wk later.

All the methods for the assessment of *H. pylori* colonization and identification in gastric samples as well as evaluation of gastritis will be described in detail below.

### Assessment of *H. pylori* colonization and histopathologic analysis of gastric tissue samples

The stomach of each mouse was removed and dissected longitudinally, the antrum and body were divided and treated separately. One-third of each longitudinal strip was fixed in 10% formalin-buffered saline, embedded in paraffin, and processed for histopathologic analysis. The other two strips were used for rapid urease test and *H. pylori* culture, respectively. Four sections were cut from each paraffin block specimen. Two sections of them were stained with hematoxylin-eosin (HE) for evaluation of gastric inflammation, the other 2 sections were used for Giemsa staining for the assessment of *H. pylori* colonization. The bacterial density was scored from 0 to 4 as follows: Score 0, no bacteria; score 1, 1-2 bacteria on average/crypt; score 2, 3-10 bacteria on average/crypt; score 3, 11-20 bacteria on average/crypt; and score 4, > 20 bacteria on average/crypt<sup>[22]</sup>. The pathologic characteristics were graded for the degree of neutrophil and mononuclear cell infiltration in the antrum and body as follows: Score 1, mildly multifocal; score 2, mildly widespread or moderately multifocal; score 3, mildly widespread and moderately multifocal or severely multifocal; score 4, moderately widespread; score 5, moderately widespread and severely multifocal; and score 6, severely widespread<sup>[8]</sup>. Histopathologic evaluation was performed with no prior knowledge of the identity of the samples by the histopathologist.

### Determination of urease activity

Urease activity was determined by a method based on the commercial rapid urease test (Sanqiang Biochemical Industry Corporation in Fujian, China) with a sensitivity of  $10^2$  bacteria. Following the instruction of the product, each strip of stomach antrum and body was homogenized and placed in 1 mL of the reaction solution [1 g of urea/mL (wt/vol) containing 850 µg phenol red/mL (wt/vol) as a pH indicator]. The solution became pink or red or dark red within 5 min as positive result, still yellow as negative.

### *H. pylori* culture

Each sample of stomach antrum and body was homogenized and suspended in 500 µL brain heart infusion broth containing 10% sheep blood, and 100 µL was inoculated onto brain heart infusion agar plates and cultured under microaerophilic conditions at 37°C for 5-7 d. Gram's staining and urease activity were detected.

### Standard of *H. pylori* infection

When at least two of the three tests of rapid urease test, *H. pylori* culture and Giemsa staining for the assessment of *H. pylori* colonization, appeared positive, *H. pylori* infection could be diagnosed.

### Standard of *H. pylori* eradication

When the three tests of rapid urease test, *H. pylori* culture

and Giemsa staining of gastric mucosa samples were all negative, the eradication was confirmed to be successful.

### Labeling of bacteria with fluorescent probe

A 100 µmol/L stock solution of fluorescence-labeled molecular probe (cFDA-SE, Invitrogen Corporation) was prepared, which was first dissolved in 90 µL dimethyl sulfoxide and then further diluted in ethanol (1 mL; reagent grade). This solution was then filter sterilized (0.2-µm-pore-size Acrodisc filter; Gelman) before being aliquoted and stored at -20°C.

*L. fermenti* was grown overnight at 37°C in MRS broth. The bacterial culture was centrifuged at 3000 r/min for 10 min, and the pellet was washed twice in sterile phosphate-buffered saline (PBS). The concentration of bacteria was regulated to  $1 \times 10^{10}$  CFU/mL prior to labeling with 50 µm cFDA-SE at 37°C for 20 min. Fluorescent labeling was terminated by pelleting the bacteria, washing twice in PBS to remove excessive cFDA-SE, and resuspending the pellet in PBS.

### Animals

A group of 30 mice were administered orally with approximately  $10^9$  cFDA-SE-labeled *L. fermenti* by orogastric intubation. The other group of 6 mice that had been orally fed with sterile PBS served as controls. The food and water intake for the experimental and control mice was measured daily. Groups of 6 mice each were sacrificed at 2, 4, 8, 12 and 24 h after cFDA-SE. The stomach and duodenum of each mouse was divided and dissected longitudinally, any visible residual food particles were removed. Both specimens were examined for the adherence of cFDA-SE-labeled *L. fermenti*. PBS 150 µL was added to each 1.0 cm of the tissue and microbes from the mucosal surface were dislodged by a plunger from a syringe (1.0 mL), then fixed with formaldehyde (0.75%, vol/vol) prior to the detection under fluorescence microscope (Nikon E80, Japan).

### Fluorescent microscopic detection

Enumeration of cFDA-SE-labeled *L. fermenti* was conducted under a fluorescent microscope (Nikon E80, Japan) at a 488-nm excitation wavelength. Upon excitation at 488 nm under the fluorescent microscope, cFDA-SE gave a maximal emission signal in the green at 518 nm.

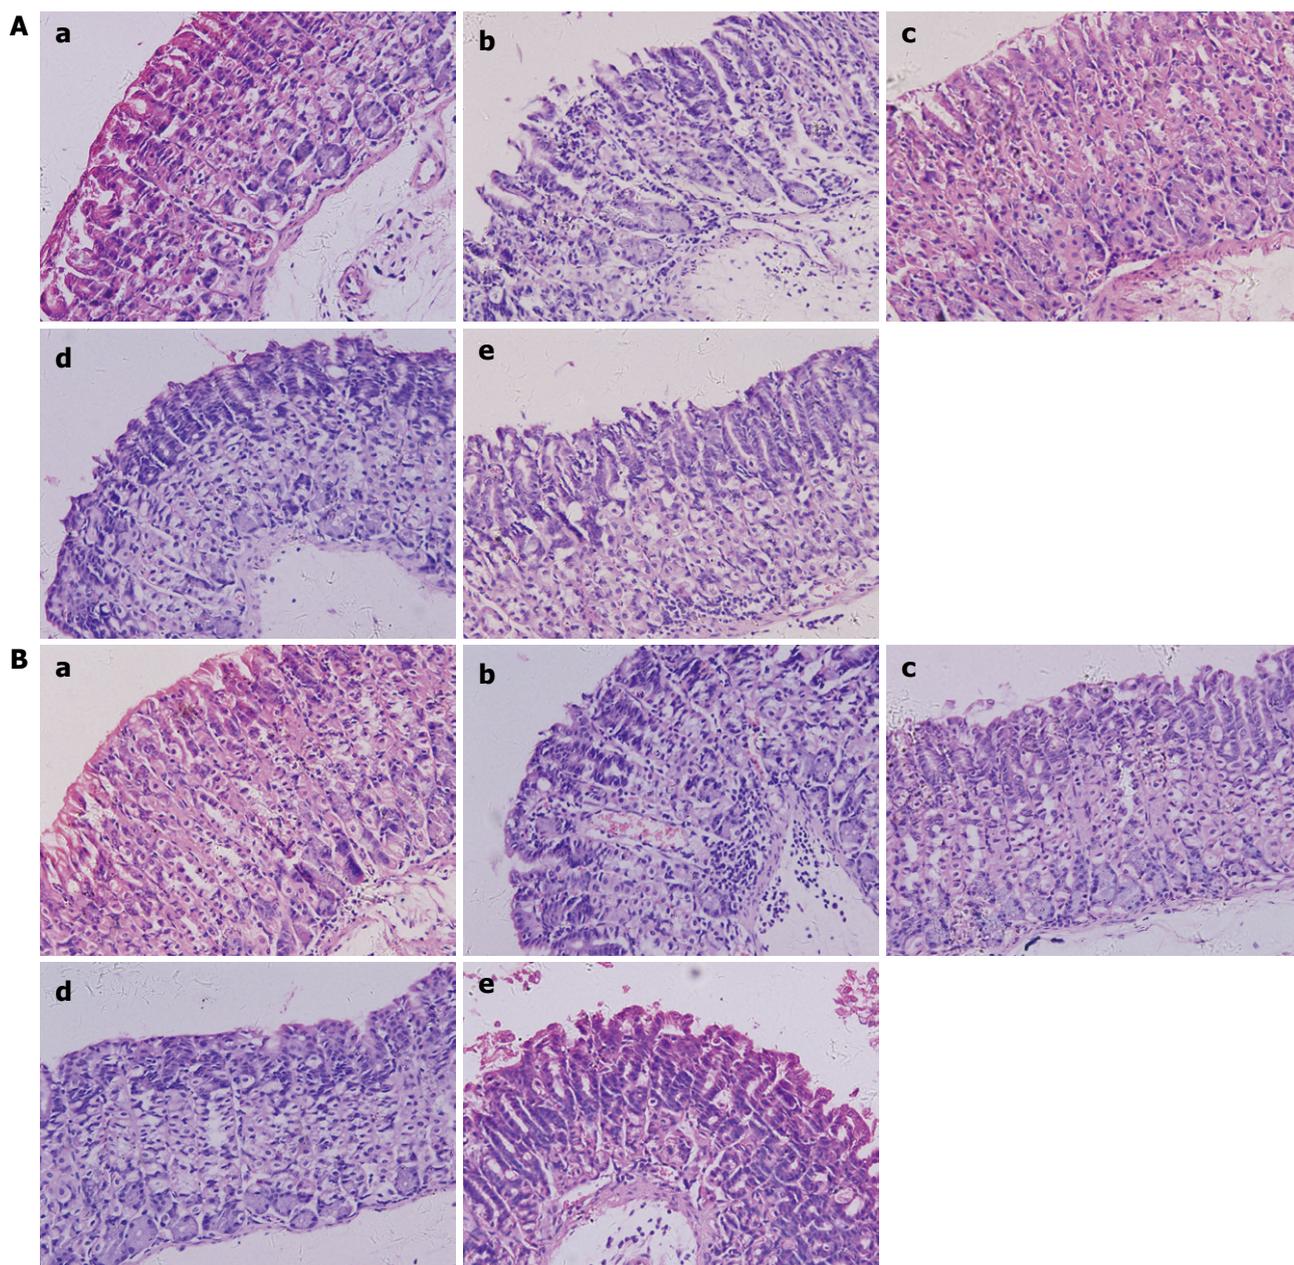

### Statistical analysis

Statistical analyses were performed using SPSS for Windows, version 13.0. Results were expressed as measurement data and enumeration data. For statistical comparisons, *t* test and  $\chi^2$  test were performed and  $P < 0.05$  was considered statistically significant.

## RESULTS

### Evaluation of mucosal inflammation in stomach

Histopathologic evaluation revealed significant improvement of mucosal inflammation in gastric antrum and

**Figure 1** Histological image of gastric antrum and gastric body. A: Histological image of gastric antrum. a: Normal group, normal mucosa, no mucosal erosion; b: NS group, extensive inflammation in the mucosal layer, massive mixed cell infiltration (mainly mononuclear); c: Triple group, slight inflammatory cell infiltration; d: *L. fermenti* group, a few incomplete mucosa; e: *L. acidophilus* group, slight inflammation with moderate cell infiltration, (HE, light microscope, × 200); B: Histological image of gastric body. a: Normal group, normal mucosa, no mucosal erosion; b: NS group, extensive inflammation in mucosal layer, even in submucosal layer with massive mixed cell infiltration; c: Triple group, a few incomplete mucosa, slight inflammatory cell infiltration; d: *L. fermenti* group, almost normal mucosa, slight cell infiltration; e: *L. acidophilus* group, moderate inflammation with cell infiltration in submucosa (HE, light microscope, × 200).

gastric body both in lactobacillus treated as well as triple treated groups. The score of pathologic characteristics of the gastric mucosa also showed obvious decrease. The score of *L. fermenti* treated group was significantly lower than normal saline control group, and almost similar as triple treated group and blank control group. The score of *L. acidophilus* treated group was also lower than normal saline control group and close to triple treated group. The score of *L. acidophilus* group in gastric body was similar to the blank control group, while it was higher in gastric antrum (Figures 1 and 2).

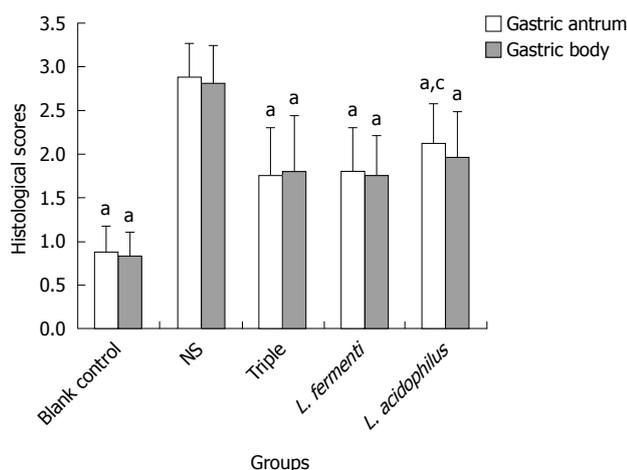

#### Effects of lactobacillus on *H. pylori* eradication rate

The *H. pylori* infection rate in normal saline control group indicated that the model was made successfully while the rate of *H. pylori* infection in blank control group suggested that there was no pollution in environment and diet. We found a significant increase of *H. pylori* eradication rate in lactobacillus treated groups and triple treated group. The eradication rate of *H. pylori* in *L. fermenti* treated group was higher than the normal saline control group and close to that in PPI triple treated group. The eradication rate of *H. pylori* in *L. acidophilus* treated group was higher than

**Table 1** Infection and eradication rate of *Helicobacter pylori* ( $n = 10$ ) (%)

Treatment	Infection rate		Eradication rate	
	Gastric antrum	Gastric body	Gastric antrum	Gastric body
Triple group	30.0 <sup>a</sup>	30.0 <sup>a</sup>	70.0 <sup>a</sup>	70.0 <sup>a</sup>
<i>L. fermenti</i> group	30.0 <sup>a</sup>	40.0 <sup>a</sup>	70.0 <sup>a</sup>	60.0 <sup>a</sup>
<i>L. acidophilus</i> group	50.0	50.0	50.0	50.0
NS group	80.0	80.0	20.0	20.0
Blank control group	0.0 <sup>a</sup>	0.0 <sup>a</sup>	0.0 <sup>a</sup>	0.0 <sup>a</sup>

<sup>a</sup> $P < 0.05$  vs normal saline group.

**Figure 2** Histological score of all groups (mean ± SD,  $n = 10$ ). <sup>a</sup> $P < 0.05$  vs NS group. The highest score was  $2.88 \pm 0.38$  in gastric antrum and  $2.82 \pm 0.42$  in gastric body in NS group. <sup>c</sup> $P < 0.05$  vs blank control group.

the normal saline control group, but without significant statistical difference (Table 1).

### Effects of *Lactobacillus* on *H. pylori* colonization

*Lactobacillus* treated groups and triple treated group showed significant decrease of *H. pylori* bacterial density. In *L. fermenti* treated group, the bacterial density was lower than the normal saline control group and close to PPI triple treated group. The bacterial density in *L. acidophilus* treated group is lower than the normal saline control group, however it was statistically insignificant (Figure 3).

### Detection of *Lactobacillus L. fermenti* colonization

The fluorescence intensity indicated the colonization of *Lactobacillus* at various time points after orogastric intubation. The bacteria were not uniformly labeled by cFDA-SE, probably due to the physiological status of the bacteria at the time of incubation with cFDA-SE (Figure 4).

## DISCUSSION

*H. pylori* is a spiral-shaped, gram-negative organism that commonly causes chronic infections and is usually acquired in childhood<sup>[23]</sup>. Patients with complications (e.g.

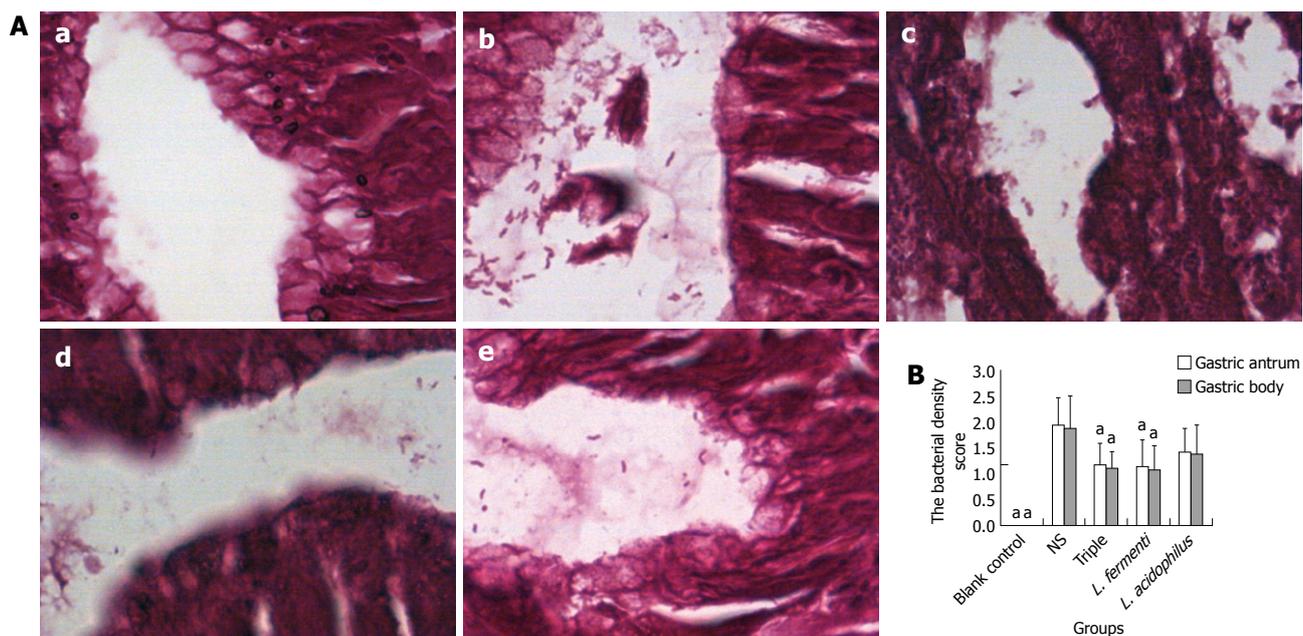

gastritis, ulcer and malignancy) should have the organism eradicated. So far, *H. pylori* can be typically eradicated using a combination of certain antibacterial agents and antacid treatment, which resulted in dramatic reduction in ulcer recurrence and associated complications. The efficacy of recommended eradication regimens is approximately 80%. In our study, standard *H. pylori* SS1 strain was used to colonize the stomach of Balb/c mouse, with an infection rate of 80.0% in gastric antrum and gastric body. This leads to the development of gastric mucosa inflammation closely mimicking human *H. pylori* associated gastritis. The eradication efficacy of *H. pylori* in our study was around 70.0% based on typical triple therapy, which proved that the mouse model of *H. pylori* infection was made successfully and could be established as an animal model to assess anti-*H. pylori* activities of potential therapeutic agents.

A recent clinical trials demonstrated that the addition of Will yogurt to triple therapy increased the *H. pylori* eradication rate by per-protocol (PP) analysis<sup>[14]</sup>. Another clinical study showed that some probiotics, such as *L. johnsonii* LA1, could be used as an adjuvant of antibiotic-antacid treatment to prevent the reemergence of *H. pylori* infection in humans<sup>[19]</sup>. It indicated that the addition of probiotics to PPI-based triple therapy could increase the likelihood of successful *H. pylori* eradication.

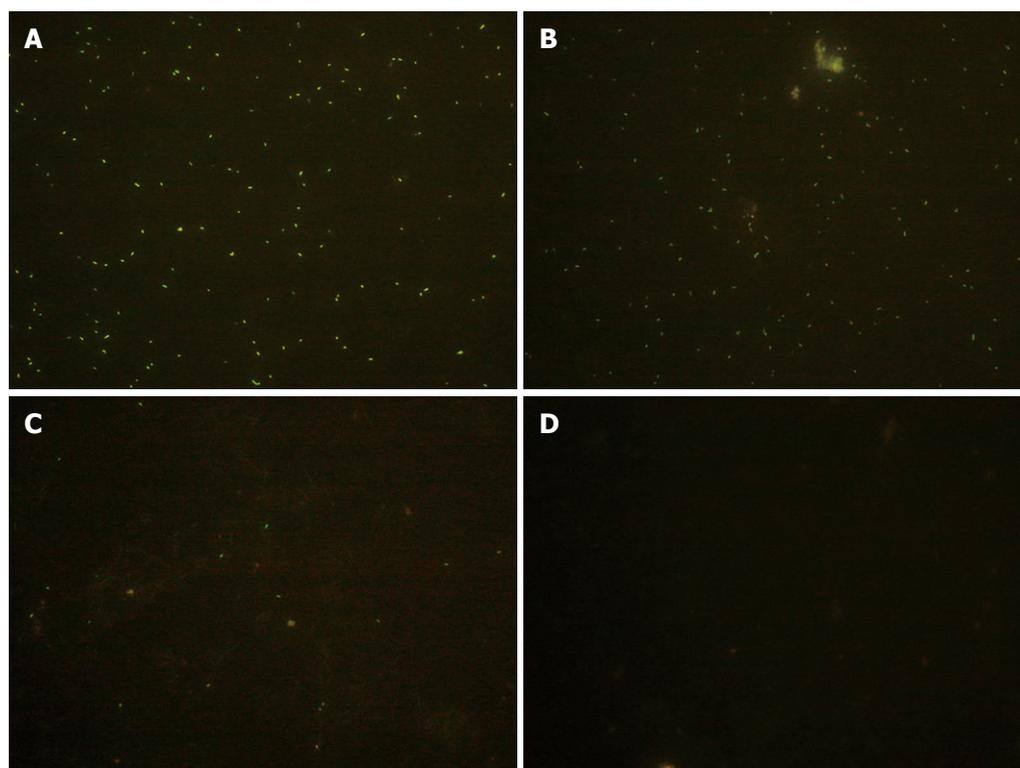

In our study, histopathologic changes on *H. pylori* SS1 mouse model showed a significant release of mucosal inflammation in both gastric antrum and gastric body in *Lactobacillus* strain *L. fermenti* and *L. acidophilus* treated groups and triple treated group. While the histological score of *L. acidophilus* treated group was higher than *L. fermenti* treated group and triple treated group. It showed that oral administration of *L. fermenti* strain could alleviate the gastric inflammation in *H. pylori*-infected Balb/c mouse model, with less significance in strain *L. acidophilus* treated group.

Accordingly, *Lactobacillus* treated groups and triple treated group showed a significant decrease of *H. pylori* bacterial density, with an eradication rate of *H. pylori* 70.0% in gastric antrum and 60.0% in gastric body in *L. fermenti* treated group, which was obviously higher than the normal saline control group and close to that in the triple treated group. The eradication rate of *H. pylori* in *L. acidophilus* treated group was 50.0% in gastric antrum and gastric body, being higher than the normal saline control group, but without statistical difference. It indicates that different *Lactobacillus* strains have various anti-*H. pylori* effects due to different *H. pylori* density and *H. pylori* eradication rate.

Our data from the SS1 mouse model with reference to *H. pylori* colonization were in agreement with the histopathological changes among different groups. *L. fermenti* can inhibit the colonization of *H. pylori* in gastric mucosa so as to improve its inflammatory injury. In the *L. fermenti* strain group, we observed a significant reduction of *H. pylori* colonization in the gastric mucosa

**Figure 3 Bacterial density and bacterial density score of *H. pylori*.** A: Bacterial density of *H. pylori*. a: Normal group, no detectable *H. pylori*; b: NS group, over 10 *H. pylori* were detected in one field of view; c: Triple group; d: *L. fermenti* group; e: *L. acidophilus* group, (Giemsa, light microscope, × 1000). B: Bacterial density score of *H. pylori*. mean ± SD, n = 10. <sup>a</sup>P < 0.05 vs NS group. The highest score was 1.95 ± 0.52 in gastric antrum and 1.88 ± 0.63 in gastric body in NS group.

**Figure 4 Fluorescent microscopic detection of *L. fermenti* labeled with cFDA-SE.** A: 2 h, a diffusely distributed cFDA-SE labeled bacteria under fluorescent microscopy; B: 4 h, slightly reduced in comparison with 2 h; C: 8 h, cFDA-SE labeled bacteria reduced obviously; D: Blank control group, no cFDA-SE labeled bacteria was detected.

throughout the entire observation period. Continuous administration of *L. acidophilus* did not reduce the *H. pylori* colonizing numbers over this experimental period. These indicate that some strains of lactobacillus can

colonize in gastric mucosa and exhibit anti-*H. pylori* colonization. These strains due to their differences in species and specificity can lead to different anti-*H. pylori* activities. Detection of living bacteria under fluorescent

microscope provided evidence of colonization of the stomach and duodenum by *L. fermenti*. The appearance of *L. fermenti* supports the idea that they come from the supplement.

As it is known, lactobacilli are components of the normal intestinal flora of healthy humans which exert antagonistic activities against pathogens<sup>[7,9,10,16]</sup>. In particular, it has been reported that the primary microorganisms associated with the stomach belong to the genus *Lactobacillus*. *Lactobacillus* earn particular capacity to survive and develop in an acidic environment and live as an indigenous bacterium in gastric mucosa, which can effectively inhibit the colonization of *H. pylori*<sup>[11,12,15,21]</sup>. Our study also adds evidence that *H. pylori* can live together with other bacteria and maintain a dynamic equilibrium state. In another word, it is rational to prevent and control *H. pylori* infection by regulating the balance of flora in stomach. Thus *Lactobacillus* can be a choice to replace antibiotics or as an adjuvant to antibiotics in treating *H. pylori*-infected diseases.

In conclusion, both *Lactobacillus* strain *L. fermenti* and *L. acidophilus*, which are isolated from human gastric mucosa, showed significant anti-*H. pylori* activity, while strain *L. fermenti* displayed more efficient antagonistic activity *in vivo* whose efficacy is close to the standard triple therapy, thus significantly improving the *H. pylori*-associated Balb/c gastritis. It would be of great interest to further explore the role of such probiotic strains in the complex regulation of anti-*H. pylori* activities and screen for more efficient clinical potential agents.

## COMMENTS

### Background

*Helicobacter pylori* (*H. pylori*) are considered to be the most important etiological agents of chronic gastritis. The eradication of *H. pylori* depends on the combination of antibiotics and acid suppression drugs. Unfortunately, the side effects of antibiotics reduce the curative effect and treatment compliance. Probiotics provides an alternative method which can inhibit *H. pylori* infection efficiently without antibiotics associated side effects.

### Research frontiers

*Lactobacilli* earn particular capacity to survive and develop in an acidic environment and live as an indigenous bacterium in gastric mucosa, which can effectively inhibit the colonization of *H. pylori*. Different strains display different effects on *H. pylori* infected gastritis.

### Innovations and breakthroughs

The study showed that *H. pylori* has some interactions with other microbes in stomach. They live together and maintain a dynamic equilibrium state. Both the strains of *Lactobacillus* isolated from human gastric mucosa showed significant anti-*H. pylori* activity while *Lactobacillus fermenti* (*L. fermenti*) displayed more efficient antagonistic activity *in vivo*. This study also provides evidences of colonization of the stomach and duodenum by *L. fermenti*.

### Applications

The study provides a new clue for the therapy of *H. pylori* associated diseases, which could be prevented and treated by regulating the balance of flora in stomach. Thus *Lactobacillus* can be a choice to replace antibiotics or as an adjuvant to antibiotics in treating *H. pylori*-infected diseases.

### Peer review

In this paper, the authors investigated the potential effects of anti-*H. pylori* activity and anti-inflammation *in vivo* of two *Lactobacillus* strains from stomach. And they found that both *Lactobacillus* strains showed significant anti-*H. pylori*

activity, and *L. fermenti* displayed more efficient antagonistic activity *in vivo* against *H. pylori* infection. This paper gave us a new point of view on the interaction of gastric microbiology and also provided a new clue for *H. pylori* treatment.

### Abstract

**AIM:** To assess the role of IgM and IgG immunohistochemistry (IHC) in the evaluation of autoimmune liver conditions - autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC), and primary sclerosing cholangitis (PSC).

**METHODS:** Forty one biopsies from untreated patients diagnosed with autoimmune liver disease (AIH,  $n = 20$ ; PBC,  $n = 13$ ; PSC,  $n = 8$ ) and fourteen biopsies of patients with chronic hepatitis C were selected. IgM and IgG-positive plasma cells were counted in each sample.

**RESULTS:** A predominance of IgG-positive plasma cells was seen in AIH (90% of cases), PSC (75% of cases), and chronic hepatitis C (100% of cases), while IgM-positive plasma cells predominated in PBC (92.8% of

cases). The IgM /IgG ratio ( $< 1$  or  $\geq 1$ ) accurately distinguished PBC from AIH in 90.9% of cases (sensitivity = 92.3%, specificity = 90%), and PBC from either AIH or PSC in 87.8% of cases (sensitivity = 92.3%, specificity = 85.7%).

**CONCLUSION:** Plasmacytic infiltrates expressing predominantly IgM are characteristic of PBC, while other forms of liver disease analyzed in this study, including AIH, typically show an IgG-predominant plasma cell infiltrate. Our data indicate that IgM and IgG IHC may be a useful tool when PBC is a diagnostic consideration.

### INTRODUCTION

Three major clinicopathologic entities are currently classified as autoimmune liver diseases: autoimmune hepatitis (AIH), primary biliary cirrhosis (PBC), and primary sclerosing cholangitis (PSC). A combination of clinical, laboratory, and pathologic criteria are necessary for the diagnosis of these conditions. Each category of autoimmune liver disease has specific biologic,

prognostic, and therapeutic implications; therefore, an accurate diagnosis is essential.

While liver biopsies represent an important part of the diagnostic evaluation of these patients, significant histopathologic overlap exists among the different autoimmune liver diseases. An important histologic finding in liver biopsies, in this setting, is the presence of plasma cells, which are characteristically found in AIH, but are also commonly present in PBC and PSC, as well as in other forms of liver disease<sup>[1-6]</sup>. Previous studies have shown that assessment of immunoglobulin subclasses in plasma cells by immunohistochemistry (IHC) may be useful in distinguishing PBC from AIH, but the use of such ancillary studies has not yet gained wide acceptance as a diagnostic tool<sup>[7-9]</sup>. Moreover, limited data are available regarding the immunophenotype of plasma cells in PSC. In this study, we evaluate the predominant plasma cell immunoglobulin subclass present in liver biopsies of patients with well-established AIH, PBC, or PSC and assess the diagnostic utility of IgM and IgG IHC in this setting.

## MATERIALS AND METHODS

This study was reviewed and approved by our Institutional Review Board. Liver biopsies from untreated patients diagnosed with autoimmune liver disease at our institution from 1993 to 2006 were selected. Inclusion criteria for patients with AIH were: (1) clinical diagnosis of AIH, according to the international autoimmune hepatitis group scoring system<sup>[10]</sup>, including positive serology for AIH-related autoantibodies [antinuclear antibody (ANA), anti-smooth muscle antibody (ASMA), anti-liver-kidney microsomal antibody (anti-LKM-1), or soluble liver antigen antibody (anti-SLA)]; and (2) liver biopsy showing consistent histopathological findings. For PBC, inclusion criteria were: (1) positive anti-mitochondrial antibody (AMA) serology; (2) elevated alkaline phosphatase levels, and (3) consistent histopathological findings. For PSC, inclusion criteria were: (1) elevated alkaline phosphatase levels, and (2) characteristic cholangiographic findings by endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP). Inclusion criteria for all groups also included availability of adequate paraffin-embedded tissue for immunohistochemical analysis. Exclusion criteria for all autoimmune liver disease groups included evidence of viral hepatitis, clinical suspicion for an alternative underlying etiology for the liver disease, and incompatible histopathological findings. For patients with AIH, PBC, and PSC, all biopsies included in this study were taken as part of the initial diagnostic workup. Patients who received any form of immunosuppressive medication (other than inflammatory bowel disease treatment in cases of PSC) or ursodeoxycholic acid previous to the biopsy procedure were excluded. Utilizing the above criteria, 41 patients were included in the study (AIH,  $n = 20$ ; PBC,  $n = 13$ ; and PSC,  $n = 8$ ). For comparison, we also studied 14 patients with chronic hepatitis C with at least focal plasma

cells identified on HE sections.

Biopsy samples were considered adequate for the purposes of this study if at least 3 complete portal tracts were present. For each biopsy, the length of each tissue fragment was multiplied by its average width (mm) and the total area of the sample (mm<sup>2</sup>) was calculated. Subsequently, all cells morphologically consistent with plasma cells showing unequivocal immunohistochemical expression of either IgM or IgG (Cell Marque, 1:20000) were counted. The absolute number and the concentration of positive cells for each immunoglobulin subtype were assessed. IgM/IgG ratio was analyzed for sensitivity and specificity in the diagnosis of autoimmune liver diseases. Confidence intervals for these values are determined by a score interval<sup>[11]</sup>. For cases of AIH, PSC, and chronic hepatitis C, the degree of fibrosis was assessed in each case using the Batts-Ludwig staging system. Histological staging of PBC cases was performed using Ludwig's classification.

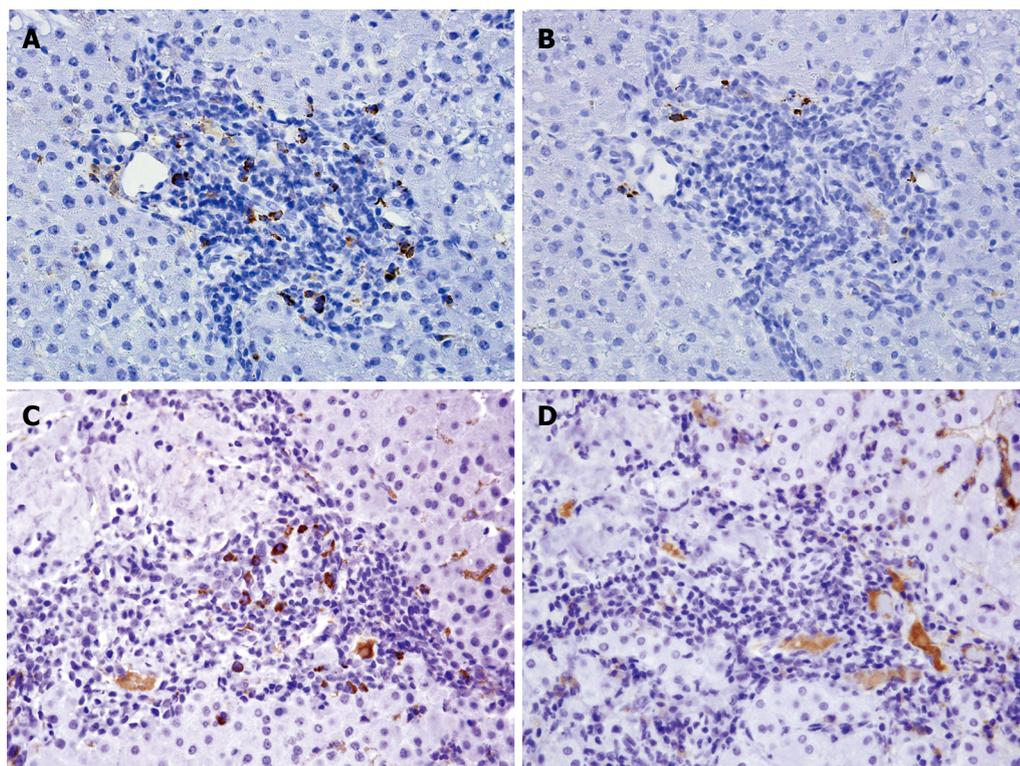

## RESULTS

Twenty patients had a diagnosis of AIH (8 males, 12 females, mean age 32, range 4-63), all of whom had positive antinuclear antibody (ANA) serology. Two pediatric patients had positive anti-smooth muscle antibody serology in addition to a positive ANA. Associated autoimmune conditions included thyroid dysfunction (3 patients), rheumatoid arthritis (1 patient), vitiligo (1 patient), and alopecia (1 patient). One patient was diagnosed with drug-induced AIH while receiving minocycline treatment for acne. Fifty percent of AIH patients had early stage fibrosis (stages 0-2) and 50% had advanced fibrosis (stages 3 and 4).

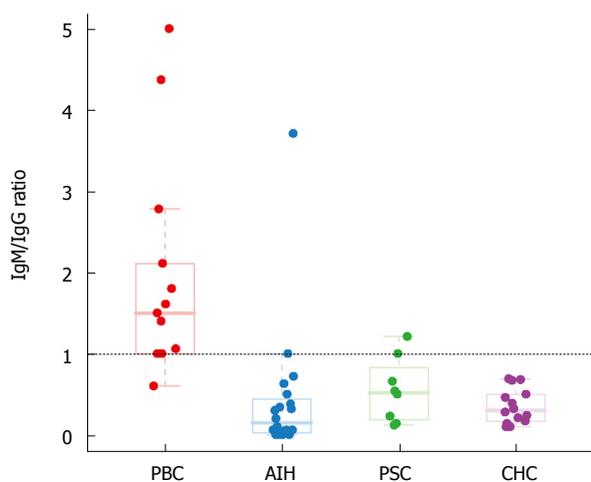

Thirteen patients had a diagnosis of PBC (1 male, 12 females, mean age 52, range 43-71). Associated autoimmune conditions included sicca syndrome (26% of patients), and hypothyroidism (6% of patients). PBC patients were staged as following: stage 1 (3/13, 23%), stage 2 (7/13, 54%), stage 3 (3/13, 23%), stage 4 (1/13, 6.6%). Typical florid duct lesions were seen in 3/13 (23%) of PBC patients (stage 2, two patients; stage 3, one patient).

Eight patients had a diagnosis of PSC (6 males, 2 females, mean age 31, range 7-67), including characteristic findings on endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP). Fifty percent of PSC patients had early stage fibrosis (stages 0-2), and 50% had advanced fibrosis (stages 3 and 4). Typical periductal fibrosis was seen in only 2 cases. Additional histologic findings included mild-moderate chronic lymphoplasmacytic portal inflammation, and bile ductular proliferation (8/10 patients). Associated conditions included ulcerative colitis (4/8, 50%), and Crohn's disease (2/8, 25%).

Fourteen patients with chronic hepatitis C infection were also included (9 males, 5 females, mean age 50, range 36-66). All patients in this group had documented

**Figure 1** Immunoglobulin expression in autoimmune hepatitis and primary biliary cirrhosis. IgG-positive plasma cells (A) outnumber IgM-positive plasma cells (B) in most cases of autoimmune hepatitis (AIH); In contrast, IgM-positive plasma (C) cells predominate over IgG-positive cells (D) in the majority of cases of primary biliary cirrhosis (PBC). IgG background staining within sinusoids and blood vessels is common due to the presence of serum IgG. (Immunohistochemistry, 400 × magnification).

**Figure 2** IgM/IgG ratio distinguishes the majority of cases of primary biliary cirrhosis (IgM/IgG ratio  $\geq 1$ ) from all other groups (IgM/IgG ratio  $< 1$ ). Single outlier in the AIH group was diagnosed with AIH-PBC sequential syndrome based on subsequent serology and pathological data (see discussion). Abbreviations: PBC: Primary biliary cirrhosis; AIH: Autoimmune hepatitis; PSC: Primary sclerosing cholangitis; CHC: Chronic hepatitis C.

chronic viral hepatitis C infection by serum polymerase chain reaction (PCR) (genotype 1,  $n = 11$ ; genotype 2,  $n = 2$ ; and genotype 3,  $n = 1$ ). Twelve patients underwent liver biopsy for grading and staging (native liver biopsies). Two patients had recurrent hepatitis C post liver transplantation. Interpretation of liver biopsy in all cases was consistent with hepatitis C (stage 0,  $n = 1$ ; stage 1,  $n = 2$ ; stage 2,  $n = 6$ ; stage 3,  $n = 3$ ; stage 4,  $n = 2$ ).

The combined number of IgG and IgM+ plasma cells in AIH (average = 9.75 cells/mm<sup>3</sup>) was higher than that seen in CHC, PBC or PSC (average = 6.90, 6.19

and 5.16 cells/mm<sup>2</sup>, respectively,  $P < 0.05$ ). In all cases, plasma cells were present predominantly within the portal tracts.

We found a predominance of IgG+ plasma cells in AIH (90% of cases), in PSC (75% of cases), and in chronic hepatitis C (100% of cases), while the majority of plasma cells in PBC were IgM positive (92.3% of cases) (Figures 1 and 2). An IgM/IgG ratio  $\geq 1$  showed high sensitivity and specificity for the distinction of PBC from other groups included in the study and accurately distinguished PBC from AIH in 90.9% (30/33) of cases, PBC from either AIH or PSC in 87.8% (36/41) of cases, and PBC from all other groups in 90.9% (Table 1). There was no correlation between age or gender and IgM/IgG ratio in any of the study groups.

## DISCUSSION

Typical cases of autoimmune liver diseases do not usually represent diagnostic dilemmas from a histopathologic standpoint. However, diagnostic findings are sometimes absent in liver biopsies of autoimmune liver diseases, and consideration of various entities has to be entertained in the differential diagnosis<sup>[12-14]</sup>.

Chronic inflammatory infiltrate, often plasma cell-rich, is a common feature in all autoimmune liver diseases<sup>[15]</sup>. There is evidence to suggest that the identification of the predominant immunoglobulin (Ig) subclasses within plasma cells in liver biopsies may be useful in the differential diagnosis of autoimmune liver diseases. van Spreuwel *et al*<sup>[8]</sup>, in 1984, studied eight patients with PBC and 18 patients with “chronic hepatitis” (which included patients with hepatitis B, as well as patients diagnosed as

**Table 1** IgM/IgG ratio in PBC compared to other autoimmune liver conditions

	Sensitivity (95% CI)	Specificity (95% CI)	Likelihood ratio - positive test (95% CI)	Likelihood ratio - negative test (95% CI)	Accuracy
PBC <i>vs</i> AIH	92.3% (66.7-98.6)	90.0% (69.9-97.2)	9.23 (2.45-34.69)	0.085 (0.012-0.56)	90.9% (30/33)
PBC <i>vs</i> AIH or PSC	92.3% (66.7-98.6)	85.7% (68.5-94.3)	6.46 (2.57-16.22)	0.089 (0.013-0.59)	87.8% (36/41)
PBC <i>vs</i> all others	92.3% (66.7-98.6)	90.5% (77.9-96.3)	9.69 (3.76-24.94)	0.085 (0.012-0.56)	90.9% (50/55)

“chronic persistent hepatitis” and “chronic aggressive hepatitis”). The authors found a significantly higher absolute and relative number of IgM-positive plasma cells, by immunohistochemistry, in patients with PBC compared to patients with chronic hepatitis. The increased number of plasma cells correlated with increased serum levels of IgM in PBC patients.

Milne *et al*<sup>[7]</sup>, in 1990, studied 14 patients with PBC and 14 patients with “chronic active hepatitis” (which included patients with hepatitis B, ANA-positive hepatitis, and idiopathic chronic hepatitis). Using immunohistochemistry for IgA, IgM, and IgG, the authors found a predominance of IgA and IgG expression in plasma cells in “chronic active hepatitis”, while IgM and IgG represented the main Ig classes seen in cases of PBC. In both studies, all cases of PBC had positive AMA serology, increased alkaline phosphatase levels, and histopathological findings which were consistent with the diagnosis. However, the “chronic hepatitis” group was heterogeneous and included patients with hepatitis B, as well as other forms of chronic hepatitis, then classified as “chronic active hepatitis” and “chronic aggressive hepatitis”, which may have included cases of hepatitis C and autoimmune hepatitis by current diagnostic standards.

Recently, Daniels *et al*<sup>[9]</sup> specifically studied the immunophenotype of plasma cells in the differential diagnosis of PBC and AIH. Thirty eight patients with AIH and 18 patients with PBC were included. All cases of AIH showed an IgG-predominant plasma cell infiltrate, while IgM prevailed over IgG in 88% of PBC cases upon qualitative analysis of IHC slides (back-to-back comparison).

In the present study, we included untreated patients meeting strict clinical and pathologic diagnostic criteria for both AIH and PBC. In addition, we also included patients with PSC, which were not included in previous studies, as this condition may also be a diagnostic consideration in this setting. A group of hepatitis C patients was included for comparison.

Our results clearly show that most cases of PBC expressed a characteristic IgM/IgG immunophenotype. There was an obvious predominance of IgM expression in plasma cells of patients with PBC (92.3% of patients), compared to an IgG-predominant expression in the majority of plasma cells in patients with AIH (90% of cases), PSC (75% of cases), and CHC (100% of cases). Among the groups of patients included in this study, the differential diagnosis between AIH and PBC is likely the

most challenging from a histopathological perspective. The IgM/IgG ratio ( $< 1$  or  $\geq 1$ ) accurately distinguishes PBC from AIH in over 90% of cases (sensitivity = 92.3%, specificity = 90%). A high sensitivity and specificity (92.3% and 90.5%, respectively) was also found for the distinction between PBC and all other groups combined (Table 1).

Interestingly, in 1 case of autoimmune hepatitis which showed a very high IgM/IgG ratio, similar to that seen in the PBC group, a positive antimitochondrial antibody (titer  $> 1:160$ ) was detected on clinical follow-up (AMA serology was negative on initial evaluation). A second liver biopsy of this patient showed lymphoplasmacytic portal inflammation and associated prominent ductocentric granulomatous inflammation with significant bile duct destruction (florid duct lesion). A diagnosis of AIH-PBC sequential syndrome was rendered 3 years after the initial biopsy. This patient remained in the AIH group of this study because criteria for AIH were met at the time of initial biopsy. Although only 1 case of overlap syndrome was identified in our database, the fact that plasma cells predominantly expressed IgM in both the initial and the follow-up biopsies is intriguing. This raises the question of whether immunohistochemistry for specific immunoglobulins could provide additional information (i.e. identify a PBC-like pattern) in the setting of suspected overlap syndrome, or even in otherwise typical autoimmune hepatitis.

PSC cases showed a predominance of IgG+ plasma cells in most cases, although a significant number (25%) showed a predominance of IgM+ plasma cells. In most cases of PSC, however, the total number of plasma cells was low, and sampling error may have occurred during the evaluation of individual cases as IgM or IgG-predominant.

Among our chronic hepatitis C samples (15 cases selected from 30 consecutive cases of chronic hepatitis C), a plasmacytic component was present within the lymphocyte-predominant infiltrate in all cases. Because the cases were selected on the basis of presence of plasma cells, an obvious selection bias is present. However, since 15 of 30 consecutive cases were included, it is clear that plasma cells are common in our chronic hepatitis C population. All biopsies from hepatitis C patients showed predominantly IgG-producing plasma cells.

Overall, IgG was the predominant immunoglobulin subclass produced by plasma cells in all groups included in this study, except for the PBC group, in which an IgM-predominant plasma cell population is seen in the majority of cases. From a diagnostic standpoint, we believe

that plasma cell-rich infiltrates seen on liver biopsies with IgM/IgG ratio  $\geq 1$  should alert the pathologist to the possibility of PBC, while an IgM/IgG ratio  $< 1$  renders a diagnosis of PBC significantly less likely. IgG-predominant infiltrates, although characteristically present in AIH, are relatively nonspecific and may be seen in a variety of conditions.

In conclusion, the histological features of the different autoimmune liver diseases may overlap considerably in some cases. While the plasma cell-rich infiltrates seen in several forms of liver disease predominantly express IgG, PBC seems to be an exception, as most plasma cells in these patients express IgM. Our data indicates that a predominantly IgM+ plasma cell infiltrate, although not pathognomonic, should strongly support the diagnosis of PBC. The IgM/IgG ratio is particularly helpful distinguishing PBC from AIH.

## COMMENTS

### Background

Increased numbers of plasma cells may be present on liver biopsies of autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis patients, and the histopathologic distinction of these entities may be difficult in some cases. Identification of characteristic immunohistochemical phenotypes of plasma cells in such cases could be useful in the differential diagnosis between the different entities in this group of diseases.

### Research frontiers

Previous studies have shown that assessment of immunoglobulin subclasses in plasma cells by immunohistochemistry may be useful in the histopathologic evaluation of autoimmune liver diseases. However, further studies are necessary in order to validate the diagnostic utility of IgM and IgG immunohistochemistry in this specific scenario.

### Innovations and breakthroughs

The histopathologic evaluation of autoimmune liver diseases has relied almost exclusively on morphologic features seen on routine stains. In this study, the authors describe the potential application of IgM and IgG immunohistochemistry in the setting of autoimmune liver diseases, especially in the differential diagnosis of PBC from other conditions. The authors have demonstrated that an IgM-predominant plasmacytic infiltrate is typical of PBC but uncommon in other forms of chronic liver disease.

### Applications

The characterization of plasma cells in liver biopsies of autoimmune liver disease patients by IgM and IgG immunohistochemistry may be very useful in selected cases and may serve as an adjunct method to conventional histopathologic evaluation.

### Terminology

Autoimmune liver disease refers to a group of chronic liver conditions that includes autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis.

### Peer review

The authors have drawn attention to the preponderance of IgM-positive

plasma cells in liver biopsies of patients with PBC, thereby providing a tool for differentiating PBC from a series of other liver conditions.

### Abstract

**AIM:** To find if patients are interested in obtaining a video recording of their colonoscopy procedure.

**METHODS:** We conducted a survey of outpatients presenting for colonoscopy regarding their interest in obtaining a video recording of their colonoscopy.

**RESULTS:** Two hundred and forty-eight patients (mean age 57.9 years; 57% male) were surveyed. Two hundred and one patients (81%) were interested in obtaining a video recording. No significant predictors of patients' interest in the video recording were identified. After reading a brief educational paragraph explaining missed lesions during colonoscopy, 135 patients (54%) were more interested in having a video recording, and none were less interested. One hundred and fifty-six patients (63%) were willing to pay for a video recording. In multivariable analyses, younger age was predictive of willingness to pay for a video recording. Prior history of colorectal cancer and a family history of colorectal cancer were predictive of willingness to pay a greater amount.

**CONCLUSION:** Patients undergoing colonoscopy expressed substantial interest in obtaining a videore-

ording of their procedure. Awareness of missing lesions during colonoscopy increased interest in having a videorecording.

### INTRODUCTION

There is increasing awareness that colonoscopy fails to prevent a substantial fraction of colorectal cancers<sup>[1-8]</sup> and that the performance of colonoscopy is highly operator dependent<sup>[9,10]</sup>. Some studies that have demonstrated imperfect protection<sup>[8]</sup> and operator dependency<sup>[9]</sup> have received considerable lay press attention. Recent studies have suggested that there is less protection against colorectal cancer by colonoscopy in the proximal compared to the distal colon<sup>[8,11]</sup>. Part of the cause of inadequate right colon protection might be exaggeration of cecal intubation rates by poorly trained colonoscopists<sup>[8]</sup>. Indeed, colonoscopies are often poorly documented with regard to cecal intubation, and reports claiming cecal intubation often fail to document cecal landmarks by notation or photography<sup>[12]</sup>.

We reasoned that as awareness of operator dependency of colonoscopy increases, some patients might be interested in obtaining a video recording of their colonoscopy, either as a way of ensuring that their examination was of high quality, or based on interest in viewing

the procedure, because patients are often not able to watch the examination in real-time.

Therefore, we conducted a survey of patients undergoing colonoscopy at Indiana University Hospital as to their interest in obtaining a video recording of their procedure and their willingness to pay for the recording.

## MATERIALS AND METHODS

The survey was conducted in 250 patients presenting to Indiana University Hospital or an ambulatory surgery center associated with the hospital. Permission to perform the survey was granted by the Institutional Review Board at Indiana University/Purdue University Indianapolis/Clarian Health Partners.

The survey identified age, gender, occupation, whether and how many prior colonoscopies the patient had undergone, any personal history of colorectal polyps or cancer, family history of colorectal cancer, and whether they owned a digital versatile disc (DVD) player. Patients were asked whether they would be interested in owning a video recording of their colonoscopy and were asked for an explanation of their response.

In the second part of the survey, there was a brief educational paragraph explaining miss rates during colonoscopy. Patients were asked if this explanation made them more or less likely to want a video recording. Patients were asked about their willingness to pay for the video recording and the amount they would pay. The paragraph read by the patients was as follows: "Colonoscopists have been shown to vary 4- to 10-fold in the number of precancerous polyps they detect and remove during colonoscopy. This means that some colonoscopists miss more than half of the precancerous polyps in the colon. Does this information make you: (A) Less likely to want a digital recording of your colonoscopy? (B) More likely to want a digital recording of your colonoscopy? (C) No change in your decision for a digital recording of your colonoscopy".

The surveys were conducted by a physician trained in internal medicine. The study was considered exploratory and the sample size was arbitrary. Patients were consecutive to the extent that the survey administrator was available and not already occupied with conducting a survey.

Chi square tests and logistic regression were used to determine whether the survey items were significant predictors of the desire to have a video recording of the colonoscopy and of willingness to pay for the video recording. Two-sample *t*-tests and correlation coefficients were used to determine how much patients were willing to pay. The amounts were analyzed two ways: (A) using only those patients who answered they were willing to pay and (B) using all patients, with those who answered they were unwilling to pay recorded as willing to pay zero dollars. To examine multiple-variable models, a backward elimination procedure was used, with all variables individually significant at  $P < 0.30$  included initially, and then removing variables one at a time until only variables with  $P$  values  $< 0.05$  remained.

## RESULTS

Two hundred and fifty patients were approached to answer the survey. One patient refused to participate and one was excluded due to inconsistent information. One patient did not answer whether they wanted a DVD, and a few data points were missing from other surveys (Tables 1 and 2). Thus, 248 patient surveys were available for analyses. Patients ranged in age from 19 to 87 years (mean 57.9 years). There were 238 patients (96%) who owned DVD players. There were 141 (57%) males, 183 (74%) had undergone a prior colonoscopy, and 123 (50%) had a prior history of polyps. Ten patients (4%) had a personal history of colorectal cancer, while 57 (23%) has a family history of colorectal cancer.

Among the 248 patients, 201 (81%) were interested in obtaining a video recording of their colonoscopy. Among the factors age, gender, prior colonoscopy, polyp history, history of colorectal cancer, and family history of colorectal cancer, none of these predicted desire to have a video recording in univariate analyses. Multivariate analysis confirmed that none of the factors was associated with an interest in obtaining a video recording (Table 1).

After a brief educational paragraph regarding polyp miss rates, interest in obtaining a video recording of colonoscopy was reassessed. One hundred thirty-five patients (54%) were more interested in video recording and none were less interested.

The most common reason for interest in having a video recording was "review" (68 patients, 27%), followed by "better records" (55 patients, 22%) and "better information" (43 patients, 17%) (Table 2). The most common reason for lack of interest in obtaining video recording was "no benefit over pictures" (Table 2).

There were 72 males (68%) and 84 females (60%) who stated they would be willing to pay for a video recording of their colonoscopy. A family history of colorectal cancer (odds ratio 2.09; 1.07-4.09) and younger age (odds ratio 1.39; 1.12-1.72 for each 10 year interval of decreasing

age) predicted willingness to pay for a video recording in univariate analyses (Table 3). In a multivariable analysis using a backward elimination procedure to remove non-significant factors, only younger age remained in the model, with a *P* value of 0.002.

With regard to the amount patients were willing to pay, univariate analyses showed that a prior history of colorectal cancer was the only predictor of willingness to pay more (mean \$354 *vs* \$65, *P* = 0.001), if only those willing to pay were considered (Table 4). If patients who were unwilling to pay for a video recording were assigned an amount of zero dollars, so that all patients interested in having a video recording were included, a prior history of colorectal cancer was the only predictor of the amount patients were willing to pay (\$319 *vs* \$40, *P* = 0.0001), though female gender approached significance (\$76 *vs* \$33, *P* = 0.06) (Table 4). In multivariable analysis, prior colorectal cancer (*P* = 0.0003) and a family history of colorectal cancer (*P* = 0.02) were both predictive of a higher amounts patients

were willing to pay, considering only those willing to pay. When all subjects were included, prior colorectal cancer (*P* = 0.0002) and a family history of colorectal cancer (*P* = 0.001) remained predictive of amount willing to pay for a video recording.

**DISCUSSION**

In this study, we report interest among outpatients presenting to Indiana University Hospital and an ambulatory surgery center operated by our gastroenterology group, in obtaining a video recording of their colonoscopy. In our study, of the 248 patient surveys included, the majority (81%) were interested in having a video recording.

Sixty-three percent of patients said they were willing to pay for a video recording of their colonoscopy. Payment by patients could offset the costs of video recording. We found no significant predictors of desire to have a video recording, but a family history of colorectal cancer and younger patients' age predicted willingness to pay for a video recording.

Following the educational paragraph on missed lesions during colonoscopy, 54% of patients showed an increased interest in a video recording. Thus, increasing awareness of imperfect detection by colonoscopy increases interest in video recordings.

While video recordings can differentiate the quality of an individual colonoscopist's examination technique and time<sup>[13,14]</sup>, they are seldom obtained routinely during clinical practice. The impact of simply performing video recording during colonoscopy on quality and medical-legal risk is unknown.

A primary limitation of the study is that we did not actually test willingness to pay for video recordings by offering them for sale. Anecdotally, video recordings

of colonoscopies are rarely made available to patients routinely in the United States, either with or without payment by patients. Our gastroenterology group has not yet decided whether to pursue sale of video recordings as routine practice or to make systematic video recordings for inclusion in medical records. We found that younger age predicted stated willingness to pay for a video recording, and prior colorectal cancer and a family history of colorectal cancer predicted willingness to pay greater amounts.

In summary, a survey of 248 patients undergoing colonoscopy was conducted. The majority expressed interest in obtaining a video recording of their procedure. Awareness of missed lesions during colonoscopy increased patient interest in having a video recording. While there were no predictors of interest in having a video recording, younger patients were more willing to pay for a video recording. Prior colorectal cancer and family history of colorectal cancer predicted willingness to pay more for a video recording. We conclude that patient interest in having a video recording of their colonoscopy is substantial, and that awareness of missed lesions during colonoscopy increases interest in having a video recording. Payment by patients for video recordings is a potential mechanism of offsetting the cost of making video recordings.

## COMMENTS

### Background

Colonoscopy is operator-dependent and substantial numbers of pre-cancerous polyps are missed during colonoscopy. Colonoscopies are often poorly documented, with only a few still photographs taken of anatomic landmarks and abnormal findings.

### Research frontiers

Video recording is rarely used in colonoscopy except for teaching purposes; therefore, the potential impact of systematic video recording on the quality of colonoscopy is unknown. In this study the authors sought to understand patient interest in obtaining video recordings of their colonoscopies, and their willingness to pay for video recordings.

### Innovations and breakthroughs

No previous investigation of this issue has been made. Therefore the whole field of video recording of colonoscopies with regard to its effect on quality and cost, and medical-legal implications, is in its infancy.

### Applications

These results indicate that 81% of patients have interest in obtaining video recordings of their colonoscopy, and for a variety of reasons. Information regarding missed lesions during colonoscopy increases interest. There is some willingness to pay for the video recording, which could in the future help to cover the costs of systematic video recording.

### Terminology

Presently, colonoscopy is typically documented by still photography. Video recording in this paper refers to recording the entire colonoscopy or the withdrawal portion of the examination, and preserving the recording as a permanent record. Systematic digital recording of colonoscopy is becoming increasingly feasible.

### Peer review

The authors conducted a survey of outpatients presenting for colonoscopy of

their interest in obtaining a video recording of their colonoscopy. In my opinion, this paper is interesting.

### Abstract

**AIM:** To compare defecographic abnormalities in symptomatic men and women and to analyze differences between men and age- and symptom-matched women.

**METHODS:** Sixty-six men (mean age: 55.4 years, range: 20-81 years) who complained of constipation and/or fecal incontinence and/or pelvic pain underwent defecography after intake of a barium meal. Radiographs were analyzed for the diagnosis of rectocele, enterocele, intussusception and perineal descent. They were compared with age- and symptom-matched women ( $n = 198$ ) who underwent defecography during the same period.

**RESULTS:** Normal defecography was observed in 22.7% of men vs 5.5% of women ( $P < 0.001$ ). Defecography in men compared with women showed 4.5%

vs 44.4% ( $P < 0.001$ ) rectocele, and 10.6% vs 29.8% ( $P < 0.001$ ) enterocele, respectively. No difference was observed for the diagnosis of intussusception (57.6% vs 44.9%). Perineal descent at rest was more frequent in women ( $P < 0.005$ ).

**CONCLUSION:** For the same complaint, diagnosis of defecographic abnormalities was different in men than in women: rectocele, enterocele and perineal descent at rest were observed less frequently in men than in women.

### INTRODUCTION

Constipation, fecal incontinence and pelvic pain require meticulous evaluation because therapy can be effective and help patients to lead a fuller life. Radiographic dynamic rectal examination (defecography) is a valuable method to assess evacuation disorders<sup>[1-5]</sup>. This method provides precise information on anorectal and pelvic floor functions<sup>[6-8]</sup>. It can be used to evaluate efficiently defecation disorders after clinical examination for the exploration of constipation, pelvic pain and anal incontinence<sup>[9-13]</sup>.

Posterior pelvic floor disorders are common and well known in women, and some are related to obstetrical consequences. Little is known about gender influence in symptomatic patients investigated by defecography<sup>[14,15]</sup>. Men can also complain of constipation, fecal incontinence and pelvic pain, and these symptoms need the same careful evaluation because they may need specific therapy<sup>[16]</sup>.

The purpose of our study was to compare prevalence of defecographic abnormalities in men and age- and symptom-matched women.

## MATERIALS AND METHODS

### Patients

Over a 6-year period, 66 symptomatic aged 20-81 years (mean  $\pm$  SD: 55.4  $\pm$  14.9 years) addressed for defecography were evaluated consecutively in our institution. All patients were referred by a gastroenterologist or a digestive tract surgeon for the exploration of constipation, pelvic pain or fecal incontinence. Constipation was defined as less than two bowel movements per week. Fecal incontinence was defined by an uncontrolled loss of liquid or solid stools that corresponded to grade C and D of Park's classification<sup>[17]</sup>.

To compare defecographic abnormalities in men with women, a case-matched series was isolated from a prospective database of women ( $n = 700$ ) investigated by defecography in the same period with the same techniques. Three women for one man were isolated. A series of 198 age- and symptom-matched women was studied. A value of 0 (absence) or 1 (presence) was attributed to each of the three types of symptoms (constipation, anal incontinence or pelvic pain) for all the patients in the database. Several age groups (5-years periods) were isolated for both genders. In these groups of similar age, three women with the same combination of symptoms were associated with one man. The choice of the symptom-matched women was done blindly of the results of the defecography from a global database that contained all the symptomatic patients who underwent defecography during this period in our unit. For example, for a 63-year-old man with constipation and pelvic pain (values = 1/0/1), three women (aged 60-65 years) with the same combination (1/0/1) were isolated. The women were aged 20-81 years (mean: 55.1  $\pm$  14 years).

### Defecography

We applied a standardized protocol to perform and evaluate all defecography examinations. All patients received a barium meal 1.5 h before the examination to opacify the pelvic small bowel for the detection of enterocele. A lateral X-ray was first performed for bone and pelvic loop visualization. In women, a thick barium paste was injected into the vagina, to mark out the posterior vaginal wall. Then, 150 mL of thickened and viscous high-density barium contrast medium was injected in the rectum with the patient in the left lateral position.

Films were taken in a standing lateral position during the following maneuvers: at rest, at voluntary and maximal contraction of the sphincter and pelvic floor ("squeeze"), and at straining without defecation ("strain"). The pubococcygeal line was defined and the distance between this line and the anorectal junction was determined for the three positions. Finally, patients sat on an upright commode attached to the footboard of the fluoroscopy table (a modified toilet), and one frame per second films were taken during expulsion and after completion of defecation at maximum straining.

Precise explanations of the entire procedure were given by the radiologist prior to defecography. In young women, defecography was always performed during the first part of the cycle. Image analysis was done by one of the senior radiologists involved in this study (CSC or EK).

Pathological patterns were defined as follows. Pelvic floor descent was assessed from standing lateral views during maneuvers. For the diagnosis of perineal descent at rest, the distance in millimeters between the anorectal junction and the pubococcygeal line was noted. Perineal descent at rest was defined as a distance of  $> 30$  mm. For perineal descent at straining, the difference in millimeters between the anorectal junction position at straining and at rest was noted. Perineal descent at straining was defined as a difference of  $> 20$  mm between the two positions. The number of male and female patients with perineal descent at rest was compared. Anterior rectocele was defined as  $> 30$  mm outpouching of the anterior rectal wall. This outpouching should persist on incomplete evacuation. Intussusception was defined as an invagination of the rectal wall, either intrarectal, intra-anal, or an external prolapse of the whole circumference. Enterocele was defined as herniation of the small bowel between the vaginal posterior wall and the anterior rectal wall.

### Statistical analysis

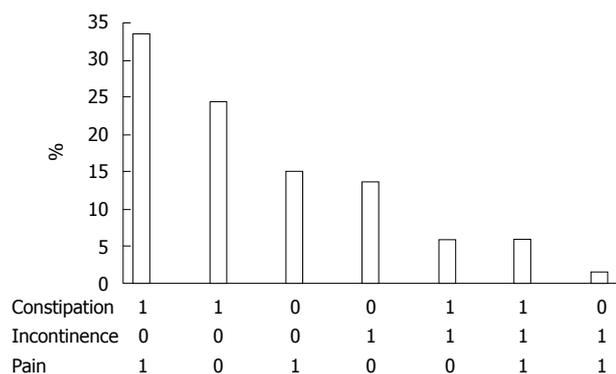

$\chi^2$  tests were used for the comparison of rectocele, enterocele, perineal descent and intussusception.  $P < 0.05$  was regarded as significant.

## RESULTS

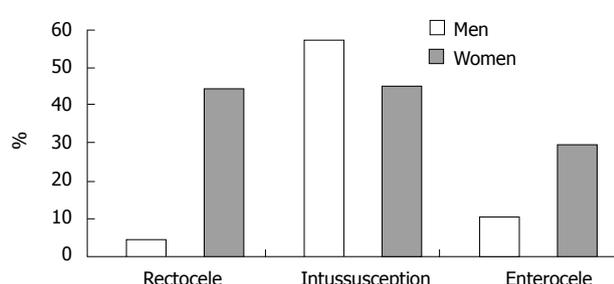

Constipation, fecal incontinence and pelvic pain were present in 69%, 27% and 56% of our male patients, respectively. These symptoms could be isolated (53%) or associated (Figure 1). The more frequent association was constipation and pelvic pain (33%).

Defecography could be satisfactorily performed in all patients and all examinations could be analyzed fully with the above-described criteria. In men, 22.7% of the defecography procedures were normal versus 5.5% in women ( $P < 0.001$ ).

Defecography in men showed intussusception in 38 patients (57.6%), enterocele in seven (10.6%), and rectocele in three (4.5%). Defecography in women showed intussusception in 89 patients (44.9%), enterocele

**Figure 1** Defecography in men: distribution with regard to the combination of symptoms (constipation and/or incontinence and/or pain). 0: Absence; 1: Presence.

**Figure 2** Results of defecography with regard to rectocele, intussusception and enterocele in men and women. Rectocele:  $P < 0.001$ , Enterocele:  $P < 0.005$ , Intussusception: NS.

in 59 (29.8%), and rectocele in 88 (44.4%). There was a significantly higher proportion of rectocele and enterocele in matched women (Figures 2 and 3). There was no statistically significant difference for the diagnosis of intussusception.

Distance between the pubococcygeal line and the anorectal junction at the three positions (rest, squeeze and strain) was significantly different between men and women, with a lower position of the perineum in women regardless of position ( $P < 0.001$ ) (Figure 4). There was a greater incidence of perineal descent at rest in women compared with men ( $P < 0.005$ ) (Figure 5). There was no difference between men and women for the diagnosis of perineal descent at straining.

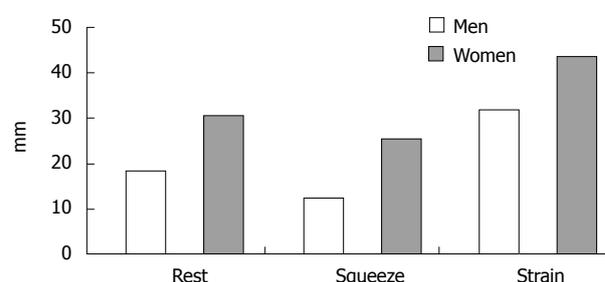

## DISCUSSION

Defecography is used commonly in women, but only a few procedures are carried out in men. In our department, men represented  $< 10\%$  of all defecography procedures. To the best of our knowledge, no specific study of defecography has been carried out to explore the gender difference in the diagnosis of defecographic abnormalities. The pairing of our case-matched study was done for age and symptoms, with one man for three matched women, as is usual in this type of study. It allowed us to establish any sex difference in the prevalence of defecographic abnormalities.

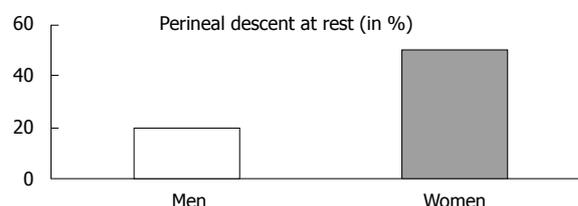

Intussusception is very common in both sexes

**Figure 3** Dynamic imaging during evacuation showed an enterocele (black arrow) associated with a rectocele (white arrow).

**Figure 4** Distance between the pubococcygeal line and the anorectal junction at rest, squeeze and strain in men and women.  $P < 0.001$ .

**Figure 5** Percentage of men and women with perineal descent at rest.  $P < 0.005$ .

(approximately half of patients undergoing defecography)<sup>[7,8]</sup>. We did not observe any sex difference in prevalence. Enterocele and rectocele were more common in matched women. This could be explained by obstetrical anteriority (vaginal delivery or hysterectomy). The consequences of obstetric damage on the perineum are well known<sup>[18,19]</sup>. Enterocele is also more frequent after hysterectomy<sup>[20]</sup>. Rectocele is diagnosed 10 times more frequently in women, and appears to be characteristic of the female population. Rectocele has been reported previously as being uncommon in men<sup>[15]</sup>. Chen *et al.*<sup>[15]</sup> have reported a prevalence higher than ours (17% *vs* 4.4%), and a frequent association between rectocele and prostatectomy (40%). We did not assess the history of all patients, but this difference could be explained by the higher mean age of the patients in the study of Chen *et al.*<sup>[15]</sup> (72.4 years) than in our study (55.4 years), because prostatectomy is more likely in older patients.

The distance between the pubococcygeal line and the

anorectal junction, which determines the position of the perineum, was greater in women for the three positions (rest, squeeze and strain). As a consequence, there was a gender difference for the diagnosis of perineal descent at rest. There was no such difference for perineal descent at straining. This raises the question that the normal level of the perineum could be different in both sexes. However, our study concerned only symptomatic patients and this needs to be investigated in control subjects. No sex-related definition of pelvic floor disorders was established, therefore, our diagnostic criteria were those commonly used, which means those used in women. However, new criteria for the diagnosis of perineal descent at rest in men could probably be defined. The same question can also be raised in elderly patients, for whom diagnostic criteria could also be adapted<sup>[21]</sup>.

Determination of the clinical value of defecographic abnormalities is also difficult and remains a subject of debate<sup>[22-26]</sup>. Defecographic abnormalities have been shown not to be symptom-related<sup>[12]</sup>. This study confirmed this finding, because there were gender differences among symptom-matched patients. Interpretation should be cautious because radiographic changes can be demonstrated in healthy subjects of various ages<sup>[27,28]</sup>. Interobserver agreement is good for rectocele and enterocele<sup>[29]</sup> but appears insufficient for perineal descent<sup>[25]</sup>. Different methods for measuring parameters, especially perineal descent, have been described, with controversy as to which is the most accurate, and with little agreement<sup>[26,30,31]</sup>. New examinations are also possible, such as magnetic resonance defecography, to assess pelvic floor disorders<sup>[32,33]</sup>.

In conclusion, defecography is a potential adjunct to clinical evaluation of men with constipation, fecal incontinence or pelvic pain. With symptoms equal, some defecographic abnormalities are sex-related: rectocele, enterocele and perineal descent at rest were observed less frequently in men.

## COMMENTS

### Background

Posterior pelvic floor disorders are caused by changes in the musculo-aponeurotic support of the pelvic floor. Defecography (radiographic dynamic rectal examination) provides precise information on anorectal and pelvic floor functions for patients with constipation, fecal incontinence and pelvic pain. These symptoms are more frequent in women, and some are related to obstetrical consequences. Little is known about the influence of gender in patients with pelvic floor disorders.

### Research frontiers

Radiological exploration of pelvic floor disorders is important to elucidate the pathophysiology and assist in deciding the therapeutic strategy. It is difficult to attribute a radiological abnormality as the direct cause of the symptoms. A better knowledge of gender difference in the prevalence of defecographic abnormalities appears to be useful.

### Innovations and breakthroughs

To the best of the authors' knowledge, no specific study of defecography has been carried out to explore the gender difference in the diagnosis of defecographic abnormalities. The strength of this study was that it assessed gender in the diagnosis of defecographic abnormalities.

### Applications

For the same complaint, defecographic abnormalities are different in men than

in women: rectocele, enterocele and perineal descent at rest were less frequent in men than in women. Discussion of sex differences in pelvic floor disorders could probably help to assess more precisely these nosological entities. New examinations are also possible, such as magnetic resonance defecography.

### Terminology

There are several defecographic abnormalities. Rectocele is an outpouching of the anterior rectal wall. Enterocele is a herniation of the small bowel between the vagina and rectum. Perineal descent is an abnormal position of the perineum under the pubococcygeal line.

### Peer review

The results of this study are interesting, although the method of this study (defecography) is relatively old and slightly controversial. The results of this study raise issue concerning gender differences in pelvic floor disorders, and may bring a new dimension.

### Abstract

**AIM:** To study the impact of an endoscopy-based long-term study on the quality of life in healthy volunteers (HV).

**METHODS:** Ten HV were included into a long-term prospective endoscopy-based placebo-controlled trial with 15 endoscopic examinations per person in 5 different drug phases. Participants completed short form-36 (SF-36) and visual analog scale-based questionnaires (VAS) for different abdominal symptoms at days 0, 7 and 14 of each drug phase. Analyses were

performed according to short- and long-term changes and compared to the control group.

**RESULTS:** All HV completed the study with duration of more than 6 mo. Initial quality of life score was comparable to a general population. Analyses of the SF-36 questionnaires showed no significant changes in physical, mental and total scores, either in a short-term perspective due to different medications, or to potentially endoscopic procedure-associated long-term cumulative changes. Analogous to SF-36, VAS revealed no significant changes in total scores for pathological abdominal symptoms and remained unchanged over the time course and when compared to the control population.

**CONCLUSION:** This study demonstrates that quality of life in HV is not significantly affected by a long-term endoscopy-based study with multiple endoscopic procedures.

### INTRODUCTION

Endoscopy is the main diagnostic tool for examination of the upper gastrointestinal tract. The main advantage

of endoscopy in comparison to other non-invasive procedures lies in its ability to obtain tissue biopsies, which permit histological evaluation of tissues for clinical as well as basic research<sup>[1]</sup>.

The majority of endoscopy-based pharmacological studies are performed in patients with or without a specific disease. Investigations surrounding this focused patient population yields answers for only a limited number of questions. Studies designed around healthy volunteers (HV) may resolve some of those issues (e.g. by reducing inter-individual differences); although at the same time may open a new series of questions. One of the main differences between patients and HV is hidden in the dilemma “treat the disease” in patients and “do no harm” in HV<sup>[2,3]</sup>. “Harm” can arise from a number of sources such as the study-related treatment, the endoscopy procedure itself, and/or other related discomfort (e.g. multiple blood samples, restriction of daily activities).

Upper GI-endoscopy is a relatively well-accepted procedure. The magnitude of discomfort to the examined person depends upon several factors such as previous contact with the examiner, appropriate elucidation of the procedure, sedation, investigator’s experience, duration of examination and the expected benefit from the procedure<sup>[4]</sup>. Because of the potential therapeutic benefit, it is easier to justify the examination of the patients. Since in most cases, HV can not expect any health-related advantages from the procedure, the involvement of HV in endoscopy-based research is a matter of ethical concern<sup>[5]</sup>.

Updated recommendations on ethics in gastrointestinal endoscopy-based research were discussed and summarized in the recent Workshop of the European Society of Gastrointestinal Endoscopy (ESGE)<sup>[6]</sup>. The main ethical considerations were as follows: first, there must be a research issue that can not be adequately addressed by the involvement of patients; and second, the inherent risk for HV is regarded to be “acceptable”. However the term “acceptable” is not well defined and it is not uncommon that different scientific and ethical committees make different conclusions concerning endoscopy-based studies. Objective methods for ethical evaluation could potentially be helpful in narrowing such differences in opinions. Targeting the quality of life (QOL) in volunteers could potentially contribute to objectivity in ethical questions, however, there are no data regarding this issue.

For this reason we aimed to evaluate the QOL in HV during endoscopy-based research. To answer these questions, we used the previously well-validated short-form 36 (SF-36) and visual analog scale-based questionnaires (VAS). In this pilot study, we demonstrate that an endoscopy-based drug trial has no significant influence on the QOL in healthy participants even under rigorous conditions and a long-term protocol.

## MATERIALS AND METHODS

### **Ethical approval and volunteer recruitment**

The study design was approved by the local ethics committee of Magdeburg University Hospital and by

government authorities. HV, as defined below, were recruited for the study in accordance with the Declaration of Helsinki principles and recommendations of the ESGE-workshop on the ethics of gastrointestinal endoscopy-based research<sup>[6]</sup>. The recruitment of HV was performed through the distribution of brochures or information posters avoiding affiliation or dependency of HV to the investigators. The purpose, risks of the procedure and the drug-related side effects were fully explained to participants and included in the written informed consent (e.g. risk of bleeding due to platelet inhibitory drugs). HV were informed about the opportunity to revoke study consent and cancel participation at any time. At least 24 h consideration time was provided to the HV before all participants provided written informed consent. Due to the extensive study protocol, all HV were financially reimbursed for their time, effort and contribution to the research. Financial compensation was equal in all HV and was modestly calculated based on generally used factors including compensation for time (or possible income shortfall due to participation in the study), risk, discomfort and inconvenience.

### **HV**

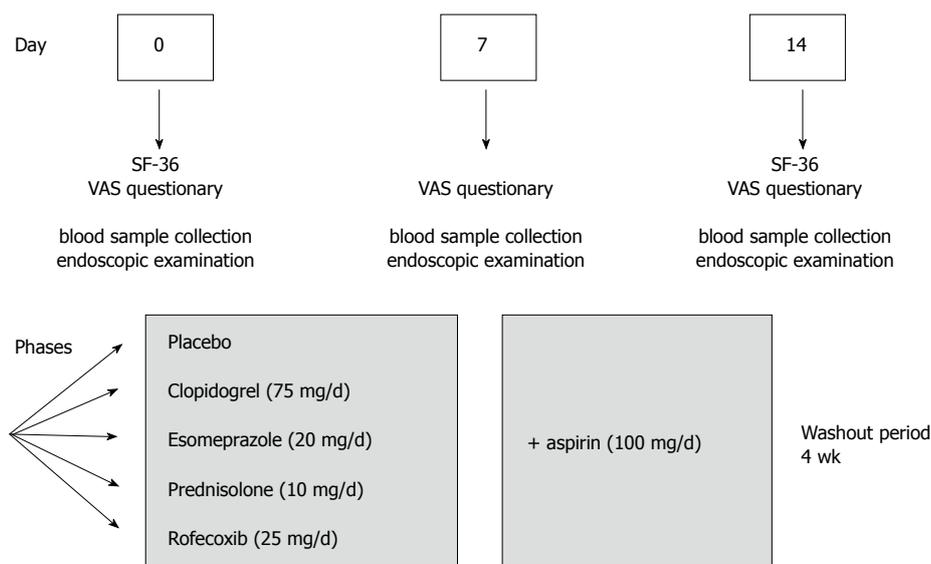

Ten HV [8 men and 2 women, age 27.8 years (22-37) and body mass index 24.7 kg/m<sup>2</sup> (22.3-27.2)] were included in the study based on previously described inclusion/exclusion criteria<sup>[7]</sup>. Briefly, HV had no abnormality at physical examination or during routine laboratory examination, no history of relevant illnesses especially history of peptic ulceration, no pregnancy in women and were negative for *H. pylori* infection.

### **Study design**

The study was conducted as a prospective double-blind, placebo-controlled study with cross-over design. The main aim of the trial was to study the influence of several frequently used drugs on the healing of gastroduodenal lesions (preliminary clinical results were reported elsewhere)<sup>[8]</sup>. In addition, we aimed to evaluate the impact of the endoscopy-based trial on QOL in HV. All volunteers were asked to fill out the questionnaires on the day of each endoscopy, describing the subjective symptoms and QOL. Rofecoxib, clopidogrel, prednisolone, esomeprazole or placebo were given alone and/or together with acetylsalicylic acid (ASA). The endoscopic procedures were performed on days 0, 7 and 14 (Figure 1). The volunteers received one of the test drugs for one week and the same drug together with ASA for another week. Total duration of the study was over 6 mo including a 4-wk washout period between 5 different drug phases.

### **Endoscopy**

After overnight fasting, the endoscopic examination was performed by an experienced endoscopist (G.T.) using a standard endoscope (GIF 145, Olympus, Germany). All HV received topical lidocaine 2% for local anesthesia and 20 mg of butylscopolaminiumbromid intravenously

**Figure 1** Flow chart of the study. The multiple drug study with cross-over design was divided into 5 phases with test drug alone and in combination with low-dose aspirin during the second week. On days 0, 7 and 14 of each study, ten HV were asked to complete the questionnaires. Upper GI-endoscopy was performed on the same days with a 4-wk wash out period between the different phases.

(iv) to inhibit gastric and small bowel propagation. Additionally, midazolam 5 mg was given iv if requested by the participants. During the procedure, patients were monitored for heart rate and oxygen saturation. After a systematic examination of the stomach and duodenum, multiple biopsies (10 per region, a total of 30 per endoscopy) were taken using standard forceps (5 mm maximum open diameter) from the distal duodenal bulb, antrum and corpus.

#### Questionnaires: Visual analog scale and SF-36

To determine the QOL in HV, we used a validated German version of the SF-36 (short form) questionnaire which includes an 8-scale profile: physical functioning, role physical, bodily pain, general health, vitality, social functioning, emotional role and mental health. These scales further represent two distinct higher-ordered clusters due to physical and mental health variance. A lower score in SF-36 indicates a greater impairment and can range from 0 (worst health) to 100 (best health). To determine the abdominal symptoms of HV, we used a previously validated visual analog scale (VAS) based questionnaire<sup>[9]</sup> with the following dimensions of symptoms: abdominal pain, bloating, reflux, nausea, vomiting, diarrhea and loss of appetite. The summary symptom score (0-70) was calculated by adding up the values of the single scores. A single score value from 1-10 was defined as presence, and 0-1 as the absence of any symptoms. As shown in Figure 1, VAS questionnaires were filled out on days 0, 7 and 14 and the SF-36 questionnaires were filled out before and after each drug phase. The score parameters of HV were compared to a previously evaluated control population of 28 patients, who underwent a single endoscopic examination and in the absence of acid suppressive drugs no visible macroscopic or histological abnormalities were found<sup>[9]</sup>.

#### Statistical analysis

All data were analyzed using the SPSS 10 (Chicago, IL, USA) and Graph Pad Prism 4.0 (San Diego, CA, USA).

The differences between the groups were analyzed according to corresponding formula and rules, using where appropriate paired or unpaired *t*-test and Friedman's test (FT) for non-normal distributed data. For all comparisons, a *P*-value (two-sided) of < 0.05 was regarded as significant.

## RESULTS

### Study participation

All 10 HV completed all 5 phases of the study with 15 endoscopies per HV. With the exception of 2 individuals who either experienced a prolonged bleeding after biopsies had been taken or melena (due to the combination of ASA and clopidogrel) without development of anemia, there were no further drug- or endoscopy-related complications. The VAS and SF-36 questionnaires were completed and returned in 99.5% and in 88% of all cases/time points, respectively. In 91% of endoscopies, HV declined to receive midazolam for sedation and received only topical anesthesia with lidocaine 2%.

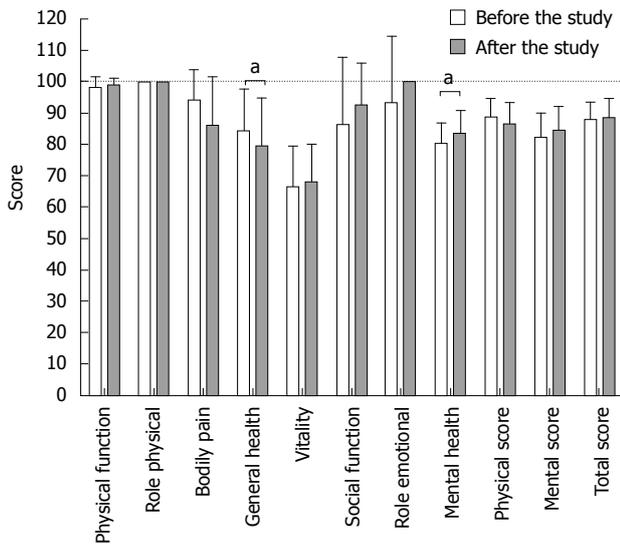

### Analyses of the SF-36 questionnaires

SF-36 questionnaires were analyzed in regard to different aspects, such as influence of study drugs, different time points, as well as long term changes in QOL. The physical, mental and total scores, determined by the short form SF-36 questionnaire ranged between 65.6 to 97.0, 65.3 to 96.0 and 75.6 to 97.1, respectively. We found no significant changes in physical, mental or total scores either between different medications or due to participation in each drug phase (data not shown). Overall changes in physical, mental and total scores are shown in Table 1. For the long-term impact of the intensive endoscopy-based trial on the QOL in HV, the SF-36 assessed data were compared between baseline (day 0 during the first phase) and the last time point of the last phase more than 6 mo later. Remarkably, physical ( $88.4 \pm 6.0$  vs  $86.4 \pm 6.7$ ), mental ( $82.1 \pm 8.1$  vs  $84.6 \pm 7.4$ ) and total scores ( $88.0 \pm 5.7$  vs  $88.6 \pm 6.1$ ) showed no significant changes over the 6-mo period (Figure 2).

**Table 1** Changes in scores on the SF-36 questionnaires in HV according to different test drugs before and after endoscopic procedures

Test drug day	Physical score		P	Mental score		P	Total score		P
	0	14		0	14		0	14	
Placebo	88.7 ± 5.9	88.2 ± 4.1	NS	85.7 ± 8.5	86.0 ± 7.8	NS	89.9 ± 6.2	89.8 ± 4.8	NS
Esomeprazole	85.7 ± 7.7	84.1 ± 6.0	NS	83.3 ± 6.2	83.0 ± 6.0	NS	86.2 ± 7.2	87.4 ± 4.8	NS
Clopidogrel	86.6 ± 6.5	85.5 ± 6.7	NS	84.0 ± 7.3	83.8 ± 8.2	NS	88.1 ± 6.1	87.0 ± 6.3	NS
Prednisolone	85.1 ± 5.2	82.2 ± 9.6	NS	81.9 ± 7.0	82.6 ± 6.4	NS	87.0 ± 5.4	85.7 ± 6.7	NS
Rofecoxib	86.2 ± 8.2	86.4 ± 3.1	NS	85.0 ± 6.2	84.5 ± 4.7	NS	88.3 ± 6.5	88.4 ± 3.1	NS
Total Scores	86.4 ± 1.3	85.4 ± 2.0	NS	83.5 ± 1.3	84.2 ± 1.2	NS	87.8 ± 1.2	87.8 ± 1.5	NS

Test drugs were given for one week alone and for an additional week in combination with low-dose aspirin. Four-week washout periods were performed between the different drug phases. Results expressed in mean ± SD, paired *t*-test: *P* > 0.05 listed as NS. HV: Healthy volunteers.

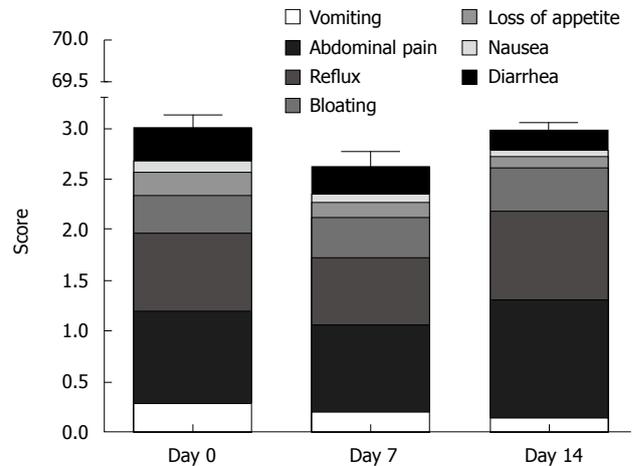

**Figure 2** Changes in different multiple dimensions and physical, mental and totals scores between baseline and end of study determined by SF-36. During the 6-mo study with cross-over design, 10 HV underwent a total of 150 endoscopic examinations and 4500 biopsies from the antrum, corpus and duodenal bulb. The results are expressed in mean ± SD. Dotted line shows the theoretical max score from 100. Significant changes were observed (a) for general (84.4 ± 13.1 vs 79.4 ± 15.4, *P* = 0.023 paired *t*-test) and mental health (80.0 ± 6.8 vs 83.2 ± 7.5, *P* = 0.022 paired *t*-test). In the remaining dimensions, physical, mental and total scores *P* > 0.05.

Single score analysis revealed that only general health decreased from 84.4 ± 13.1 to 79.4 ± 15.4 (mean ± SD; paired *t*-test *P* = 0.023) and mental health increased from 80.0 ± 6.8 to 83.2 ± 7.5 (*P* = 0.022).

**Analyses of physical symptoms with visual analog scale (VAS) questionnaires**

Physical complaints were assessed for different symptoms with VAS and analyzed in a similar manner to the SF-36 questionnaires. As anticipated, subjective physical and emotional perception even at baseline differed from one person to another (high inter-individual variability, data not shown). Almost 60% of all complaints were due to abdominal pain and reflux, but these scores showed no significant changes when compared with baseline (Figure 3). The rarest complaints with < 10% of the maximal score were nausea and loss of appetite. To

**Figure 3** Changes between different symptoms and summary scores due to the endoscopy-based study determined by visual analog scale (VAS) based questionnaires. Upper endoscopies were performed on days 0, 7 and 14 of each phase. During every medication phase, HV underwent 3 upper endoscopies with multiple biopsies from the antrum, corpus and duodenal bulb. Maximal complaint score for any symptom or summary scores are 10 and 70, respectively. The results are expressed as mean ± SE and analyzed using Friedman's test (*P* > 0.05 for physical, mental and total-scores).

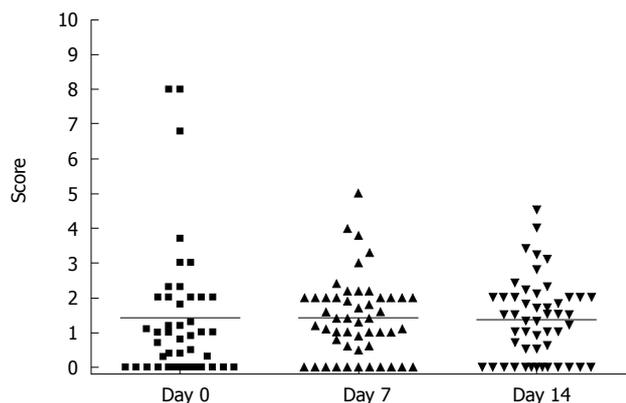

evaluate the global changes we constructed a summary score; values at baseline (3.2 ± 5.1) were comparable to scores at day 7 (2.6 ± 3.7) and day 14 (3.0 ± 3.4) and were less than 5% of the theoretical maximal score.

**Analyses of the impairment of endoscopic examination**

To analyze the subjective endoscopy-related impairment in HV, we used VAS which allows the volunteers to score the procedure-oriented discomfort. In analogy to physical complains VAS, we observed high inter-individual variability with the overall range varying from absence to 80% of maximum possible impairment during the endoscopy. As demonstrated in Figure 4, there was no significant difference between self-assessed scores for complaints about endoscopic procedures (1.4 ± 2.0, 1.4 ± 1.1 and 1.35 ± 1.1 for day 0, 7 and 14, RM ANOVA, *P* > 0.05).

**Difference between HV and controls**

The VAS-scores from HV were compared with previously

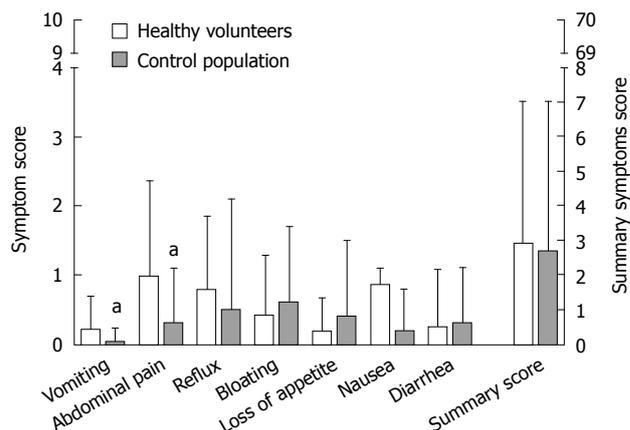

**Figure 4** Changes in compliance scores due to endoscopic procedures between different time points determined by visual analog scale (VAS) based questionnaire. Upper endoscopies were performed on days 0, 7 and 14 of each phase and 30 biopsies were taken during each procedure. Maximal complaint score is 10. The results are presented as scatter plots with means as the lines and were analyzed by ANOVA test ( $P > 0.05$ ).

published VAS-scores from a control population<sup>[9]</sup>. The overall mean for summary symptom scores of HV and controls were comparable (HV  $2.9 \pm 4$  and controls  $2.7 \pm 4.4$ ,  $t$ -test:  $P > 0.05$ ) and was lower than 5% of the theoretically possible value. We found significantly more complaints for abdominal pain ( $0.98 \pm 1.37$  vs  $0.3 \pm 0.8$ ,  $P = 0.012$ ) and vomiting ( $0.22 \pm 0.5$  vs  $0.03 \pm 0.2$ ,  $P = 0.046$ ) in the HV group (Figure 5), but due to the limited number of HV we could not perform age adjustment for the symptoms. The difference between both scores were below the defined cut-off value for the presence or absence of symptoms and were significantly lower than a symptomatic population as previously published<sup>[9]</sup>.

## DISCUSSION

QOL of HV is one of the major ethical concerns in endoscopy-based research. Due to the lack of objective data, the decision to include or not to include HV into a clinical trial is made rather arbitrarily and is mostly based on the individual judgment of clinicians and the opinion of expert committees. Therefore, there is a strong need for prospective data that would help to gain knowledge directly related to HV. To test if the endoscopy-based study impacted the QOL of HV, we prospectively evaluated QOL in HV under rigorous conditions. During the study of multiple potentially GI-harmful medications, HV underwent multiple (150) endoscopic examinations with over 4500 biopsies in 5 independent phases. We demonstrated that by accurate implementation of recommendations and guidelines, even a long-term endoscopy-based study has only a little or no impact on the QOL in HV.

Several different methods to measure QOL, for example Sickness Impact Profile, Medical Outcome Study Short-Form 36 (SF-36), Nottingham Health Profile, Quality of Well Being Scale and other disease-specific scales have been previously validated<sup>[10]</sup>. We

**Figure 5** Different symptoms and summary scores due to the endoscopy-based study compared in HV and the control group determined by visual analog scale (VAS) based questionnaires. Every HV completed 5 medication phases with 15 endoscopic examinations. Control population (data previously published in<sup>[9]</sup>, adopted with permission) underwent only one upper GI endoscopy without endoscopic or histological pathology. Maximal complaint score for any symptom or summary scores are 10 and 70, respectively. The absolute symptom value was below the cut-off for presence of the symptom.

decided to use the SF-36 questionnaire for its brevity and its comprehensiveness. SF-36 is one of the best validated and widely used questionnaires both in clinical practice and research work in gastroenterology<sup>[11]</sup>. To increase the reliability of the study, we also used VAS which was previously validated in dyspeptic patients by our group<sup>[9]</sup>. Both questionnaires are based on self-evaluation which minimizes the investigator-related impact, and further contributes to reliability of the outcome results.

In this pilot study, we found that the endoscopy-based trial was not associated with significant changes in QOL scores. These scores were comparable between different phases and time points as well as when compared to the general population<sup>[12]</sup> and to the control population<sup>[9]</sup>. Based on our results and previous knowledge, several conclusions can be made<sup>[6]</sup>. First, implementation of the current guidelines and recommendation are a reliable fundament for the successful realization of an endoscopy-based study. Second, careful selection of volunteers might be important, especially taking into account the motivation of the HV. Motivation is - at least in part - based on an idealistic character, even if financial compensation is provided. However, especially in developing countries, financial compensation may become the dominant stimulus for participation which may overcome the study-related discomfort<sup>[5,13]</sup>. In our study, inclusion of HV was based on a "first come, first served" principle, however, there is still a chance of creating a bias due to personal motivation, willingness to participate in the study or even financial interest<sup>[5,13]</sup>. In this regard it is important to mention that analogous to other studies, all the HV were reimbursed for their time, effort and contribution to the research, but financial compensation was modest at best. Since personal motivation may vary considerably, testing HV with higher and lower tolerance

to endoscopy-based studies, especially in relation to financial reward, could add interesting and valuable information and should be considered in future studies. Besides motivation, physician/clinician and nursing care (GCP) also plays an important role in subjective cognition of impaired QOL. All endoscopic examinations were performed by an experienced endoscopy team which could have influenced the satisfaction, and thereby tolerance to the procedure<sup>[14]</sup>.

To the best of our knowledge, the only comparable study that has addressed a similar issue was from Adachi *et al.*<sup>[15]</sup>. This group analyzed cardiac stress in HV without sedation, and showed that endoscopic examination of HV without sedation increased cardiac stress (without affecting cardiac output) by 66%<sup>[15]</sup>. Although evaluation of objective physiological parameters may add valuable information, especially if correlated to VAS or even SF-36, the correlation to personal impairment is still unknown. The VAS impairment score in our study was constant throughout the study, with mean impairment of 15% as a maximal value. Although premedication would improve tolerance to endoscopic procedures, premedication with midazolam was only used in 9% of procedures. From another perspective, the “social life” of HV may also have had an impact on the decision to use or not use premedication. Necessary daily activities like study, work or transportation could be significantly influenced by premedication, especially because the duration of this study was 6 mo. Furthermore, it is worth mentioning that none of the HV interrupted the study, and all of them declared that they would re-participate. Some of them did participate in a later endoscopy-based study with 4 endoscopic procedures within 2 h<sup>[7]</sup>.

It was not the aim of our study to clarify whether endoscopy-based research is ethical or not, but primarily to evaluate QOL in HV following the implementation of current recommendations and guidelines. Nevertheless, this information could indirectly contribute to the ethical considerations of endoscopy-based research, if the guidelines and recommendations are acceptable. Therefore, safety standards including experienced endoscopists are a pre-requisite in such studies. Endoscopy-based studies have some risks for complications, which in the worse case can be lethal, even if volunteers are young and healthy<sup>[16]</sup>. However, the risk is negligible if the procedure is carried out with maximum accuracy and according to the recommendations for standards of sedation and monitoring of patients during GI-endoscopy<sup>[3,17,18]</sup>.

In summary, in this pilot study we show for the first time that participation in long-term endoscopy-based trials is not necessarily associated with significant changes in QOL in HV. Evaluation of QOL might be a valuable tool regarding ethical questions in further studies. Larger studies are warranted to confirm the data and to further analyze the interaction between QOL and motivation of HV.

## ACKNOWLEDGMENTS

The authors are grateful to Dr. Ajay Goel and Dr.

Klaus Moenkemueller for their helpful discussions and critical reading of the manuscript, and to Mrs. Kathrin Beier, Mrs. Diana Worm, Mrs. Martina Leucke and the endoscopy team for providing excellent care of the HV. We are also thankful to the HV for their commitment to the study.

## COMMENTS

### Background

Involvement of healthy volunteers (HV) is absolutely essential in gaining valuable knowledge in clinical and preclinical research. The involvement of HV (HV) has a long history, but many unresolved issues of ethical, methodological or even legal concerns in this regard still remain unanswered. The importance of this becomes even more pronounced when invasive procedures like GI endoscopy are undertaken. Existing ethical recommendations and guidelines on this topic are mostly based on the opinion of experts, but many of these questions have not been studied in a systematic manner.

### Research frontiers

Multiple studies have shown that the motivation of HV plays a key role in recruiting volunteers. Financial reward is one of the crucial motivating factors in HV. Participation in research studies might be associated with study-related risks, discomfort and inconvenience that might become even more relevant in endoscopy-based studies. Impairment in the quality of life in HV may play a crucial role in understanding these ethical concerns, however, so far no study has addressed the impact of endoscopy-based research on the quality of life of HV.

### Innovations and breakthroughs

In this pilot study the authors evaluate the changes in quality of life in HV in a long-term endoscopy-based drug study. The study was conducted according to existing ethical recommendation and guidelines. Using the well-validated SF-36 and visual analog scale-based questionnaires, they show that endoscopy-based research has no significant impact on quality of life in HV even under rigorous conditions.

### Applications

This study provides valuable and important information regarding the quality of life of HV who participate in endoscopy-based studies, and supports the existing recommendation and guidelines on this topic in Gastroenterology.

### Terminology

Healthy volunteer: is a person who voluntarily participates in a research study. Volunteer come from volunteering which means working, participating or being involved in something without being motivated by financial or material gain. The historical intention, such as to promote good, serve society and improve human quality of life show static movement in paid volunteerism. Endoscopy-based research: are studies or trials performed on individuals which involve endoscopic techniques. Short Form 36: is a well-validated and widely used short survey which includes 36 specific questions on health-related quality of life.

### Peer review

This study examines the impact of a demanding endoscopy protocol on gastrointestinal symptoms and quality of life in 10 human volunteers. The study involved 15 endoscopic procedures over a period of 6 mo.

*babB* and *babA2/B* genes. Statistical analysis was performed using the  $\chi^2$  test and the Fisher's exact probability test and multivariate analysis was performed by logistic regression adjusting for gender and age.  $P < 0.05$  was regarded as statistically significant.

**RESULTS:** The PCR-based genotyping of 95 Costa Rican and 95 Japanese isolates showed a higher prevalence of *babA2* in Japan (96.8%) than in Costa Rica (73.7%), while that of *babA2/B* was higher in Costa Rica (11.6%) than in Japan (1.1%). In Costa Rican isolates only, *babA2* was significantly associated with atrophic gastritis ( $P = 0.01$ ).

**CONCLUSION:** These results suggest that the status of *babA2* and *babA2/B* shows geographic differences, and that *babA2* has clinical relevance in Costa Rica.

Clinical relevance of *Helicobacter pylori* *babA2* and *babA2/B* in Costa Rica and Japan. *World J Gastroenterol* 2010; 16(4): 474-478 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i4/474.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i4.474>

### Abstract

**AIM:** To evaluate the prevalence of *Helicobacter pylori* (*H. pylori*) *babA2*, *babB* and a recombinant gene between *babA2* and *babB* (*babA2/B*), and their role in the development of atrophic gastritis in Costa Rican and Japanese clinical isolates.

**METHODS:** A total of 95 continuous *H. pylori*-positive Costa Rican (41 males and 54 females; mean age, 50.65 years; SD,  $\pm$  13.04 years) and 95 continuous *H. pylori*-positive Japanese (50 males and 45 females; mean age, 63.43; SD,  $\pm$  13.21 years) patients underwent upper endoscopy from October 2005 to July 2006. They were enrolled for the polymerase chain reaction (PCR)-based genotyping of the *H. pylori* *babA2*,

### INTRODUCTION

*Helicobacter pylori* (*H. pylori*) infects the human stomach causing chronic inflammation, which can lead to peptic ulcer and gastric cancer<sup>[1,2]</sup>. The diverse clinical outcome of

gastric disease may involve differences in the prevalence or expression of bacterial virulence factors. *H. pylori* BabA is a blood-group antigen-binding adhesin encoded by the *babA2* gene, which has been shown to mediate adherence of *H. pylori* to human Lewis b blood-group (Le<sup>b</sup>) antigens<sup>[3,4]</sup>. Although three *bab* alleles have been identified (*babA1*, *babA2* and *babB*), only the *babA2* gene product is functional for Le<sup>b</sup> binding activity<sup>[5,6]</sup>. Studies in Western countries have disclosed associations between the presence of *babA2* gene and digestive diseases such as duodenal ulcer and gastric cancer<sup>[4]</sup>. However, in Asia, most of the *H. pylori* strains are *babA2*-positive, irrespective of clinical outcome<sup>[7,8]</sup>. Thus, conclusions about the relationship between *H. pylori* genotypes and clinical outcome derived from one geographic region may not be true for other geographic regions. Evidence concerning BabA adhesin-associated genes is insufficient in Costa Rica, where the incidence of gastric cancer is very high, similar to Japan<sup>[9]</sup>. The *babA2* gene, which encodes BabA, may play a role in the development of gastric cancer in the Costa Rican population. In order to investigate this hypothesis we aimed to correlate the status of *babA2* in Costa Rican clinical isolates with atrophic gastritis, a gastric premalignant lesion. In addition, because *H. pylori* populations are highly diverse and are constantly changing their genome by point mutations, substitutions, insertions, and/or deletions of their genome<sup>[10-12]</sup>, we decided to evaluate the prevalence of a recombinant gene between *babA2* and *babB* (*babA2/B*), already identified *in vitro*<sup>[13,14]</sup>, in Costa Rican as well as in Japanese clinical isolates, which were used also in this study for comparative purposes.

## MATERIALS AND METHODS

### Study population

Half of the patients in this study attended a digestive center in San Jose, Costa Rica and the other half attended a National University in Kochi, Japan. A total of 95 continuous *H. pylori*-positive Costa Rican (41 males and 54 females; mean age, 50.65 years; SD,  $\pm$  13.04 years) and 95 continuous *H. pylori*-positive Japanese (50 males and 45 females; mean age, 63.43; SD,  $\pm$  13.21 years) patients underwent upper endoscopy from October 2005 to July 2006. They were enrolled for the polymerase chain reaction (PCR)-based genotyping of *H. pylori* *babA2*, *babB* and *babA2/B* genes. Informed consent was obtained from each patient and the study was approved by the Ethics Committee of the institutions. Information was collected on age, gender, symptoms and medication. None of the participating patients had undergone *H. pylori* eradication therapy or gastric surgery. In addition, none of the patients had recent intake of proton pump inhibitors, antibiotics, or non-steroidal anti-inflammatory drugs. The patients were histopathologically classified into two groups; atrophic gastritis (AG) group (29 Costa Rican and 48 Japanese) and non-atrophic gastritis (NAG) group (66 Costa Rican and 47 Japanese) according to the updated Sydney System for the classification of gastritis<sup>[15]</sup>.

### Endoscopic and histological evaluations

Endoscopy was performed with Olympus EVIS EXERA I/II systems (Olympus America Inc., San Jose, CA, USA). From each participating subject, at least four biopsies (from the antrum, corpus and cisura angularis) were collected for histological examination. In addition, one antral biopsy was also taken to obtain the clinical isolates following bacterial culture.

The biopsy samples were conventionally fixed in 100 mL/L formaldehyde anidre and embedded in paraffin. Serial 3- to 4- $\mu$ m sections were stained with hematoxylin and eosin for histological observation. All biopsies were examined for the presence of glandular atrophy and were scored into four grades (0: none, 1: mild, 2: moderate and 3: marked) for both the antrum and the body of the stomach, according to the updated Sydney System of classification and grading of gastritis<sup>[15]</sup>. Gastric glandular atrophy was defined as the loss of gastric glands and its replacement with fibrosis or metaplastic epithelium.

### Determination of *H. pylori* infection

*H. pylori* infection was determined by either the rapid urease test (RUT) or histological examination in biopsy specimens obtained from the antrum, cisura angularis and body of the stomach. Patients were considered *H. pylori*-positive if either the biopsy specimen was positive for RUT or the bacterium was observed in any of the hematoxylin and eosin-stained sections.

### Isolation of *H. pylori* from biopsy specimens and DNA extraction

The homogenized biopsy specimens were placed on *H. pylori* selective agar plates (Helico VI agar, E-MS70, Eiken Chemical Co., Ltd., Japan) and cultured at 37°C under microaerobic conditions (100 mL/L CO<sub>2</sub>) for five to seven days. The presence of *H. pylori* colonies was confirmed by typical morphology, Gram staining and a positive urease test. Eventually, a total of 190 clinical isolates obtained from antrum specimens were subjected to genomic DNA (gDNA) extraction using a DNA kit (Qiagen, Tokyo, Japan) according to the manufacturer's instructions.

### Detection of *H. pylori* *babA2*, *babB* and *babA2/B* genes by PCR

The genomic DNAs were subjected to PCR-based genotyping of *babA2*, *babB* and *babA2/B* using two primer pairs including primers previously described<sup>[4,16]</sup> and new primers (Table 1) designed based on sequences of referential *H. pylori* strains 26695 and J99. We used PCR conditions exactly matching those described<sup>[4,16]</sup> and the conditions for the new primers used in this study are shown in Table 1. Whenever necessary, in particular, to determine *babA2/B*, sequence analysis of the putative products was performed using Applied Biosystems 3130 Genetic Analyzer (Applied Biosystems, Foster City, CA, USA) and these sequences were compared with *babA* and *babB* genes of strains 26695 (HP1243 and HP896, respectively) and J99 (jhp833 and jhp1164, respectively)

using the BLAST 2 SEQUENCES system (<http://www.ncbi.nlm.nih.gov/blast/bl2seq/wblast2.cgi>)<sup>[17]</sup>. When the putative recombinant gene was shown to be only homologous at the 5' and 3' positions of *babA2* gene open reading frame (ORF) and *babB* gene ORF, respectively, the gene was considered to be a recombinant *babA2/B* gene.

**Statistical analysis**

Statistical analysis was performed using the  $\chi^2$  test and the Fisher's exact probability test [STATA SE (version 8) statistical software].  $P < 0.05$  was regarded as statistically significant. Multivariate analysis was performed by logistic regression [SPSS 13.0 Japanese version (SPSS Japan Inc., 2005)] adjusting for gender and age. Odds ratios with 95% confidence intervals were used to study the influence of these genes on the development of gastric atrophy.

**RESULTS**

**Comparison of gender and age of patients between AG and NAG**

There was no significant difference in gender between the AG group and NAG group from either Costa Rica or Japan (Table 2). However, mean age was significantly higher in the AG group than in the NAG group of both Costa Rican and Japanese patients.

**Prevalence of gastric atrophy in Costa Rican and Japanese patients**

In Costa Rican patients, the prevalence of gastric atrophy was 30.5% (29/95) while that in Japanese patients was considerably higher (50.5%, 48/95).

***H. pylori* *babA2*, *babB* and *babA2/B* genes in clinical isolates**

In Costa Rican patients, the prevalence of *babA2* was 73.7% (70/95) and after gender and age adjustment, this gene was found to be significantly associated with AG in this population ( $P = 0.01$ ) (Table 3). The prevalence of *babB* and *babA2/B* was 81.1% (77/95) and 11.6% (11/95), respectively, and no significant differences were found between any of these genes and AG.

In Japanese patients, almost all patients were found to be *babA2*-positive (96.8%, 92/95), while only one patient had the *babA2/B* gene (98.9%). The prevalence of *babB* was 90.5% (86/95). After gender and age adjustment, no significant differences were found between any of these genes and AG in this population.

**DISCUSSION**

The prevalence of *babA2* in Costa Rican isolates was 73.7%, which was higher than that shown in Western studies (38%-43%)<sup>[18-20]</sup>, but lower than that in Asian studies (80%-100%)<sup>[7,21-23]</sup>, including that in our Japanese

Pos: Positive; Neg: Negative; OR: Odds ratio; CI: Confidence intervals. Separate models were fitted to obtain an odds ratio for each gene with adjustment for gender and age in each country.  $P < 0.05$  was considered significant.

isolates (96.8%) (Table 3). It seems that the prevalence of *babA2* does not parallel the incidence rate of gastric cancer in those countries, since Costa Rica, has an incidence rate comparable to that of Japan and China<sup>[9]</sup>.

The *babA2* and *babB* genes exhibit extensive homologies at their 5' and 3' ends that should facilitate frequent recombination between them, suggesting that a recombination might interfere in the expression and functional activity of BabA. In this study, this recombination was found in 11 and 1 Costa Rican and Japanese (KMT28) isolates, respectively, irrespective of clinical outcome. However, in the Costa Rican strains, the *babA2* gene was found to be significantly associated with AG ( $P = 0.01$  and OR = 7.8) (Table 3). This association has been reported previously in Western studies<sup>[9]</sup>.

The PCR products of 12 *babA2/B* recombinant strains were employed for sequence analysis, revealing that several stop-codons in the amino acid sequence were found in all 11 Costa Rican strains, suggesting that these genes were non-functional. In contrast, since the Japanese strain KMT28 had complete in-frame sequence, the *babA2/B* gene was thought to be functional. In addition, reverse transcription-PCR (Toyobo Co., Ltd., Japan) using mRNA extracted from the KMT28 strain possessing the *babA2/B* gene with Trizol reagent (Invitrogen Corp., Carlsbad, CA, USA), and sequence analysis were performed, demonstrating that the *babA2/B* transcript of KMT28 was definitely obtained and the sequence was identical to the *babA2/B* sequence (data not shown).

The relationship between *babA2*-positive *H. pylori* and an increased risk of developing clinical outcomes is controversial<sup>[7,18,20,24-26]</sup>, because the presence of *babA2* is not always to reflect the BabA binding activity due to regulation by the number of transcriptional start adenine [poly (A)] residues in the promoter region<sup>[5]</sup> and the presence of chimeric *babA/B* or *babB/A* genes<sup>[14,27]</sup>. Moreover, it is relatively difficult to detect the *babA2* gene by PCR with a single primer pair due to high homology between the sequences of *babA1* and *babA2*. Thus, to determine BabA binding activity and/or the presence of its transcript it was critical to consider the

functionality of BabA and its pathogenesis. Therefore we used at least two primer pairs to confirm the presence of *babA2* and recombinant *babA2/B* genes and investigated the relationship between the status of these genes and clinical outcomes.

Taken together, the status of *babA2* and *babA2/B* shows geographic differences, and *babA2* seems to have clinical relevance only in Costa Rica. A functional *babA2/B* was found in one Japanese isolate. However, we believe that a binding assay with Le<sup>b</sup> antigen is necessary to confirm whether the BabA is functional and/or the adhesive strength is regulated individually depending on an adaptation of the microorganism in the stomach involved in clinical manifestation.

## COMMENTS

### Background

The clinical outcome of gastric disease may involve differences in the prevalence or expression of bacterial virulence factors. Contrary to Asian studies, western studies have disclosed associations between the presence of *babA2* gene and gastric cancer. Evidence concerning BabA adhesin-associated genes is insufficient in Costa Rica, where the incidence of gastric cancer is very high, similar to Japan. The *babA2* gene, which encodes BabA, may play a role in the development of gastric cancer in the Costa Rican population.

### Research frontiers

The research in this area is focused on the correlation between the status of *babA2* in Costa Rican clinical isolates and atrophic gastritis, a gastric premalignant lesion, and on the evaluation of the prevalence of a recombinant gene between *babA2* and *babB* (*babA2/B*), in Costa Rican and Japanese clinical isolates.

### Innovations and breakthroughs

The PCR-based genotyping of 95 Costa Rican and 95 Japanese isolates showed a higher prevalence of *babA2* in Japan (96.8%) than in Costa Rica (73.7%), while that of *babA2/B* was higher in Costa Rica (11.6%) than in Japan (1.1%). In Costa Rican isolates only, *babA2* was significantly associated with atrophic gastritis ( $P = 0.01$ ).

### Applications

These results suggest that the status of *babA2* and *babA2/B* shows geographic differences, and that *babA2* has clinical relevance in Costa Rica.

### Terminology

*Helicobacter pylori* (*H. pylori*) is a Gram-negative microaerobic bacterium that persistently colonizes the human gastric mucosa. *H. pylori* BabA is a blood-group antigen-binding adhesin encoded by the *babA2* gene, which has been shown to mediate adherence of *H. pylori* to human Lewis b blood-group antigens.

### Peer review

This paper has a correct design and is presented adequately. Title, results and discussion are clear and properly expressed. This topic is controversial, in some way, and this investigation constitutes an interesting contribution.

### Abstract

**AIM:** To assess the possible association between *PTPN22* (R620W) gene polymorphism and inflammatory bowel disease (IBD).

**METHODS:** One hundred and sixty-four patients with IBD [105 Crohn's disease (CD) and 59 ulcerative colitis (UC)] and 100 healthy controls were recruited. Genotyping of the *PTPN22* gene 1858C→T polymorphism was performed by restriction fragment length polymorphism-polymerase chain reaction with *Rsa* I digestion.

**RESULTS:** The genotypic and allelic frequencies of (R620W) *PTPN22* gene polymorphism reveal a significant association of the *PTPN22* 620-W allele with IBD, compared to the healthy control group (OR: 17.81, 95% CI: 4.18-21.86,  $P = 0.00001$ ). Nevertheless, no

difference in this polymorphism was found between CD and UC patients. No significant association was found between the frequencies of genotypes of the *PTPN22* gene with either the clinical features such as sex, age, age at disease onset, and extent of colitis, or the production of serological markers (anti-Saccharomyces cerevisiae antibody in CD and perinuclear anti-neutrophil cytoplasmic antibody in UC).

**CONCLUSION:** These observations confirm the association of IBD susceptibility with the *PTPN22* 1858T (620-W) allele in Tunisian patients.

### INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease (CD) are chronic inflammatory bowel diseases (IBDs) that are characterized clinically by periods of well being punctuated by episodes of clinical disease activity that involve various sites in the gastrointestinal tract<sup>[1]</sup>. Several environmental, microbial, immunological, genetic, and life-style factors have been suggested to play a role in disease initiation<sup>[2]</sup>. Heterogeneity is observed in terms of disease location,

behavior, age of onset and serologic markers<sup>[3,4]</sup>. There is some support for the concept that this heterogeneity may be in large measure genetically determined<sup>[5]</sup>. Genome-wide scans performed in patients with IBD have failed to find a major unique susceptibility locus and have prompted the general agreement that these diseases are polygenic entities in which several genes may contribute to susceptibility<sup>[6-8]</sup>. Significant linkages in chromosomes 1, 3, 6, 7, 12, 14, 16, and 19 have been reported<sup>[9,10]</sup>.

The *PTPN22* gene, located on chromosome 1p13, encodes a lymphoid-specific protein tyrosine phosphatase (LYP), a member of a family of proteins involved in suppressing spontaneous T-cell activation via a negative regulatory C-terminal Src kinase (Csk)<sup>[11]</sup>. Indeed, LYP is implicated in maintaining the resting phenotype of lymphocytes and in controlling signals caused by an antigen, co-stimulation and cytokines<sup>[12]</sup>. A functional C1858T single nucleotide polymorphism (SNP), which encodes an arginine to tryptophan substitution at residue 620 (R620W), is located in the P1 proline-rich motif of *PTPN22*, which binds with high affinity to the Src homology 3 (SH3) domain of the tyrosine kinase<sup>[13,14]</sup>. Thus, it is plausible that this genetic discrepancy in *PTPN22* influences a range of diseases in which the phenotypic spectrum includes an aberrant or hyperactive immune response<sup>[14,15]</sup>. An association of *PTPN22* (R620W) polymorphism was reported first with type 1 diabetes<sup>[16,17]</sup> and later also with myasthenia gravis<sup>[18]</sup>, systemic lupus erythematosus<sup>[19]</sup>, and rheumatoid arthritis<sup>[14]</sup>. However, there are also some inflammatory diseases such as psoriasis, multiple sclerosis and Behcet's disease<sup>[20]</sup> without an association with this polymorphism.

In this study, we analyzed the *PTPN22* (R620W) polymorphism in Tunisian patients with CD and UC, to evaluate the contribution of the C1858T SNP to IBD susceptibility.

## MATERIALS AND METHODS

### Patients and controls

Blood samples were obtained from 164 subjects with IBD. There were 105 patients with CD (50 men, 55 women) with a mean age of 36.07 years (range: 23-60 years), and 59 patients with UC (17 men, 42 women) with a mean age of 37.89 years (range: 25-74 years). All subjects were unrelated Tunisians treated at the Department of Gastroenterology of Charles Nicolle and La Rabta Hospitals in Tunis. The diagnosis of CD and UC was determined in accordance with the standardized set of clinical, endoscopic and/or radiological and histological criteria<sup>[21]</sup> provided by International Organization for the study of IBD. Data obtained from each patient included age at diagnosis, disease location and extent, disease characteristics, and extra-intestinal manifestations (especially peripheral arthritis, ankylosing spondylitis in CD disease and primary sclerosing cholangitis in UC), which were used to group the patients according to the Vienna classification<sup>[22]</sup> (Table 1).

In the CD sample group, 47 sera out of 105 (44.8%)

**Table 1** Clinical characteristics and serological markers of CD and UC

CD patients	n = 105
Sex	55 men and 50 women
Mean age (yr)	36 ± 10.2
Age at diagnosis (yr)	31.2 ± 12.8
Disease location	
Ileitis (%)	27 (25.7)
Ileocolitis (%)	54 (51.5)
Colitis (%)	24 (22.8)
Anal involvement (%)	44 (42)
Extra-intestinal manifestations (%) (peripheral arthritis and/or ankylosing spondylitis)	20 (19.04)
ASCA (%)	47 (44.8)
UC patients	n = 59
Sex	17 men and 42 women
Mean age (yr)	38 ± 12.4
Age at diagnosis (yr)	36.3 ± 10.8
Disease extent	
Pancolitis (%)	38 (64.4)

were anti-Saccharomyces cerevisiae antibodies (ASCA)-positive, and in UC sample group, 16 sera out 59 (27.1%) were perinuclear anti-neutrophil cytoplasmic antibodies (p-ANCA)-positive.

A total of 100 unrelated healthy subjects (52 men and 48 women) matched for age, sex and ethnic origin were used as the control population. None of the healthy controls had any evidence of autoimmune diseases such as IBD or diabetes.

All patients and controls gave informed consent to participate in this study, which was approved by the Ethics Committee of Charles Nicolle Hospital in Tunis.

### Methods

Genomic DNA isolated from EDTA-anticoagulated peripheral blood samples of unrelated healthy blood donors and IBD patients was extracted by a salting-out process.

Genotyping was performed using the restriction fragment length polymorphism-polymerase chain reaction method. The PCR reactions were performed in 10- $\mu$ L final volume using 10 pmol of each primer: 5'-TGCCCATCCC ACACTTTAT-3', forward primer and 5'-ACCTCCTGGG TTTGTACCTTA-3', reverse primer, and contained 50 ng extracted DNA, 1 U Taq polymerase (Promega, Madison, WI, USA), 1.5 mmol/L MgCl<sub>2</sub> and 0.2 mmol/L dNTP. After an initial denaturing time of 15 min at 95°C, PCR reactions were run for 35 cycles including 1 min at 94°C, 1 min at 55°C and 1 min at 72°C, with a final extension at 72°C for 10 min. The PCR product was digested by 1 U of the enzyme *Rsa* I (Promega) at 37°C for 1.5 h, subjected to electrophoresis in 3% agarose gel, and stained with

Table 2 Genotype and allele frequencies of PTPN22 polymorphism in controls and patients

Groups	n	Genotype frequency			Allele frequency		P
		R/R	R/W	W/W	R	W	
Controls (%)	100	98 (98)	2 (2)	0 (0)	0.990	0.010	P/C: 0.00001 (OR: 17.81 CI 95%: 4.18-21.86)
IBD patients (%)	164	114 (69.5)	50 (30.5)	0 (0)	0.848	0.152	
CD (%)	105	68 (64.8)	37 (35.2)	0 (0)	0.823	0.177	CD/UC: NS
UC (%)	59	46 (78)	13 (22)	0 (0)	0.889	0.111	

P: Patients; C: Controls; NS: Not significant.

ethidium bromide. The PCR generated a 326-bp fragment that contained a restriction site for *Rsa* I, which permitted differentiation of the R620- allele (228 bp) and the 620-W allele (272 bp).

### Statistical analysis

All statistical analyses were performed with SPSS version 13.0 (Chicago, IL, USA). The Hardy-Weinberg equilibrium was assessed by the goodness-of fit test for biallelic markers. Calculation was done using internet programs from (<http://ihg2.helmholtz-muenchen.de/cgi-bin/hw/hwa1.pl>). Statistical power was calculated using a web power calculator (<http://calculators.stat.ucla.edu/powercalc/>). Allelic and genotypic frequencies were evaluated by direct counting. Statistical comparisons were performed, between patients and controls, by Pearson's  $\chi^2$  test calculated on  $2 \times 2$  contingency tables. Fisher's exact test was used when an expected cell value was  $< 5$ .  $P < 0.05$  was considered to be statistically significant. The strength of the association of PTPN22 R620W genotypes as a genetic factor with the frequency of an IBD symptom was estimated by the calculation of OR ( $> 1$ : positive association;  $= 1$ : no influence;  $< 1$ : protective) and 95% CI, using the same software. For groups of equal variance, the correlation between age at onset of symptoms and PTPN22 genotype was followed by two-sample Student's *t* test, to compare the means of the individual groups.

## RESULTS

The allele frequencies were in Hardy-Weinberg equilibrium both in the patients and controls. When comparing IBD patients with the control group, the frequency of the PTPN22 620-W allele was found to be significantly higher in IBD patients than in controls (Pc: 0.00001; OR: 17.81, 95% CI: 4.18-21.86). Nevertheless, no difference in this polymorphism was found between CD and UC patients (Table 2). Indeed, analysis of IBD patients according to clinical behavior revealed no difference between those carrying or not carrying the PTPN22 (R620W) allele (data not shown), in both CD and UC patients.

When stratifying IBD patients according to the Vienna classification, we did not find a statistically significant association between the frequencies of genotypes of the PTPN22 gene and the clinical features such as sex, age, age of disease onset, or extent of colitis. Moreover, no correlation was found between polymorphism studied

and the production of p-ANCA and ASCA in UC or CD patients, respectively.

## DISCUSSION

Autoimmune diseases represent a different set of associated phenotypes that are supposed to have common underlying mechanisms and thus, some degree of common genetic predisposition<sup>[23]</sup>. IBD is a chronic inflammatory condition of the gastrointestinal tract that manifests as UC or CD. Notwithstanding intensive research, the etiology of this condition remains unknown<sup>[24]</sup>. However, it is thought to result from a combination of genetic predisposition and environmental factors that may be channelled through an abnormality in gut-barrier function, with a loss of antigen tolerance. Some genetic markers that predispose to inflammatory disease have been identified (alleles DRB1\*0103, DRB\*12, and mutations in the *NOD2/CARD15* gene on chromosome 16). Nevertheless, the *CARD15* variations are not sufficient to explain the entire risk for predisposition to IBD<sup>[25]</sup>. Other polymorphisms in genes that code for proteins involved in the immune response also appear to exert an influence on the immunological mechanisms that lead to loss of tolerance to commensal microflora.

A specific role of PTPN22 in T-cell regulation has been confirmed by the results of knocking out the murine homologue of PTPN22, which results in lowered thresholds for T-cell-receptor signaling in these animals. Recent findings have revealed that the PTPN risk-associated variant, W620, results in a gain of PTPN22 phosphatase activity in T cells, which opens up new approaches for exploring disease mechanisms<sup>[26]</sup>.

Initially identified as a susceptibility allele for type 1 diabetes<sup>[17]</sup>, the PTPN22 variant has now been implicated in the genetic etiology of rheumatoid arthritis<sup>[14]</sup>, Hashimoto thyroiditis, juvenile idiopathic arthritis<sup>[27]</sup>, Graves' disease<sup>[28]</sup> and most recently, systemic lupus erythematosus<sup>[19]</sup>. Despite the association of PTPN22 C1858T SNP with several different autoimmune disorders, a role for this polymorphism in susceptibility to IBD does not appear so clear. Wagenleiter *et al*<sup>[29]</sup> have revealed no association of the 620-W allele with CD in 146 patients of Northern German origin. Additionally, they have not found any difference in PTPN22 allele frequencies between *CARD15+* and *CARD15-* patients. These results are in agreement with previous studies of Criswell

*et al.*<sup>[30]</sup>, Martin *et al.*<sup>[31]</sup> in Spanish subjects, Prescott *et al.*<sup>[32]</sup> in British subjects, and van Oene *et al.*<sup>[33]</sup> in Canadian patients. However, given the relatively small sample size of the patient and control cohort in these studies, a false-negative result cannot be ruled out.

Our data showed the association of IBD susceptibility with the *PTPN22* 1858T (620-W) allele in Tunisian patients. Similar findings were detected in Takayasu's arteritis in which *PTPN22* R620W polymorphism revealed a wide variation in allele frequencies among different populations; the polymorphic allele being present most in Scandinavia, but absent in Asian and African populations<sup>[34,35]</sup>.

No explanations have been presented for the discrepancy between positive findings, like ours, and the negative findings of others. The most plausible is the known genetic diversity of the different populations at the haplotype level. The reason for this divergence is not clear but might reflect an ethnic difference in the contribution of genetic factors.

Kyogoku *et al.*<sup>[19]</sup> have suggested that the *PTPN22* C1858T variant predisposes persons to autoimmune diseases by assisting the production of certain disease-associated antibodies, thereby contributing to disease development. IBD is thought to be primarily a T-cell mediated disease, currently, a serology panel including p-ANCA and ASCA is used for auxiliary diagnosis of IBD. However, relying exclusively on serum antibodies for IBD diagnosis is not justified yet, because the available sero-immunological markers are not sensitive and specific enough, and their role in disease pathogenesis and progression is not well established<sup>[36]</sup>. In this study, we showed an association of IBD susceptibility with the *PTPN22* 1858T (620-W) allele in Tunisian patients but no significant association was found between the frequencies of genotypes of the *PTPN22* gene and the production of ASCA in CD or p-ANCA in UC.

*PTPN22* encodes LYP, which dephosphorylates the kinases LCK, Fyn and Zap-70, all known to be important in T-cell signaling<sup>[37]</sup>. An additional function of LYP is to downregulate activation of T cells by binding to Csk<sup>[14]</sup>, an important suppressor of kinases that mediate T-cell activation. Furthermore, LYP has been demonstrated to bind to the adaptor molecule growth factor receptor-bound protein 2, and this interaction is thought to play a negative regulatory role in T-cell signaling<sup>[38,39]</sup>. The *PTPN22* 1858 C/T SNP changes the amino acid at position 620 from an arginine (R) to a tryptophan (W), disturbs the interaction between LYP and Csk, which avoids formation of the complex, and therefore, the suppression of T-cell activation.

It remains to be determined precisely how the *PTPN22* (620-W) allele influences the progression of IBD, especially since our study indicates that the analyzed polymorphism of the *PTPN22* gene do not appear to be involved in the severity of CD or UC, as defined by the need for surgery (data not shown).

In conclusion, our data showed the association of IBD susceptibility with the *PTPN22* 1858T (620-W) allele in Tunisian patients. However, no correlation was found between this *PTPN22* polymorphism and the clin-

ical or biological characteristics of CD or UC. Further studies are needed to confirm this association in more subjects and to determine the mechanisms by which this polymorphism affects the pathogenesis of this disease.

## COMMENTS

### Background

In recent years, a few studies have been published that have addressed the question of where and under which conditions *PTPN22* is produced in the gut in the normal and neoplastic situation. Some of these studies have considerably influenced our view of the role of the *PTPN22* system. That is why it has appeared necessary to analyze the *PTPN22* 1858 C/T SNP in unrelated Tunisian patients with Crohn's disease (CD) and ulcerative colitis (UC) to evaluate the contribution of the *CD95* gene to genetic susceptibility to inflammatory bowel disease (IBD).

### Research frontiers

Recent findings have revealed that the *PTPN* risk-associated variant, W620, results in a gain of *PTPN22* phosphatase activity in T cells, which has opened new approaches for exploring disease mechanisms.

### Innovations and breakthroughs

The relationship between *PTPN22* polymorphism and IBD has not been reported yet. This is probably the first report on the association of *PTPN22* polymorphisms in Tunisian IBD patients. However, this polymorphism was associated with the development of CD and UC, which provides strong support for an IBD susceptibility gene in the region surrounding *PTPN22*.

### Applications

By understanding how the *PTPN22* polymorphism is associated with the development of CD and UC, this study may indicate a future strategy for therapeutic intervention in patients with IBD.

### Peer review

This clinical study focused upon the frequency of polymorphism in a specific gene in a small group of individuals with IBD. The results are of great interest and relevance to understanding the pathogenesis of IBD.

### Abstract

**AIM:** To test the hypothesis that the shape and length of Barrett's epithelium are associated with prevalence of erosive esophagitis.

**METHODS:** A total study population comprised 869 patients who underwent endoscopy during a health check-up at our hospital. The presence and extent of Barrett's epithelium were diagnosed based on the Prague C & M Criteria. We originally classified cases of Barrett's epithelium into two types based on its shape, namely, flame-like and lotus-like Barrett's epithelium, and into two groups based on its length, its C extent < 2 cm, and  $\geq$  2 cm. Correlation of shape and length of Barrett's epithelium with erosive esophagitis was examined.

**RESULTS:** Barrett's epithelium was diagnosed in 374 cases (43%). Most of these were diagnosed as short-segment Barrett's epithelium. The prevalence of erosive esophagitis was significantly higher in subjects with flame-like than lotus-like Barrett's epithelium, and in those with a C extent of  $\geq$  2 cm than < 2 cm.

**CONCLUSION:** Flame-like rather than lotus-like Barrett's epithelium, and Barrett's epithelium with a longer segment were more strongly associated with erosive esophagitis.

### INTRODUCTION

In patients with Barrett's epithelium, the resulting replacement of normal squamous epithelium with columnar epithelium can be seen in the distal esophagus as a salmon-pink-colored area that is readily visible during endoscopic examination. Barrett's epithelium is recognized as a complication of erosive esophagitis and is the pre-malignant condition for adenocarcinoma

of the esophagus<sup>[1,2]</sup>. The incidence of esophageal adenocarcinoma is rapidly increasing in the United States and Europe<sup>[3-5]</sup>, and is reported to account for up to 50% of esophageal cancers seen in white males in the United States<sup>[5]</sup>. For esophageal carcinoma in Japan, however, the ratio of adenocarcinoma to squamous cell carcinoma is low, and no significant changes have been identified<sup>[6]</sup>. As the prevalence of erosive esophagitis is increasing, further observation of Barrett's epithelium and esophageal adenocarcinoma is required in Japan. However, the reasoning behind the recommendation for regular endoscopic screening and biopsies in patients with Barrett's epithelium in Japan is unclear, and whether all patients with Barrett's epithelium, or only a subgroup with risk factors for the development of adenocarcinoma should be screened, remains controversial.

It has been known for more than a century that chronic inflammation can contribute to cancer formation. Chronic inflammatory conditions of the gastrointestinal tract, such as ulcerative colitis and chronic pancreatitis, are well known to predispose patients to carcinogenesis. Lassen *et al.*<sup>[7]</sup> have reported that the risk of esophageal adenocarcinoma was fivefold greater among patients with diagnosed esophagitis, but most of these cancers seemed to be related to Barrett's esophagus. Several studies have indicated that a dose-response relationship exists between the severity of erosive esophagitis and the incidence of esophageal adenocarcinoma<sup>[8-11]</sup>. These findings suggest that the major risk factor for esophageal adenocarcinoma is the existence of Barrett's epithelium complicated with erosive esophagitis.

We hypothesized that some macroscopic features of Barrett's epithelium might be useful for identifying a subgroup with a high risk for the development of esophageal adenocarcinoma. Therefore, we conducted a retrospective cohort study to examine the correlation of the shape and length of Barrett's epithelium with erosive esophagitis.

## MATERIALS AND METHODS

### Patients

A total of 869 patients (463 men, 406 women; median age, 66 years; age range, 29-91 years) who had undergone an upper endoscopy at the Gastroenterology Division of Yokohama City University Hospital between August 2005 and July 2006 were enrolled in the study. The total study population consisted of consecutive patients who had undergone endoscopy for a health checkup in our hospital. The majority of the patients were outpatients. None of the patients had previously undergone an upper digestive tract operation. Ten patients were excluded, because their profiles were unsatisfactory or they refused to participate in the present study.

### Endoscopic findings

At the Yokohama City University Hospital, when endoscopically examining and photographing the esophageal

mucosa, the gastroesophageal junction (GEJ) is always prospectively photographed. Our hospital operates a digital filing system for endoscopic images. All digital endoscopic images were independently and retrospectively reviewed by two trained endoscopists to investigate the endoscopic findings, including gastric mucosal atrophy (GMA), hiatal hernia, erosive esophagitis, and Barrett's epithelium. If there was any inconsistency in the assessment of the digital endoscopic images, a final diagnosis was decided upon by a joint review of the digital endoscopic images.

### Barrett's epithelium

The presence and extent of Barrett's epithelium were diagnosed based on the Prague C & M Criteria<sup>[12]</sup>. According to these criteria, Barrett's epithelium is defined as the macroscopic identification, using a standard endoscopy examination, of abnormal columnar esophageal epithelium suggestive of columnar-lined distal esophagus. The length of Barrett's epithelium is measured (in cm) using the circumferential extent (the C extent) and the maximum extent (the M extent) above the GEJ, which is identified as the proximal margin of the gastric mucosal folds in centimeters<sup>[12]</sup>.

### Shape of Barrett's epithelium

We originally classified Barrett's epithelium into two types based on its shape. As shown in the Figure 1, we classified the shape of Barrett's epithelium as follows: (A) the L type, in which the difference between the C extent and M extent was  $< 2$  cm and the visible red columnar epithelium could be observed as a lotus-like shape; and (B) the F type, in which the difference was  $\geq 2$  cm and the columnar epithelium of Barrett's epithelium was observed as a flame-like shape.

### Length of Barrett's epithelium

We further classified Barrett's epithelium into two groups based on its length as follows: (1) Barrett's epithelium  $< 2$  cm, defined as a C extent of  $< 2$  cm in length; and (2) Barrett's epithelium  $\geq 2$  cm, defined as a C extent of  $\geq 2$  cm.

### Erosive esophagitis

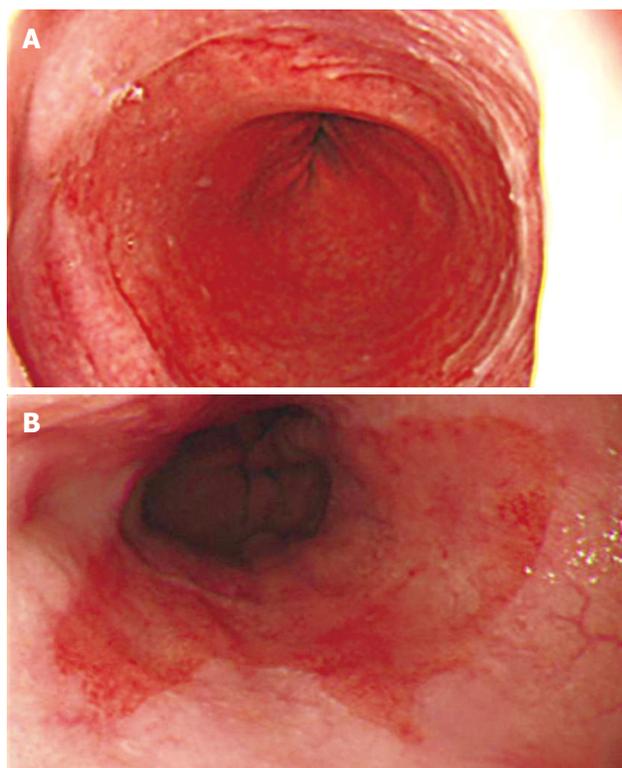

Erosive esophagitis was diagnosed based on the Los Angeles (LA) Classification<sup>[13]</sup> and was divided into three groups: none, mild (grades A and B), or severe (grades C and D).

### Hiatal hernia

Hiatal hernia was diagnosed when the distance between the GEJ and the diaphragmatic hiatus was  $\geq 2$  cm.

### GMA

The atrophic area of the stomach that can be visualized endoscopically is known to extend from the antrum to the body. Previously, Kimura and Takemoto endoscopically divided GMA into six groups (C1, C2, C3, O1, O2, and

**Figure 1 Shape of Barrett's epithelium.** We originally divided Barrett's epithelium into two types based on its shape. A: L type, in which the difference between the C extent and M extent was < 2 cm and the visible red columnar epithelium could be observed as a lotus-like shape; B: F type, in which the difference was ≥ 2 cm and the columnar epithelium of Barrett's epithelium was observed as a flame-like shape.

O3; C, closed; O, open)<sup>[14]</sup>. GMA has been shown to progress from C1 to O3 successively, and this classification correlates well with the histological features of GMA<sup>[14]</sup>. Gastric acid secretion in patients with open-type GMA has been reported to be lower than that in patients with closed-type GMA<sup>[15]</sup>. In the present study, we defined closed-type (C1-C3) cases as mild GMA and open-type (O1-O3) cases as severe GMA.

**Patient profiles**

Complete patient information, including age, sex, body mass index (BMI), regular drinking habit and smoking habit, at the time of the initial diagnosis was obtained from the patient's medical records.

**Ethics**

The study was conducted in accordance with the Declaration of Helsinki. The study protocol was approved by the Ethics Committee of Yokohama City University Hospital. The patients gave their signed informed consent to be involved in the study.

**Statistical analysis**

In our cohort study, to investigate the correlation between the shape and length of Barrett's epithelium and erosive esophagitis, the variables were compared between patients with different shapes and between

patients with different lengths. The statistical analysis included a  $\chi^2$  test or a Fisher exact test to compare percentages, and a Mann-Whitney *U* test to compare continuous data. The level of significance was defined as *P* < 0.05. All statistical analyses were performed using Stat View software (SAS Institute, Cary, NC, USA).

**RESULTS**

The baseline characteristics of the study population are summarized in Table 1. A total of 374 patients (43.0%) (211 men and 163 women; mean age, 68 years; range, 31-91 years) were diagnosed as having Barrett's epithelium based on the Prague C & M Criteria<sup>[10]</sup>. These consisted of 370 cases (42.6%) with short-segment Barrett's epithelium (SSBE), whose C extent was < 3 cm, and four cases (0.5%) with longer segment Barrett's epithelium (LSBE), whose C extent was ≥ 3 cm. A total of 165 cases (19.0%) had erosive esophagitis: 152 (17.5%) had mild esophagitis (LA grades A and B), and 13 (1.5%) had severe esophagitis (LA grades C and D).

Table 2 shows the clinical characteristics of the subjects according to the two types of Barrett's epithelium shape. No significant differences in age, sex, BMI, and hiatal hernia were observed between the subjects with F type and L type Barrett's epithelium. The subjects with F type Barrett's epithelium tended to have higher prevalence of regular drinking and smoking compared with those with L type Barrett's epithelium, but without statistical significance. The prevalence of open-type GMA was significantly lower in the subjects with F type than L type Barrett's epithelium. The prevalence of erosive

esophagitis, especially severe esophagitis, was significantly higher in the subjects with F type than L type Barrett's epithelium.

Table 3 shows the clinical characteristics broken down by the two lengths of Barrett's epithelium. The prevalence of hiatal hernia and erosive esophagitis was significantly higher in subjects with Barrett's epithelium with a C extent of  $\geq 2$  cm.

## DISCUSSION

Chronic inflammation, such as ulcerative colitis and chronic pancreatitis, is a well known risk factor for cancer formation. As mentioned above, several clinical studies have suggested that the major risk factor for esophageal adenocarcinoma is Barrett's epithelium with complicated erosive esophagitis<sup>[7-11]</sup>. The histological evidence of moderate to severe inflammation, along with the expression of the pro-inflammatory cytokines interleukin (IL)-1 $\beta$ , IL-8, and nuclear factor (NF)- $\kappa$ B have been detected in biopsies of Barrett's epithelium<sup>[16,17]</sup>. Moreover, the infiltrating inflammatory cells are not the only source of pro-inflammatory cytokines, because Barrett's epithelial cells themselves have been found to express IL-8, IL-1 $\beta$ , and IL-10<sup>[16,18]</sup>. NF- $\kappa$ B activation and epithelial cell expression of tumor necrosis factor (TNF)- $\alpha$  and its receptor TNFR1 all have been found to increase as Barrett's epithelium develops dysplastic changes of progressive severity, which suggests that the inflammatory response might contribute to carcinogenesis<sup>[16,19]</sup>. Although elevated levels of IL-8 and IL-1 $\beta$  have not been found in dysplastic Barrett's epithelium, higher expression levels of both cytokines have been detected in esophageal adenocarcinoma<sup>[16]</sup>. These biohistochemical studies have demonstrated that chronic inflammation caused by

gastroesophageal reflux disease (GERD) is an important factor in the etiology of carcinogenesis in Barrett's epithelium, which suggests an increase in the malignant potential of Barrett's epithelium, especially when it is accompanied by erosive esophagitis. The identification of a subgroup with a high risk for the development of esophageal adenocarcinoma may be helpful in developing more efficient screening programs for patients with Barrett's epithelium.

We hypothesized that some macroscopic features of Barrett's epithelium might be useful for identifying a subgroup with a high risk for the development of esophageal adenocarcinoma. Therefore, we conducted the present study with the aim of examining the correlation of the shape and length of Barrett's epithelium with erosive esophagitis.

The present study demonstrated that 43.0% (SSBE, 42.6%; LSBE, 0.5%) of the study population were diagnosed as having Barrett's epithelium based on the Prague C & M Criteria<sup>[12]</sup>. These findings were consistent with those from other reports in Japan in which SSBE was frequent, whereas LSBE was rare compared with the United States and Western Europe<sup>[20,21]</sup>. The frequency of Barrett's epithelium might be affected by differences in its definition, with particular regard as to whether histological confirmation of specialized intestinal metaplasia is required. In western countries, several physicians think that confirmation of intestinal metaplasia with an esophageal biopsy is needed to identify correctly the pathology as Barrett's epithelium<sup>[22]</sup>, because it is considered a risk factor for esophageal adenocarcinoma<sup>[23]</sup>. In this regard, the cases of Barrett's epithelium in the present study based on the Prague C & M Criteria<sup>[12]</sup> were diagnosed endoscopically without histological confirmation, and were defined as endoscopic Barrett's epithelium.

We elucidated a significant correlation between the shape and length of Barrett's epithelium and prevalence of erosive esophagitis. The prevalence of erosive esophagitis, especially severe esophagitis, was significantly higher in the subjects with F type than L type Barrett's epithelium (Table 2). F type Barrett's epithelium might originate as a direct result of columnar replacement of areas damaged by erosive esophagitis. It was possible that F type Barrett's epithelium had more severe esophagitis because less had been transformed into Barrett's epithelium, and when the transformation to columnar epithelium had taken place, the previous area with erosive esophagitis would naturally decrease. Yamagishi *et al*<sup>[24]</sup> have reported that the localization of Barrett's epithelium was similar to the localization of mild esophagitis, which was the most prevalent form of erosive esophagitis in Japan, which suggests that tongue-like Barrett's epithelium arises as a result of erosive esophagitis. The prevalence of erosive esophagitis was significantly higher in subjects with LSBE (Table 3), which was consistent with several studies that have shown that the extent of Barrett's epithelium is correlated with severe esophageal exposure to acid (an increased percentage of the time during which the esophagus is exposed to a pH below 4)<sup>[25-27]</sup>. These findings may explain partly why LSBE has a higher risk of the development of esophageal adenocarcinoma. Harle *et al*<sup>[28]</sup> and Ransom *et al*<sup>[29]</sup> have suggested a positive relationship between the extension of Barrett's epithelium and the risk of developing adenocarcinoma in the esophagus. The Rotterdam Esophageal Tumor Study Group has demonstrated that a doubling of the length of Barrett's epithelium increased the risk of adenocarcinoma by 1.7 times<sup>[30]</sup>.

The present study demonstrated that F type Barrett's epithelium and LSBE were significantly more strongly associated with erosive esophagitis, as an important factor in the development of esophageal adenocarcinoma, which suggests that patients with Barrett's epithelium with these macroscopic features are at higher risk for carcinogenesis compared to other types. The development of esophageal adenocarcinoma is usually seen as a sequence - GERD - erosive esophagitis - Barrett's epithelium - low-grade dysplasia - high-grade dysplasia - esophageal adenocarcinoma. Barrett's epithelium with these macroscopic features may have a risk of complication of low- or high-grade dysplasia and development of esophageal adenocarcinoma.

Our study had several limitations that may need to be considered. First, the data were collected from a review of endoscope images. The shape and length of Barrett's epithelium evaluated in a retrospective fashion were undoubtedly subject to some uncertainty. To minimize this limitation, we assessed the extent of Barrett's epithelium based on the Prague C & M Criteria, which consist of two indicators: the C extent and M extent, and defined F type Barrett's epithelium by the criterion in which the difference between the C extent and M extent should be  $\geq 2$  cm. Second, the present study might not have had a large enough population to

examine in detail the association between the shape and length of Barrett's epithelium and erosive esophagitis. Third, a disadvantage was the lack of histopathological examination of the samples to confirm the diagnosis, and also the ability to classify further into low- and high-grade dysplasia. Further large population-based cohort studies with histopathological examination of Barrett's esophagus to classify into low- or high-grade dysplasia are needed to confirm this assumption.

In conclusion, F type Barrett's epithelium and LSBE were significantly more strongly associated with erosive esophagitis, as an important factor in the development of esophageal adenocarcinoma. The identification of a subgroup with these macroscopic features of Barrett's epithelium may be helpful in developing more efficient screening programs for patients with Barrett's epithelium. Further prospective large population-based cohort studies are needed to confirm this assumption.

## COMMENTS

### Background

Barrett's epithelium is recognized as a complication of erosive esophagitis and is the pre-malignant condition for adenocarcinoma of the esophagus.

### Research frontiers

The authors hypothesized that some macroscopic features of Barrett's epithelium might be useful for identifying a subgroup with a high risk for the development of esophageal adenocarcinoma.

### Innovations and breakthroughs

Recent studies have suggested that the major risk factor for esophageal adenocarcinoma is the existence of Barrett's epithelium complicated with erosive esophagitis. The prevalence of erosive esophagitis was significantly higher in subjects with flame-like than with lotus-like Barrett's epithelium, and in those with a C extent of  $\geq 2$  cm than  $< 2$  cm.

### Applications

By understanding the shape of Barrett's epithelium, this study may represent a future strategy for intervention in the prevention of esophageal adenocarcinoma.

### Terminology

The development of esophageal adenocarcinoma is usually seen as a sequence - gastroesophageal reflux disease - erosive esophagitis - Barrett's epithelium - low-grade dysplasia - high-grade dysplasia - esophageal adenocarcinoma. Barrett's epithelium with these macroscopic features may have a risk of complication of low- or high-grade dysplasia and development of esophageal adenocarcinoma.

### Peer review

This is well-written paper on the important subject of trying to identify those subjects with Barrett's esophagus who might develop esophageal adenocarcinoma. The structure is clear and the presentation is good.

### Abstract

**AIM:** To assess the indications, findings, therapeutic procedures, safety, and complications of endoscopic retrograde cholangiopancreatography (ERCP) performed in Korean children.

**METHODS:** The demographic characteristics, indications for ERCP, findings, therapeutic procedures, and complications of 122 pediatric patients who underwent 245 ERCs in the Asan Medical Center between June 1994 and March 2008 were investigated.

**RESULTS:** The mean age of the 122 patients was  $8.0 \pm 4.2$  years. Indications were biliary pathology in 78 (64.0%), pancreatic pathology in 43 (35.2%), and chronic abdominal pain in one. Biliary indications included choledochal cysts in 40, choledocholithiasis in 24, suspected sclerosing cholangitis in 8, trauma in 2, and other conditions in 4. Pancreatic indications included

acute pancreatitis in 7, acute recurrent pancreatitis in 11, chronic pancreatitis in 20, trauma in 3, and pancreatic mass in 2. Of the 245 ERCs, success rate was 98.4% and 190 (77.6%) were for therapeutic purposes, including endoscopic nasal drainage (51.8%), biliary sphincterotomy (38.0%), pancreatic sphincterotomy (23.3%), stent insertion (15.1%), stone extraction (18.8%), and balloon dilatation (11.0%). Complications were post-ERCP pancreatitis in 16 (6.5%), ileus in 23 (9.4%), hemorrhage in 2 (0.8%), perforation in 2 (0.8%), sepsis in 1 (0.4%), and impacted basket in 1 (0.4%). There were no procedure-related deaths, and most complications improved under supportive care.

**CONCLUSION:** This study showed that there is a high incidence of choledochal cyst and diagnostic and therapeutic ERCP for the management of various biliary and pancreatic diseases was safe and effective in Korean children.

Endoscopic retrograde cholangiopancreatography in pancreatic and biliary tract disease in Korean children. *World J Gastroenterol* 2010; 16(4): 490-495 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i4/490.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i4.490>

### INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) is

a standard diagnostic and therapeutic modality for pancreaticobiliary diseases in adults<sup>[1]</sup>. Its standard use in children, however, has been limited by technical difficulties, low incidence of pancreaticobiliary disease, and lack of knowledge of ERCP by pediatric surgeons and pediatricians<sup>[2]</sup>. Pediatric ERCP is used as a therapeutic tool in addition to its diagnostic applications<sup>[3,4]</sup>. Regional differences in indications have been observed for pediatric ERCP<sup>[3-7]</sup>. Although the frequency of choledochal cysts is higher in Asian than in Western populations, there have only been a few studies of pediatric ERCP in Asian countries, with each involving small numbers of patients<sup>[5,7]</sup>. We therefore describe our experience in performing 245 ERCPs in 122 Korean children with pancreatobiliary diseases, focusing on the presenting diseases, diagnostic and therapeutic efficacy, and safety.

## MATERIALS AND METHODS

Between June 1994 and March 2008, 122 children (mean age,  $8.0 \pm 4.2$  years; range, 1 month to 16 years) underwent 245 ERCPs at the Asan Medical Center, Seoul, Korea. Of these 122 patients, 52 were boys and 70 were girls. We retrospectively reviewed the computerized hospital records of all patients to determine indications for ERCP, success of the procedure, diagnostic findings, therapeutic procedures, and complications. We also reviewed the basic characteristics of patients and the types of sedation used. Indications for ERCPs included biliary disease, pancreatic disease, and recurrent abdominal pain. ERCP was performed by standard techniques, using either a conventional adult duodenoscope (JF: Olympus America Inc.), a therapeutic duodenoscope (TJF: Olympus America Inc.), Pediatric duodenoscope (PJF-7.5E: Olympus America Inc.). The first few ERCPs were supervised by an adult gastroenterologist, with most subsequent procedures were performed by a pediatrician alone, except for some complicated cases. Informed, written consent was obtained from the parents of all patients, and this study was approved by our Internal Review Board. All ERCPs were performed under general anesthesia or deep sedation (midazolam, ketamine, and fentanyl). Successful ERCP was defined as cannulation of the bile duct or pancreatic duct along with completion of any planned diagnostic study or therapeutic procedure. Post-ERCP pancreatitis was defined as pancreatic abdominal pain with serum amylase/lipase elevated to over 3 times the upper normal limit.

## RESULTS

During the 14-year time period, we performed 245 ERCPs, including 55 (22.4%) diagnostic and 190 (77.6%) therapeutic procedures, on 122 children. Sixty-seven ERCPs (27.3%) were performed under general anesthesia and 178 (72.7%) under deep sedation. Of these 245 procedures, 241 (98.4%) resulted in successful cannulation. There were 78 (64.0%) patients with biliary indications,

Table 1 Indications for ERCP in 122 children *n* (%)

Indications	No. of patients	No. of procedures
Biliary indication	78 (64.0)	103 (42.0)
Choledochal cyst	40 (32.8)	60 (24.5)
Choledocholithiasis	24 (19.7)	27 (11.0)
Suspected sclerosing cholangitis	8 (6.6)	8 (3.3)
Trauma	2 (1.6)	4 (1.6)
Biliary complication after liver transplantation	2 (1.6)	2 (0.8)
Biliary stenosis after operation	1 (0.8)	1 (0.4)
Biliary atresia	1 (0.8)	1 (0.4)
Pancreatic indication	43 (35.2)	141 (57.6)
Acute pancreatitis	7 (5.7)	10 (4.1)
Acute recurrent pancreatitis	11 (19.7)	23 (9.4)
Chronic pancreatitis	20 (16.4)	102 (41.6)
Pancreatic mass	2 (1.6)	2 (0.8)
Trauma	3 (2.4)	4 (1.6)
Chronic abdominal pain	1 (0.8)	1 (0.4)
Total	122	245

ERCP: Endoscopic retrograde cholangiopancreatography.

43 (35.2%) with pancreatic indications, and one (0.8%) with chronic abdominal pain (Table 1).

### Biliary indications

The most common biliary indication was choledochal cyst (CC), also known as congenital biliary dilatation. Table 2 shows the diagnostic findings in 78 patients with biliary indications. Forty patients with choledochal cysts underwent 60 ERCPs. Choledochal cysts were divided to 4 types using the Todani classification<sup>[8]</sup>. There were 14 patients with type I c, 2 with type III, and 24 with type IV CC. Thirty of these 40 patients had bile duct stones (choledocholithiasis) and 9 had common bile duct (CBD) strictures. Anomalous union of the pancreaticobiliary duct (AUPBD) was detected in 25 patients with CC. Endoscopic sphincterotomy was performed on 2 CC type III patients without recurrence. Patients with acute biliary pancreatitis and choledocholithiasis underwent various procedures, including endoscopic sphincterotomy, endoscopic nasal biliary drainage, and stone extraction. ERCPs were performed for preoperative treatment or evaluation, except for one patient who underwent ERCP after surgery for removal of remnant stones. Two patients (one type Ic and one type IVa), who showed much improved bile duct dilatation after ERCP, underwent laparoscopic cholecystectomy. Eight type Ic patients and 18 type IVa patients underwent Roux-en-Y hepaticojejunostomy after acute pancreatitis or acute biliary colic had resolved. One type IVa patient showed improved bile duct dilatation and cholestasis after ERCP, but died of an underlying disease, acute myeloid leukemia. Ten patients, 6 of type Ic and 4 of type IVa, are well, with mild dilatation of the CBD; surgery is planned for each. Two patients with type I CC showed improved dilatation, with the disappearance of CC confirmed by ultrasound.

Of the 24 patients with choledocholithiasis, 19

**Table 2** Diagnostic findings in 78 patients with biliary indications

Diagnosis (number of patients)	ERCP findings							
	Bile duct stone	CBD dilatation	CBD stricture	SC	Bile leak	AUPBD	Normal	Failure
Choledochal cyst ( <i>n</i> = 40)	30	38	9			25		1
Choledocholithiasis ( <i>n</i> = 24)	24	19	4			6		
Suspected SC ( <i>n</i> = 8)				4			4	
Trauma ( <i>n</i> = 2)			1		1			
Biliary complication after liver transplantation ( <i>n</i> = 2)					1		1	
Biliary stenosis after operation ( <i>n</i> = 1)			1					1
Biliary atresia ( <i>n</i> = 1)								1

CPD: Common bile duct; SC: Sclerosing cholangitis; AUPBD: Anomalous union of the pancreaticobiliary duct.

**Table 3** Diagnostic findings in 43 patients with pancreatic indications

Diagnosis (number of patients)	ERCP findings									
	PD dilatation	PD stenosis	Pancreaticolith	PD anomaly	AUPBD	Pancreas divisum	Trans-section of pancreas	Other	Normal	Failure
Acute pancreatitis ( <i>n</i> = 7)		1	1					1 CBD stenosis	4	
Acute recurrent pancreatitis ( <i>n</i> = 11)		2		2	2	2			3	
Chronic pancreatitis ( <i>n</i> = 20)	16	11	6	1	1	8				1
Pancreatic mass ( <i>n</i> = 2)	1							1 SPPN		
Trauma ( <i>n</i> = 3)							3			

SPPN: Solid pseudopapillary neoplasm; PD: Pancreatic duct.

showed CBD dilatation, however they did not show the evidence of CC and 4 had CBD stricture. AUPBD was found in 6 patients. Only 2 patients had specific hematologic diseases, one each with hereditary spherocytosis and glucose-6-phosphate dehydrogenase (G6PD) deficiency. Eight patients underwent ERCP for suspected sclerosing cholangitis, but only 4 showed evidence of sclerosing cholangitis, with the other 4 showing no abnormalities. Two patients who experienced blunt trauma underwent ERCP; one had intrahepatic bile duct leakage and one had a benign CBD stricture. Two patients were suspected to have biliary complications after liver transplantation; one showed a bile leak and the other showed no abnormal findings. One patient had a CBD stricture after resection of a duodenal web. Cannulation was unsuccessful in one patient with biliary atresia.

**Pancreatic indications**

The most common pancreatic indication was chronic pancreatitis, observed in 20 patients. Other pancreatic indications included acute pancreatitis (7 patients), acute recurrent pancreatitis (11 patients), pancreatic mass (2 patients), and trauma (3 patients). Table 3 shows the diagnostic findings in 43 patients with pancreatic indications. Pancreas divisum was observed in 10 patients, 7 of whom underwent repeated endoscopic minor pancreatic sphincterotomy because of minor duct stenosis. Of the 8 patients with acute pancreatitis, 4 showed normal findings, and one each showed evidence of pancreatic duct stenosis, pancreaticoliths, and CBD stenosis. ERCP on a boy aged 9 years, with pancreatitis and a suspected

intraductal papillary mucinous neoplasm, showed a bulge of the ampulla of Vater and large amounts of sticky mucinous materials, but histology after surgery showed only chronic pancreatitis. Of the 11 patients with acute recurrent pancreatitis, 2 showed pancreatic duct stenosis, 2 showed pancreatic duct anomalies, 2 had AUPBD, 2 had pancreas divisum, and 3 showed normal findings. Preoperative ERCP on 2 patients with pancreatic masses showed that one had a retroperitoneal teratoma with extrinsic distal CBD compression, and the other had a solid pseudopapillary neoplasm in the tail of the pancreas with abrupt interruption of the distal pancreatic duct. Three patients with traumatic pancreatitis showed transection of the pancreas.

**Abdominal pain**

ERCP showed that one patient with recurrent abdominal pain had a normal anatomy of the pancreaticobiliary system. We did not perform the sphincter of Oddi manometry because of its technical problems and difficulties of translation with no definite normal range in children with ERCP.

**Therapeutic procedures**

Of the 245 ERCPs, 127 (51.8%) were for endoscopic nasal drainage, 93 (38.0%) were for biliary sphincterotomy, and 57 (23.3%) were for pancreatic sphincterotomy. Stents were inserted during 37 procedures (15.1%), stone extraction was achieved during 46 (18.8%), balloon dilatation of a strictured CBD or pancreatic duct was performed in 27 (11.0%). Endoscopic drainage of a

Table 4 Therapeutic procedures during 245 ERCPs

Type of endoscopic therapy	Number of procedures (% of 245 cases)
Endoscopic nasal drainage	127 (51.8)
Biliary sphincterotomy	93 (38.0)
Pancreatic sphincterotomy	57 (23.3)
Stone extraction	46 (18.8)
Stent insertion	37 (15.1)
Balloon dilatation	27 (11.0)
Endoscopic drainage of pseudocyst	2 (0.8)

pseudocyst complicating acute pancreatitis was performed in 2 patients (Table 4). One had a pneumoperitoneum, which was improved by supportive care with nil by mouth. In early times, we placed the nasobiliary drain in patients but nowadays we prefer to insert 5 to 7 Fr plastic stents depending on age for biliary obstruction or septic cholangitis.

### Complications

Post-ERCP pancreatitis was observed after 16 procedures (6.5%), and post-ERCP ileus after 23 (9.4%). In 16 cases of post-procedure pancreatitis, there were 4 mild, 10 moderate, 2 severe cases and all cases developed early (a few hours) after ERCP by Cotton's definition<sup>[9]</sup>. Two patients had major episodes of hemorrhage at the sphincterotomy site, requiring red blood cell transfusion. These patients underwent additional ERCPs and epinephrine injections. Intestinal perforation developed in 2 patients. One, with perforation of the CC wall and bile leakage, underwent an emergency operation, and the other, with perforation of the posterior duodenal wall, improved following supportive care. Culture-proven sepsis was observed in one patient and an impacted basket in one. In the latter, the basket was broken during the removal of a large, firm, pancreatic duct stone, which was being managed by extracorporeal shock wave lithotripsy followed by endoscopic removal of the remaining basket with stones. There was no procedure-related mortality in our patients (Table 5).

## DISCUSSION

ERCP has become a new diagnostic and therapeutic modality in children with pancreaticobiliary disease<sup>[3,10]</sup>. Almost all studies, however, have been performed on Western children, with few in Asian children. The most common indications for ERCP in Western children are choledocholithiasis and pancreatitis<sup>[3,10]</sup>. Indications differ, however, in Asian countries<sup>[5,7,11]</sup>. For example, the most common indication in Saudi Arabia was choledocholithiasis in patients with sickle-cell anemia<sup>[11]</sup>, whereas the most frequent indication in Japan and India was CC<sup>[5,7]</sup>. As in Japan, the most common indication in our group of 122 Korean children was CC. Almost all patients with CC had acute biliary pancreatitis or obstructive jaundice with stone/sludge; these patients were treated by endoscopic sphincterotomy, stone removal, endoscopic nasal biliary

Table 5 Incidence of complications following 245 ERCPs

Type of complications	Number of episodes (% of 245 cases)
Pancreatitis	16 (6.5)
Ileus	23 (9.4)
Hemorrhage	2 (0.8)
Perforation	2 (0.8)
Sepsis	1 (0.4)
Impacted basket	1 (0.4)

drainage (ENBD), or stent insertion. We previously reported that biliary pancreatitis is a common cause of acute pancreatitis in Korean children and that intervention with ERCP may be a useful treatment modality<sup>[12]</sup>. We found that ERCP helped to improve pancreatitis and associated inflammation, and offered relief of acute symptoms. For this purpose, we performed ENBD or indwelling stent implantation prior to operation of CC. ERCP-guided interventions in patients with complicated CCs, combined with AUPBD, have been reported to be helpful in refractory cases and to optimize patient condition prior to definitive surgery<sup>[13-16]</sup>. In addition to symptomatic relief, preoperative ERCPs also may provide surgeons with more precise anatomical knowledge of the bile duct and the pancreatic duct, which may help during total surgical excision, the optimal treatment for CC. Surgeons require information on the length of the distal narrow portion of the dilated bile duct and clear visualization of its confluence with the pancreatic duct<sup>[7]</sup>. In addition, ERCP has been reported to be superior to magnetic resonance cholangiopancreatography (MRCP) in evaluation of minor ductal anomalies<sup>[17]</sup> although MRCP is a noninvasive, safe technique. Endoscopy is the treatment of choice for uncomplicated choledochoceles (type III)<sup>[18]</sup>, and we treated two such patients with endoscopic sphincterotomy.

A total of 33 patients had AUPBD, including 25 with CC, 6 with choledocholithiasis, and 2 with acute recurrent pancreatitis. Thirty patients underwent endoscopic sphincterotomy and drainage. The incidence of AUPBD in Asian patients undergoing ERCP has been reported to be 1.5%-2.6%<sup>[19]</sup>. These patients require surgical treatment, because biliary cancer can arise from chronic inflammation of the bile duct because of the reciprocal regurgitation of pancreatic and bile juice reflux, although endoscopic sphincterotomy can be considered for most symptomatic patients<sup>[16]</sup>. Using an AUPBD puppy model, sphincteroplasty was shown to be effective in reducing bile duct dilatation and mucosal hyperplasia<sup>[20]</sup>. Prophylactic cholecystectomy is considered the best treatment option for patients with AUPBD but without bile duct dilatation<sup>[21]</sup>. We found that bile duct dilatation improved in 2 such patients, both of whom underwent laparoscopic cholecystectomy.

Choledocholithiasis is the second most frequent biliary indication for ERCP. Such patients were treated by endoscopic sphincterotomy and stone removal with basket/balloon extraction. Only 2 patients had hematologic diseases: hereditary spherocytosis and G6PD deficiency.

ERCP is considered the treatment of choice in children with CBD stones<sup>[11]</sup>. One patient with both CBD and gallbladder stones underwent endoscopic CBD stone removal and subsequent laparoscopic cholecystectomy for gallbladder stones or sludges. Therefore, surgery was minimally invasive.

The most common pancreatic indication in our study was chronic pancreatitis, observed in 20 patients who underwent 102 ERCPs (40.8%; mean 5.2 ERCPs per patient). These patients underwent repeated sphincterotomy with nasal drainage, and stents were placed in 9 patients.

Pancreas divisum was observed in 10 patients with pancreatic indications, 8 with chronic pancreatitis and 2 with acute recurrent pancreatitis. ERCP is a useful diagnostic and therapeutic procedure in patients with pancreas divisum<sup>[22]</sup>. Minor papilla sphincterotomy and stent insertion can decrease the rate of recurrent acute pancreatitis<sup>[23]</sup>. We performed minor duct sphincterotomy and inserted stents in 7 of these 10 patients, without specific complications.

Other pancreatic indications included suspected intraductal mucinous pancreatic adenoma, which was revealed to be chronic pancreatitis, pancreatic duct lesions related to a pancreatic mass, and transected pancreas arising from trauma. Although recurrent abdominal pain has been reported to be a common indication for ERCP<sup>[3]</sup>, we found that only one patient underwent ERCP for suspected pancreatic abdominal pain and that, on ERCP, this patient showed normal findings.

Among the ERCP-associated procedures now becoming therapeutic options in children with pancreaticobiliary disease are sphincterotomy, balloon dilatation, stone extraction, stent insertion, and nasal drainage<sup>[2,3,6,10,11]</sup>. We also performed various therapeutic procedures (Table 4), almost all of which relieved acute symptoms, as well as revealing more exact anatomy to the pediatric surgeons.

ERCPs performed by expert endoscopists in children have been reported to have similar success rates and lower complication rates compared with ERCPs in adult patients<sup>[4]</sup>. Although we experienced some complications, there was no procedure-related mortality. Post-ERCP pancreatitis occurred after 16 ERCPs (6.5%) however all showed improvement with supportive care. The incidence of pancreatitis following ERCPs in adults has been reported to be 2.6%-13.1%<sup>[24-26]</sup>.

In conclusion, diagnostic and therapeutic ERCPs were performed safely and effectively in Korean children for the management of various biliary and pancreatic diseases. Pediatricians and pediatric surgeons, especially those working in Asian countries, should become more familiar with ERCP as a diagnostic and therapeutic modality, as Asia has a high incidence of CCs and anomalous union of the pancreaticobiliary duct.

application of ERCP in therapeutic purposes besides diagnostic evaluations in pediatric patients.

### Research frontiers

This study is the first report on ERCP in a large number of Korean pediatric patients.

### Innovations and breakthroughs

The authors demonstrated that diagnostic and therapeutic ERCPs were performed safely and effectively for managements of various biliary and pancreatic diseases.

### Applications

ERCP can be considered as an effective and safe modality in children with pancreaticobiliary disease.

### Peer review

In this study, ERCPs were performed in a large number of Korean children with various biliary and pancreatic diseases safely and effectively. Pediatricians and pediatric surgeons, especially those working in Asian countries, should become more familiar with ERCP as a diagnostic and therapeutic modality, as Asia has a high incidence of CCs and anomalous union of the pancreaticobiliary duct.

### Abstract

**AIM:** To identify the mucosal patterns of *Helicobacter pylori* (*H. pylori*)-related gastritis in the gastric corpus using standard endoscopy and to evaluate their reproducibility.

**METHODS:** A total of 112 consecutive patients underwent upper gastrointestinal endoscopy. The endoscopists classified the endoscopic findings into 4 patterns. In the second part of the study, 90 images were shown to 3 endoscopists in order to evaluate the inter-observer and intra-observer variability in image assessment.

**RESULTS:** The mucosal patterns of the gastric body

were categorized into 4 types. Type 1 pattern was defined as cleft-like appearance, type 2 as regular arrangement of red dots, type 3 pattern as the mosaic mucosal pattern and type 4 pattern as the mosaic pattern with a focal area of hyperemia. Type 1 and type 2 mucosal patterns were statistically significant in predicting *H. pylori*-negative status as compared with other mucosal types ( $\chi^2 = 12.79$  and  $61.25$  respectively,  $P < 0.01$ ). Type 3 and type 4 mucosal patterns were statistically significant in predicting a *H. pylori*-positive status as compared with other mucosal types ( $\chi^2 = 21.22$  and  $11.02$  respectively,  $P < 0.01$ ). Furthermore, the sensitivity, specificity, positive and negative predictive values of type 3 plus type 4 patterns for predicting *H. pylori*-positive gastric mucosa were 100%, 86%, 94%, and 100%, respectively. The mean  $\kappa$  values for inter- and intra-observer agreement in assessing the various endoscopic patterns were 0.808 (95% CI, 0.678-0.938) and 0.826 (95% CI, 0.727-0.925) respectively.

**CONCLUSION:** Our study suggests that mucosal patterns in *H. pylori*-infected gastric mucosa without atrophy can be reliably identified using standard endoscopy in the gastric corpus.

## INTRODUCTION

After the discovery of *Helicobacter pylori* (*H. pylori*) in 1983, strong evidence has indicated that *H. pylori* infection plays an important role in the pathogenesis of chronic gastritis, peptic ulcer and gastric carcinoma<sup>[1,2]</sup>. *H. pylori* infection can be diagnosed by invasive and noninvasive techniques; however, at least 2 different tests are necessary to make the diagnosis of infection according to the European guidelines<sup>[3]</sup>. Although endoscopic features of *H. pylori* have been reported in the literature, there is still some debate over whether *H. pylori*-related gastritis can be diagnosed *via* endoscopic features alone. Most studies concluded that it is not possible to diagnose *H. pylori*-related gastritis on the basis of endoscopic findings<sup>[4-7]</sup>. Recent publications suggest that high resolution magnification endoscopy has been proved to be useful in the identification of normal gastric mucosa and *H. pylori*-related gastritis<sup>[8-10]</sup>. However, practicing high resolution magnification endoscopy in daily endoscopy examinations seems not to be feasible, because it takes more examination time and needs more training and experience. If specific mucosal patterns of *H. pylori*-related gastritis can be identified using standard endoscopy, they may be applicable to targeted biopsy of suspected *H. pylori* infection in daily practice. Up to the present, there have been no reports regarding specific mucosal patterns of *H. pylori*-related gastritis in the gastric corpus using standard endoscopy.

The aim of this study was to classify the mucosal patterns of *H. pylori*-related gastritis in the gastric corpus using standard endoscopy and to evaluate their reproducibility.

## MATERIALS AND METHODS

A pilot phase of this study was conducted from May 2007 to July 2007, in which 2 experienced endoscopists observed mucosal morphology of the gastric body, and agreed on the classification of mucosal patterns. From August 2007 to February 2008, a total of 112 consecutive patients who underwent upper gastrointestinal endoscopy for the investigation of dyspeptic symptoms were enrolled in the study. The exclusion criteria were the following: anemia; history of cirrhosis; use of certain drugs, including non-steroidal antiinflammatory drugs, proton pump inhibitors, and H2-receptor antagonists; bleeding tendency; a history of gastric surgery; and a history of eradication of *H. pylori*. The study was performed in accordance with the principles of the Declaration of Helsinki, and approved by the audit department of our institution.

### Endoscopic findings

Premedication was the same as for conventional upper gastrointestinal (GI) endoscopic examination. The endoscopic procedures were performed using an upper GI videoendoscope (Fujinon Corporation, Saitama, Japan). The whole stomach was examined first with conventional

endoscopy. The gastric corpus was chosen for observation according to previous studies using magnification endoscopy<sup>[8-10]</sup>. The observed mucosal morphology of the gastric body was classified into 4 patterns. Type 1 was defined as cleft-like appearance mainly extending along the longitudinal axis of gastric body (Figure 1A). Type 2 was defined as regular arrangement of red dots (Figure 1B). Type 3 was defined as the mosaic mucosal pattern without a focal area of hyperemia (Figure 1C). Type 4 was defined as the mosaic pattern with a focal area of hyperemia (Figure 1D). Four biopsy samples were taken directly from the observation sites as shown in Figure 1. Two samples were sent for histological analysis and 2 for a rapid urease test (Hpfast, GI Supply, Camp Hill, PA, USA). If a gastric ulcer or gastric atrophy was present, the nearby non-atrophic mucosa was chosen for observation and biopsy sampling. All endoscopies were performed by 2 experienced endoscopists (Yan SL and Chen CH), who were unaware of the results of histology and rapid urease tests before determining the mucosal types of examined patients. The sensitivity, specificity, positive and negative predictive values of various mucosal types were calculated.

### Histological analysis

Specimens for histological analysis were placed in 10% formalin solution and routinely processed. The hematoxylin and eosin stain and Giemsa stain were used for identification of *H. pylori*. The pathologist was blinded to the clinical and endoscopic findings but was aware of the region in the stomach where each biopsy specimen had been obtained.

### Diagnosis of *H. pylori* infection

A diagnosis of *H. pylori* infection was made if *H. pylori* were seen on histopathological examination and the rapid urease test was positive. Patients with negative results in both examinations were considered to be *H. pylori*-negative. According to the European guidelines for the diagnosis of *H. pylori* infection<sup>[3]</sup>, patients were excluded from the study when they had only one positive result of the rapid urease test or histological examination.

### Image evaluation

All endoscopic examinations were digitally recorded and still images of observation site were captured for use in the reproducibility study. The selected images were transferred to a software program without distorting brightness, contrast or color balance. Three endoscopists (Hung YH, Yang TH and Pang VS) who had performed over 2000 upper endoscopies were invited to review these still images and were asked to classify them into type 1 to type 4 mucosal patterns as described above. All endoscopists were blinded to the result of *H. pylori* status and histology before reviewing the slides. A total of 110 images were selected and 20 of these were shown to endoscopists as a reference guide to the 4 types of mucosal pattern. The remaining 90 images (3 type 1, 19 type 2, 50 type 3, 18 type 4) were shown to each endoscopist independently. One week after initial

**Figure 1** Mucosal patterns. A: Type 1 mucosal pattern showing cleft-like appearance; B: Type 2 mucosal pattern showing regular arrangement of red dots; C: Type 3 mucosal pattern showing mosaic appearance; D: Type 4 mucosal pattern showing mosaic appearance with focal area of hyperemia.

**Table 1** Correlation between *H. pylori* infection and the observed mucosal patterns

Pattern	<i>H. pylori</i> (+)	<i>H. pylori</i> (-)	Total
Type 1	0	7	7
Type 2	0	24	24
Type 3	54	5	59
Type 4	22	0	22
Total	76	36	112

assessment, all endoscopists had to reassess the same images in a random sequence. No time limit for reviewing the slide was imposed. The endoscopists recorded their results on a preprinted form. Data obtained were used for calculation of inter- and intra-observer variabilities.

**Statistical analysis**

Statistical analysis was performed using Minitab 14.1 (Minitab Incorporated, Pennsylvania, USA). Inter-group differences were evaluated by the  $\chi^2$  test. A *P* value < 0.05 was considered to be statistically significant. The sensitivity, specificity, positive and negative predictive values of the various mucosal patterns were calculated. To examine the chance-adjusted agreement, the  $\kappa$  value was calculated for inter- and intra-observer variabilities. Inter-observer variation was calculated from the results of the first reading, with 3 pairs in all. Intra-observer variation was determined by comparing the first and second assessment for each endoscopist, with 3 pairs in all.  $\kappa$  values below 0.4 indicated poor agreement, values between 0.4 and 0.8 represent moderate agreement, values between 0.6 and 0.8 represented substantial agreement,

and values greater than 0.8 corresponded to excellent agreement.

**RESULTS**

A total of 112 consecutive patients (59 men, 53 women; mean age 47.0 years, range 17-91 years) were enrolled in the study from August 2007 to February 2008. Of the 112 patients included, 7 patients showed type 1 pattern, 24 patients showed type 2, 59 patients showed type 3, and 22 patients showed type 4 (Table 1). *H. pylori* infection was demonstrated by a positive result of the rapid urease test and histological examination in 76 patients (68%).

**Type 1 findings**

All 7 patients with a type 1 mucosal pattern corresponded to an *H. pylori*-negative stomach (type 1 *vs* other mucosal types,  $\chi^2 = 12.79$ , *P* < 0.01). The sensitivity, specificity, positive and negative predictive values of the type 1 pattern for predicting *H. pylori*-negative gastric mucosa were 20%, 100%, 100%, and 72%, respectively (Table 2).

**Type 2 findings**

All 24 patients with a type 2 mucosal pattern corresponded to an *H. pylori*-negative stomach (type 2 *vs* other mucosal types,  $\chi^2 = 61.25$ , *P* < 0.01). The sensitivity, specificity, positive and negative predictive values of the type 2 pattern for predicting *H. pylori*-negative gastric mucosa were 67%, 100%, 100%, and 86%, respectively (Table 2).

**Type 3 findings**

Fifty four out of 59 patients with a type 3 mucosal pattern

**Table 2** The value of various mucosal patterns in predicting negative and positive *H. pylori* status (%)

Pattern predicting	Sensitivity	Specificity	Positive predictive value	Negative predictive value
<i>H. pylori</i> (-)				
Type 1	20	100	100	72
Type 2	67	100	100	86
Type 3	14	29	8	42
<i>H. pylori</i> (+)				
Type 3	71	86	92	58
Type 4	29	100	100	40
Type 3+4	100	86	94	100

corresponded to an *H. pylori*-positive stomach (type 3 *vs* other mucosal types,  $\chi^2 = 21.22$ ,  $P < 0.01$ ). The sensitivity, specificity, positive and negative predictive values of type 3 pattern for predicting *H. pylori*-positive gastric mucosa were 71%, 86%, 92%, and 58%, respectively (Table 2).

#### Type 4 findings

All 22 patients with a type 4 pattern corresponded to an *H. pylori*-positive stomach (type 4 *vs* other mucosal types,  $\chi^2 = 11.02$ ,  $P < 0.01$ ). The sensitivity, specificity, positive and negative predictive values of type 4 pattern for predicting *H. pylori*-positive gastric mucosa were 29%, 100%, 100%, and 40%, respectively (Table 2).

Type 3 and type 4 patterns were combined for analysis because these 2 mucosal types were generally mosaic in appearance. A combination of these 2 mucosal types was statistically significant in predicting *H. pylori*-positive status as compared with other mucosal types ( $\chi^2 = 82.80$ ,  $P < 0.01$ ). The sensitivity, specificity, positive and negative predictive values of type 3 plus type 4 patterns for predicting *H. pylori*-positive gastric mucosa were 100%, 86%, 94%, and 100%, respectively (Table 2).

#### Inter- and intra-observer variability assessment

The mean  $\kappa$  values for inter- and intra-observer agreement in assessing the various endoscopic patterns were 0.808 (95% CI: 0.678-0.938) and 0.826 (95% CI: 0.727-0.925), respectively.

## DISCUSSION

Few studies have addressed the endoscopic features of *Helicobacter*-related gastritis and most of these studies concluded that *H. pylori* infection cannot be diagnosed based on endoscopic findings alone<sup>14-71</sup>. Recently, Yagi *et al*<sup>91</sup> first described the characteristic magnification endoscopic findings of the *H. pylori*-negative stomach. Further, Anagnostopoulos *et al*<sup>81</sup> demonstrated the usefulness of magnifying endoscopy in the identification of *H. pylori*-associated gastritis in a Western population. However, practicing magnification endoscopy takes more examination time and needs more training and experience. It seems not to be feasible to practice magnification endoscopy in daily endoscopy examinations.

In our study, mucosal patterns of the gastric corpus were classified into 4 patterns using standard endoscopy. The type 1 pattern corresponded to *H. pylori*-negative gastric mucosa with a specificity of 100% but a rather low sensitivity of 20%. The type 2 pattern corresponded to *H. pylori*-negative gastric mucosa with a sensitivity of 67% and a specificity of 100%. Type 1 and type 2 mucosal patterns were both statistically significant in predicting *H. pylori*-negative status compared to other mucosal types ( $P < 0.01$ ). The red-dot appearance of the type 2 mucosal pattern represented the regular arrangement of collecting venules (RAC) of the gastric corpus under magnification endoscopy. Yagi *et al*<sup>91</sup> first proposed this magnification endoscopic finding as the normal gastric mucosa. In their study, RAC had a sensitivity of 93.8% and a specificity of 96.2% as an indicator of the *H. pylori*-negative stomach. Nakagawa *et al*<sup>111</sup> further classified the morphology of collecting venules into 3 magnification endoscopic patterns: regular (R), irregular (I), and obscure (O). The R pattern corresponded to *H. pylori*-negative gastric mucosa with a sensitivity of 66.7% and a specificity of 100% in the greater curvature of the gastric body.

Type 3 and type 4 mucosal patterns were both statistically significant in predicting *H. pylori*-positive status as compared with other mucosal types ( $P < 0.01$ ). Because type 3 and type 4 were generally mosaic in appearance, these 2 mucosal patterns were further combined for analysis, yielding a higher sensitivity of 100%, and a specificity of 86%. The positive and negative predictive values for predicting *H. pylori*-positive gastric mucosa were 94%, and 100%, respectively. The mosaic mucosa pattern in our study was similar to prominent areae gastricae, which has been shown to be a characteristic double contrast radiological finding in gastritis caused by *H. pylori* infection<sup>121</sup>. Furthermore, the prominent areae gastricae observed in our study is also similar to the mosaic mucosal pattern in patients with portal hypertension<sup>131</sup>. However, patients with cirrhosis were excluded in our study. Therefore, the mosaic mucosal pattern in our study seems to be a good indicator in predicting *H. pylori*-positive gastric mucosa in the gastric corpus.

The reproducibility of a classification system is very important in clinical practice. The  $\kappa$  values below 0.4 correspond to poor agreement, values between 0.4 and 0.8 indicate moderate agreement, values between 0.6 and 0.8 represent substantial agreement, and values greater than 0.8 correspond to excellent agreement. In our reproducibility study, the mean  $\kappa$  values for inter- and intra-observer agreement in assessing the various endoscopic patterns were 0.808 (95% CI: 0.678-0.938) and 0.826 (95% CI: 0.727-0.925) respectively. Therefore, our classification system is good to excellent.

In conclusion, our study suggests that mucosal patterns in *H. pylori*-infected gastric mucosa without atrophy can be reliably identified using standard endoscopy in the gastric corpus.

## COMMENTS

### Background

Although endoscopic features of *Helicobacter pylori* (*H. pylori*) infection have been reported in the literature, most studies concluded that it is not possible to diagnose *H. pylori*-related gastritis on the basis of endoscopic findings alone. Recent studies suggest that high resolution magnification endoscopy has been proved to be useful in the identifying of normal gastric mucosa and *H. pylori*-related gastritis. However, there have been no reports regarding specific mucosal patterns of *H. pylori*-related gastritis in the gastric corpus using standard endoscope.

### Research frontiers

Although high resolution magnification endoscopy has been proved to be useful in the identifying of normal gastric mucosa and *H. pylori*-related gastritis, practicing high resolution magnification endoscopy in daily endoscopy examinations takes more examination time and needs more training and experience. If specific mucosal patterns of *H. pylori*-related gastritis can be identified using standard endoscope, they may be applicable to targeted biopsy of suspected *H. pylori* infection in daily endoscopy examinations.

### Innovations and breakthroughs

In this study, endoscopic findings in the gastric corpus without atrophy were classified into 4 patterns. Type 3 and type 4 patterns were generally mosaic in appearance. The sensitivity, specificity, positive and negative predictive values of type 3 plus type 4 patterns for predicting *H. pylori*-positive gastric mucosa were 100%, 86%, 94%, and 100%, respectively.

### Applications

The result of this study suggests that the mosaic mucosal pattern in the gastric corpus seems to be a good indicator in predicting *H. pylori*-positive gastric mucosa and may guide endoscopists to targeted biopsy of suspected *H. pylori* infection.

### Peer review

This is an interesting paper that may be very beneficial for the gastroenterologist who performs significant numbers of endoscopy and treats patients with *H. pylori* infection.

### Abstract

**AIM:** To evaluate the efficacy of 6 noninvasive liver fibrosis models and to identify the most valuable model for the prediction of liver fibrosis stage in chronic hepatitis B (CHB) patients.

**METHODS:** Seventy-eight CHB patients were consecutively enrolled in this study. Liver biopsy was performed and blood serum was obtained at admission. Histological diagnosis was made according to the METAVIR system. Significant fibrosis was defined as stage score  $\geq 2$ , severe fibrosis as stage score  $\geq 3$ . The diagnostic accuracy of 6 noninvasive liver fibrosis models, including serum aspartate aminotransferase (AST) to platelet ratio index (APRI), FIB-4, Forn's index, Fibrometer, Hepascore, and Shanghai Liver Fibrosis Group's index (SLFG), was investigated.

**RESULTS:** The APRI, FIB-4 and Forn's index under receiver operating characteristic curve (AUROC) for sig-

nificant fibrosis were 0.71, 0.75 and 0.79, respectively, with a diagnosis accuracy of 67%, 77% and 80%, respectively, and 0.80, 0.87 and 0.86, respectively, under the AUROC for severe fibrosis. The Hepascore, SLFG, and Fibrometer were 0.80, 0.83 and 0.85, respectively under the AUROC for significant fibrosis ( $P < 0.01$ ). The diagnosis accuracy of Hepascore and SLFG was 86% and 88%, respectively. The Hepascore, SLFG, and Fibrometer were 0.95, 0.93, and 0.94, respectively, under the AUROC for severe fibrosis ( $P < 0.01$ ).

**CONCLUSION:** The models containing direct serum markers have a better diagnostic value than those not containing direct serum markers.

Wu SD, Wang JY, Li L. Staging of liver fibrosis in chronic hepatitis B patients with a composite predictive model: A comparative study. *World J Gastroenterol* 2010; 16(4): 501-507 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i4/501.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i4.501>

### INTRODUCTION

Chronic hepatitis B virus (HBV) infection affects 350 million individuals worldwide. At least one million people chronically infected with HBV would die of chronic liver diseases each year<sup>[1]</sup>. Thus, it is important to prevent the progression of early liver fibrosis to

cirrhosis<sup>[2]</sup>. Although liver biopsy is the gold standard for the assessment of fibrosis, it has several disadvantages, such as poor patient compliance, sampling error, limited usefulness for dynamic surveillance, and poor intra- and inter-observation concordance<sup>[3-5]</sup>. Considering these limitations, noninvasive histology predictors are urgently needed<sup>[6]</sup>.

Since single fibrosis surrogate cannot measure fibrosis, an alternative approach combined with a number of parameters can generate algorithms capable of evaluating fibrosis. A number of noninvasive models containing serum markers, such as serum aspartate aminotransferase (AST) to platelet ratio index (APRI), FIB-4, Forn's index, Fibrometer, Hepascore, Shanghai Liver Fibrosis Group's index (SLFG) have been studied worldwide<sup>[7-12]</sup>. Additionally, except for SLFG, little has been known about the role of these models in predicting fibrosis stage of chronic hepatitis B (CHB) because most studies were performed in chronic hepatitis C (CHC). China has a high prevalence of CHB, and most hepatocellular carcinomas result from chronic HBV infection. Therefore, we carried out this study to identify the best practical noninvasive model of liver fibrosis in CHB.

## MATERIALS AND METHODS

### Patients

Seventy-eight consecutive eligible CHB patients who underwent a liver biopsy in March 2006-August 2008 at Zhongshan Hospital, Fudan University, Shanghai, China, were included in this study. Blood serum was collected and stored at -80°C for further test. Chronic HBV infection was diagnosed based on positive surface antigen of HBV (HBsAg) and fluctuated alanine aminotransferase. Exclusion criteria included chronic liver disease due to other causes or co-infection with hepatitis D, clinically overt cirrhosis, previous or concomitant anti-HBV therapy, alcohol consumption exceeding 20 g/d in men and exceeding 10 g/d in women. Data were retrospectively analyzed. The study protocol was approved by the Institutional Review Board in our hospital. Written informed consent was obtained from each patient.

### Liver histology and quantification of fibrosis

Liver tissue was obtained by sono-guided percutaneous biopsy (Bard<sup>®</sup>, Magnum<sup>®</sup>, 18G, USA) and stained with hematoxylin-eosin-safran and Masson's trichrome. Fibrosis staging (F) and inflammatory activity (A) were decided according to the METAVIR system. Fibrosis staging was divided into F0-F4 (F0 = no fibrosis, F1 = portal fibrosis without septa, F2 = periportal fibrosis with few septa, F3 = septal fibrosis with many septa, and F4 = cirrhosis). Inflammatory activity was divided into A0-A3 (A0 = no histologic necroinflammatory activity, A1 = minimal activity, A2 = moderate activity, A3 = severe activity). The activity was assessed by integrating the severity and intensity of piecemeal (periportal) and lobular necrosis<sup>[13]</sup>. According to the American Association for the Study of Liver Disease Practice

Guidelines, we defined significant fibrosis as METAVIR fibrosis with a score  $\geq 2$  (F2, 3, 4) and severe liver fibrosis as METAVIR fibrosis with a score  $\geq 3$  (F3, 4)<sup>[14]</sup>.

### Serum parameters

Following parameters, including AST, alanine aminotransferase (ALT),  $\gamma$ -glutamyl transpeptidase (GGT), bilirubin, total cholesterol, urea, prothrombin time (PT), prothrombin index (PI), hemoglobin and platelet count (PLT) were assayed. AST, ALT, GGT, bilirubin, total cholesterol, urea were tested with Hitachi 7600, Japan. PT and PI were tested with Sysmex CA7000, Japan. Hemoglobin and PLT was tested with Sysmex routine blood test pipeline, Japan. The reference value was 0-75 IU/L for ALT and AST. Serum  $\alpha_2$ -macroglobulin (A<sub>2</sub>M) (GenWay Biotech, San Diego, USA) and hyaluronic acid (HA) (Shanghai High Medical Biotech, Shanghai, China) concentrations were measured by enzyme linked immunosorbent assay.

APRI, FIB-4, Forn's index, SLFG, Hepascore, and Fibrometer were detected according to the following formulas: APRI = [AST (/ULN)/PLT ( $10^9$ /L)]  $\times$  100, FIB-4 = [age (yr)  $\times$  AST (U/L)]/[{PLT ( $10^9$ /L)]  $\times$  (ALT (U/L))<sup>1/2</sup>}, Forn's index = 7.811 - 3.131  $\times$  ln [PLT ( $10^9$ /L)] + 0.781  $\times$  ln [GGT (U/L)] + 3.467  $\times$  ln [age (yr)] - 0.014  $\times$  [cholesterol (g/L)], SLFG = 10  $\times$  e<sup>Y</sup>/(1+e<sup>Y</sup>), Y = -13.995 + 3.220  $\times$  lg [A<sub>2</sub>M (g/L)] + 3.096  $\times$  lg [age (yr)] + 2.254  $\times$  lg [GGT (U/L)] + 2.437  $\times$  lg [HA (ng/mL)], Hepascore = e<sup>Y</sup>/(1+e<sup>Y</sup>), Y = -4.185818 - [0.0249  $\times$  age (yr)] + [0.7464  $\times$  sex (male = 1, female = 0)] + [1.0039  $\times$  A<sub>2</sub>M (g/L)] + [0.0302  $\times$  HA (ng/mL)] + [0.0691  $\times$  TB ( $\mu$ mol/L)] - [0.0012  $\times$  GGT (U/L)]; Fibrometer = -0.007  $\times$  PLT ( $10^9$ /L) - 0.049  $\times$  PI (%) + 0.012  $\times$  AST (U/L) + 0.005  $\times$  A<sub>2</sub>M (g/L) + 0.021  $\times$  HA (ng/mL) - 0.270  $\times$  urea (mmol/L) + 0.027  $\times$  Age (yr) + 3.718.

### Statistical analysis

Statistical analysis was performed using Spearman's two-tail test and univariate analysis.  $P < 0.05$  was considered statistically significant. Sensitivity, specificity, positive and negative predictive values (NPV and PPV) were calculated by using cutoffs according to the original studies. The overall diagnostic performance of scores was evaluated by area under ROC curves (AUROCs). We used DANA method, which was developed by Poynard *et al.*<sup>[15,16]</sup>, to adjust the observed AUROCs in our study. All the AUROCs were adjusted to a standard DANA of 2.5 using the formula: Adjusted AUROC (AdAUC) = Observed AUROC + 0.1056  $\times$  (2.5 - Observed DANA). The AUROCs were compared with the method of Hanley-McNeil<sup>[17]</sup>.

## RESULTS

### Patient characteristics

The mean age of the 78 patients (66 males, 12 females) was 32.6  $\pm$  12.3 years. The mean length of liver biopsies was 18.2  $\pm$  3.4 mm, and the liver specimen length was longer than 15 mm. Significant fibrosis was found in 32

patients (41.0%), severe fibrosis in 19 patients (24.4%), and early cirrhosis in 9 patients (11.5%), respectively. Main features of the patients are summarized in Table 1.

### Correlation between non-invasive model and fibrosis stage

METAVIR fibrosis stages were significantly correlated with APRI, FIB-4, Forn's index, Fibrometer, Hepascore and SLFG. A better correlation was observed between Fibrometer ( $r = 0.69$ ), SLFG ( $r = 0.68$ ) and Hepascore ( $r = 0.62$ ) ( $P < 0.001$ ). The box-plots of fibrosis scores are shown in Figure 1. A correlation was also found between scores and histological activity, especially between SLFG ( $r = 0.55$ ), Fibrometer ( $r = 0.54$ ) and APRI ( $r = 0.51$ ) ( $P < 0.001$ ).

### Overall diagnostic performance of serum markers

The mean levels of AST, GGT, PT, PI, A<sub>2</sub>M and HA were higher in patients with F2-F4 fibrosis than in those with F0-F1 fibrosis ( $P < 0.01$ ). The mean levels of hemoglobin, PLT and albumin were lower in patients with F2-F4 fibrosis than in those with F0-F1 fibrosis ( $P < 0.01$ ). Multiple regression analysis showed that A<sub>2</sub>M and HA were the independent factors for significant fibrosis (A<sub>2</sub>M, OR = 5.36, 95% CI: 1.58-18.13,  $P = 0.007$ ; HA, OR = 1.01, 95% CI: 1.00-1.02,  $P = 0.007$ ). AUROC

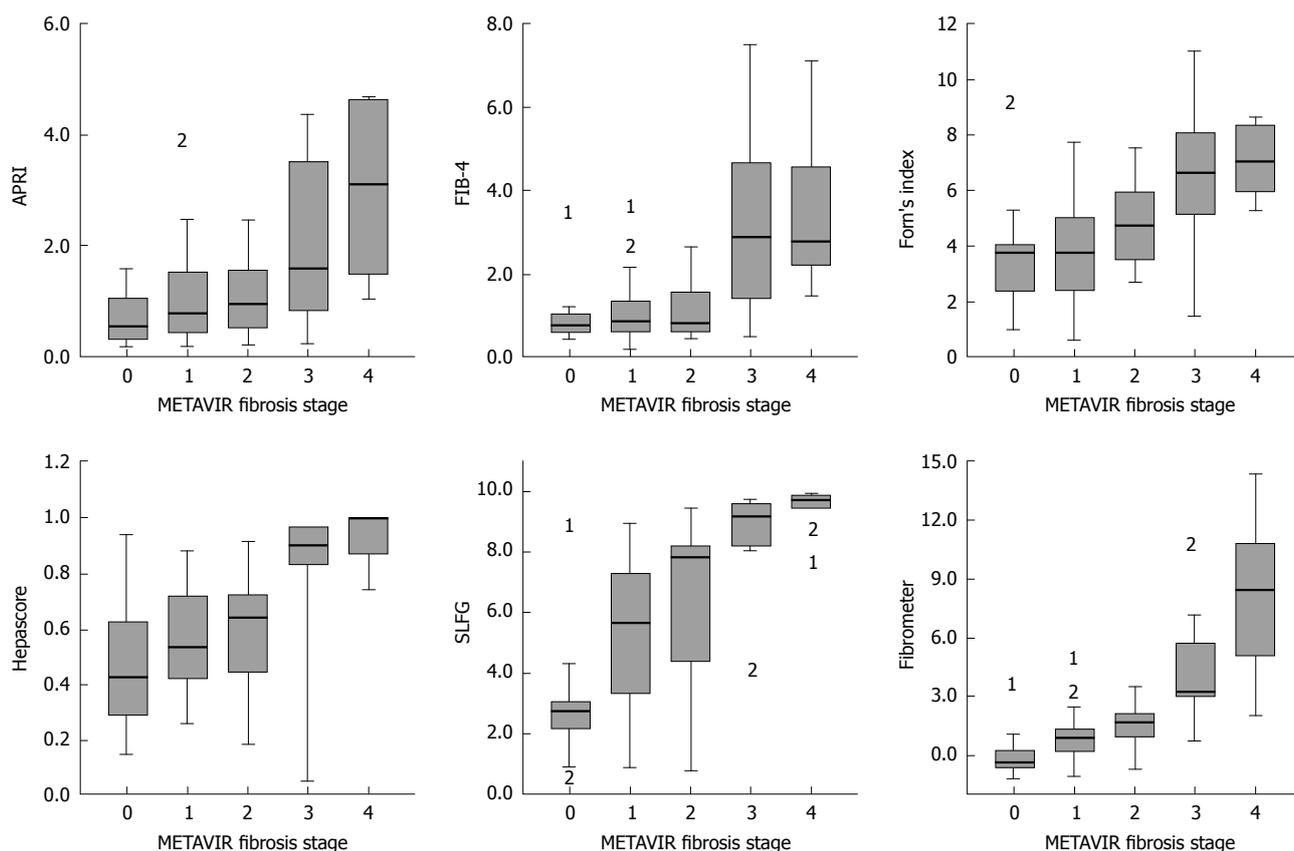

was used to evaluate the overall diagnostic performance of scores (Table 2).

The APRI, FIB-4, Forn's index, Hepascore, SLFG and Fibrometer were 0.71, 0.75, 0.79, 0.80, 0.83, and 0.85 respectively under the AUROC for F0-F4 (Figure 2A), and 0.75, 0.79, 0.83, 0.84, 0.86, and 0.88 respectively under the adjusted AUROC for F0-F4 with DANA method. The AUROC for Fibrometer, SLFG and Hepascore was better than that for APRI and FIB-4 ( $P < 0.01$ ).

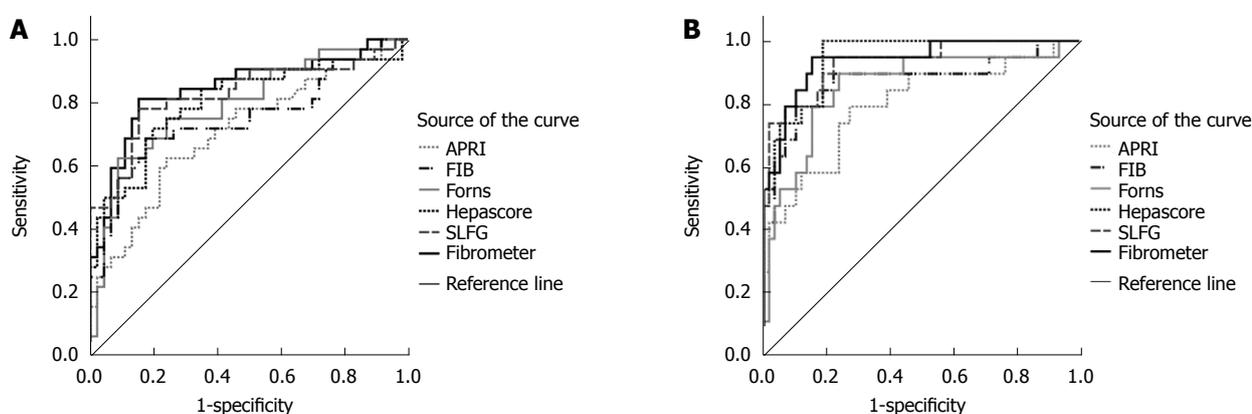

The APRI, FIB-4, Forn's index, Hepascore, SLFG and Fibrometer were 0.80, 0.87, 0.86, 0.95, 0.93, and 0.94 under the AUROC for F0-F4 (Figure 2B). The Hepascore, Fibrometer and SLFG levels were significantly higher than the APRI level under the AUROC for F0-F4 ( $P < 0.01$ ).

### Sensitivity, specificity, positive and negative predictive values

NPV and PPV for the diagnosis of significant fibrosis are presented in Table 3. Cutoffs were chosen for each model as previously described. This analysis could not be performed for Fibrometer since no cutoff was provided in the study by Calès *et al*<sup>[10]</sup>. When different cutoffs were used for each model, the percentage of classifiable subjects was 45%-78%, with a diagnostic accuracy of

**Figure 1 Model values according to METAVIR fibrosis stages.** The top and bottom of each box are the 25th and 75th centile interval, the line through the box is the median and the error bars are the 5th and 95th centile interval. 1 and 2 indicate the extreme values.

**Figure 2 ROC curves for the 6 fibrosis models to discriminate METAVIR fibrosis stages F0-1 from F2-4 (A) and F0-2 from F3-4 (B).**

67%-86% (Table 4). Significant fibrosis (F2-4) was predicted in 13%-32% of patients with their PPV ranged 62%-88%. Since lower cutoffs were originally described to rule out significant fibrosis, attention must be paid to NPV ranging 76%-85%. The best positive predictive value (PPV = 0.88) for significant fibrosis was observed when SLFG > 8.7.

## DISCUSSION

Noninvasive models have been proposed for the assessment of liver fibrosis. The diagnostic performance of

APRI, FIB-4, Forn's index, Fibrometer, Hepascore and SLFG was evaluated for the assessment of liver fibrosis in CHB patients. These models are mainly based on two kinds of serum markers, direct and indirect. Direct serum markers are directly linked to the modifications in extracellular matrix (ECM) metabolism. Indirect serum markers have no direct link with liver fibrosis but reflect liver dysfunction or other phenomena caused by fibrosis. We focused on the serum markers of fibrosis. The main end-point of our study was to evaluate the global diagnostic performance of models by comparing their AUROCs. Our study indicated that models containing

Table 2 AUROC for FOF1 vs F2-4 and FO-2 vs F3-4

	FO-1 vs F2-4				FO-2 vs F3-4		
	AUROC	SD	95% CI	AdAUC	AUROC	SD	95% CI

	> 8.70	17 (22)	15 (88)		

direct serum markers (Fibrometer, SLFG, Hepascore) performed much more accurately than models containing only indirect serum markers (APRI, FIB-4, Forn's index).

Direct serum markers are useful for assessing the speed of liver fibrogenesis. HA, a component of ECM, is a glycosaminoglycan synthesized by hepatic stellate cells and degraded by liver sinusoidal cells<sup>[18]</sup>. A<sub>2</sub>M is a protease inhibitor with its concentration increased due to stellate cell activation and liver fibrosis<sup>[19]</sup>. Studies have demonstrated that HA and A<sub>2</sub>M levels are correlated with hepatic fibrosis in patients with CHB or CHC<sup>[11,20-22]</sup>, which is consistent with the findings in our study. Multiple

regression analysis in our study showed that HA and A<sub>2</sub>M were the independent factor for significant fibrosis and had a better diagnostic accuracy.

It has been reported that APRI under the AUROC for significant fibrosis is 0.76 (95% CI: 0.74-0.79)<sup>[23]</sup>. It has been shown that the accuracy of APRI under the AUROC for significant fibrosis is 0.63 and 0.72 in CHB patients<sup>[24,25]</sup>. Zhang *et al*<sup>[26]</sup> showed that APRI has low diagnostic accuracy of liver fibrosis and APRI combined HA can achieve a better diagnostic accuracy of liver fibrosis. FIB-4 has a high diagnostic accuracy of severe fibrosis<sup>[27]</sup>. Mallet *et al*<sup>[28]</sup> reported that FIB-4 is 0.81 under the AUROC for severe fibrosis. In our study, the FIB-4 was 0.87 under the AUROC for severe fibrosis. The reported Forn's index is 0.76 under the AUROC for significant fibrosis<sup>[29]</sup>. In our study, the Forn's index was 0.79 under the AUROC for significant fibrosis. The diagnostic value of APRI, FIB-4 and Forn's index was much lower in CHB patients than in CHC patients.

Calès *et al*<sup>[10]</sup> have developed Fibrometer for the diagnosis of significant fibrosis and found that its diagnostic performance is stable in patients with different chronic liver diseases<sup>[30,31]</sup>. Hepascore has been used in diagnosis of significant and severe fibrosis<sup>[12]</sup>. In our study, the Hepascore was 0.80 and 0.95 under the AUROC for significant and severe fibrosis. SLFG is the first developed model in CHB patients. In our study, the NPV and PPV of SLFG under AUROC are similar to the reported

data<sup>[11]</sup>. These results indicate that Fibrometer, SLFG and Hepascore can be used in diagnosis of liver fibrosis. However, these noninvasive models should be validated in a larger number of CHB patients.

Broadly speaking, no true noninvasive model could exactly reflect liver fibrosis. Transient elastography (fibroScan) is another noninvasive method to detect the mean liver stiffness for diagnosing fibrosis. However, it is expensive and may be limited in those with narrow intercostal spaces, morbid obesity or significant ascites<sup>[32,33]</sup>. These noninvasive models can be used in clinical management of CHB by offering an attractive alternative to liver biopsy.

In our study, since the sample size was small, further study is needed before these models are used in clinical practice. Validating against not only histological stage scores but also digital image analysis and clinical outcomes may also be a better choice.

In conclusion, serologic models containing direct serum markers of Hepascore, SLFG, and Fibrometer have better diagnostic values in CHB patients than those containing only indirect serum markers of APRI, FIB-4, Forns' index.

## COMMENTS

### Background

Clinically, developing noninvasive methods for diagnosing liver fibrosis is important. Noninvasive models have been established most in hepatitis C patients.

### Research frontiers

Noninvasive models have been proposed for the assessment of liver fibrosis. These models have been evaluated at many medical centers in chronic hepatitis C (CHC), but few in chronic hepatitis B (CHB). In this study, the efficacy of 6 noninvasive models was evaluated and the more valuable models were identified for predicting liver fibrosis in CHB.

### Innovations and breakthroughs

The efficacy of 6 noninvasive models was evaluated in a cohort of Chinese patients with CHB. The results indicate that their efficacy is not influenced by ethnic and virus factors. This study also showed that the serologic models containing direct serum markers, such as hyaluronic acid (HA) and  $\alpha_2$ -macroglobulin (A<sub>2</sub>M) have better diagnostic values in CHB patients than in those not containing direct serum markers.

### Applications

Noninvasive models can be used in diagnosis of liver fibrosis in patients with CHB in China or in Asia.

### Terminology

DANA method: A method used to adjust the differences caused by the prevalence of fibrosis stages. Standard prevalence is defined as a prevalence of 0.20 for each of the five stages.

### Peer review

The study adds information that helps establishment of strategies against liver fibrosis diagnosis using noninvasive methods. The study was scientifically designed. The manuscript is logical and readable.

### Abstract

**AIM:** To evaluate the detection and differentiation ability of contrast-enhanced intraoperative ultrasonography (CE-IOUS) in hepatocellular carcinoma (HCC) operations.

**METHODS:** Clinical data of 50 HCC patients were retrospective analyzed. The sensitivity, specificity, false negative and false positive rates of contrast enhanced magnetic resonance imaging (CE-MRI), IOUS and CE-IOUS were calculated and compared. Surgical strategy changes due to CE-IOUS were analyzed.

**RESULTS:** Lesions detected by CE-MRI, IOUS and CE-IOUS were 60, 97 and 85 respectively. The sensitivity, specificity, false negative rate, false positive rate of CE-MRI were 98.2%, 98.6%, 98.6%, 60.0%, respectively; for IOUS were 50.0%, 90.9%, 1.8%, 1.4%, respectively; and for CE-IOUS were 1.4%, 40.0%, 50.0%, 9.1%, respectively. The operation strategy of 9 (9/50, 18.0%) cases was changed according to the results of CE-IOUS.

**CONCLUSION:** Compared with CE-MRI, CE-IOUS performs better in detection and differentiation of small metastasis and regenerative nodules. It plays an important role in the decision-making of HCC operation.

### INTRODUCTION

The incidence rate of hepatocellular carcinoma (HCC) and cirrhosis in the hepatic B infection population is high in China, about 53.8%-85.9%, and more than 95% in some reports. There are several stages of hepatocarcinogenesis, from regenerative nodule, to degenerative nodule and to HCC. While comparing preoperative imaging results and pathological results after operation, the sensitivity of contrast enhanced magnetic resonance imaging (CE-MRI) is not satisfactory and can hardly detect some lesions<sup>[1,2]</sup>. It has been shown that intraoperative ultrasound (IOUS) is the most accurate diagnostic technique for detecting focal liver lesions (FLL) and has a great impact on the surgical approach to liver

tumors<sup>[3,4]</sup>. However, in cirrhotic patients with HCC, not all nodules detected by IOUS are neoplastic<sup>[5]</sup>. How to differentiate small HCC from the nodules detected by IOUS poses a big challenge for surgeons. The application of intravenous ultrasound contrast agents during transcutaneous ultrasonography of the liver has been shown to improve nodule characterization in comparison with unenhanced ultrasound<sup>[6-10]</sup>. Therefore, we investigated whether the application of contrast-enhanced ultrasound examination intraoperatively could solve the aforementioned deficiencies of IOUS during liver exploration.

## MATERIALS AND METHODS

### Common materials

The data from 50 HCC patients, including 38 males, 12 females, mean age 45 years (range, 19-67 years) was retrospectively analyzed. Thirty nine cases had a history of hepatitis B infection and 2 of hepatitis C infection; nine had no hepatitis history. Three cases had undergone surgical resection for HCC before. Preoperative MRI, IOUS and contrast-enhanced intraoperative ultrasonography (CE-IIOUS) were performed in 395 liver segments of 50 patients.

### CE-MRI

CE-MRI examinations were performed with a 1.5 T imaging system (Gyrosan Intera, Philips Medical Systems Best, Netherlands), using a breathhold 3D gradient echo sequence with fat saturation sequence, following an iv bolus of 0.1 mmol gadobenate dimeglumine (MultiHance, Bracco SpA, Milan, Italy) per kg of body weight at a rate of 2 mL/s. Data was acquired in the hepatic arterial, portal venous, and equilibrium phases.

### IOUS

IOUS scans were done by a VIVID4 (GE, US) ultrasound system with I-shaped 10-4 MHz intraoperative probe. After mobilization of the liver, IOUS was performed to search for nodules. Suspected lesions were counted and mapped.

### Contrast-enhanced intraoperative ultrasonography (CE-IIOUS)

CE-IIOUS scans were carried out both for lesion characterization and new nodule detection. Since no specific intraoperative probe is available for contrast study, we used the IU22 unit (Philips, USA) equipped with a 5-2 MHz convex transducer and a 9-3 MHz linear transducer instead. Both of the probes have the capacity for contrast enhanced ultrasound studies. The contrast agent was SonoVue (Bracco Imaging, Milan, Italy) which consists of sulphur hexafluoride microbubbles stabilized by a phospholipid shell; 4.8 mL of SonoVue per exploration was injected intravenously through a peripheral vein. A low mechanical index (MI) < 0.1 mode was used. All phases of contrast enhancement, including arterial (10-20 s to 25-35 s after injection),

portal (30-45 s to 120 s) and late parenchymal (> 120 s) phases were recorded and analyzed.

### Imaging analysis

In the CE-IIOUS study, HCC is characterized by arterial phase hyper-enhancing and wash out of microbubbles during the portal and late phase, while benign solid lesions are characterized by persistence of contrast enhancement during the portal and late phase.

### Surgery and follow up

Lesions considered malignant were removed surgically. Ultrasound-guided biopsy and ethanol ablation would be an alternative if the lesion can not be removed surgically. Nodules regarded as benign were removed only in cases located close to the main lesion and others were followed by examinations of  $\alpha$ -fetoprotein (AFP) level and ultrasound and/or CE-MRI every 3 mo for more than 6 mo.

### Golden standard

Pathologic examination was taken as the golden standard. Those unresected lesions with negative findings during 3 mo follow-up were regarded benign.

### Statistical analysis

$\chi^2$  tests were used to analyze the data,  $P < 0.05$  was considered to be statistically significant.

## RESULTS

### Imaging results

Preoperative MRI detected 60 lesions in total and IOUS found 96 nodules in 50 patients (Figure 1A-C). A total of 85 lesions were detected by CE-IIOUS, among them, 73 HCC (Figure 2A and C) and 7 benign nodules (Figure 2B) were proved by pathology; another 5 lesions which were considered benign were not removed. Follow-up ultrasound showed no sign of malignancy with normal AFP levels after 6-15 mo in 4 patients and the size of the lesion in the other patient increased during 3 mo follow up. Further surgery was performed in this patient and proved to be HCC at histology.

Malignant and benign lesions detected by CE-MRI, IOUS and CE-IIOUS were listed in Table 1.

The sensitivity, specificity, false negative ratio and false positive ratio of CE-MRI, IOUS and CE-IIOUS, respectively, were shown in Table 2.

Particularly, one isoechoic HCC nodule was missed by IOUS, but showed a typical contrast agent wash-out pattern on CE-IIOUS late parenchymal phase (Figure 2D). Another hypo-enhanced nodule was diagnosed as malignant by CE-IIOUS but proved to be a necrotic nodule at histology.

### Operation

Among 18 additional malignant lesions detected by CE-IIOUS, 1 patient had 3 lesions, 4 patients had 2 lesions, and 7 patients had 1 lesion. The size of lesions was 5-20

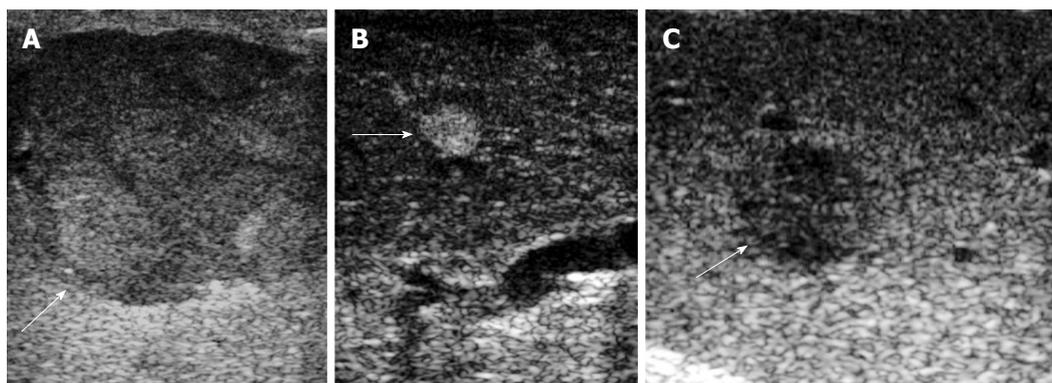

Figure 1 IOUS showing typical sonographic appearance of HCC nodules with mosaic pattern (A, arrow) and hyperechoic regenerative nodules (B, arrow); It is hard for IOUS to accurately diagnose a hypoechoic nodule (C, arrow) which could be a regenerative nodule or a small HCC nodule or focal fatty sparing nodule.

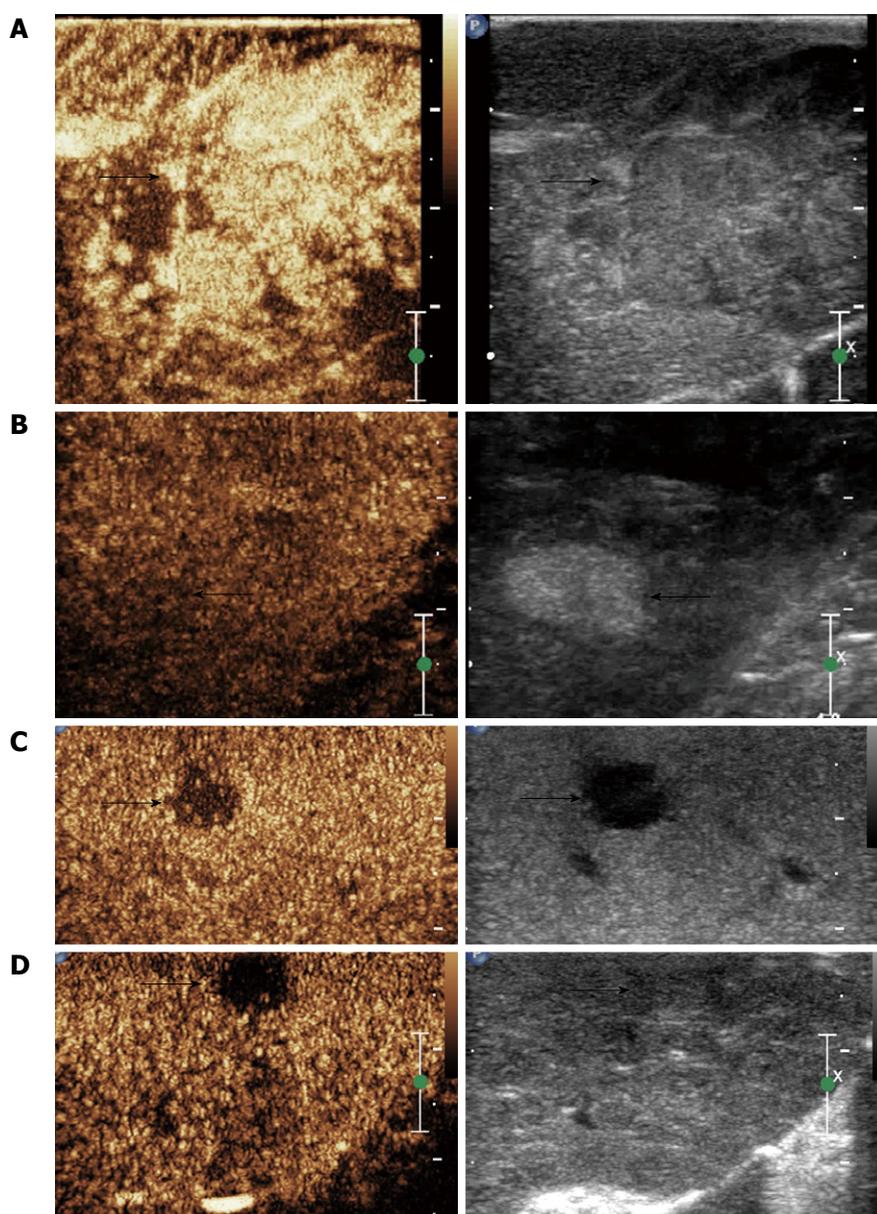

Figure 2 CE-IUS showing an HCC nodule with hyperenhancement in arterial phase (A, arrow) while a regenerative hyperechoic nodule shows isoenhancement on CE-IUS (B, arrow); Hypoechoic intrahepatic metastatic nodule showing wash out of contrast agent on late phase (C, arrow); Isoechoic nodule missed on IOUS showing a clear margin on CE-IUS (D, arrow).

mm (mean 12 mm). Surgical strategies of 9 patients (18.0%, 9/50) were changed because newly detected lesions were not in the same segment as the old ones (Table 3).

## DISCUSSION

Recently, the incidence of HCC has had a tendency to

Table 1 Malignant and benign lesions detected by CE-MRI, IOUS and CE-IOUS

	Malignant lesions	Pathology	Benign lesions	Pathology + follow up
CE-MRI	56	54	4	3
IOUS	89	72	8	7
CE-IOUS	74	73	11	10

CE-MRI: Contrast enhanced magnetic resonance imaging; IOUS: Intraoperative ultrasonography; CE-IOUS: Contrast-enhanced intraoperative ultrasonography.

Table 2 Sensitivity, Specificity, False negative rate and False positive rate of CE-MRI, IOUS and CE-IOUS (%)

	Sensitivity	Specificity	Accuracy	False negative rate	False positive rate
CE-MRI	98.2	60	95	1.8	40
IOUS	98.6	50	81.4	1.4	50
CE-IOUS	98.6 <sup>a</sup>	90.9 <sup>c</sup>	97.6	1.4 <sup>e</sup>	9.1 <sup>f</sup>

<sup>a</sup> $P > 0.05$  compared with CE-MRI and IOUS, <sup>c</sup> $P < 0.05$  compared with CE-MRI and IOUS, <sup>e</sup> $P > 0.05$  compared with CE-MRI and IOUS, <sup>f</sup> $P < 0.05$  compared with CE-MRI and IOUS.

Table 3 Operation changed according to the newly detected lesions by CE-IOUS

	Operation (liver resection)								Liver transplantation	Liver resection + ethanol injection
	1 segment	2 segments	3 segments	Right liver	Left liver	Right 3 segment	Left 3 segment			
Pre-operation	13	21	7	4	3	1	1	0	0	
Intra-operation	9	18	8	6	4	2	1	1 <sup>1</sup>	1	

<sup>1</sup>This patient accepted right lobe of liver resection and ethanol injection in the I stage, then accepted liver transplantation 4 mo later.

increase and radical resection is considered to be the most effective therapy<sup>[11,12]</sup>. The rate of HCC with cirrhosis is high in China; therefore, differentiation of regenerative nodules from malignant ones plays an important role in the decision-making about surgery. However, the performance of preoperative CE-MRI is not satisfactory in detection of small lesions and unenhanced IOUS can hardly make the differential diagnosis of regenerative nodules from malignant ones in cirrhotic patients. The purpose of our research is to find a better imaging method with high sensitivity and specificity.

CE-IOUS is a real time gray scale imaging with low mechanical index (MI), which can clearly show microcirculation and perfusion of a tumor. HCC is a typical hyper-vascular tumor with the majority of blood contained in microvessels which can be demonstrated by CE-IOUS. The contrast agent we used in our research is SonoVue which consists of sulphur hexafluoride microbubbles stabilized by a phospholipid shell. Microbubbles of SonoVue can stay in blood for about 8 min which makes it possible for us to observe dynamic changes of liver enhancement. Pulse inversion harmonic technology can use non-linear signals in low acoustic pressure while restraining the linear signals from liver parenchyma<sup>[13]</sup>, so it has the high sensitivity of harmonic signal detection.

Sensitivity of CE-MRI (98.2%), IOUS (98.6%) and CE-IOUS (98.6%) were high, but compared with CE-IOUS, the specificity of CE-MRI and IOUS were fairly poor. In our study, 85 lesions were diagnosed in 50 patients finally, preoperative CE-MRI only detected 60 lesions, indicating the diagnosis rate of CE-MRI for micro lesions is poor. In the 97 lesions that were detected by IOUS, only 74 malignant lesions were finally diagnosed, and the false positive rate of IOUS is too

high compared with CE-IOUS. Consequently, we believe that CE-IOUS is an ideal diagnostic method in the decision-making about hepatocellular carcinoma surgery. Among 85 lesions detected by CE-IOUS, we had one false negative and one false positive case. The reason for the false negative case is that the minor lesion was located under the right diaphragm, and the probe we used for CE-IOUS was too big to thoroughly scan that area. The reason for the false positive case is that the minor nodule was a necrosis nodule. Parenchymal phase was used to search for malignant nodules during the CE-IOUS study and both necrotic nodules and small HCC shows hypoenhancement in parenchymal phase.

CE-MRI had 19 false negative cases (27%), with size 5-20 mm (mean 12 mm). Among these, 3 HCCs and 5 metastatic nodules had typical hyper-enhancement in artery phase and hypo-enhancement in portal phase in CE-IOUS. All patients accepted surgery and malignancy was proved by pathological results. Research found that CE-IOUS with low MI is more sensitive than CE-MRI in revealing artery perfusion of liver tumors. Time resolution of CE-MRI is relatively low, so it can not observe the dynamic enhancement of lesions, which is very important in differential diagnosis of HCC. Therefore, CE-IOUS is proved to be another sensitive imaging method with high diagnostic value<sup>[14]</sup>.

CE-IOUS is of vital importance in detection and differentiation of lesions which were not detected pre-operatively with other imaging methods. Newly found tumors in pre-considered normal liver segments may lead to expanded resection, or combination treatment with radiofrequency ablation and ethanol injection. Sometimes, surgeons were obliged to give up or change their operation strategy. It had been reported that IOUS changed 18%-51% of operation strategies in liver

metastasis patients with rectal cancer<sup>[15-19]</sup>. Eighteen newly detected malignant liver nodules by CE-IOUS in all 50 patients were proved by histology. The primary operation strategy was changed in 9 cases but not in another 3 cases. Two cases proved to have micro-metastatic lesions in another lobe of the liver during operation which can not be radical cured. One had half liver resection and ethanol injection of another nodule. Another patient had right part of liver resection and ethanol injection of another nodule. After operation, the patient's AFP level decreased to normal and gradually increased over 2 and 4 mo later, he received cadaveric liver transplantation.

In our preliminary study, CE-IOUS is proved to be better than CE-MRI and IOUS in detecting and differentiating micro-metastatic liver lesions and hyperplastic nodules, which helped decision-making about surgical strategy. However its impact on increasing the long-term survival rate need further follow-up.

## COMMENTS

### Background

In cirrhotic patients with hepatocellular carcinoma (HCC), preoperative imaging was unsatisfactory in detection of some lesions. Intraoperative ultrasonography (IOUS) was sensitive in finding small lesions but not all nodules detected by IOUS are neoplastic. How to differentiate small HCC from the nodules detected by IOUS poses a big challenge for surgeons. Contrast enhanced ultrasound of the liver has been shown to improve nodule characterization. Therefore, the authors investigated if the application of contrast-enhanced ultrasound examination intraoperatively could solve the aforementioned problems during liver exploration.

### Research frontiers

Radical resection is the goal of surgery for HCC and the key is to find all the malignant lesions.

### Innovations and breakthroughs

CE-IOUS proved to be better than CE-MRI and IOUS in detecting and differentiating micro-metastatic liver lesions and hyperplastic nodules, which helped decision-making about operation strategy.

### Applications

The application of CE-IOUS in surgery for HCC has a positive impact on the decision making about surgical strategy.

### Terminology

CE-IOUS is an ultrasound exam performed by applying contrast agent during surgery. Besides the high sensitivity of detecting focal liver lesion, it shows tumor vascularity and tissue microcirculation, thus helping differentiate malignant nodules from benign ones.

### Peer review

This article aims to determine the role of CE-IOUS vs IOUS vs CE-MRI in the detection and characterization of suspicious nodules in cirrhotic patients.

### Abstract

**AIM:** To introduce and evaluate the new method used in treatment of pancreatic and peripancreatic infections secondary to severe acute pancreatitis (SAP).

**METHODS:** A total of 42 SAP patients initially underwent ultrasound-guided percutaneous puncture and catheterization. An 8-Fr drainage catheter was used to drain the infected peripancreatic necrotic foci for 3-5 d. The sinus tract of the drainage catheter was expanded gradually with a skin expander, and the 8-Fr drainage catheter was replaced with a 22-Fr drainage tube after 7-10 d. Choledochoscope-guided debridement was performed repeatedly until the infected peripancreatic tissue was effectively removed through the drainage sinus tract.

**RESULTS:** Among the 42 patients, the infected peripancreatic tissue or abscess was completely removed from 38 patients and elective cyst-jejunum anastomosis was performed in 4 patients due to formation of pancreatic pseudocysts. No death and complication occurred during the procedure.

**CONCLUSION:** Percutaneous catheter drainage in combination with choledochoscope-guided debridement is a simple, safe and reliable treatment procedure for peripancreatic infections secondary to SAP.

Percutaneous catheter drainage in combination with choledochoscope-guided debridement in treatment of peripancreatic infection. *World J Gastroenterol* 2010; 16(4): 513-517 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i4/513.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i4.513>

### INTRODUCTION

Severe acute pancreatitis (SAP) is an extremely dangerous and refractory disease characterized by complicated pathogenesis and high mortality<sup>[1]</sup>. Secondary peripancreatic infection is a severe complication of SAP, which is one of the main causes for death of SAP patients<sup>[2]</sup>. Clinically, peripancreatic infection can be divided into infected effusion containing rich pancreatin around the pancreas occurring in early SAP, and infected pancreatic and peripancreatic necrosis, peripancreatic abscess usually observed during the course of SAP progress. In addition to the clinical signs and symptoms of bacterial infection, SAP patients have a large amount of necrotic peripancreatic tissue and fluid which can be

found by imaging analysis, computed tomography (CT) or ultrasonography<sup>[3,4]</sup>.

Open surgical debridement is a traditional procedure for SAP patients with infected peripancreatic foci<sup>[5-7]</sup>. However, it should not be performed in early SAP<sup>[2,7-9]</sup>. Since the infected peripancreatic foci in early SAP are not well encapsulated by fibrous connective tissue and no visible distinct boundary can be observed between infected necrotic tissue and living pancreas or peripancreatic tissue, it is difficult to completely remove the necrotic tissues, with a re-operation rate of 18%-68%<sup>[10]</sup>. In addition, the function of vital organs, including lung and kidney, is often insufficient in early SAP patients, and is further deteriorated by open-abdominal surgery, leading to multiple vital organ failure and death. Therefore, it is generally agreed that surgical debridement should be delayed until the infected peripancreatic foci are well demarcated<sup>[2,7]</sup>.

If debridement could not be performed in early SAP, the infected peripancreatic necrotic tissue and effusion would become the source of infection in other organs. In addition, peripancreatic effusion containing enzyme-enriched pancreatic juice can further corrode the peripancreatic tissue, leading to more severe peripancreatic necrosis. Furthermore, retroperitoneal necrotic tissue and effusion may stimulate celiac nerves that can induce enteroparalysis and exacerbate abdominal distension, leading to respiratory and cardiac failure in severe cases. Thus, it is necessary to remove the infected peripancreatic tissue and effusion promptly and effectively.

In this retrospective study, early SAP patients were treated with ultrasound-guided puncture and catheter drainage in combination with early debridement under choledochoscope.

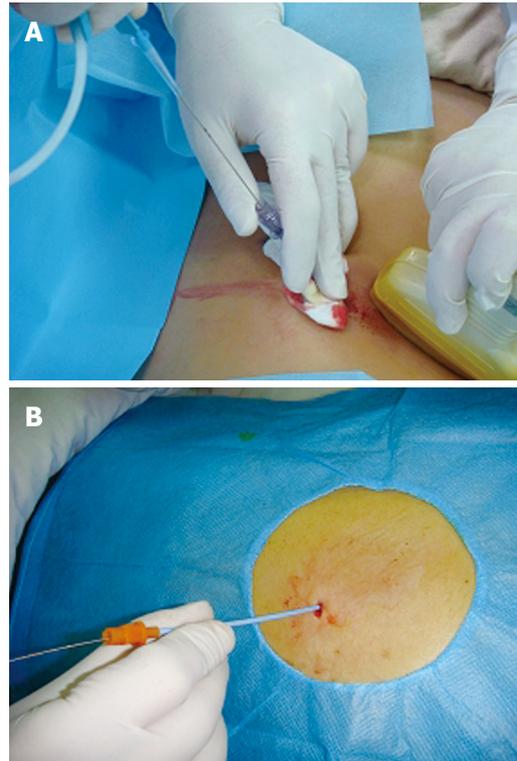

## MATERIALS AND METHODS

### Patients

A total of 42 patients (25 males and 17 females), at the age of 24-67 years, were diagnosed as SAP according to the "Atlanta classification of acute pancreatitis" in 2001-July 2008 in our hospital<sup>[11]</sup>. The disease was due to alcohol drinking, stones in the common bile duct, and unknown etiology in 9, 8, and 25 patients, respectively. Physical examination revealed abdominal tenderness, rebound pain, distention, and hypoactive or absent bowel sounds, one or more organ failure, pulmonary insufficiency, renal failure, systemic complications, low calcium, presence of infected necrotic tissue and fluid surrounding the pancreas. Patients received relevant treatment to maintain their vital organ functions. However, infected peripancreatic foci still remained after treatment. Once the infected foci were localized, patients should be immediately treated with ultrasound-guided percutaneous puncture and catheter drainage.

### Ultrasound-guided percutaneous puncture and catheter drainage

Patients underwent abdominal ultrasound examination at

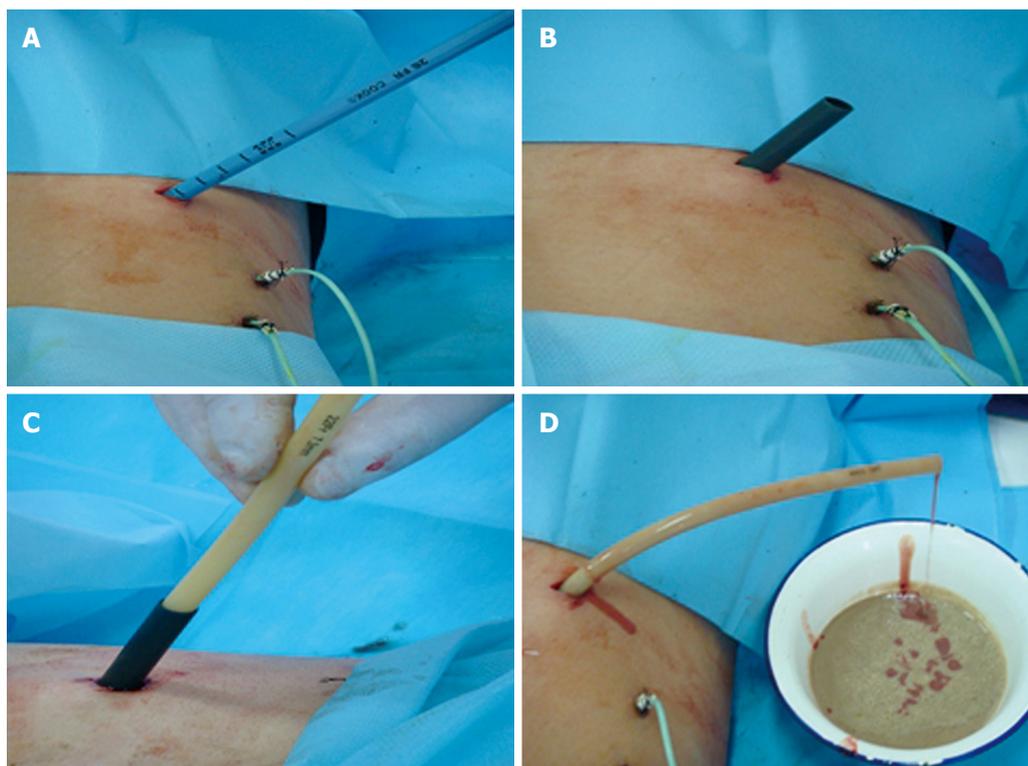

**Figure 1** Ultrasound-guided percutaneous puncture and catheter drainage.

A: An 18-G puncture needle is inserted into the peripancreatic focus under the guidance of ultrasound with a guidewire placed in the focus through the puncture needle lumen; B: An 8-Fr drainage catheter is immediately delivered into the focus along the guidewire after adequate expansion of abdominal wall layers.

a supine position to determine the safe site and direction of percutaneous puncture. The selected puncture site was close to the focus. Under the guidance of ultrasound, an 18-G puncture needle (Promex Company, USA) was inserted into the focus through the abdominal wall and the needle core was then pulled out. Pus and necrotic tissue fragments were drawn out from the focus. A guidewire was then placed in the deepest location of the focus *via* the puncture needle lumen under ultrasonic monitoring (Figure 1A). After the puncture needle was slowly removed, an 8-Fr skin expander (Cook Corporation, USA) was inserted along with the guidewire. Once the abdominal wall layers were properly expanded, the skin expander was removed and an 8-Fr drainage catheter (Hakko International Trading Co., Ltd.) was immediately inserted into the focus along with the guidewire (Figure 1B). Finally, the guidewire was pulled out with the drainage catheter fixed on the abdominal wall.

### Replacement of drainage catheter with a larger drainage tube

The infected peripancreatic fluid was drained through the 8-Fr drainage catheter for 3-5 d, and then the drainage catheter was replaced with a large drainage tube. First, a guidewire was inserted into the focus through the lumen of the 8-Fr drainage catheter which was then removed. In order to apply a larger tube, patients were given local anesthesia with 0.5% procaine and a 1 cm-deep small

**Figure 2** Replacement of the drainage catheter with a larger-diameter drainage tube. A: Gradual expansion of the drainage catheter sinus tract using different Fr skin expanders along with the guidewire; B: Pulling out the expander with its sheath left in the focus after insertion of a sheath matching the 24-Fr skin expander into the focus; C: Insertion of a 22-Fr drainage tube into the focus through the sheath lumen of a skin expander; D: Left in the focus.

**Figure 3** Debridement guided by choledochoscope. Formation of sinus tract around the drainage tube (A) with a choledochoscope slowly inserted into the focus through the sinus tract (B) 7 d after drainage with a large drainage tube, flushing of accumulated pus and necrotic tissue fragments from the foci of SAP by injecting a large amount of sterile saline and 0.5% metronidazole into the infected foci via the water inlet of choledochoscope (C).

incision was made through the skin and subcutis, and then the 8-Fr skin expander was inserted along with the guidewire to expand the sinus tract made initially by the drainage catheter. Second, the 8-Fr skin expander was pulled out, and 12-, 16-, 20-, and 24-Fr skin expanders with a diameter of 8 mm were inserted to gradually expand the sinus tract (Figure 2A). A sheath matching the 24-Fr skin expander was inserted and left in the focus (Figure 2B), and the expander was then removed. Finally, a 22-Fr drainage tube was inserted into the focus through the sheath lumen of the 24-Fr skin expander (Figure 2C and D).

#### **Debridement under the guidance of choledochoscope**

A sinus tract around the drainage tube was firmly

formed 7 d after drainage with the larger drainage tube. Meanwhile, the peripancreatic focus was also encapsulated with fibrous connective tissue, and then debridement was performed under choledochoscope (Pentax Co. Japan). The large drainage tube was removed, and a choledochoscope was slowly inserted into the peripancreatic focus through the sinus tract of the drainage tube (Figure 3A and B). Sterile saline was rapidly injected into the focus through the water inlet of choledochoscope. After a certain amount of saline was injected into the focus, the choledochoscope was removed with pus and necrotic tissue fragments flushed out. During the procedure, bigger pieces of necrotic tissue were removed with biopsy forceps under choledochoscope.

The necrotic tissue fragments were irrigated until the effluent became clear (Figure 3C). The focus was finally flushed with 0.5% metronidazole. A drainage tube was placed into the focus through the original sinus tract and left there for next debridement.

## RESULTS

The time from the onset of pancreatitis to drainage was 4-11 d (mean 5.3 d). The number of 8-Fr drainage catheters used for external drainage was 1-5 (mean 2.2 catheters) depending on the number and locations of infected peripancreatic foci. Before the sinus tract was expanded, the external drainage was maintained for 3-5 d (mean 3.6 d). A large 22-Fr drainage tube was used for 7-10 d (mean 8.2 d).

Based on the amount of infected peripancreatic necrotic tissue and pus, the presence of systematic infection symptoms, each of the 42 patients underwent 5-14 times of choledochoscope-guided debridement (mean 8.5 times) at an interval of 2-7 d (mean 4.5 d).

After the infected peripancreatic foci were removed, the infection of patients was well controlled with decreased body temperature and normal blood leukocyte count, and the overall conditions of patients were significantly improved. CT or ultrasonic scanning showed that their infected peripancreatic necrotic tissue and fluid were significantly diminished or completely disappeared. Thirty eight out of the 42 patients were discharged from the hospital with a cure rate of 90.5%. The remaining 4 patients underwent elective cyst-jejunum anastomosis due to formation of pancreatic pseudocysts. The hospital stay time of the patients was 1-3 mo (mean 1.5 mo) depending on the severity of SAP. No complications such as hemorrhage or intestinal leakage occurred.

## DISCUSSION

Death of SAP patients may occur due to multiple organ dysfunction and severe peripancreatic infection secondary to SAP. In recent years, most SAP patients can survive after proper treatment. Since secondary peripancreatic infection may become the most refractory cause for death of SAP patients, its effective treatment is an urgent challenge for surgeons. In fact, peripancreatic effusion and infection have been existed in the early pathological process of SAP. As early as 1980s, the risk of early peripancreatic infection was recognized, and early surgical debridement in combination with postoperative drainage has become the effective procedure since then. However, it is difficult for the procedure to completely remove the infected peripancreatic necrosis tissue, and the procedure itself may result in multiple complications with high mortality. Therefore, it is generally recommended that surgical debridement should be delayed until the infected peripancreatic focus is localized and encapsulated. However, if the infected peripancreatic focus is not removed or drained, it can further exacerbate peripancreatic infection and SAP symptoms.

Some minimal invasive treatment modalities are available for pancreatic and peripancreatic infection, including CT-guided percutaneous catheter drainage<sup>[12,13]</sup>, retroperitoneal debridement and drainage<sup>[14,15]</sup>, and laparoscopic-assisted percutaneous drainage<sup>[16,17]</sup>. These procedures can resolve peripancreatic fluid collection and reduce peripancreatic infection-associated mortality. However, they are insufficient to treat peripancreatic infection secondary to SAP. Segal *et al*<sup>[15]</sup> used CT-guided percutaneous puncture and catheterization to drain the infected peripancreatic effusion and found that only slender drainage catheters can be placed in the infected focus and the infected effusion secondary to SAP is mixed with necrotic pancreatic and peripancreatic tissue fragments, which in turn block the slender drainage catheter and make it difficult to drain the infected effusion.

In the present study, an 8-Fr drainage catheter was placed into the focus under the guidance of ultrasound for a few days, and the sinus tract was expanded using a skin expander, and then a large drainage tube was used to drain the effusion. Since more and more necrotic tissue and pus are accumulated in the peripancreatic focus due to the pathological features of SAP itself, it is almost impossible to completely drain the infected necrotic tissue fragments with only one or several drainage tubes. Accordingly, debridement followed by postoperative drainage appears to be the only effective procedure. However, it causes additional traumas and postoperative complications, such as hemorrhage and intestinal leakage. Even though the infected focus is localized or well encapsulated, it is also difficult to completely remove the infected peripancreatic necrotic foci during an open-abdominal operation.

Choledochoscope is widely used in biliary surgery because of its easy manipulation and good flexibility. Flexible choledochoscope can reach various locations of the infected foci, thus guiding the flushing and debridement with minimal invasive intervention but no general anesthesia. In our study, choledochoscope was used to assist the debridement and flushing after the infected peripancreatic focus was drained with a large drainage tube for a few days when a fibrous wall was formed around the sinus tract. In this way, continuously generated necrotic tissue can be completely discarded. As a result, 38 out of the 42 SAP patients completely recovered without any complications with cure rate of 90.5% and no death occurred after treatment with the procedure, indicating that this procedure is safe, reliable and efficient to treat peripancreatic infection.

The following points should be addressed. First, in order to avoid damage to adjacent blood vessels and vital organs during puncture prior to catheterization, the puncture site should be carefully located under the guidance of ultrasound and the needle should be close to the focus. Second, the choledochoscope should not be inserted arbitrarily as it may prick the blood vessels in the focus leading to bleeding. Third, since smaller fragments of removable necrotic tissue in the focus can be cleaned by flushing with a large amount of sterile saline through

the water inlet of choledochoscope, and larger removable necrotic tissue pieces can be gently removed with a biopsy forceps. However, adhered necrotic tissue pieces should not be fiercely removed with the forceps since they will gradually become loose during the pathological process of SAP and can be removed in the next debridement under choledochoscope.

In summary, peripancreatic infection secondary to SAP can be treated promptly and efficiently with ultrasound-guided puncture and percutaneous catheter drainage followed by multiple debridement under choledochoscope. This procedure, in particular, can be performed in early SAP. Since this procedure does not require general anesthesia and open the peritoneal cavity with minimal surgical traumas, it can be safely performed for critically ill patients or for those who are unfit to undergo conventional surgical debridement. Percutaneous catheter drainage combined with choledochoscope-guided debridement can serve as an alternative to surgical debridement. We believe that this procedure is a novel and effective approach to the treatment of peripancreatic infection secondary to SAP.

## COMMENTS

### Background

Peripancreatic infection is a severe complication of severe acute pancreatitis (SAP) with a high mortality. Surgical debridement is necessary to remove infected tissue but it should be delayed till the peripancreatic infected tissue is demarcated. However, the presence of infected peripancreatic tissue without prompt debridement can further deteriorate the clinic condition of SAP patients. Thus, removal of the infected peripancreatic tissue timely and effectively becomes an urgent challenge for treatment of SAP patients.

### Research frontiers

Peripancreatic infection is one of the main causes for death of SAP patients. Open surgical debridement is a traditional treatment for peripancreatic infection, but it is believed that open surgical debridement can not completely remove necrotic tissues and further lead to multiple vital organ failure and death. Thus, it is necessary to remove infected peripancreatic tissue and effusion with minimal invasive approaches promptly and effectively.

### Innovations and breakthroughs

The results of this study have provided the evidence of successful treatment for early SAP patients using the ultrasound-guided puncture and catheter drainage combined with repeated debridement under choledochoscope, which can achieve satisfactory outcome.

### Applications

The procedure introduced in this study can be used as an alternative to the conventional open-abdominal surgical or laparoscopic debridement in treatment of peripancreatic infection of early SAP patients.

### Peer review

The study is interesting and impressive. The authors revealed the effectiveness

and safety of the new procedure they used. Although no control group was provided, the results can be accepted.

### Abstract

Gastrointestinal tuberculosis (TB) is quite rare, representing only 3% of all extra-pulmonary cases. Blind gut and ileum are the most common gastrointestinal localizations, while appendix involvement is infrequent. Appendix involvement is usually related to symptoms of acute appendicitis since the caseous necrosis may lead to adhesions and surgical complications such as perforation. For this reason patients with suspected appendicular TB usually undergo surgery even without a secure diagnosis. In these cases, due to the absence of specific symptoms and signs, the diagnosis is delayed after surgery, thus resulting in a high percentage of important, and sometimes lethal, complications. Histopathological examination is often the only way to reach a diagnosis and to establish specific antibiotic therapy, while an early diagnosis could avoid surgical treatment. We report a case of appendicular TB not only for its rarity but also to

### INTRODUCTION

Although tuberculosis (TB) can affect all human organs, the most commonly affected region is the lung<sup>[1]</sup>. Among the extra-pulmonary patterns, bones and the urinary system are the most frequently affected (30% and 24%, respectively), followed by lymph nodes (13%) and other localizations<sup>[1]</sup>. It is estimated that 1.3 million cases of TB and 450 000 deaths due to TB occur worldwide annually<sup>[1]</sup>.

Intestinal TB is rare in Western countries<sup>[2]</sup>, with incidence rates of 35.7 and 0.43 per 100 000 per year for the immigrant and native populations, respectively<sup>[3]</sup>. Despite a clear increase in the frequency of extra-pulmonary TB in immuno-suppressed patients, the clinical features of intestinal TB are rarely seen<sup>[3]</sup>. Blind gut and ileum are the most common gastrointestinal localizations, while appendix involvement is infrequent. Prompt diagnosis is dependent on a high index of suspicion as clinical signs may be non-specific and microbiological confirmation is difficult.

Furthermore, the tuberculin skin test and chest radiograph may initially be negative in as many as 50% of patients<sup>[4]</sup>. We report a case of appendicular TB and the difficulty in its diagnosis.

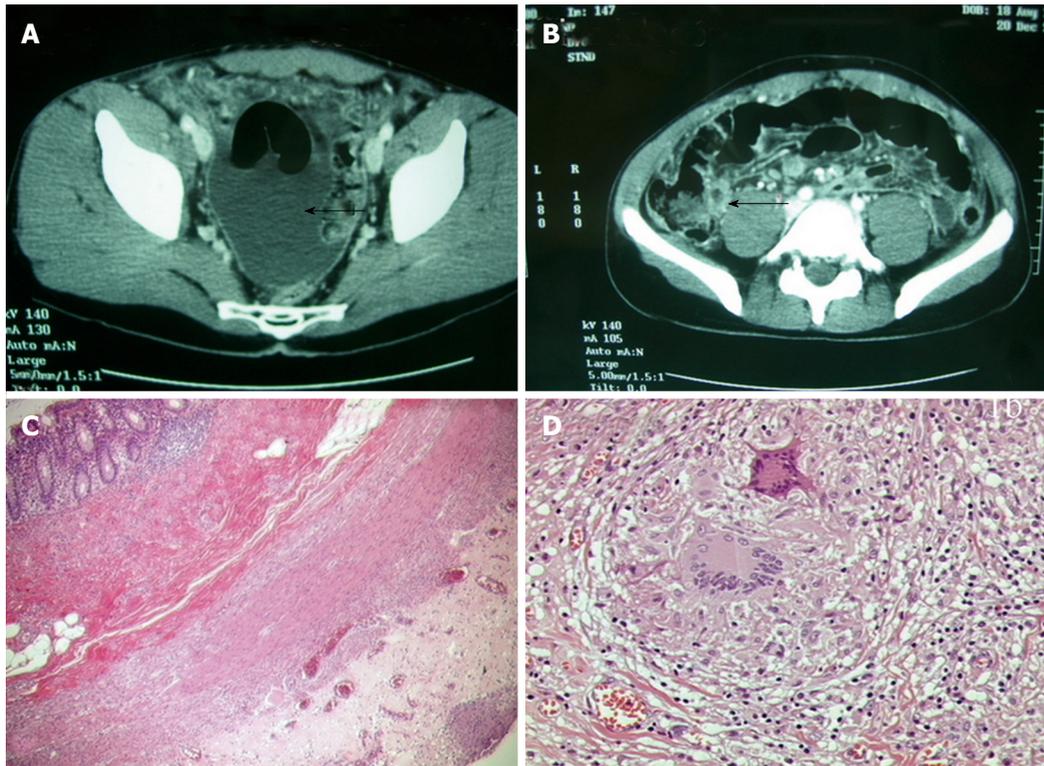

## CASE REPORT

A 25-year-old male was admitted to the Infective Diseases Department of our hospital with asthenia and a light evening temperature since about a month. Backache and earache were also present. The patient was an Italian white man who had not traveled to foreign countries in the recent past. During the last two weeks the patient had a high temperature (up to 40°C), together with nausea and vomiting. The physical examination showed signs of bilateral pleural deposit, globoid abdomen, tense and hardly manageable but still canalized to gas and feces. Clinical examination only showed enhancement of the sedimentation rate. After a first assessment with thoracic X-ray and abdominal ultrasound (US) examination which demonstrated the presence of thoracic and modest abdominal fluid deposit, the patient underwent a thoracic and abdominal computed tomography (CT)-scan which confirmed the presence of a light bilateral pleural deposit, heavier on the right side, ascites and an unexpected appreciable peritoneal deposit (Figure 1A). This was associated with a solid-liquid bilobate formation of about 8 cm in diameter, with a thickened wall and peripheral enhancement (Figure 1B). The CT-scan did not describe or identify the origin of the formation from the ileum or the appendix and the patient was promptly transferred to our department and submitted to surgery, which consisted of an explorative laparoscopy soon converted to laparotomy with appendectomy and omentectomy. At a first view after laparotomy, the abdomen seemed to be affected by a diffuse peritoneal carcinosis (Figure 2A), however, on closer inspection showed the presence of a diffuse micronodular aspect involving the bowels and omentum, and tenacious adhesions especially in the appendix-ileum-blind gut region were identified (Figure 2B). The aspect was diffusely inflammatory (Figure 2C), hyperemic and edematous and was soon defined as “military” in the operative theater. A diagnosis of TB was suspected and was confirmed by definitive histopathological examination, which described the presence of “granulomatous nodular epithelioid appendicitis and mesenteritis with gigantic and Langhans cells and diffuse caseous necrosis” (Figure 1C-D). The patient was started on specific antibiotic therapy for two months consisting of daily doses of isoniazid 400 mg, rifampicin 600 mg and pirazinamide 2 g, followed by four months of isoniazid and rifampicin therapy; the treatment lasted six months and the patient made a complete recovery without complications. One, three, six and twelve months after antibiotic therapy, the patient showed no signs of recurrence on thoracic X-ray and expectorate culture.

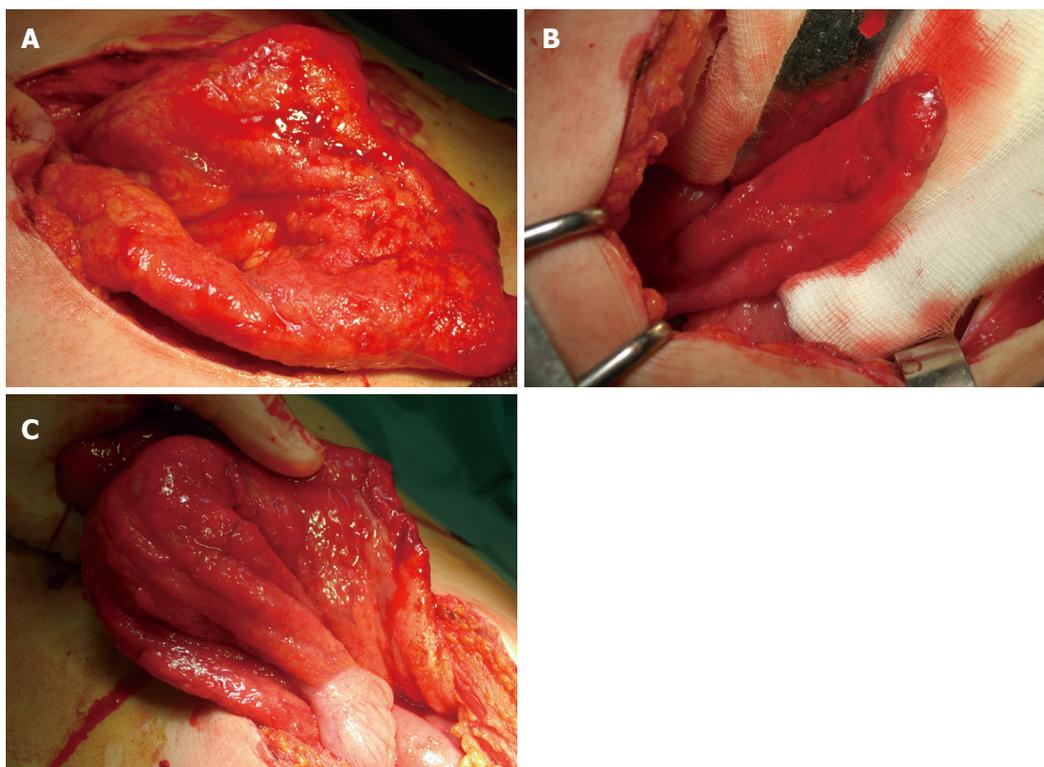

## DISCUSSION

According to the WHO Report of 2009 (WHO/HTM/

TB/2009.411) an estimated one third of the world's population is infected with *Mycobacterium tuberculosis*, and nearly 9 million people develop disease caused by *M. tuberculosis* each year. This resurgence is accompanied by a rise in multidrug-resistant TB (MDR TB), which is resistant to the two most effective first-line therapeutic drugs, isoniazid and rifampicin. In addition, virtually untreatable strains of *M. tuberculosis* are emerging globally. Extensively drug-resistant TB (XDR TB) is MDR TB that is also resistant to the most effective second-line therapeutic drugs used commonly to treat MDR TB; these drugs are fluoroquinolones and at least one of three injectable second-line drugs used to treat TB (amikacin, kanamycin, or capreomycin). XDR TB has been identified in all regions of the world. Because of the limited responsiveness of XDR TB to available antibiotics, mortality rates among patients with XDR TB are similar to those of TB patients in the pre-antibiotic era<sup>[5]</sup>. The peritoneum is one of the most common extra-pulmonary sites of TB infection. Peritoneal TB remains a significant problem in parts of the world where TB is prevalent. Increasing population migration, the use of more potent immuno-suppressant therapies and the acquired immunodeficiency syndrome epidemic have contributed to a resurgence of this disease in regions where it had previously been largely controlled<sup>[6]</sup>. Gastrointestinal TB can occur as a primary or secondary form: the first form is due to a primary infection of the intestinal mucosa by *Mycobacterium bovis*; the second form is usually a consequence and complication of primary pulmonary TB by *M. tuberculosis*. It may involve any part of the intestinal tract but the most common localizations are the ileum, the blind gut and the ascending colon. Appendicular TB is rare and of uncertain physiopathological etiology. Several authors agree that the appendix as a secondary localization by a more frequent ileum, cecal or genital infection due to blood contamination<sup>[7]</sup>. In our case, no signs of TB involvement were detected other than in the appendix itself, and all the other CT aspects were compatible with reactive signs and referable to the appendicular infection. This led us to consider it as a primary localization of TB since there was no other way to distinguish it from a secondary infection in the absence of other demonstrable localizations. Histopathological examination distinguishes three types of intestinal TB: the ulcerative form, which represents 60% of all cases and the hypertrophic and ulcer-hypertrophic forms, which represent 10% and 30%, respectively, of the remaining cases. Clinical presentation is usually dominated by ascites (100%), fever (76.2%) and abdominal pain (73.8%)<sup>[8]</sup>. Signs and symptoms of abdominal TB are nonspecific and similar to those of several other chronic abdominal diseases such as Crohn's syndrome; otherwise it may simulate an acute appendicitis such as the present case. It is very important to make a correct differential diagnosis, but in most cases this is not possible until histopathological examination is carried out, which is almost always after surgery. The diagnosis of a secondary localization by a pulmonary infection is usually more simple since the radiological aspects of pulmonary TB are often characteristic and a secondary interest in the

**Figure 1** CT scan pre-operative images and histopathological images. A: CT-scan image showing relevant amount of fluid in the Douglas; B: CT-scan image showing clear thickening of the appendicular wall (arrows) and "target" image as an evident sign of appendicitis; C, D: Histopathological aspects of the bioptical and resected samples.

**Figure 2** Specimen after laparotomy. A: Diffuse military aspect, simulating a peritoneal carcinosis; B: Tenacious adhesions in the appendix-ileum-blind gut region; C: Diffuse inflammatory, hyperemic and edematous aspects of the intestine.

bowel become at least assumable. In the case of a primary abdominal infection there are no characteristic radiological or serological signs and a presumptive diagnosis is really difficult to make. In these cases, great attention should be paid to the history of the patients and their contact with active TB<sup>[9]</sup>. Other than surgical diagnosis, when TB is first suspected a tuberculin skin test (TST) should be carried out although the positivity has been reported to be

only 18%-27%<sup>[10-12]</sup> in several studies. The literature also shows that culture positivity of peritoneal fluid is rarely seen<sup>[11,13-15]</sup>. High levels of adenosine deaminase (ADA) in the ascitic fluid have been shown to be compatible with the diagnosis of TB with high sensitivity (100%) and specificity (97%), but the analysis of ADA activity may not be available everywhere<sup>[15-17]</sup>. US can also be useful in detecting ascites and, in very expert hands, the caseous necrosis

causing hypoechogenic centers of the bloated lymph nodes<sup>[9,15]</sup>. The most accurate diagnostic alternative to surgery may be endoscopic biopsy of the lesions, but this still depends on the localization of the lesion itself (impossible in a case such as ours) and on the gravity of the case, possibly requiring urgent surgery. Serum tests are usually negative, other than nonspecific inflammatory signs, similar to radiological signs, which are evident but not specific for suspected TB such as mucosal wall thickening, distortions of the intestinal crests, ulcers and stenosis. During laparoscopy or open surgery, the intestinal wall appear thicker and it is usually possible to identify an inflammatory mass near the ileum-cecal region; mesenteric lymph nodes are frequently bloated and hardened with a caseous necrosis; the mucosa is often hyperemic, edematous and sometimes infected. Cytology shows the presence of Langhans cells. With or without surgical intervention, antibiotic therapy is always necessary and is similar to that of the pulmonary forms, consisting of isoniazid 300 mg/d, etambutol 15 mg/kg per day, and rifampicin 600 mg/d. Many authors suggest combining corticosteroid administration with specific antibiotic treatment to reduce the complications of abdominal TB<sup>[18-20]</sup>.

In conclusion, appendicular tuberculosis is a very rare occurrence but still a significant cause of morbidity and mortality worldwide. In the absence of specific symptoms and signs, its diagnosis is delayed, thus resulting in a high percentage of important, and sometimes lethal, complications. An assumed diagnosis of TB should be made in all patients presenting with ascites not liver related, accompanied by fever and abdominal pain. Appendicular TB is more frequent in younger patients and especially in these cases, when surgery is not yet necessary, TST, ADA peritoneal activity, culture of peritoneal fluid or endoscopic biopsy should be performed. Moreover, in patients with features similar to peritoneal carcinosis seen during surgery, TB in its military form should always be suspected. Histopathological examination after surgery for acute appendicitis often remains the only way to reach a secure diagnosis and to establish the best therapy, since surgery is often necessary but specific antibiotic therapy must be started as soon as possible. We are all seeing a resurgence of this old disease even in developed countries where it was thought to have disappeared. This is probably due to the migration of a great, and not always controlled, number of people from countries where TB still has a high incidence. The only way to resolve this problem is prophylaxis and prevention worldwide, but in the meanwhile a renewed acquaintance with this old disease is imperative.

### Abstract

Perivascular epithelioid cell tumor (PEComa) is a rare mesenchymal neoplasia and currently well recognized as a distinct entity with characteristic morphological, immunohistochemical and molecular findings. We report a case of PEComa arising in the antrum of a 71-year-old female with melena. The tumor, located predominantly in the submucosa as a well delimited nodule, measured 3.0 cm in diameter and was completely resected, with no evidence of the disease elsewhere. Histologically, it was composed predominantly of eosinophilic epithelioid cells arranged in small nests commonly related to variably sized vessels, with abundant extracellular material, moderate nuclear variation and discrete mitotic activity. No necrosis, angiolymphatic invasion or perineural infil-

### INTRODUCTION

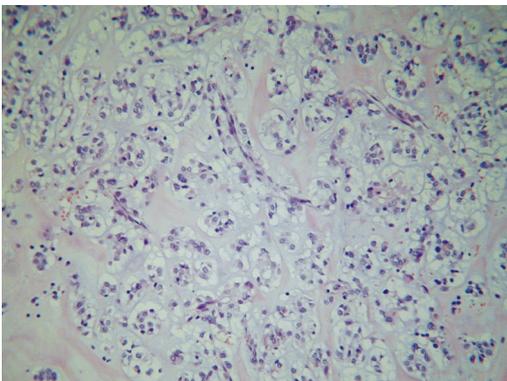

Perivascular epithelioid cell tumor (PEComa) is defined by the World Health Organization (WHO) as a mesenchymal neoplasia composed of perivascular epithelioid cells, with characteristic morphologic and immunohistochemical distinctive features<sup>[1]</sup>. It belongs to a heterogeneous family of tumors and genetic alterations have been related to cases associated with tuberous sclerosis complex (TSC)<sup>[1-3]</sup>. PEComa has been described in numerous locations, especially digestive system and uterus<sup>[1-3]</sup>, but rarely in gastrointestinal tract<sup>[4-13]</sup>. We present a case of PEComa of the stomach, a site of origin not previously reported.

### CASE REPORT

A 71-year-old female was admitted to our emergency

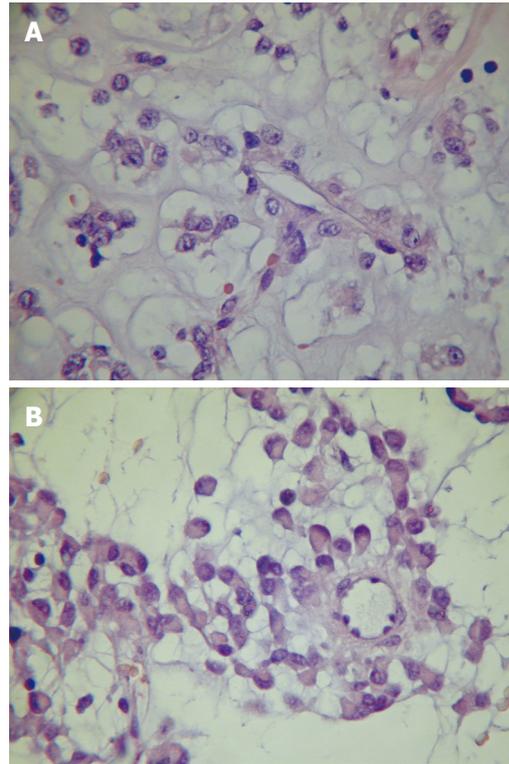

**Figure 1** Low power view showing the tumor predominantly located in the submucosa with focal ulceration of the adjacent mucosa.

**Figure 2** Microscopy showing the tumor cells mostly arranged as small nests commonly related to variably sized vessels, with abundant extracellular material and mucinous or collagenous characteristics.

room due to a recent episode of melena, referring previous similar occurrences. She had a past history of multiple laparotomies for colonic diverticulitis, acute cholecystitis and associated complications. On admission, an upper endoscopy revealed elevated gastric antral mucosa with ulceration, probably due to a submucosal lesion. A biopsy did not represent the tumor. A colonoscopy showed only diverticular disease without signs of hemorrhage or inflammation. The patient underwent a partial gastrectomy with complete resection of the lesion, during which no lymph node or peritoneal metastasis was found. After histopathological diagnosis, the patient was scanned for systemic disease, including a positron emission tomography-computed tomography (PET-CT), but nothing was found. She recovered well and was discharged 7 d after operation.

Specimen showed a predominant submucosal nodule, with focal extension to the muscularis propria. The lesion caused a discrete elevation of the adjacent mucosa with focal ulceration (Figure 1). The tumor measured 3.0 cm × 2.8 cm × 1.6 cm. Microscopic examination revealed a well-circumscribed but not encapsulated lesion. The cells were mostly arranged as small nests commonly related to variably sized vessels, with abundant extracellular material and mucinous or collagenous characteristics (Figure 2). Pseudoalveolar and focal fusocellular pattern was

**Figure 3** Neoplastic cells showing eosinophilic and clear epithelioid characteristics and perivascular arrangement (A) and focal rhabdoid features (B).

observed in some areas. The neoplasia was predominantly composed of eosinophilic and clear epithelioid cells (Figure 3A), also presenting focal rhabdoid features (Figure 3B). Moderate nuclear variation and discrete mitotic activity (1 mitosis/50 HPF) were observed, but there were no necrosis, angiolymphatic invasion or perineural infiltration. Immunohistochemically, the tumor cells were positive for vimentin, smooth muscle actin, desmin, melan A, and for CD56, but negative for pan-cytokeratin AE1/AE3, chromogranin A, CD34, CD31, CD117, S100 protein, muscle specific actin HHF-35 and HMB-45.

## DISCUSSION

PEComa is a rare tumor, resulting from the proliferation of PEC. There is a female predominance with a wide age distribution. The tumor has been described in numerous locations outside the kidney, but not in the stomach. It was reported that the findings of a conventional angiomyolipoma of the stomach, presented as a submucosal lesion, are similar to those of its renal counterpart<sup>[14]</sup>. Only 13 cases of PEComa, primarily located in the gastrointestinal tract, have been reported, including 3 in the small bowel, 5 in the colon, 1 in the appendix and 4 in the rectum<sup>[1-13]</sup>. All these cases were females, except for a 12-year-old boy with a past history of cervical neuroblastoma, probably related to TSC<sup>[10]</sup>. The age of these patients ranged 6-63 years, with an average age of 29 years, and the greatest tumor

size varied from 1.3 to 10.0 cm. Interestingly, all the four reported cases of gastrointestinal angiomyolipoma were males, with their age ranged 55-67 years (average age of 59 years), and smaller tumors (2 in the colon, 1 in the stomach, and 1 in the rectum, measuring 1.0-3.0 cm in diameter<sup>[14-17]</sup>.

PEComa is characterized by perivascular location, and the tumor cells have mostly epithelioid and spindle appearance, with clear to lightly granular eosinophilic cytoplasm. The PEC is positive for melanocytic and muscle markers<sup>[1]</sup>. The pathological findings in our case were very consistent with those of PEComa and immunohistochemistry confirmed the diagnosis.

In PEComa, the most sensitive melanocytic markers are HMB-45, Melan-A and microphthalmia transcription factor<sup>[1]</sup>. Although our experience is limited, in part due to the rarity of the disease, we have seen other cases which were weakly and even dubiously positive for HMB-45, but strongly and uniformly positive for melan A. Now, we routinely include a panel of at least three melanocytic markers to better characterize this entity.

The main differential diagnosis includes gastrointestinal stromal tumor (GIST), smooth muscle tumor, metastatic melanoma and endocrine neoplasia. GIST is the most common primary mesenchymal neoplasm of the gastrointestinal (GI) tract, but rarely shows oncocytic or rhabdoid morphology, clear cell features or pleomorphism. On the other hand, PEComa may mimic GIST when it contains fusocellular arrangement or expressing CD117. The morphology of leiomyoma and leiomyosarcoma may be very similar to that of PEComa. Some of the cases diagnosed in the past as smooth muscle tumor may indeed represent PEComas. Immunohistochemical analysis is the only way to establish the diagnosis of PEComa. Metastatic melanoma should always be considered, especially with diffuse expression of melanocytic markers. Our case was negative for S100 protein and HMB-45, but strongly and uniformly positive for smooth muscle actin and desmin. Some cases, however, may not present with such a characteristic profile. The distribution of these positive substances may be useful in the differential diagnosis. Most gastric endocrine neoplasms are represented by well-differentiated tumors or carcinoids, but small and large cell neuroendocrine carcinomas may infrequently occur. Adenocarcinomas with neuroendocrine differentiation, and mixed tumors with glandular and endocrine features have been reported. We included epithelial and neuroendocrine markers in our panel to consider these possibilities.

Ultrastructural findings, like abundant cytoplasmic glycogen, pre-melanosomes, thin filaments with occasional dense bodies, hemidesmosomes and poorly-formed intercellular junctions<sup>[1]</sup>, would help to define the lineage or origin of these peculiar cells, but we do not routinely perform ultrastructural analysis in our laboratory.

The criteria of malignancy for PEComa have not been well established. WHO guidelines based on the data from well-documented malignant PEComas, suggest

that PEComas should be regarded as malignant when they display infiltrative growth, marked hypercellularity, nuclear enlargement, hyperchromasia, high mitotic activity, atypical mitotic figures and coagulative necrosis<sup>[1]</sup>. More recently it has been reported that tumor size over 5 cm, infiltrative growth pattern, high nuclear grade, necrosis and mitotic activity over 1/50 HPF is significantly associated with aggressive clinical behavior of PEComas of soft tissue and gynecologic origin<sup>[3,7,13]</sup>.

Optimal treatment of PEComas is not well established. Currently, surgery is the main treatment modality for primary tumor, local recurrence and metastasis<sup>[18]</sup>. It is obviously difficult to perform therapeutic trials, but perhaps in the near future new specific targeted therapy may be used in patients with locally advanced or metastatic disease, when chemotherapy and immunotherapy are considered. The present case was treated exclusively with surgical resection and the patient was well, free of disease after 19 mo.

In conclusion, gastric PEComa, as an isolated lesion, is presented with gastrointestinal hemorrhage, without evidence of the disease elsewhere. Although unusual, PEComa should be considered in the differential diagnosis of gastric neoplasia with characteristic epithelioid and oncocytic features and prominent vasculature.

### Abstract

Conventional hepatectomy is an effective way to treat hepatocellular carcinoma. However, it is invasive and stressful. The use of laparoscopy in hepatectomy, while technically demanding, reduces surgical invasiveness and stressfulness but still achieves complete resection with adequate margins. Compared with conventional hepatectomy, laparoscopic hepatectomy provides a better chance and situation for further surgery in the case of recurrence of hepatocellular carcinoma. Even aged patients can successfully endure repeated hepatectomy using laparoscopy, as shown in the present report. This report presents a case of repeated laparoscopic hepatectomy treating hepatocellular carcinoma and its recurrence in an aged patient having cirrhosis, a disease causing extra difficulty for performing laparoscopic hepatectomy. The report also describes techniques of the operation and displays characteristic results of laparoscopic hepatectomy such as smaller wounds, less blood loss, less pain, less scars and adhesion, shorter postoperative hospital stay, and faster recovery.

### INTRODUCTION

Laparoscopic surgery, a kind of minimally invasive surgery, has recently gained considerable advances. Nonetheless, laparoscopic hepatectomy still presents various kinds of difficulties to surgeons. Initial laparoscopic approaches in hepatic surgery were first limited to staging procedures, then extended to non-anatomical resection for hepatic lesions such as cyst, adenoma, hemangioma, and solitary liver metastasis<sup>[1-3]</sup>. Challenges of liver manipulation, parenchymal transection and hemostasis were hurdles in the progress of laparoscopic hepatectomy. Hazards such as gas embolism and difficulty in controlling bleeding discouraged many surgeons. However, with the accumulation of experience, laparoscopic hepatectomy, albeit technically demanding, is being employed to treat hepatocellular carcinoma (HCC), and reports on its safety, efficacy and reproducibility are emerging.

Like conventional hepatectomy, laparoscopic hepatectomy allows complete resection of tumors with adequate margins; but on top of this, it has a number of advantages over the former. It causes smaller wounds, less blood loss, less pain, less scars and adhesion, and smaller chance of incisional hernia. These advantages provide a better chance and situation for further surgery

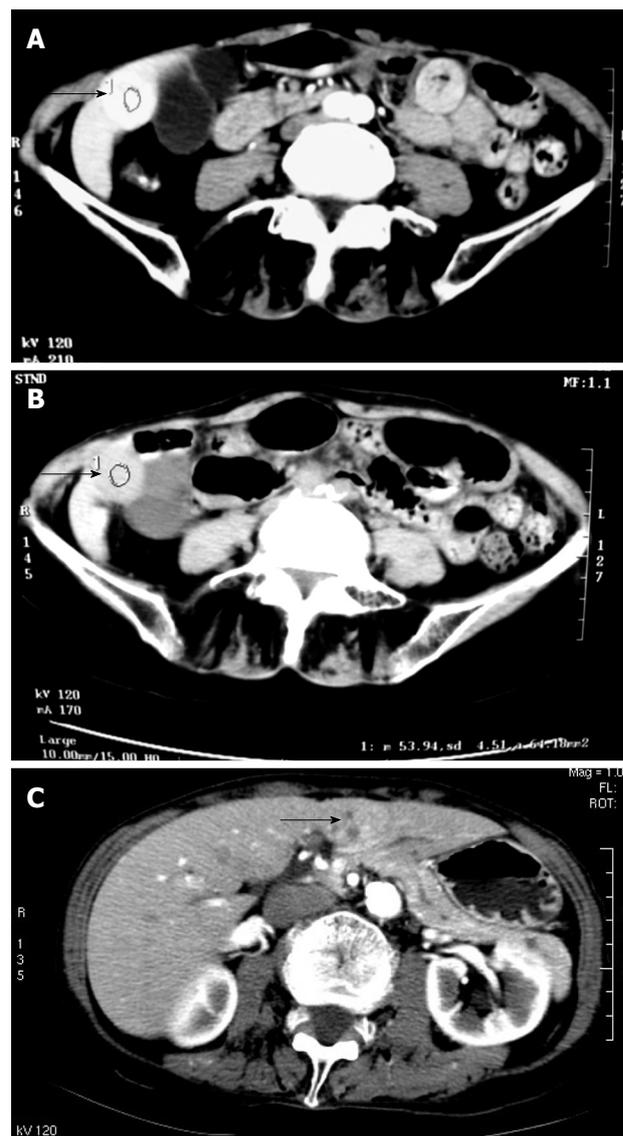

in the case of HCC recurrence which is common and hence anticipated<sup>[4]</sup>. Moreover, they render the operation less invasive and less stressful, and so make it a good treatment option for aged patients. Patients also need shorter postoperative hospital stay and have faster recovery. In the past, laparoscopic hepatectomy was not recommended for cirrhotic livers because of their high tendency towards bleeding during operation, but with improved magnification and illumination in laparoscopy today, the risk of bleeding has lessened and laparoscopic hepatectomy is no longer precluded by cirrhosis<sup>[5-7]</sup>.

This report presents a case of repeated laparoscopic hepatectomy treating HCC and its recurrence in an aged cirrhotic patient and describes the surgical techniques therein.

## CASE REPORT

An 85-year-old woman who had left radical mastectomy performed 30 years ago for carcinoma of the left breast was referred to us because of deranged liver function associated with elevated serum alpha-fetoprotein level. An ultrasound study was carried out and revealed a 2.7-cm hypoechoic lesion at the inferior tip of the right hepatic lobe. She had a serum alpha-fetoprotein level of 80 ng/mL and  $\gamma$ -glutamyl transferase level of 226 U/L. Her platelet count was  $132 \times 10^9$ /L. She was negative for both hepatitis B virus and hepatitis C virus, and her liver function was classified as Child-Pugh class A. Her indocyanine green retention rate at 15 min was 12.7%. Computed tomography (CT) scan with contrast revealed a 2.5-cm hypervascular tumor with early washout of contrast in segment 5 of the liver (Figure 1A and B). The overall picture was indicative of HCC, and laparoscopic wedge resection was planned.

The operation was performed under general anesthesia. The patient was placed in a supine position with a 30-degree Trendelenburg adjustment. The surgeon and an assistant stood at the right side of the patient. A 12-mm port was created using the open method. Pneumoperitoneum was introduced by insufflation of CO<sub>2</sub>, and intra-abdominal pressure was maintained at 12 cmH<sub>2</sub>O. A second 12-mm port was created 2 cm below the left costal margin along the anterior axillary line. A third 12-mm port was made at the right iliac fossa. Three trocars were positioned along a semicircular line, with the concavity facing the right subcostal margin. Finally, a 5-mm port was made in the subxiphoid region (Figure 2). Standard diagnostic and staging laparoscopy was performed, and the liver was examined using laparoscopic ultrasound (Aloka, Tokyo, Japan) to confirm the extension of the tumor and its relationship to the vasculature (Figure 3). The area to be transected was marked by diathermy. Resection was performed with the no-touch technique, and the liver parenchyma was transected using electrocautery supplemented by 6 cycles of radiofrequency ablation using a 3-cm single cooled-tip electrode. Each cycle of radiofrequency ablation lasted for 2 min. Hemostasis was achieved using metallic clips and by argon beam coagulation. A 1-cm resection margin was

**Figure 1** Contrast CT scan of the abdomen. A, B: CT scan of the abdomen showing a 2.5-cm tumor in segment 5 of the liver (arrow); C: CT scan of the abdomen showing a 3-cm tumor in the left lateral segment of the liver (arrow).

achieved. The operation lasted 180 min. No complication occurred during the operation. Blood loss of 120 mL was recorded and no blood transfusion was needed. Pringle maneuver was not applied in the operation.

Feeding started on the second day of the operation. Liver function returned to preoperative level on the fifth day. The patient was discharged home on the sixth day.

Pathology confirmed the presence of moderately differentiated HCC measuring 2.5 cm, 8 mm from the resection margin (Figure 4).

The patient was regularly followed up with CT scan and serum alpha-fetoprotein check every three months. Her serum alpha-fetoprotein level returned to 50 ng/mL three months after surgery and remained static in subsequent follow-ups, until the end of the first year when it rose to 3489 ng/mL.

CT scan with contrast was done and revealed an arterial enhancing mass measuring 3 cm × 1.8 cm × 3 cm in

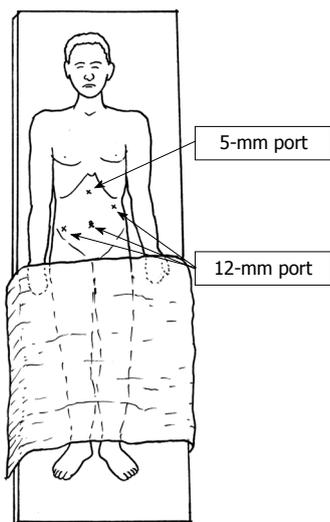

Figure 2 Port placement for laparoscopic hepatectomy.

Figure 3 Intraoperative ultrasound scan of the liver showing a tumor measuring 23.9 mm × 21.4 mm in segment 5.

segment 2 and segment 3 of the liver, which suggested HCC (Figure 1C). Repeated laparoscopic hepatectomy was to be performed.

The patient was placed in the Lloyd-Davis position under general anesthesia. The surgeon stood between the legs with one assistant on each side. Ports were re-created at sites as in the previous operation, and pneumoperitoneum was performed. The ports measured between 5 mm and 12 mm, allowing easy change of instruments, offering flexibility in the use of ultrasonic dissector with both hands, and facilitating the introduction of endo-staplers. The falciform ligament was divided and laparoscopic ultrasound was applied to identify the vasculature of the liver. The left lateral segment was mobilized and parenchymal transection was performed with a Cavitron ultrasonic surgical aspirator (CUSA). The left lateral segment pedicle was divided using an endovascular stapler. The liver was delivered through a 6-cm left subcostal incision. The operation lasted 250 min. No adhesion was encountered and no complication occurred. Blood loss of 200 mL was recorded and no blood transfusion was needed. Pringle maneuver was not applied in the operation.

The patient was monitored in the intensive care unit for one day, and was transferred to the general surgical ward on the second day when feeding was resumed. Her liver function returned to preoperative level on the fifth day. She was discharged home on the ninth day.

Pathology confirmed the presence of moderately differentiated HCC measuring 7 cm, 7 mm from the resection margin.

The patient was faring well and remained disease-free at follow-up 18 mo later.

## DISCUSSION

Different new techniques for hepatic resection have arisen, but they remain controversial. Amongst these new techniques, the minimally invasive approach using laparoscopy has been drawing much attention<sup>[8-11]</sup>. Since the introduction of laparoscopic cholecystectomy in 1987, the laparoscopic approach has been developed for differ-

Figure 4 The 2.5-cm resected tumor that originated in segment 5 of the liver after laparoscopic wedge excision.

ent kinds of abdominal surgery, such as gastrointestinal treatment. As to hepatic treatment, initial laparoscopic procedures in hepatectomy were limited to biopsy, tumor staging, fenestration of liver cysts, and resection of benign liver tumors. Currently, there are a few reported series on laparoscopic resection of HCC in patients with cirrhosis<sup>[6,7,12-15]</sup>. Experience of laparoscopic hepatectomy is still scarce, and laparoscopic resection of cirrhotic liver is still considered technically difficult, especially in patients with deranged liver function.

Lesurtel *et al*<sup>[16]</sup> reported the results of 16 laparoscopic left lateral segmentectomies for benign liver diseases, HCC and metastasis. Compared with laparotomy, laparoscopic left lateral lobectomy displayed longer operation time (202 min *vs* 145 min,  $P < 0.01$ ) and longer portal triad clamping time (39 min *vs* 23 min,  $P < 0.05$ ), but less blood loss (236 mL *vs* 429 mL,  $P < 0.05$ ). The morbidity rate of the laparoscopic group was 11% and that of the open group was 15%. No death occurred. No specific complication of hepatic resection (hemorrhage, subphrenic collection, biliary leak) was observed after the laparoscopic operation, but in the open group there were some such complications.

Wounds created by laparoscopic surgery are generally smaller than those made by open surgery. In laparoscopic hepatic surgery, 4 to 5 ports are used, each measuring

5 mm to 12 mm only, so the wounds are smaller than those in traditional hepatectomy, resulting in less severe pain and smaller dosage of postoperative narcotics. The risk of incisional hernia after laparoscopic liver resection is also lower. Moreover, shorter hospital stay is observed. In most studies, the mean hospital stay after laparoscopic hepatectomy was 2 d shorter than that after open hepatectomy<sup>[16-18]</sup>.

Another generally observed advantage of laparoscopic surgery over open resection is that it causes less scarring and less adhesion. Future hepatectomy and repetition of laparoscopic resection for recurrent HCC thus become feasible. Abdominal postsurgical adhesions develop following mesothelial trauma, which can be caused by surgical handling and contact of instruments and foreign materials such as sutures and glove dusting powder, as well as by desiccation and overheating. Postoperative adhesions occur after most surgical procedures and can result in serious complications including intestinal obstruction, infertility and pain. This is a long-term unpredictable problem and impacts surgical workload and hospital resources, resulting in considerable health-care expenditure<sup>[19-21]</sup>.

Adhesions result from normal peritoneal wound-healing response and develop in the first five to seven days after injury. Adhesion formation and adhesion-free re-epithelialization are the two alternative pathways, and both begin with coagulation which initiates a cascade of events resulting in the build-up of fibrin gel matrix. If not removed, the fibrin gel matrix may become the progenitor of adhesion by forming a band or bridge when two peritoneal surfaces coated with it are apposed. The band or bridge is the basis for organization of adhesion. Protective fibrinolytic enzyme systems of the peritoneum, such as the plasmin system, can remove the fibrin gel matrix. However, surgery dramatically diminishes fibrinolytic activity. The apposition of two damaged surfaces and the extent of fibrinolysis are pivotal in determining whether the pathway taken is adhesion formation or adhesion-free re-epithelialization<sup>[20,22]</sup>.

Oncologic clearance is an important issue in laparoscopic liver resection. Risks of tumor-cell seeding and port-site metastasis are of great concern. In the early era of laparoscopic surgery in the management of malignant diseases, it was particularly worrying that pneumoperitoneum would increase tumor seeding and promote peritoneal or even intraportal spread<sup>[23]</sup>. In the first operation of the present case, the tumor to be resected was maintained intact and put in a plastic specimen bag before removal through the subumbilical port<sup>[24,25]</sup>. The tumor resection margin was 1 cm. This was to minimize the risk of tumor seeding during laparoscopic handling of the malignant tissue. In the second operation, the laparoscopic approach was again adopted for resection of the recurrent tumor because it was well localized, without invasion to any major vessel or organ, and free of adhesion. It was proven technically feasible to resect the tumor with a clear margin.

Elderly patients and patients having multiple diseases are prone to morbidity and mortality instigated by open hepatectomy. Choices of surgical management are relatively limited when the possibility of complications is taken into consideration. Minimally invasive surgery provides a chance of complete surgical resection of recurrent tumors for these patients. In the present case, the patient underwent two hepatic resections completed in the laparoscopic approach under general anesthesia within 13 mo and recovered well without complications. This is, to our knowledge, the first report regarding repeated laparoscopic hepatectomy in an elderly HCC patient with cirrhosis.

Laparoscopic hepatectomy demands a high level of technical skill, especially when bleeding is anticipated. Control of major vessel bleeding is difficult and there may be indications of conversion. With recent advancement in laparoscopic instruments, laparoscopic surgical difficulties are decreasing. Various instruments have been designed for safe transection of the liver. In the present case, we adopted a combined use of radiofrequency ablation, ultrasonic dissector, endoscopic CUSA, and endovascular stapler. We completed the liver transection by applying the endovascular stapler to the Glisson's pedicle of the left lateral segment. This stapling technique makes it fast and safe to control hepatic pedicles with an outside chance of complications, and is widely employed in both the open approach and the laparoscopic approach because it reduces the risk of bleeding and shortens operation time<sup>[8,9,12,26,27]</sup>.

Owing to anticipated technical difficulties and the possibility of bleeding during surgery, laparoscopic hepatectomy is still not a common practice amongst most hepatic surgeons. However, it is given recognition for causing less intraoperative blood loss, intractable ascites, encephalopathy and other complications of decompensation of cirrhosis. These advantages can partly be attributed to good illumination and magnification in laparoscopy. Magnification in laparoscopy can be increased up to five times without compromise of the visual field and allows even small vessels to be clearly identified, which helps in decreasing blood loss. The performance of diagnostic ultrasonographic assessment of laparoscopy can avoid unnecessary laparotomy for tumors that are too advanced.

In conclusion, laparoscopic hepatectomy for HCC is a good alternative to open hepatectomy because it has advantages including causing less adhesion after surgery, which renders re-operation much easier in cases of recurrence. It is a comparatively less invasive procedure that offers a chance of surgical clearance of tumors. Further studies with greater numbers of patients and longer follow-up are needed for a better perspective regarding the role of laparoscopic hepatectomy in the management of HCC.

## Meetings

### Events Calendar 2010

January 25-26  
 Tamilnadu, India  
 International Conference on Medical Negligence and Litigation in Medical Practice

January 25-29  
 Waikoloa, HI, United States  
 Selected Topics in Internal Medicine

January 26-27  
 Dubai, United Arab Emirates  
 2nd Middle East Gastroenterology Conference

January 28-30  
 Hong Kong, China  
 The 1st International Congress on Abdominal Obesity

February 11-13  
 Fort Lauderdale, FL, United States  
 21th Annual International Colorectal Disease Symposium

February 26-28  
 Carolina, United States  
 First Symposium of GI Oncology at The Caribbean

March 04-06  
 Bethesda, MD, United States  
 8th International Symposium on Targeted Anticancer Therapies

March 05-07  
 Peshawar, Pakistan  
 26th Pakistan Society of Gastroenterology & Endoscopy Meeting

March 09-12  
 Brussels, Belgium  
 30th International Symposium on Intensive Care and Emergency Medicine

March 12-14  
 Bhubaneswar, India  
 18th Annual Meeting of Indian National Association for Study of the Liver

March 23-26  
 Cairo, Egypt  
 14th Pan Arab Conference on Diabetes PACD14

March 25-28  
 Beijing, China  
 The 20th Conference of the Asian

Pacific Association for the Study of the Liver

March 27-28  
 San Diego, California, United States  
 25th Annual New Treatments in Chronic Liver Disease

April 07-09  
 Dubai, United Arab Emirates  
 The 6th Emirates Gastroenterology and Hepatology Conference, EGHC 2010

April 14-17  
 Landover, Maryland, United States  
 12th World Congress of Endoscopic Surgery

April 14-18  
 Vienna, Austria  
 The International Liver Congress™ 2010

April 28-May 01  
 Dubrovnik, Croatia  
 3rd Central European Congress of surgery and the 5th Croatian Congress of Surgery

May 01-05  
 New Orleans, LA, United States  
 Digestive Disease Week Annual Meeting

May 06-08  
 Munich, Germany  
 The Power of Programming: International Conference on Developmental Origins of Health and Disease

May 15-19  
 Minneapolis, MN, United States  
 American Society of Colon and Rectal Surgeons Annual Meeting

June 04-06  
 Chicago, IL, United States  
 American Society of Clinical Oncologists Annual Meeting

June 09-12  
 Singapore, Singapore  
 13th International Conference on Emergency Medicine

June 14  
 Kosice, Slovakia  
 Gastro-intestinal Models in the Research of Probiotics and Prebiotics-Scientific Symposium

June 16-19  
 Hong Kong, China  
 ILTS: International Liver Transplantation Society ILTS Annual International Congress

June 20-23  
 Mannheim, Germany  
 16th World Congress for Bronchoesophagology-WCBE

June 25-29  
 Orlando, FL, United States  
 70th ADA Diabetes Scientific Sessions

August 28-31  
 Boston, Massachusetts, United States  
 10th OESO World Congress on Diseases of the Oesophagus 2010

September 10-12  
 Montreal, Canada  
 International Liver Association's Fourth Annual Conference

September 11-12  
 La Jolla, CA, United States  
 New Advances in Inflammatory Bowel Disease

September 12-15  
 Boston, MA, United States  
 ICAAC: Interscience Conference on Antimicrobial Agents and Chemotherapy Annual Meeting

September 16-18  
 Prague, Czech Republic  
 Prague Hepatology Meeting 2010

September 23-26  
 Prague, Czech Republic  
 The 1st World Congress on Controversies in Gastroenterology & Liver Diseases

October 07-09  
 Belgrade, Serbia  
 The 7th Biannual International Symposium of Society of Coloproctology

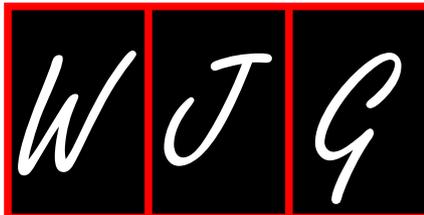

October 15-20  
 San Antonio, TX, United States  
 ACG 2010: American College of Gastroenterology Annual Scientific Meeting

October 23-27  
 Barcelona, Spain  
 18th United European Gastroenterology Week

October 29-November 02  
 Boston, Massachusetts, United States  
 The Liver Meeting® 2010--AASLD's 61st Annual Meeting

November 13-14  
 San Francisco, CA, United States  
 Case-Based Approach to the Management of Inflammatory Bowel Disease

December 02-04  
 San Francisco, CA, United States  
 The Medical Management of HIV/AIDS

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board

members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systematically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Article: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce Consensus and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

## Instructions to authors

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/1007-9327/Instructions-toAuthprs.asp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com), or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

## MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

### Title page

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. [montgomery.bissell@ucsf.edu](mailto:montgomery.bissell@ucsf.edu)

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

### Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g.  $6.92 \pm 3.86$  vs  $3.61 \pm 1.67$ ,  $P < 0.001$ ; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>; Writing requirements of abstract at: <http://www.wjgnet.com/1007-9327/links/Abstract.doc>.

### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the

main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A...; B...; C...; D...; E...; F...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### Patent (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

### Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as  $\nu$  (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6  $24.5 \mu\text{g/L}$ ; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub>, not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

### Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

### Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr-A*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E coli*, etc.

## RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

### Editorial Office

#### World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)

<http://www.wjgnet.com>

Telephone: +86-10-5908-0039

Fax: +86-10-85381893

### Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

### Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/1007-9327/news/10.doc>.

### Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/1007-9327/news/12.doc>.

### Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

### Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

### Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

## Contents

Weekly Volume 16 Number 5 February 7, 2010

### EDITORIAL

- 531 MicroRNAs, development of Barrett's esophagus, and progression to esophageal adenocarcinoma  
*Smith CM, Watson DI, Michael MZ, Hussey DJ*
- 538 A focus on parietal cells as a renewing cell population  
*Karam SM*

### REVIEW

- 547 A systematic review of efficacy and tolerability of mebeverine in irritable bowel syndrome  
*Darvish-Damavandi M, Nikfar S, Abdollahi M*
- 554 Hepatitis D: Scenario in the Asia-Pacific region  
*Abbas Z, Jafri W, Raza S*

### ORIGINAL ARTICLE

- 563 Effects of perinatal protein deprivation and recovery on esophageal myenteric plexus  
*Greggio FM, Fontes RBV, Maifrino LB, Castelucci P, de Souza RR, Liberti EA*
- 571 Significance and relationship between Cripto-1 and p-STAT3 expression in gastric cancer and precancerous lesions  
*Zhang JG, Zhao J, Xin Y*

### BRIEF ARTICLE

- 578 Understanding of chemoprophylaxis and concordance in inflammatory bowel disease  
*Low A, Love M, Walt R, Kane K, Eksteen B, Goh J*
- 583 Crypt abscess-associated microbiota in inflammatory bowel disease and acute self-limited colitis  
*Sokol H, Vasquez N, Hoyeau-Idrissi N, Seksik P, Beaugerie L, Lavergne-Slove A, Pochart P, Marteau P*
- 588 Large endoscopic mucosal resection for colorectal tumors exceeding 4 cm  
*Ah Soune P, Ménard C, Salah E, Desjeux A, Grimaud JC, Barthet M*
- 596 Phlebotomy improves histology in chronic hepatitis C males with mild iron overload  
*Sartori M, Andorno S, Rossini A, Boldorini R, Bozzola C, Carmagnola S, Del Piano M, Albano E*

- 603** Metabolic investigations in patients with hepatitis B and C  
*Mastoi AA, Devrajani BR, Shah SZA, Rohopoto Q, Memon SA, Baloch M, Qureshi GA, Sami W*
- 608** Hemodynamics in the immediate post-transplantation period in alcoholic and viral cirrhosis  
*Al-Hamoudi WK, Alqahtani S, Tandon P, Ma M, Lee SS*
- 613** Effect of domperidone therapy on nocturnal dyspeptic symptoms of functional dyspepsia patients  
*Chen SL, Ji JR, Xu P, Cao ZJ, Mo JZ, Fang JY, Xiao SD*
- 618** Natural course of chronic hepatitis B is characterized by changing patterns of programmed death type-1 of CD8-positive T cells  
*Liang XS, Zhou Y, Li CZ, Wan MB*
- 625** Serum thymosin  $\beta$ 4 levels in patients with hepatitis B virus-related liver failure  
*Han T, Liu Y, Liu H, Zhu ZY, Li Y, Xiao SX, Guo Z, Zhao ZG*
- 631** Clinical and endoscopic analysis of gastric Dieulafoy's lesion  
*Ding YJ, Zhao L, Liu J, Luo HS*
- 636** Inhibition of allogeneic T-cell response by Kupffer cells expressing indoleamine 2,3-dioxygenase  
*Yan ML, Wang YD, Tian YF, Lai ZD, Yan LN*
- 641** DNA polymorphism and risk of esophageal squamous cell carcinoma in a population of North Xinjiang, China  
*Ma WJ, Lv GD, Zheng ST, Huang CG, Liu Q, Wang X, Lin RY, Sheyhidin I, Lu XM*

**CASE REPORT**

- 648** Rectal perforation from endometriosis in pregnancy: Case report and literature review  
*Pisanu A, Deplano D, Angioni S, Ambu R, Uccheddu A*
- 652** Primary mixed germ cell tumor of the liver with sarcomatous components  
*Xu AM, Gong SJ, Song WH, Li XW, Pan CH, Zhu JJ, Wu MC*

**LETTERS TO THE EDITOR**

- 657** No evidence of Permacol rejection presented by Wotton and Akoh  
*Smart NJ*

**ACKNOWLEDGMENTS** I Acknowledgments to reviewers of *World Journal of Gastroenterology*

**APPENDIX** I Meetings  
I-IV Instructions to authors

**AIM AND SCOPE**

*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

### Abstract

Barrett's esophagus is a premalignant condition caused by gastroesophageal reflux. Once developed, it can progress through varying grades of dysplasia to esophageal adenocarcinoma. Whilst it is well accepted that Barrett's esophagus is caused by gastroesophageal reflux, the molecular mechanisms of its pathogenesis and progression to cancer remain unclear. MicroRNAs (miRNAs) are short segments of RNA that have been shown to control the expression of many human genes. They have been implicated in most cellular processes, and the role of miRNAs in disease development is becoming increasingly evident. Understanding altered miRNA expression is likely to help unravel the molecular mechanisms that underpin the development of Barrett's esophagus and its progression to cancer.

Smith CM, Watson DI, Michael MZ, Hussey DJ. MicroRNAs, development of Barrett's esophagus, and progression to esophageal adenocarcinoma. *World J Gastroenterol* 2010; 16(5): 531-537  
Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i5/531.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i5.531>

### INTRODUCTION

Barrett's esophagus is characterized by a metaplastic transition whereby a columnar-lined epithelium with intestinal metaplasia arises within the squamous epithelium of the distal esophagus<sup>[1,2]</sup>. The development of Barrett's esophagus appears to be a protective action, initiated in response to the esophagus being continually exposed to chronic gastroesophageal reflux<sup>[3,4]</sup>. The clinical significance of Barrett's esophagus lies with the increased risk for cancer development, as it can progress through varying grades of dysplasia to esophageal adenocarcinoma. Barrett's esophagus is the principle identifiable precursor to esophageal adenocarcinoma. The prevalence of esophageal adenocarcinoma has been increasing significantly in Western countries, and it has a poor prognosis, with the overall 5-year survival remaining less than 20%<sup>[5,6]</sup>.

Due to the increased prevalence of esophageal adenocarcinoma, the precursor lesion, Barrett's esophagus, has come under the spotlight. Although a number of alterations in gene expression have been identified in its progression to cancer, the current sequence of molecular events that drive the development of Barrett's esophagus, and its subsequent progression to cancer, remains un-

clear<sup>[4]</sup>. Great interest surrounds the identification of early molecular changes which contribute to the pathogenesis of Barrett's esophagus, as these may present opportunities for therapeutic development, or new strategies for the prevention of esophageal adenocarcinoma. Of particular interest is the relatively newly identified class of molecules known as microRNAs (miRNAs), and the potential roles they play in the development of Barrett's esophagus and adenocarcinoma.

## miRNAs

miRNAs are approximately 21 nucleotide long, non-coding segments of RNA that act to regulate gene expression<sup>[7]</sup>. Since their initial discovery in *Caenorhabditis elegans* in 1993, an enormous body of research has been published, implicating miRNAs in almost every cellular process investigated<sup>[7,8]</sup>. Both miRNA biogenesis and miRNA regulation of protein synthesis have been reviewed extensively<sup>[7,9-12]</sup>. In short, miRNA biogenesis begins with primary miRNAs (pri-miRs, inactive form), which are either transcribed by RNA polymerase II or are excised as portions of introns<sup>[9,12]</sup>. Pri-miRs are processed in the nucleus by Drosha ribonuclease and the resultant precursor-miRNA (pre-miR) is then exported to the cytoplasm<sup>[9,12,13]</sup>. In the cytoplasm, Dicer ribonuclease processes the pre-miR and a single RNA strand is transferred to an argonaute protein within the RNA-induced silencing complex (RISC) complex<sup>[9,12]</sup>. The mature (active) miRNA-RISC complex targets complementary mRNA transcripts to repress translation<sup>[9,10]</sup>.

## THE ROLE OF miRNAs IN BARRETT'S ESOPHAGUS DEVELOPMENT

Key areas of interest for miRNAs in Barrett's esophagus include their involvement in transdifferentiation and its links with the development of columnar metaplasia, and also cancer development within Barrett's esophagus. miRNAs are useful biomarkers for tumor classification, and their expression pattern may have a role to play in the early detection of cancer development<sup>[14,15]</sup>.

### Can the developing esophagus provide insight?

To understand where miRNAs may fit into the development of Barrett's esophagus, it is important to consider how the normal esophagus develops and also how developmental mechanisms may drive pathogenesis. The esophagus begins to form during week four of embryonic development, with the formation of the foregut<sup>[16]</sup>. However, it is not until week five that the foregut can be visually divided into esophagus, stomach and duodenum<sup>[17]</sup>. Development of the esophageal lumen begins in weeks seven and eight, when the epithelium begins to proliferate, and by week 10 the lumen is enclosed and lined with a ciliated epithelium<sup>[16]</sup>. In the fourth month of gestation, the ciliated epithelium begins to be

replaced by a squamous epithelium. Residual islands of ciliated epithelium remain, and these give rise to esophageal glands<sup>[16]</sup>.

It is interesting that the human embryonic esophagus is initially lined with a columnar epithelium, which is then replaced by a stratified squamous epithelium<sup>[16]</sup>. A reversal of normal developmental mechanisms is observed in Barrett's esophagus where a columnar epithelium with intestinal metaplasia arises in the squamous-lined esophagus. Transdifferentiation involves a change from one differentiated cell type to another, occurring as metaplasia, resulting in a change in cell fate or a switch in phenotype<sup>[18]</sup>. The columnar-squamous transition that occurs in the developing esophagus is likely to result from a transdifferentiation event, as it is not dependent on cell division. In addition, some epithelial cells express both squamous and columnar markers during the transition period<sup>[19]</sup>. Although these two criteria are not a requirement for transdifferentiation, they do suggest that the epithelium is not being replaced with new epigenetically distinct cells. Therefore, gene expression profiles can be initiated to drive a squamous or columnar phenotype in the esophagus. As miRNAs function by regulating gene expression<sup>[20]</sup>, it is likely that miRNAs are involved in directing gene expression in esophageal development, and they may contribute to the development of the columnar-lined epithelium which colonizes the luminal surface of the esophagus in Barrett's esophagus.

### miRNAs can directly regulate transdifferentiation

What drives the formation of a columnar-lined epithelium with intestinal metaplasia in the esophagus? It is known that Barrett's esophagus is caused by chronic exposure of the esophagus to gastroesophageal reflux. Chang *et al.*<sup>[21]</sup> showed that squamous epithelium exposed to all-trans retinoic acid (ATRA) drove a sequence of events, beginning with the removal of surface squamous epithelia, which allowed for the esophageal sub-mucosal glands to access the luminal surface. The evidence implicating miRNAs in transdifferentiation/metaplasia is limited. However, a study by Tsonis *et al.*<sup>[22]</sup> implicated the let-7 miRNA family in regulating dedifferentiation (a critical event in transdifferentiation) in the lens and inner ear hair cell regeneration. In alveolar epithelial cells, miR-375 has been shown to regulate transdifferentiation *via* the Wnt/ $\beta$ -catenin pathway<sup>[23]</sup>. Finally, the miR-200 family and miR-205 have been implicated in driving epithelial to mesenchymal transdifferentiation, a crucial event in tumor metastasis<sup>[24]</sup>. These studies provide further evidence that fluctuations in miRNA expression play crucial roles in directing transdifferentiation.

ATRA interacts with retinoic acid receptors and retinoid X receptors (RXR) to mediate the suspected transdifferentiation response observed in the study by Chang *et al.*<sup>[21]</sup>. Importantly, lithocholic acid (LCA), a component of gastroesophageal refluxate, has been shown to interact with human RXR- $\beta$ <sup>[25]</sup>, providing evidence that ATRA exposure is relevant to the conditions

experienced in patients with chronic gastroesophageal reflux. Interestingly, RXR- $\beta$  expression is up-regulated in Barrett's esophagus compared with tissue from non-refluxing patients, and it also correlates with RXR- $\alpha$  expression<sup>[26]</sup>. This provides evidence that retinoid-induced differentiation is suppressed in normal squamous epithelia due to receptor down-regulation. In theory, following chronic exposure of the esophagus to refluxate, there could be a change in gene expression facilitated by differential expression of miRNAs targeting RXR receptor mRNA. Consequential up-regulation of RXR receptor translation would follow, allowing for increased binding of LCA to the RXR- $\beta$  receptor.

Among the retinoic acid targets are the *CDX1/2* genes, transcription factors shown to play a major role in driving intestinal gene expression required for developing a Barrett's esophagus phenotype<sup>[4,27,28]</sup>. Therefore, the initiation of RXR expression could be a crucial step in the early development of Barrett's esophagus.

There are examples of miRNA interaction with transcription factors forming negative feedback loops to regulate gene expression. One example includes the miR-200 family and miR-205 targeting of *ZEB1* and *ZEB2* transcription factors in epithelial-mesenchymal transition. The miR-200 family and miR-205 have been shown to directly repress *ZEB1* and *ZEB2* while these transcription factors regulate the transcription of the miR-200 family<sup>[29]</sup>. A miRNA regulatory loop, similar to that described by Bracken *et al.*<sup>[29]</sup>, could be directing the expression of transcription factors such as *CDX1/2* genes that are critical to the development of Barrett's esophagus.

Chronic gastroesophageal reflux is often associated with esophagitis. This condition provides the earliest disease state available for analysis prior to the development of Barrett's esophagus. Our laboratory has shown that some miRNAs are differentially regulated in response to chronic gastroesophageal reflux (unpublished results). miRNAs shown to be differentially regulated during exposure to acid or specific bile components may be involved in directing early molecular events required for the development of Barrett's esophagus. It is possible that miRNA de-regulation observed in patients with chronic reflux and esophagitis may allow RXR expression and initiate the early events required for Barrett's esophagus to develop.

## MAINTAINING A SPECIALIZED COLUMNAR EPITHELIUM

Whether miRNAs directly alter the gene expression profile in esophageal cells, thereby directing the development of a columnar epithelium with intestinal metaplasia, is unclear. Although the initial development of Barrett's esophagus may occur *via* transdifferentiation, it must be maintained. The sustained presence of the columnar epithelium suggests a continual gene expression profile is established in progenitor cells. It is possible that aberrant

miRNA expression acts to establish the required gene expression that allows progenitor cells to differentiate to a columnar phenotype. The role of miRNAs in driving differentiation is well established. An excellent example of this is miR-203, a miRNA down-regulated in Barrett's esophagus<sup>[30,31]</sup>.

### *miR-203 and squamous epithelia*

miR-203 has been implicated in driving terminal differentiation in skin epithelial cells<sup>[32]</sup>. The luminal surface of the esophagus is continually replaced by cells that migrate from the basal layer<sup>[33]</sup>. Once these basal cells become suprabasal, proliferative capacity is lost and terminal differentiation is initiated<sup>[32]</sup>. Suprabasal cells in the esophagus undergo terminal squamous differentiation to maintain a stratified squamous epithelium<sup>[33]</sup>. In skin epithelia, miR-203 has been shown to target and repress the transcription factor p63<sup>[32,34]</sup>. p63 plays a crucial role in maintaining stem cells in stratified squamous epithelium<sup>[32,35]</sup>. miR-203-directed repression of p63 acts to repress a cell's proliferative capacity and induce cell cycle exit<sup>[32,34]</sup>. It is therefore likely that induction of miR-203 expression is a crucial checkpoint required for terminal squamous differentiation. Whether miR-203 expression is linked with replenishment of the esophageal epithelium is unclear, although miR-203 expression is lost in Barrett's esophagus, and therefore it is likely that the miR-203-directed mechanism of epithelial replacement is lost in this tissue.

## miRNAs AND BARRETT'S ESOPHAGUS: CLINICAL INSIGHTS

Increasing evidence supports the application of knowledge about miRNAs to clinical settings. Recent publications have shown that miRNA expression patterns can be used as prognostic and pathogenic markers of numerous disease states, and can predict response to therapeutic strategies and outcomes from clinical procedures<sup>[36-40]</sup>. One clinically relevant example in carcinogenesis involves miR-21. miR-21 is reported to be up-regulated in a number of different solid tumors, and increased expression correlates with poor prognosis<sup>[38]</sup>. In the context of Barrett's esophagus, miR-196a expression has been shown to correlate with different disease states in the Barrett's metaplasia-dysplasia-carcinoma sequence<sup>[39]</sup>. Currently, Barrett's esophagus is the principle identifiable precursor to esophageal adenocarcinoma and, therefore, miR-196a expression may provide a valuable tool in early cancer detection. Standard clinical management of Barrett's esophagus involves continual endoscopic surveillance. Surveillance efficacy has been the topic of much scrutiny and a less invasive, more cost-effective patient management strategy is highly sought after<sup>[41,42]</sup>. Such an alternative management strategy could be one in which miRNA expression profiling may play a major role.

## miRNAs AND CANCER DEVELOPMENT

Aberrant miRNA expression has been linked with the development and progression of almost all cancers studied to date. The influence of miRNAs in the regulation and control of crucial cellular processes, including signaling, proliferation, apoptosis, motility and angiogenesis, has implicated a number of miRNAs in cancer development and progression<sup>[43]</sup>. Functional studies of miRNAs in cancer development have identified miRNAs acting as both oncogenes (e.g. miR17-92 cluster) and tumor suppressors (let-7)<sup>[44-46]</sup>. Forced expression of the miR17-92 cluster in mice leads to the accelerated development of B-cell lymphoma<sup>[45]</sup>. Also, the miR17-92 cluster is over-expressed in lung cancer, and this is associated with an increase in cellular proliferation<sup>[45,47]</sup>. Let-7 acts as a tumor suppressor through negative regulation of Ras<sup>[44,46]</sup>. In lung cancer, decreased let-7 expression results in increased cellular proliferation<sup>[46]</sup>. Also, increased let-7 expression *in vivo* has been shown to inhibit lung cancer cell xenograft growth in mice<sup>[48]</sup>.

### Tumor profiling and classification

Advances in the ability to profile different aspects of tumorigenesis have led to the rapid identification of differentially expressed miRNAs in cancer<sup>[49]</sup>. Different miRNA expression profiles are observed for normal and tumorigenic tissues<sup>[49]</sup>, where miRNA expression is generally down-regulated in tumor compared with normal samples<sup>[15]</sup>. Studies of miRNA expression in cancer have identified miRNA tumor profiles which can be used to classify different tumor subtypes<sup>[10,15]</sup>. Studies have also constructed miRNA expression profiles that can identify tumor origin<sup>[15]</sup>. This is particularly useful in the classification of poorly differentiated tumors.

## CURRENT KNOWLEDGE OF miRNAs IN BARRETT'S ESOPHAGUS AND ESOPHAGEAL ADENOCARCINOMA

Recent reports describe altered miRNA expression in Barrett's esophagus and esophageal adenocarcinoma. Initial work performed by Feber *et al*<sup>[50]</sup> identified miRNA alterations in these conditions. This study<sup>[50]</sup> provided preliminary evidence for using miRNAs in the identification of patients at risk of esophageal adenocarcinoma development. Since then, several publications have described miRNA expression in Barrett's esophagus and esophageal adenocarcinoma<sup>[31,39,51,52]</sup>. In a further study, our laboratory performed miRNA microarray and q-PCR analysis of miRNA expression in squamous esophageal epithelia, normal gastric epithelia, Barrett's esophagus with intestinal metaplasia and esophageal adenocarcinoma<sup>[30]</sup>. Our analysis identified miRNAs differentially regulated in Barrett's esophagus development and its subsequent progression to esophageal adenocarcinoma. miRNAs with differential expression patterns included

miR-21, miR-143, miR-145, miR-194, miR-203, miR-205 and miR-215. With respect to Barrett's esophagus and esophageal adenocarcinoma, current literature regarding miRNA expression allows for speculation about the potential molecular consequences of the aberrant miRNA expression identified in our study.

### The oncomiR, miR-21

Our group's research has shown that miR-21 expression is up-regulated in Barrett's esophagus and esophageal adenocarcinoma, compared with squamous esophageal epithelia. This finding is in accord with other publications where miR-21 has been shown to be up-regulated in various solid tumors<sup>[38]</sup>. Elevated miR-21 has been implicated in many cellular processes required for neoplastic development and progression. Elevations in miR-21 have been shown to promote survival in myeloma cells<sup>[53]</sup>, confer apoptotic resistance in prostate cancer cells<sup>[54]</sup>, increase cell proliferation, migration and invasion in hepatocellular carcinoma cells<sup>[55]</sup>, and increase invasion and metastasis in colorectal cancer cells<sup>[56]</sup>. Also, reduced miR-21 expression has been shown to reduce proliferation in MCF7 breast cancer cells and tumor growth in a mouse xenograft model<sup>[57]</sup>, reduce anchorage-independent colony formation in hepatocellular carcinoma cells<sup>[58]</sup>, and reduce invasion, intravasation and metastatic capacity of colon cancer cells<sup>[56]</sup>. It is possible that the observed up-regulation of miR-21 in esophageal adenocarcinoma may either provide a selective advantage to cells within a metaplastic columnar epithelium, increasing the chance for neoplastic development, or confer on esophageal adenocarcinoma similar molecular traits to those reported in the literature.

### Dual roles for miR-194

miR-194 is up-regulated in Barrett's esophagus and esophageal adenocarcinoma<sup>[30]</sup>. miR-194 expression is regulated by HNF-1a, a transcription factor induced in Barrett's esophagus and esophageal adenocarcinoma<sup>[59]</sup>. A study by Hino *et al*<sup>[59]</sup> also showed that miR-194 expression is induced during intestinal epithelial cell differentiation. Furthermore, miR-194 expression is induced in metastatic pancreatic cell lines<sup>[60]</sup>. Taken together, these results could suggest that elevated miR-194 may be contributing to intestinal differentiation observed in Barrett's esophagus, and may also contribute to the molecular phenotype required for tumor metastasis.

### miRNAs as tumor suppressors

miR-143, miR-145 and miR-215 are down-regulated in esophageal adenocarcinoma<sup>[30]</sup>. Similar alterations are observed in other expression profiling studies. miR-143, 145 and 215 are all down-regulated in colonic adenocarcinoma<sup>[61,62]</sup>. miR-143 and 145 have been shown to be down-regulated in gastric cancer<sup>[63]</sup> and miR-145 has been shown to be down-regulated in lung cancer<sup>[64]</sup>.

More specific roles for miR-143, 145, and 215 in carcinogenesis have been elucidated. miR-143 has been

shown to target the *KRAS* oncogene, suppressing colorectal cancer cell growth *via* inhibition of *KRAS* translation<sup>[65]</sup>. Therefore, loss of miR-143 expression in esophageal adenocarcinoma could result in a loss of *KRAS* regulation contributing to neoplastic development. Also, miR-143 up-regulation in Jurkat T cells has been linked with the regulation of FAS-mediated apoptosis<sup>[66]</sup>. miR-145 has also been implicated in regulating apoptosis *via* a negative feedback loop involving TP53, and also *via* translational inhibition of RTKN in breast cancer cell lines<sup>[67,68]</sup>. Furthermore, miR-143 and miR-145 expression are induced by p53 in response to DNA damage<sup>[69]</sup>. Therefore, the loss of both miR-143 and miR-145 in the progression of Barrett's esophagus to esophageal adenocarcinoma may alter the cell's ability to direct the appropriate apoptotic responses.

miR-215 expression is induced by *p53*, and it acts in cooperation with miR-192 to regulate cell cycle events through their ability to induce cell cycle arrest<sup>[61,70]</sup>. Loss of miR-215 expression causes a reduction in the ability of cells to regulate proliferation, a key neoplastic attribute. It is therefore possible that miR-143, 145 and 215 may act as tumor suppressors, with loss of expression contributing to the development of esophageal adenocarcinoma.

## CONCLUSION

It is now clear that altered regulation of miRNA expression results in numerous cellular consequences. Functional studies of miRNAs, which drive different disease states including neoplastic progression, are increasing in number. This literature is matched by an increase in studies evaluating miRNA expression in the clinical setting as a possible prognostic and diagnostic marker, with miRNA analysis of blood samples providing exciting potential for new avenues in disease diagnosis<sup>[71]</sup>. Although miRNA research in Barrett's esophagus and esophageal adenocarcinoma is in its early stages, increasing evidence allows for speculation about the potential roles of miRNAs in the development of Barrett's esophagus and its progression to esophageal adenocarcinoma.

### Abstract

The fact that the acid-secreting parietal cells undergo continuous renewal has been ignored by many gastroenterologists and cell biologists. In the past, it was thought that these cells were static. However, by using <sup>3</sup>H-thymidine radioautography in combination with electron microscopy, it was possible to demonstrate that parietal cells belong to a continuously renewing epithelial cell lineage. In the gastric glands, stem cells anchored in the isthmus region are responsible for the production of parietal cells. The stem cells give rise to three main progenitors: prepit, preneck and preparietal cells. Parietal cells develop either directly from the non-cycling preparietal cells or less commonly *via* differentiation of the cycling prepit and preneck cell progenitors. The formation of a parietal cell is a sequential process which involves diminishment of glycocalyx, production of cytoplasmic tubulovesicles, an increase in number and length of microvilli, an increase in number and size of mitochondria, and finally, expansion and invagination of the apical membrane with the formation of an intracellular canalicular system. Little is known about the genetic counterparts of these morphological events. However, the time dimension of parietal cell production and the consequences of its alteration on the biological features of the gastric gland are well

documented. The production of a new parietal cell takes about 2 d. However, mature parietal cells have a long lifespan during which they migrate bi-directionally while their functional activity for acid secretion gradually diminishes. Following an average lifespan of about 54 d, in mice, old parietal cells undergo degeneration and elimination. Various approaches for genetic alteration of the development of parietal cells have provided evidence in support of their role as governors of the stem/progenitor cell proliferation and differentiation programs. Revealing the dynamic features and the various roles of parietal cells would help in a better understanding of the biological features of the gastric glands and would hopefully help in providing a basis for the development of new strategies for prevention, early detection and/or therapy of various gastric disorders in which parietal cells are involved, such as atrophic gastritis, peptic ulcer disease and gastric cancer.

### INTRODUCTION

The gastric parietal cells have attracted great interest in scientists mainly due to their dramatic morphological and biochemical changes which occur during acid

secretion. Little attention is paid to the fact that these cells are genetically programmed to have a limited life span and that they undergo perpetual renewal. In this editorial the plan is to focus on the dynamism of the parietal cell population and the tools utilized over the years to study this phenomenon.

Leblond<sup>[1]</sup> generally defined renewing cell populations by two major criteria: (1) Frequent mitoses which are restricted to a definite subpopulation of cells; and (2) Cell loss which is required to balance cell production and to keep the steady state of the population. In addition, he described 5 successive stages in the life history of renewing cells. They are first present as stem cells which divide and produce new stem cells as well as uncommitted and/or committed progenitor cells which represent the second stage in the renewing cell life. The uncommitted progenitor cells exhibit dual lineage features and eventually become committed progenitor cells with features of one lineage. These progenitor cells are usually capable of undergoing equivalent mitosis and thus amplifying the population before entering the next stage. Transit cells represent the third stage during which cellular specification gradually occurs by synthesizing new gene products. This may be encountered morphologically by gradual changes in cell structure, immunocytochemically by expression of new proteins or sugar residues, and biochemically by changes in enzymatic activities, protein composition and messenger RNA expression. The fourth stage is that of the mature cells which have completed their differentiation and thus become actively functional. In the fifth stage of terminal cells there is a gradual deterioration and eventually death and elimination<sup>[1,2]</sup>.

Parietal cells belong to the oxyntic (gastric) epithelium which is composed of one layer of heterogeneous cell populations. These cell populations have a common source of origin, but remarkably vary in their morphological features and functional potentials. The gastric epithelium is organized to form many long tubular units (gastric or oxyntic glands). Based on the allocation of the different cell types, each gastric gland is divided into pit, isthmus, neck and base regions (Figure 1)<sup>[3,4]</sup>.

Studying the dynamism of parietal cells is important for several reasons: (1) The gastric epithelium is highly vulnerable and the turnover of its cells is one of the effective defense mechanisms against damaging agents (e.g. alcohol and drugs); (2) Analysis of the normal production and loss of parietal cells provides the basis for understanding the pathogenesis of several diseases that affect parietal cell mass (e.g. Zollinger-Ellison syndrome and chronic atrophic gastritis); (3) The common gastric pathogen, *Helicobacter pylori*, is believed to play an important role in the pathogenesis of gastritis and peptic ulcer disease and may have an effect on parietal cell dynamics; (4) Studying gastric adenocarcinoma and "parietal cell carcinoma"<sup>[5]</sup> requires better understanding of the normal process of parietal cell production and loss; and (5) Identifying the origin of parietal cells, their immature

forms and the factors controlling their differentiation may lead to the design of new drugs for the treatment of peptic ulcer disease, chronic atrophic gastritis and gastric tumors.

## METHODS USED TO STUDY PARIETAL CELL DYNAMISM

Over the years, four main methods have been used to study the dynamic features of gastric epithelial parietal cells.

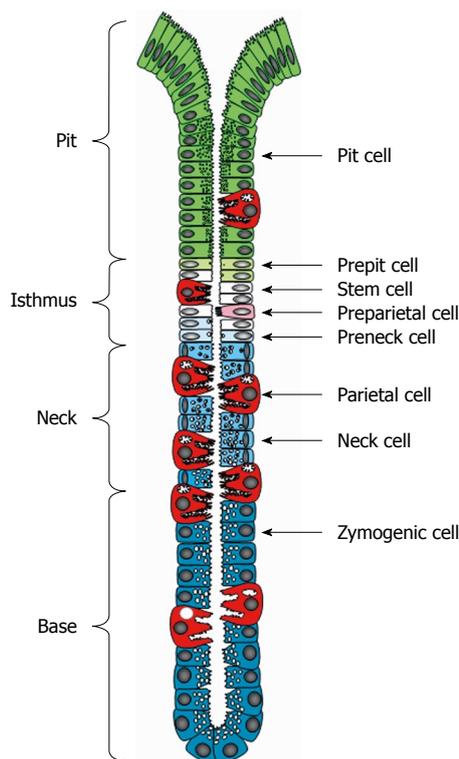

### **Search for mitotic figures**

The microscopic search for mitotic figures was the method used by pioneers in this field who first discovered mitotic cells at the bottom of gastric pits<sup>[6]</sup>. Some of these mitotic figures were thought to be parietal cells<sup>[7]</sup>. The area of mitotic activity described by Bizzozero<sup>[6]</sup> was later called the "isthmus" by Stevens *et al*<sup>[8]</sup>. Bizzozero<sup>[6]</sup> correlated the presence of mitotic cells with the gradual increase in the secretion content of the pit lining cells from the bottom of the foveola to the free surface. He then concluded that the cells at the bottom of the pits were poorly differentiated, multiply by mitosis and migrate outward to the free surface while completing their differentiation. Deep in the mucosa, cells of the long tubular glands (including parietal cells) were thought to be stable permanent structures. Bizzozero's conclusion was then confirmed by Benseley<sup>[9]</sup> who also observed degenerated cells from the pit within the gastric lumen. Benseley<sup>[9]</sup> then proposed that, upon reaching the free surface, pit cells were desquamated in response to damage by food. Later this food damaging idea was considered a rapid replacement of the surface epithelium following damage induced by dilute acid or alcohol. This replacement was generally considered as a regenerative process in response to damage.

A disadvantage of this mitosis search method is that no measurement of time is involved, and thus the rate at which cells are replaced cannot be calculated. The mitotic index is the parameter that can be estimated by this method. This index would only be valuable when relative measurements are needed in comparing various agents on the renewal of a cell population. However, in that case, it should be assumed that the agents have no effect on the duration of mitosis.

### **Colchicine method**

In the 1950s, the colchicine method of arresting and accumulating mitotic cells at metaphase was applied in the gastric epithelium by Stevens *et al*<sup>[8]</sup>. The site of mitotic activity, the isthmus region, became apparent. Moreover, by examining fasting and normally-fed rats sacrificed at different times of the day 4 h after colchicine injection, it was found that the mitotic activity and desquamation of cells were not dependent on ingested food. Thus, it was concluded that mitosis is not just a

**Figure 1** Diagrammatic representation of the gastric unit or gland. It is composed of 4 regions: pit, isthmus, neck and base and populated by a heterogeneous population of cell types. Pit, parietal and neck cells originate in the isthmus from stem (granule-free) cells and their immediate descendants (prepit, preparietal and preneck cells). Neck cells are not end cells and therefore, at the neck-base border, they transform into zymogenic cells.

response to damage, but is a sign of the normal constant “renewal” phenomenon. Moreover, Stevens *et al*<sup>[8]</sup> found that the mucous cells lining the surface and pit turnover very quickly and have a turnover time of about 3 d. Deep in the glandular epithelium, the turnover time of mucus-secreting neck cells was estimated to be about 1 wk.

### <sup>3</sup>H-thymidine radioautography

Mitosis occurs rapidly, so unless mitotic figures are frequent they may not be observed even with the colchicine method. A third method was thus developed which took advantage of the long duration of S-phase, the preparatory stage for mitosis. In mice, while the combined duration of metaphase and anaphase is about 0.4 h, the period of DNA synthesis (S-phase) extends over 7.3 h<sup>[10,11]</sup>, therefore the chances of detecting S-phase cells are high. If a radioactive DNA-precursor is injected into an animal, it will be incorporated into the DNA of dividing cells and will be retained throughout the entire life span of their daughter cells. Thus, by using radioautography not only would sites of mitotic activity be visualized, but also the post-mitotic differentiation and migration pathway of the daughter cells may be traced<sup>[12]</sup>. Based on these facts, the third method of radio-thymidine labeling of dividing cells was developed and used to study cell proliferation and migration in the gastric epithelium.

In 1960, Messier *et al*<sup>[13]</sup> demonstrated in radioautographs taken at different time intervals, evidence of the migration of mucus-secreting pit cells in rats. Labeled cells were initially present in the isthmus; within a few days they were found at the free surface. This observation was later confirmed in the mouse<sup>[14]</sup>, hamster<sup>[15]</sup>, and man<sup>[16,17]</sup>.

To analyze the dynamic parameters of a renewing cell population, <sup>3</sup>H-thymidine may be administered either by single injection, by multiple injections or by continuous infusion. It should be assumed that the population is in a steady state; i.e. cell production balances cell loss. Then, any of the three methods may be used to determine the rate at which the cells turn over (turnover rate) and the time taken for cells to be replaced (turnover time). The turnover rate may be defined as the fraction of the cell population which is replaced per unit time, whereas the turnover time is the interval taken for the replacement of the total number of cells in the population.

**Single injection method:** The use of the single injection method is based on the premise that some cells in S-phase will incorporate the label during the period between injection and sacrifice (30 min). These cells will eventually divide and yield all the cells in the population. With this single injection method, it is possible to determine the percentage of cells in the population which are synthesizing DNA and, thereby, preparing to divide. Animals, therefore, are sacrificed 30 min after a single injection of <sup>3</sup>H-thymidine, and the labeling index would be the ratio of the number of labeled cells to the total number of cells (labeled plus unlabeled cells). Because of diurnal variation, it is recommended that the average of labeling indices measured at different times throughout a 24-h period be used. The calculation of the number of new cells produced or the labeling index depends on the length of time each dividing cell spends in the S phase. Therefore, in order to calculate the turnover rate, the duration of S phase must be known. It may be obtained by plotting the percentages of labeled mitoses at different times (hours) following a single <sup>3</sup>H-thymidine injection. The distance between the ascending and descending portions of the resulting curve measured at the 50% labeling level provides the mean duration of the S phase in hours. In the mouse pyloric antrum, the S duration is 7.3 h<sup>[11]</sup>. The turnover rate is then calculated by dividing the labeling index by the S phase duration and is expressed as the percentage of cells formed per hour. The turnover time is the inverse of the turnover rate, i.e. 100/turnover rate = turnover time expressed in hours.

The single injection method has two disadvantages: the results depend on the time of day the experiment was carried out (diurnal variation), and the cells labeled after a single injection are not all necessarily committed to a single cell line.

**Multiple injection method:** The multiple injection

method is based on accumulating a labeled fraction of the cell population within a certain period of time, and then following the disappearance of these labeled cells at different time intervals after the last injection. Thus, the percentage of labeled cells would decrease steadily with time along a regression line. The rate of labeled cell loss is obtained from the decreasing slope of the line. Assuming a steady state, the rate of cell loss would be equal to the turnover rate.

The proliferative capacity of certain types of cells can be determined not only from the 30-min labeling experiment (as mentioned above) but also from the multiple injection experiment. This can be done by counting the number of silver grains over cell nuclei at different time intervals following the last injection. The percentages of cells with a given grain count are then plotted against grain count. Similar curves are prepared at the other time intervals. If the labeled cells have divided, the grains would be equally distributed to daughter cells and thus, a shift in the grain count curves with time toward a lower number of grains should occur.

A disadvantage of this method is the stress induced with the multiple injections over several days. Thus the following method is usually preferred.

**Continuous infusion method:** The continuous infusion method is based on the radio-labeling of newly produced cells in the population for different periods of infusion time. This technique minimizes the disadvantages of the single (diurnal variation) and the multiple (stress) injection methods. The percentage of labeled cells would increase steadily with time along a regression line. The rate of cell production, which under steady state is equal to the turnover rate, is the slope of the line. The “production rate” of a certain cell type can be estimated by simply multiplying the turnover rate by the number of these cells in the population. Assuming steady state, the “exit rate” of these cells would be equal to their production rate.

### Genetic manipulation

The use of genetic engineering technology for studying cell specification and differentiation has become a powerful tool for unraveling the role of the parietal cell population in maintaining homeostasis of the gastric glands. Promoters of parietal cell-specific genes are available to deliver biologically interesting foreign gene products exclusively to a parietal cell lineage throughout the lifespan of the organism<sup>[18]</sup>. These promoters can be used to design parietal cell-specific gain-of-function experiments as well as loss-of-function experiments. Thus, the mouse has become the model system for chimeric, transgenic, chimeric-transgenic, knock-out, and knock-in technology. These models will help answer many questions of parietal cell dynamics, including factors regulating their production and maintaining their organization along the pit-gland unit.

## SIZE OF THE PARIETAL CELL POPULATION

Parietal cells are scattered along the gastric glands and occupy much space due to their large size. Helander *et al*<sup>[19,20]</sup> estimated that in gastric mucosal tissue sections, the parietal cell number comprises 16%-21% of all epithelial cells, in rats<sup>[19]</sup> and 12% in humans<sup>[20]</sup>.

When some individual gastric glands of adult mice were followed in serial cross sections starting from the bottom of their base regions all the way up to opening of their pits, the parietal cell number was found to comprise about 13% of the total cell population, representing an average of 26 parietal cells out of the 194 epithelial cells present per gland<sup>[3]</sup>. An average of 4 parietal cells was found in the pit; 6 in the isthmus; 5 in the neck and 11 in the base region.

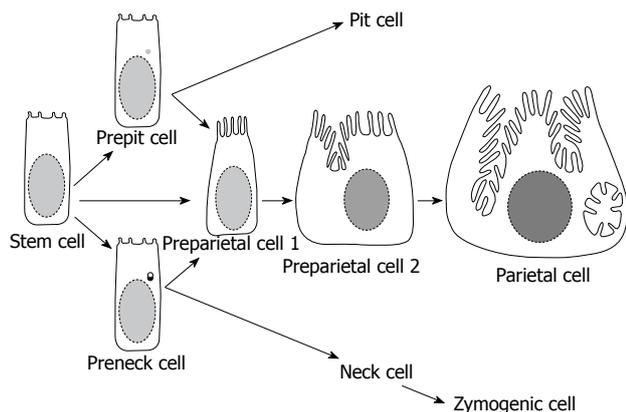

Preparietal cells are the least numerous cell type found in the gastric gland. They comprise about 0.3% of all epithelial cells, representing 0-3 cells per gland<sup>[3]</sup>.

## PARIETAL CELL PROGENITORS AND THEIR SPECIFICATION

Over the years, several theories have been raised regarding the source of parietal cells. The first idea was that parietal cells were able to divide<sup>[7]</sup> and to reproduce themselves. This idea was later refuted by studies using the colchicine arrest technique<sup>[8]</sup>, <sup>3</sup>H-thymidine radioautography<sup>[17,21,22]</sup>, and the method of time-grain count curve<sup>[23]</sup>. Then, various investigators<sup>[24,25]</sup> re-supported the self renewal theory. It was Hunt *et al*<sup>[21]</sup> who first demonstrated radio-labeled parietal cells in paraffin sections of the rat stomach only 2 d after a pulse of <sup>3</sup>H-thymidine injection. No labeled parietal cells were found earlier than that. Hunt *et al*<sup>[21]</sup> suggested that parietal cells are not able to divide and that they originate from the mucus-secreting neck cells which were labeled at earlier time intervals. On the other hand, studies using electron microscopy<sup>[26]</sup> and in regenerating mouse gastric mucosa<sup>[27]</sup> have led to the proposal that parietal cells come from immature mucus-secreting pit cells.

In the 1960s, undifferentiated cells were identified in the oxyntic epithelium of the immature hamster<sup>[28]</sup> and bullfrog tadpole<sup>[29]</sup>. It was suggested that these cells are epithelial stem cells which are the source of parietal cells. The idea of the gastric epithelial stem cell was supported by Hattori<sup>[30]</sup> but questioned and even denied by Tamura *et al*<sup>[25]</sup>. Kataoka<sup>[14]</sup> first reported the existence of these stem cells which could be the source of parietal cells in the mouse. Later Kataoka *et al*<sup>[31]</sup>, observed some parietal cells which contained a few mucous granules and proposed that they came from the mucus-secreting neck cells.

In a systematic electron microscopic study, all cell types lining the epithelial unit of the mouse stomach were defined and quantified in serial cross sections. The tissue sections included the whole thickness of the gastric units starting from the bottom of the base region next to the

**Figure 2** Diagram summarizing the origin and differentiation program of parietal cells. The stem cell either directly or indirectly (via prepit or preneck cells) give rise to the committed progenitors of parietal cells (preparietal cells). Preparietal cells evolve in 4 successive stages (2 are depicted here) to become mature parietal cells. Preparietal cell 1 is characterized by long microvilli and preparietal cell 2 by an incipient canaliculus which expands around the nucleus in the mature parietal cell.

muscularis mucosae, up to the orifice of the pit where mucus-secreting surface cells are found. In addition to the well recognized mature cell types of the gastric epithelium (pit, neck, parietal and zymogenic cells), four different poorly differentiated cell types were identified in a narrow region along the gastric gland (Figure 1)<sup>[3]</sup>. This is the isthmus region observed earlier by Stevens *et al*<sup>[8]</sup>, which could be delimited between the first pit cell inward and the first neck cell outward (Figure 1)<sup>[3]</sup>. While one of these isthmal cells did not show any sign of differentiation, each of the three others exhibited one sign of early commitment. Thus, the first cell type was named granule-free (stem) cell and the three others, prepit, preneck and preparietal cells, reflecting their early commitment to three different cell lineages<sup>[3]</sup>.

In 30-min <sup>3</sup>H-thymidine-labeling experiments, three of the isthmal cells incorporated the radio-marker and thus were proliferative<sup>[32]</sup>. The preparietal cells, however, were never seen in mitosis and did not incorporate the label early after injection of the isotope. Thus, it was concluded that preparietal cells cannot divide and may have come from other cells which are capable of dividing and differentiating. In the isthmus, granule-free cells are similar to many embryonic cells. These cells have significant free ribosomes and dispersed chromatin, and large nucleoli, but other organelles are fewer and smaller. In addition, these are the most proliferative cell type within the gastric epithelium. All these criteria made granule-free cells good candidates as the source, not only for parietal cell lineage, but also for all other cell lineages (Figures 1 and 2).

The search for signs of cell lineage specification in the Golgi apparatus of granule-free (stem) cells revealed that they constitute three different subtypes<sup>[32]</sup>: (1) Cells with primitive Golgi having no sign of secretory activity and, hence, named “undifferentiated granule-free cells”; (2) Cells with trans-Golgi face including prosecretory

vesicles with homogeneous dense material similar to those in the pit cell lineage and, hence, considered to be “prepit cell precursors”; and (3) Cells with trans-Golgi face exhibiting prosecretory vesicles with irregular dense material in the center and light periphery similar to those of the neck cell lineage, hence, named “preneck cell precursors”.

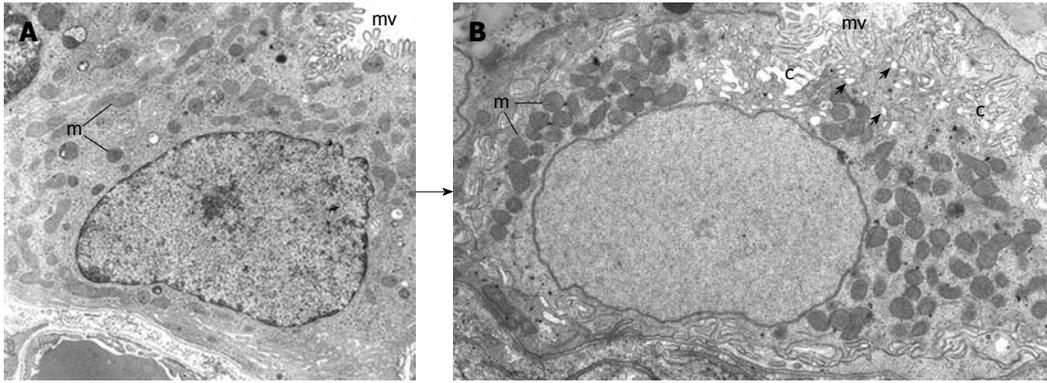

Three different forms of preparietal cells have also been identified based on (1) the absence of secretory granules (as in granule-free cells) or (2) the presence of dense granules (as those of the pit cell lineage) or (3) the presence of cored-granules (as those of the neck cell lineage). The expression of pit- or neck-like mucous granules in a preparietal cell reflected the diversity in parietal cell origin and the phenotypic plasticity of the derivatives of granule-free cells. Thus, each subtype of granule-free cells provided a slightly different phenotype of preparietal cells which would then all pool into a single phenotype (parietal cells). Whether or not this phenotypic plasticity is unidirectional (from mucous to parietal), or bidirectional is not known. However, the occasional existence of a few mucous granules in mature parietal cells and the absolute absence of any parietal cell features (long microvilli or canaliculus, or H,K-ATPase expression) in mature mucous (pit or neck) cells suggest that it is unidirectional and only from prepit or preneck cell precursors to preparietal cells.

The origin of parietal cells was also demonstrated by radioautography. A pulse of <sup>3</sup>H-thymidine given to a group of mice first appeared in granule-free cells after 30 min. After 1 d, label started to appear in preparietal cells. At least 2 d later, some labeled mature parietal cells appeared, reflecting the short time required for their differentiation<sup>[33]</sup>.

The occasional presence of bi-nucleated parietal cells might give the impression that parietal cell mitosis could occur. However, during the years of our studies we have never visualized a mitotic parietal or even a preparietal cell, or observed an immuno-labeled (using antibodies for the nuclear CC-3 phosphoprotein or the proliferating cell nuclear antigen or by using the bromodeoxyuridine method) or a <sup>3</sup>H-thymidine-labeled cell. Our interpretation for these bi-nucleated parietal cells is that their early ancestors (prepit cell precursors, preneck cell precursors or undifferentiated granule-free cells) underwent an incomplete mitosis i.e. during telophase, karyokinesis occurred without cytokinesis and then the cell differentiated and matured as a bi-nucleated parietal cell<sup>[33]</sup>.

## DIFFERENTIATION COMMITMENT OF PARIETAL CELLS

Once a precursor cell enters the pathway to become a parietal cell, the gradual acquisition of specific features for acid secretion means differentiation commitment. It was Arnold<sup>[28]</sup> who first reported the presence of immature parietal cells in the hamster embryo. Similarly,

**Figure 3** Electron micrographs depicting 2 stages of the differentiating preparietal cells as seen in the human stomach. Original magnification,  $\times 12000$ . A: Preparietal cell showing relatively long numerous microvilli (mv). The mitochondria (m) are relatively few and small; B: Preparietal cell showing an incipient canaliculus (c) and relatively numerous mitochondria (m) which appear larger than those in A. The apical cytoplasm shows few tubulovesicles (small arrows) and long numerous microvilli (mv). A is reproduced from Karam *et al*<sup>[4]</sup> with permission from Wiley-Blackwell/AlphaMed press.

differentiating oxyntic cells were identified in the metamorphosing bullfrog tadpole<sup>[29]</sup>. In the adult mouse stomach, such growing cells were also identified<sup>[31]</sup> and named “preparietal cells”<sup>[3]</sup>. These cells are also found in the human stomach<sup>[4]</sup>. They gradually lose features of their precursors (large nucleoli, many free ribosomes, and relatively few organelles) and simultaneously acquire features of acid-secreting cells (long apical microvilli, intracellular canaliculi, and large numerous mitochondria).

There are four successive stages in the maturation of preparietal cells (two of them are diagrammatically presented in Figure 2)<sup>[33]</sup>. The first stage was revealed only when preparietal cells were amplified in a transgenic mouse model<sup>[34]</sup>. This stage is characterized by an increased number of apical microvilli and diminishment of their glycocalyx. The second stage (similar to that described by Arnold<sup>[28]</sup> and Forte *et al*<sup>[29]</sup>) is characterized by elongation of apical microvilli to reach the same size and shape as those of mature parietal cells (Figure 3A)<sup>[4,33]</sup>. This stage is diagrammatically represented in Figure 2 as preparietal cell 1. In the third stage, gradual invagination of the apical cytoplasm leads to the formation of an intracellular incipient canaliculus on one side of the nucleus. In addition, a few tubules and vesicles appear in the apical cytoplasm as an early indication of the formation of the tubulovesicular system (preparietal cell 2 in Figures 2 and 3B)<sup>[4,33]</sup>. In the fourth stage, the canaliculus expands and appears at both sides of the nucleus. The four stages are characterized by abundant free ribosomes and a relatively large nucleolus. With maturation of the cell from the first to the fourth stage, there is a gradual increase in the cell size and the size and number of mitochondria are gradually increased (Figure 3)<sup>[4,33]</sup>.

## PARIETAL CELL MIGRATION AND FORMATION OF TWO PHYSIOLOGICALLY DISTINCT POPULATIONS

In the mouse, the central position of preparietal cells in

the isthmus and the distribution of mature parietal cells throughout the four unit regions is the first indication of the bi-directional migration of parietal cells. In man, rat and rabbit, parietal cells are also scattered in the four regions, but are fewer in the pit<sup>[4,35]</sup>.

Continuous <sup>3</sup>H-thymidine-infusion in mice for different time intervals varying from 1 up to 52 d shows that labeled parietal cells start to appear in the isthmus after 3 d of infusion. With time, labeled parietal cells increase in the isthmus and then gradually appear in the pit region and, with time, ascend the pit. Simultaneously, labeled parietal cells make their appearance in the neck region and descend, eventually crossing the neck-base border and continuing their migration toward the bottom of the gland. An estimation of the turnover rate of parietal cells in the four unit regions indicated that it was 2.84, 3.20, 1.86, and 0.53, respectively in the pit, isthmus, neck and base. Since the average number of parietal cells in each region is known, simple calculations revealed that, every month, 6 parietal cells are produced in one isthmus. Within the same period, 3 cells appear in the pit and 3 in the neck. Thus, every month the newly produced parietal cells in the isthmus equal the sum of those appearing in both the pit and neck (6 cells). This indicates that there is a steady state in the parietal cell population.

It is likely that parietal cells located in the pit are those which originated from prepit cell precursors which were already assigned to migrate upward. The same might apply to basal parietal cells which might have originated from preneck cell precursors and are committed for inward migration.

The bidirectional migration of parietal cells along the pit-gland axis is associated with a gradual loss in their functional activity. Thus, young parietal cells present in the isthmus and neck would be expected to be structurally and functionally different from the old cells found in the pit and base regions. Evidence for this comes from at least five groups of studies on the heterogeneity of parietal cells. (1) It was Lawn<sup>[36]</sup> who first noticed that

parietal cells in the neck region have narrow and less extensive canaliculi than basal ones. Helander<sup>[37]</sup> then reported that neck parietal cells have fewer tubulovesicles and more elaborate secretory canaliculi than base parietal cells. This was later confirmed by Jacobs *et al*<sup>[38]</sup> who, in a morphometric study, found that parietal cells in the neck region have higher canalicular volume and rER surface area than those located in the base region. Electron microscopic studies on the mouse stomach revealed that, while almost all isthmus and neck parietal cells are morphologically normal, 25% of those in the pit and those in the base show signs of degeneration<sup>[33]</sup>. Similar but less pronounced degeneration of old parietal cells was also found in the rabbit<sup>[35]</sup> and this was enhanced by the omeprazole-induced inhibition of acid secretion; (2) After a 24-h-fasting, Coulton *et al*<sup>[39]</sup> were able to actively stimulate neck parietal cells with food but base parietal cells remained inactive. They proposed that basal parietal cells are either switched off or have a function other than acid secretion; (3) In a histochemical study, Firth *et al*<sup>[40]</sup> found that the H,K-ATPase activity is prominent in neck parietal cells, but absent in the basal cells; (4) In gastric glands isolated from rabbits, measurements of the morphological responsiveness of parietal cells to acid inhibitors and secretagogues revealed that luminal parietal cells respond much more efficiently than basal parietal cells<sup>[41]</sup>; and (5) The detection of H,K-ATPase  $\beta$ -subunit mRNA using a digoxigenin-labeled cRNA probe revealed a differential pattern of expression. Parietal cells located in the isthmus-neck region have high level of mRNA, while the level was low in the senescent pit and base parietal cells<sup>[41]</sup>.

The senescence-related decrease in functional and synthetic activity of parietal cells could be a sign of an alteration either in the membrane receptors, or in an intracellular mediator of the cAMP activation pathway, or in the effector proteins (proton pumps) themselves.

## ROLE OF PARIETAL CELLS AS GOVERNORS OF PROLIFERATION AND DIFFERENTIATION OF STEM/PROGENITOR CELLS

Several genetic manipulation studies have revealed different lines of evidence confirming the important role that parietal cells play as governors of both progenitor/stem cell proliferation and their differentiation into other cell lineages in the oxyntic glands. (1) In the first approach, forced expression of Simian virus 40 large T antigen gene in preparietal cells to induce their proliferation and thus block parietal cell production was also associated with a block of zymogenic cell differentiation and a progressive increase in the number of progenitor cells starting from embryonic day 18<sup>[34,42]</sup>. With age, the situation in these mice became more dramatic due to development of dysplastic changes leading to invasive gastric adenocarcinoma with distant

metastasis<sup>[43]</sup>; (2) Genetically engineered ablation of parietal cells using the attenuated Diphtheria toxin gene in transgenic mice was also associated with a block in terminal differentiation of zymogenic cells and a massive increase in the proliferation of the multipotent stem cells and committed progenitors<sup>[44]</sup>; (3) Genetic enhancement of parietal cell apoptosis leading to a reduction in their population is also associated with a blockade in zymogenic cell differentiation and glandular hyperplasia<sup>[45]</sup>; and (4) Deletion mutants of the potassium channel, KCNQ1 in parietal cells of both mice and rats showed altered zymogenic cell lineage differentiation and hyperproliferation of glandular progenitor cells<sup>[46]</sup>.

## PHYSIOLOGICAL VS INDUCED DEATH OF PARIETAL CELLS

In physiologically renewing cell populations, before the life of a cell ends, it enters a "terminal stage" where its functional activity deteriorates and it gradually degenerates until death<sup>[1]</sup>. An occasional degeneration of parietal cells has been reported in the mouse by Kataoka *et al*<sup>[31]</sup>. When parietal cells degenerate they either show signs of necrosis or apoptosis<sup>[33]</sup>. Dead parietal cells are immediately eliminated from the epithelium by different mechanisms. Necrotic cells are usually extruded into the gland lumen, whereas, apoptotic ones are phagocytosed by neighboring pit cells, zymogenic cells or connective tissue macrophages invading through a break in the basement membrane<sup>[33,35]</sup>.

In addition to their physiological loss, death of parietal cells has been induced by various compounds. (1) Omeprazole is known to bind to the catalytic  $\alpha$  subunit of H,K-ATPase and hence, inhibit acid secretion. This covalent binding was found to be associated with a reduction in the amount of H,K-ATPase due to induced degeneration of parietal cells in rabbits<sup>[35]</sup>; (2) H2 receptor antagonists (ranitidine and cimetidine) which inhibit acid secretion have also been shown to enhance parietal cell degeneration and loss in mice<sup>[47]</sup>; and (3) The orally active, cell-permeant neutrophil elastase inhibitor DMP-777 induces a rapid degeneration and loss of parietal cells in rodents<sup>[48]</sup>. This induced loss of parietal cells is associated with enhanced progenitor cell proliferation and, hence, hyperplasia develops.

## CONCLUSION

Revealing the renewal concept of parietal cells and analyzing their dynamic features have improved our understanding of the biology and pathophysiology of the gastric glands. For example: (1) The fact that parietal cells are not static provides an explanation for their functional heterogeneity. Therefore, young parietal cells in the isthmus and neck regions are more active in acid secretion than old parietal cells which have migrated to the glandular base; (2) Maturation of parietal cells in the isthmus region seems to be necessary to maintain the normal

proliferation and differentiation program of gastric epithelial stem cells and their immediate descendents; (3) Migration of parietal cells to the base region seems to be a prerequisite for the transformation of mucous neck cells into pepsinogen-secreting zymogenic cells; and (4) Regeneration of parietal cells explains the recurrence of symptoms following therapy aimed at inhibiting acid secretion and explains the possibility of hyperplastic changes and carcinoids.

women and 203 (37%) men in all subtypes of IBS. The pooled relative risk (RR) for clinical improvement of mebeverine was 1.13 (95% CI: 0.59-2.16,  $P = 0.7056$ ) and 1.33 (95% CI: 0.92-1.93,  $P = 0.129$ ) for relief of abdominal pain. The efficacy of mebeverine 200 mg compared to mebeverine 135 mg indicated RRs of 1.12 (95% CI: 0.96-1.3,  $P = 0.168$ ) for clinical or global improvement and 1.08 (95% CI: 0.87-1.34,  $P = 0.463$ ) for relief of abdominal pain. Thus, mebeverine is mostly well tolerated with no significant adverse effects; however, its efficacy in global improvement of IBS is not statistically significant.

### Abstract

We evaluated the efficacy and tolerability of mebeverine, a musculotropic antispasmodic agent, in irritable bowel syndrome (IBS) and compared its usual dosages by meta-analysis. Medical databases and all relevant literature were searched from 1965 to June 2009 for any placebo-controlled clinical trials of mebeverine, using search terms such as mebeverine, clinical trials, and IBS. Eight randomized trials met our criteria, including six trials that compared mebeverine with placebo and two that compared mebeverine tablets with capsules. These eight trials included 555 patients randomized to receive either mebeverine or placebo with 352 (63%)

### INTRODUCTION

Irritable bowel syndrome (IBS) is a complex and widely-encountered syndrome. It is a condition characterized by abdominal pain associated with disordered defecation in the absence of any demonstrable abnormality. Despite recent advances in the treatment of IBS<sup>[1-3]</sup> the exact pathophysiology of IBS is still incompletely understood<sup>[4]</sup>. Alteration in neurohumoral mechanisms and psychological factors, bacterial overgrowth, genetic factors, gut motility, visceral hypersensitivity, and immune system factors are currently believed to influence the

pathogenesis of IBS<sup>[4,5]</sup>. There are three IBS subgroups: those with constipation, those with diarrhea, and those with alternating constipation or diarrhea<sup>[6]</sup>. The treatment of IBS is targeted at the management of constipation, diarrhea, and abdominal pain and usually includes pharmacotherapy with alosetron and other 5-HT(3)-receptor antagonists<sup>[7]</sup>.

Mebeverine is an antispasmodic that has been successfully used in the management of IBS for many years. Mebeverine is a musculotropic agent that has antispasmodic activity and regulatory effects on the bowel function<sup>[8]</sup>. During oral administration at doses of 135-270 mg *tid*, it shows no typical anticholinergic side effects, such as dry mouth, blurred vision, and impaired micturition. The incidence of side effects caused by mebeverine has not been demonstrated to be higher than that of a placebo<sup>[9]</sup>. This agent is now sold in approximately 56 countries, and its efficacy and tolerability have been demonstrated in 10 controlled studies and in many open clinical trials<sup>[9-19]</sup>. Although several clinical trials on the utility of mebeverine in patients with IBS exist, no statistical meta-analysis has been done regarding its efficacy and safety. In the present work, we systematically reviewed all the available data to examine the dose level efficacy and tolerability of mebeverine in IBS by a meta-analysis technique.

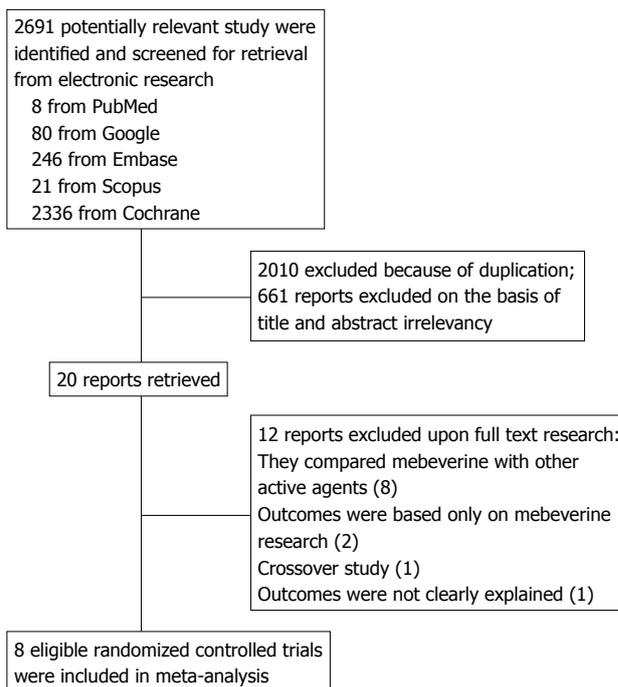

### DATA SOURCES AND META-ANALYSIS

PubMed, Embase, Scopus, Cochrane, and Google were searched from 1965 to June 2009 for clinical trials on the efficacy of mebeverine *vs* placebo. The search terms were mebeverine, clinical trial, and IBS. No language restriction was applied. The reference list from retrieved articles was also reviewed for additional applicable studies.

A total of 2691 results were examined and studies that were duplicates, case studies, and uncontrolled trials were eliminated. A high fiber diet or fiber supplementation with mebeverine was not considered a source of exclusion. Trials were disqualified if they compared mebeverine with other active agents, had not used a placebo, had used a combination of drugs, were crossover studies, and their outcomes did not relate to efficacy. Included studies used at least one clinical end point of “global assessment of symptoms by the patient or physician” or “abdominal pain and distention”. The definition of global response varied widely among studies. Some trials recorded improvement *vs* no improvement, whereas others evaluated the subject’s global assessment of relief. Responders in the included studies were patients who showed a global response according to the study’s definition. In studies lacking a global response definition, patients who showed global improvement in symptoms were included. Two reviewers independently extracted data on patients’ characteristics, therapeutic regimens, dosage, trial duration, and outcome measures. Disagreements, if any, were resolved by consensus. Among eight included studies, two compared mebeverine 135 mg with

**Table 1** Jadad quality score of randomized, controlled trials included in the meta-analysis

Study	Total score	Withdrawals and dropouts	Blinding	Randomization
Kruis <i>et al</i> <sup>[21]</sup> 1986	4	0	2	2

mebeverine 200 mg, and the remaining studies compared mebeverine with placebo (Figure 1).

The methodological quality of included trials was assessed using the Jadad score, which judges the descriptions of randomization, blinding, and dropouts (withdrawals) in the trials<sup>[20]</sup> (Table 1). This is summarized as follow: (1) whether randomized or not (yes = 1 point, No = 0); (2) whether randomization was described appropriately or not (yes = 1 point, No = 0); (3) double blind (yes = 1 point, No = 0); (4) was the double blinding described appropriately (yes = 1 point, No = 0); and (5) whether withdrawals and dropouts described or not (yes = 1 point, No = 0). The quality scale ranges from 0 to 5 points with a low quality report of score 2 or less and a high quality report of score at least 3.

Data from selected studies were extracted in the form of 2 × 2 tables. All included studies were weighted and pooled. The data were analyzed using Statsdirect (2.7.7; 9/13/2009). Relative risk (RR) and 95% confidence intervals (95% CI) were calculated using the Mantel-

Haenszel and DerSimonian-Laird methods. The Cochran *Q* test was used to test heterogeneity. The event rate in the experimental (intervention) group against the event rate in the control group was calculated using L'Abbe plots as an aid to explore the heterogeneity of effect estimates. Funnel plot analysis was used as a publication bias indicator.

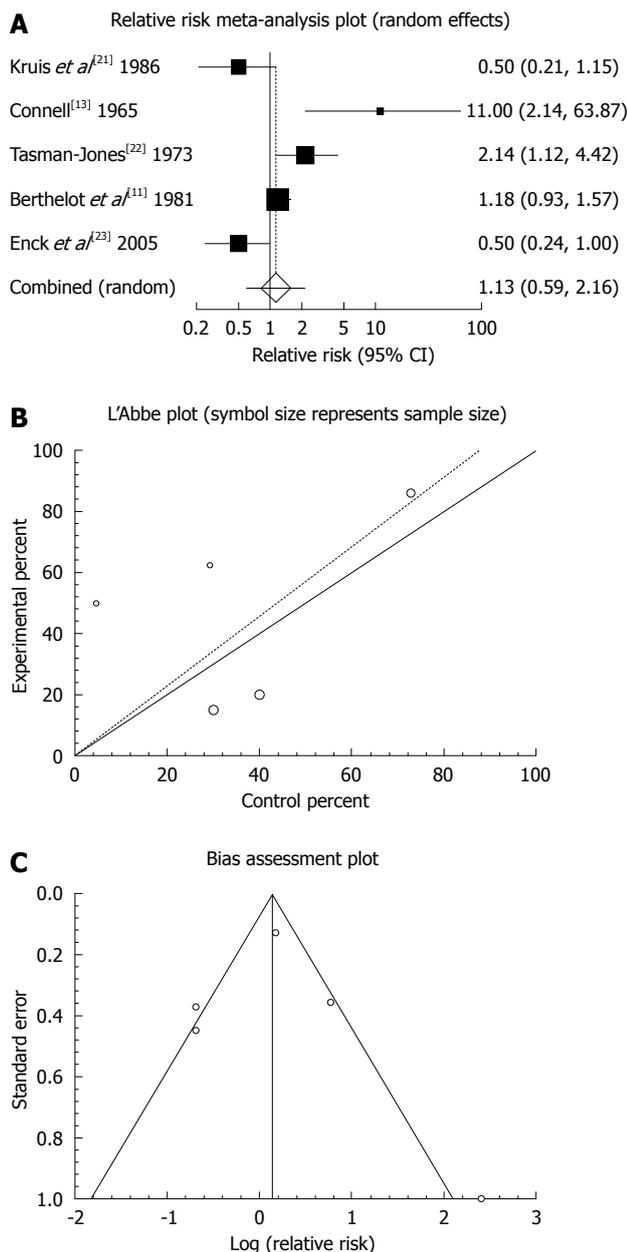

## RESULTS

The electronic searches yielded 2691 items: eight from PubMed, 80 from Google, 246 from Embase, 21 from Scopus, and 2336 from Cochrane. Of these, 20 were scrutinized in full text, eight were considered eligible and had a well-defined global response outcome and

were included in this analysis (Figure 1). The quality of the eligible studies was assessed by Jadad score. From eight studies, seven had Jadad scores  $\geq 4$ <sup>[11,13,19,21-24]</sup> and the other study had a Jadad score of 3<sup>[25]</sup> (Table 1). These eight trials included 555 patients randomized to receive either mebeverine or placebo. 352 (63%) were women and 203 (37%) were men. All subtypes of IBS were represented. Abdominal pain was prevalent in only one study<sup>[24]</sup>. Patient's characteristics, type, and dosage of mebeverine and placebo, duration of treatment, and outcomes (clinical improvement and the relief of abdominal pain) for each study are shown in Tables 2-5.

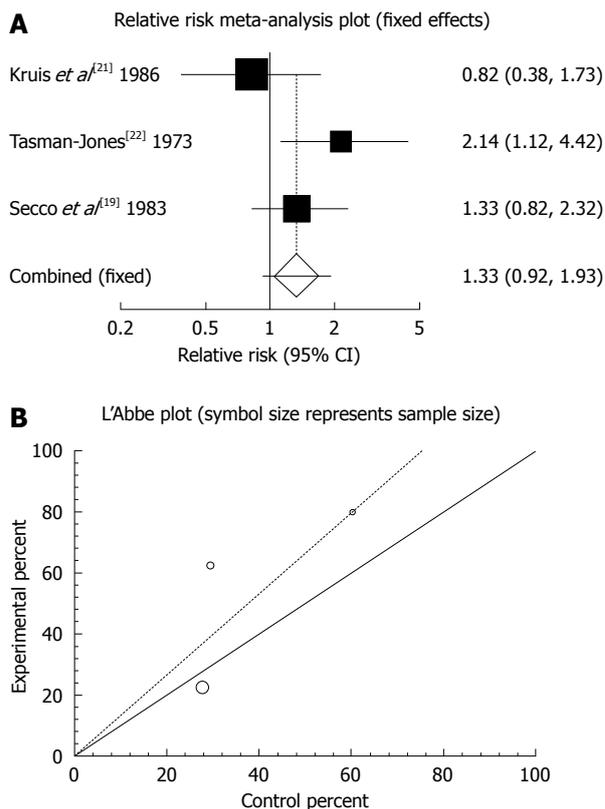

### Efficacy of mebeverine compared to placebo

The summary RR for global or clinical improvement in

**Figure 2 Individual and pooled relative risk (A), heterogeneity indicators (B), and publication bias indicators (C) for the outcome of "global or clinical improvement" in the studies comparing mebeverine vs placebo therapy.**

five trials including<sup>[11,13,21-23]</sup> was 1.13 with a 95% CI of 0.59-2.16 and a non-significant RR ( $P = 0.7056$ , Figure 2A). The Cochrane  $Q$  test for heterogeneity indicated that the studies were heterogeneous ( $P = 0.0022$ , Figure 2B) and could not be combined, thus the random effects for individuals and summary of RR was applied. Regression of normalized effect *vs* precision for all included studies for clinical response among mebeverine *vs* placebo therapy was 0.217719 (95% CI: -5.538784 to 5.974221,  $P = 0.9118$ ), and Kendall's test on standardized effect *vs* variance indicated  $\tau_{au} = 0.2$ ,  $P = 0.8167$  (Figure 2C). Summary RR for relief of abdominal pain in three trials<sup>[19,21,22]</sup> was 1.33 with a 95% CI of 0.92-1.93, a non-significant RR ( $P = 0.129$ , Figure 3A). The Cochrane  $Q$  test for heterogeneity

**Figure 3 Individual and pooled relative risk (A) and heterogeneity indicators (B) for the outcome of "relief of abdominal pain" in the studies comparing mebeverine vs placebo therapy.**

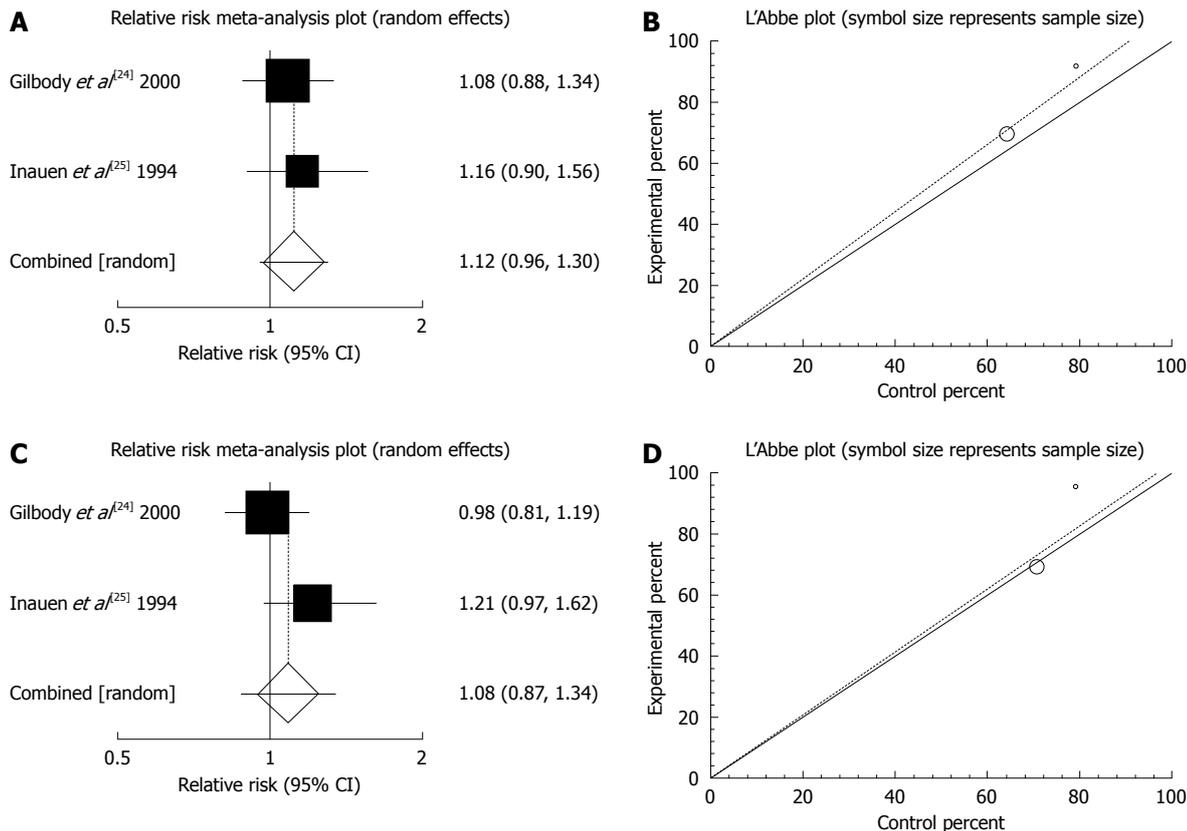

indicated that the studies were homogenous ( $P = 0.1871$ , Figure 3B) and could be combined, thus fixed effects for individuals and summary of RR was applied. Regression of normalized effect *vs* precision for all included studies for clinical response among mebeverine *vs* placebo therapy could not be calculated because of too few strata.

**Tolerability of mebeverine compared to placebo**

Adverse effects were rare or unknown in four of the six studies where mebeverine was compared to placebo. In two studies, 24% (15/62) of the mebeverine group and 22.5% (14/62) of the placebo group reported adverse effects<sup>[13,23]</sup>.

**Efficacy of mebeverine 200 mg compared to mebeverine 135 mg**

The summary RR for global or clinical improvement in two trials<sup>[24,25]</sup> was 1.12 with a 95% CI of 0.96-1.3 and a non-significant RR ( $P = 0.168$ , Figure 4A). The Cochrane  $Q$  test for heterogeneity indicated that the studies were homogenous ( $P = 0.6654$ , Figure 4B) and could be combined, but because of few included studies, the random effects for individuals and summary of RR was applied. Regression of normalized effect *vs* precision for all included studies for clinical response among mebeverine *vs* placebo therapy could not be calculated because of too few strata. Summary RR for relief of abdominal pain in two trials<sup>[24,25]</sup> was 1.08 with a 95% CI

**Figure 4** Individual and pooled relative risk and heterogeneity indicators for the outcome of “global or clinical improvement (A, B)” and “relief of abdominal pain (C, D)” in the studies considering mebeverine 200 mg compared to mebeverine 135 mg.

of 0.87-1.34, a non-significant RR ( $P = 0.463$ , Figure 4C). The Cochrane  $Q$  test for heterogeneity indicated that the studies were homogenous ( $P = 0.1398$ , Figure 4D) and could be combined, but because of few included studies, the random effects for individuals and summary of RR were applied. Regression of normalized effect *vs* precision for all included studies for clinical response among mebeverine *vs* placebo therapy could not be calculated because of too few strata.

### Tolerability of mebeverine 200 mg compared to mebeverine 135 mg

Of the two studies comparing mebeverine 200 mg to mebeverine 135 mg, only one of them reported adverse effects in about 61.5% (66/107) of the mebeverine 135 mg group and 59.5% (63/106) of the mebeverine 200 mg group<sup>[24]</sup>. The other study found no serious adverse effects in the trial<sup>[25]</sup>.

## DISCUSSION

The results of this meta-analysis demonstrate that the clinical improvement and relief of abdominal pain observed for mebeverine is not statistically significant compared to placebo.

It is well tolerated without any significant adverse effects. The meta-analysis also showed that mebeverine 200 mg is as effective as mebeverine 135 mg in the

clinical improvement and relief of abdominal pain. The results also indicated no significant adverse effects for mebeverine 200 mg.

Although placebo effects in IBS clinical trials that measure a global outcome, are highly variable<sup>[26]</sup>, the last meta-analysis on myorelaxants indicated that compounds like mebeverine are superior to placebo for global improvement of IBS and reducing pain. This drug showed significant efficacy on global assessment despite a high placebo effect (38% global improvement). The efficacy was also significant and in the same range for pain relief<sup>[9]</sup>. The present results are also consistent with a previous report that indicated low incidence of side effects<sup>[11]</sup>.

Another systematic review on the safety and tolerability of antispasmodics in the treatment of IBS also confirmed the low incidence of adverse effects associated with mebeverine incidence (0.1-0.6 events per patient-year of exposure) and the investigators provided a favorable judgment regarding tolerance of mebeverine in dosages of both 600 mg and 400 mg<sup>[27,28]</sup>. Among other active agents for the treatment of IBS, probiotics can be used only as supplements of standard therapy. In addition, low doses of antidepressants induce clinical response and reduce abdominal pain score in patients with IBS<sup>[1,2]</sup>. Selective serotonin reuptake inhibitors (SSRIs) are often better tolerated than tricyclic antidepressants and have anxiety reducing benefits with a potential value

in IBS<sup>[7,29]</sup>. Despite this, results of a recent meta-analysis showed that SSRIs overall are not significantly better than placebo for the relief of individual IBS symptoms<sup>[2]</sup>. Recent trials have demonstrated that alosetron, a 5-HT<sub>3</sub> receptor antagonist, is effective in the treatment of IBS in non-constipated female *vs* placebo and *vs* mebeverine<sup>[7,30]</sup>. However, mebeverine could still be useful, particularly in treating males and constipated female with IBS, and it could diminish stool frequency or improve global feeling in diarrhea predominant IBS patients<sup>[9,31]</sup>. Thus it can be concluded that mebeverine is more effective than placebo in the management of diarrhea- or constipation-predominant IBS, without significant adverse effects.

Moreover, mebeverine 200 mg *bid* was shown to be therapeutically equivalent to mebeverine 135 mg *tid* in treatment of abdominal pain in IBS without a higher incidence of adverse effects. Studies also confirmed that both formulations of mebeverine were regarded as effective in more than 80% of cases. Tolerability was also excellent, with only few adverse effects and compliance close to 100% for most of patients. Of course, reducing the number of daily doses from three to two is an advantage of the mebeverine SR capsule in terms of patients' compliance<sup>[24,25,32]</sup>.

Fortunately, all the included studies in the present meta-analysis were well randomized, had acceptable Jadad scores, and included all subtypes of IBS (diarrhea predominant, constipation predominant, pain predominant and alternating). Some general limitations are unavoidable in meta-analyses, such as dissimilarities among patient characteristics (age, sex, lifestyle, and compliance), different duration of treatment, and different IBS subtypes; however, in this meta-analysis the high homogeneity of the included trials helped us to reach convincing conclusions. Of course, it would have been better to individualize patients based on IBS subtype and sex and evaluate outcomes for each subtype and gender, but it was not always applicable in the present study. Indeed, there is a need for more controlled, randomized trials considering the above-mentioned limitations.

## CONCLUSION

Although the effects of mebeverine on clinical improvement and relief of abdominal pain are not statistically significant, it could be considered clinically effective until more studies are added to this meta-analysis to increase the power of the conclusions. Comparing doses, the mebeverine capsule (200 mg *bid*) is effective and well tolerated without significant adverse effects and, in terms of compliance, it could be considered as an appropriate form of dosage.

### Abstract

Hepatitis D virus (HDV) infection is present worldwide and affects all age groups. Around 18 million people are estimated to be infected with HDV. An important trend in HDV infection is global decline. HDV prevalence has decreased significantly in Europe since the 1970s and 1980s when it was first reported. The Asia-Pacific region now seems to be where HDV is a major health concern. There is a lack of available data from most of the countries from this region; hence, the true status of HDV cannot be determined. In South Asia, most of the countries have conditions that are favorable for the spread of hepatitis B and other related infections. Countries like Pakistan and Iran have shown an increase in HDV prevalence over a period of time. Other countries and region like China, Turkey, Australia, Japan, India and Taiwan, some of which had very high HDV prevalence in the past, have shown a decline in the incidence, but high prevalence persists in some. Intravenous drug abusers, homosexual men and women, prostitutes, and people on hemodialysis are the groups with very high HDV prevalence.

### INTRODUCTION

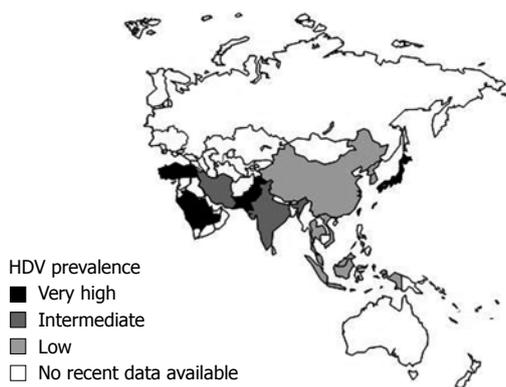

Hepatitis D virus (HDV) infection is present worldwide and affects all age groups. However, it does not have uniform distribution and its general pattern is parallel to that of hepatitis B virus (HBV). Its prevalence is highest in some parts of Africa, South America, Romania, Russia and the Mediterranean region included Southern Italy<sup>[1]</sup>. It is also noteworthy that approximately 5% of the global HBV carriers are co-infected with HDV. Out of approximately 350 million carriers of HBV worldwide, 18 million people are infected with HDV<sup>[2]</sup>.

Hepatitis D prevalence has declined significantly in Europe since the 1970s and 1980s when it was first reported. The new foci of infection now seem to be in the developing countries. The Asia-Pacific region seems to be where HDV exists with high prevalence rates in some of the countries<sup>[3]</sup>.

### HDV

HDV is also known as hepatitis delta virus, and is a defective RNA virus that requires HBV for its virion assembly and penetration into hepatocytes<sup>[4]</sup>. There are three genotypes of HDV, identified on the basis of analysis of HDV genomes from various parts of the world<sup>[5]</sup>. The most prevalent worldwide is genotype I, which is related to a broad spectrum of pathogenicity.

Hepatitis Delta-Scenario in the Asia-Pacific region

**Figure 1** Hepatitis D prevalence in the Asia-Pacific region.

The United States, Middle East and Europe are the places where genotype I is predominant, with some geographically based subtypes<sup>[6,7]</sup>. Genotype II is predominant in the Far East<sup>[5]</sup>. Genotype III is associated with severe forms of hepatitis and is predominant in Northern South America<sup>[8]</sup>.

## GLOBAL TREND OF DECLINE

An important trend in worldwide HDV infection is a global decline in the prevalence of hepatitis D infection, which is true for both acute and chronic forms of the disease<sup>[9]</sup>. This decreasing trend is the result of global HBV vaccination, increasing awareness, improved prevention strategies and socioeconomic conditions<sup>[10]</sup>. Italy, which was considered a traditionally prevalent area for HDV and where the virus was first reported, has shown a steady decline in the prevalence of this infection from 23% in 1987 to 14% in 1992 and 8.3% in 1997<sup>[11-13]</sup>. Figure 1 summarizes the prevalence of hepatitis D in the Asia-Pacific region, incorporating the recent data.

## HDV IN PAKISTAN

In South Asia, most of the countries offer conditions that are favorable for the spread of hepatitis B and other related infections. These conditions mainly include lack of defensive strategies and approaches for these infections, extreme and persistent poverty, densely populated areas, and deteriorating public health and educational infrastructure. According to a study conducted from January 1994 to April 2001, the prevalence of HDV infection in Pakistani hepatitis B surface antigen (HBsAg)-positive individuals was 16.6%. A large belt with high prevalence exists in the middle of the country, which comprises rural areas<sup>[10]</sup>. The predominant genotype of HDV is genotype I and that of HBV is genotype D<sup>[5]</sup>.

A recently conducted study shows a very high HDV prevalence of 58.6% in HBsAg-positive patients who visited liver clinics in Karachi and Jacobabad. The study showed a higher prevalence compared to that in a previous study by Mumtaz *et al.*<sup>[10]</sup>. The prevalence

in these patients coming from districts of Sindh and Balochistan Provinces was 67% in Jacobabad, 65.4% in Jafferabad, 60% in Naseerabad, 69.2% in Kashmore, 65.2% in Quetta and 36.6% in Karachi<sup>[14]</sup>.

The high prevalence could be due to the frequent use of therapeutic injections and drips, contaminated needles, surgical and dental equipment, reusing traditional razors by barbers, use of injectable drugs, and sexual transmission<sup>[10]</sup>. There is higher seroprevalence of HDV in younger male subjects who are positive for HBsAg.

## HDV IN INDIA

In India, the trend is much different from that in Pakistan and HDV infection does not seem to be very common. It is suggested that the infection is switching towards low prevalence in this country<sup>[15]</sup>. A number of studies have been done in India to estimate the prevalence of HDV infection but there is lack of a national survey.

In Northern India, the prevalence of hepatitis D in HBsAg-positive individuals from New Delhi was reported to be 8.1% in 1996<sup>[16]</sup> and 10.6% in 2005<sup>[15]</sup>, which was lower than in Chandigarh in Northern India, where the infection was reported endemic in 1995 and showed a prevalence of 14.2%<sup>[17]</sup>. In Central India, a study in Indore showed higher prevalence of 5.7% in patients with chronic liver disease, 1.9% in those with acute viral hepatitis, 15% in those with hepatic failure, and 2.3% in those with chronic renal failure<sup>[18]</sup>. In Kolkata, the prevalence was found to be 3.3% in 1998<sup>[19]</sup>.

In Mumbai, according to a study done in 1992, the HDV prevalence was 37.46% in HBsAg-positive patients. There was a higher HDV prevalence of 63% in patients with fulminant hepatitis<sup>[20]</sup>. However, another study from this city showed a prevalence of 16% in patients with acute viral hepatitis, 17% in asymptomatic HBsAg carriers, and 19% in patients with chronic liver disease. Among the high-risk population, HDV prevalence was 20% in chronic renal failure patients, 29% in medical professionals, and 38% in recipients of multiple transfusions<sup>[21]</sup>. Delta infection in Ludhiana was reported to be 33% in children with a high prevalence of HDV<sup>[22]</sup>. Another study from Ludhiana in the same year showed a prevalence of 10% in HBsAg-positive patients<sup>[23]</sup>. In Southern India, low HDV prevalence in patients undergoing hemodialysis was reported in a study published in 1991<sup>[24]</sup>. However, there is high prevalence of HDV in the resident tribes of Nicobar and Andaman islands<sup>[25]</sup>.

## HDV IN IRAN

HDV is a major public health issue in Iran<sup>[26]</sup>. Studies from different areas of the country show varied prevalence rates. Although overall HBV, and therefore, HDV prevalence might have decreased in Iran, studies have indicated an increase in HDV occurrence in HBsAg-positive patients. Anti-HDV prevalence in asymptomatic HBV carriers from Southern Iran was 14% in 1989<sup>[27]</sup>. A recently published study reported a prevalence of 9.7%

in chronic HBV patients from Shiraz, which represented a decrease in prevalence from 1989<sup>[28]</sup>. In Midwest Iran, a low prevalence of 2.4% in 1989 was reported in HBsAg carriers<sup>[26]</sup>. A study conducted during 1986-1988 has estimated the prevalence of hepatitis D in various high-risk groups. The prevalence of anti-delta was found to be 2.5% (3/120) in asymptomatic chronic carriers of HBsAg, 33.33% (2/6) in hemophilic patients, 44.5% (16/36) in HBsAg-positive hemodialysis patients. Five out of eight patients with hepatocellular carcinoma (HCC) were also positive for anti-HDV<sup>[29]</sup>. In 2000, 1.3% of blood donors positive for HBsAg and 25.2% of HBsAg-positive hemodialysis patients were found to be anti-HDV positive<sup>[30]</sup>.

In Tehran, HDV prevalence was found to be 5.7% in chronic HBV patients in 2004<sup>[31]</sup>. In Golestan Province, Northeastern Iran, a recent study has shown an anti-HDV prevalence of 5.8% in HBsAg carriers<sup>[32]</sup>. Another study also has shown an HDV prevalence of 5.8% (8/139) in this part of Iran. These studies suggest an increase in HDV prevalence over the past decade<sup>[33]</sup>.

In Babol, Northern Iran, HDV prevalence was 2% in chronic hepatitis B patients in 2002<sup>[34]</sup>. However in Kerman, Southern Iran, HDV prevalence was found to be 20.7% in chronic hepatitis B patients<sup>[35]</sup>. In Tabriz, Northwestern Iran in 2000, HDV prevalence was observed to be 6.15% in chronic HBV patients<sup>[36]</sup>. A recently published study (2008) has shown a high HDV prevalence of 31.57% in HIV/HBV co-infected individuals in Kermanshah, Western Iran<sup>[37]</sup>.

## HDV IN AFGHANISTAN

Not enough data are available from Afghanistan to estimate recent prevalence of HDV. A study was conducted between 1976 and 1984 in which sera were collected from 362 persons in various epidemiological groups with chronic and acute HBV infection. Some sera were also collected from drug addicts and hemophiliacs with antibodies for hepatitis B. It was seen that hepatitis D was common in drug addicts, hemophiliacs, hemodialysis patients and prisoners. However, HDV was uncommon in homosexual men, people with sporadic hepatitis B, and in people from other endemic areas for hepatitis B. HDV prevalence was 18% in patients with chronic liver disease, 2% in asymptomatic carriers of hepatitis B, and 5% in acute hepatitis B patients. No infection was observed in institutionalized mentally retarded persons and health-care workers. During the 9 years of the study, no change was seen in HDV frequency<sup>[38]</sup>.

## HDV IN MAINLAND CHINA

In mainland China, HDV infection is not very prevalent but it does exist. The results of a study done in Sichuan Province in 1987 have suggested a low prevalence of 0.8% in HBsAg-positive patients, although the prevalence rate of HBV was high<sup>[39]</sup>. In 1989, the prevalence of anti-

HDV was 4.3% in Tibet, Inner Mongolia, and Xinjiang, whereas no HDV infection was observed in Henan, Fujian, Liaoning, Heilongjiang, Guangxi, Sichuan, Beijing and Shanghai<sup>[40]</sup>. In 1990, 2346 liver samples were tested from 17 different areas of China for the intrahepatic hepatitis D antigen (HDAg). The observed detection rate was 9.47%<sup>[41]</sup>.

In the area of Guangzhou, the prevalence of HDAg in 1990 was 13.3% in adults and 13.6% in children, which showed an insignificant difference in prevalence between the two age groups<sup>[42]</sup>. In the area of Shijiazhuang, the prevalence of HDV infection was observed to be 12.92% in 1990 and the study suggested Shijiazhuang as a high-HDV-prevalence area<sup>[43]</sup>.

In the province of Henan, a study conducted between 1991 and 1993 showed that 3.5% of the HBsAg-positive blood samples were anti-HDV positive. The investigators did not observe any significant difference of HDV prevalence with sex. However, noteworthy differences were observed in different age groups, particularly in those aged > 60 years<sup>[44]</sup>. In Shandong province, 7.72% of the HBsAg-positive patients were found to be anti-HDV positive in 1998. The prevalence rates were 13.15% in patients with hepatitis B and only 3.16% in HBsAg carriers<sup>[45]</sup>. A 2006 study conducted in Wuhan City has shown a low prevalence of HDV infection of 2.22% in intravenous drug users. However, the HBV and HCV prevalence rates were much higher in this population<sup>[46]</sup>.

## HDV IN HONG KONG, CHINA

In Hong Kong, hepatitis D has high prevalence rates among intravenous drug abusers (IVDAs). These findings were reported by a study that tested the sera of a large number of patients with acute or chronic HBV infection for anti-HDV between January 1988 and December 1990. HDV was detected in 13 out of 14 IVDAs, which corresponds to a prevalence of 93% in this group, whereas the prevalence was only 0.15% in 664 non-IVDAs<sup>[47]</sup>.

## HDV IN TAIWAN, CHINA

Taiwan is considered to be endemic for hepatitis B, but as a result of effective immunization, HBV prevalence has decreased markedly. Hepatitis D prevalence in Taiwan was very high in the 1990s and before, but the prevalence has decreased greatly since then and new cases of HDV infection are now encountered rarely<sup>[48]</sup>.

In 2003, the HDV prevalence in HBsAg carriers was 15.3% (56/366)<sup>[49]</sup>. A study published in 1997 identified 77 patients with acute HDV superinfection among 527 consecutive HBsAg carriers over the past 12 years. From June 1983 to May 1995, the prevalence decreased considerably by each 3-year period (23.7, 15.5, 13.1 and 4.2%, respectively). This change in the endemicity might have occurred due to the effective preventive measures taken against sexually transmitted diseases (STDs) and promiscuity and encouragement to use disposable

needles<sup>[50]</sup>. In 1990, a high HDV superinfection prevalence of 24.7% (21/85) was observed in HBsAg carriers from Southern Taiwan<sup>[51]</sup>.

Prostitutes are considered a high-risk group for hepatitis B and D. In 1993, the HDV prevalence in adult licensed prostitutes was 55%, 36% in adult unlicensed prostitutes, and 16% in teenage unlicensed prostitutes. Important factors identified for this high HDV prevalence were use of unsterilized needles for tattooing and ear piercing, and frequent sexual contact with multiple partners, which resulted in genital ulcers<sup>[52]</sup>. From 1986 to 1989, a two fold increase in HDV prevalence was observed in prostitutes. However there was no change in the HDV prevalence in IVDAs and the general population<sup>[53]</sup>. In 1992, the HDV prevalence in HBsAg carriers was 9.6% in STD patients, 33.1% in prostitutes, 2.2% in blood donors from the general population, and 68.1% in drug abusers<sup>[53]</sup>.

In 2002, HDV prevalence in IVDAs was 39%. From 1986 to 1997, a decreasing rate of 4.7% every year was observed in this high-risk group<sup>[54]</sup>. In 1990, 91% (119/131) of the HbsAg-positive IVDAs were found to be positive for anti-HDV, which showed an extremely high HDV prevalence in this high-risk group<sup>[55]</sup>. In 1989, 78.5% of the HbsAg-positive parenteral drug abusers tested positive for anti-HDV in Southern Taiwan<sup>[56]</sup>. In 1988, a study showed a high HDV prevalence of 85% in 151 IVDAs/HBsAg carriers, and in 1986, the results of a study showed that HDAG was detected in 78.9%<sup>[19]</sup> of 115 IVDAs/HBsAg carriers<sup>[57,58]</sup>.

In 1988, a study showed an HDV prevalence of 10.3% (3/29) in children with acute hepatitis B, and 1.4% (1/68) in children with chronic HBV. No asymptomatic HBsAg carrier child tested positive for HDV<sup>[59]</sup>.

## HDV IN JAPAN

In Japan, certain areas are highly HDV prevalent, especially Miyako Islands in Okinawa<sup>[60]</sup>. A study published in 1990 has assessed the prevalence of HDV infection in Japan at different time periods. Hepatitis D was first observed in 1979-1983 and the prevalence was 16% in acute hepatitis B, 6.8% in HBV carriers, and 26% in chronic liver disease. Anti-HDV was later rarely observed. The findings of this study suggest limited sporadic HDV infection in Japan<sup>[61]</sup>. In 1993, a study compared the HDV prevalence rates between area of high HBV incidence, i.e. Kamigoto Islands and an area of average HBV carriage rate, i.e. Oita City. The HDV prevalence in Kamigoto Islands was 8.3%, while that in Oita City was 0%. The study pointed towards the possible risk of outbreak of this infection in HBV prevalent areas in the future<sup>[62]</sup>.

As compared to other parts of the country, Okinawa Islands, especially Miyako Islands, which are located in the southernmost part of the country, are considered to be endemic for the virus, where HDV genotype II b is prevalent<sup>[60]</sup>. In 1995, the HDV prevalence in Miyako Islands was 23.5%<sup>[63]</sup>. In 1998, the HDV prevalence in

Miyako Islands was 21.1%. It has been suggested that the rate of HDV prevalence is likely to increase with increasing age or underlying disease severity<sup>[64]</sup>. However, in 2000, the HDV prevalence further decreased to 8.5% among the 4728 inhabitants of the islands<sup>[65]</sup>.

In Irabu Islands, Okinawa the HDV prevalence among HBsAg-positive patients was 23.6% in 1997, which indicated another high-prevalence area in Okinawa. The incidence rates were different in the seven districts of Irabu Islands, and ranged from 0% to 63.3%<sup>[66]</sup>.

## HDV IN KOREA

In Korea, HDV prevalence was estimated to be 0.85% in 1985. In 2003, a study was conducted in which 194 HBsAg-positive Korean patients were tested for anti-HDV, out of which, seven (3.6%) tested positive. Six of these patients had HCC and one had cholangiocarcinoma. Therefore, HDV was mainly associated with patients with HCC with a prevalence rate of approximately 4%, which has not changed greatly during the past 20 years<sup>[67]</sup>.

## HDV IN INDONESIA

In Indonesia, only a few studies are available on the prevalence of HDV, thus, this infection does not seem to be a major problem in this area unlike some other Asian countries. A study published in 1988 assessed the prevalence of hepatitis D in pregnant women in Bandung, a densely populated area of Indonesia. Out of the 926 pregnant women included in the study, only 2.8% (26) were carriers of HBsAg, among which, none tested positive for delta antibodies in spite of the fact that in this Indonesian population, HBsAg was frequent<sup>[68]</sup>. However, in 2003, the prevalence was found to be < 0.5% in the HBsAg carriers of Surabaya, which is also very low<sup>[69]</sup>.

## HDV IN MALAYSIA

In Malaysia, hepatitis D was first described in 1986 in some population groups. The HDV prevalence was found to be 12.5% in cases of acute hepatitis B, 6.7% in homosexual individuals, and 17.8% in drug abusers who were positive for HBsAg<sup>[70]</sup>. In 1989, the HDV prevalence was found to be 4.9%<sup>[71]</sup>. In 1996, 0.9% of the 923 jaundiced patients were found to be positive for anti-HDV<sup>[72]</sup>. In 1985, surveillance results for the detection of anti-HDV in IVDAs showed an absence of anti-HDV. However, in 1986, a prevalence of 17.8% was observed in the same group. The prevalence increased to 20% in 1989 and in 1994, 34% of the drug addicts tested positive for anti-HDV<sup>[73]</sup>.

## HDV IN THAILAND

In Thailand, hepatitis D is prevalent among IVDAs, a

high-risk group for viral hepatitis. A study conducted in 1988 tested 84 HBsAg-positive IVDAs, of which, 65.48% showed anti-HDV positivity. The HDV prevalence in 20 chronic hepatitis patients was 11.11% and 8.33% in 12 cirrhotic patients. No anti-delta antibodies were detected in 46 asymptomatic carriers<sup>[74]</sup>. A study in 2002 tested 55 HBsAg-positive sera of IVDAs, among which, 12 (21.8%) tested positive for anti-HDV. Among these anti-HDV-positive sera, eight (66%) tested positive for HDV RNA, and all had genotype I virus<sup>[75]</sup>.

Another study in 2002 tested 269 sera from the Hmong people of Northern Thailand for the seroprevalence of viral hepatitis. Despite the high seroprevalence of 76.0% for hepatitis B, the seropositivity of HDV was only 0.7%<sup>[76]</sup>.

### HDV IN PHILIPPINES

A study was conducted in 1990 to estimate the prevalence of HDV. Of the 64 patients with acute viral hepatitis, 1.6% tested positive for HDV. HBV was present in 40.6% of the acute viral hepatitis patients<sup>[77]</sup>.

### HDV IN VIETNAM

Vietnam is considered to be highly endemic for hepatitis B, which is one of the most important public health concerns. In order to estimate the prevalence of HBV and HDV in this area, a cross-sectional seroprevalence study was conducted in Thai Binh Province in 2007. Nineteen percent of the samples were HBsAg-positive, out of which, 1.3% were positive for HDV<sup>[78]</sup>. Thus, HDV does not seem to be prevalent in this HBV-endemic area. The results of another study conducted in Ho Chi Minh City in 2003 has shown that, except for HDV, other hepatitis viruses are spreading among the patients with liver diseases<sup>[79]</sup>.

### HDV IN AUSTRALIA

A study was conducted in Melbourne to establish the epidemiology of hepatitis D over a period of 15 years. Three thousand nine hundred and eighty-six HbsAg-positive patients were tested for HDV markers between 1971 and 1985. Hepatitis D markers were detected mostly in IVDAs and among their close contacts, and the results suggested the introduction of HDV in this group in 1970. The delta infection prevalence in carriers with no chronic liver disease was the highest (19.2%) among the IVDAs. Out of the 23 carriers with recurrent acute hepatitis, all tested positive for HDV markers and 20.1% of the carriers with chronic liver disease tested positive for the HDV markers<sup>[80]</sup>.

Apart from IVDAs, homosexual men are another high-risk group for HBV and HDV. In a study from Sydney in 1989, 204 homosexual men with acute or chronic HBV were tested for markers of HDV (total antibody to delta and delta antigen). Eight tested positive

for total antibody to delta, whereas delta antigen was detected in only one of the tested individuals, which showed a total HDV prevalence of 4.4%. All individuals who tested positive for the markers were IVDAs<sup>[81]</sup>.

### PACIFIC ISLANDS

Kiribati is an island located in the central tropical Pacific Ocean. HDV prevalence in this island is said to be very high. A serological survey was undertaken between May 1985 and February 1986 in which blood samples collected from 13 different places of the Southeast Asia and Pacific region were tested for HIV, HBV and HDV. The maximum HDV prevalence was observed in Kiribati, which was 84% in HBsAg-positive patients<sup>[82]</sup>. Another study in 1989 reported a prevalence of 69% (90/130) in individuals infected with HBV<sup>[83]</sup>.

Nauru, an isolated Pacific Island is considered hyperendemic for HDV. High HDV prevalence was reported here in 1986, in a study in which 2645 HBsAg-positive patients from several places in the Western Pacific were tested for HDV<sup>[84]</sup>. According to the results of a national epidemiological survey, published in 1989, in which 88% of the population was screened for HBV and HDV, 69.1% were reported positive for HBV markers, whereas HDV superinfection was observed in 22.7% of hepatitis B carriers<sup>[85]</sup>.

### HDV IN SAUDI ARABIA

HDV prevalence in Saudi Arabia was 8% (3/36) in HBsAg carriers in 1986<sup>[86]</sup>. The prevalence in the Riyadh area in the same year was 22.2% in patients with chronic hepatitis B, 7.9% in those with acute hepatitis B, and 6.7% in HBsAg carriers. In Najran, the prevalence was 9.6% in HBsAg carriers, and 5.3% in Al-Hafouf. In the areas of Khaiber and Jaizan, no anti-delta was found in the tested HBsAg carriers<sup>[87]</sup>. In 1987, a high HDV prevalence of 32% was detected in HBsAg-positive Saudi patients with liver disease, while the prevalence was 13% in patients with other illnesses. In healthy individuals, the prevalence was found to be 5.4%<sup>[88]</sup>. In 1988, the prevalence was 8% in HBsAg carriers in Gizan, an area considered hyperendemic for HBV<sup>[89]</sup>. A prevalence rate of 9.7% was detected in HBsAg-positive pregnant women in 1988. However, follow-up of 17 infants showed no indication of perinatal transmission<sup>[90]</sup>. In 1991, the prevalence in HBsAg-positive patients was found to be 17.6%<sup>[91]</sup>. In 1998, a study conducted in Jeddah showed an HDV prevalence of 13.6%. The HDV prevalence in IVDAs/carriers of HBsAg was 14.7% while there was 0.0% prevalence in non-IVDAs positive for HbsAg<sup>[92]</sup>.

In 2004, the HDV prevalence among HBsAg-positive healthy donors was 3.3%, while that in clinic- and hospital-based HBsAg patients was 8.6%. HDV infection is expected to decrease in Saudi Arabia with decreasing HBV prevalence due to global vaccination<sup>[93]</sup>.

## HDV IN OMAN

In Oman, according to a study conducted in 1991, the HDV prevalence was 7.7% (1/13) in HBsAg-positive dialysis patients and 22.2% (2/9) in HBsAg-positive renal transplant patients who have been previously transfused<sup>[94]</sup>. In 1994, HbsAg was detected in 11% of patients with kidney transplants and 12.7% of patients on dialysis. Anti-HDV was detected only in one HBsAg-positive patient on dialysis and two HbsAg carriers with renal transplants, which shows a low HDV prevalence among these patients<sup>[95]</sup>.

## HDV IN LEBANON

Hepatitis D was first detected in Lebanon in 1987 when a study reported 57% HDV prevalence in patients with chronic active hepatitis<sup>[96]</sup>. In 2007, the results of a study in which 258 HBsAg-positive patients from 10 health centers were included showed 1.2% (3/258) HDV prevalence, which shows a decrease in prevalence since 1987<sup>[97]</sup>.

## HDV IN TURKEY

In Turkey, like many other countries, a decline in HDV infection has been observed, but it is still a significant public health concern<sup>[98]</sup>. A recently published meta-analysis of HDV seropositivity has shown the decline in HDV infection but also points to the significant health concern in low socioeconomic parts of the country<sup>[99]</sup>. HDV prevalence is much higher in the southeast of the country, being 27% in chronic hepatitis B patients and 46% in hepatitis-B-induced cirrhosis patients. This is in comparison to the HDV prevalence in the West of the country of 5% in chronic hepatitis B patients and 20% in hepatitis-B-induced cirrhosis patients. The analysis also compared prevalence of HDV before and after 1995. It was observed that HDV prevalence in chronic hepatitis B patients decreased from 38% to 27% in Southeast Turkey and from 29% to 12% in Central Turkey. HDV prevalence in cirrhosis patients has decreased from 66% to 46% in Southeast and from 38% to 20% in West Turkey<sup>[99]</sup>.

## CONCLUSION

The prevalence of hepatitis D shows a decreasing trend due to preventive measures like vaccination against hepatitis B and awareness campaigns with regard to risk factors for the transmission of hepatitis B and D. Although preventive measures against hepatitis B including vaccination have decreased the prevalence of hepatitis D, there is no effective way of preventing HDV infection in HBV carriers in endemic areas. This can only be achieved by educating such individuals to prevent further exposures to risk factors. In spite of the global trend of decline, significant and persistent transmission is present in some countries.

### Abstract

**AIM:** To evaluate effects of pre- and postnatal protein deprivation and postnatal recovery on the myenteric plexus of the rat esophagus.

**METHODS:** Three groups of young Wistar rats (aged 42 d) were studied: normal-fed (N42), protein-deprived (D42), and protein-recovered (R42). The myenteric neurons of their esophagi were evaluated by histochemical reactions for nicotinamide adenine dinucleotide (NADH), nitroergic neurons (NADPH)-diaphorase and acetylcholinesterase (AChE), immunohistochemical reaction for vasoactive intestinal polypeptide (VIP), and ultrastructural analysis by transmission electron microscopy.

**RESULTS:** The cytoplasm of large and medium neu-

rons from the N42 and R42 groups were intensely reactive for NADH. Only a few large neurons from the D42 group exhibited this aspect. NADPH detected in the D42 group exhibited low reactivity. The AChE reactivity was diffuse in neurons from the D42 and R42 groups. The density of large and small varicosities detected by immunohistochemical staining of VIP was low in ganglia from the D42 group. In many neurons from the D42 group, the double membrane of the nuclear envelope and the perinuclear cisterna were not detectable. NADH and NADPH histochemistry revealed no group differences in the profile of nerve cell perikarya (ranging from 200 to 400  $\mu\text{m}^2$ ).

**CONCLUSION:** Protein deprivation causes a delay in neuronal maturation but postnatal recovery can almost completely restore the normal morphology of myenteric neurons.

### INTRODUCTION

Several studies have been published that deal with the

effects of several forms of malnutrition on the myenteric plexus (MP) of the gastrointestinal tract. From the amassed data, it is obvious that different regions of the gut are differently affected in their morphology, both quantitatively and qualitatively<sup>[1-5]</sup>. However, information whether these changes are reversible following re-feeding are scarce.

The effects of re-feeding on both the peripheral and central nervous system (CNS) have been investigated. The optic nerve of rats undergoes a reduction in the number of myelinated fibers when subjected to malnourishment; that effect is reversed when adequate protein intake is restored early<sup>[6]</sup>. Similar results have been verified in the tibial and ulnar nerves of monkeys<sup>[7]</sup>. In the CNS, however, neurons lost in the hippocampal formation of rats or alteration of the dendritic orientation of pyramidal cells in the neocortex of rats are never recovered with a normal protein diet<sup>[8,9]</sup>.

That behavior, however, should not be expected from all other neurons. Cell size and MP appearance in colonic neurons return to baseline after restoration of a normal protein-content diet, as shown in our previous work, in sharp contrast to CNS neurons<sup>[1]</sup>. The estimated number of myenteric neurons of the small intestine in protein-recovered animals of the same age does not differ from that of normally nourished rats<sup>[4]</sup>. The reaction to undernourishment would thus be more correctly described as a developmental delay from the morphological standpoint, but not fully recovered in functional terms.

Several ultrastructural changes have also been described after protein deprivation. Recently, we have demonstrated drastic alterations in the esophageal neurons of 21-d-old weanling rats submitted to pre- and post-natal protein deprivation, such as altered disposition of both nuclear chromatin and ribosomes in the granular reticulum, as well as a poorly developed granular component of the nucleolus. These data are further compatible with a delay in the development of the myenteric neurons<sup>[3]</sup>. However, information on the structural and ultrastructural characteristics of the MP of the esophagus specifically remains unknown as to whether these modifications are reversible after adequate protein rehabilitation in the early postnatal period. Therefore, in the present work, we evaluated some of the histochemical, immunohistochemical, and ultrastructural features of the myenteric neurons of the esophagi of protein-deprived and protein-recovered young rats (42 d old).

## MATERIALS AND METHODS

### Experimental animals

This study was conducted according to current legislation on animal experiments of the Instituto de Ciencias Biomedicas da Universidade de Sao Paulo (ICB-USP). Young adult male and female Wistar rats (200-240 g body weight) were mated during a period of 7-10 d. After conception, the females were placed in individual cages and maintained under standard conditions at 21°C with a 12-h light/dark cycle. During pregnancy, the nourished mothers (N) received an AIN-93G<sup>[10]</sup> normal protein diet and the malnourished (protein-deprived)

mothers (D) received the AIN-93G low-protein diet (5% casein) (Rhoister, Sao Paulo, Brazil). Both groups were supplied with water *ad libitum*.

Following birth, the dams and pups of both groups continued to receive their respective assigned diets. At the end of the weanling period (21 d) N and D male pups were separated from the dams and maintained on their respective diets until day 42. They were studied as N42 and D42 groups, respectively. Exactly half of the malnourished pups from the first phase (up to 21 d) received the AIN-93G normal protein diet from day 22 to 42 and formed the protein-recovery group, R42.

The animals from all groups (N42, D42 and R42) were weighed, euthanized with hypnol (Fontoveter, Sao Paulo, Brazil) and had their esophagi entirely removed. After measurement of the surface area using a planimeter<sup>[11]</sup> (OTT, Germany), the esophagi were processed using the following techniques.

### Histochemical nicotinamide adenine dinucleotide (NADH)-diaphorase reaction

NADH-diaphorase histochemistry was employed as our "pan-neuronal" marker for the MP; the controversy about the ideal neuronal marker has not been satisfactorily settled and shall not be addressed here<sup>[11]</sup>. Five animals from each group were used for NADH-diaphorase reaction histochemistry<sup>[12,13]</sup>. After being washed in Krebs solution (120 mmol/L NaCl, 5 mmol/L KCl, 25 mmol/L NaHCO<sub>3</sub>, 1.2 mmol/L NaH<sub>2</sub>PO<sub>4</sub>, 1.2 mmol/L MgSO<sub>4</sub>, 2.5 mmol/L CaCl<sub>2</sub>, and 11.5 mmol/L glucose), the oral portion of each esophagus was ligated with cotton threads and filled with Krebs solution using a syringe needle introduced in the lumen. When the walls of the viscera were slightly distended, the needle was withdrawn and a ligature was performed in the aboral section. After incubation in Krebs solution at room temperature for 15-30 min, the specimens were transferred to a permeabilizing agent (0.3% Triton-X in Krebs solution) for 90 s and then washed in three 10-min cycles with Krebs solution.

The esophagi were incubated for 60 min at 20°C in 20 mL of a solution that contained 0.5 mg/mL nitro blue tetrazolium (Sigma, St Louis, MO, USA) in 5 mL distilled water, 5 mL 0.1 mol/L sodium phosphate buffer (pH 7.3), 10 mL distilled water and 0.5 mg/mL β-nicotinamide adenine dinucleotide (reduced form). The reaction was stopped by fixation in 4% buffered formaldehyde (24 h). Subsequently, the esophagi from all groups (N42, D42 and R42) were opened longitudinally and three circular fragments, 2 mm<sup>2</sup> each, were obtained from the oral (*Or*), medium (*Me*) and aboral (*Ab*) parts using a puncture device. The mucosa and submucosa from the fragments were then removed, washed in distilled water, arranged as whole-mount preparations in glycerol on a microscope slide, and sealed with Entellan (Merck KGaA, Darmstadt, Germany).

### Histochemical nitrenergic neurons (NADPH)-diaphorase reaction

The histochemical NADPH-diaphorase reaction<sup>[14,15]</sup> was

performed in five esophagi from each animal group (N42, D42 and R42). The specimens were washed in Krebs solution and filled with 4% paraformaldehyde in phosphate buffer pH 7.4. After ligation, the oral and aboral parts from each esophagus were immersed in the same fixative solution for 2 h at 4°C, washed in phosphate-buffered 0.9% NaCl for 2.5 h, and incubated in medium that contained 1 mg/mL  $\beta$ -NADPH (reduced form; Sigma) in phosphate buffer for 35 min. Thereafter the *Or*, *Me* and *Ab* circular fragments were obtained from each esophagus and prepared as whole-mount preparations as mentioned above.

### Demonstration of acetylcholinesterase (AChE) activity

In an attempt to characterize further the cytoarchitecture of the MP, indirect detection of cholinergic neurons was attempted by demonstration of AChE activity<sup>[3]</sup>. Three esophagi from each group (N42, D42 and R42) were subjected to the direct coloring method to demonstrate AChE<sup>[16-18]</sup>. The specimens were filled with 4% paraformaldehyde in phosphate buffer (pH 7.4), ligated at their oral and aboral limits, and immersed in the same fixative solution for 2 h at 4°C. After this period, the esophagi were opened and the *Or*, *Me* and *Ab* circular fragments incubated overnight at 4°C in solution A - hyaluronidase (Hialozime; Apsen, Brazil), Krebs solution and tetraiso-propylpyrophosphoramidate (Sigma). The fragments were then washed in Krebs solution and further incubated overnight at 4°C in a solution that contained 50% of solution A plus 0.17 mol/L acetylthiocholine iodide, 0.1 mol/L phosphate buffer (pH 7.1), 100 mmol/L sodium citrate, 30 mmol/L cupric sulfate, 5 mmol/L potassium ferricyanide and 0.3% Triton X-100. The mucosal and submucosal layers were removed and the fragments were dehydrated in an increasing alcohol series (70%-100%), immersed in benzene for 20 min, and mounted on microscope slides with Entellan.

### Immunohistochemistry

Vasoactive intestinal peptide (VIP) staining<sup>[19]</sup> was performed on three fresh segments of esophagus (approximate area: 3 mm<sup>2</sup>). Segments were removed from three animals each of the N42, D42 and R42 groups and placed in PBS (0.15 mol/L NaCl in 0.01 mol/L sodium phosphate buffer, pH 7.2) that contained nicardipine (10<sup>-6</sup> mol/L; Sigma) to inhibit tissue contraction. The specimens were then pinned out tautly, mucosa side down, onto a balsawood board and fixed overnight at 4°C in a paraformaldehyde solution (0.2 mol/L, pH 7.3). The specimens were then cleared with three 10-min cycles in 100% dimethylsulfoxide, followed by three 10-min washes in PBS. All samples were stored at 4°C in PBS that contained sodium azide (0.1%). After removing the mucosa, submucosa, and circular muscular layers, the whole-mount preparations were pre-incubated in 10% normal horse serum in PBS that contained 1% Triton X-100 for 30 min at room temperature to reduce nonspecific binding and to permeabilize the tissue. Rabbit anti-VIP antibody was then used at a concentration of 1:2000. This antibody was diluted in antibody diluent (1.8% NaCl in 0.01 mol/L sodium phos-

phate buffer that contained 0.1 sodium azide). Following incubation in the primary antibody for two nights in a humid chamber at 4°C, the specimens were washed three times in PBS (10-min cycles) and then incubated for 1 h at room temperature with a fluorescence-labeled secondary antibody (Donkey anti-rabbit IgG Alexa 488 at 1:500; Molecular Probes, Eugene, OR, USA). After washing in PBS, the specimens were mounted in 0.5 mol/L sodium carbonate-buffered glycerol (pH 8.6). The specimens were finally examined for fluorescence on a Leica Microscope equipped with the appropriate filter for Alexa 488 fluorescence (set to 00 for Alexa 488). The images were captured using an Image Proplus System.

### Transmission electron microscopy (TEM)

Following systemic perfusion with a fixative solution (3% glutaraldehyde in Millonig's buffer (pH 7.2-7.4) with 0.25% tannic acid)<sup>[20]</sup>, esophagi of three animals from each group (N42, D42 and R42) were removed. Two fragments (approximately 2 mm in length) from the *Or*, *Me* and *Ab* sections were obtained from each specimen and incubated for 6 h in the same fixative solution. Specimens were subjected to post-fixation treatment in a 2% osmium tetroxide solution and embedded in adhesion medium. Ultra-thin sections were stained with uranyl acetate/lead citrate<sup>[21]</sup> and examined with a JEOL JEM-1010 (Jeol, Tokyo, Japan) electron microscope.

### Nerve cell perikarya

A semiautomatic device (Axioskop 40, AxioCam HRC, Axiovision software 4.5; Zeiss, Germany) was utilized for morphometric neuronal examination. The cross-sectional (profile) areas of 20 neuronal perikarya from each *Or*, *Me* and *Ab* circular fragment stained with NADH and NADPH were determined in each specimen at 400 × magnification.

### Statistical analysis

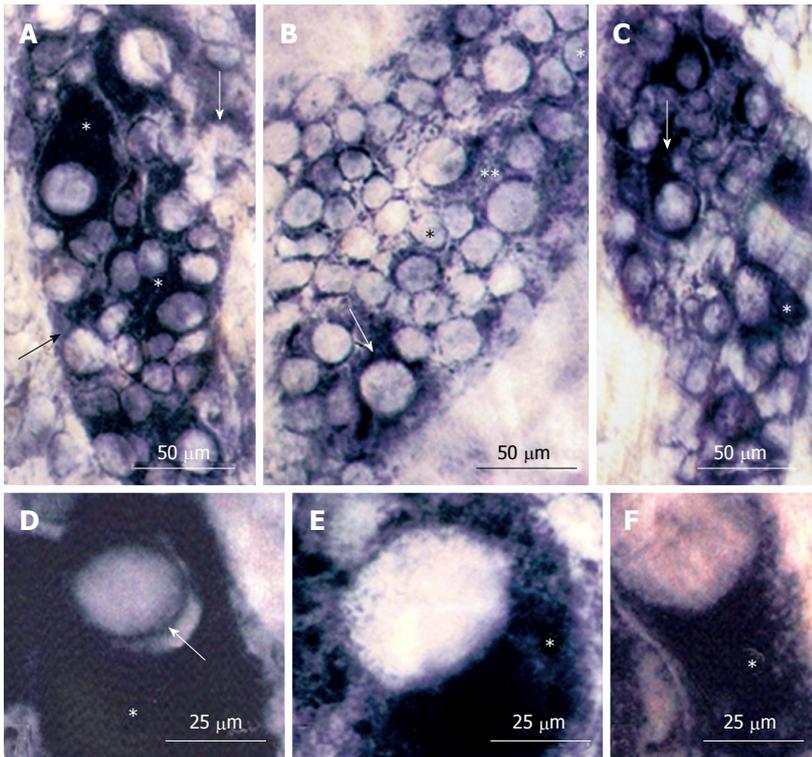

mean  $\pm$  SE were calculated and compared by analysis of variance (ANOVA), Student's *t* test, and Duncan's test for multiple comparisons as appropriate, with the level of significance set at  $P < 0.05$ <sup>[22]</sup>.

## RESULTS

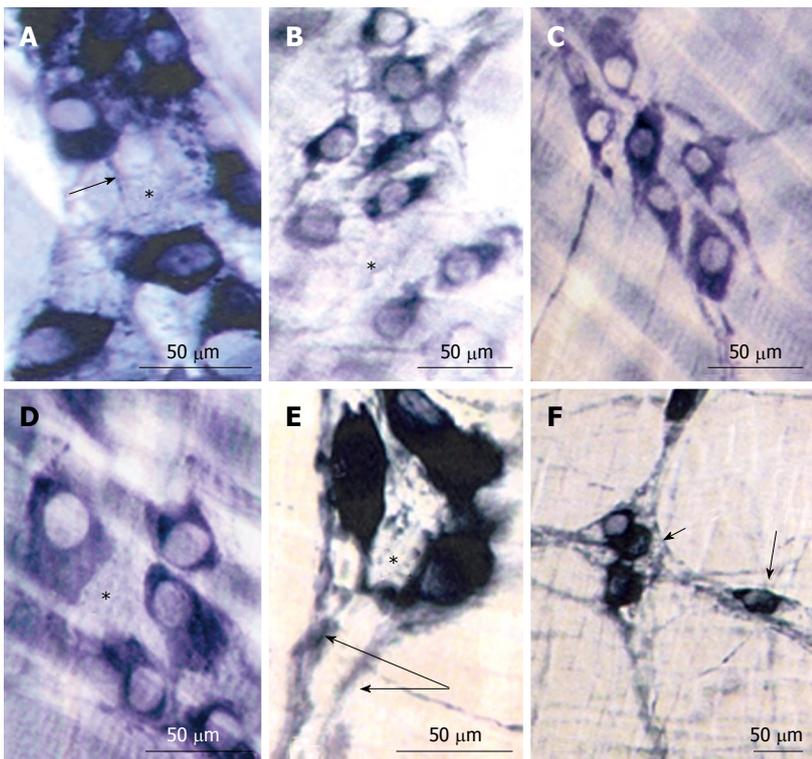

### Histochemistry (NADH, NADPH and AChE)

No significant differences were detected among the *Or*, *Me* and *Ab* esophageal segments in all groups. The NADH-diaphorase-stained whole-mount preparations of esophagi from all groups (N42, D42, R42) had myenteric neurons of varying size and reactivity (Figure 1). Most of the large and medium neurons in animals from the N42 and R42 groups had intense staining of the cytoplasm; an aspect detected in only a few large neurons of the D42 group (Figure 1A-C). Under high magnification, the dark and homogeneous aspects of the cytoplasm from N42 neurons were partially observed in R42 neurons. In contrast, the neurons from the D42 group had cytoplasm with granular aspects (Figure 1D-F).

The reactivity for NADPH-diaphorase was detected

**Figure 1 NADH-diaphorase reaction.** A: N42 group. Myenteric neurons of large and medium sizes with intensely reactive cytoplasm (\*) and neurons of diverse size weakly reactive (arrows); B: D42 group. Nuclei of small neurons (\*). The cytoplasm of large neurons had low (\*\*) or diffuse (arrow) reactivity; C: R42 group. Note large neurons with intense (arrow) and diffuse (\*) cytoplasmic reactivity; D-F: Large neurons, respectively from N42 (D), D42 (E) and R42 (F) groups. The well-delineated nucleus (arrow) from N42 was not clearly detected in malnourished and protein-recovered animals. Compare the patterns of reactivity of the cytoplasm (\*).

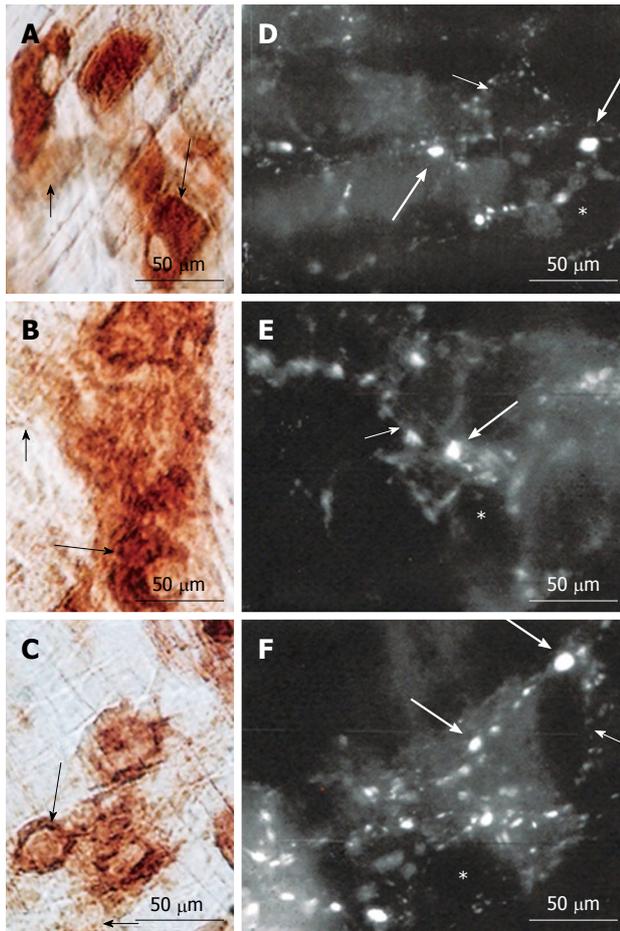

**Figure 2 NADPH-diaphorase reaction.** A and D: N42 group. Note that most of the myenteric neurons were intensely reactive and spaces inside the ganglia (\*) are surrounded by thin neuronal branches (arrow); B and E: D42 group. Neurons with diverse intensities of reaction, spaces inside the ganglia (\*) and thick neuronal meshes (double-arrow) were evident; C and F: R42 group. Neuronal meshes surrounded the ganglion (small arrow). Some neurons were detected inside the meshes (large arrow).

in both neurons and meshes from the MP. The space inside the myenteric ganglia of all groups (N42, D42, R42) was occupied by non-nitroergic neurons (Figure 2). The cytoplasm from most of the neurons from the N42 group exhibited intense NADPH-diaphorase staining with only a few showing weaker staining (Figure 2A and D). The variability of intensity distinguished the cytoplasm of the myenteric neurons from the D42 and R42

groups, however, more neurons from the R42 group exhibited darker staining (Figure 2B and C). The intra- and interganglionic meshes were detected in all groups (Figure 2A, E and F).

The myenteric ganglia from all groups contained neurons either strongly or weakly reactive for AChE. Qualitatively, the reactivity was diffuse in the neurons from the D42 and R42 groups (Figure 3A, C and E).

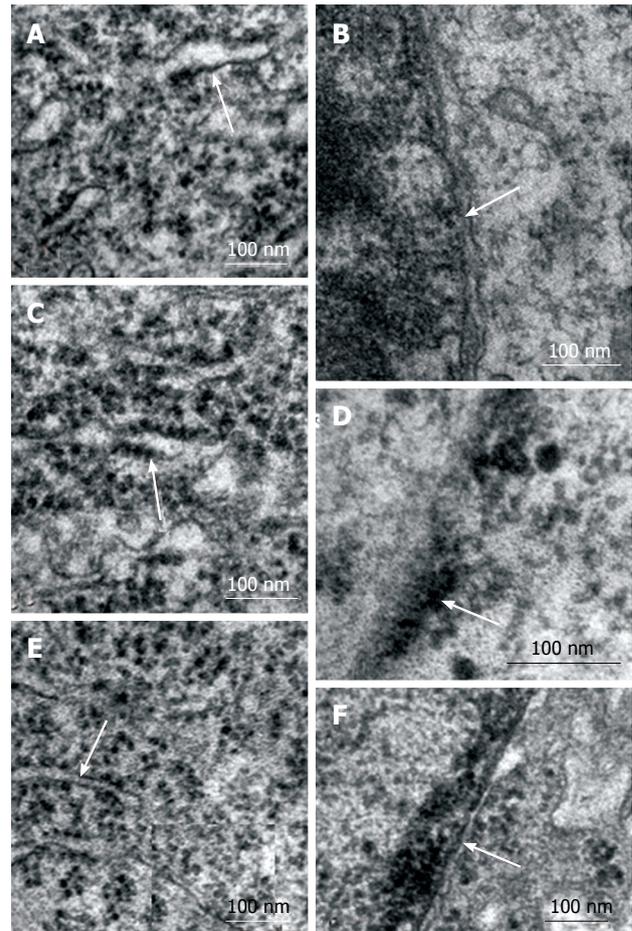

**Figure 3** AChE reactive (A, C and E) and VIP immunoreactive (B, D and F) myenteric neurons. Intensely (large arrows) and weakly (small arrows) reactive neurons were observed in N42 (A), D42 (C) and R42 (E) groups. Large and small varicosities (respectively, large and small arrows) were present around the neurons (\*) in the N42 (B), D42 (D) and R42 (F) groups. Apparently, the varicosities were more abundant in the N42 and R42 groups.

### Immunohistochemistry

The immunohistochemical reaction for VIP revealed the presence of large and small varicosities around the shadows of the neuron perikarya. The low density of these structures in ganglia of D42 animals was evident. No apparent differences were observed between the N42 and R42 groups concerning these structures (Figure 3B, D and F).

### TEM

Specific organelles of the myenteric neurons were selected for comparative analysis using TEM. The granular reticulum from all groups exhibited ribosomes aligned on the outer surface of the regularly arranged membrane of the cisternae (Figure 4A, C and E). The nuclear double membrane and the perinuclear cisterna were well defined in the myenteric neurons from the N42 and R42 groups and the electron-dense nuclear chromatin was detected on the inner membrane of the nuclear envelope (Figure 4B and F). In several neurons of the D42 group, the double membrane of the nuclear envelope and the perinuclear cisterna were not distinguishable (Figure 4D). The euchro-

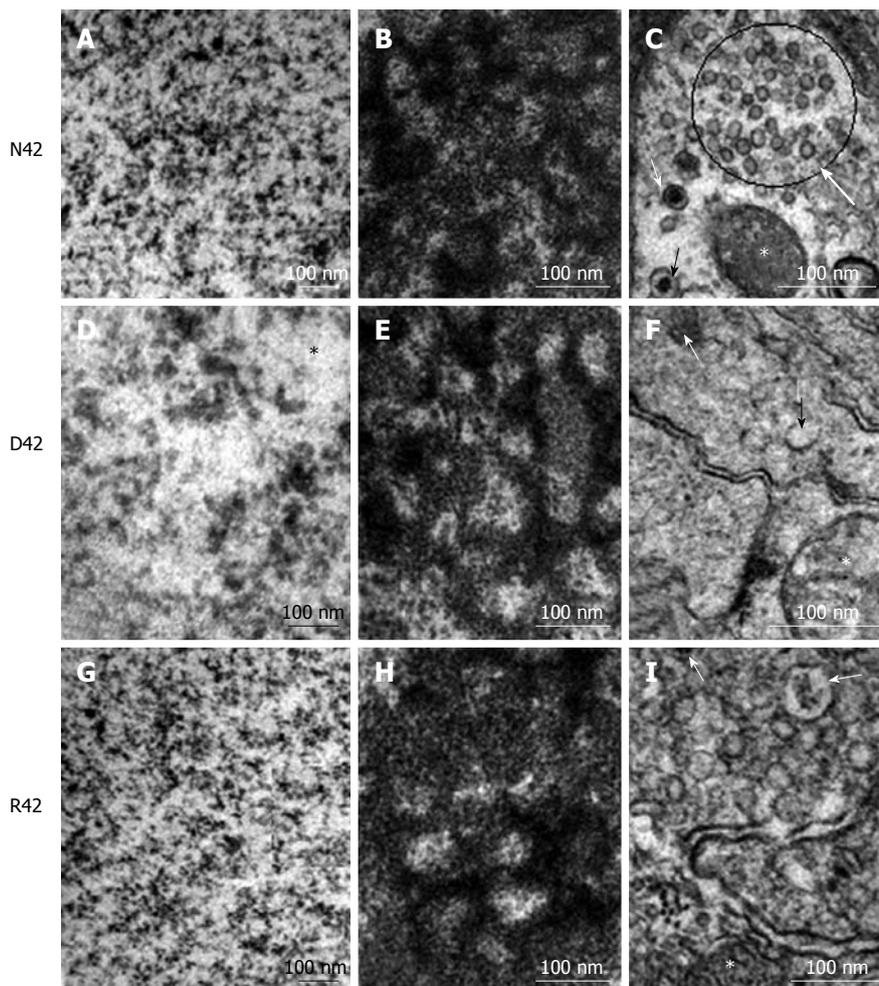

**Figure 4** Electron micrographs of myenteric neurons from N42 (A and B), D42 (C and D), and R42 (E and F) groups. A: In all groups, the granular reticulum showed that the ribosomes were aligned on the outer surface of the regularly arranged membrane (arrows). A well-defined nuclear double membrane and perinuclear cisterna were observed in neurons from N42 (B) and R42 (F) rats. Note that these structures were not delineated in the neurons of malnourished animals (D).

matin was homogeneously dispersed in the nucleus of myenteric neurons from all groups (Figure 5A, D and G). No group-specific differences in the granular and fibrillar parts of the nucleoli were detected (Figure 5B, E and H). Agranular, large, and small granular vesicles were observed in the neurons from all groups. However, large granular vesicles were only delineated in the N42 group. In the D42 and R42 groups, many of the neurons had ill-defined membranes and showed a weak electron-dense content (Figure 5C, F and I).

### Nerve cell perikarya

In all groups, most of the NADH-stained neurons had perikarya that ranged in cross-sectional area from 200 to 400  $\mu\text{m}^2$  (percentage of neurons in that range: 62%, 78% and 59%, respectively) with the following respective mean  $\pm$  SD: 375  $\pm$  169, 323  $\pm$  134 and 393  $\pm$  133  $\mu\text{m}^2$ . The perikarya of nitroergic neurons (NADPH+) also ranged from 200 to 400  $\mu\text{m}^2$  for the N42, D42 and R42 groups (66%, 67%, 62%, respectively), with the following

**Figure 5 Electron micrographs of myenteric neurons.** A, D and G: Nuclear chromatin (\*) homogeneously distributed; B, E and H: Granular and fibrillar parts of the nucleolus were similarly arranged; C, F and I: Many small vesicles (circle) were detected in neurons from all groups. Compare the intensity of large granular vesicles among the groups (arrows) (\* mitochondria).

respective mean  $\pm$  SD:  $376 \pm 118$ ,  $366 \pm 132$  and  $382 \pm 117 \mu\text{m}^2$ . No statistically significant differences were detected among any of the groups with respect to the neuronal area profiles for the NADH and NADPH reactions.

## DISCUSSION

In our previous work, we examined the effects of malnutrition on the MP of diverse regions of the gut in 21-d-old weanling rats subjected to pre- and postnatal protein deprivation using diverse time-honored histochemical methods<sup>[1-3,23-25]</sup>. We observed a decrease of approximately 15% in the cross-sectional areas of neurons in the colon of malnourished rats relative to normal-fed controls<sup>[1]</sup>. Average perikaryon area of myenteric neurons in the small intestine of malnourished animals was approximately half that observed for the normally fed controls. Moreover, most of the neurons that were reactive to NADH-diaphorase from malnourished animals showed weaker cytoplasmic staining<sup>[2]</sup>. In the esophagus, perikaryon area of myenteric neurons did not differ significantly between normally fed and protein-deprived animals. Nevertheless, the reactivity for AChE was clearly reduced in neurons from protein-deprived animals<sup>[3]</sup>.

At a later stage of MP development (42 d old), we

observed less NADH-diaphorase staining in large intestinal neurons from protein-deprived rats than in the controls, although the average size of the nerve cell perikaryon area was not significantly different from that of normally fed animals<sup>[1]</sup>. In the small intestine of rats of the same age, there was no detectable difference in the average perikaryon area of myenteric neurons between normally fed and protein-deprived animals. However, AChE histochemical activity and choline acetyltransferase (ChAT) immunoreactivity showed that most ganglionic neurons from the protein-deprived animals were unstained or moderately stained<sup>[4]</sup>. Similar aspects were detected in the MP from the duodenum of 90-d-old rats given protein and vitamin B complex. The effects did not alter the mean perikaryon area but did considerably reduce the reactivity of the myenteric neurons for NADPH-diaphorase (nitroergic neurons)<sup>[5]</sup>.

The absence of neuron cell profile reduction in protein-deficient animals (D42) shown in the present study is in line with previously described data using the esophagus of 21-d-old protein-deficient animals<sup>[3]</sup>. This observation also fits with data from other viscera of the digestive tract, such as the small intestine, where the neuron cell profiles were similar in 42-d-old nourished, malnourished and protein-recovered rats<sup>[4]</sup>. However, the myenteric neurons from the large intestine of protein-deprived 42-d-old rats

had a smaller mean perikaryon area than that normally found in fed and protein-recovered animals<sup>[4]</sup>. This finding corroborates data from 3-mo-old rats subjected to inadequate nutrition over a long time period. A decrease in the perikaryon area of myenteric neurons has been verified in the duodenum and ascending colon of these animals<sup>[26,27]</sup>. Mean area of neuronal perikarya does not change with age<sup>[28,29]</sup>. However, exposure of the myenteric neurons to other factors, such as dietary sodium intake and chagasic infection, effectively causes an irreversible hypertrophy of the neuron perikaryon area<sup>[30,31]</sup>. Although myenteric neurons may react differently depending on the extrinsic (i.e. dietary) and/or intrinsic (i.e. aging) factors they are exposed to, early protein recovery can reestablish their mean perikaryon area<sup>[4]</sup>. This has also been recently confirmed in the CNS (personal communication from Dr. Liberti EA).

Most of the reactive neurons in the D42 and R42 groups exhibited a diffuse pattern of AChE staining with a predominance of weakly reactive cells in the D42 group. Similar findings were verified in myenteric neurons from the colon of a chagasic mouse<sup>[32]</sup> and this fits with our previous observations from esophagi of 21-d-old malnourished animals. In that study, we only observed a few myenteric neurons that showed intense AChE staining in protein-deprived animals<sup>[3]</sup>. In the present study, although the myenteric neurons from the N42 and R42 animals had similar mean perikaryon areas assessed with AChE staining, the pattern of reactivity of neurons from the R42 group resembled that of the D42 group. This result is not in accordance with observations from the small intestine. In the small intestine, we have detected the same pattern of reactivity for nourished and protein-recovered animals when the myenteric neurons are immunohistochemically stained for ChAT<sup>[4]</sup>.

We observed similar patterns of VIP immunoreactivity in R42 and N42 cells. In addition, the pattern of NADH and NADPH reactivity of myenteric neurons was similar to that of AChE. However, the homogeneity of the reaction for NADH detected in the cytoplasm of most neurons from the N42 group was not totally recovered in neurons of the R42 group. Moreover, although the R42 group exhibited many intensely staining neurons for NADPH, their presence was far less frequent than that for the N42 group. The ultrastructural aspects of the large granular vesicles support this assertion. Although some neurons from the R42 group exhibited electron-dense areas, most of them clearly had less dense content. In consideration of the current study, it is possible that different enteric neurotransmitter systems respond differently to the protein-recovery regimen.

The deleterious effect of protein deficiency on myenteric neurons of the esophagus has not been previously considered. Our data from protein-deprived (D42) and protein-recovered (R42) animals suggest that protein deficiency retards neuronal maturation in a manner that is to some extent, but far from completely recovered with 20 d of protein reinstatement.

## COMMENTS

### Background

Malnutrition affects the myenteric plexus (MP) of the gastrointestinal tract in different manners according to location. Definite changes in neuronal population, morphometry and morphology have been described.

### Research frontiers

It is not known whether morphometrical and morphological parameters return to normal after adequate refeeding, that is, whether modifications induced by malnutrition are permanent.

### Innovations and breakthroughs

The present study shows that postnatal refeeding of perinatally malnourished rats restores almost all of the normal characteristics of the neurons of the MP of the esophagus.

### Applications

The present study suggests that adequate nutrition can restore almost all of the changes induced by malnutrition on MP neurons. Changes in malnourished individuals should thus be reverted with adequate nutrition with hopefully significant clinical impact.

### Peer review

The manuscript by Dr. Greggio and co-workers describes the evaluation of myenteric neurons from esophagi of young rats. They investigated normal, protein-deprived and protein-recovered groups of rats. This is an extension to studies previously done by this group and others, and an important aspect previously not done is the investigation of whether the structural and ultrastructural characteristics of the MP of the esophagus are reversible. The manuscript is in general very clearly written and the data are convincing.

### Abstract

**AIM:** To explore the relationship between Cripto-1 (CR-1) and tyrosine phosphorylation STAT3 (p-STAT3) expressions in gastric cancer (GC) and gastric carcinogenesis and metastasis.

**METHODS:** The PV9000 immunohistochemical method was used to detect the expression of CR-1 and p-STAT3 in 178 cases of GC, 95 matched normal gastric mucosa, 40 chronic atrophic gastritis (CAG), 48 intestinal metaplasia (IM) and 25 dysplasia (DYS).

**RESULTS:** The positive rates of CR-1 and p-STAT3 expression were significantly higher in CAG (65.0% and 60.0%), in IM (83.3% and 77.1%), in DYS (80.0% and 68%) and in GC (71.3% and 60.1%) than in normal gastric mucosa (43.2% and 41.1%,  $P < 0.05$ ), respectively. The expressions of CR-1 and p-STAT3 (78.3% and 66.7%) were significantly higher in GC with lymph

node metastasis than in those without metastasis (53.1% and 42.9%,  $P < 0.05$ ). CR-1 expression was also related to histological and Lauren's types of GC ( $P < 0.001$ ). Furthermore, there was positive relationship between CR-1 and p-STAT3 expressions in GC ( $r_k = 0.189$ ,  $P = 0.002$ ).

**CONCLUSION:** The up-regulation of CR-1 and p-STAT3 may play important roles in gastric carcinogenesis and lymph node metastasis. CR-1 and p-STAT3 expression in GC was positively correlated, and the relevant molecular mechanism requires further investigations.

### INTRODUCTION

Human Cripto-1 (CR-1), the founder member of the epidermal growth factor-Cripto-FRL1-Cryptic family, plays an important role during early embryonic development and cellular transformation<sup>[1]</sup>. CR-1 is also an oncogenic growth factor involved in tumorigenesis through influencing cell proliferation, survival, migration

and invasion<sup>[2-4]</sup>. CR-1 is absent or in low levels in normal tissues but over-expressed in most malignant tumors, such as breast, colon, stomach, pancreas, lung, cervix and ovary cancers, which is being assessed as a tumor-specific target for immunotherapy<sup>[1,5]</sup>. *STAT3*, a well recognized oncogene, is an important member of the STAT family that are normally inactive within the cytoplasm and become activated by tyrosine phosphorylation in response to cytokines and growth factors<sup>[6]</sup>. Its signal pathway is closely associated with the proliferation, differentiation and apoptosis, and constant activation of *STAT3* can promote cell proliferation and carcinogenesis<sup>[7,8]</sup>. Given the importance of CR-1 over-expression and *STAT3* activation in carcinogenesis, we investigated the expression and clinicopathological significance of CR-1 and phosphorylation *STAT3* (p-*STAT3*) in gastric cancer (GC), and also explored the relationship between abnormal expressions of the two oncoproteins in GC.

## MATERIALS AND METHODS

### Clinicopathological data and tissue microarray construction

Surgically resected GC specimens were collected from the First Affiliated Hospital of China Medical University, including 178 cases of GC, 95 matched normal gastric mucosa (obtained at > 5 cm apart from the edge of primary tumor focus), 40 chronic atrophic gastritis (CAG), 48 intestinal metaplasia (IM), and 25 dysplasia (DYS). There were 121 males and 57 females. The mean age of patients was 61 years. According to Borrmann's classification, gross types of primary tumors were classified as follows: 4 cases of Borrmann I, 22 cases of Borrmann II, 140 cases of Borrmann III, and 12 cases of Borrmann IV. In the light of the WHO's histological classification of GC, 178 cases were classified as follows: 2 papillary adenocarcinoma, 9 well and 65 moderately and 74 poorly differentiated adenocarcinoma, 3 undifferentiated adenocarcinoma, 19 mucinous adenocarcinoma and 6 signet ring cell carcinoma. Samples were fixed in 10% formalin, embedded in paraffin, cut into 4  $\mu$ m thick sections and constructed in blocks for tissue microarray. All the samples were evaluated by two experienced pathologists for diagnosis. None of the patients had received chemotherapy or radiation therapy preoperatively.

### Immunohistochemistry

Expression of CR-1 and p-*STAT3* in GC, precancerous lesions and normal gastric mucosa were detected using an IHC method. The PV-9000 kit was purchased from Beijing Zhongshan Golden Bridge Biotechnology Company. Mouse monoclonal antibody against human CR-1 was from the R&D systems (working dilution 1:80). Rabbit monoclonal antibody against human p-*STAT3* was from the Signalway Antibody (working dilution 1:25). All procedures were implemented according to the manufacturer's instructions. For negative controls, sections

were treated with 0.01 mol/L phosphate-buffered saline instead of primary antibodies.

### Immunohistochemical staining evaluation

Specific immunoreactivity of CR-1 protein was located in the cytoplasm, while p-*STAT3* protein was located in the nucleus and cytoplasm. Two hundred cells from two selected representative fields of each section were counted by two independent observers for the determination of their immunostaining intensity. Staining intensity (A) was classified as 0 (negative), 1 (weak), 2 (moderate) and 3 (strong). The percentage of positive cells (B) examined in 200 cells were divided into 0 (< 5%), 1 (5%-25%), 2 (26%-50%), 3 (51%-75%) and 4 (> 75%). According to the product of A and B, the IHC result was classified as 0, negative (-); 1-4, weakly positive (+); 5-8, moderately positive (++) and 9-12, strongly positive (+++).

### Statistical analysis

Statistical analysis was performed using SPSS 11.5 Package, and  $\chi^2$  test, Fisher's exact test and Kendall's *tau-b* test were used to differentiate the rates of different groups and test the correlation between the two factors.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Expression of CR-1 in normal gastric mucosa, CAG, IM, DYS and GC

The immunoreactivity of CR-1 protein was located diffusely in the cytoplasm. The positive rates of CR-1 presence in CAG (65.0%, 26/40), IM (83.3%, 40/48), DYS (80.0%, 5/25) and GC (71.3%, 127/178, Figure 1A) were significantly higher than that in normal gastric mucosa (43.2%, 41/95, Figure 1B), respectively,  $P < 0.05$ ; there was no statistically significant difference in CR-1 expression between DYS and GC ( $P = 0.246$ ), but the positive rate of CR-1 in IM was significantly higher than that in GC (Table 1).

### Expression of p-STAT3 in normal gastric mucosa, CAG, IM, DYS and GC

The immunoreactivity of p-*STAT3* protein was located in the nucleus and cytoplasm. The positive rates of p-*STAT3* expression in CAG (60%, 24/40), IM (77.1%, 37/48), DYS (68.0%, 17/25) and GC (60.1%, 107/178, Figure 1C) were significantly higher than that in normal gastric mucosa (41.1%, 35/95, Figure 1D), respectively,  $P < 0.05$ . There was no significant difference in p-*STAT3* expression among IM, DYS and GC ( $P = 0.087$ ,  $P = 0.103$ , Table 2).

### Correlation between CR-1, p-STAT3 expression and clinicopathological features of GC

Tables 3 and 4 showed the correlation of immunohistochemical (IHC) expression of CR-1 and p-*STAT3* with clinicopathological parameters. Statistical analysis showed

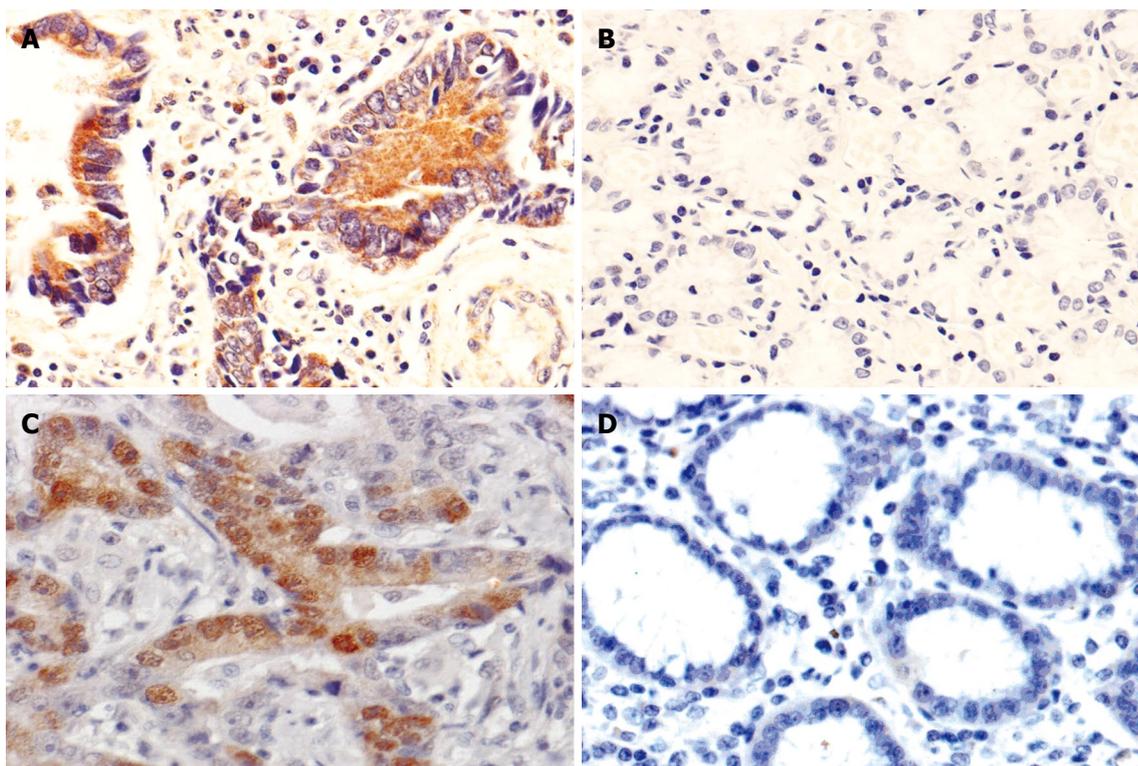

Figure 1 Expression of Cripto-1 (CR-1) and phosphorylation STAT3 (p-STAT3) in gastric cancer (GC) (A, C) and normal gastric mucosa (B, D). IHC PV9000 × 400.

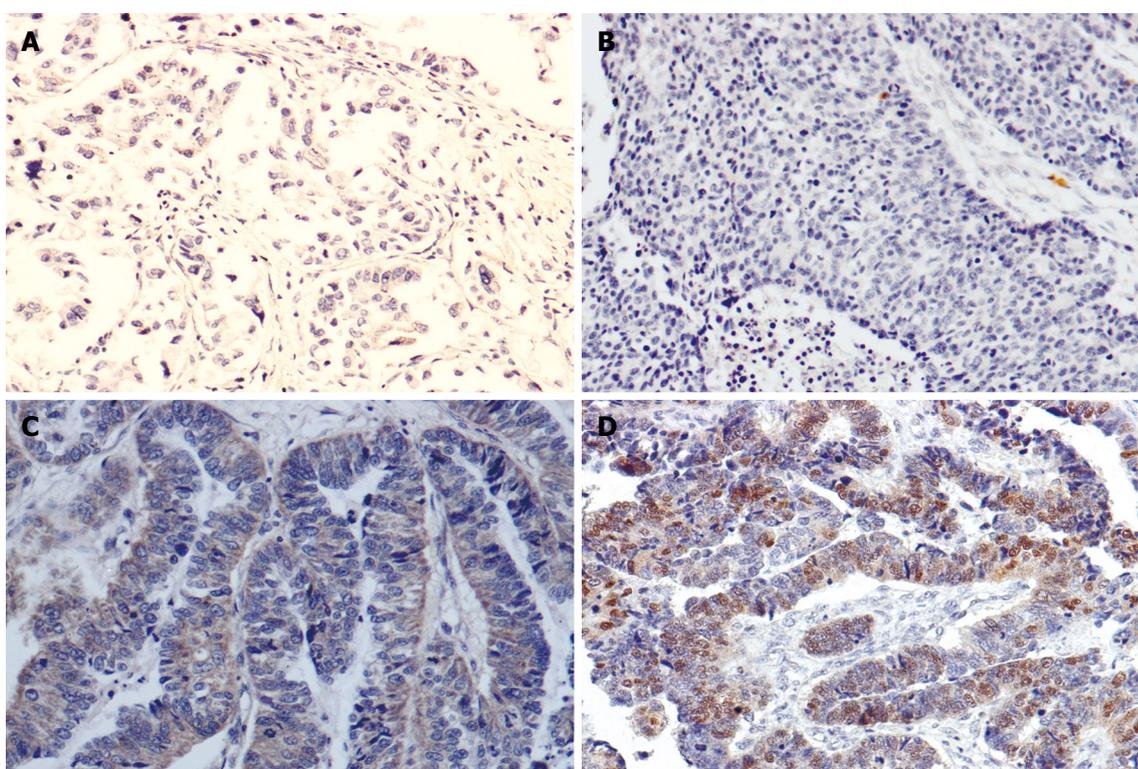

Figure 2 Expression of CR-1 and p-STAT3 in GC without lymph node metastasis (A,B) and with lymph node metastasis (C,D). IHC PV9000 × 200.

the expression of CR-1 was related to histological differentiation ( $P < 0.001$ ), Lauren's types ( $P < 0.001$ ) and lymph node metastasis ( $P = 0.006$ ) (Figure 2A and C), but not related to the age and gender of patients, or Bor-

rmann's classification of GC. There was no relation between p-STAT3 expression and gender, age, Borrmann's classification, histological types or Lauren's types, but p-STAT3 expression was significantly higher in tumors

with lymph node metastasis (66.7%) than in those without metastasis (42.9%),  $P < 0.05$  (Figure 2B and D).

**Correlation between expressions of CR-1 and p-STAT3 in GC**

The positive relationship was observed between CR-1 and p-STAT3 expression in GC ( $r = 0.189$ ,  $P = 0.002$ ) (Table 5).

**DISCUSSION**

Human CR-1, also known as teratocarcinoma-derived growth factor-1 (TDGF-1), was originally isolated and cloned from a human NTERA-2 teratocarcinoma cDNA library and was classified among the epidermal growth factor (EGF) family of peptides due to amino acid sequence similarities within the EGF-like domain<sup>[9]</sup>. CR-1 maps to human chromosome 3p21.3 and encodes a 188-amino acid glycosylphosphatidylinositol-linked glycoprotein. CR-1 protein contains a signal sequence, a characteristic EGF-like domain, a second cysteine-rich region motif (CFC domain), and a hydrophobic COOH-terminus<sup>[11]</sup>. Several findings suggested that CR-1 can specifically bind to Glypican-1, a membrane-associated heparan sulfate proteoglycan, and activate the tyrosine kinase c-Src, triggering the mitogen-activated protein kinase and Akt signaling pathways and then promote cell proliferation, survival, migration, and invasion<sup>[4,10]</sup>. In addition, by forming complex with activin and growth factor  $\beta$  (TGF- $\beta$ ) ligand and the receptor, CR-1 inhibited activin and TGF- $\beta$ -signaling, while activin and TGF- $\beta$  are potent inhibitors

of cell growth in various target tissues<sup>[11,12]</sup>. Disruption of their signaling was associated with carcinogenesis. CR-1 may be a potential target for therapy in human malignancies<sup>[5]</sup>. In fact, anti-CR-1 antisense oligonucleotides or neutralizing blocking anti-CR-1 monoclonal antibodies have been shown to strongly inhibit the *in vitro* and *in vivo* growth of human breast, colon, ovarian, testicular, and leukemia carcinoma cells<sup>[5,13,14]</sup>.

Bianco *et al.*<sup>[15]</sup> determined CR-1 plasma levels using a sandwich-type ELISA in 21 healthy volunteers, 54 patients with breast cancer, 33 patients with colon carcinoma, and 21 patients with benign breast lesions. Very low levels of CR-1 were detected in the plasma of healthy volunteers ( $0.32 \pm 0.19$  ng/mL). A significant increase in the levels of plasma CR-1 was found in patients with colon carcinoma ( $4.68 \pm 3.5$  ng/mL) and in patients with breast carcinoma ( $2.97 \pm 1.48$  ng/mL,  $P < 0.001$ ), indicating that measurement of plasma CR-1 level can help in early detection of malignancies. Similar observations were made in IHC analysis and real-time reverse transcription-PCR detection. Zhong *et al.*<sup>[16]</sup> evaluated CR-1 expression in 118 cases of GC, and found that the positive rate of CR-1 was associated with lymph node metastasis, liver metastasis and late TNM stage ( $P < 0.05$ ). Our IHC investigation showed that the expression of CR-1 in CAG, IM, DYS and GC was significantly higher than that in normal gastric mucosa, suggesting the over-expression of CR-1 may contribute to malignant transformation of the gastric mucosa. We speculated that CR-1 may play an important role as a tumorigenic factor and early gastric tumorigenic molecule during gastric carcinogenesis. In

Total	71	69	23	15	178

$r_s = 0.189, P = 0.002.$

IM, the positive rates of CR-1 was significantly higher than in normal gastric mucosa ( $P < 0.05$ ), and in GC of the intestinal type was significantly higher than that in the diffused type ( $P < 0.001$ ), indicating that CR-1 may be involved in the occurrence of intestinal type of GC. The expression of CR-1 in the well-to-moderately differentiated cancer group was higher than in the poorly differentiated cancer group ( $P < 0.001$ ), which showed that CR-1 expression was correlated with differentiation of GC. Moreover, our results showed a positive correlation between CR-1 expression and lymph node metastasis, in GC with lymph node metastasis, the positive rates of CR-1 was significantly higher than that without metastasis ( $P < 0.05$ ), which was consistent with the reported findings<sup>[16]</sup>, indicating that CR-1 may participate in the development and lymph node metastasis of GC. CR-1 can act as a prognostic indicator for GC patients.

STAT3 maps to human chromosome 2q13-14.1 and encodes 750-795 amino acids protein. STAT3 protein contains six basic domains: an N-terminal conserved sequence, a helix domain, a DNA binding domain, a joining region, a Src homology 2 domain (SH2) and a transcription activation domain. The SH2 domain, being most conserved region in STAT3, acts as the cardinal part in STAT3 function by participating in tyrosin phosphorylation. STAT3 is mainly located in the cytoplasm when the cells are in resting state. Upon induction (activation) of tyrosine phosphorylation by a wide variety of cytokines or growth factors, STAT3 is activated and forms p-STAT3. p-STAT3 dimerizes and translocates to the nucleus, further regulating transcription of target genes<sup>[17,18]</sup>. Many reports have shown that p-STAT3 is abnormally activated in most malignant tumors, including squamous cell carcinoma of the head and neck, breast and GCs<sup>[7,19,20]</sup>. Lee *et al.*<sup>[20]</sup> detected p-STAT3 expression in 307 cases of GC, correlative analyses between p-STAT3 and clinical parameters demonstrated a positive correlation with prognosis of patients with GC. In this study, we found that the expression of p-STAT3 in CAG, IM, DYS and GC was significantly higher than that in normal gastric mucosa ( $P < 0.05$ ), but there was no significant difference in p-STAT3 expression between DYS and GC, suggesting that DYS of gastric mucosa with p-STAT3 abnormal activation has a canceration tendency, and p-STAT3 may be involved in the early events of gastric carcinogenesis. There was no relation between p-STAT3 expression and gender,

age, Borrmann's types, histological types or Lauren's types, but p-STAT3 expression was significantly higher in GC with lymph node metastasis than without metastasis ( $P < 0.05$ ), which suggested that the level of p-STAT3 expression may indicate the potential for lymph node metastasis and facilitate the prognostic judgment of GC.

CR-1 can induce activation of the cytoplasmic tyrosine kinase c-Src through specifically binding to Glypican-1<sup>[21]</sup>, and also can indirectly interact with epidermal growth factor receptor (EGFR) to promote cell survival and proliferation<sup>[22]</sup>; STAT3 can be activated by both EGFR and c-Src<sup>[23-25]</sup>. Based on the previous findings mentioned above and the results in our study that there is a significant association between CR-1 expression and p-STAT3 activation in GC ( $r_s = 0.189, P = 0.002$ ), we presume that STAT3 may be the downstream molecule of CR-1, and over-expressed CR-1 protein participated in occurrence and development of GC through activating STAT3 signaling pathway. The relevant molecular mechanism requires further investigations.

In conclusion, CR-1 and p-STAT3 may take part in the occurrence, development and metastasis of GC, which can provide theoretical foundation for early diagnosis and judging the prognosis of GC. We discovered that the CR-1 expression in GC was positively related to p-STAT3 expression. These findings provide new insights into understanding the molecular mechanism involved in gastric carcinogenesis and progression, and may lead to the development of new approaches for early detection and effective therapy. However, whether CR-1 and p-STAT3 collaborate to contribute to gastric carcinogenesis and development need further studies.

## COMMENTS

### Background

Gastric cancer (GC) is one of the malignant diseases with highest incidence and mortality rates and it is of great significance to investigate the mechanisms behind the occurrence and development of GC. The over-expression of Cripto-1 (CR-1) and phosphorylation STAT3 (p-STAT3) has been shown to play an important role in the tumorigenesis and cancer progression. Therefore, the exploration into the correlation and significance of the expression of CR-1 and p-STAT3 in GC and precancerous lesions may sheds a new light on early detection and therapy of GC.

### Research frontiers

CR-1 and p-STAT3 have been shown to exert oncogenic effects in various human neoplasms. In this study, the authors investigated the expression of CR-1 and p-STAT3 proteins in atrophic gastritis, normal mucosa, intestinal metaplasia (IM) and GC to explore its correlation with gastric carcinogenesis and metastasis. They found that over-expression of CR-1 and p-STAT3 may take part in early carcinogenesis and metastasis of GC.

### Innovations and breakthroughs

CR-1 and STAT3 are over-expressed in a wide range of human cancers such as gastric, colorectal and breast carcinomas, and may play a key role in cancer pathogenesis. Over-expression of CR-1 and STAT3 increases cancer cell proliferation, migration, invasion and angiogenesis. This is the first study to report that the expression of CR-1 and p-STAT3 in GC was positively correlated, and speculate that there might be a functional relationship between CR-1 and STAT3, where STAT3 might be a the downstream molecule of CR-1.

### Applications

The positive rates of CR-1 and p-STAT3 expression were significantly higher in chronic atrophic gastritis, IM, dysplasia and GC than that in normal gastric mucosa. And the expression rates of CR-1 and p-STAT3 protein was also

significantly higher in GC with lymph node metastasis when compared with those without metastasis. Detection of CR-1 and p-STAT3 protein expressions might be helpful in early detection and prognosis judgment of GC patients. In addition, CR-1 and p-STAT3 may serve as a potential therapeutic target for GC.

### Terminology

Human CR-1, also known as teratocarcinoma-derived growth factor-1 (TDGF-1), is a member of the epidermal growth factor-Cripto-FRL1-Cryptic family including mouse CR-1, cryptic *Xenopus* FRL-1, zebrafish one-eyed pinhead and chick Cripto. CR-1 functions as an oncogene involved in *in vitro* cellular transformation and enhancement of cancer cell proliferation, migration, invasion and angiogenesis. STAT3 belongs to the STAT family of signal transducers and activators of transcription, which play a critical role in mediating cellular responses to various stimuli, mainly from those of growth factors and cytokines.

### Peer review

In this study, Zhang *et al* investigated the expression of CR-1 and p-STAT3 proteins in normal mucosa, IM and GC to explore its correlation with gastric carcinogenesis and metastasis. In general, this is an interesting study with new precision on known markers for GC progression.

### Abstract

**AIM:** To assess patients' understanding for the reasons for taking 5-aminosalicylic acid or ursodeoxycholic acid as chemoprophylaxis against colorectal carcinoma associated with inflammatory bowel disease (IBD).

**METHODS:** A questionnaire-based study using a 5 point opinion scale was performed. One hundred and ninety-two patients with colitis only and 74 patients with primary sclerosing cholangitis and IBD were invited to take part.

**RESULTS:** Overall response rate was 58%. Sixty-four percent of patients claimed full concordance with chemoprophylaxis for maintenance of remission. Eighty-four percent of patients considered daily concordance

during remission to be very important. Seventy-five percent stated they understood the reasons for taking the drugs. However, only 50% of the patients were aware of any link of their condition to bowel cancer. Seventy-nine percent of patients felt their concordance and understanding would be improved if they were informed of the chemoprophylactic potential of the medication.

**CONCLUSION:** Despite good self-reported concordance, half of the patients were unaware of an association between colitis and bowel cancer. Explaining the potential chemoprophylactic benefits may enhance patients' overall concordance to 5-aminosalicylic acid and ursodeoxycholic acid and help maintain remission.

### INTRODUCTION

The risk of colorectal carcinoma (CRC) associated with inflammatory bowel disease (IBD) has long been established<sup>[1]</sup>, increasing with the duration, extent and severity

of inflammation. Primary sclerosing cholangitis (PSC) is known to be associated with colitis and an increased risk of CRC<sup>[2,3]</sup>. Over 60% of PSC patients have associated IBD, with associated increased risk of CRC as well as hepatocellular carcinoma. Five percent of patients with ulcerative colitis will go on to develop liver dysfunction, primarily cholestasis, of which 40% will develop PSC<sup>[4]</sup>. The risk of colorectal cancer in colitis patients has been estimated to be as high as 30% over 35 years in some populations<sup>[1]</sup>. There are similar rates of mucosal cell metaplasia and dysplasia in ulcerative colitis and Crohn's colitis.

5-aminosalicylic acids (5-ASAs), for example mesalazine, are the most commonly prescribed anti-inflammatory drugs used in the management of IBD<sup>[5,6]</sup>. The evidence for their chemoprophylactic use in IBD is accumulating, including case control studies<sup>[7-10]</sup>, prospective cohort studies<sup>[11,12]</sup>, and a large UK based epidemiological study<sup>[5]</sup>. The use of ursodeoxycholic acid (UDCA) as a chemopreventative agent in PSC with ulcerative colitis is now accepted practice<sup>[13]</sup>. Chemoprophylaxis with these drugs is now part of core recommendations in the treatment of colitis published in guidelines, for example guidance issued by the British society of Gastroenterology<sup>[14]</sup>. The use of 5-ASA compounds for chemoprophylaxis in ulcerative colitis patients was considered to be evidence level 2 in recent guidance published by ECCO, and UDCA for PSC patients was considered to have an evidence level 1b<sup>[15]</sup>.

Surveillance techniques for the detection of CRC and metaplastic cell changes are invasive endoscopic procedures. A systematic review of the available evidence concluded that while cancer was detected at an earlier stage through surveillance colonoscopy screening of colitis patients, there was no clear evidence of prolonged survival<sup>[16]</sup>. There was indirect evidence for screening programmes cost effectiveness, but the acceptability of colonoscopy to all patients remains an important prohibitive factor. It remains to be seen if novel techniques such as chromoendoscopy, confocal microscopy and emerging molecular markers can directly influence survival.

Chemoprophylaxis with 5-ASAs and UDCA as a means of reducing the risk of colorectal cancer to IBD and PSC/IBD patients is becoming an increasingly attractive concept. Current literature on drug concordance in IBD has been largely focussed on 5-ASA and factors influencing non-adherence<sup>[17-25]</sup>. Important factors identified include male gender, young age at diagnosis, occupation and depression<sup>[17,18]</sup>. The preparation and treatment regime for 5-ASA have also been highlighted as contributing to non-concordance and therefore poorer outcome<sup>[18-20]</sup>. All studies emphasize the importance of the physician-patient relationship and utilizing management strategies to reduce non-adherence. The concerns over 5-ASA preparations and dosing regimes are being addressed through the novel delivery of mesalazine as a once daily preparation<sup>[26,27]</sup>. Despite this and advancing knowledge of chemoprophylaxis, relatively little is known about patients' understanding of the risk of developing colitis-associated CRC and the role of 5-ASA

in reducing these risks. There is no doubt that patient education is important in not only establishing a good patient-physician working relationship, but also improving outcome through improved concordance with treatment regimes. More energy and strategies, such as the employment of specialist IBD nurse practitioners, are being used to educate patients about their conditions from the time of first diagnosis.

The aim of our study was to assess patients' understanding of the risk of developing colitis-associated CRC and their understanding of the role of 5-ASA/UDCA as part of their treatment, as well as identifying means of improving overall concordance with chemoprophylaxis, through a qualitative questionnaire-based survey and patient feedback.

## MATERIALS AND METHODS

A simple patient questionnaire comprising of seven questions using a validated five-point opinion scale, was designed. The questionnaires were altered appropriately for the PSC/IBD patients giving two similar short questionnaires. Patients were also provided with clear written instruction on how to complete questions using a five-point opinion scale and contact details if they had any further queries. Finally, they were given the opportunity to provide feedback on proposed methods we could use to improve overall concordance as well as their own opinions on the matter.

The questions assessed disease activity, the importance patients assigned to daily concordance when both symptomatic and in remission, how often they forgot to take their medication, whether they understood the reasons for being on the medication, how well their doctor had explained the reasons for taking 5-ASA/UDCA and whether they were aware that 5-ASA/UDCA may help reduce the risk of developing CRC. PSC/IBD patients were also asked whether the UDCA was to treat their liver, bowel, or both to further assess how fully they understood reasons for taking UDCA daily. The patients' opinions on ways of improving concordance were also sought. They were asked to rate how much the following proposals could improve concordance: a once-daily preparation, a clear explanation of the reasons for taking the medication and how it works from a health care professional, and being provided with evidence that 5-ASA/UDCA can reduce risk of CRC.

One hundred and ninety two patients with IBD (both Crohn's disease and ulcerative colitis patients) receiving 5-ASAs were identified from our University Hospital Birmingham IBD database and a further 74 patients with PSC and associated IBD from our Liver Medicine department records were also included. The patients in the IBD group were in clinical remission at the time of the study. The PSC/IBD group were a post-liver transplant cohort with their colon intact.

Patients were given the questionnaires to complete on a voluntary basis when they attended the out-patient department clinics. All responses were anonymised for

results analysis. Patients who were not given the opportunity to complete a questionnaire in the clinic were posted questionnaires with a stamped, addressed return envelope.

The questionnaire was approved by the hospitals Clinical governance board. Responses were processed and analysed by two of the authors using a standardised database.

## RESULTS

Response rates were 59% (114/192) and 56% (42/74) for the IBD only and the IBD/PSC cohorts, respectively. Of the 42 patients in the IBD/PSC group who responded, 5 patients were excluded from further analysis as they were not taking UDCA (1 had never been prescribed it and 4 had stopped it due to side effects), making the total for subsequent analysis 37.

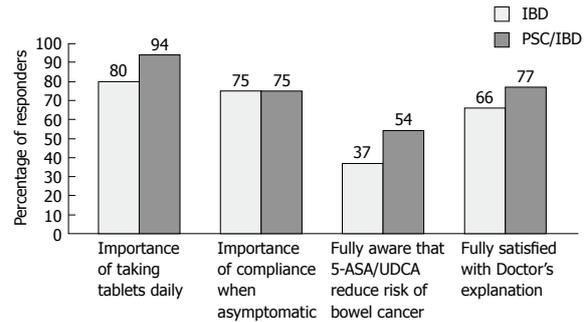

Sixty-four percent (98/151) of the total responders stated that they were fully concordant with 5-ASA/UDCA (60% IBD *vs* 78% IBD/PSC). Sixty-two percent of patients had had a flare up of symptoms in the past year, and of these, 67% reported full concordance with their medications, suggesting that disease activity may improve overall concordance.

Eighty-four percent (126/151) of patients considered daily concordance to be very important and 75% (114/151) maintained concordance to be very important while in remission, stating that they fully understood the reasons for being prescribed the medications. Sixty-seven percent (101/151) of patients felt they had been given a full explanation by their doctor for 5-ASA/UDCA maintenance treatment (66% IBD *vs* 70% IBD/PSC). Twenty percent of patients had only received a partial explanation while 13% (12% IBD *vs* 16% IBD/PSC) felt they had received no explanation from either their doctor or any health professional. A bar chart comparing the responses of the IBD cohort to the PSC/IBD cohort is shown in Figure 1.

Despite 75% of patients claiming full understanding of the reasons for 5-ASA/UDCA maintenance treatment, 50% of the total cohort reported that they were completely unaware of any link between their condition and CRC (54% IBD *vs* 37% IBD/PSC). Of the IBD/PSC cohort, only 55% of patients were aware that UDCA is protective for both bowel and liver, suggesting the patients may not have been fully informed, despite 75% believing they fully understood the reasons for taking UDCA.

Of the three methods proposed to improve overall concordance in the future, 92% of patients agreed that a once daily preparation of 5-ASA would improve their overall concordance, 87% felt that a clear and full explanation from a health professional would be beneficial, and 94% felt that it would be helpful if they were given evidence that 5-ASA would help to reduce the risks of developing colitis-associated CRC.

Methods of improving patient concordance with 5-ASA/UDCA are proposed in Table 1. Table 2 contains samples of feedback patients gave of ways that their concordance to chemoprophylactic medications could be

**Figure 1** A comparison of the IBD vs PSC/IBD cohorts. IBD: Inflammatory bowel disease; PSC: Primary sclerosing cholangitis; 5-ASA: 5-aminosalicylic acid; UDCA: Ursodeoxycholic acid.

**Table 1** The percentage of patients who agreed with three proposed methods of improving concordance with chemoprophylaxis

Proposed method to improve concordance	Agree (%)	Disagree (%)
Given evidence 5-ASA/UDCA reduces CRC risk	94	6
Once a day preparation	92	8
Clear explanation from Health Professional	87	13

5-ASA: 5-aminosalicylic acid; UDCA: Ursodeoxycholic acid; CRC: Colorectal carcinoma.

**Table 2** Some comments written by patients, including possible reasons for poor concordance and suggestions for improving concordance

- Difficult to remember when feeling well. Reminders would be useful
- Unaware of reasons for taking the medication
- Need reassurance regarding side effects
- Full explanation, counselling and education on condition
- Newsletters and workshops on developments in research and treatment
- Re-enforcement about why on treatment when it has been started and stopped in the past
- Unfortunately you cannot teach common sense if they do not stick to the prescribed dose there is not a lot you can do
- Smaller, easier to take tablets

improved. Some salient examples include “Re-enforcement about why I’m on a treatment when it has been started and stopped in the past would be useful” and “newsletters and workshops on developments in research and treatment...”.

## DISCUSSION

Patients had a high self-reported level of concordance with their medications. Our study made no attempt to verify this through biochemical testing<sup>[22]</sup>. A study using urinary analysis identified 6 (12.7%) out of 47 patients who self reported full concordance tested negative for mesalamine or its metabolite<sup>[23,24]</sup>. We did not verify patients’ concordance against the frequency of pharmacy prescription collection. These results suggest that overall concordance in our patient group may be lower than claimed.

It is clear from patients' responses that their understanding of the reasons for being on maintenance treatment and chemoprophylaxis is incomplete and that not all patients are fully informed about the risk of colitis-associated CRC. Patients need to have this information given to them by health professionals and reinforced by other resources. This information would also help IBD/PSC patients to better understand the need to continue their medication even when their condition is quiescent.

While the risk of CRC in IBD and PSC has been fully appreciated by health care professionals for decades, it is evident from our study that this knowledge is not being clearly communicated to patients. Potential obstacles may include time pressure in clinics, the physicians' reluctance to discuss cancer potential with an asymptomatic patient, or patients not retaining this information. From our unpublished data, many patients undergoing regular colonoscopy surveillance for IBD are not fully aware of the cancer association and the potential need for colectomy in the event of dysplasia detection.

Patient education has been demonstrated to improve clinical outcome in the management of diabetes mellitus<sup>[28]</sup> and can easily be applied to IBD. The role of nurse practitioners in gastroenterology, in particular IBD, is evolving. An exceedingly useful resource, they work alongside gastroenterologists in the clinics and on the wards to educate patients on their condition and treatment<sup>[29]</sup>. Additional resources for patient education include patient information leaflets in a language that is easy to interpret, support groups and relevant websites.

Reassurance with regards to the safety, efficacy and side effect profile of these medications has also been identified by our patients as an important factor to improve concordance. This observation is in keeping with the study by Loftus *et al.*<sup>[25]</sup>, who also identified a lower pill burden and less frequent dosing as important. Ninety-two percent of patients in our study believed that a once daily preparation would improve concordance. Several once daily 5-ASA preparations are now available<sup>[26,27,30]</sup>.

Optimising surveillance strategy using risk stratification and novel techniques coupled with advances in molecular markers may transform the way we manage this at-risk group. The emerging link between inflammation and cancer presents a very strong case for optimal disease control and chemoprophylaxis with 5-ASA and UDCA.

While the definitive randomised control study proving the benefit of chemoprophylaxis may remain elusive for the near future, the accumulating *in vitro*, *in vivo* and observational evidence are hard to ignore. To translate this into clinical benefit, it is important that physicians communicate these clinical rationales clearly to patients with IBD to improve the likelihood of them taking these medications even when they feel well.

## ACKNOWLEDGMENTS

Many thanks to the Gastroenterology Department for assisting in data collection in the outpatient department clinics. Thanks to Dr. Pathmakanthan for assistance with

arranging for postal questionnaires to be sent out to patients and to Dr. Hall and Dr. May for kind assistance with preparing questionnaires and distribution of questionnaires to patients.

## COMMENTS

### Background

Risk of colorectal neoplastic changes increase with length and duration of inflammation, making inflammatory bowel disease (IBD) and primary sclerosing cholangitis (PSC) patients particularly at risk of colorectal carcinoma. Management of these patients now includes chemoprophylaxis with 5-aminosalicylic acid and ursodeoxycholic acid during disease quiescence as well as symptomatic flare ups. These therapies are now endorsed in guidance on disease management such as that issued by the British Society of Gastroenterology and European Crohn's and Colitis Organisation, and is therefore accepted clinical practice, yet little is known of patient's understanding of why they are taking these therapies, their understanding of the risks of colorectal carcinoma associated with their condition and how their concordance to chemoprophylaxis may be improved.

### Research frontiers

Research is focussing on improved surveillance techniques and screening in this high risk group to try to ensure early detection of neoplastic changes. However, interventions have little impact on overall patient survival and acceptability of invasive screening procedures such as colonoscopy remains in doubt. Therefore, management focuses increasingly on chemoprophylaxis in the meantime.

### Applications

Those prescribing chemoprophylaxis to IBD/PSC patients should take the time to explain to patients the reason for starting these therapies, even during times of disease quiescence, especially the fact that inflammation is associated with a higher chance of subsequent lower gastrointestinal carcinoma and that it is therefore important to minimise the risks with chemoprophylaxis. This information should not just be given at initial consultation, but should be regularly re-enforced to improve overall concordance with chemoprophylaxis. Specialist nurses have a key role in this educational aspect of disease management and patient education should be utilised for optimal results.

### Peer review

This paper is acceptable for publication with some revision.

### Abstract

**AIM:** To evaluate whether crypt abscesses from inflammatory bowel disease (IBD) patients contain bacteria and to establish their nature.

**METHODS:** We studied 17 ulcerative colitis patients, 11 Crohn's disease patients, 7 patients with acute self-limited colitis (ASLC) and normal colonic biopsies from 5 subjects who underwent colonoscopy for colon cancer

screening. A fluorescent *in situ* hybridization technique was applied to colonic biopsies to assess the microbiota composition of the crypts and crypt abscesses.

**RESULTS:** Crypts colonized by bacteria were observed in 42.9% and 3.6% of ASLC and IBD patients, respectively ( $P = 0.019$ ). Crypt abscesses colonized by bacteria were observed in 28.6% and 0.0% of ASLC and IBD patients, respectively ( $P = 0.035$ ).

**CONCLUSION:** These results do not support the hypothesis that crypt abscesses in IBD are the result of localized dysbiosis arising from persistence of living bacteria colonizing the crypts.

### INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease (CD) are the 2 most common types of inflammatory bowel disease

(IBD). Although their pathophysiology is still unknown, the gut microbiota is considered to play a crucial role<sup>[1]</sup>. The microbiota close to the mucosa differs from the luminal microbiota<sup>[2]</sup>. We and others described a luminal and mucosal dysbiosis in IBD<sup>[3-8]</sup> including a high proportion of unusual bacteria<sup>[6,8]</sup> and a restricted microbial biodiversity<sup>[7,9]</sup>. Nevertheless, no difference in the dominant microbiota was observed between inflamed and non-inflamed mucosa in CD and UC<sup>[5,10]</sup>.

It would be of great importance to establish the early events leading to IBD onset or to perpetuation of inflammation. Crypt abscesses are early lesions observed in IBD, particularly in UC<sup>[11]</sup>, consisting of dilated crypts containing polymorphonuclear cells. They can also occur in acute self limited colitis (ASLC)<sup>[12]</sup>, collagenous and lymphocytic colitis<sup>[13]</sup>, diverticula-associated colitis<sup>[14]</sup> and diversion colitis<sup>[15]</sup>. Defensins are antimicrobial peptides secreted in intestinal and colonic crypts and recent studies pointed out a defensin secretion defect in IBD patients<sup>[16-20]</sup>. The aim of this study was to evaluate if crypt abscesses in UC, CD and ASLC patients contained bacteria and, if so, to establish their nature i.e. investigate localized dysbiosis in this specific ecosystem.

## MATERIALS AND METHODS

### Patients

We studied 35 patients with acute colitis and crypt abscesses at histological examination of colon biopsy: 17 UC patients, 11 CD patients and 7 patients with ASLC (bacteria involved: *Shigella sonnei*, *Campylobacter sp.* and no identified pathogenic bacteria in the 5 other cases). We also analyzed normal colonic biopsies from 5 subjects who underwent colonoscopy for colon cancer screening. The characteristics of the patients are described in Table 1. Rectocolonic biopsies containing crypt abscesses were analyzed.

### Tissues, histological examination and fluorescent in situ hybridization (FISH)

Histological examination and assessment of the bacterial composition of the crypts and crypt abscess microbiota were performed as previously described using FISH with one general probe (Eubacteria) and 6 group-specific probes, [*Bacteroides-Prevotella*,  $\gamma$  Proteobacteria, *Bifidobacterium*, *Clostridium coccoides*, *Faecalibacterium prausnitzii* (*F. prausnitzii*) and *Lactobacillus-Enterococcus*]<sup>[21]</sup>.

**Histological examination:** Colonic biopsy sections were deparaffined in xylene and successively rehydrated for 3 min in 100%, 96%, and 70% ethanol. They were then stained with hematoxylin and eosin for morphological assessment.

**FISH:** Prior to FISH, sections were deparaffinized, rehydrated, and postfixed in 4% paraformaldehyde for 5 min. Fixation was stopped in phosphate-buffered saline (PBS) 3  $\times$  and slides were washed twice for 1 min in

PBS 1  $\times$ . Tissue sections were incubated 10 min at room temperature with Tris-EDTA buffer containing 10 mg/mL of lysozyme and then washed using the hybridization solution (0.9 mol/L NaCl, 20 mmol/L Tris HCl, pH 8, 0.01% SDS, 30% formamide). Fixed tissue sections were then hybridized with the previous hybridization solution containing 4.5 ng/ $\mu$ L of one of the 5'-end-Cy3-labeled 16S rRNA targeted oligonucleotide probes. Hybridizations were performed at 35°C overnight in a microscope slide incubator and stringent washings were carried out at 37°C (2  $\times$  15 min) in a buffer containing 65 mmol/L NaCl, 20 mmol/L Tris HCl, pH 8.0, 5 mmol/L EDTA, and 0.01% SDS to remove nonspecific binding. The sections were mounted with Vectashield [mounting medium with 4',6'-diamidino-2-phenylindole (DAPI), Vector Laboratories, Burlingame, CA, USA]. DNA was stained with DAPI to visualize all cells.

### Detection of crypt abscess-associated-bacteria

Bacteria were visualized with an epifluorescence microscope Leica DMRB using Cy3- and DAPI-specific filters at 100  $\times$ , 400  $\times$ , and 1000  $\times$  magnification and images were captured with Leica DFC 300 FX camera and FW 4000 software (Leica microsystemes SAS, Rueil-Malmaison, France). The entire mucosal surface (crypts and crypts abscess) of each colonic biopsy section was examined for the presence of bacteria. Pure cultured bacteria belonging to each group were hybridized as positive and negative controls for the FISH procedure.

### Statistical analysis

We first performed a "patient analysis" considering that a patient had colonized crypts or crypt abscesses if at least one of his crypts or crypt abscesses was colonized

**Figure 1** Colonized crypt (A, B) and colonized crypt abscess (C, D). A, C: 4',6'-diamidino-2-phenylindole (DAPI); B, D: Hybridization with the Eubacteria probe.

by bacteria. As colonic biopsies harbored a different number of crypts or crypt abscesses, we also normalized the data by calculating in each patient group the ratio: total number of colonized crypts or crypt abscesses/total number of crypts or crypt abscesses. The  $\chi^2$  test was performed for comparison of qualitative variables.

## RESULTS

The FISH technique allowed detection of crypts and crypt abscesses colonized by bacteria as shown in Figure 1. Crypts colonized by bacteria (general probe targeting Eubacteria) were observed in 42.9% and 3.6% of ASLC and IBD patients (only UC patients), respectively ( $P = 0.019$ , Figure 2). No colonized crypt was observed in biopsies from CD patients. Crypt abscesses colonized by bacteria were observed in 2 patients with ASLC (28.6% of total ASLC patients) and in no biopsy from the 28 IBD patients ( $P = 0.035$ , Figure 2). Neither colonized crypts nor crypt abscesses were observed in colonic biopsies from control patients.

### Global and normalized analysis

We observed 2317, 2499 and 2405 crypts in UC, CD and ASLC groups, respectively. None were colonized by bacteria (general probe for Eubacteria) in CD patients

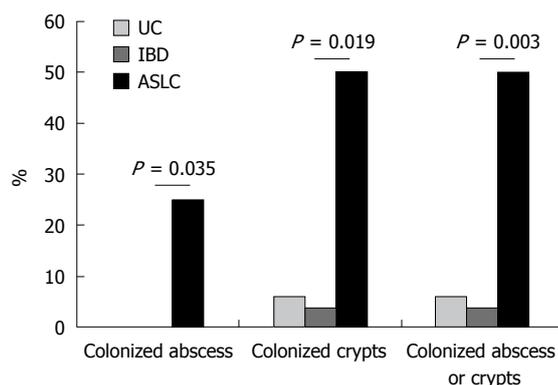

whereas 2 (0.09%) and 46 (1.91%) were colonized in UC and ASLC patients, respectively (Figure 3). We observed 121, 76 and 100 crypt abscesses in UC, CD and ASLC patients, respectively. Among these, 6 were colonized by bacteria in ASLC patients (6.0%) and none in UC and CD patients (Figure 3).

### Group/species-specific probe analysis

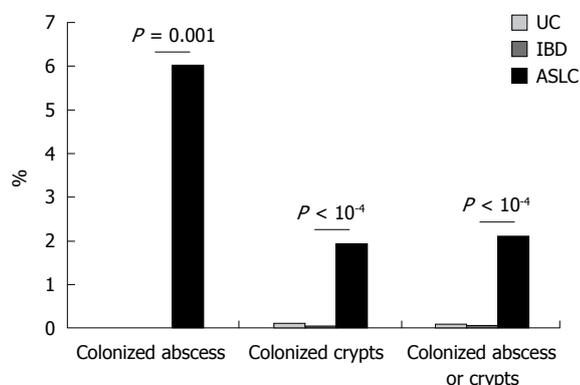

In order to determine what kind of bacteria was present in colonized crypts and crypt abscesses, we performed FISH analysis using 6 group- or species-specific probes on the sample previously identified to harbor colonized crypts or crypt abscesses. No fluorescent signal was detected in any of the crypt abscesses analyzed with the 6 specific probes. No bacteria-colonizing crypts were recognized by the *F. prausnitzii* or the *Lactobacillus-Enterococcus* probes. The 2 colonized crypts in UC patients contained *Enterobacteria* (detected by the *gamma Proteobacteria* probe) whereas 39.1%, 8.7%, 4.3% and 2.2% of the colonized crypts in ASLC patients contained bacteria from the *Bacteroides* (*Bacteroides-Prevotella* probe), the *Clostridium coccoides*, the *Enterobacteria* and the *Bifidobacteria* groups, respectively.

## DISCUSSION

This study shows for the first time that crypt abscesses

**Figure 2** Proportion of patients with at least one colonized crypt abscess, one colonized crypt or at least one crypt abscess or one crypt colonized by bacteria. UC: Ulcerative colitis; IBD: Inflammatory bowel disease; ASLC: Acute self-limited colitis.

**Figure 3** Proportion of crypt abscesses and crypts harboring bacterial colonization.

from IBD patients do not contain bacteria (aseptic abscess); colonic crypts of these patients are less often colonized than those from ASLC patients. These results do not support the hypothesis of the role of localized dysbiosis in the pathogenesis of crypt abscesses.

Dysbiosis is involved in the perpetuation of inflammation in IBD but it is presently not known whether it occurs early in the disease process and whether a localized dysbiosis in a specific ecological niche could trigger early inflammatory events. No previous study searched for bacteria inside crypt abscess in IBD or in other conditions. Swidsinski *et al.*<sup>[22]</sup> also looked at colonic crypts and found bacteria inside the crypts more frequently in IBD patients than in control subjects without inflammation or infection. In the current study, we did not find any colonized crypts in healthy subjects, and colonized crypts in IBD patients were infrequent. The differences between these 2 studies could arise from the population studied but also from the method used for the fixation of the colon biopsy. Indeed Swidsinski *et al.*<sup>[22]</sup> used a nonaqueous Carnoy solution which focuses at preserving the mucus layer on the surface epithelium while we used 4% buffered formalin. Nevertheless, in our hands, nonaqueous Carnoy solution and formalin gave similar results (unpublished data).

One can hypothesize that the results may be different

in a cohort of newly diagnosed patients without any antiinflammatory or immunomodulatory therapy. It is not possible to address this question. Nevertheless, the fact that 53.6% of the IBD patients in our cohort received no treatment or only 5-aminosalicylic acid, and that in 36% the IBD diagnosis was performed in the previous year suggested that the results would be similar in naive patients.

In ASLC, pathogenic bacteria induce an acute and transient breakdown of the intestinal barrier. On the other hand, many pathogenic bacteria involved in ASLC developed a strategy to escape the host immune system<sup>[23,24]</sup>. Alteration of the intestinal barrier could lead to deep penetration of gut microbiota bacteria (and also pathogenic bacteria) into the crypts where they could proliferate. In the current study, bacteria found in crypts from ASLC patients belonged to various phylogenetic bacterial groups of the normal gut microbiota, suggesting a non-specific intestinal barrier breakdown in this pathology, allowing the penetration of any bacteria in the crypts.

Our results do not support the hypothesis that crypt abscesses in IBD are the result of persistent localized dysbiosis with a focused reaction against high numbers of living bacteria specifically colonizing the crypts. On the other hand, the absence of entire bacteria in crypt abscesses does not rule out the implication of bacteria in their onset as one may hypothesize that bacteria could stimulate the genesis of crypt abscesses, with recruitment of polymorphonuclear leukocytes which would then destroy them but also contribute to chronic epithelial lesions. The dysbiosis in IBD seems to affect the surface of the whole mucosa (diffuse mucosal dysbiosis) and more studies should be performed to understand its specificity and the ways to influence it.

## COMMENTS

### Background

Ulcerative colitis (UC) and Crohn's disease (CD) are the 2 most common types of inflammatory bowel disease (IBD). Although their pathophysiology is still unknown, the gut microbiota is considered to play a crucial role. The microbiota close to the mucosa differs from the luminal microbiota. We and others described a luminal and mucosal dysbiosis in IBD. Nevertheless, no difference in the dominant microbiota was observed between inflamed and non-inflamed mucosa in CD and UC.

### Research frontiers

It would be of great importance to establish the early events leading to IBD onset or to perpetuation of inflammation. Crypt abscesses are early lesions observed in IBD, particularly in UC, but they can also occur in acute self limited colitis. The aim of this study was to search for a localized dysbiosis in crypt abscesses from UC, CD and acute self-limited colitis patients.

### Innovations and breakthroughs

The results do not support the hypothesis that crypt abscesses in IBD are the result of localized dysbiosis arising from persistence of living bacteria colonizing the crypts.

### Terminology

Dysbiosis: Breakdown in the balance between putative species of "protective" vs "harmful" intestinal bacteria.

### Peer review

This is an interesting and original study, which attempts to characterize dysbiosis associated with cryptitis and crypt abscesses in patients with early IBD. The results suggest that these lesions are in fact sterile.

### Abstract

**AIM:** To evaluate the feasibility and the outcome of endoscopic mucosal resection (EMR) for large colorectal tumors exceeding 4 cm (LCRT) undergoing piecemeal resection.

**METHODS:** From January 2005 to April 2008, 146 digestive tumors larger than 2 cm were removed with the EMR technique in our department. Of these, 34 tumors were larger than 4 cm and piecemeal resection was carried out on 26 colorectal tumors. The mean age of the patients was 71 years. The mean follow-up duration was 12 mo.

**RESULTS:** LCRTs were located in the rectum, left colon, transverse colon and right colon in 58%, 15%, 4% and 23% of cases, respectively. All were sessile tumors larger than 4 cm with a mean size of 4.9 cm (4-10 cm). According to the Paris classification, 34% of the tumors were type I s, 58% type II a, 4% type II b and 4% type II c. Pathological examination showed tubulovillous adenoma in 31%, tubulo-villous adenoma in 27%, villous adenoma in 42%, high-grade dysplasia in

38%, *in situ* carcinoma in 19% of the cases and mucosal carcinoma (m2) in 8% of the cases. The two cases (7.7%) of procedural bleeding that occurred were managed endoscopically and one small perforation was treated with clips. During follow-up, recurrence of the tumor occurred in three patients (12%), three of whom received endoscopic treatment.

**CONCLUSION:** EMR for tumors larger than 4 cm is a safe and effective procedure that could compete with endoscopic submucosal dissection, despite providing incomplete histological assessment.

Large endoscopic mucosal resection for colorectal tumors exceeding 4 cm. *World J Gastroenterol* 2010; 16(5): 588-595 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i5/588.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i5.588>

### INTRODUCTION

Endoscopic mucosal resection (EMR) allows complete and curative removal of the affected mucosa by excising through the middle or the deeper part of the submucosa following isotonic saline injection<sup>[1-3]</sup>. Thanks to a very simple technique, the endoscopic resection of superficial colorectal adenomas and tumors has been made

possible in selected patients with little or no ganglion risk. The therapeutic management of polyps larger than 3 cm, however, often relies on surgery. The frequency of degeneration is indeed increased, and piecemeal resection is carried out in 76% of cases<sup>[4]</sup>. Laparoscopic surgery has reduced the length of hospitalization, but a substantial morbidity rate of 20% and a mortality rate of 1% persist<sup>[5]</sup>. Endoscopic submucosal dissection (ESD) is a technique currently undergoing evaluation. This technique offers the advantage of a monobloc resection, enabling the analysis of the lateral margins and leading to a reduction of the risk of recurrence. However, this technique's learning curve is steep, and the morbidity associated with it is higher than that of mucosectomy<sup>[6]</sup>.

This study aimed to evaluate the feasibility and the outcome of endoscopic piecemeal mucosal resection of sessile polyps of the colorectum exceeding 4 cm in size.

## MATERIALS AND METHODS

### Patients

Between 2005 and 2007, our department carried out 146 mucosal resections larger than 2 cm throughout the gastrointestinal tract. Of these, 34 involved parietal tumors larger than 4 cm, and 26 tumors were colorectal. These large colorectal tumors exceeding 4 cm were treated by piecemeal resection in 25 of the 26 patients. Among these, 44% were female and the mean age was 71 years (46-89 years).

### Methods

The lesions were first identified by visual inspection (Figure 1A). Computed virtual chromoendoscopy with Fujinon Intelligent Color Enhancement<sup>®</sup> was used for estimating surface extension. The size of the lesions was measured and compared using open biopsy forceps. Deep tumor extension was estimated using three parameters. Polyps were classified according to the Paris morphological classification<sup>[7]</sup>. All lesions were analyzed according to Kudo's pit pattern classification<sup>[8]</sup>. Finally, endosonography was performed on all rectal lesions. Only lesions classified as T1N0 were treated endoscopically.

Certain lesions were excluded from the study and treated by surgery if they met one or more of the following criteria: (1) Type 0-III, Paris classification; (2) Type V, Kudo's classification; (3) Endosonographic lesions > T1 or N+; and (4) Absence of lifting after submucosal injection (negative lifting sign).

A video colonoscope type Fuji 450<sup>®</sup> was used for total colonoscopy, carried out under general anesthesia. Patients received endocarditis prophylaxis according to the recommendations of the *Société Française d'Endoscopie Digestive*<sup>[9]</sup>. Mucosal resection was performed using the conventional method<sup>[10]</sup>. In order to create a detachment of the pathological mucosa, a solution containing physiological serum (0.9%) and epinephrine (dilution of 1:10000) was injected into the submucosa by means of a 25 gauge needle inserted into the operating channel

(Figure 1B). A diathermic snare was tightened around the elevated lesion, grasping also adjacent healthy mucosal tissue (Figure 1C). Two snare types were used: large snare of 6 cm × 3 cm (Jumbo Wilson Cook<sup>®</sup>, USA) and needle snare of 5.5 cm × 2.5 cm (Wilson Cook<sup>®</sup>, USA). Removal was performed with pure cutting current in the caecum and with endocut current in the remaining colon (Figure 1D). Considering that the injection could have masked the polyp's limits, the healthy peripheral mucosa was previously marked with a bistoury in order to ensure complete polyp removal. In case of doubt as to the normality of the resection margins, a complementary treatment was performed by applying a coagulation current to the mucosectomy margins, either *via* the tip of the snare or *via* argon plasma, at a flow rate of 1 L/min and a power of 60 W (Erbe<sup>®</sup>, Tuebingen, Germany). One-time resection was attempted in all patients (Figure 1E). If the mucosectomy was considered incomplete due to the persistence of residual adenomatous tissue, a further mucosectomy was planned.

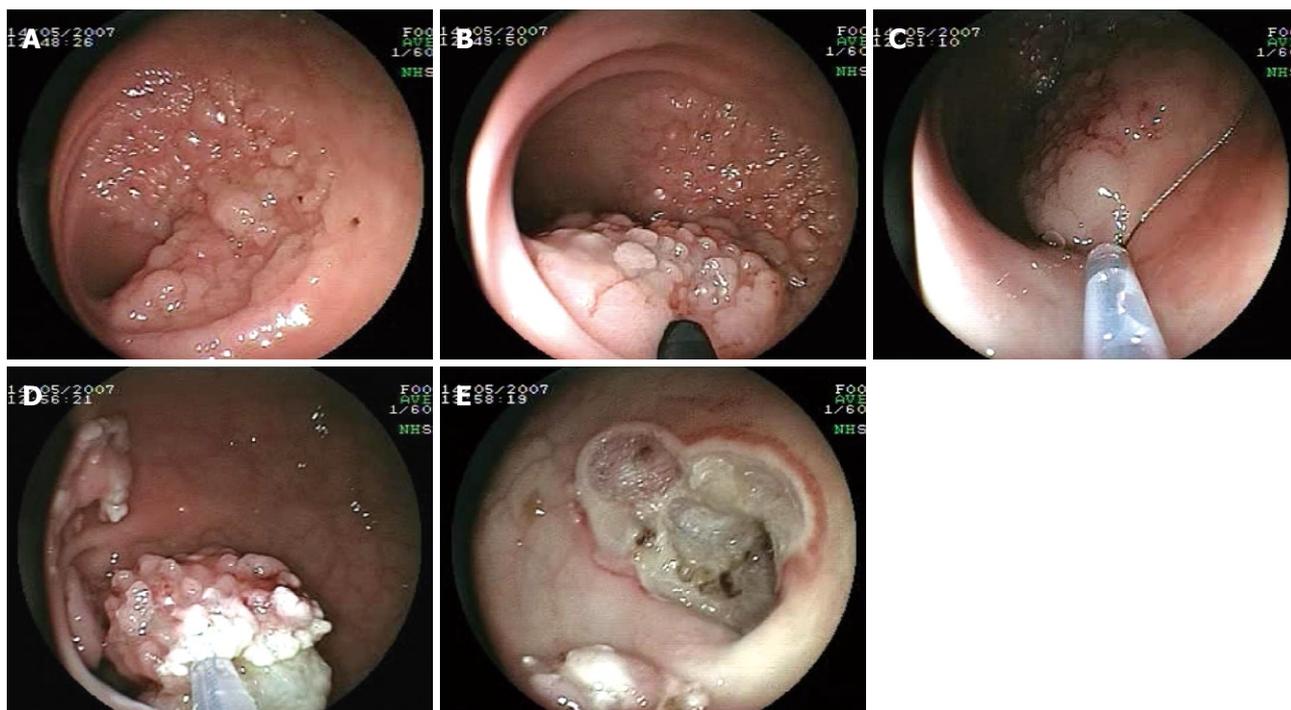

Each fragment of removed tissue was spread out and pinned on a 5 mm thick cork surface in order to avoid retraction of the polyp's base and permit improved histological assessment of the deep margins. Deep resection limits were marked with China ink and the tissue pieces were then fixed in 4% formol saline for 3 d. All fragments were routinely processed for paraffin embedding. Slices (5 μm) were stained with hematein-eosin-safran. Modified Vienna classification was used for the histological assessment according to the severity of dysplasia<sup>[11]</sup>. Lateral margins could not be evaluated due to the impossibility of displacing fragments in relation to each other. Histological assessment was carried out using the Japanese classification with deep submucosal invasion limited to 1000 μm<sup>[8]</sup>.

Following mucosal resection, colonoscopic surveillance included a first early endoscopic control examination between 3 and 6 mo, and further examinations at 1 and 3 years (Figure 2). Resection was considered complete if no residual adenomatous tissue was noted following completion of mucosectomy. Local recurrence was defined as the presence (on biopsy) of adenomatous tissue in areas of previously treated mucosa at endoscopic control between 3 and 6 mo after therapy. In the case of a recurrence of small-sized tumors, an additional mucosectomy was carried out. If a lesion could not be lifted due to fibrous tissue development in the submucosa, argon plasma coagulation (APC) following multiple biopsies was performed. When the biopsy revealed recurrent cancer, the patient underwent surgery.

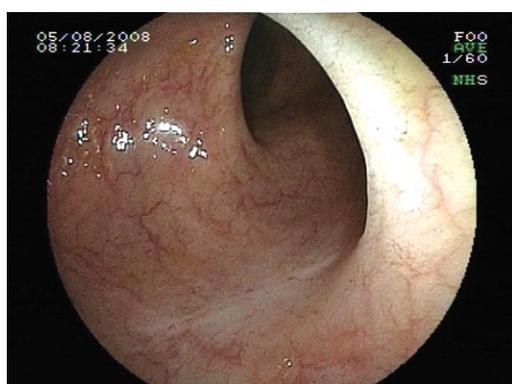

## RESULTS

### Lesion description and evaluation

The 26 sessile polyps were removed by piecemeal resection. The mean polyp size was 4.9 cm (4-10 cm). Lesion analysis according to the Paris classification revealed the presence of type 0-I s in 9 cases (34%), type

**Figure 1** Endoscopic piecemeal mucosal resection image. A: Large lateral spreading rectal tumor (adenoma with high grade dysplasia); B: Submucosal lifting of the tumor using saline with adrenaline 1/10000; C: Capture of the lifted part of the tumor with a needle snare; D: Piecemeal resection of the rectal tumor; E: Final aspect at the end of the resection (procedure duration 70 min).

**Figure 2** One year follow-up: a scar is visible without any sign of recurrence.

0-II a in 15 cases (58%) and type 0-II b in one lesion (4%), with some mixed forms. The only lesion classified as type 0-II c (4%) showed low-grade dysplasia and two lesions classified as type 0-II a were intramucosal carcinomas. There was no ulcerated lesion of type 0-III. The most frequently identified pit pattern was pit pattern type IV in 24 cases (92%) followed by type III. The predominant location was the rectum in 15 cases (58%), and all lesions were classified as T1N0 (Table 1).

**Technique**

A one-time resection was performed in 23 cases (88.5%). For two lesions located in the rectum (7.7%), three sessions were necessary, and for one lesion located at the right colonic angle (3.8%), two sessions were needed. The lesions' mean size was 6.7 cm (4-10 cm). Coagulation of

3	Rectum	4	IV	0-II a + 0-II c	DBG	3	3	Surgery

### Pathology

All polyps were adenomatous. The most common histological type was villous adenoma in 42% (11 cases), followed by tubular adenoma in 31% (8 cases) and finally tubulovillous adenoma with a mixed villous and tubular architecture in 27% (7 cases). In total, 35% of lesions exhibited low-grade dysplasia (9 cases), 38% high-grade dysplasia (10 cases), 19% a carcinoma *in situ* (5 cases). Two polyps (8%) were reported as intramucosal carcinoma (m2), neither of which reached the submucosa. Contrary to the lateral margins (0%), deep margin analysis was possible on all samples. Resection was performed within a safe deep margin in 100% of cases.

### LEMR efficacy and follow-up

In total, 24 patients underwent endoscopic surveillance, while one patient refused to undergo control endoscopy. The mean duration of follow-up was 12 mo (3-37 mo). Three recurrences were detected (12.5%) (Table 2). All three patients had initially received a complementary treatment using APC. The median delay until recurrence diagnosis was 3 mo (3-9 mo). Two patients underwent endoscopic treatment and the remaining patient received surgical therapy. The first patient received an additional mucosectomy, followed by APC due to the absence of lifting after the injection. For the second patient, a single session of tissue destruction *via* coagulation was the immediate resort. These two endoscopically-treated recurrences were of the same histological type as the initial polyp. Following treatment of recurrences, a further endoscopic control was scheduled for 3 mo later. The third patient, who was followed-up for Crohn's disease which was surgically treated by ileorectal anastomosis, underwent rectal stump resection. After three successive endoscopic treatments, one using mucosectomy and the two others using APC, the low-grade dysplastic lesion detected at biopsy could not be eradicated. Histological examination of the surgically removed specimen revealed an infiltrating adenocarcinoma that was classified as pT2N0 with a colloid mucosal component of less than 50%. In total, endoscopic resection was effective in 96% of cases.

### Complications

Intra-operative bleeding occurred in two patients but in neither patient was there any need for blood transfusion or a drop in hemoglobin levels exceeding 2 g/dL. Late postoperative bleeding, at day 6, was observed in two patients (7.7%) but no case of severe bleeding as defined in the standards of practice of the American Society for

Gastrointestinal Endoscopy was noted<sup>[12]</sup>. Endoscopic injection therapy with epinephrine (diluted 1:10 000) was performed along with the deployment of hemostatic clips (Resolution® Boston Scientific, USA).

Perioperative perforation was diagnosed in one case (4%) upon visualisation of the peritoneal fat at the bottom of the resection zone. The abdominal radiography without preparation did not reveal a pneumoperitoneum because of the perforation's sub-peritoneal rectal location. The patient underwent conservative treatment with endoscopic closure of the perforation using clips, in addition to the administration of antibiotics and 48 h fasting.

Scar stenosis was observed in another patient who presented a 10 cm circumferential lesion within the upper rectum. The interval between the first colonoscopy and the diagnosis of the stenosis was 6 mo. The patient was asymptomatic and the endoscopic CRE balloon dilatation was able to traverse the stenosis.

Ten days after his examination, one patient experienced septic shock following *Staphylococcus epidermidis* endocarditis. The patient had a bicuspid aortic valve, and underwent prosthetic valve replacement surgery. The microbiology did not support a bacterial translocation from the digestive tract.

## DISCUSSION

This study aimed to demonstrate the efficacy of piecemeal mucosectomy in the management of large non-polypoid colorectal lesions. The success rate was 96% despite a mean lesion size of 4.9 cm. These results are comparable to those reported in the literature, which show success rates of endoscopic treatment for large polyps (those exceeding 2 cm) ranging from 83% to 100% (Table 3). Kaltenbach *et al*<sup>[13]</sup> recently described a series of 125 mucosectomy-treated colorectal plane lesions whose mean size was 16.7 mm. Of the 62 patients followed up for a mean period of 4.5 ± 1.4 years, none had developed colorectal cancer or metastasis, resulting in a success rate of 100%<sup>[13]</sup>.

The Japanese Society for Cancer of the Colon and Rectum's current criteria for curative endoscopic resection are: a submucosal invasion of less than 1000 µm, moderate or well-differentiated lesion characteristics and the absence of vascular invasion<sup>[14,15]</sup>. Depending on the study reported, the presence of invasive lesions, which cross the muscular mucosa, varies from 0% to 44%, notably for sessile elevated tumors<sup>[1,16]</sup>. In our series, there was no submucosal invasion and only 2 cases (8%) with invasion of the mucosa (m2). This was

accounted for by the parietal extension assessment, which was based on a series of complementary examinations. On one hand, the Paris endoscopic classification allows the exclusion of ulcerated lesions<sup>[8]</sup>. On the other hand, magnified chromoendoscopy has been shown to permit a 97% diagnostic precision of deep submucosal invasion (69/71)<sup>[17]</sup>. However, another study found a specificity of only 50%<sup>[18]</sup>. Echoendoscopy with high-frequency mini probes was not used, as muscular mucosa is only visualized in 50% to 65% of cases<sup>[19,20]</sup>. Mini probes of 7.5 MHz were employed, permitting the detection of T1 cancers without separating mucosal and sub-mucosal lesions. The evaluation of extension depth is an essential step prior to resection in order to select the patients for whom endoscopic treatment will be curative with minimal lymphatic risk.

The late bleeding rate reported by Doniec *et al*<sup>[21]</sup> was only 2%. The higher late bleeding rate observed in our study (7.7%) can be explained by the 49 mm mean extension of the resection. Lesion size has been identified as an independent predictive factor of postpolypectomy delayed bleeding<sup>[22]</sup>. However, the bleeding complications of the current study and those aforementioned were effectively treated with the deployment of hemoclips and the injection of an adrenaline serum, without resorting to surgery. Perforation rates reported after the resection of polyps exceeding 2 cm have been shown to vary from 0% to 1.2%<sup>[23,24]</sup>. If the perforations are of small size (< 1 cm) and are properly diagnosed during endoscopy, they may be treated with endoscopic clip closure in 70% of cases<sup>[25]</sup>. Scar stenosis of the colon is a complication following endoscopic mucosectomy which has not yet been explained. Two factors appear to play a role: the initial lesion's extended circumferential shape, and its location in the upper rectum (where the diameter is smallest).

Local recurrence was detected in 13.4% of cases, despite APC of the area of the defect which has proved effective in preventing recurrences following piecemeal mucosal resection<sup>[26]</sup>. Previous studies have reported recurrence rates ranging from 0% to 39% for lesions larger than 2 cm<sup>[22,27]</sup>. In the largest series, that of Seitz *et al*<sup>[28]</sup>, 288 patients with large (> 3 cm) sessile and pediculated

polyps were treated using piecemeal resection, and the recurrence rate was 17% for a mean follow-up duration of 36 mo. The mean delay for diagnosis of recurrence was 5 mo. We followed the recommendations of Higaki concerning postpolypectomy surveillance<sup>[29]</sup>. Most recurrences occur within the first 6 mo. Our own experience and published data encourage close endoscopic control between 3 and 6 mo, and at 1 year, in cases of piecemeal resection. Patients who have undergone resection of a large dysplastic or cancerous polyp require tighter endoscopic control<sup>[30]</sup>. Several risk factors for recurrence have been identified; piecemeal resection, lesion size<sup>[31]</sup>, granulous appearance of the lesion, and a lesion location at the bottom of the rectum attaining the pectineal line<sup>[23,32]</sup>. Among these factors, endoscopic piecemeal procedure appears to play the most important role. In a series by Ishihara *et al*<sup>[33]</sup>, 78 esophageal squamous cell carcinomas of ≥ 2 cm were treated by endoscopy. The strongest predictor for recurrence was the number of resected fragments; 0/34 in patients with monobloc resection (0%), 4/24 in those with 2 and 4 fragments (15%) and 8/17 in those with more than 5 fragments (47%)<sup>[33]</sup>. In addition to the risk of local recurrence, piecemeal resection may prevent a good assessment of the lateral margins, with the consequence of incomplete interpretation and the risk of leaving small carcinomas around the main lesion. In a recent retrospective study by Kim *et al*<sup>[34]</sup>, 44 patients who had initially received imperfect EMR for colorectal cancers were subsequently treated by either EMR or ESD. Gross incomplete resection and deep margin positivity were found to be risk factors of residual cancer. No residual cancer cells were found after supplementary surgery in all cases with positive lateral resection margins. The authors proposed the hypothesis that the application of an electrocoagulation current can destroy residual cancer cells at the resection margins<sup>[34]</sup>. Hurlstone *et al*<sup>[35]</sup> have shown that recurrence rate could be decreased from 8.7% to 0.5% with the analysis of the pit patterns of the resection margins.

If the recurrence is of small size, removal by hot forceps is a therapeutic option. If the recurrence exceeds 5 mm, a further mucosectomy session may be carried out so as to obtain a complete histological analysis of

residual tumor tissue. In our series, such a thorough histological analysis was not possible in two out of three cases. The thermal lesion provoked by the coagulation current leads to a desmoplastic reaction in the submucosa, preventing another mucosal lifting (non lifting sign)<sup>[36]</sup>. Destruction of tumors by APC is an alternative therapeutic option. In a series of 68 recurrent colorectal adenomas following EMRP, APC treatment was effective in 90%<sup>[37]</sup>. We believe that in all cases without malignant recurrence, the best choice is to try to perform a new EMR, in order to assess the margins. However, the submucosal fibrotic scar due to thermal injury may prevent the lifting sign leading to a management by local destruction, mainly with APC treatment. Surgery remains essential in the presence of a carcinomatous recurrence whose extension depth cannot be properly assessed, and which therefore has a risk of metastatic spread<sup>[38]</sup>. In our series, one patient followed-up for Crohn's disease with ileorectal anastomosis underwent surgery. The operative specimen revealed an infiltrating cancer classified as pT2N0. A recent meta-analysis has shown that the positive predictive value of a plane low-grade dysplastic lesion, associated with chronic inflammatory bowel disease, correlated with the presence of colorectal cancer in 22% of cases<sup>[39]</sup>.

The technique of large EMR for rectal tumor might be challenged by two new techniques: ESD and transanal endoscopic microsurgery (TEMS). ESD permits single-fragment resection with safe margins in 70% of cases, as has been shown in a series of 200 colorectal lesions ranging in size from 20 to 150 mm<sup>[40]</sup>. There are only a few follow-up studies, but the risk of recurrence appears low. In a study by Fujishiro *et al*<sup>[41]</sup>, 35 rectal polyps were treated using the ESD method. Monobloc resection with safe margins was possible in 62.9% of cases, with a local recurrence rate of 2.8% for a mean follow-up duration of 36 mo. Initially developed for the treatment of superficial gastric tumors, the application of this technique in the colon exposes the patient to a higher risk of complications. For instance, ESD is associated with a higher risk of perforation, ranging from 5% to 14%, due to the thinness of the colonic wall<sup>[40,25]</sup>. The intra-operative bleeding risk is also significantly higher for ESD as compared to EMR (22.6% for ESD *vs* 7.6% for EMR,  $P < 0.01$ )<sup>[42]</sup>. The "inject and cut" mucosectomy has the advantage of being a simple technique that may be performed by the endoscopy practitioner with routinely-used equipment. In contrast, ESD practitioners require extensive training, operating initially on animals because the endoscopist's experience inversely correlates with the risk of perforation and monobloc resection rate<sup>[43,44]</sup>. The mean time required for the procedure is significantly higher and has been compared in a study by Oka *et al*<sup>[42]</sup>. The mean time for the resection of gastric lesions smaller than 1 cm was  $3.5 \pm 1.3$  min for EMR and  $58.5 \pm 28.7$  min for ESD ( $P < 0.01$ ). If the lesion is larger than 2 cm, the mean time required for the procedure is  $17.2 \pm 9.3$  min for EMR and  $123.8 \pm 101.4$  min for

ESD ( $P < 0.01$ )<sup>[42]</sup>. ESD is at present a non-standardized technique. It has the advantage of allowing monobloc resection of gastrointestinal tumors, which permits the assessment of lateral margins. However, the technique is difficult to learn, its complication rates are high and the time required for the procedure is long. To date, this technique cannot be proposed as a standard technique for the management of colorectal adenomas<sup>[44]</sup>.

For TEMS, major complications have been reported. In a series of 288 patients, 9% of patients experienced complications; severe digestive hemorrhages, perforations, and temporary anal incontinence. Non-surgical complications accounted for the low but relevant mortality rate of 0.3%. Duration of hospitalization was approximately 2 d<sup>[45]</sup>. Hurlstone *et al*<sup>[46]</sup> have evaluated EMR as an alternative to TEMS. In 62 patients, the success rate of endoscopic treatment was 98%, with a recurrence rate of 8%. Patients were discharged the same day as the procedure in 97% of cases<sup>[46]</sup>. Another major drawback of TEMS is economic, since it necessitates a financial investment of 50 000 Euros for the purchase of the equipment<sup>[47]</sup>.

In conclusion, endoscopic piecemeal resection is a safe and effective procedure. In spite of higher recurrence rates than with the ESD method, its technical simplicity, low complication rates, and lower costs are major advantages. Moreover, endoscopic management of recurrence has proven effective, with no risk of submucosal invasion in patients without chronic inflammatory colitis. A large lesion size (> 4 cm) is not a limiting factor for an endoscopic approach, provided that the risk of submucosal invasion has been carefully evaluated. However, further studies are needed to specify the time intervals required for endoscopic surveillance and to develop new techniques that would allow the histological assessment of lateral margins.

## COMMENTS

### Background

Large colorectal adenomatous sessile polyps are neoplastic premalignant lesions, which carry a high risk of transformation into invasive cancer. The management of these lesions is usually surgical by segmental colonic resection. The treatment of these lesions by piecemeal mucosectomy represents a mini-invasive procedure and the resection is effective for selected lesions.

### Research frontiers

Endoscopic mucosectomy is a technique approved for lesions less than 2 cm because it allows *en bloc* resection. The endoscopic resection of lesions more than 4 cm involves a systematic piecemeal resection, which could result in the absence of anatomopathologic analysis of the margins and may expose the patient to the risk of recurrence.

### Innovations and breakthroughs

This is an original study taking place in a single centre that describes the effectiveness and the feasibility of this technique as less risky and simpler than that of endoscopic submucosal dissection (ESD), for the management of polyps of large size (giant polyps). This study confirms that the size of the polyps should not be a contraindication for endoscopic treatment. However, the risk of deep parietal infiltration must be evaluated in a precise way because this controls the effectiveness of the treatment as well as the risk of metastatic dissemination to lymph nodes which could preclude the endoscopic resection. It is associated with a low risk of complications and recurrence.

### Applications

The results of this study show that mucosectomy for large colorectal polyps is effective whatever the size of the lesions if the estimation of lymph node infiltration is rigorously evaluated by the degree of infiltration into the layers of the wall of the colon. However, new studies should be realized in order to confirm these data and to determine the degree and regularity of follow-up monitoring.

### Terminology

Mucosectomy is an endoscopic technique of resection of a lesion that requires the separation of the submucosa using normal saline solution. ESD is a new method of resection, allowing the dissection of the lesion within the thickness of the submucosa or the interface between the submucosa and the muscularis propria. FICE: Technique of virtual chromoendoscopy by processing the image in a narrow spectral band.

### Peer review

Great paper, well written, appeals to our audience, favor acceptance.

### Abstract

**AIM:** To investigate the usefulness of mild iron depletion and the factors predictive for histological improvement following phlebotomy in Caucasians with chronic hepatitis C (CHC).

**METHODS:** We investigated 28 CHC Caucasians with persistently elevated serum aminotransferase levels and non responders to, or unsuitable for, antiviral therapy who underwent mild iron depletion (ferritin  $\leq$  70 ng/mL) by long-term phlebotomy. Histological improvement, as defined by at least one point reduction in the staging score or, in case of unchanged stage, as at least two points reduction in the grading score (Knodell), was evaluated in two subsequent liver biopsies (before and at the end of phlebotomy, 48  $\pm$  16 mo apart).

**RESULTS:** Phlebotomy showed an excellent safety profile. Histological improvement occurred in 12/28 phlebotomized patients. Only males responded to phlebotomy. At univariate logistic analysis alcohol intake ( $P = 0.034$ ), high histological grading ( $P = 0.01$ ) and high hepatic iron concentration (HIC) ( $P = 0.04$ ) before treatment were associated with histological improvement. Multivariate logistic analysis showed that in males high HIC was the only predictor of histological improvement following phlebotomy (OR = 1.41, 95% CI: 1.03-1.94,  $P = 0.031$ ). Accordingly, 12 out of 17 (70%) patients with HIC  $\geq$  20  $\mu$ mol/g showed histological improvements at the second biopsy.

**CONCLUSION:** Male CHC Caucasian non-responders to antiviral therapy with low-grade iron overload can benefit from mild iron depletion by long-term phlebotomy.

### INTRODUCTION

Hepatitis C virus (HCV) infection affects 130 million

people worldwide causing chronic hepatic inflammation that in about 20% of the patients evolves to liver cirrhosis and/or hepatocellular carcinoma<sup>[1]</sup>. The progression of chronic hepatitis C (CHC) is not linear and is greatly influenced by a variety of factors including male gender, age at the infection, obesity, co-infection with hepatitis B or HIV viruses, alcohol consumption and iron overload<sup>[2,3]</sup>. The diffusion of anti-HCV therapies based on the association of pegylated interferon and ribavirin will probably modify the natural history of the disease, as more than half of the treated patients achieve a sustained eradication of the virus<sup>[4,5]</sup>. Nonetheless, for those patients who do not respond to anti-viral therapy, have contraindications to the use of interferon or cannot afford the therapy costs there is an urgent need of other therapeutic options capable of preventing the progression of the disease.

Mild hepatic iron accumulation is frequent in CHC patients and is associated with higher aminotransferase levels and more severe fibrosis<sup>[6]</sup>. Moreover, experimental studies have shown that dietary supplementation with iron worsens hepatic damage in HCV-infected chimpanzees and promotes the onset of hepatocarcinomas in transgenic mice expressing the HCV core protein<sup>[7,8]</sup>.

Growing evidence indicates that HCV proteins stimulate the formation of reactive oxygen species within hepatocytes and oxidative stress associated with HCV infection is recognized as an important factor in the pathogenesis of hepatic damage in CHC<sup>[9]</sup>. In this context the capacity of iron to exacerbate oxidative damage suggests that iron accumulation might amplify oxidative stress-mediated events leading to both hepatocellular damage as well as to the pro-fibrogenic activation of hepatic stellate cells<sup>[10]</sup>.

In recent years several groups have reported on the efficacy of iron reduction therapies based on phlebotomy in combination or not with an iron-restricted diet in reducing aminotransferase levels in CHC patients non-responders to the interferon treatment<sup>[11-16]</sup>. However, in many of these studies the iron depletion (serum ferritin below 20 ng/mL) was rather severe<sup>[13-16]</sup>. We have previously reported that menstruating women experienced a milder CHC than men of the same age in relation to the lower hepatic iron concentration (HIC) due to blood loss<sup>[17]</sup>. As patient compliance to long-term iron depletion is an important factor in the success of this therapy we have investigated whether, and in which conditions, mild iron depletion (serum ferritin  $\leq$  70 ng/mL) might be effective in inducing histological improvement in a group of Caucasian patients with CHC not responding to anti-viral therapy or having contraindications to the use of interferon, who were histologically re-evaluated within 2-5 years from the first liver biopsy and the start of iron depletion therapy.

## MATERIALS AND METHODS

### Patient selection

In this study we investigated retrospectively 28 patients (21

men, 7 women; mean age  $58 \pm 7.6$  years) with CHC, who were either non responders ( $n = 13$ ) or had contraindications to antiviral therapy ( $n = 15$ ) who gave informed consent to be treated between January 2001 and December 2006 exclusively with iron reduction by phlebotomy in two Italian centres (Ospedale Maggiore della Carità in Novara and Spedali Civili in Brescia) and underwent liver biopsies before phlebotomy and 2 to 5 years after the achievement of iron depletion. Criteria of exclusion were alcohol intake  $> 80$  g/d, active drug addiction, HBs-Ag and/or HIV-Ab positivity, personal or familial history of haemochromatosis, haemoglobin  $< 13$  g/dL for men and  $< 11$  g/dL for women, interferon based therapy or immunosuppressive therapy during the last 6 mo, and refusal to undergo liver biopsies before and at the end of phlebotomy. The mean daily alcohol intake was evaluated by trained medical staff according to a standardized questionnaire, presented as part of a survey on life habits. Genetic tests for haemochromatosis mutations were not performed. However, HIC, iron index and the amount of iron removed during phlebotomy excluded phenotypic haemochromatosis.

All the patients underwent an initial period of bi-monthly or monthly phlebotomy of 250 mL of blood, until serum ferritin levels of 35 ng/mL or less were reached. Thereafter, maintenance phlebotomies were performed every 1 to 3 mo during a minimum 2 years period to maintain a serum ferritin level at 70 ng/mL or less. In the case of haemoglobin values  $< 11$  g/dL phlebotomy was postponed until haemoglobin levels exceeded the cut-off. For all patients histology was re-evaluated by a second liver biopsy after a period of  $48 \pm 16$  mo, as part of a study approved by a local ethical committee to evaluate on an individual basis whether iron depletion by phlebotomy was effective and worth being continued.

None of the patients were treated with antiviral drugs during the study. Eight patients were on oral treatment for chronic unrelated diseases (hypertension, diabetes, vascular diseases) and another diabetic patient was treated with insulin. All were allowed to continue with these treatments throughout the study period.

The demographic, clinical and laboratory characteristics of the patients included in the present study are summarized in Table 1. The study was planned according to the guide-lines of the local ethical committee in conformity the 1975 Declaration of Helsinki.

### Assessment of liver histology

Liver biopsies were performed using a modified Menghini procedure. Five micron-thick sections were stained with haematoxylin/eosin, Masson's trichrome and periodic acid-Schiff after diastase digestion as well as with the Gomori's method for reticulin and the Perls's method for iron staining. Only specimens with a minimum length of 15 mm and at least 6 portal tracts were considered adequate for histological assessment. Liver biopsy specimens were scored in a blind fashion (including the date - pre or post phlebotomy) by two expert pathologists (RB,

**Table 1** Epidemiological, clinical and laboratory characteristics at the time of their first liver biopsy of 28 patients with chronic hepatitis C included in the study

Variable <sup>1</sup>		Range	SD
Age (yr)	58	43-73	7.6
Gender (males/females)	21/7		
Body mass index (kg/m <sup>2</sup> )	24.5	19-38.4	3.9

Steatosis grade (0/1/2/3) <sup>3</sup>	9/12/5/0	0-2	

<sup>1</sup>Values are means, counts or medians when indicated; <sup>2</sup>Yes:  $\geq 50$  g/d for men or 20 g/d for women; <sup>3</sup>Data were available for 26 out of 28 patients. Steatosis grade: 0, no steatosis; 1,  $\leq 33\%$  of hepatocytes; 2, 34%-66%; 3, > 66%.

CB) unaware of the clinical data. In the case of discordant opinions, the two examiners analyzed the discrepancies to reach a consensus.

The original histology activity index proposed by Knodell<sup>[18]</sup> was used for grading inflammation/necrosis and for staging fibrosis. By this scoring system inflammation/necrosis score ranges from 0 to 18 (0-10 periportal  $\pm$  bridging necrosis, 0-4 intralobular degeneration and focal necrosis, 0-4 portal inflammation), while fibrosis stage includes only four stages: 0 (no fibrosis), 1 (fibrous portal expansion), 3 (bridging fibrosis), 4 (cirrhosis). Steatosis was scored semi-quantitatively as: 0, no steatosis, 1, steatosis  $\leq 33\%$  of hepatocytes, 2, steatosis in 34%-66% of hepatocytes, 3, > 66% of hepatocytes. Intrahepatic iron deposition was evaluated in specimens stained by the Perls' method and evaluated using the Searle's semi quantitative score<sup>[19]</sup>. As in previous studies, patients were defined to have a histological improvement when they showed at least one point reduction in the staging score or, in the case of an unchanged staging score, at least a two point reduction in the grading score<sup>[20,21]</sup>.

### Measurement of hepatic iron content

HIC was measured by atomic absorption spectroscopy on

a portion of each liver biopsy, as previously reported<sup>[22]</sup>, and the values were expressed as  $\mu$ mol/g dry weight. Hepatic iron index was calculated to rule out phenotypic hemochromatosis.

### Statistical analysis

Stata Statistical Software (release 9.0 College Station, Stata Corporation, TX, USA) was used in all the statistical analyses. Each variable predictive or associated with presence of histological response was analysed with univariate logistic regression. The variables selected by the univariate analysis were entered into logistic regression models with the use of a forward stepwise elimination algorithm (terms with  $P > 0.05$  were eligible for removal). The paired Student's  $t$ -test was used to compare the continuous variables among groups and the Wilcoxon matched-pairs signed-rank test was used to compare discrete variables among groups.

## RESULTS

The long-term effects of mild iron depletion by phlebotomy were investigated in 28 CHC patients who were either non responders or had contraindications to antiviral therapy and received intensive phlebotomy followed by maintenance phlebotomy to maintain serum ferritin levels below 70 ng/mL. All the patients underwent a histological re-evaluation by a second biopsy within 2-5 years from the achievement of iron depletion. Two patients (a man aged 65 years and a woman aged 68 years who were treated with phlebotomy, respectively for 31 and 29 mo) were excluded from the study, because the second liver biopsy specimens did not meet the established criteria - minimum length and number of portal tracts - and, therefore, were not considered adequate. Both showed a decrease of HIC and aminotransferase levels > 50%.

The patients showed excellent compliance to phlebotomy. In particular, none of the patients reported increased fatigue, reduced exercise capacity, cheilosis, koilonychia or other side effects related to mild iron depletion.

The changes in clinical and laboratory values before and at the end of therapy are shown in Table 2. As expected hemoglobin, transferrin saturation, serum iron, serum ferritin, hepatic iron grade and the HIC were significantly decreased in phlebotomized patients (Table 2). At the time of the second biopsy aspartate aminotransferase (AST) ( $P < 0.0001$ ), alanine aminotransferase (ALT) ( $P = 0.001$ ) and  $\gamma$  glutamyltranspeptidase (GGT) ( $P = 0.004$ ) levels were significantly lowered after phlebotomy (Table 2). Overall, ALT levels decreased in all 28 phlebotomized patients, while AST and GGT levels were lowered, in respectively, 27/28 (96%) and 22/28 (78%) of the patients (Table 3). Moreover, 7 out of the 28 phlebotomized patients (25%) achieved persistently normal aminotransferase levels during the iron-depleting treatment. No statistical correlation was found between the decreases of HIC and those of ALT levels ( $r = 0.22$ ,

**Table 2** Clinical and laboratory changes between the two liver biopsies of 28 patients with chronic hepatitis C included in the study

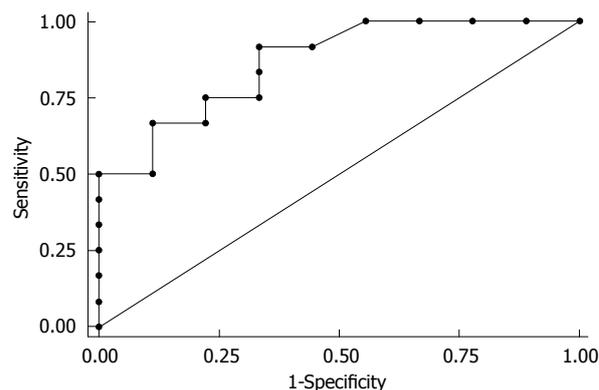

Variable	First biopsy <sup>1</sup>	Second biopsy <sup>1</sup>	P <sup>2</sup>
Body mass index (kg/m <sup>2</sup> )	24.5 ± 3.9	24.5 ± 3.8	0.93
Alcohol intake (g/d)	15 ± 18	7.5 ± 9.7	0.034
HCV-RNA (× 10 <sup>6</sup> copies/mL) <sup>3</sup>	4.54 ± 3.6	3.96 ± 3.5	0.11
Aspartate aminotransferase (U/L, 0-40)	108 ± 58	64 ± 49	0.0001
Alanine aminotransferase (U/L, 0-40)	130 ± 57	70 ± 43	< 0.0001
γ glutamyl transpeptidase (U/L, 0-50)	86 ± 59	56 ± 56	0.004
Hemoglobin (g/100 mL, 13.7-17)	14.7 ± 1.6	14 ± 1.4	0.0001
Serum iron (μmol/L, 11-32)	24.3 ± 6.9	16.4 ± 6	< 0.0001
Transferrin saturation (% , 20-50)	43 ± 11	24.5 ± 10	< 0.0001
Serum ferritin (ng/mL, 5-365)	387 ± 238	46 ± 51	< 0.0001
Hepatic iron grade (Searle's score 0/1/2/3)	6/17/5/0	27/1/0/0	< 0.0001
Hepatic iron concentration (μmol/g dry tissue, < 25)	23.3 ± 7	8 ± 5.6	< 0.0001
Histological grade (Knodell's score, median)	5	4.5	0.43
Histological stage (Knodell's score 0/1/3/4)	0/14/9/5	0/13/9/6	0.61
Steatosis grade (0/1/2/3) <sup>4</sup>	9/12/5/0	11/11/3/1	0.41

<sup>1</sup>Values are mean ± SD, counts or medians when indicated; <sup>2</sup>Paired Student's *t*-test or Wilcoxon matched-pairs signed-ranks test; <sup>3</sup>Data were available for 20 out of 28 patients; <sup>4</sup>Data were available for 26 out of 28 patients. Steatosis grade: 0, no steatosis; 1, ≤ 33% of hepatocytes; 2, 34%-66%; 3, > 66%.

*P* = 0.26). Mean alcohol intake slightly decreased during phlebotomy (15 ± 18 g/d *vs* 7.5 ± 9.7 g/d, *P* = 0.034) as a possible consequence of counseling. Serum HCV RNA levels were determined before and at the end of phlebotomy in 20/28 patients and no significant difference was observed (4.5 ± 3.6 × 10<sup>6</sup> copies/mL *vs* 4 ± 3.5 × 10<sup>6</sup> copies/mL, *P* = 0.11).

Overall, the scores for the necroinflammatory grading and the fibrosis staging were not modified by iron depletion (Table 2). However, by evaluating the histological improvement, as defined by at least one point reduction in the individual staging score or, in the case of unchanged staging, as at least two points reduction in the grading score, we observed that after phlebotomy 5 patients showed a reduction in both the grading and the staging scores and 7 had a two or more points reduction in the grading score with unchanged staging score (Table 3). Therefore, the frequency of histological improvements in the subjects undergoing mild iron depletion was 43% (12 out of 28).

Histological improvement was not significantly associated with the reduction of alcohol intake (reduction > 50%, *P* = 0.11), or body mass index (*P* = 0.12), nor was predicted by the magnitude of the reduction of the aminotransferase levels that occurred during iron depletion (reduction > 50%, *P* = 0.4) (Table 3). However, the pa-

**Figure 1** Receiver operating characteristics (ROC) curve relative to the capacity of hepatic iron concentration (HIC) values to discriminate histological improvement in males with chronic hepatitis C patients undergoing long-term iron depletion by phlebotomy. HIC ≥ 20 μmol/g was the best cut-off value to discriminate CHC patients with histological improvement. Area under the curve = 0.866 (95% CI: 0.71-1.00).

tients with histological improvement had HIC significantly higher than in those without (26.55 ± 6.37 *vs* 20.81 ± 6.47, *P* = 0.028) (Table 3).

To determine the factors responsible for the histological improvement induced by long-term mild iron depletion, univariate logistic analysis of the putative predictors was performed (Table 4). We observed that only the males responded to treatment. Moreover, alcohol intake (*P* = 0.034), high histological grading (*P* = 0.013) and high HIC before phlebotomy (*P* = 0.043) were significantly associated with the histological improvement (Table 4). At multivariate logistic analysis, high HIC was the only independent predictor (OR = 1.41, 95% CI: 1.03-1.94, *P* = 0.031) of the histological improvement (Table 4). Furthermore, receiver operating characteristics (ROC) curve showed that HIC ≥ 20 μmol/g was a suitable cut-off value (sensitivity 91.7%; specificity 66.7%) to discriminate CHC patients with histological improvement (Figure 1). Indeed, 12 out of 17 men (70%) with HIC ≥ 20 μmol/g dry tissue at the time of the first biopsy achieved histological improvement following the mild iron depletion.

## DISCUSSION

Iron accumulation is a common feature of liver biopsies from CHC patients and HCV infected patients with increased hepatic iron content show increased serum aminotransferase and liver fibrosis as compared to patients without iron accumulation<sup>[6]</sup>. Moreover, elevated iron indices have been associated with a poor response to interferon therapy<sup>[6]</sup>.

At present, the mechanisms responsible for hepatic iron accumulation during HCV infection are not fully understood. It has been proposed that necroinflammation sustained by the virus together with genetic factors that modify iron trafficking might contribute to the alterations in iron homeostasis<sup>[6,23,24]</sup>. Recent studies in transgenic mice expressing the HCV polyprotein have shown

Alcohol: Alcohol intake (g/d); BMI: Body mass index; AST: Aspartate aminotransferase (U/L); ALT: Alanine aminotransferase (U/L); HIC: Hepatic iron concentration ( $\mu\text{mol/g}$  dry tissue); Staging: Knodell's score; Grading: Knodell's score; HI: Histological improvement defined by at least one point reduction in the histological staging score or, in case of unchanged stage, as at least two points reduction in the histological grading score.

that iron accumulation is associated with a low mRNA expression of hepcidin<sup>[25]</sup>, a 25 amino acid peptide synthesized in the liver that regulates iron efflux from the enterocytes as well as the recycling of the metal by the macrophages<sup>[26]</sup>. Low liver hepcidin mRNA levels have also been detected in patients with CHC<sup>[27]</sup>, suggesting the possibility that iron accumulation in CHC might be due to an inappropriate hepcidin response. According to the importance of iron as a worsening factor in the progression of CHC several studies have demonstrated that lowering of hepatic iron by phlebotomy alone or in combination with an iron-restricted diet reduces serum aminotransferase levels in CHC patients who failed a sustained virological response by interferon-based treatment<sup>[11-14]</sup>. Although phlebotomy does not interfere with HCV RNA levels<sup>[12]</sup>, the efficacy of long term iron reduction in preventing the evolution of CHC has been substantiated by a recent histological follow-up study<sup>[16]</sup>. In their report Yano *et al*<sup>[16]</sup> showed that a 5 years iron-reducing treatment significantly lowered necroinflammatory grading and prevented the increase in fibrosis staging when they compared two sequential liver biopsies from non-responder CHC patients to interferon receiving or not phlebotomy. In addition, Kato *et al*<sup>[28]</sup> have reported that phlebotomy in combination with an iron-restricted

diet significantly reduces the development of hepatocarcinomas associated with CHC. Although none of these studies reported side effects of iron lowering (serum ferritin below 20 ng/mL), the long term compliance to such a condition might be problematic in many patients. Therefore, in the present study, we investigated whether, and in which condition, mild iron depletion (serum ferritin below 70 ng/mL) might be effective in inducing histological improvement. Considering that iron depletion might be a simple and inexpensive treatment for those patients not responding to antiviral therapy or having contraindications to the use of interferon it would be important to verify whether similar results might be obtained by a milder iron depletion.

The present study shows that attaining serum ferritin levels  $\leq 70$  ng/mL is effective in decreasing aminotransferase release in Caucasian CHC patients and that 25% of the phlebotomized subjects achieve persistently normal aminotransferase levels during the iron-depleting treatment. Unlike Yano's report<sup>[16]</sup> we did not observe significant changes in the median values of the necroinflammatory score among patients receiving phlebotomy. This likely reflects the lower degree of iron reduction achieved in our patients. However, the different scoring system used for evaluating necroinflammation, as well

**Table 4** Univariate and multivariate logistic regression analysis of the putative predictors of the histological improvement in 28 patients with chronic hepatitis C treated with phlebotomy

	Odds ratio (95% CI)	P

Multivariate analysis on male patients		
Hepatic iron concentration (μmol/g dry tissue)	1.41 (1.03-1.94)	0.031

<sup>1</sup>Only two subjects were drug addicts, so the univariate analysis was not performed; <sup>2</sup>Yes:  $\geq 50$  g/d for men or 20 g/d for women; <sup>3</sup>These variables were selected to enter in the multivariate model; <sup>4</sup>Data were available for 26 out of 28 patients. Steatosis grade: 0, no steatosis; 1,  $\leq 33\%$  of hepatocytes; 2, 34%-66%; 3,  $> 66\%$ .

as the bias caused by the worsening of the grading in our phlebotomized patients who do not respond to iron depletion, might also account for the discrepancy. Nonetheless by taking into account the individual responses to treatment we have observed that mild iron depletion causes histological improvement in male subjects. In these patients multivariate logistic analysis reveals that increased HIC is the only independent predictor of the histological response to mild iron depletion. By using ROC curve we also found that a HIC  $\geq 20$  μmol/g can be used as cut-off to discriminate the CHC patients with high probability of histological improvement while undergoing mild long-term iron depletion.

So far the mechanisms responsible for the beneficial effects of phlebotomy in preventing the evolution of CHC have not been characterized in detail. Recent observations suggest that HCV proteins stimulate the formation of reactive oxygen species within the hepatocytes<sup>[9]</sup>. Thus, iron accumulation probably amplifies oxidative stress-mediated events, worsening both hepatocellular damage and fibrogenic processes. Indeed, mild iron accumulation in the liver of transgenic mice over-expressing HCV polyprotein enhances lipid peroxidation<sup>[8]</sup>. Sup-

porting this view, a recent paper by Fujita *et al.*<sup>[29]</sup> shows that the immunohistochemical detection of 8-hydroxy-2' deoxyguanosine (8-OHdG), a well recognized marker of oxidative stress, is strongly increased in liver biopsies from CHC patients. In these patients hepatic 8-OHdG levels are significantly associated with the hepatic iron content as well as with the necroinflammation indices. Interestingly, iron depletion by phlebotomy greatly reduces the liver content of 8-OHdG in patients with CHC<sup>[30]</sup>, suggesting that the efficacy of phlebotomy in preventing the progression of CHC might rely on the reduction of oxidative damage promoted by the combination of HCV infection and iron accumulation. In this context, our observation that a high HIC is an independent predictor of the histological response to mild iron depletion further points to the possible importance of iron-mediated oxidative damage in the progression of CHC.

In conclusion, the study shows that mild iron depletion might be effective in improving liver histology in Caucasian CHC males with low-grade iron overload non-responders or with contraindications to established antiviral treatments. Prospective randomized studies should further address the long term efficacy of mild iron depletion in CHC patients with signs of iron accumulation.

## COMMENTS

### Background

Iron reduction therapies based on phlebotomy reduce aminotransferase levels and can improve liver histology in patients with chronic hepatitis C (CHC).

### Research frontiers

Although the management of patients with CHC has been improved by antiviral therapies, there is still an urgent need for alternative therapeutic options capable of preventing the progression of the disease in those patients who do not respond to antiviral drugs, have contraindications to the use of interferon and/or ribavirin or cannot afford the cost of therapy. Therefore, it is important to know which patients can benefit from iron reduction therapies.

### Innovations and breakthroughs

The present study shows that male CHC Caucasian patients, with low-grade iron overload (hepatic iron concentration  $\geq 20$  μmol/g), non-responders or with contraindications to antiviral therapy can particularly benefit from mild iron depletion by long-term phlebotomy.

### Applications

This retrospective study demonstrates that mild iron depletion is a safe and effective strategy for preventing the histological progression of the disease in males with CHC and low-grade iron overload. Further randomized prospective studies are warranted.

### Terminology

In this study mild iron depletion means the achievement of a ferritin level below 35 ng/mL after intensive phlebotomy and a ferritin level below 70 ng/mL during long-term maintenance phlebotomy.

### Peer review

This work is very interesting in demonstrating that serial phlebotomy still remains a current method of treatment despite its medieval origins. The results of this study are interesting to clinicians.

### Abstract

**AIM:** To investigate the similarities and dissimilarities in patients with hepatitis B and hepatitis C, clinically and metabolically.

**METHODS:** Fifty patients with hepatitis B virus and hepatitis C virus infection were included in this study, along with fifty healthy controls for comparison purposes. Intravenous blood (10 mL) samples from patients and healthy subjects were collected and made to clot before serum was separated and immediately levels of the enzymes, alkaline phosphatase (ALK), creatinine phosphokinase (CPK), lactate dehydrogenase (LDH), serum glutamate oxaloacetate transaminase (s-GOT) and serum glutamate pyruvate transaminase (s-GPT) were determined by a kit method. For total con-

tent of each metal the serum samples were analyzed using atomic absorption spectrophotometry. Levels of cholesterol, triglycerides, urea, creatinine and uric acid were determined using a kit method on Microlab 300.

**RESULTS:** Serum magnesium and copper levels remained unchanged, whereas the concentration of zinc decreased and iron increased significantly in both groups of patients. Total antioxidant activity was significantly decreased in both hepatitis B and C. Among the enzymes analyzed, ALK, s-GPT, LDH and s-GOT were all significantly increased in both patients with hepatitis B and C whereas CPK was significantly decreased in patients with hepatitis B and remained unchanged in patients with hepatitis C.

**CONCLUSION:** The information accumulated by this study will help provide a better understanding of involved metabolic processes in order to design appropriate therapeutic approaches for treating these patients, so they can recover and lead normal lives.

### INTRODUCTION

The liver is one of the most important organs in energy

metabolism. Most plasma apolipoproteins, endogenous lipids and lipoproteins are synthesized in the liver. This depends on the integrity of liver cellular function, which ensures homeostasis of lipid and lipoprotein metabolism. Hepatitis B virus (HBV) infection, a major world health problem, is hyper-endemic in South-East Asia and sub-Saharan Africa. Being a major cause of morbidity and mortality, prophylaxis using the highly efficacious hepatitis B vaccine is recommended for those at risk<sup>[1]</sup>. The hepatitis C virus (HCV) is a linear, single-stranded RNA virus of the *Flaviviridae* family that was identified in 1989 and is recognized as the major causal agent of non-A, non-B hepatitis<sup>[2]</sup>. HCV is one of the leading causes of chronic liver disease worldwide, affecting 3% of the world's population. Diagnosis and treatment of HCV-related autoimmune features has become a clinical challenge in HCV-infected patients, in whom chronic liver disease associated with severe autoimmune features may contribute to a very poor prognosis<sup>[3,4]</sup>.

Enzymes are biocatalysts and catalyze relevant bio-reactions. Metals such as magnesium (Mg), copper (Cu), zinc (Zn) and iron (Fe) are the cofactors of enzymes. Enzymes are released into the blood by injured tissue along with the metals and each affected tissue can be identified by evaluation of the variation in enzyme activity and metals in blood serum. Metals are present in bones, tissues and body fluids and are built into key ingredients in enzymes and hormones. They also assist in every aspect of life from production of hormones, vitamins and energy, digestion, neurotransmission and muscle contraction to regulation of pH, metabolism, cholesterol and blood sugar. Our physical wellbeing is more dependent upon the minerals we take into our system than upon calories or vitamins or carbohydrates and proteins.

In the present study, the estimation of serum enzyme activity of alkaline phosphatase (ALK), glutamate pyruvate transaminase (SGPT or ALT), lactate dehydrogenase (LDH) and serum glutamic oxaloacetic transaminase (SGOT or AST) along with levels of metals (Cu, Fe, Mg, and Zn) are evaluated in patients with hepatitis B and C to study similarities and dissimilarities in these hepatitis groups, with the aim of defining biochemical mechanisms to help in selecting or designing chemotherapy suitable for these patients.

## MATERIALS AND METHODS

Third-generation micro-ELISA assays were used for detection of hepatitis B surface antigen, antibody to hepatitis B core and surface antibody, secretory form of hepatitis B envelop antigen (HBeAg), antibody to secretory form of HBeAg, and ELISA for antibody to HCV. Clinical and laboratory features are helpful, but liver biopsy is essential for definitive diagnosis. Once the diagnosis was confirmed, 50 patients in each group of HBV and HCV were included in this study. Fifty healthy controls were included for comparison purposes. The

clinical data regarding patient and healthy control groups are shown in Table 1.

Intravenous blood (10 mL) samples from hepatitis B/C patients and healthy subjects were collected and made to clot before serum was separated by centrifuging at 5000 r/min for 20 min and immediately the enzymes ALK, creatinine phosphokinase (CPK), LDH, serum glutamate oxaloacetate transaminase (s-GOT) and serum glutamate pyruvate transaminase (s-GPT) were determined by a kit method. For total content of each metal the serum samples were analyzed using a Hitachi atomic absorption spectrophotometer (Tokyo, Japan). Cholesterol, triglycerides, urea, creatinine and uric acid were determined using a kit method on Microlab 300.

## Statistical analysis

All values are expressed as mean  $\pm$  SE. For comparison between the patients *vs* healthy controls, Student's *t* test, non-parametric Mann-Whitney test and SPSS 15 were used. A *P* value less than 0.05 was considered statistically significant.

## RESULTS

Table 2 shows plasma levels of urea, creatinine and uric acid in B and C hepatitis patients and healthy controls. Among the biochemical parameters associated with kidney function, the levels of urea and creatinine were significantly decreased in both HBV and HCV patients,

**Table 3** Enzyme activity in blood serum of patients with Hepatitis B/C and healthy controls

<sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01, <sup>c</sup>*P* < 0.001 *vs* controls.

however, uric acid was increased significantly in both patient groups. With regard to plasma cholesterol levels (total, HDL and LDL) and triglycerides in hepatitis groups (HBV and HCV) and control subjects; cholesterol level was decreased in both patient groups whereas triglyceride levels decreased significantly in HCV and remained unchanged in HBV group. Table 2 also shows the serum levels of Mg, Fe, Zn and Cu. There was no significant difference in Mg and Cu levels for both HBV and HCV groups. Serum levels of Fe increased significantly whereas Zn decreased significantly in both patient groups. Total antioxidant activity showed significant decreases in both groups of patients.

Table 3 shows activity of the enzymes ALK, ALT, AST, CPK and LDH. ALK was only increased significantly in HBV patients and remained unchanged in HCV patients. ALT increased significantly in both patient groups but markedly in HCV patients. CPK was decreased in HBV but remained unchanged in HCV patients. LDH increased significantly in both group of patients and markedly in HCV patients. AST increased in both groups of patients. The ratio between ALT and AST was increased significantly in both patient groups.

## DISCUSSION

Hepatitis C infection is associated with diabetes mellitus and insulin resistance and it is suggested that metabolic syndrome is common in patients with hepatitis C. Microalbuminuria is common in patients with diabetes and metabolic syndrome<sup>[5]</sup>.

A decade ago, various authors described the association of chronic HCV infection with a heterogeneous group of non-hepatic conditions, such as pulmonary fibrosis, cutaneous vasculitis, glomerulonephritis, Mooren's ulcer, porphyria cutanea tarda and lichen planus<sup>[6]</sup>. The drug regimens available for treating chronic HCV infection are monotherapy with interferon  $\alpha$  (IFN- $\alpha$ ) and combined therapy with IFN- $\alpha$  and ribavirin<sup>[7]</sup>. With progressive liver disease serum albumin levels fall, reflecting its decreased synthesis. We found a significant decrease in albumin levels in patients with both hepatitis B and C.

HCV viremia appears to be associated with lower serum cholesterol and triglyceride levels which implies that HCV itself might play a significant role in serum

lipid profiles of patients with chronic HCV infection<sup>[8]</sup>. In our study, low levels of cholesterol (total, HDL and LDL) were found in both groups of hepatitis patients whereas significant decrease in triglycerides was only observed in HCV patients. It is known that about 50% of insulin secreted by the pancreas is removed by first-pass extraction in the liver. Insulin promotes glycogen synthesis (glycogenesis) in the liver and inhibits its breakdown (glycogenolysis). It promotes protein, cholesterol, and triglyceride synthesis and stimulates formation of very-low-density lipoprotein cholesterol. The liver is the primary target organ for glucagon action, where it promotes glycogenolysis, gluconeogenesis, and ketogenesis<sup>[9]</sup>.

Among the metals, the central importance of Fe in the pathophysiology of disease is derived from the ease with which Fe is reversibly oxidized and reduced. This property, while essential for its metabolic functions, makes Fe potentially hazardous because of its ability to participate in the generation of powerful oxidant species such as the hydroxyl radical<sup>[8]</sup>. It is now well established that oxidants can cause the release of catalytic Fe<sup>[7]</sup>; thus, a vicious cycle is initiated that leads to the formation of more reactive oxygen species.

In our study, the serum level of Fe was elevated significantly in both HBV and HCV patients. These data on the relevance of Fe as a prognostic factor prompted us to ascertain whether HCV- and HBV-related liver damage is mediated by Fe accumulation. We have also observed decreased total oxidative activity in both patient groups and hence increases in Fe generate reactive oxygen species which may exceed the capacity of the antioxidant system and perpetuate oxidative stress to cells. Oxidative stress with the attendant low-grade inflammation is implicated in a number of pathological conditions, including aging, atherosclerosis, and diabetes<sup>[6]</sup>. In a study of patients with unexplained hepatic Fe overload, most were found to be insulin-resistant, which suggests a common etiologic link between hepatic Fe, hepatic dysfunction, and insulin resistance<sup>[10]</sup>. Insulin deficiency due to iron deposition in the interstitial pancreatic cells, with resultant excess collagen deposition and defective microcirculation<sup>[10]</sup> and insulin resistance<sup>[11]</sup>, are the likely mechanisms for type 2 diabetes. It has been shown that treatment with intravenous or oral chelation improves glucose tolerance in up to one-third of these patients, suggesting a causal role for Fe<sup>[12,13]</sup>. In one study it was shown that Fe overload may be responsible for insulin resistance, or *vice versa*<sup>[11]</sup>. Other metals such as Cu and Zn are essential trace elements for several metabolic processes. Regarding Zn, patients with chronic hepatic encephalopathy have been shown to have low serum Zn levels. Moreover, in a controlled study, significant improvement was seen in those patients on oral Zn supplementation<sup>[14]</sup>. In our patients with HBV and HCV, both groups showed significantly decreased Zn levels. Various studies have shown both Cu and Mg levels in serum remained unchanged in HBV and HCV patients, though content of Zn and selenium in plasma and erythrocytes were significantly lower in hepatitis C

and B patients<sup>[15,16]</sup>. Our results show a similar tendency in HBV and HCV patients.

Disturbances in the antioxidant system could play a role in the pathogenesis of chronic liver disease. During the course of chronic liver disease we may observe slight irregularities in iron status relating to both the serum and store pool of this element. The most significant disturbances are seen in patients with alcoholic cirrhosis of the liver<sup>[17]</sup>. These findings suggest that disturbances in antioxidant parameters in the blood of patients with chronic liver disease may be the cause of the peroxidative damage of cells. In both HBV and HCV, antioxidant activity is significantly decreased. The release of oxidative free radicals, deficiency in antioxidant enzymes and the expression of bcl-2 protein might play a role in the pathogenesis of viral hepatitis. The ability to measure bcl-2 protein in the serum could be useful as a prognostic marker in cancer patients<sup>[18]</sup>.

The availability of serum blood chemistry tests for screening both symptomatic and asymptomatic patients has resulted in a marked increase in the number of abnormal liver chemistry tests that must be interpreted by physicians. Usually the first step in the evaluation of a patient with elevated liver enzymes is to repeat the test to confirm the result. There is a hypothesis that enzymes conventionally associated with liver dysfunction, AST, ALT and  $\gamma$ -glutamyltransferase (GGT), may predict diabetes. However, the role of enzymes such as ALK, s-GPT, LDH, CPK and s-GOT or AST is controversial in many studies<sup>[15]</sup>. In our study, significantly increased levels of ALK, SGPT (or ALT), LDH and SGOT (or AST) were found, whereas, CPK activity decreased in both groups of hepatitis patients. A recent study showed that one-third of the hospitalized patients with liver cirrhosis are infected with HBV or HCV infection, with raised ALT/AST and ALK being more common with superadded viral infection<sup>[19]</sup>. Another study showed that there were also significant correlations between Fe status, as indicated by transferrin saturation or serum ferritin levels, and SGOT, SGPT, and GGT levels. Moreover, abnormal liver function, as represented by elevated levels of SGOT, SGPT, GGT and serum ALK, was observed more frequently in patients with Fe overload than in patients with a lower degree of Fe burden<sup>[16]</sup>.

AST is present in cytosolic and mitochondrial isoenzymes and is found in the liver, cardiac muscle, skeletal muscle, kidneys, brain, pancreas, lungs, leucocytes, and red cells<sup>[18]</sup>. ALT, a cytosolic enzyme, is found in its highest concentrations in the liver and is more specific to the liver<sup>[20,21]</sup>. The most common causes of elevated AST levels are chronic hepatitis B and C, autoimmune hepatitis, non-alcoholic steatohepatitis, hemochromatosis, Wilson's disease, celiac sprue, muscle damage and myocardial infarction<sup>[21,22]</sup>.

Among the liver enzymes, ALT is both sensitive and specific for liver disease of a hepatocellular injury type. Elevations in ALT levels should be interpreted as indicative of liver disease with only rare exceptions:

severe rhabdomyolysis or systemic myopathies. Our study showed that this enzyme increased significantly in both HCV and HBV patients. ALT to AST ratios greater than 1 are typically found in patients with viral hepatitis, drug-induced liver disease, autoimmune disorders, *etc.*, whereas ratios less than 1 are more often associated with alcohol-induced liver disease, ischemic forms of liver disease (passive congestion or under-perfusion), biliary tract obstruction and certain disorders that tend to result in a predominantly mitochondrial form of cell injury such as fatty liver of pregnancy, tetracycline toxicity, Reye's syndrome, *etc.* The use of this ratio can also be helpful when assessing the severity of liver disease, because once liver disease has progressed to cirrhosis (regardless of the underlying etiology) an elevated ALT to AST ratio often falls to values of 1 or less<sup>[23]</sup>. Indeed, in our study high ALT to AST ratios were observed in HCV and HBV patients.

From the results of our study, we conclude that parameters such as enzyme activity and the levels of metals such as Fe, Zn, Mg and Cu, along with total antioxidant activity, in patients with hepatitis B and C can be used to measure the status of the disease. We recommend further research in the area of antioxidant therapy.

## COMMENTS

### Background

Patients with hepatitis B and C are at risk for poor nutritional status, poor response to bacterial and viral infections, stomach ulcers, kidney disorders, gallstones, liver cancer, and diabetes mellitus. All such events lead to life threatening complications and act as poor prognostic factors.

### Research frontiers

Disturbances in liver biochemistry, serum metal levels and dyslipidemia are usually observed in patients with chronic viral hepatitis. There has been no study to differentiate between the two hepatitis viruses in terms of metabolic derangement as compared with healthy subjects. This study is designed with the objective of investigating the similarities and dissimilarities in patients with hepatitis B and hepatitis C, clinically and metabolically.

### Innovations and breakthroughs

It was identified that serum magnesium (Mg) and copper (Cu) levels remained unchanged, whereas the concentration of zinc (Zn) decreased and iron (Fe) increased significantly in both groups of patients. Total antioxidant activity was significantly decreased in both hepatitis B and C. Among the enzymes analyzed, ALK, s-GPT, LDH and s-GOT were all significantly increased in both patients with hepatitis B and C, whereas CPK was significantly decreased in patients with hepatitis B and remained unchanged in patients with hepatitis C.

### Applications

By understanding the liver enzyme profile, serum biochemistry and metal levels in relation to hepatitis B and C virus, one can assess the exact health status of such patients and plan the specific and necessary parameters to control such life-threatening biochemical modifications. For the development of future therapeutic strategies, this study may need to be continued in a more advanced and extensive manner at different health care centers.

**Peer review**

This study shows the comparison of serum metal content of healthy individuals to HCV or HBV infected persons. As most of the parameters have already been known for HBV and HCV infected individuals, peer reviewer think it should be accepted as a brief report after the consolidation of the discussion part.

### Abstract

**AIM:** To study the hemodynamics in the immediate post transplant period and compare patients with alcoholic vs viral cirrhosis.

**METHODS:** Between 2000-2003, 38 patients were transplanted for alcoholic cirrhosis and 28 for postviral cirrhosis. Heart rate (HR), central venous pressure (CVP), mean arterial pressure (MAP), pulmonary capillary wedge pressure (PCWP), cardiac index (CI), systemic vascular resistance index (SVRI), pulmonary artery pressure (PAP), and pulmonary vascular resistance index (PVRI) were measured immediately and 24 h post transplantation.

**RESULTS:** Hyperdynamic circulation persisted at 24 h

following transplantation with an elevated CI of  $5.4 \pm 1.3$  L/(min  $\times$  m<sup>2</sup>) and  $4.9 \pm 1.0$  L/(min  $\times$  m<sup>2</sup>) in the viral and alcoholic groups, respectively, and was associated with a decreased SVRI. Within the first 24 h, there was a significant decrease in HR and increase in MAP; the extent of the change was similar in both groups. The CVP, PCWP, and SVRI increased, and CI decreased in the viral patients, but not the alcoholic patients. Alcoholics showed a lower PVRI ( $119 \pm 52$  dynes/(cm<sup>5</sup>  $\times$  m<sup>2</sup>) vs  $166 \pm 110$  dynes/(cm<sup>5</sup>  $\times$  m<sup>2</sup>),  $P < 0.05$ ) and PAP ( $20 \pm 7$  mmHg vs  $24 \pm 7$  mmHg,  $P < 0.05$ ) compared to the viral group at 24 h.

**CONCLUSION:** Hyperdynamic circulation persists in the immediate post-transplant period with a faster improvement in the viral group. Alcoholic patients have a more pronounced pulmonary vasodilatation.

Hemodynamics in the immediate post-transplantation period in alcoholic and viral cirrhosis. *World J Gastroenterol* 2010; 16(5): 608-612 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i5/608.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i5.608>

### INTRODUCTION

Patients with end stage liver disease manifest a hyperdynamic circulation characterized by a decrease in the systemic vascular resistance and arterial pressure, and

an increase in cardiac output<sup>[1-5]</sup>. Many patients with advanced cirrhosis also have pulmonary vascular abnormalities, ranging from hepatopulmonary syndrome to pulmonary hypertension. Although several studies have examined these aspects of the circulation in the medium- and long-term postoperative period after liver transplantation (weeks to months), the cardiovascular profile in the immediate postoperative period remains unclear.

To what extent these changes persist following liver transplantation is unclear, and whether patients with alcoholic cirrhosis who are also at risk of alcoholic cardiomyopathy manifest a different hemodynamic pattern compared to patients with post viral cirrhosis is yet to be determined.

Therefore we conducted a retrospective review of orthotopic liver transplantation (OLT) performed at the Alberta Liver Transplant program between 2000-2003 to assess the systemic and pulmonary hemodynamics within the first 24 h following liver transplantation in patients transplanted for both alcoholic and viral induced cirrhosis.

## MATERIALS AND METHODS

### Patients

Systemic and pulmonary hemodynamics for 66 patients (38 alcoholic, 28 viral) receiving a cadaveric liver transplantation for end stage liver disease between January 2000 and January 2003 were evaluated immediately following surgery and 24 h later. There were 26 male patients in the alcohol group and seven in the viral group. The average age was 51 years (range 35-57 years) and 49 years (range 41-74 years) in the two groups, respectively. All included patients were thoroughly evaluated for any coexisting cardiovascular or pulmonary disease as part of the pre-transplant workup.

Following liver transplantation, these patients were transferred to the intensive care unit at the University of Alberta hospital. Postoperative care included: (1) Frequent daily rounds conducted by the intensive care team, transplant hepatologist, transplant surgeons, and other consultants as required; (2) Endotracheal intubation and mechanical ventilation to maintain adequate oxygenation with frequent intra-arterial monitoring through a catheter inserted prior to surgery; intubation was discontinued as soon as possible following the transplantation; (3) Continuous monitoring of the heart rate (HR), blood pressure, and oxygenation, as well as a continuous electrocardiographic tracing; (4) Systemic and pulmonary hemodynamics, including cardiac index (CI), systemic vascular resistance index (SVRI), pulmonary capillary wedge pressure (PCWP), central venous pressure (CVP), mean arterial pressure (MAP), pulmonary artery pressure (PAP), and pulmonary vascular resistance index (PVRI) were measured every 8 h during the first 24 h through a pulmonary arterial (Swan Ganz) catheter inserted preoperatively; (5) Laboratory investigations including a complete cell count, electrolytes, kidney function, coagulation

Table 1 Pulmonary and systemic hemodynamics at 24 h

	Alcohol	Viral
MELD score	16.2 ± 6.6	16.5 ± 7.3
HR (beats/min)	88 ± 16	86 ± 13
MAP (mmHg)	94.0 ± 17.2	95.1 ± 11.4
PAP (mmHg)	20.3 ± 6.9	24.1 ± 7.5 <sup>a</sup>
PCWP (mmHg)	13.5 ± 6.5	15.2 ± 4.6
CVP (mmHg)	10.3 ± 4.7	13.0 ± 5.0
CI [L/(min × m <sup>2</sup> )]	4.8 ± 1.1	4.8 ± 0.9
SVRI [dynes/(cm <sup>5</sup> × m <sup>2</sup> )]	1391 ± 425	1398 ± 350

profile, liver enzymes, and albumin were obtained twice a day (or more if indicated) for the first few days; and (6) Fluid balance was charted every 8 h with measurements of total fluid input and output, including surgical drains. Patients who suffered a gastrointestinal bleed or who had a sudden unexplained drop in the hemoglobin (> 2 g/L) underwent the appropriate investigation and were not included in the study. Patients were also excluded from the study if they developed sepsis within the first 72 h following transplantation, required dialysis, had an adverse intraoperative or immediate post operative course requiring continuous pressure support, or were being transplanted for the second time. This study was approved by the Research Ethics Committee of the hospital.

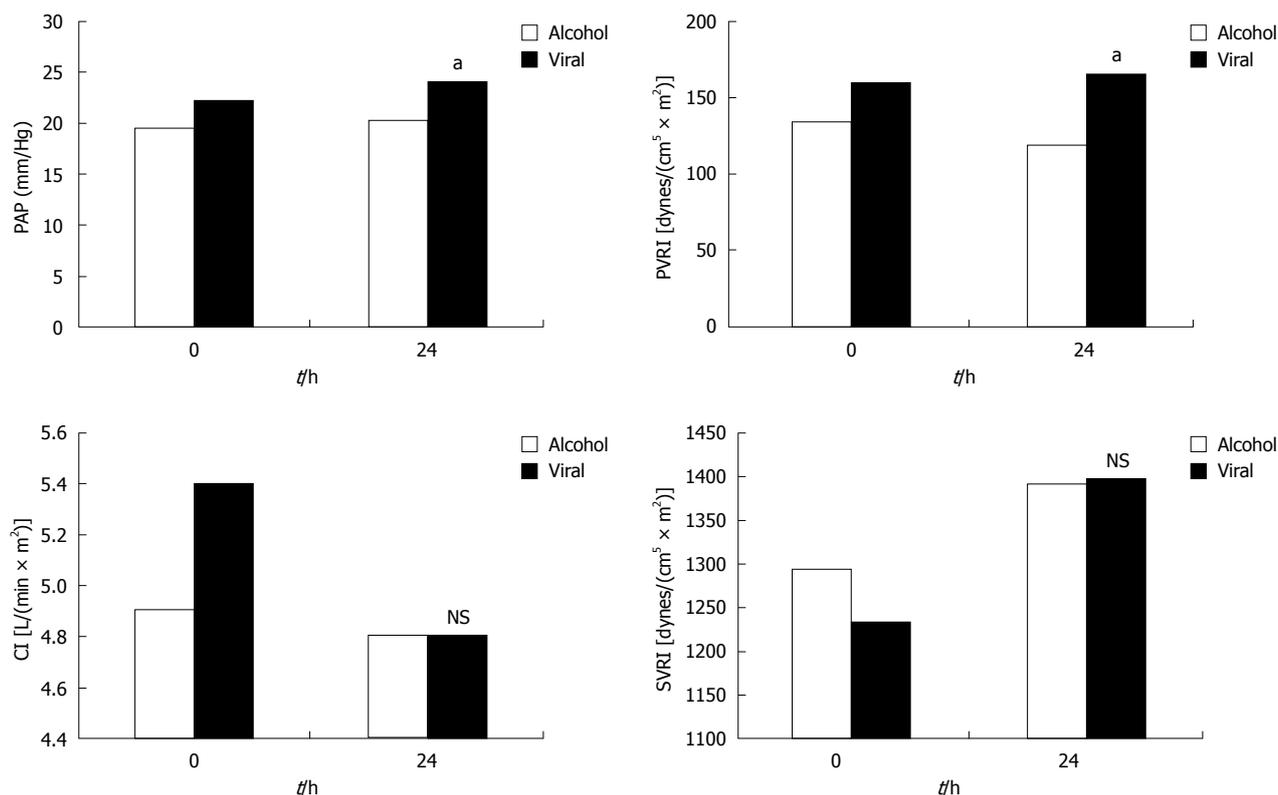

### Statistical analysis

Results were expressed as mean ± SD. Statistical analysis was done using STATA software (Version 8). Analysis was done using Student's *t*-test. A *P* value of less than 0.05 (two-sided test) was considered statistically significant. The correlations of disease severity graded by the model for end-stage liver disease (MELD) score and the various hemodynamic parameters were analyzed using Spearman's rank correlation coefficient.

## RESULTS

Hyperdynamic circulation persisted within the first 24 h with an elevated mean CI of 5.4 and 4.9 L/(min × m<sup>2</sup>), immediately following surgery in the viral and alcoholic group, respectively. The SVRI was also low at 1232 and 1294 dynes/(cm<sup>5</sup> × m<sup>2</sup>) in the two groups, respectively; however, these differences were not statistically significant.

Patients with alcoholic cirrhosis manifested a lower PVRI and a lower PAP, compared to the viral group at 24 h post transplant (*P* = 0.024 and 0.037, respectively) (Figure 1, Table 1). There were no significant differences in CVP, PCWP, HR, and MAP between the two groups at both time periods. The HR decreased significantly in association with an increase in the MAP over the first

**Figure 1** Hemodynamic changes within the first 24 h in both groups. \**P* < 0.05. NS: Not significant; PAP: Pulmonary artery pressures; PVRI: Pulmonary vascular resistance index; CI: Cardiac index; SVRI: Systemic vascular resistance index.

24 h in both groups. There was also an increase in the CVP, PCWP, SVRI, and a decrease in the CI in both groups over the first 24 h; these changes reached statistical significance only in the viral cirrhosis group (Table 2).

There were weak, insignificant correlations between the pre transplant MELD score and the CO, SVRI, PAP, PVRI with a Spearman's rank correlation coefficient of 0.0919, -0.1881, 0.0945, -0.0939, respectively.

## DISCUSSION

In this study, we showed that cirrhosis-associated hyper-

dynamic circulation persists in the immediate postoperative period, regardless of the etiology of the underlying liver disease. To our knowledge, this is the first study to compare hemodynamic changes in alcohol *vs* viral induced cirrhosis in the immediate postoperative period. Our results suggest that patients with viral-related cirrhosis have a rapid improvement in systemic hemodynamics, with a decrease in the cardiac output and an increase in the systemic vascular resistance; these changes were lacking in the alcohol group. We also showed that the increase in systemic vascular resistance was associated with a proportionate increase in CVP and PCWP unmasking the cardiac dysfunction of cirrhotic cardiomyopathy<sup>[3-5]</sup>. These results emphasize the additional effect of alcohol on the pathogenesis of the associated hyperdynamic circulation. Autonomic dysfunction has been clearly described in alcoholics<sup>[6,7]</sup>, alcoholic liver disease<sup>[8-10]</sup>, and to a lesser degree, in non-alcoholic chronic liver disease; the latter is thought to be related to the severity of the underlying liver disease<sup>[11,12]</sup>. Liu *et al*<sup>[13]</sup> demonstrated the role of vagal stimulation in the hyperdynamic circulation of cirrhotic rats, and by blocking this pathway the hyperdynamic circulation significantly decreased in the portal hypertensive rats. Lindgren *et al*<sup>[14]</sup> demonstrated that the autonomic, particularly vagal, nerve dysfunction of chronic liver disease is further exaggerated by alcohol abuse, suggesting that in alcoholic liver disease, sympathetic neuropathy adds to the parasympathetic dysfunction, which further contributes to the altered vascular

responsiveness in patients with alcoholic cirrhosis. It has also been suggested that alcohol consumption has a short and long term effect in reducing the vascular responses to endogenous vasoconstrictors<sup>[15,16]</sup>. Other factors that might contribute to the hyperdynamic circulation in both groups include vasoactive substances (such as nitric oxide and carbon monoxide), A-V shunts, increased blood volume, and central neural dysregulation<sup>[5,17-19]</sup>.

The consequences of these cardiovascular alterations can lead to significant cardiovascular derangements at the time of transplantation. OLT induces severe stresses on the cardiovascular system, during both intra- and postoperative periods<sup>[20,21]</sup>. Intraoperatively, the sudden reduction in the preload and the impaired cardiac contractility can result in significant reduction in cardiac output. Postoperatively, patients are at risk of hypovolemia from various factors, including hemorrhage, third space losses, and ongoing ascites formation. On the other hand, volume overload from aggressive fluid replacement can also stress the heart. Furthermore, the rapid improvement of systemic vasodilatation can result in a sudden increase in the afterload, adding extra stress to the heart. Metabolic derangements, in the form of acidosis, hypothermia, and electrolyte disturbance in the immediate postoperative period, can also impair the cardiac contractility and lead to hemodynamic instability and fluctuation. Hemodynamic depression caused by hypocalcemia-induced citrate intoxication from massive transfusion, or as a result of the reperfusion syndrome, has been described following OLT.

Cardiac complications following liver transplantation are common, involving 25%-70% of patients; fortunately most of these complications are mild and subclinical, with no significant impact on patient or graft survival<sup>[22-24]</sup>. Pulmonary edema following OLT is the most common cardiovascular complication, with at least 50% of these episodes developing within the first 24 h<sup>[21,25]</sup>. Careful fluid management and continuous cardiac monitoring in the immediate post transplant period is extremely important to avoid cardiac-related complications.

Studies examining hemodynamics after liver transplantation are limited and the results of those studies do not always agree with each other. Glauser<sup>[26]</sup> studied the systemic hemodynamics within the first 96 h following liver transplantation in 21 patients; his results suggested a progressive improvement towards normal within the study period. Navasa *et al.*<sup>[27]</sup> examined hemodynamics at 2 wk and 2 mo following liver transplantation, and suggested that most of the hemodynamic changes reverse. However, the limitations of these two studies are the small number of patients included (21 and 12, respectively), as well as the diverse indications for liver transplantation—thus only three and five patients were transplanted for alcoholic liver disease in the two studies, respectively. In contrast, other studies suggested persistence of hyperdynamic circulation for at least 6 mo<sup>[28-30]</sup>. In our study, we excluded factors that might affect the systemic circulation, such as anemia, sepsis, and renal failure. Patients

who were transplanted previously and were receiving their second or third transplant were also excluded; such surgeries disrupt local innervations and blood supply and might impact the vascular hemodynamics.

A low pulmonary vascular resistance has been described in patients with cirrhosis<sup>[31-34]</sup>. This also is thought to be related to endogenous vasodilators, as measured nitric oxide in exhaled air was higher in patients with cirrhosis compared to the general population<sup>[35]</sup>. Our data suggests that this pulmonary vasodilatory effect persists in the immediate post-transplant period. Furthermore, we showed that patients with alcoholic cirrhosis have a more profound decrease in the pulmonary vascular resistance associated with a significantly lower PAP; this could be related to a higher degree of intrapulmonary vascular shunting in patients with alcoholic cirrhosis and could, in part, be related to alcohol-induced depression in the vascular response to endogenous vasoconstrictors<sup>[36]</sup>.

In our study the MELD score did not significantly correlate with hemodynamic disturbance. We believe this is because the study cohort had a limited range of dispersion of MELD scores and hyperdynamic circulation, i.e. almost all patients had high MELD scores and also a significantly abnormal extent of hyperdynamic circulation. It is possible that inclusion of a larger range of less sick patients with lower MELD scores and less hyperdynamic circulation might have allowed a correlation to become more evident. However, such patients would not be considered for transplantation.

In conclusion, our data suggests that the systemic hyperdynamic circulation persists in the immediate post-transplant period. The pattern of changes in hemodynamics in the immediate post transplant period, as well as in the pulmonary circulation, differed in the two groups, suggesting an alcohol-related impact on the neurohumoral factors involved in the pathogenesis of hyperdynamic circulation of cirrhosis.

## COMMENTS

### Background

Cirrhosis is associated with hyperdynamic circulation and pulmonary vascular abnormalities; whether these abnormalities persist in the immediate post-transplantation, and differ according to the cause of cirrhosis remains unclear. The aim of this study was to compare the hemodynamics in alcoholic vs viral cirrhosis.

### Research frontiers

Cirrhosis is associated with significant cardiovascular abnormalities including hyperdynamic circulation, systemic vasodilatation, and cirrhotic cardiomyopathy. The immediate effect of liver transplantation on these cardiovascular changes has not been adequately studied. Prior studies on the effect of transplantation on the cardiovascular abnormalities were variable and not consistent.

### Innovations and breakthroughs

This is the first study to compare hemodynamics in the immediate post transplant period in patients with alcoholic and viral related cirrhosis. The results indicate that, although the hyperdynamic circulation persists in the immediate post-transplant period, systemic parameters improve faster in the viral group. Pulmonary hemodynamics differ significantly between alcoholic and postviral patients within the first 24 h, suggesting that alcoholics might have more pronounced pulmonary vasodilation than viral-cirrhotic patients.

**Applications**

Following liver transplantation, careful patient monitoring and frequent assessment of the cardiac and fluid volume status is essential to avoid any cardiac-related adverse effects.

**Peer review**

This is a retrospective study comparing the immediate hemodynamic status of patients with viral cirrhosis with that of those with alcoholic cirrhosis after liver transplantation. The authors found that the viral group has better recovery in hyperdynamic circulation after transplant than the alcoholic group, which has more pronounced pulmonary vasodilatation. This finding is interesting, but the clinical importance of this finding has to be further elaborated by the authors.

### Abstract

**AIM:** To investigate the incidence of nocturnal dyspeptic symptoms in patients with functional dyspepsia (FD) and whether prokinetic drugs can alleviate them.

**METHODS:** Eighty-five consecutive Chinese patients with FD were included in this study. One week after single-blinded placebo run-in treatment, baseline nocturnal intragastric pH, bile reflux and nocturnal dyspeptic symptoms of eligible patients, including epigastric pain or discomfort, abdominal distention and belching, were investigated with questionnaires. Patients exhibiting nocturnal dyspeptic symptoms were randomly and double-blindly assigned to domperidone group or placebo group. Nocturnal intragastric pH and percentage of duodenogastric bile reflux time were determined after treatment.

**RESULTS:** Of the 85 FD patients, 2 females without

nocturnal symptoms, who responded to placebo run-in treatment, were excluded from the study, 30 (36.1%) exhibited nocturnal dyspeptic symptoms with increased duodenogastric bile reflux time (intragastric bilirubin absorbance > 0.14) and mean gastric pH (confirming the existence of bile reflux) ( $P = 0.021, 0.023$ ) at night were included in the study. Of these 30 patients, 21 (70%) had overt nocturnal duodenogastric bile reflux, which was significantly higher than that of those without nocturnal symptoms ( $P = 0.026$ ). The 30 patients were allocated to domperidone group or placebo group ( $n = 15$ ). The nocturnal duodenogastric bile reflux and gastric pH were significantly decreased after domperidone treatment ( $P = 0.015, 0.021$ ). The severity score of nocturnal dyspeptic symptoms was also significantly decreased after domperidone treatment ( $P = 0.010, 0.015, 0.026$ ), which was positively correlated with the reduced nocturnal bile reflux or gastric pH ( $r = 0.736, 0.784, 0.753$  or  $r = 0.679, 0.715, 0.697, P = 0.039, 0.036, 0.037$  or  $P = 0.043, 0.039, 0.040$ ).

**CONCLUSION:** A subgroup of Chinese FD patients show overt nocturnal dyspeptic symptoms, which may be correlated with the excessive nocturnal duodenogastric bile reflux. Domperidone therapy can alleviate these symptoms.

## INTRODUCTION

Functional dyspepsia (FD) is a common chronic disorder with non-specific upper abdominal symptoms such as persistent or relapsing pain or discomfort<sup>[1]</sup>. Its underlying pathophysiological mechanism has not been fully elucidated. Besides the role of excessive chemical (both acidic and alkaline) stimuli in the gastric lumen and/or hypersensitivity to these stimuli, impaired gastrointestinal (GI) motility is intensively involved in FD pathogenesis<sup>[2-4]</sup>. Delayed gastric emptying or intestinal peristalsis may influence GI secretion function which may in turn further affect GI motility, resulting in alterations in luminal chemical environment, abnormal duodenogastric bile reflux and FD symptoms<sup>[5]</sup>.

Although the optimal treatment of FD has not yet been established, empirical pharmacological interventions with prokinetic agents are effective in a subgroup of FD patients<sup>[6-8]</sup>. Domperidone, a peripheral dopamine (D<sub>2</sub>) receptor antagonist, acts as an antiemetic and prokinetic agent through its effects on the chemoreceptor trigger zone and motor function of the stomach and small intestine, thus promoting gastric emptying by augmenting gastric peristalsis and improving antroduodenal coordination<sup>[9,10]</sup>. Domperidone has been used in treatment of a variety of GI motility disorders, such as gastroparesis and gastroesophageal reflux disease, with an acceptable safety profile and a relatively good therapeutic efficacy for FD<sup>[7,10]</sup>.

In clinical practice, gastroenterological physicians frequently meet a subgroup of FD patients with obvious nocturnal dyspeptic symptoms such as epigastric pain or discomfort, abdominal distention or belching. Up to now, however, their prevalence and mechanism and whether prokinetic drugs can alleviate them are still unknown.

This study was aimed to evaluate the prevalence of nocturnal dyspeptic symptoms, the relation between such symptoms and nocturnal intragastric pH or duodenogastric bile reflux, and the effect of 2-wk oral administration of domperidone on these symptoms.

## MATERIALS AND METHODS

### Patients

Eighty-five consecutively patients, including 38 males at the age of 22-56 years who were diagnosed as FD according to Rome II criteria, were enrolled in this study. All patients were admitted because of dyspeptic symptoms and underwent routine biochemistry, bilimetry, upper GI endoscopy and abdominal ultrasonography. Inclusion criteria included the presence of dyspeptic symptoms for at least 3 mo in the past year, the absence of organic, systemic or metabolic disease, 2 or more dyspeptic symptoms present at least in 3 d per week such as epigastric pain or discomfort, abdominal distention and belching. Exclusion criteria were the presence of esophagitis, severe atrophic gastritis, erosive or ulcerative gastroduodenal lesions on endoscopy, heartburn as a predominant symptom, a history of peptic ulcer, major

abdominal surgery, or underlying psychiatric illness, and use of nonsteroidal anti-inflammatory drugs, steroids, or drugs affecting gastric motility and acid secretion during the last week.

### Study protocol

This study was conducted at Department of Gastroenterology, Shanghai Institute of Digestive Diseases, Renji Hospital, Shanghai Jiaotong University School of Medicine, according to the ethical principles in Declaration of Helsinki and the requirements of local laws and regulations. The study protocol was approved by the Ethics Committee of Renji Hospital. Written informed consent was obtained from each participant prior to the study.

Patients with a severity score of at least two individual symptoms decreased by 50% were excluded. One week after single-blinded placebo run-in treatment, baseline nocturnal intragastric pH, bile reflux and nocturnal dyspeptic symptoms of eligible patients, including epigastric pain or discomfort, abdominal distention and belching, were investigated. Those exhibiting nocturnal symptoms were randomly and double-blindly assigned to either domperidone group or placebo group. Patients in domperidone group received domperidone (10 mg *qid*, before meal and at bedtime) for 2 wk and those in placebo group received placebo. Nocturnal dyspeptic symptoms, intragastric pH and percentage of bile reflux time during nighttime (22:00 PM to 6:00 AM) were determined after treatment.

### Nocturnal intragastric pH monitoring and bilimetry

Following 2-h fasting, an initial manometric localization (CTD-Synectics, Sweden) of the lower esophageal sphincter (LES) was carried out. Nocturnal intragastric pH was then recorded using a pH sensitive microelectrode (Synectics Digitrapper MK III, Medtronic Synectics, Sweden) connected to a portable Synectics medical Digitrapper III (CTD-Synectics). The electrode was inserted transnasally and positioned at about 8-10 cm below the manometrically determined LES. A two-point calibration of the probe was made before each recording, using standard buffers of pH 1 and pH 7. The Digitrapper data were downloaded onto a personal computer to calculate the nocturnal mean intragastric pH.

A fiber-optic spectrophotometer, Bilitec 2000 (Medtronic Synectics), was used to quantify duodenogastric bile reflux. The system consists of a probe (1.5-mm in diameter) that carries light signals into the stomach and back *via* a plastic fiber-optic bundle. Before each study, the probe was calibrated in water and located at 8-10 cm below the LES. An episode of duodenogastric bile reflux was defined as a rise of bilirubin absorbance above the cut-off level ( $> 0.14$  at 470 nm) lasting longer than 10 s<sup>[11]</sup>. The Digitrapper data were downloaded onto a personal computer to calculate the percentage of bile reflux time with the absorbance of bilirubin  $> 0.14$ .

### Evaluation of dyspeptic symptoms

Nocturnal dyspeptic symptoms were evaluated with a

<sup>a</sup>*P* < 0.05 vs baseline.

self-recorded questionnaire. Each patient was instructed on how to fill in the questionnaire. The symptom questionnaire consisted of 4 questions related to nocturnal upper gastrointestinal symptoms, including epigastric pain or discomfort, abdominal distention and belching. The intensity and frequency of each symptom were rated at 7 levels according to 3 grades with half steps between each rating: 0 = absent, 1 = mild, 2 = relevant and 3 = severe<sup>[12]</sup>. The severity of symptoms was scored as the product of intensity and frequency. The patients were asked to record the severity score of different nocturnal symptoms before and at end of the treatment.

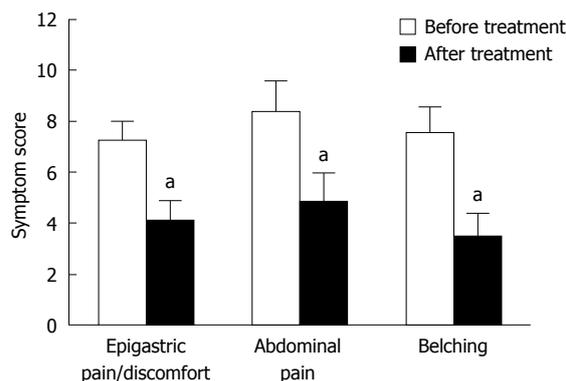

### Statistical analysis

All data were presented as mean  $\pm$  SD. Student's *t*-test and Wilcoxon rank sum test were used to compare the difference between means of before and after treatment. Incidence was compared using  $\chi^2$  test and correlation was assessed by Pearson correlation analysis. *P* < 0.05 was considered statistically significant.

## RESULTS

### Patients

Of the 85 patients, 2 females without nocturnal symptoms with a severity score of at least 2 individual symptoms decreased by 50% after placebo run-in treatment were excluded from the study, 30 (36.1%) including 13 males at the age of 22-56 years who exhibited overt noc-

**Figure 1** Severity scores of nocturnal dyspeptic symptoms in a subgroup of Chinese FD patients before and after domperidone (10 mg *qid*) treatment. Data are expressed as mean  $\pm$  SD, *n* = 15. FD: Functional dyspepsia. <sup>a</sup>*P* < 0.05 vs before treatment.

turnal dyspeptic symptoms were allocated to domperidone group or placebo group (*n* = 15). Demographic and baseline clinical characteristics did not differ between the two groups (Table 1).

### Nocturnal intragastric bilirubin and pH in FD patients with or without nocturnal dyspeptic symptoms

Of the 30 patients with nocturnal dyspeptic symptoms, 21 (70%) including 9 males had overt nocturnal duodenogastric bile reflux, which was higher than that of those without nocturnal symptoms (17.0%) including 2 males (*P* < 0.05). Moreover, the percentage of duodenogastric bile reflux time (intragastric bilirubin absorbance > 0.14) and mean gastric pH at night in the subgroup of patients with nocturnal symptoms was 5.9%  $\pm$  1.7% and 4.9%  $\pm$  1.9%, respectively, both were significantly higher than those in patients without nocturnal symptoms (bile reflux time = 2.4%  $\pm$  0.8%, mean gastric pH = 2.5  $\pm$  1.4, *P* < 0.05).

In domperidone group, 11 patients (73.3%) including 5 males had overt nocturnal duodenogastric bile reflux at baseline and mean nocturnal gastric pH > 4, which were significantly decreased after domperidone treatment (*P* < 0.05). In placebo group, 10 patients (66.7%) including 4 males had obvious nocturnal bile reflux and mean gastric pH > 4 at baseline, which were not markedly changed after placebo treatment (Table 2).

### Severity of nocturnal dyspeptic symptoms

The severity score of nocturnal dyspeptic symptoms such as epigastric pain or discomfort, abdominal distention and belching was significantly lower in FD patients after domperidone treatment than before domperidone treatment (4.1  $\pm$  0.8 vs 7.3  $\pm$  0.7, 4.9  $\pm$  1.1 vs 8.4  $\pm$  1.2 and 3.5  $\pm$  0.9 vs 7.6  $\pm$  1.0, *P* < 0.05, Figure 1). Improved nocturnal symptoms after domperidone treatment were positively correlated with reduced nocturnal duodenogastric bile reflux or intragastric pH in patients with marked duodenogastric bile reflux and mean nocturnal gastric pH > 4 at baseline (*r* = 0.736-0.784 or *r* = 0.679-0.715, *P* < 0.05) (Table 3).

**Table 3** Pearson R-values for improved nocturnal dyspeptic symptoms and reduced nocturnal bile reflux or gastric pH in domperidone-treated FD patients

	% of bile reflux time	Gastric pH
Epigastric pain/discomfort	0.736 <sup>a</sup>	0.679 <sup>a</sup>
Abdominal distention	0.784 <sup>a</sup>	0.715 <sup>a</sup>
Belching	0.753 <sup>a</sup>	0.697 <sup>a</sup>

<sup>a</sup>*P* < 0.05.

### Safety assessment

No patients stopped their medication or withdrew from the study due to side effects of domperidone during the study.

## DISCUSSION

The pathophysiological mechanism underlying FD is complex and its treatment remains a clinical challenge. Impaired GI motility seems to play a pivotal role in pathogenesis of FD. Gastric emptying is delayed in about 30% of FD patients<sup>[4,13]</sup>. It has been shown that domperidone and other prokinetic agents can markedly improve dyspeptic symptoms of FD patients<sup>[6-8]</sup>. However, the prevalence of nocturnal symptoms and the effect of domperidone on these symptoms have not been extensively elucidated.

Nocturnal intragastric pH and bilirubin level are hardly affected by food taking and other diurnal activities, thus relatively more stable and better reflecting the chemical environment in the gastric cavity. Increased gastric pH is thought to be an indicator of gastric bile reflux, which is related to impaired antroduodenal motility<sup>[14-16]</sup>. Therefore, the profile of gastric pH and bile reflux at night were selected as the main endpoints in the present study.

In this study, over 35% of FD patients exhibited nocturnal dyspeptic symptoms, and about 70% of the patients in this subgroup had a marked nocturnal duodenogastric bile reflux at baseline, manifested as prolonged time of absorbance of gastric bilirubin > 0.14 confirmed by alkalinization of the acidic intragastric environment (mean pH > 4), suggesting that nocturnal dyspeptic symptoms of FD patients may be associated with abnormal nocturnal duodenogastric bile reflux. There is evidence that decreased antroduodenal motility is the main factor for increased duodenogastric reflux<sup>[15,16]</sup>. Our findings also indicate that nocturnal dyspeptic symptoms are related with impaired antroduodenal motility.

In our study, the severity score of nocturnal epigastric pain or discomfort, abdominal distention or belching, as well as nocturnal gastric pH and bile reflux in FD patients, were significantly lower after domperidone treatment than before domperidone treatment. Furthermore, alleviation of bile reflux was well correlated with the improved nocturnal symptoms, suggesting that the efficacy of domperidone therapy may be associated with

the inhibition of nocturnal duodenogastric bile reflux resulting from improved gastric peristalsis and antroduodenal coordination.

Since the placebo effect on FD can be high<sup>[17]</sup>, 1-wk single-blind placebo run-in treatment was used in patients before they received domperidone or placebo treatment in this study.

In conclusion, a subgroup of FD patients exhibit overt nocturnal dyspeptic symptoms, which may be related to an increased nocturnal duodenogastric bile reflux. Domperidone therapy can alleviate such symptoms by attenuating nocturnal duodenogastric bile reflux resulting from improved GI motility.

## ACKNOWLEDGMENTS

The authors thank Professor Xiu-Cai Fang, Department of Gastroenterology, Peking Union Medical College Hospital for her valuable comments on the manuscript.

## COMMENTS

### Background

The pathophysiological mechanism of functional dyspepsia (FD) is complex and its treatment remains a clinical challenge. There exists a subgroup of FD patients with nocturnal dyspeptic symptoms, such as epigastric pain or discomfort, abdominal distention or belching. Up to now, the prevalence and mechanism of FD and its effective drug therapy have not been established.

### Research frontiers

Impaired gastrointestinal motility plays a pivotal role in pathogenesis of FD, and empirical pharmacological interventions with prokinetic agents have been shown to be effective on FD. However, whether abnormal antroduodenal motility, which can lead to increased nocturnal duodenogastric bile reflux, contributes to nocturnal dyspepsia symptoms of FD patients and whether prokinetic drugs can alleviate these symptoms are still unknown.

### Innovations and breakthroughs

This is the first study to report that a subgroup of FD patients exhibit overt nocturnal dyspeptic symptoms, which may be related to excessive nocturnal duodenogastric bile reflux. Prokinetic therapy can alleviate these syndromes by attenuating nocturnal bile reflux, thus representing a promising treatment modality for nocturnal dyspeptic symptoms of FD patients.

### Applications

The incidence of nocturnal dyspeptic symptoms and the effect of prokinetic drugs on FD were studied in this study, which may provide valuable data for the treatment of nocturnal dyspeptic symptoms of FD patients.

### Peer review

A RCT in dyspeptic patients with nocturnal symptoms was described. The results are clear cut in the sense that many FD patients in China complain of nocturnal symptoms and that domperidone is a promising agent in treatment of these patients. The study also suggests that duodenogastric reflux during night is of a pathophysiological relevance.

### Abstract

**AIM:** To investigate if and how programmed death type-1 (PD-1) expression affects the natural course of hepatitis B virus (HBV) infection.

**METHODS:** Sixty-four patients in different natural stages of chronic HBV infection were enrolled in this study. PD-1 expression in total T cells was detected by flow cytometry. Levels of total CD8+ T cell responses and proliferation in relation to PD-1 expression levels were analyzed with intracellular staining and PD-1/PD-L1 blockage.

**RESULTS:** The PD-1 expression in T cells was dynamically changed during the natural course of chronic HBV infection, did not significantly increase in the immune tolerance phase, and returned to normal in the inactive

virus carrier stage. Blockage of the PD-1/PD-L1 pathway could not affect the T-cell response in the immune tolerance and inactive virus carrier stages of chronic HBV infection. However, it could significantly restore the T-cell response in the immune clearance stage of chronic HBV infection. Furthermore, the PD-1 expression level in T cells was associated with the alanine aminotransferase level during the immune clearance stage of chronic HBV infection.

**CONCLUSION:** The PD-1/PD-L1 pathway plays a different role in T-cell response during the natural course of chronic HBV infection.

### INTRODUCTION

During chronic hepatitis B virus (HBV) infection, a dynamic balance between viral replication and host immune response is pivotal to the pathogenesis of liver

disease. In accordance with immune characteristics, chronic HBV infection can be clinically categorized into three periods, namely immune tolerance phase, immune clearance phase, and immune stable phase or inactive virus carrier phase<sup>[1,2]</sup>. It has been widely accepted that adaptive immune responses, particularly cellular immune responses, mediate the clearance of HBV<sup>[3-6]</sup>. Unfortunately, HBV-specific T-cell function is impaired in patients with chronic HBV infection characterized by low levels of antiviral cytokines, impaired cytotoxic T lymphocyte activity, and persistent viremia<sup>[7,8]</sup>. However, the mechanism underlying this T-cell malfunction in chronic HBV infection has not been completely understood<sup>[9]</sup>.

The immunologic receptor programmed death type-1 (PD-1), a 55 kDa transmembrane protein containing an immunologic receptor tyrosine-based inhibitory motif, was originally isolated from a T-cell line exhibiting a high sensitivity to apoptosis<sup>[10]</sup>. The PD-1/PD-L1 pathway has been well documented to play a negative role in the regulation of activation and proliferation of T-cells and production of cytokines<sup>[11-13]</sup>. There is evidence that the PD-1 pathway plays an important role in inhibiting the function of virus-specific CD8+ T-cells in chronic viral infection involving human immunodeficiency virus (HIV)<sup>[14-16]</sup>, hepatitis C virus (HCV)<sup>[17,18]</sup>, and HBV<sup>[19]</sup>.

Although reports are available on the changes in expression levels of PD-1 and T-cell responses in patients with HBV infection<sup>[20]</sup>, the change pattern of PD-1 expression in the natural course of chronic HBV infection has not yet been presented. Understanding such changes in PD-1 expression and T-cell responses in the course of chronic HBV infection is crucial in the management of HBV carriers. For this reason, we analyzed the PD-1 expression in T cells and tested the role of the PD-1/PD-L1 pathway in the regulation of T-cell response during different stages of chronic HBV infection. Our results suggest that activated PD-1 signaling is closely related with T-cell malfunction in the immune clearance phase but not in the other two phases of chronic HBV infection.

## MATERIALS AND METHODS

### Subjects

Sixty-four patients with chronic HBV infection (53 males and 11 females), enrolled in this study, were positive for HBsAg and anti-HBc but negative for antibodies (Abs) to HCV, delta virus (HDV), HIV-1 and -2, and other symptoms of chronic liver damage. The patients were observed for more than 48 wk during which liver function and serum DNA level were tested once every 3 mo. Of the 64 patients, 9 were in the immune tolerance stage with the presence of HBeAg, high serum DNA level, normal serum alanine aminotransferase (ALT) and minimal or no evident inflammation on liver biopsy, 10 were in the inactive virus carrier stage and negative for HBeAg and positive for anti-HBe antibody with undetectable or low HBV DNA level, and 45 were in the immune

clearance phase with persistent elevated serum ALT level and positive serum HBV DNA. The morphology of liver was examined by ultrasonography or computerized tomography, which showed no radiologic or histological evidence of cirrhosis. None of the patients received antiviral therapy and/or immune regulate therapy before they were admitted (clinical information is listed in Table 1). Twelve healthy blood donors served as normal controls.

All the patients and normal controls were Chinese. Our study was approved by the local ethics committee, and all patients provided their written informed consent.

### Virology assessment

HBsAg, HBeAg, anti-HBs, anti-HBc, anti-HBe, and antibodies to HCV, HDV, HIV-1, and HIV-2 were detected by enzyme linked immunosorbent assay with commercially available kits (Sino-American Biotechnology Company, SABC). Serum HBV-DNA level was measured by fluorescent quantitative PCR with commercially available kits (PE/B/MJ/L, Shenzhen, China).

### Isolation of peripheral blood mononuclear cells

EDTA- and heparin-anticoagulated blood (5-7 mL) was collected from each patient and used either directly for fluorescence-activated cell sorting (FACS) or for peripheral blood mononuclear cell (PBMC) isolation. PBMC ( $2 \times 10^6$ - $6 \times 10^6$ ) were isolated by Ficoll-Hypaque density gradient centrifugation, washed twice in phosphate-buffered saline, and analyzed immediately.

### Flow cytometry

Cells were stained with fluorescein isothiocyanate (FITC)-, phycoerythrin (PE)-, and allophycocyanin (APC)-labeled monoclonal antibodies, respectively, according to their manufacturers' instructions. Flow cytometry was performed using FACSCalibur (Becton Dickinson, San Jose, CA). FACS data were analyzed using CellQuest software (Becton Dickinson Rutherford, NJ). The PE-labeled anti-PD-1 monoclonal antibodies were obtained from BD PharMingen (BD Biosciences, San Jose, CA). FITC-anti-CD4 and APC-anti-CD8 antibodies were purchased from eBioscience (San Diego, CA).

### PD-1/PD-L1 blockage

Fresh PBMC ( $1 \times 10^5$ - $5 \times 10^5$ ) isolated from patients with chronic HBV infection were incubated for 45 min at 37°C with anti-PD-L1 (10 g/mL) or isotype control antibody (IgG2b clone MPC 11; 10 µg/mL e-Bioscience, Boston, MA) or without anything, washed and co-incubated with the Dybeads CD3/CD28 T-cell expander ( $4 \times 10^7$ /mL, Invitrogen) for 3 d. On the third day of incubation, the cells were stained with surface antibodies, perforin, and granzyme B, respectively, for flow cytometry analysis.

### Intracellular perforin and granzyme B staining

*In vitro* expanded cells ( $0.2 \times 10^6$ - $0.3 \times 10^6$ ) were stained with anti-CD8 APC mAb (BD Biosciences) before they

**Table 1** Demographic and clinical parameters of 4 groups

Subjects	Sex		Age (yr)	ALT (U/L)	eAg (+)	HBV DNA			
	Male	Female				ND	< 10 <sup>3</sup>	10 <sup>3</sup> -10 <sup>7</sup>	> 10 <sup>7</sup>
NC	8	4	23.5 ± 4.5	24.5 ± 9.7	-	12	-	-	-

were fixed and permeabilized (Cytofix-Cytoperm by BD Biosciences) for intracellular staining (ICS) with anti-perforin-FITC (BD Biosciences) or anti-GRZ-A-FITC (BD Biosciences) mAbs.

**Proliferation of CD8 T cells**

Freshly isolated peripheral lymphocytes were re-suspended at the concentration of 1 × 10<sup>6</sup> cells/mL in RPMI 1640 medium supplemented with 10% heat-inactivated fetal calf serum (R10; Invitrogen) and stimulated with the Dybeads CD3/CD28 T cell expander (4 × 10<sup>7</sup> cells/mL, Invitrogen), with or without anti-PD-L1 Mab (10 g/mL) or isotype control antibody (IgG2b clone MPC 11; 10 µg/mL e-Bioscience, Boston, MA). On day 3, the cells re-suspended in 300 µL PBS were double-stained with anti-CD8-FITC and 7-amino-actinomycin D. Cellular data were acquired for analysis. The total number of cells in each well was calculated according to the following formula: Total number of cells = (number of live cells/number of beads) × 10<sup>5</sup>.

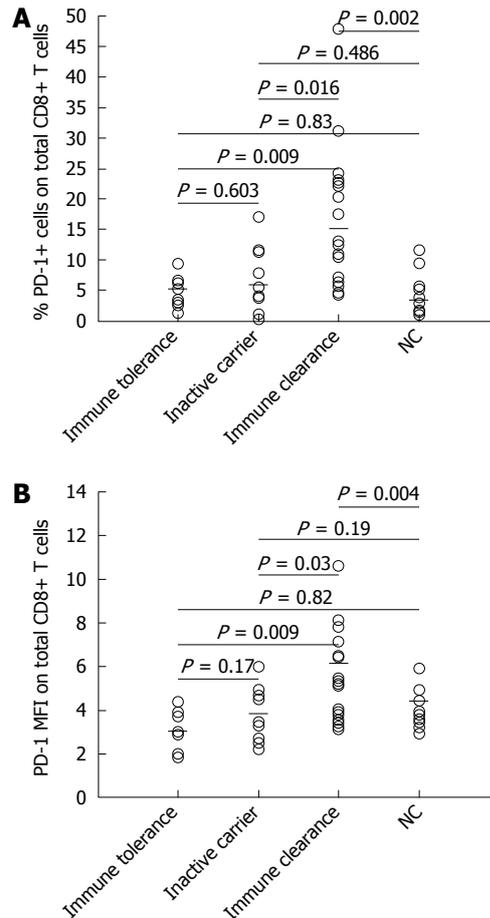

**Statistical analysis**

Wilcoxon matched paired test and Mann-Whitney test of SSPS 12.0 were used to assess the difference between different groups. Spearman correlation analysis of PD-1 expression and HBV viral titers or ALT level was performed. *P* < 0.05 was considered statistically significant. The test of significance was two sided.

**RESULTS**

**PD-1 expression in CD8+ T cells during the natural course of chronic HBV infection**

To determine the surface expression of PD-1 in total peripheral CD8+ T cells during the natural course of chronic HBV infection, the total number of peripheral T cells of 39 patients (9 in the immune tolerance phase, 10 in the inactive virus carrier phase, and 20 in the immune clearance phase) were analyzed by flow cytometry. The PD-1 expression levels in CD8+ T cells in the immune tolerance and inactive virus carrier stages of chronic HBV infection patients did not significantly differ from those of the normal controls. However, the PD-1 expression levels were significantly higher in the immune clearance stage of chronic HBV infection patients than in normal controls and in the other two natural stages of chronic HBV infection patients (Figure 1).

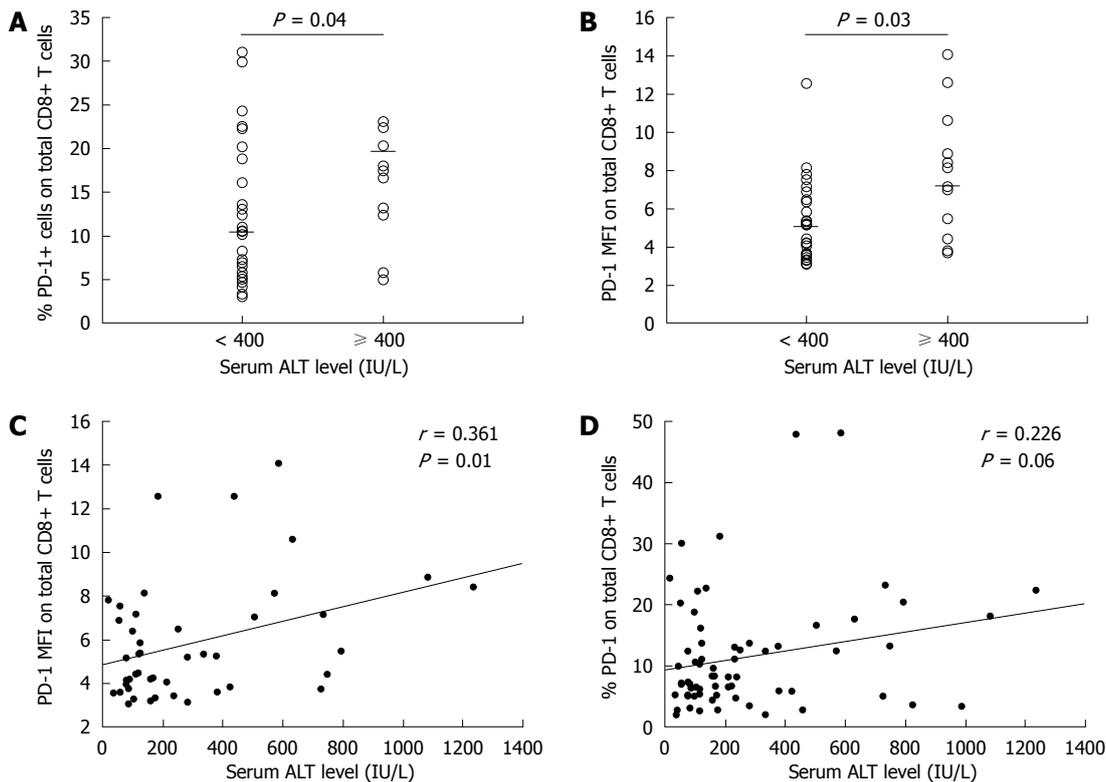

**Figure 1** Programmed death type-1 (PD-1) expression in total peripheral CD8+ T cells in the natural stages of chronic hepatitis B virus (HBV) infection. A: The dot plots showing the percentage of PD-1+ CD8+ T cells in different natural stages of chronic HBV infection patients and normal controls and the horizontal bars indicating the median percentage of positive PD-1 in CD8+ T cells; B: The dot plots showing the PD-1 mean fluorescence intensity (MFI) expression in total CD8+ T cells, and the horizontal bars indicating the median PD-1 MFI expression level in CD8+ T cells. NC: Normal control.

**PD-1 expression level was positively correlated with serum ALT level in the immune clearance stage of chronic HBV infection**

The PD-1 expression level was significantly higher in the immune clearance stage of chronic HBV infection patients than in normal controls and in the other two natural stages of chronic HBV infection patients.

The patients were divided into two groups according to their ALT level. Based on the exacerbation or flare of

**Figure 2** PD-1 expression levels in the total T cells in the immune clearance stage of chronic HBV infection and liver inflammatory groups. A: The dot plots showing the percentage of positive PD-1 in CD8+ T cells in high and low liver inflammatory groups; B: The dot plots showing the PD-1 MFI expression level in the total CD8+ T cells in high and low liver inflammatory groups; C: Positive correlation between PD-1 MFI expression and alanine aminotransferase (ALT) levels in CD8+ T cells; D: Positive PD-1 percentage and ALT level in CD8+ T cells.

hepatitis B<sup>[21]</sup> and general indications of antiviral therapy for CHB with interferon<sup>[22]</sup>, we used 10 times the upper limit of normal ALT level ( $10 \times$  ULT, 400 IU/L) as the cut-off value in dividing the patients. Patients with their ALT level higher than 400 IU/L were defined as the high immune response group, while those with their ALT levels lower than 400 IU/L were defined as the low immune response group. The PD-1 expression level in CD8+ T cells was much higher in the high immune response group than in the low immune response group ( $P < 0.05$ , Figure 2A and B).

Further analysis showed that the PD-1 expression level was positively correlated with the ALT level in total CD8+ T cells ( $P < 0.05$ , Figure 2C and D).

#### **PD-1 expression level was not correlated with serum HBV DNA level in total T cells during the immune clearance phase of chronic HBV infection**

In this study, no significant correlation was found between the percentage and mean fluorescence intensity (MFI) of PD-1 expression and the serum viral load in total T cells. Similarly, no difference was observed in PD-1 expression in CD4+ T cells and CD8+ T cells between the HBe+ and HBe- groups.

#### **Relation between CD8+ T cell response and PD-1 expression level in the immune clearance stage of chronic HBV infection**

The relation between total CD8+ T cell response and

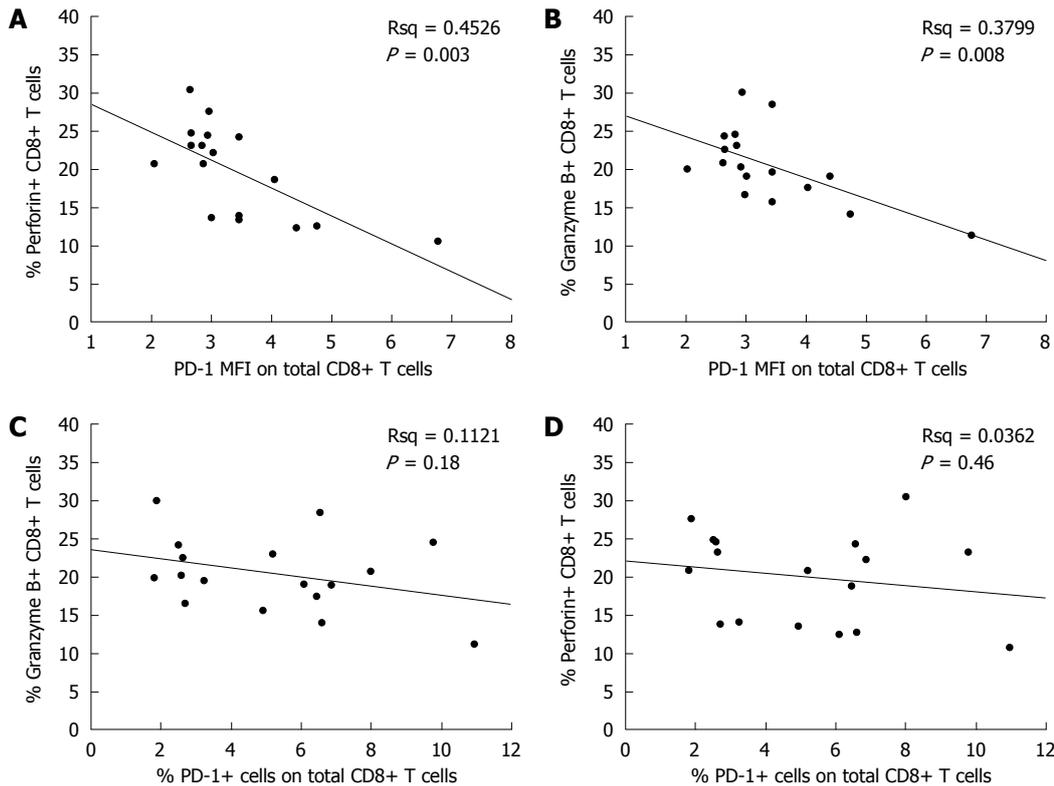

PD-1 expression level was analyzed with ICS, which showed that the CD8+ T cell response level was inversely correlated with PD-1 MFI (Figure 3A-D).

#### **Blocking PD-1/PD-L1 engagement in the total CD8+ T cells during the immune clearance stage of chronic HBV infection**

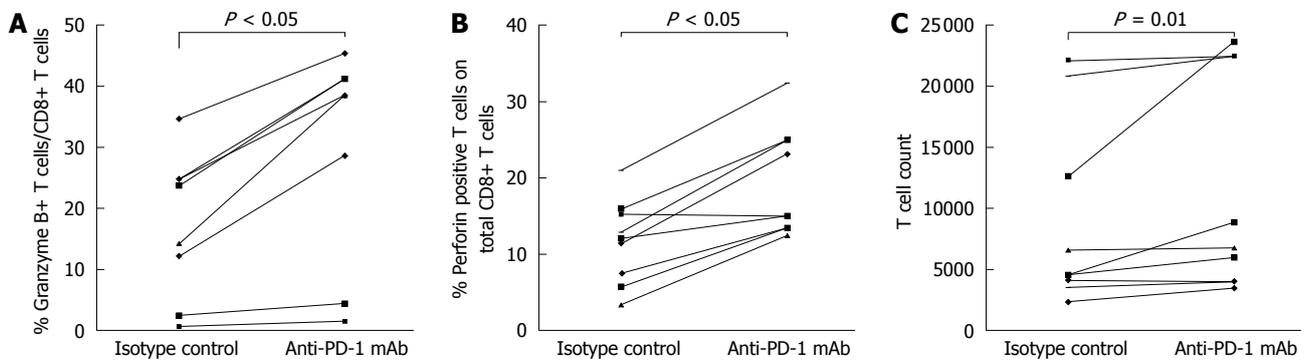

To investigate the role of PD-1 expression in CD8+ T cell responses in the natural stages of chronic HBV infection, expansion of CD8+ T cells and production of cytokines were detected 3 d after *in vitro* stimulation in the presence or absence of anti-PD-L1 antibody. The blockage of PD-1/PD-L1 significantly enhanced the expansion of T cells in the immune clearance stage of chronic HBV infection (Figure 4C), and increased the production of perforin and granzyme B by CD8+ T cells in the immune clearance, immune tolerance and inactive virus carrier stages of chronic HBV infection (Figure 4A and B).

## **DISCUSSION**

As a negative co-stimulatory receptor, PD-1 interacts with its ligands, PD-L1 and PD-L2, to attenuate T-cell responses and appears particularly important in regulating T-cell tolerance. In chronic infection with viruses such as HIV and HCV<sup>[18,23]</sup>, the PD-1 expression level remains high in virus-specific T cells. In our study, the PD-1 expression level in T cells was dynamically changed during the natural stage of chronic HBV

**Figure 3** Relation between PD-1 expression level in CD8+ T cells and CD8+ T-cell responses in the immune clearance stage of chronic HBV infection. A: Inverse relation between the percentage of perforin and PD-1 MFI in positive CD8+ T cells; B: Inverse relation between the percentage of granzyme B and PD-1 MFI in positive CD8+ T cells; C: No correlation between the percentages of granzyme B and PD-1 in positive CD8+ T cells; D: No significant correlation between the percentages of perforin and PD-1 in positive CD8+ T cells.

**Figure 4** Effect of anti-PD-L1 antibody on the function of CD8+ T cells in the immune clearance stage of chronic HBV infection. A, B: Significant restoration of CD8+ T cell response after blockage of PD-1/PD-L1; C: Restoration of T-cell proliferation after blockage of PD-1/PD-L1.

infection, indicating that it is up-regulated when the host antiviral immune is activated and down-regulated when the virus is cleared and the antiviral immune is inactivated.

Among the natural stages of chronic HBV infection, the immune clearance stage is the most critical phase for the host in eliminating the virus. In this study, the PD-1 expression level in T cells was significantly higher in the immune clearance stage than in the other two stages of chronic HBV infection and in normal controls. The PD-1 expression level in CD8+ T cells was related with serum ALT level but not with serum viral load, which is not consistent with the reported findings<sup>[14,18,24]</sup>. The

difference may be due to the different study groups and detection methods used. Furthermore, the PD-1 MFI in CD8+ T cells was inversely correlated with CD8+ T cell responses, and blockage of PD-1/PD-L1 interaction significantly restored the proliferation of T-cells and the secretion of antiviral cytokines in the immune clearance stage of chronic HBV infection, suggesting that the PD-1/PD-L1 pathway affects the progress of chronic HBV infection by regulating T-cell response in the immune clearance stage of chronic HBV infection.

CHB is characterized by loss of virus-specific CD8+ T cells and varying degrees of functional impairment of virus-specific T-cell responses. In patients with chronic

HBV infection, the PD-1 is highly expressed in virus specific CD8+ T cells, and the spectrum of anti-HBV immunity can be improved by blocking the PD-1<sup>[19]</sup>. In this study, the PD-1 expression level in CD8+ T cells was up-regulated, and blocking the PD-1/PD-L1 pathway increased the proliferation of T-cells and restored the response of CD8+ T cells in the immune clearance stage but not in the immune tolerance and inactive virus carrier stages of chronic HBV infection, suggesting that the PD-1 inhibitory pathway particularly acts on the immune clearance stage of chronic HBV infection, and that the PD-1 expression level and the role of the PD-1/PD-L1 pathway are dramatically changed with the antiviral immune change in the natural stage of chronic HBV infection.

In conclusion, PD-1 expression participates in modulating the host antiviral immunity throughout the natural course of chronic HBV infection. However, in this study, we only examined the total number of CD8+ T cells but did not calculate the number of HBV-specific CD8+ T cells as targets. Further study is needed on the virus-specific anti-viral immunity.

## COMMENTS

### Background

Adaptive immune response, particularly cellular immune response, mediates the clearance of hepatitis B virus (HBV). Unfortunately, HBV-specific T-cell function is severely impaired in chronic HBV infection patients, characterized by low levels of antiviral cytokines, impaired cytotoxic T lymphocyte activity and persistent viraemia. The mechanism underlying T-cell malfunction in chronic HBV infection has not yet been completely understood.

### Research frontiers

The programmed death type-1 (PD-1)/PD-L1 pathway plays a negative role in the regulation of activation and proliferation of T cells and production of cytokines. There is evidence that the PD-1 pathway plays an important role in inhibiting the function of virus-specific CD8+ T-cells in chronic viral infections involving human immunodeficiency virus, hepatitis C virus, and HBV. However, the change pattern of PD-1 expression in the natural course of chronic HBV infection has not been presented. The results of this study indicate that the PD-1/PD-L1 pathway plays a different role in T-cell response in the natural course of chronic HBV infection.

### Innovations and breakthroughs

Recent reports have highlighted the importance of the PD-1 pathway in T-cell response in different stages of chronic HBV infection. This study showed PD-1 expression participated in modulating host antiviral immunity throughout the natural course of chronic HBV infection.

### Applications

By discussing the changes in expression of PD-1 and T cell responses in the natural course of chronic HBV infection, this study may represent a future strategy for therapeutic intervention in treatment of patients with HBV infection.

### Terminology

PD-1: A 55 kDa transmembrane protein containing an immunologic receptor tyrosine-based inhibitory motif, which was originally isolated from a T-cell line exhibiting a high sensitivity to apoptosis. As a negative co-stimulatory receptor, PD-1 interacts with its ligands, PD-L1 and PD-L2, to attenuate T-cell responses and appears to be particularly important for regulating T-cell tolerance.

### Peer review

By employing well-designed immunological techniques, the authors found that the expression of PD-1 was significantly up-regulated in T-cells of patients in the immune clearance phase of chronic HBV infection and was closely correlated with increasing serum ALT levels but not with serum HBV DNA in the same phase, which may contribute to the elucidation of the pathophysiology underlying the different natural courses of chronic HBV infection.

### Abstract

**AIM:** To investigate whether serum thymosin  $\beta$ 4 can provide diagnostic or prognostic information in liver failure patients caused by chronic hepatitis B virus (HBV) infection.

**METHODS:** Serum thymosin  $\beta$ 4 levels were measured in 30 patients with acute-on-chronic liver failure (ACLF), 31 patients with chronic liver failure (CLF), 30 patients with compensated liver cirrhosis (CR) and 32 patients with chronic hepatitis B and 30 healthy controls. Serum thymosin  $\beta$ 4 levels were measured by enzyme-linked immunosorbent assay and Child-Pugh and model for end-stage liver disease (MELD) scores were calculated for each patient on admission.

**RESULTS:** Compared with healthy controls, serum thymosin  $\beta$ 4 levels in ACLF, CLF, CR and chronic hepatitis B patients were significantly lower, 6.5047 (4.7879-10.5314)  $\mu$ g/mL vs 0.4632 (0.2759-0.8768)  $\mu$ g/mL, 0.6981 (0.5209-1.2008)  $\mu$ g/mL, 1.8053 (0.8110-2.3397)  $\mu$ g/mL, 3.7803 (1.8570-6.4722)  $\mu$ g/mL, respectively ( $P < 0.001$ ). The levels of thymosin  $\beta$ 4 in liver failure (ACLF or CLF) patients were markedly lower than that in CR ( $P < 0.001$ ), and a difference was also found between CLF and ACLF patients ( $P = 0.038$ ). In patients with chronic liver disease, there was a positive relationship between thymosin  $\beta$ 4 levels and albumin, choline esterase, and platelet ( $P < 0.001$ ), and negative relationship with alanine aminotransferase ( $P = 0.020$ ), aspartate aminotransferase, total bilirubin, international normalized ratio of prothrombin time, and Child-Pugh and MELD scores ( $P < 0.001$ ). Of the 61 liver failure patients, the thymosin  $\beta$ 4 levels of non-survivors were significantly lower than that of survivors ( $P = 0.007$ ). Receiver operating characteristics analysis identified a thymosin  $\beta$ 4 cutoff level of 0.5708  $\mu$ g/mL for predicting poor prognosis in all liver failure patients. The serial thymosin  $\beta$ 4 values were observed in 13 liver failure inpatients. Lower initial values were observed in the death. While greater improvement in thymosin  $\beta$ 4 value was found in those who recovered from the disease.

**CONCLUSION:** Serum thymosin  $\beta$ 4 can be used as an important potential predictor for liver failure caused by chronic HBV infection.

## INTRODUCTION

Chronic hepatitis B virus (HBV) infection remains one of the most challenging public health problems in Asia. Acute-on-chronic liver failure (ACLF) and chronic liver failure (CLF) are common serious conditions with a high mortality among chronic HBV infected patients. The prognosis is clearly related to the stage of the disease and early diagnosis has resulted in a significant reduction in mortality<sup>[1-4]</sup>. Unfortunately, a differential diagnosis from non-liver failure patient is sometimes very difficult to make since the current biomarkers used in clinical diagnosis are still lack of sensitivity and reliability<sup>[5,6]</sup>. Thus, it is very important to discover new biomarkers for liver failure diagnosis.

Thymosin  $\beta$ 4 is a 4.9-kDa polypeptide widely distributed in human tissues, which is considered as the major G-actin sequestering protein<sup>[7-9]</sup>. Thymosin  $\beta$ 4 has been shown to have multiple biological activities involved in a variety of physiologic and pathologic processes. For example, thymosin  $\beta$ 4 is known to promote wound healing, tumor metastasis and angiogenesis<sup>[10-12]</sup>. Recently thymosin  $\beta$ 4 has been found to stimulate cardiac cell migration and survival related to cardiac repair. It was also considered to play an important role in healing hypoxic injury in the heart by preventing apoptotic cell death of cardiomyocytes and reducing scarring<sup>[13]</sup>, meanwhile, hypoxia and oxidative stress also play a key role in the pathophysiology of liver failure. Recent findings suggested that thymosin  $\beta$ 4 could be beneficial for the treatment of chronic liver disease (CLD)<sup>[14]</sup>. These data have attracted more consideration of whether thymosin  $\beta$ 4 plays an important role in liver failure. However, the levels of thymosin  $\beta$ 4 in liver failure patients are still unknown.

This present study aims to determine serum thymosin  $\beta$ 4 levels in CLD patients with HBV infection, and to assess the potential usefulness of thymosin  $\beta$ 4 in diagnosis and prognosis prediction of HBV-related liver failure, including ACLF and CLF.

## MATERIALS AND METHODS

### Patients

The study included 61 patients with liver failure (44 males, 17 females), of whom 30 (23 males, 7 females) were diagnosed as having ACLF, the other 31 (21 males,

10 females) patients as having CLF. And 30 (20 males, 10 females) patients with Child-Pugh A cirrhosis, and 32 (26 males, 6 females) patients with chronic hepatitis B were also enrolled. All patients had chronic HBV infection. Those with concurrent hepatocellular carcinoma (HCC), splenectomy, fatty liver, and hepatitis C or alcohol-related liver diseases were excluded. ACLF was defined as acute deterioration of liver function within 4 wk in CLD, with severe jaundice [serum total bilirubin (TBIL)  $\geq$  171  $\mu$ mol/L or an increase of TBIL  $\geq$  17.1  $\mu$ mol/L per day] and coagulopathy [international normalized ratio of prothrombin time (INR)  $>$  1.5 or PTA  $<$  40%]. CLF was defined as chronic decompensation of an end-stage liver disease, complicated with refractory ascites and/or encephalopathy and hepatorenal syndrome<sup>[3]</sup>. The diagnosis of liver cirrhosis (CR) was based on the clinical manifestation, physical examination, biochemical, endoscopic and ultrasound findings and/or liver biopsy, with features of liver fibrosis, portal hypertension and hypersplenism. All patients infected with HBV were recruited from January to July 2009 at Tianjin Third Central Hospital. Thirty healthy volunteers served as controls, including 20 males and 10 females, aged 41 (31-49) years [median (inter-quartile range, IQR)].

The study was approved by Tianjin Third Central Hospital Ethics Committee. Informed consent was obtained from either the patients or their immediate family members.

### Collection of clinical data

INR, platelets (PLT), serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), choline esterase (CHE), albumin (ALB), TBIL and renal function were tested. Child-Pugh and model for end-stage liver disease (MELD) scores were calculated on admission.

### Measurement of serum thymosin $\beta$ 4 levels

All the samples were collected in the morning when the patients were admitted to our hospital. Blood collected without anticoagulant was spun at 2600  $\times$  g for 15 min, and the serum obtained was immediately stored at -80°C until thymosin  $\beta$ 4 measurement. Thymosin  $\beta$ 4 was measured with a newly developed commercial enzyme-linked immunosorbent assay (ELISA) (Immunodiagnostik AG, Bensheim, Germany). The test principle was based on a competition between antigen in the sample or standards and the antigen coated on the wells of microplate. A peroxidase-conjugated antibody was used for detection and quantification, and tetramethylbenzidine as a peroxidase substrate. The enzymatic reaction was terminated by acidic stop solution. The results were obtained by measuring the absorbance at 450 nm in an ELISA reader.

### Statistical analysis

Kruskal-Wallis and Mann-Whitney *U* tests were used. Correlations were analyzed by Spearman rank test. Results were expressed as median and IQR. Cutoff values for the identification of non-survivors with liver failure (ACLF

Table 1 Clinical characteristics of the patients [median (IQR)]

	ACLF	CLF	CR	Chronic hepatitis B	Healthy subjects
<i>n</i>	30	31	30	32	30
Age (yr)	54 (48-61)	50 (46-55)	50 (37-55)	39 (31-45)	41 (31-49)

PLT	0.541	< 0.001
Child-Pugh score	-0.629	< 0.001
MELD	-0.587	< 0.001

and CLF) and survivors were determined using the receiver operating characteristic (ROC) analysis. A *P* value of < 0.05 was considered to be statistically significant. All analyses were performed with SPSS 13.0 software.

## RESULTS

### Group comparison

The clinical characteristics of CLD patients in the study are listed in Table 1.

Thymosin  $\beta$ 4 levels in the groups of ACLF, CLF, CR, chronic hepatitis B (CHB) and healthy controls are shown in Figure 1. Patients in ACLF, CLF, CR and CHB groups had significantly lower median (IQR) thymosin  $\beta$ 4 levels than healthy controls, 0.4632 (0.2759-0.8768)  $\mu$ g/mL, 0.6981 (0.5209-1.2008)  $\mu$ g/mL, 1.8053 (0.8110-2.3397)  $\mu$ g/mL, 3.7803 (1.8570-6.4722)  $\mu$ g/mL *vs* 6.5047 (4.7879-10.5314)  $\mu$ g/mL, respectively (*P* < 0.001). The thymosin  $\beta$ 4 in ACLF and CLF patients was markedly reduced as compared with that in CR patients (*P* < 0.001). A difference was also found between ACLF and CLF (*P* = 0.038).

### Relationship between thymosin $\beta$ 4 and biochemical parameters in liver failure patients

Table 2 shows the relationship between thymosin  $\beta$ 4 values and biochemical parameters in CLD patients

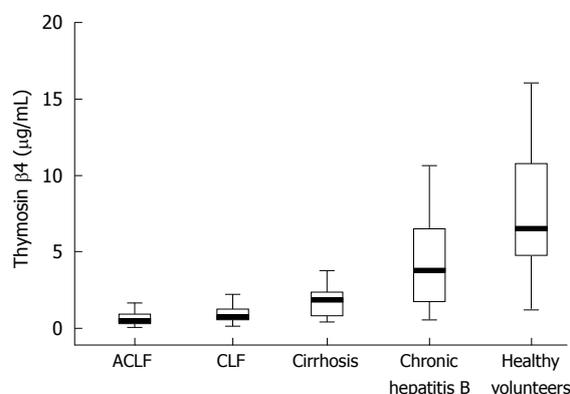

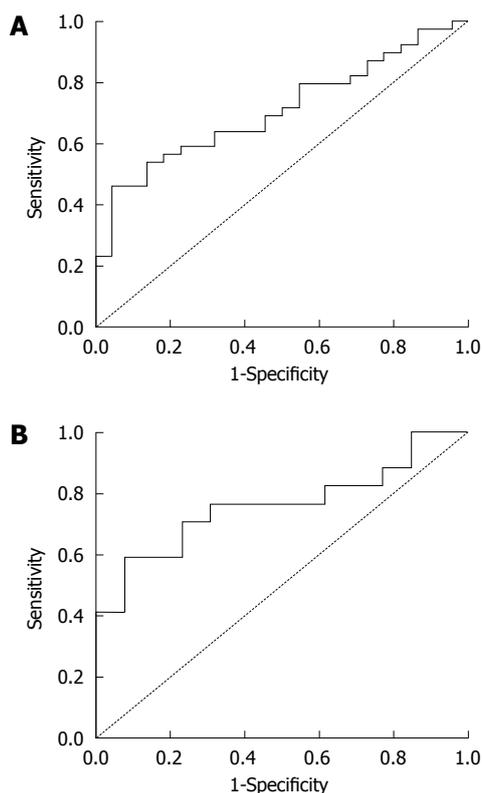

Figure 1 Comparison of thymosin  $\beta$ 4 levels ( $\mu$ g/mL) between ACLF, CLF, cirrhosis, chronic hepatitis B patients and healthy volunteers. ACLF: Acute-on-chronic liver failure; CLF: Chronic liver failure.

(including ACLF, CLF, CR and CHB). There was a positive relationship between thymosin  $\beta$ 4 levels and ALB, CHE, and PLT (*P* < 0.001). And in CLD patients, thymosin  $\beta$ 4 was negatively correlated with ALT (*r* = -0.210, *P* = 0.020), AST (*r* = -0.553, *P* < 0.001), TBIL (*r* = -0.581, *P* < 0.001), INR (*r* = -0.605, *P* < 0.001), Child-Pugh (*r* = -0.629, *P* < 0.001) and MELD scores (*r* = -0.587, *P* < 0.001).

### Analysis of liver failure group

Among the 61 liver failure patients, the survival rate was 63.93% (39 patients), while the non-survival rate was 36.07% (22 patients). The thymosin  $\beta$ 4 level of non-survivors was significantly lower than that of the survivors (*P* = 0.007) (Table 3). ROC analysis identified a thymosin  $\beta$ 4 cutoff value of 0.5708  $\mu$ g/mL [area under the ROC (AUROC) 0.710] with a sensitivity of 64.1% and a specificity of 68.2% for predicting poor prognosis in all liver failure patients (Figure 2A).

To further investigate the prediction value of thymosin  $\beta$ 4 for different liver failure status, the 61 patients were divided into two groups: CLF and ACLF. Table 3 shows the median (IQR) thymosin  $\beta$ 4 values of the two groups. In the ACLF group, ROC analysis identified a thymosin

**Figure 2** Receiver operating characteristics curve. A: Liver failure patients; B: ACLF patients.

**Table 3** Comparison of thymosin  $\beta$ 4 levels between survivors and non-survivors in liver failure group [median (IQR)]

Group	n	Survivors	Non-survivors	P value
LF	61	0.8144 (0.3979-1.1510)	0.4699 (0.2771-0.6658)	0.007
ACLF	30	0.8144 (0.4042-1.0998)	0.3656 (0.2291-0.4458)	0.016
CLF	31	0.8329 (0.4306-1.4280)	0.6581 (0.5603-0.7713)	0.317

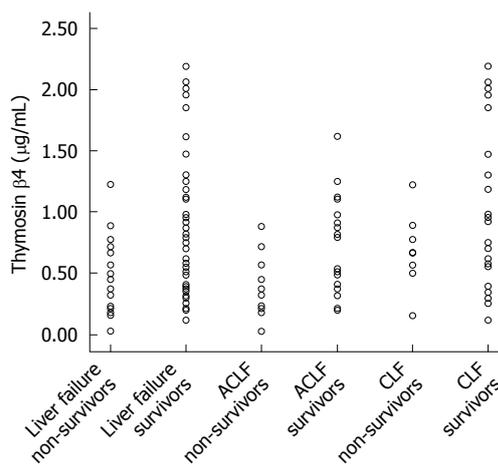

**Table 4** Median (IQR) thymosin  $\beta$ 4 values ( $\mu$ g/mL) in 13 liver failure patients

Group	1 wk	2 wk	3 wk	4 wk	5 wk
Survivors	0.9402	1.2146	1.2762	1.2226	1.5486
Non-survivors	0.5458	0.6765	0.5056	0.3986	0.3488

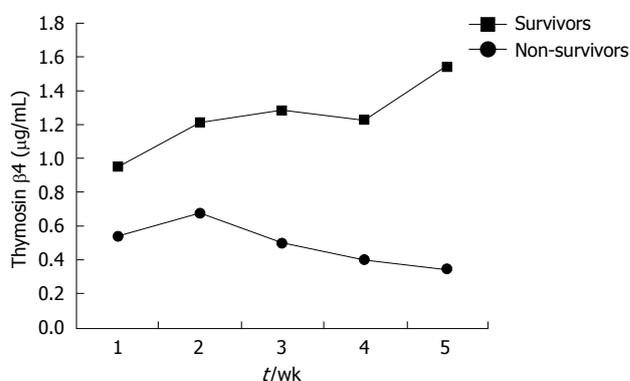

$\beta$ 4 cutoff value of 0.3873  $\mu$ g/mL (AUROC 0.760) with a sensitivity of 76.5% and a specificity of 69.2 % for predicting poor prognosis (Figure 2B). In CLF group, lower thymosin  $\beta$ 4 levels were observed in non-survivors, but there was no statistically significant difference between the survivors and non-survivors of CLF group. Figure 3 shows the distribution of thymosin  $\beta$ 4 levels in the survivors and non-survivors with liver failure in the groups of ACLF and CLF.

**Dynamic changes of serum thymosin  $\beta$ 4 values in liver failure patients**

In this study, 13 liver failure patients were selected to

**Figure 3** Thymosin  $\beta$ 4 levels in non-survivors and survivors of liver failure patients.

**Figure 4** Median (inter-quartile range, IQR) thymosin  $\beta$ 4 values ( $\mu$ g/mL) observed in 13 liver failure patients.

observe the dynamic changes of their serum thymosin  $\beta$ 4 values. Among them, 6 patients survived and the other 7 patients died. Blood samples were taken from these patients every week during their hospitalization. The median thymosin  $\beta$ 4 concentrations of non-survivors were significantly lower than those of survivors ( $P < 0.001$ , Table 4). And greater improvement in thymosin  $\beta$ 4 values was observed in those who recovered than in the non-survivors (Figure 4). Figure 5 shows the serial thymosin  $\beta$ 4 changes in 6 typical liver failure patients of the 13 patients.

**DISCUSSION**

In this study, we found that serum thymosin  $\beta$ 4 levels were significantly lower in patients with chronic hepatitis B infection. The magnitude of reduction of thymosin  $\beta$ 4 was closely related to the severity of the hepatic injury. Serum thymosin  $\beta$ 4 concentrations were most significantly decreased in ACLF and CLF. Dynamic changes of serum thymosin  $\beta$ 4 values could reflect the recovery or death in some liver failure patients.

Liver failure occurs in the hepatocytes with extensive injury, which represents either a failure to regenerate after

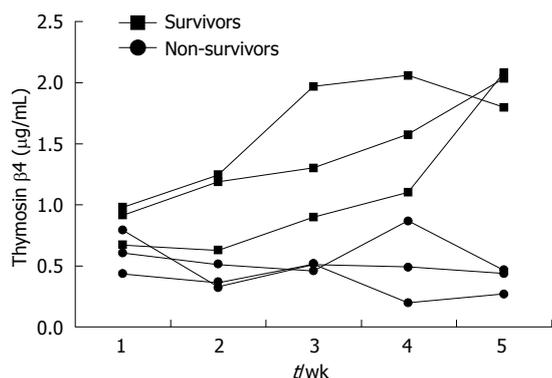

Figure 5 Serial thymosin  $\beta$ 4 concentrations in 6 patients with liver failure.

accelerated destruction of hepatocytes from necrosis or apoptosis<sup>[15]</sup>. As a result, surviving hepatocytes cannot maintain adequate metabolic functions. ALB and CHE are synthesized by hepatocyte, and their content can directly reflect the state of liver function. In this study, the levels of thymosin  $\beta$ 4 in CLD patients had a significantly positive correlation with ALB and CHE. In addition, a negative correlation between serum levels of thymosin  $\beta$ 4 and other parameters (INR, ALT, AST and TBIL) was found, which reflected the severity of acute hepatocellular injury in patients with liver failure. There was a strong correlation between composite scores of CLF (Child-Pugh and MELD scores) and thymosin  $\beta$ 4. Thymosin  $\beta$ 4 significantly decreased in ACLF and CLF patients. These results suggested that serum thymosin  $\beta$ 4 can be used as an important potential predictor of liver failure caused by chronic HBV infection.

Liver failure occurs when the extent of hepatocyte death exceeds the liver's regenerating capacity. Liver regeneration is considered to be suppressed in liver failure. Hepatocyte growth factor (HGF) is a promising therapeutic agent for the treatment of liver failure. HGF not only stimulates liver regeneration, but also acts as an antiapoptotic factor in experimental liver failure models<sup>[16]</sup>. Recent findings showed that thymosin  $\beta$ 4 upregulates the expression of HGF and downregulates the expression of PDGF- $\beta$  receptor in human hepatic stellate cells<sup>[14]</sup>. HGF could induce apoptosis of hepatic stellate cells and hepatocyte regeneration<sup>[17,18]</sup>. So it is conceived that thymosin  $\beta$ 4 protects the liver from injury. The study demonstrated that thymosin  $\beta$ 4 level was significantly lowered in liver failure patients, suggesting that thymosin  $\beta$ 4 might become a new therapeutic agent for liver failure caused by chronic HBV infection. Of course, more investigations will be needed to answer this question.

In addition, thymosin  $\beta$ 4 promotes wound healing and modulates inflammatory mediators in different tissue injury<sup>[19-21]</sup>. Thymosin  $\beta$ 4 reduces lethality and down-regulates inflammatory mediators in endotoxin-induced septic shock<sup>[22]</sup>. Liver failure is a systemic inflammatory reaction, which is characterized by a predominantly proinflammatory cytokine profile, causing the transition from stable clinical condition to severe deterioration in

liver function. So it is considered that the more severe the liver inflammatory reaction is, the lower level of thymosin  $\beta$ 4. In this study, thymosin  $\beta$ 4 significantly decreased in liver failure patients.

In this study, we also found that serum thymosin  $\beta$ 4 was an attractive parameter in the assessment of prognosis for liver failure patients. Thymosin  $\beta$ 4 levels were markedly lower in the non-survivors than the survivors in liver failure cohorts. ACLF group had the same result with the liver failure group. A trend toward higher thymosin  $\beta$ 4 levels was seen in survivors as compared with non-survivors of CLF patients. A possible explanation for the absence of a statistically significant difference could relate to heterogeneity in complications of CLF. In addition, the relatively small number of patients may not permit small differences to be detected. Dynamic changes of thymosin  $\beta$ 4 concentration may further help determine the prognosis of liver failure patients.

In conclusion, our study has demonstrated a clear relationship between reductions in serum thymosin  $\beta$ 4 level and severity of liver failure. Serum thymosin  $\beta$ 4 level could be used as an important potential marker for predicting the prognosis of HBV-related liver failure (ACLF and CLF) patients. Further investigations including comparison with Child-Pugh or MELD scores are needed to assess the thymosin  $\beta$ 4 value and explore the mechanism of lower thymosin  $\beta$ 4 levels in liver failure caused by chronic HBV infection. More studies in different etiologies and a larger number of subjects of liver failure should also be considered.

## COMMENTS

### Background

Chronic hepatitis B virus (HBV) infection remains one of the most challenging public health problems in Asian region. Acute-on-chronic liver failure (ACLF) and chronic liver failure (CLF) are common serious conditions with a high mortality among chronic HBV infected patients. The prognosis is clearly related to the stage of the disease and early diagnosis has resulted in a significant reduction in mortality. This study aims to discover a new biomarker for diagnosing liver failure caused by chronic HBV infection.

### Research frontiers

Thymosin  $\beta$ 4 is a 4.9-kDa polypeptide widely distributed in human tissues, which is considered as the major G-actin sequestering protein. Thymosin  $\beta$ 4 has been shown to have multiple biological activities involved in a variety of physiologic and pathologic processes. Recent findings suggested that thymosin  $\beta$ 4 could be beneficial for the treatment of chronic liver diseases (CLD). However, the levels of thymosin  $\beta$ 4 in liver failure patients are still unknown.

### Innovations and breakthroughs

In this study, the authors examined the serum thymosin  $\beta$ 4 level in the HBV-related CLD patients and investigated the relationship between thymosin  $\beta$ 4 values and biochemical parameters and observed the dynamic changes of serum thymosin  $\beta$ 4 in liver failure patients. The results suggested that a lower serum thymosin  $\beta$ 4 level could be a potential marker for predicting HBV-related liver failure (ACLF and CLF) prognosis.

### Applications

Serum thymosin  $\beta$ 4 level could become an important potential marker for liver failure diagnosis and is helpful in predicting the prognosis of patients with liver failure caused by chronic HBV infection.

### Terminology

ACLF was defined as acute deterioration of liver function within 4 wk in

CLD, with severe jaundice and coagulopathy. CLF was defined as chronic decompensation of an end-stage liver disease, complicated with refractory ascites and/or encephalopathy, and hepatorenal syndrome.

### Peer review

This study is an interesting piece of work investigating whether serum thymosin  $\beta$ 4 can provide diagnostic or prognostic information in liver failure patients caused by chronic HBV infection.

### Abstract

**AIM:** To investigate the incidence, location, clinical presentation, diagnosis and effectiveness of endoscopic treatment of gastric Dieulafoy's lesion (DL) in China.

**METHODS:** All patients who received emergency upper gastrointestinal (GI) endoscopy due to gastric DL from February 2000 to August 2008 at GI endoscopy center of Renmin Hospital of Wuhan University were included in this study. The clinical presentation, medical history, location and characteristics of DL methods and effectiveness of therapy of patients with DL were retrospectively analysed by chart reviews. Long-term follow-up data were collected at outpatient clinics or telephone interviews.

**RESULTS:** Fifteen patients were diagnosed with DL, which account for 1.04% of the source of bleeding in acute non-variceal upper GI bleeding. Common comorbidities were found in one patient with hypertension and diabetic mellitus. Hemoclip or combined therapy with hemoclip produced primary hemostasis in 92.8% (13/14) of patients.

**CONCLUSION:** DL is uncommon but life-threatening in China. Hemoclip proved to be safe and effective in controlling bleeding from DL.

### INTRODUCTION

Dieulafoy's lesion (DL), an abnormal arterial lesion in the digestive tract, was first described by Gallard in 1884, then designated by George Dieulafoy in 1898 and named for this French surgeon<sup>[1]</sup>. It refers to a submucosal "caliber-persistent" artery which protrudes through a minute 2-5 mm mucosal defect, which fails to diminish to the minute size of the mucosal capillary microvasculature and becomes elongated with a diameter 10 times that of the normal arteries at the same level<sup>[2,3]</sup>.

The most common and classic location of this lesion is in the proximal lesser curvature within 6 cm of the gastro-esophageal junction. However, uncommon occurrences in other sites including esophagus, duodenum, Billroth II anastomoses after gastrectomy, jejunum, colon, and rectum have also been described<sup>[3-5]</sup>. The erosion of "caliber-persistent" artery in DL may lead to massive and serious gastrointestinal (GI) bleeding, which accounts for 1%-5% of the origin of acute non-variceal upper GI bleeding<sup>[6-8]</sup>. Endoscopic diagnosis may be very difficult especially on the first episode due to the minute size of the lesion and the intermittent nature of the related bleeding. A wide variety of endoscopy techniques including injection of epinephrine (EPI) and sclerosing substances, heater and Argon probe coagulation, and mechanical

procedures including endoscopic band ligation (EBL) and hemoclippping have been applied in the treatment of the lesion and achieve satisfactory hemostasis with low recurrence and complication rates<sup>[5-11]</sup>. However, no single modality has been proven superior to the others. The choice depends on the endoscopist's preference and experience, as well as the clinical setting. Recently, there has been a trend suggesting that hemoclippping and EBL may be the first-line choice, while endoscopic ultrasound (EUS) guided angiotherapy appears to be promising<sup>[12,13]</sup>.

Although studies on the management and long-term outcome of GI DL have been widely documented, gastric DL and its clinical features in Chinese patients is poorly understood. In this retrospective study, we investigate the incidence, location, clinical presentation, diagnosis, and effectiveness of endoscopy treatment on gastrointestinal DL in Renmin Hospital of Wuhan University, with the aim of presenting experience on diagnosis and treatment of DL in China.

## MATERIALS AND METHODS

All patients who underwent emergency upper GI endoscopy due to acute non-variceal upper GI bleeding from February 2000 to August 2008 at GI endoscopy center of Renmin Hospital of Wuhan University were included in this study. Diagnosis of DL was established based on the following published criteria: (1) active arterial spurting or micropulsatile streaming from a minute mucosa defect; (2) visualization of a protruding vessel with or without active bleeding within a minute mucosal defect within normal surrounding mucosa; and (3) densely adherent clot with a narrow point of attachment to a minute mucosal defect or normal appearing mucosa<sup>[6,8,12]</sup>. Hemodynamic instability was defined as meeting one or more of the following criteria: (1) systolic blood pressure < 100 mmHg and pulse rate > 100 bpm; (2) orthostatic change in systolic blood pressure > 20 mmHg; and (3) decrease in hemoglobin of at least 2 g/dL in 24 h and need for blood transfusion before endoscopy.

Endoscopies were performed with Olympus video-endoscope after hemodynamic support treatment including intravenous fluids and blood transfusion if necessary. Endoscopic therapy was performed immediately after diagnosis with informed consent and the choice of endoscopy technique were decided by the endoscopist performing the procedure. Local injection was performed with an EPI solution 1:10000 in 4-quadrant fashion. Thermocoagulation was performed with a 2.3 mm diameter heat probe (HP) set at 25-30 J/pulse. Hemoclips (MD-850, Olympus) were applied with a rotatable clip-fixing device (HX-6UR-1) by using an endoscope with a 3.2 mm diameter accessory channel. Primary hemostasis was defined as no further bleeding from the site of DL for 5 min before withdrawal of the endoscope or disappearance of the vessel. Omeprazole 40 mg twice daily was given intravenously to all patients after initial endoscopy for 5-7 d and stopped if there was no further bleeding; feeding started 3-5 d after initial endoscopy

if no recurrent bleeding occurred. Recurrent bleeding was defined as hemodynamic instability due to bleeding symptoms or requirement of blood transfusions more than 5 units or decrease in hemoglobin more than 3 g/dL within 48 h associated with a fresh adherent clot or active bleeding from the same site of DL found in the initial endoscopy. Another endoscopy was performed 72 h after the initial hemostatic procedure or earlier if recurrent bleeding occurred in all patients. Angiography and gel-foam embolism were applied if it was difficult to identify the location of bleeding or achieve hemostasis after repeat endoscopy and surgery intervention was not selected by surgeon. The clinical presentation, medical history, location and characteristics of DL, methods and effectiveness of therapy of those patients were retrospectively analyzed by chart review. Long-term follow-up data were collected at outpatient clinics or by telephone interviews. This study was approved by the Ethics Committee of Renmin Hospital of Wuhan University and was in accordance with the Declaration of Helsinki.

## RESULTS

Fifteen out of 1433 patients with acute non-variceal upper GI bleeding were diagnosed as having DL from February 2000 to August 2008 at GI endoscopy center of Renmin Hospital of Wuhan University, Wuhan, China, which accounted for 1.04% of the sources of bleeding in acute non-variceal upper GI bleeding. The clinical presentation and endoscopy diagnosis of DL are listed in Table 1. Endoscopy treatment and outcome of DL are listed in Table 2. The median age was 36.1 years, ranging from 11-80 years. Most patients presented with melena and/or hematemesis while 1 female, an 80-year-old patient presented (patient No. 10) with only hypotension without external signs of bleeding. She had a previous history of hypertension and diabetic mellitus. No other common comorbidity causes for DL was found in other patients. No patients were receiving anticoagulant therapy, platelet aggregation inhibitors (PAI), or non-steroidal anti-inflammatory drugs medication.

Eleven patients presented with hemodynamic instability and needed blood transfusion before endoscopy. Active bleeding was detected during first endoscopy in 13 patients. A nonbleeding visible vessel was detected in 1 patient, and a minute mucosal defect below an adherent clot was detected in 1 patient. Three patients failed to establish diagnosis of DL during first endoscopy and needed more than one endoscopy to achieve conclusive diagnosis and exact location of DL. The most frequent location was the fundus (11/15, 73.3%), followed by the subcardinal area (2/15, 13.3%), and proximal corpus (2/15, 13.3%). For hemostasis, three endoscopic techniques were used: (1) only EPI in 1 case; (2) only hemoclippping in 11 cases; (3) EPI plus hemoclippping in 1 case; and (4) EPI, heat probe plus hemoclip in 1 case. Primary hemostasis was achieved in 14 patients. No endoscopic complications were found. Recurrent bleeding was detected in 3 patients (patient No. 8, 10 and 11) within 30 h. Angiography and gel-foam embolism were applied to identify location and hemostasis

Table 1 Clinical presentation and endoscopy diagnosis of DL

Patient No.	Sex/age (yr)	Clinical presentation	Hemodynamic instability	Location	Stigmata (forrest)	Diagnosis at initial endoscopy
1	M/40	Melena/hematemesis	+	Subcardinal area (remnant stomach)	I a	+
2	M/60	Melena/hematemesis	+	Subcardinal area	I a	+
3	M/36	Melena	-	Fundus	II a	+
4	F/15	Melena/hematemesis	+	Fundus	I b	+
5	M/11	Melena/hematemesis	+	Fundus	I a	+
6	M/20	Hematemesis	+	Proximal corpus	I a	+
7	F/54	Melena/hematemesis	+	Fundus	I a	+
8	M/23	Melena/hematemesis	+	Proximal corpus	I a	-
9	F/43	Melena	-	Fundus	I a	+
10	F/80	Hypotension	+	Fundus	II b	-
11	M/25	Melena/hematemesis	+	Fundus	I a	+
12	M/35	Melena/hematemesis	+	Fundus	I a	+
13	M/25	Melena/hematemesis	+	Fundus	I a	-
14	M/47	Melena/hematemesis	+	Fundus	I a	+
15	M/28	Melena/hematemesis	+	Fundus	I a	+

I a: Spurting bleeding; I b: Oozing bleeding; II a: Nonbleeding visible vessel; II b: Minute mucosal defect below an adherent clot. For patients who were not diagnosed with DL during initial endoscopy, the location and stigmata refer to the findings during repeated endoscopy. DL: Dieulafoy's lesion.

Table 2 Endoscopy treatment and outcome of DL

Patient No.	Endoscopy treatment	Primary hemostasis	Relapse within 30 h	Treatment for relapse	Hemostasis for relapse	Follow-up (mo)
1	EPI + hemoclip	+	-	-	-	22
2	EPI + HP + hemoclip	+	-	-	-	10
3	Hemoclip	+	-	-	-	17
4	EPI	+	-	-	-	33
5	Hemoclip	+	-	-	-	28

14	Hemoclip	+	-	-	-	35
15	Hemoclip	+	-	-	-	21

EPI: Epinephrine; HP: Heat probe.

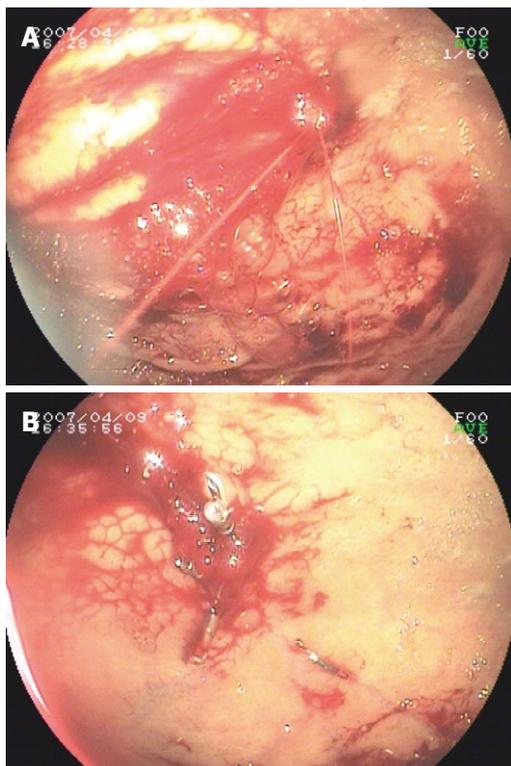

in patient No. 10 and No. 11 during the second bleeding. In patient No. 10, the source of bleeding was concluded to be located in the colon by angiography but colonoscopy failed to identify the source of bleeding in the colon. DL in the stomach was identified by gastroscopy during the third bleeding, while hemostasis was subsequently achieved by hemoclipping. Patient 11 died of recurrent bleeding and fever 1 d after embolization. For patient No. 8, a hemoclip was placed during the second endoscopy. Subsequently, surgical intervention was selected due to uncontrolled bleeding during the third episode. Multiple DL was identified at the same site during the initial endoscopy by emergency endoscopy during the operation. Hemostasis was achieved by oversewing at the location of DL. Typical bleeding of gastric DL and hemostasis after hemoclipping are shown in Figure 1A and B.

Follow-up was conducted in 14 patients, ranging from 6 to 44 mo after effective treatment. No recurrent bleeding was noted in all patients.

## DISCUSSION

In this study, we found that DL accounts for 1.04% (15/1433) of acute non-variceal upper GI bleeding according to an 8 years clinical investigation in a provincial general hospital in Middle China. This proportion, consistent with other previously published epidemiological series, indicates that DL appears not to be a common source of acute non-variceal upper GI bleeding in China<sup>[4,5,12,14,15]</sup>. On the other hand, 86.7% (13/15) patients with active bleeding and hemodynamic instability were diagnosed with DL, which suggests that DL should be fully recognized as a potentially severe cause of upper GI bleeding and a life-threatening GI emergency.

As some clinical and epidemiological data have previously suggested, DL usually affects elderly patients with significant comorbidities, including cardiovascular disease, respiratory disease, chronic renal failure, liver cirrhosis, neurological disease or medication, which influence blood

**Figure 1** Typical bleeding of gastric Dieulafoy's lesion (DL) in one male patient before (A) and after (B) hemoclipping.

coagulation<sup>[1,4,5,8,12,14,16]</sup>. It has been speculated that those systemic conditions may disturb normal angiogenesis, including the formation of aberrant caliber persistent vessels, thus increasing the incidence of DL. Our data detected only 2 patients > 60 years and 1 elderly patient with significant comorbidities including hypertension and diabetic mellitus. Having relatively few comorbidities in the present study may be attributed to the much younger mean ages of patients with DL, which seems not agree with those of previous studies. However, the actual incidence of DL in elderly patients may be underestimated in that (1) Elderly patients are more reluctant to undertake emergency endoscopy; (2) Concomitant systemic conditions in elderly patients may dramatically increase the risk of emergency endoscopy and compel clinicians to give up emergency endoscopy; and (3) Systemic conditions may obscure the manifestations of DL and decrease suspicion by clinicians. For example, melena or hematemesis was persistently absent in 1 elderly patient during 3 episodes of massive GI bleeding from DL in our study, which delayed the diagnosis of DL until repeat endoscopy was performed. Similar conditions may also occur in other elderly patients with DL, leading to failure of diagnosis.

Data on the distribution of DL in the GI tract showed that the majority of DL occurs in the stomach in the upper GI tract and is located in the region within 6 cm of the gastroesophageal junction<sup>[1,6,14,16,17]</sup>. In this study, the most frequent location of DL was also found at this classic site of DL. Therefore, this site should be highly suspicious and exhaustively explored during emergency

endoscopy in order to achieve an early diagnosis of DL. In our series, the first endoscopy failed to identify the location of DL in 3 patients. Failure to detect DL initially may be attributed to (1) intermittent bleeding and retracted vessels make DL invisible; (2) an excessive quantity of blood in stomach obscures the visual field; (3) alternative lesions give rise to GI bleeding already detected which prevents further detection of DL. In those special cases, repeat endoscopy is frequently necessary, and gastric lavage or position shifting may be needed for an accurate diagnosis.

Endoscopic therapy is currently advocated as a first-line choice for homeostasis of DL. A large variety of hemostasis techniques including injection of epinephrine or sclerosant, heater or Argon probe coagulation, elastic band ligation (EBL), hemoclip or a combination of those methods have been used for hemostasis of DL with permanent hemostasis achieved in more than 90% of patients<sup>[1,4-9,14-16,18-20]</sup>. Up to now, it has not been concluded that one single therapeutic modality is superior to another in well designed retrospective or randomized controlled trials<sup>[10,15,18]</sup>. The choice of technique should be individualized for each patient and depend on the type and location of DL, endoscopist's experience and competency, and the risk and complication of techniques. In the present study, hemoclip or combined therapy of EPI or HP followed by hemoclip achieved primary hemostasis in 92.8% (13/14) of patients. Recurrent bleeding occurred in only 1 patient with multiple DL during the second endoscopy. No recurrent bleeding occurred in long-term follow-up, demonstrating that the hemoclip is effective and safe for controlling bleeding from DL. According to our experience, hemoclipping has a special advantage in that (1) it is easier to perform technically than other techniques like EBL or sclerosis; (2) it causes less damage to the surrounding tissues, thus avoiding the possibility of necrosis or perforation caused by sclerosant injection or thermal coagulation; (3) it is effective for proximal gastric lesions with protruding vessels or active bleeding; and (4) it is an easy and safe method for controlling recurrent bleeding. Additionally, we found that use of EPI or HP before application of the hemoclip may achieve a better visual field in cases with profound bleeding, which will facilitate the application of the hemoclip.

Angiography and gel-foam embolism were applied to identify the location and hemostasis of DL in 2 patients with recurrent bleeding in our study. Bleeding from the colon as a false-positive result was concluded in 1 patient and death due to fever and profound bleeding immediately after gel-foam embolism occurred in another patient. Therefore, the accuracy and risk of this technique should be fully evaluated when choosing treatment for DL bleeding. Furthermore, bleeding from multiple DL was found in 1 patient during recurrent episodes of bleeding, which were controlled by surgical oversewing. Further explanation for this phenomenon is needed.

In conclusion, DL, as an uncommon cause, accounts for 1.04% of the instances of non-variceal upper GI bleeding in Middle China. Hemoclipping proved to be safe

and effective in controlling bleeding from DL. Further investigations are needed to accumulate more experience on endoscopic treatment for elderly patients with DL. Better options and approaches should be explored for identifying the location of DL which are difficult to define and refractory to routine endoscopy techniques.

## COMMENTS

### Background

Dieulafoy's lesion (DL) refers to submucosal "caliber-persistent" artery which fails to diminish to the minute size of the mucosal capillary microvasculature and becomes elongated with a diameter 10 times that of the normal arteries at the same level. The erosion of "caliber-persistent" arteries in DL may lead to massive and serious gastrointestinal (GI) bleeding, which accounts for 1%-5% of the origin of acute non-variceal upper GI bleeding. Endoscopy diagnosis may be very difficult especially on the first episode due to the minute size of the lesion and the intermittent nature of the related bleeding.

### Research frontiers

Endoscopy diagnosis may be very difficult especially on the first episode due to the minute size of the lesion and the intermittent nature of the related bleeding. A wide variety of endoscopy techniques including injection of epinephrine and sclerosing substances, heater and Argon probe coagulation, and mechanical procedures including endoscopic band ligation and hemoclippping have been applied in the treatment of the lesion and achieve satisfactory hemostasis with a low recurrence and complication rate. However, no single modality has been proven superior to the others.

### Innovations and breakthroughs

This study investigated the incidence, location, clinical presentation, and diagnosis of gastric Dieulafoy's lesion in a Chinese region and evaluated the options and effectiveness of endoscopic treatment for DL.

### Applications

This study indicated that DL is an uncommon cause of non-variceal upper GI bleeding in Middle China. Hemoclippping proved to be safe and effective in controlling bleeding from DL. Those results provide a background for further investigation for better options and approaches.

### Peer review

In the method section, the trends of selected endoscopic methods in the hospital should be described during the 8 years' study period, because almost all cases were treated by hemoclips.

### Abstract

**AIM:** To explore the possibility and mechanism of inhibiting allogeneic T-cell responses by Kupffer cells (KC) pretreated with interferon- $\gamma$  (IFN- $\gamma$ ) *in vitro*.

**METHODS:** The expressions of indoleamine 2,3-dioxygenase (IDO) mRNA and FasL mRNA in KC pretreated with IFN- $\gamma$  were studied with real-time polymerase chain reaction (PCR). The catabolism of tryptophan by IDO from KC was analyzed by high performance liquid chromatography. Allogeneic T-cell response was used to confirm the inhibition of KC *in vitro*. The proliferation of lymphocytes was detected using [ $^3$ H] thymidine incorporation. Cell cycle and lymphocyte apoptosis were evaluated by flow cytometric assay.

**RESULTS:** Real-time PCR revealed IDO mRNA and FasL mRNA expressions in KC pretreated with IFN- $\gamma$ , and IDO catabolic effect was confirmed by a decrease in tryptophan and increase in kynurenine concentration. KC expressing IDO and FasL in BABL/c mice acquired the ability to suppress the proliferation of T-cells from C57BL/6, which could be blocked by addition

of 1-methyl-tryptophan and anti-FasL antibody. KC expressing IDO could induce allogeneic T-cell apoptosis.

**CONCLUSION:** In addition to Fas/FasL pathway, IDO may be another mechanism for KC to induce immune tolerance.

### INTRODUCTION

The acceptance of the fetus during pregnancy by the mother is a successful model of tolerance against allogeneic tissues. The exact mechanism of immunosuppression in pregnancy will help develop novel therapeutic strategies in clinical transplantation. Indoleamine 2,3-dioxygenase (IDO) plays an important role in maintenance of maternal T-cell tolerance to fetal alloantigen, and IDO-specific inhibitor, 1-methyl-tryptophan (1-MT), can selectively reject allogeneic fetuses<sup>[1,2]</sup>, which was observed in liver allografts<sup>[3]</sup>. The mechanism of IDO immunosuppression may be the localized depletion of the essential amino acid tryptophan and formation of its metabolites<sup>[4-7]</sup>.

Kupffer cells (KC), act as effective antigen-presenting cells (APC) in the liver, can directly interact with passenger leukocytes and may play an important role in intrahepatic

immunoregulation. KC can regulate allogeneic T-cell response *in vitro* and *in vivo* by Fas/FasL pathway, but blocking anti-FasL antibody could not thoroughly suppress the effect of KC on T-cell proliferation<sup>[8]</sup>, and some other mechanisms may contribute to KC-dependent suppression. Many experiments<sup>[9,10]</sup> showed that APC, such as dendritic cells and monocyte-derived macrophages, could induce IDO expression by certain treatment and acquire the capacity to suppress T-cell proliferation.

In this study, we hypothesized that IDO expressed by KC was another mechanism of KC immunoregulation. To confirm this, we analyzed whether KC pretreated with interferon- $\gamma$  (IFN- $\gamma$ ) can be induced to express IDO and FasL, and the impact of KC expressing IDO and FasL on allogeneic T-cell response *in vitro*.

## MATERIALS AND METHODS

### Animals

Male BABL/c and C57BL/6 mice were purchased from the West China Animal Center and those aged 10-12 wk were used for the experiment.

### Lymphocyte and KC isolation

Spleens were harvested from male C57BL/6 mice and the lymphocyte (LC) was isolated as described previously<sup>[5]</sup>. KCs were isolated as described by Yan *et al.*<sup>[11]</sup>. This technique of cell isolation yielded 10-20 million KCs per liver on average, with a 92%-95% viability, as determined by trypan blue exclusion. KCs were determined by phagocytosed carbon bead and stained positively for nonspecific esterase.

### Relative quantitation for FasL mRNA and IDO mRNA expression

Total RNA of KC was extracted using TRIzol (Life Technologies, Rockville, USA) and subjected to reverse transcription polymerase reaction (RT-PCR) using the following primers: FasL 5'-GCACAGAAGGGAAGGAG-TA-3' and 5'-CCAGGAGAATCGCAGTAGA-3'; IDO 5'-TATTGCTGTTCCCTACTG-3' and 5'-GGTCTT-GACGCTCTACT-3'; GAPDH 5'-CCTCAAGATTGT-CAGCAAT-3' and 5'-CCATCCACAGTCTTCTGAGT-3'. And they yielded a fragment size of 163, 255 and 141 bp, respectively. Amplification was performed on an iCycler (Bio-Rad, Hercules, USA). For quantitative PCR, amplification was performed using SYBR Green PCR Master Mix (Applied Biosystems, Foster City, USA). Fluorescence was detected at 490 nm using the iCycler IQ real-time PCR (Bio-Rad, Hercules, USA). The Ct of negative samples was defined as 45. A comparative Ct method was used to quantitate IDO and FasL cDNA levels<sup>[12]</sup>. Melting curve analysis consisted of a denaturation step at 95°C for 1 min, lowered to 55°C for 30 s, and followed by 40 cycles of incubation, in which the temperature was raised to 95°C at a rate of 1°C/30 s per cycle with continuous reading of fluorescence. The size of amplification products was verified by agarose gel electrophoresis.

### Mixed leukocyte reaction

KC ( $2.0 \times 10^4$ ) from BABL/c was co-incubated with allogeneic spleen lymphocytes ( $4.0 \times 10^5$ ) from C57BL/6 in 0.2 mL RPMI1640 medium containing 10% fetal calf serum (FCS), 100 U/mL penicillin, and 100 mg/mL streptomycin. Positive controls consisted of KC pretreated with IFN- $\gamma$  (Cytolab Ltd., USA) for 24 h and allogeneic lymphocytes with anti-FasL antibody (MFL4; BD PharMingen, San Diego, CA) or 1-MT (Aldrich Chemical, Milwaukee, WI), or KC pretreated with IFN- $\gamma$  (200 U/mL) or without allogeneic lymphocytes, whereas negative controls included KC or lymphocytes only. These cells were cultured in a 37°C, 5% CO<sub>2</sub> incubator in 96-well flat bottom plates (COSTAR, Corning, NY, USA). After 5 d, [<sup>3</sup>H] thymidine (<sup>3</sup>H-TdR) (Inotech Biosystems, USA) was added and kept for 12 h and the number of counts per minute (cpm) was determined in a  $\beta$ -counter.

### High performance liquid chromatography for functional IDO expression

To verify functional IDO expression, tryptophan and kynurenine levels were measured in culture media. IDO activity was expressed as the concentration of kynurenine in the sample. KC was treated with IFN- $\gamma$  (200 U/mL) for 6 and 24 h in 200  $\mu$ L RPMI1640 containing 24.5  $\mu$ mol/L tryptophan. The supernatant was harvested and the quantity of kynurenine and tryptophan was determined by high performance liquid chromatography (HPLC) and UV detection (UV265 nm, Shimadzu, Japan). HPLC was performed according to Carlin *et al.*<sup>[13]</sup> with minor modifications.

Protein-free supernatant of 100  $\mu$ L was injected onto the column. Kynurenine and tryptophan concentrations in the supernatants were determined based on their peak heights relative to standard solutions obtained in the chromatograms. The standard solutions of kynurenine and tryptophan, purchased from Sigma, were prepared and kept fresh each day at concentrations ranging from 0 to 30  $\mu$ mol/L and submitted to precipitation with 30% trichloroacetic acid and incubation at 50°C for 30 min. Chromatography of the standards and the samples was performed under the same conditions.

### Flow cytometric analysis

KCs ( $1 \times 10^6$ ) were seeded and after an overnight incubation, they were pretreated with IFN- $\gamma$  (200 U/mL) for 24 h. T-cell alone was used as controls. KCs were cocultured with allogeneic T-cells (E/T = 1:1) for 24 h. T-cells were harvested and washed twice with 0.01 mol/L PBS and fixed with 70% ethanol for 2 h at 25°C. Finally, the cells were washed twice with PBS and stained with propidium iodide. The apoptosis of T-cells was analyzed by a flow cytometer (Beckman-Coulter, USA).

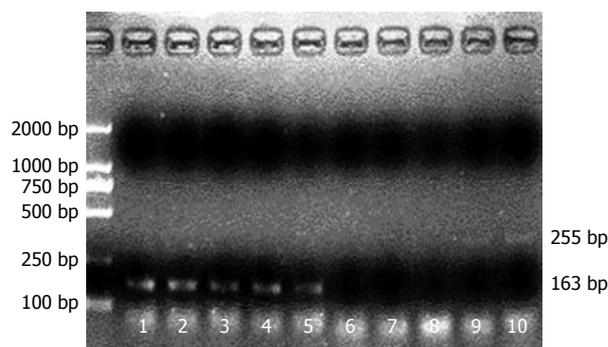

### Statistical analysis

The Chinese law on the Protection of Animals was followed. The data were presented as mean  $\pm$  SD. Parametric data was analyzed by Student's *t* test. *P* < 0.05 was considered statistically significant.

**Table 1** IDO mRNA expression of KC pretreated with IFN- $\gamma$  at different time points

**Figure 1** Reverse transcription polymerase chain reaction (RT-PCR) shows indoleamine 2,3-dioxygenase (IDO) and FasL expression in Kupffer cells (KC) before and after activation with recombinant interferon- $\gamma$  (IFN- $\gamma$ ). RT-PCR showing FasL expression in KC before (lanes 1 and 2) and after activation for 6 h (lanes 3 and 4) or 24 h (lane 5) with IFN- $\gamma$ . RT-PCR showing IDO expression in KC before (lanes 6-8) and after activation for 6 h (lane 9) or 24 h (lane 10) with IFN- $\gamma$ .

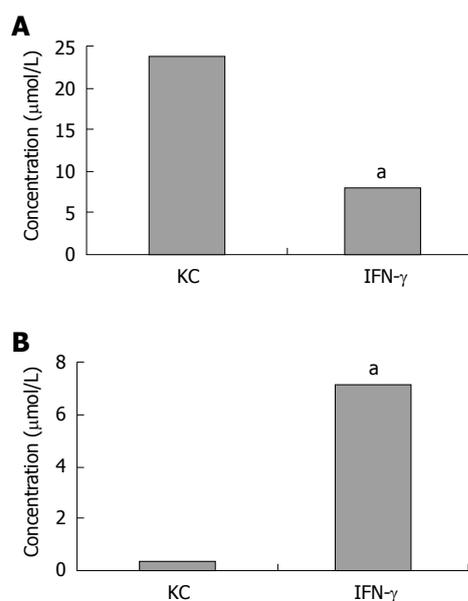

## RESULTS

### IFN- $\gamma$ induces the expression of IDO mRNA and FasL mRNA in KC

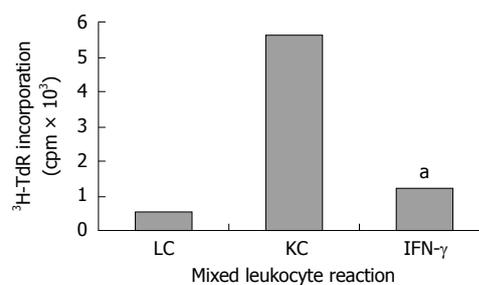

We measured KC FasL mRNA and IDO mRNA using real-time RT-PCR. Treatment of mouse KC with IFN- $\gamma$  resulted in the time-dependent induction of IDO and FasL. The results were expressed in terms of change in Ct values ( $\Delta$ Ct),  $\Delta$ Ct = average Ct<sub>specific gene</sub> - average Ct<sub>GAPDH</sub>. Because GAPDH is an abundant message, lower  $\Delta$ Ct values corresponded to a higher level of expression. Expression of FasL and IDO in KC pretreated with IFN- $\gamma$  was significantly decreased in comparison with KC without IFN- $\gamma$  pretreatment (Table 1). IDO and FasL expression was determined by RT-PCR in KCs before and after activation for 6 and 24 h with recombinant IFN- $\gamma$  (Figure 1).

### Tryptophan depletion of culture medium

To verify whether IDO induced by KC exerted its catabolic effect, tryptophan as well as kynurenine were measured by HPLC in KCs pretreated with or without IFN- $\gamma$  for 24 h. Tryptophan and kynurenine concentrations were determined using 1 mL of culture medium that was harvested from a 3.5 cm<sup>2</sup> culture dish. As expected, the kynurenine concentration significantly increased while tryptophan decreased. Tryptophan concentration in KC group and IFN- $\gamma$  group was 23.6  $\pm$  0.9  $\mu$ mol/L and 7.8  $\pm$  0.6  $\mu$ mol/L while kynurenine concentration was 0.3  $\pm$  0.08  $\mu$ mol/L and 7.1  $\pm$  1.4  $\mu$ mol/L, respectively (Figure 2).

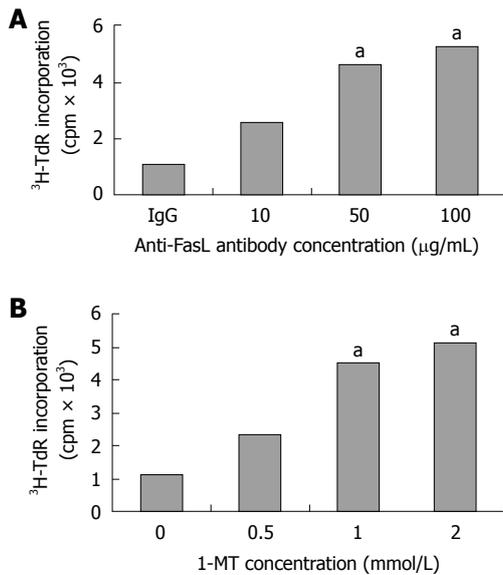

**Figure 2** Tryptophan (A) and kynurenine (B) concentration in cultures of KC. The kynurenine concentration significantly increased while tryptophan decreased in KC pretreated with IFN- $\gamma$  for 24 h. <sup>a</sup>*P* < 0.05 vs KC group.

**Figure 3** Reduction of allogeneic T-cell stimulation by IDO and FasL-expressing KC. Naive lymphocyte (LC), naive KC, KC pretreated with IFN- $\gamma$  were cocultured with allogeneic spleen T-cell for 5 d and cell proliferation measured by <sup>3</sup>H-TdR incorporation. <sup>a</sup>*P* < 0.05 vs KC group.

### Inhibition of allogeneic T-cell response by KCs expressing IDO and FasL

Whether KCs expressing IDO and FasL can inhibit the proliferation of allogeneic T-cells was confirmed in the experiment. KC pretreated with IFN- $\gamma$  for 24 h and naive KC were cocultured with allogeneic T-cells, respectively, the proliferation was determined by <sup>3</sup>H-TdR incorporation. KCs expressing IDO and FasL were significantly more effective than naive KC (Figure 3) in inhibiting the allogeneic T-cell proliferation (*P* < 0.05).

**Figure 4** Anti-FasL antibody (A) or 1-methyl-tryptophan (1-MT) (B) enhances the proliferation of allogeneic T-cell stimulated with KC pretreated with IFN- $\gamma$ . <sup>a</sup> $P < 0.05$  vs control group.

#### 1-MT and anti-FasL antibody blocks the inhibitory effect of KC pretreated with IFN- $\gamma$

To confirm whether the inhibition of T-cell proliferation was due to the enzymatic activity of IDO, inhibitory tests were performed in the presence of 1-MT, anti-FasL antibody or IgG. The addition of 1-MT or anti-FasL antibody showed an augmented proliferative response in a dose-dependent manner as compared with the control group (Figure 4). These results indicate that the inhibitory effect of KC pretreated with IFN- $\gamma$  was induced by the IDO activity and Fas/FasL interaction.

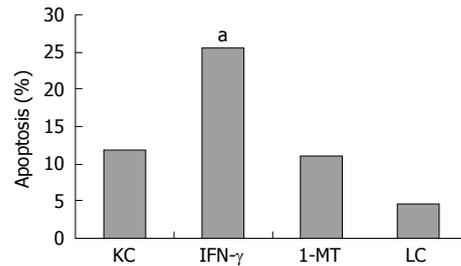

#### KCs induce allogeneic T-cell apoptosis

In order to clarify the underlying mechanism by which KC inhibits the proliferation of allogeneic T-cells, we confirmed that KC has the ability to induce apoptosis of allogeneic T-cells. The apoptosis rate of allogeneic T cells was 11.7%  $\pm$  1.2% in KC group, 25.53%  $\pm$  1.31% in IFN- $\gamma$  group, 10.9%  $\pm$  0.25% in 1-MT group and 4.53%  $\pm$  0.65% in LC group. Figure 5 shows that KC pretreated with IFN- $\gamma$  was more effective to induce T-cell apoptosis than naive KC, but the effect was abrogated by addition of 1-MT (1 mmol/L).

## DISCUSSION

KC pretreated with IFN- $\gamma$  can be induced to express IDO mRNA and FasL mRNA as shown in this study. KC expressing FasL and IDO can inhibit the proliferation of allogeneic T-cells and induce their apoptosis by increasing kynurenine and reducing tryptophan *in vitro*, which could be blocked by addition of 1-MT and anti-FasL antibody. These results are consistent with our hypothesis that IDO is another mechanism of KC immunoregulation.

The interaction between T-cell and KC has an important impact on antigen-specific immune response in

**Figure 5** KC induces apoptosis of allogeneic T-cell. The KC pretreated with IFN- $\gamma$  exhibit a significant allogeneic T-cell apoptosis. <sup>a</sup> $P < 0.05$  vs KC group.

the liver. The expansion of specifically activating T-cell requires the presence of KC, which holds a key position in regulation of hepatic immune response<sup>[14,15]</sup>. Apoptosis induced by Fas/FasL interactions have been proposed as a mechanism of immune privilege and peripheral tolerance<sup>[16]</sup>. Sun *et al*<sup>[8]</sup> identified that KC induced T-cell apoptosis and may be involved in the development of hepatic immune tolerance through Fas/FasL pathway. But the addition of anti-FasL antibody could not thoroughly block the inhibitory effect of KC on allogeneic T-cell proliferation. We propose that KC-induced T-cell apoptosis is dependent on the Fas/FasL pathway and IDO. IDO as well as FasL are known to be expressed in immune-privileged sites and believed to induce peripheral tolerance<sup>[12,17]</sup>. Our data showed that KC pretreated with IFN- $\gamma$  induced the expression of both FasL and IDO. The blockade of IDO activity by 1-MT would negate the induction of apoptosis *in vitro* by IFN- $\gamma$ -treated KC. This suggests that IDO induction is another mechanism by which IFN- $\gamma$  acts on KC to mediate apoptosis of T-cells.

Munn *et al*<sup>[7]</sup> confirmed that macrophages expressing IDO caused the lack of tryptophan in a cell-culture system. In the current series of experiments, the amount of tryptophan reduced by KC expressing IDO was not so dramatic as by macrophages. The phenomena were due to different activities of the IDO gene. In the presence of tryptophan, IDO-expressing KCs also suppressed the proliferation of allogeneic T-cells. So the concentration of tryptophan in culture may not be the only reason contributing to the effect. Some reports<sup>[4,6,18,19]</sup> have shown that tryptophan-derived catabolites, such as kynurenine, 3-hydroxykynurenine, 3-hydroxyanthranilic acid and picolinic acid, also suppress the allogeneic T-cell responses *in vitro* and *in vivo*. The concentration of kynurenine in our study also increased after KCs were pretreated with IFN- $\gamma$ . Tryptophan metabolites may be another reason that IDO-expressing KCs inhibit the proliferation of allogeneic T-cells.

KCs expressing IDO and FasL may drive the differentiation of Th2/Th3. Th2 cells expressed higher levels of FAP-1 that inhibited Fas/FasL pathway and were not sensitive to FasL-induced apoptosis, but Fas/FasL pathway promoted the rapid death of Th1 cells and selective survival of Th2 cells<sup>[20]</sup>. It may be a mechanism for differential regulation of Th cells by KC. Furthermore, tryptophan metabolites, such as 3-hydroxykynurenine and quinolinic acid, can selectively induce apoptosis of

Th1 cells, but not Th2 cells<sup>[19]</sup>. It was associated with the activation of caspase 28 and cytochrome C released by mitochondrion without the participation of Fas/FasL interaction. KC pretreated with IFN- $\gamma$  may control the differentiation of Th cells by the two mechanisms.

In conclusion, our results showed that IDO expressed by KC is another mechanism associated with induction of allogeneic T-cell apoptosis in addition to Fas/FasL interaction.

## COMMENTS

### Background

The acceptance of the fetus during pregnancy by the mother is a successful model of tolerance against allogeneic tissue. Indoleamine 2,3-dioxygenase (IDO) plays an important role in maintenance of maternal T-cell tolerance to fetal alloantigens. The mechanism of IDO immunosuppression may be the localized depletion of tryptophan and formation of its metabolites. Kupffer cells (KC) plays an important role in intrahepatic immunoregulation and induction of tolerance by Fas/FasL pathway. But blocking the anti-FasL antibody could not thoroughly suppress the effect of KC on T-cell proliferation. IDO expressed by KC may be another mechanism of KC immunoregulation.

### Research frontiers

How to induce specific immune tolerance is a hot topic of research. Killing the transplantation antigen-activated T cells is an important way to induce specific immune tolerance. IDO plays an important role in inducing the apoptosis of antigen-activated T cells. The activation and apoptosis of T cell is the central link in the formation of immune tolerance, but the apoptosis requires the activation of antigen presenting cells in the liver mainly by KC. KC can regulate allogeneic T-cell response *in vitro* and *in vivo* by Fas/FasL pathway.

### Innovations and breakthroughs

The study found that KC pretreated with interferon- $\gamma$  (IFN- $\gamma$ ) could express IDO and FasL. KCs expressing IDO and FasL from BALB/c mice acquire the ability to suppress the proliferation of T-cells from C57BL/6, which could be blocked by 1-methyl-tryptophan and anti-FasL antibody. In addition to Fas/FasL pathway, IDO may be another mechanism in KC to induce immune tolerance.

### Applications

IDO may be another mechanism in KC to induce immune tolerance, indicating that KC may be the potential target for immune tolerance in liver transplantation.

### Terminology

IDO is a monomeric protein heme iron, which was found in rabbit intestinal tissues in 1967. IDO has been found widely expressed in the immune system, including the thymus, placenta, gastrointestinal mucosa, anterior chamber, epididymis and other immune tolerance or immunologically privileged sites, particularly in a number of inhibitory antigen-presenting cells. IDO is involved in the regulation of T-cell proliferation and apoptosis.

### Peer review

This is an interesting paper devoted to the role of IDO in KC in inhibiting allogeneic T-cell responses. In this study, the authors investigated whether KC pretreated with IFN- $\gamma$  can be induced to express IDO and FasL, and analyzed the impact of KC expressing IDO and FasL on allogeneic T-cell response *in vitro*. The study shows IDO is another mechanism of KC immune regulation. Overall, the study is interesting and significant, and the data are presented in a clear and logical manner.

### Abstract

**AIM:** To investigate the role of metabolic enzyme and DNA repair genes in susceptibility of esophageal squamous cell carcinoma (ESCC).

**METHODS:** A case-control study was designed with 454 samples from 128 ESCC patients and 326 gender, age and ethnicity-matched control subjects. Genotypes of 69 single nucleotide polymorphisms (SNPs) of metabolic enzyme (aldehyde dehydrogenase-2, *ALDH2*; alcohol dehydrogenase-1 B, *ADHB1*; *Cytochrome P450 2A6*, *CYP2A6*) and DNA repair capacity genes

(excision repair cross complementing group 1, *ERCC1*; *O*<sup>6</sup>-methylguanine DNA methyltransferase, *MGMT*; xeroderma pigmentosum group A, *XPA*; xeroderma pigmentosum group A, *XPD*) were determined by the Sequenom MassARRAY system, and results were analyzed using unconditional logistic regression adjusted for age, gender.

**RESULTS:** There was no association between the variation in the *ERCC1*, *XPA*, *ADHB1* genes and ESCC risk. Increased risk of ESCC was suggested in *ALDH2* for frequency of presence C allele of SNP [Rs886205: 1.626 (1.158-2.284)], *XPD* for C allele [Rs50872: 1.482 (1.058-2.074)], and *MGMT* for A allele [Rs11016897: 1.666 (1.245-2.228)]. Five variants of *MGMT* were associated with a protective effect on ESCC carcinogenesis, including C allele [Rs7069143: 0.698 (0.518-0.939)], C allele [Rs3793909: 0.653 (0.429-0.995)], A allele [Rs12771882: 0.719 (0.524-0.986)], C allele [Rs551491: 0.707 (0.529-0.945)], and A allele [Rs7071825: 0.618 (0.506-0.910)]. At the genotype level, increased risk of ESCC carcinogenesis was found in homozygous carriers of the *ALDH2* Rs886205 [CC vs TT, odds ratios (OR): 3.116, 95% CI: 1.179-8.234], *MGMT* Rs11016879 (AA vs GG, OR: 3.112, 95% CI: 1.565-6.181), Rs12771882 (AA vs GG, OR: 2.442, 95% CI: 1.204-4.595), and heterozygotes carriers of the *ALDH2* Rs886205 (CT vs TT, OR: 3.930, 95% CI: 1.470-10.504), *MGMT* Rs11016879 (AG vs GG, OR: 3.933, 95% CI: 2.216-6.982) and Rs7075748 (CT vs CC, OR: 1.949, 95% CI: 1.134-3.350), respectively. Three variants were associated with a protective effect on ESCC carcinogenesis, carriers of the *MGMT* Rs11016878 (AG vs AA, OR: 0.388, 95% CI: 0.180-0.836), Rs7069143 (CT vs CC, OR: 0.478, 95% CI: 0.303-0.754) and Rs7071825 (GG vs AA, OR: 0.493, 95% CI: 0.266-0.915). Increased risk of ESCC metastasis was indicated in *MGMT* for frequency of presence C allele [Rs7068306: 2.204 (1.244-3.906)], A allele [Rs10734088: 1.968 (1.111-3.484)] and C allele [Rs4751115: 2.178

(1.251-3.791)]. Two variants in frequency of presence C allele of *CYP2A6* [Rs8192720: 0.290 (0.099-0.855)] and A allele of *MGMT* [Rs2053139: 0.511 (0.289-0.903)] were associated with a protective effect on ESCC progression. Increased risk of ESCC metastasis was found in heterozygote carriers of the *MGMT* Rs7068306 (CG vs CC, OR: 4.706, 95% CI: 1.872-11.833).

**CONCLUSION:** Polymorphic variation in *ALDH2*, *XPD* and *MGMT* genes may be of importance for ESCC susceptibility. Polymorphic variation in *CYP2A6* and *MGMT* are associated with ESCC metastasis.

## INTRODUCTION

Esophageal cancer (EC) is one of the most common malignancies throughout the world, ranking the eighth in incidence and the sixth in mortality among tumors of all sites<sup>[1]</sup>. However, the incidence of EC varies extremely among different regions<sup>[1,2]</sup>. The high-risk areas for esophageal squamous cell carcinoma (ESCC) (with an incidence ranging from 15 to 150/100 000) included distinct areas of South America, and the so-called "Asian Esophageal Cancer Belt" from eastern Turkey, through Iraq, Iran and the southern former Soviet Union (Kazakhstan, Turkmenistan, Uzbekistan, Tajikistan) to Mongolia and Western/Northern China<sup>[3]</sup>. Residents in the Asian EC Belt have a 10-100 fold greater chance suffering from EC than those living in the neighboring areas. ESCC is the most frequent type of EC in Asia. More than half of all ESCC cases in the world occurred in China, in the southern parts of the Taihang mountains at the borders of Henan, Shanxi and Hebei Provinces (Lin xian/Linzhou and Anyang County in Henan, and Cixian in Hebei, which will be designated below as "Linxian area"), in northern Jiangsu (Huai'an county) and in northern Xinjiang (with age standardized rates of 90-150/100 000)<sup>[4,5]</sup>.

Epidemiological studies revealed that the incidence of ESCC is associated with environmental factors, such as tobacco smoking, alcohol consumption, exposure to Nitrosamines, and nutritional deficiencies<sup>[6-8]</sup>. However, since only a fraction of individuals exposed to these risk factors actually develop EC, the role played by genetic determinants in response to environmental exposures needs to be addressed.

Data have also identified chronic alcohol consumption as a significant risk factor for alimentary tract cancer<sup>[9]</sup>. Ethanol is almost totally broken down by oxidative metabolism *in vivo*. Individuals who accumulate acetaldehyde due to polymorphic differences in the genes encoding the enzymes responsible for acetaldehyde generation and detoxification have been thought to show an ethanol associated carcinogenesis.

Ethanol is first metabolized into acetaldehyde through several enzymatic and nonenzymatic mechanisms, the main enzymatic pathways being alcohol dehydrogenase, cytochrome P450 (*CYP*) and catalase. Most of the acetaldehydes generated during alcohol metabolism *in vivo* are promptly eliminated by aldehyde dehydrogenase-2 (*ALDH2*), and alcohol dehydrogenase-1B (*ADH1B*, previously called *ADH2*)<sup>[10,11]</sup>.

Cytochrome P450 is a Phase I enzyme responsible for activating most environmental pre-carcinogens, whereas glutathione S-transferases (*GSTs*) are Phase II enzymes capable of detoxifying the electrophile carcinogens that result from the action of *CYP* enzymes. *CYP2A6*, the main enzymes capable of activating nitrosamines and other carcinogens in humans, are expressed in esophageal mucosa of Brazilian patients, with a high degree of variation in expression<sup>[12]</sup>. The *CYP2A6* gene is located on chromosome 19, and 30 different alleles have been described<sup>[13]</sup>.

DNA repairing capacity (DRC) is an essential component in EC progression. Sufficient DNA repair activity ensures the stability and fidelity of the genome when exposed to carcinogens in the process of cell growth and differentiation<sup>[14]</sup>, whereas instability in the genome in cancer patients may indicate a possible involvement of defective DRC<sup>[15]</sup>. DNA repair processes generally consist of direct reversal (DR), base excision repair, nucleotide excision repair (NER), or mismatch repair pathways<sup>[16]</sup>. Each pathway is specific for the repair of one or more types of DNA damage.

Key proteins in the transcription-coupled NER pathway (involved in correcting UV-induced lesions, chemical adducts, and crosslinks) include xeroderma pigmentosum group A and D (*XPA* and *XPD*), and excision repair cross complementing group 1 (*ERCC1*)<sup>[17,18]</sup>.

*O*<sup>6</sup>-methylguanine DNA methyltransferase (*MGMT*) is a single protein responsible for the DR pathway. The major defense against alkylating mutations is from *MGMT*, a 207 amino acid DNA repair protein that transfers potentially carcinogenic *O*<sup>6</sup> alkylation adducts from the DNA to a cysteine residue of *MGMT*<sup>[19,20]</sup>. For each adduct removed, an *MGMT* molecule is inactivated, hence the capacity for each cell to repair DNA depends upon the total number of *MGMT* molecules in the cell.

When genes essential for a variety of DNA repair pathways display aberrant activities, this may influence DRC with consequent carcinogenesis and progression. Several studies suggested that reduced expression of certain DNA repair genes were associated with the risk of environment-related esophageal adenocarcinoma<sup>[21-23]</sup>. There are few studies that examined the roles of gene polymorphism, metabolic enzyme and several DNA repair genes in risk of ESCC.

In the present study, Sequenom MassARRAY system was utilized to determine the relationship between ESCC and seven genes (*ADHB1*, *ALDH2*, *ERCC1*, *MGMT*, *XPA*, *XPD*, and *CYP2A6*) involved in two different DNA damage and repair pathways. The relationship between the polymorphism of candidate DNA repair genes and ESCC was determined in peripheral blood mononuclear cells from 128 patients with newly diagnosed, untreated ESCC and 326 healthy controls from the northern Xinjiang.

## MATERIALS AND METHODS

### Study subjects

This study included 128 ESCC patients and 326 healthy controls. All cases were from the Northern Xinjiang, China. Patients were newly diagnosed with histologically confirmed primary ESCC and not treated with radiotherapy or chemotherapy previously from January 2006 to December 2008. Healthy control subjects were recruited from a cancer-screening program for early detection of EC in the same area and matched with ESCC patients on age ( $\pm 5$  years), gender, ethnicity and residence. The selection criteria included no individual history of cancer and digestive disease. After written consent of blood donation for research purposes was obtained from cases and control, each subject donated 5 mL peripheral blood collected in K<sub>2</sub>EDTA tubes and stored at -80°C until DNA was extracted.

### Single nucleotide polymorphism (SNP) selection

The International Haplotype Mapping ([www.hapmap.org](http://www.hapmap.org)) and Cancer SNP databases (<http://snp500cancer.nci.nih.gov/snp.cfm>) were used to select SNPs in seven genes. The selection criteria was that SNPs had an  $r^2$  of  $\geq 0.8$  for all SNPs with a minor allele frequency  $> 5\%$  in CHB. According to the above rules, 69 *Taq* SNPs were selected in seven genes, including 6 for *XPD*, 5 for *XPA*, 5 for *ERCC1*, 6 for *ALDH2*, 3 for *ADHB1*, 3 for *XYP2A6*, and 41 for *MGMT*.

### Interview

A trained interviewer administered a questionnaire to cases and control, gathering clinical and demographical information. The questions included demographic variables (age, gender, and ethnicity), and a comprehensive smoking and alcohol intake profile. Smoking habits, and alcohol status were all defined at 1 year prior to diagnosis for cases, or 1 year prior to interview for controls. Smoking of the patients was classified as never-smokers, ex-smokers (quit  $> 1$  year), and current smokers (smoking

currently or quit  $< 1$  year). Alcohol use was defined as patients who never consumed alcohol *vs* those who had consumed alcohol at any time in the past.

### Genotyping

Genomic DNA was extracted within 1 wk after sampling using proteinase K digestion followed by a salting out procedure according to the method published by Miller *et al*<sup>[24]</sup>. SNPs were genotyped using the Sequenom MassARRAY system. The i-PLEX assay was performed according to manufacturer's instructions ([www.sequenom.com](http://www.sequenom.com)) using 5 ng of genomic DNA.

SNP typing was conducted using the Sequenom<sup>TM</sup> iPLEX<sup>TM</sup> protocol. PCR reactions were performed in standard 384-well plates containing 10 ng genomic DNA, 0.5 U of *Taq* polymerase (HotStarTaq, Qiagen, CA), 500  $\mu$ mol of dNTPs and 100 nmol of both forward and reverse PCR primers. Thermocycling conditions within the ABI-9700 (Applied Biosystems, USA) consisted of an initial 15 min denaturation at 94°C, followed by 45 cycles of 20 s denaturing at 94°C, 30 s annealing at 56°C, and 60 s extension at 72°C. PCR products were purified by incubation at 37 using 0.15 U of Shrimp Alkaline Phosphatase for 30 min followed by a 5 min inactivation at 85°C. A primer extension reaction mixture including 0.1  $\mu$ L of a 10  $\times$  termination mix, 0.02  $\mu$ L DNA polymerase and 1000 nmol/L of the extension primers was used in both the initial (denaturation at 94°C for 30 s, followed by 5 annealing and extension cycles at 52 and 80°C, respectively) and secondary (40 cycles of 5 s denaturation at 94°C, 5 s annealing at 52°C and 5 s extension at 80°C) iPLEX reactions. A final extension for 3 min at 72°C was conducted prior to cooling at 20°C. Products were diluted and desalted with 15  $\mu$ L sterile water and 3  $\mu$ L of resin prior to spotting onto a SpectroChip for analysis in the Compact Mass Spectrometer, using Workstation software version TYPER 4.0 (Sequenom). Genotype accuracy was calculated for all SNPs tested at 99.95%.

For quality control, genotyping was repeated randomly in at least 5% of the samples, and two of the authors independently reviewed all results. Allele frequencies of controls were calculated using the formula (example genotypes AA, AB and BB): Allele B frequency = [number of genotypes AB + 2  $\times$  (number of genotypes BB)]/[2  $\times$  (number of genotypes AA + number of genotypes AB + number of genotypes BB)].

### Statistical analysis

All cases and controls were compared for age, gender and ethnicity to ensure frequency matching. Hardy-Weinberg equilibrium of allele distributions was tested in cases and controls, separately. We used unconditional multivariate logistic regression to assess the main effects of genetic polymorphisms on ESCC risk by estimating odds ratios (OR) and associated confidence intervals (CI). Genotypes were categorized into three groups when the allele frequencies were allowed (major allele homozygous, heterozygous and homozygous variants).

**Table 1** Characteristics of ESCC patients and controls *n* (%)

Variables	Controls ( <i>n</i> = 326)	Patients ( <i>n</i> = 128)	<i>P</i> value

## RESULTS

### Subject characteristics

The frequency of 69 sequence variants was assessed in DNA samples from 128 ESCC cases and 326 controls from the population of North-Western China. The distributions of age and gender, smoking history, alcohol consumption history, and pathological grade among the study subjects are summarized in Table 1. There were no statistically significant differences among cases and controls in terms of mean age, gender and ethnicity, suggesting that the frequency matching was adequate.

As expected, the prevalence of smoking and alcohol was both significantly higher in ESCC cases than in the controls (Table 1).

There was a greater proportion of ex-smokers and current-smokers in the cases than in the controls ( $P = 0.007$ ). The percentage of ever alcohol users in the cases was higher than in the controls ( $P = 0.002$ ). There were 36 (28.1%) cases with metastasis and 92 (71.9%) cases without metastasis.

### Analysis of seven genes allele in ESCC carcinogenesis

The results in this study showed no associations between variations in the *ADHB1*, *ERCC1* and *XPA* genes and ESCC risk.

Possible allele and genotypes of investigated SNPs in relation to ESCC carcinogenesis are listed in Tables 2 and 3. Increased risk of ESCC was suggested in *XPD* for frequency of presence C allele of SNP [Rs50872: 1.482 (1.058-2.074)], in *ALDH2* for C allele of SNP [Rs886205: 1.626 (1.158-2.284)] and in *MGMT* for A allele of SNP [Rs11016897: 1.666 (1.245-2.228)]. Five variants of *MGMT* were associated with a protective effect on ESCC carcinogenesis: C allele [Rs7069143: 0.698 (0.518-0.939)], C allele [Rs3793909: 0.653 (0.429-0.995)], A allele [Rs12771882: 0.719 (0.524-0.986)], C allele [Rs551491: 0.707 (0.529-0.945)] and A allele [Rs7071825: 0.618 (0.506-0.910)].

### Analysis of seven genes genotype in ESCC carcinogenesis

At the genotype level, increased risk of ESCC was found in homozygous carriers of the *ALDH2* Rs886205 (CC *vs* TT, OR: 3.116, 95% CI: 1.179-8.234), *MGMT* Rs11016879 (AA *vs* GG, OR: 3.112, 95% CI: 1.565-6.181) and Rs12771882 (AA *vs* GG, OR: 2.442, 95% CI: 1.204-4.595). Increased risk of ESCC was also observed in heterozygotes carriers of the *ALDH2* Rs886205 (CT *vs* TT, OR: 3.930, 95% CI: 1.470-10.504), *MGMT* Rs11016879 (AG *vs* GG, OR: 3.933, 95% CI: 2.216-6.982) and Rs7075748 (CT *vs* CC, OR: 1.949, 95% CI: 1.134-3.350), respectively.

Three variants were associated with a protective effect on ESCC carcinogenesis: the carriers of the *MGMT* Rs11016878 (AG *vs* AA, OR: 0.388, 95% CI: 0.180-0.836), Rs7069143 (CT *vs* CC, OR: 0.478, 95% CI: 0.303-0.754) and Rs7071825 (GG *vs* AA, OR: 0.493, 95% CI: 0.266-0.915).

### Analysis of seven genes allele in ESCC progression

Tables 4 and 5 show the possible allele and genotypes of the investigated SNPs in relation to ESCC metastasis. Increased risk of ESCC metastasis was indicated in *MGMT* for frequency of presence C allele [Rs7068306: 2.204 (1.244-3.906)], A allele [Rs10734088: 1.968 (1.111-3.484)] and C allele [Rs4751115: 2.178 (1.251-3.791)].

Two variants were associated with a protective effect on ESCC carcinogenesis in frequency of presence C allele of *CYP2A6* [Rs8192720: 0.290 (0.099-0.855)] and A allele of *MGMT* [Rs2053139: 0.511 (0.289-0.903)].

### Analysis of seven genes genotype in ESCC progression

Increased risk of ESCC metastasis was found in heterozygote carriers of the *MGMT* Rs 7068306 (CG *vs* CC, OR: 4.706, 95% CI: 1.872-11.833).

## DISCUSSION

ESCC is one of the major health issues in China because of its high incidence and poor survival. Although the exact mechanism on EC is unclear, several possible mechanistic pathways have been proposed, including metabolic enzyme and DNA repair factors.

Alcohol consumption and tobacco smoking are established major risk factors for ESCC in Western populations<sup>[25,26]</sup>. However, studies in high-incidence regions are scarce and their results have been inconsistent<sup>[27-29]</sup>.

In the present study, we first conducted a case-control study to evaluate the associations between metabolic enzyme polymorphisms of *ADHB1*, *ALDH2* and *CYP2A6* and ESCC risk in population from northern Xinjiang, China. Consistent with previous studies<sup>[30-32]</sup>, the present study demonstrated that alcohol consumption and cigarette smoking are strongly associated with the incidence of ESCC. Moreover, individuals with *ALDH2* for frequency of presence C allele of SNP in Rs886205 and heterozygote carriers of the *ALDH2* in Rs886205 (CT *vs* TT) had significantly increased risk for ESCC carcinogenesis while individuals with frequency of

**Table 2** Analysis of genes allele in ESCC carcinogenesis

presence C allele in *CYP2A6* of Rs8192720 were inversely associated with ESCC metastasis.

Genomic fidelity and genetic stability usually depend on the efficiency of DRC when an organism is exposed to environmental and endogenous carcinogens. Peltomäki<sup>[33]</sup> showed that aberrant DRC might be involved in the pathogenesis of some cancers.

Previous molecular epidemiological studies have found that the *XPD* polymorphism is associated with increased risks for head and neck cancers<sup>[34]</sup>. However, inconsistent findings were also reported, including inverse associations with esophageal adenocarcinoma<sup>[35]</sup>. Our results suggested that *XPD* for frequency of presence C allele of SNP in Rs50872 increased the risk of ESCC carcinogenesis, which is consistent with the reported findings<sup>[36,37]</sup>.

*MGMT* is a major gene in the pathway of DNA repair and frequently found to be silenced by CpG island hypermethylation in many cancers, such as gastric cancer<sup>[38]</sup> and esophageal adenocarcinoma<sup>[39]</sup>. However, the studies on the ESCC are still rare. Fang *et al.*<sup>[40]</sup> reported that 29% (5 of 17) of normal esophageal tissues, 50% (10 of 20) of basal cell hyperplasia, 67% (8 of 12) of dysplasia, and 72% (13 of 18) of ESCC samples obtained from Linzhou City of Henan Province in northern China had DNA hypermethylation in *MGMT* promoter region. Until now, no investigation has been carried out about the associations between *MGMT* polymorphism and ESCC in a population of high incidence region of Northern Xinjiang. Our findings displayed that *MGMT* for frequency of presence A allele of SNP in Rs11016879, carriers of *MGMT* Rs11016879 (AA *vs* GG, AG *vs* GG), Rs12771882 (AA *vs* GG), and Rs7075748 (CT *vs* CC) significantly increased the risk of ESCC carcinogenesis. Our results are in agreement with the previous studies on EC<sup>[41-43]</sup>.

Furthermore, increased risk of ESCC metastasis was indicated in *MGMT* for frequency of presence C allele in Rs7068306, A allele in Rs10734088 and C allele in Rs4751115, and carriers of *MGMT* Rs7068306 (CG *vs* CC).

In addition, variants of *MGMT* were associated with a protective effect on ESCC carcinogenesis, including C allele in Rs7069143, C allele in Rs3793909, A allele in Rs12771882, C allele in Rs551491, and A allele in Rs7071825, and the carriers of the *MGMT* in Rs11016878 (AG *vs* AA), Rs7069143 (CT *vs* CC) and Rs7071825 (GG *vs* AA). Frequency of C allele in Rs8192720 and A allele in Rs2053139 were associated with a protective effect on ESCC metastasis which was inconsistent with previous studies<sup>[44,45]</sup>.

Difference in study population may be one of the reasons leading to the different results. However, since this is only a retrospective study and our findings could not be stratified because of the relatively small number in the groups, further epidemiological studies with enlarged samples are worth doing to warrant the results.

A limitation of our study may be missing covariate data. There have been many studies of individual environmental risk factors for EC<sup>[46-48]</sup>. We did not collect information on dietary factors and occupational history and so we were unable to study gene-environmental interactions in the etiology of ESCC. Gene-smoking and gene-alcohol interactions cannot be accurately measured due to sample size considerations. However, an improved

understanding of the main separate effects of genes and environment will allow detailed gene-environmental interactions to be examined in larger-scale studies in the future. Our study population size is too small to avoid spurious results although they are suggestive, and further larger validation studies are certainly needed. The biological meaning and function of interesting SNPs need to be confirmed especially in advanced researches.

However, the strong points in our study are that both cases and healthy control subjects were recruited from the same area and matched on age, gender, ethnicity and residence, and all our control subjects were under Hardy-Weinberg equilibrium. Moreover, all our cases were pathologically confirmed, and followed by a strict quality control from genotyping.

To conclude, this study provides no evidence on a role of common variation of genes *ERCC1*, *XPA* and *ADH1* in ESCC. However, our data indicated that variation in the *ALDH2*, *XPD* and *MGMT* genes may be related to the risk of ESCC carcinogenesis. The polymorphic variation in *CYP2A6* and *MGMT* are associated with ESCC metastasis.

## COMMENTS

### Background

Because of the high incidence and poor survival, esophageal cancer (EC) is one of the major health issues in Western/Northern, China. Although the exact mechanism is unclear, several possible mechanistic pathways have been proposed, including metabolic enzyme and DNA repair factors.

### Research frontiers

The relationship between gene polymorphism of metabolic enzyme, DNA repair and EC in Western/Northern China needs to be addressed. The present study indicated that metabolic enzyme and DNA repair factors were involved in the risk of esophageal squamous cell cancer (ESCC).

### Innovations and breakthroughs

The variation of *ALDH2*, *XPD* and *MGMT* genes may be of relevance to the risk of ESCC. The polymorphic variation of *CYP2A6* and *MGMT* were associated with ESCC metastasis.

### Applications

By understanding the gene polymorphism in *ALDH2*, *CYP2A6*, *MGMT* and

*XPD*, further researches may represent a future strategy for detecting the susceptibility to ESCC.

### Peer review

The paper deals with a very interesting subject. The authors analyzed genotypes of sixty-nine single nucleotide polymorphisms (SNPs) of metabolic enzyme and DNA repair capacity related genes in a moderate scale, and found some SNPs correlated with the risk of ESCC and tumor metastasis. These results are attractive and interesting. In general, the manuscript is written well and the data is presented clearly.

consistent with decidualization of the rectal wall. Only 20 cases of intestinal perforation due to endometriosis have been reported in the literature. This report is believed to be the first case of spontaneous rectal perforation from endometriosis in pregnancy, and it shows the potential occurrence of serious and unexpected complications of the disease.

### Abstract

This case report describes a woman with spontaneous rectal perforation from decidualized endometriosis in pregnancy. A 37-year-old woman was admitted to our hospital at 30 wk of pregnancy with symptoms suggestive of pyelonephritis, which persisted until 33 wk of gestation when delivery of a premature male baby was performed through a cesarean section. On postoperative day 2, an abdominal computed tomography showed free air in the peritoneal cavity and a pelvic abscess. Explorative celiotomy revealed a diffuse severe fecaloid peritonitis that originated from a 3-cm wide rectal perforation. A Hartmann operation was then performed. Histopathological findings were

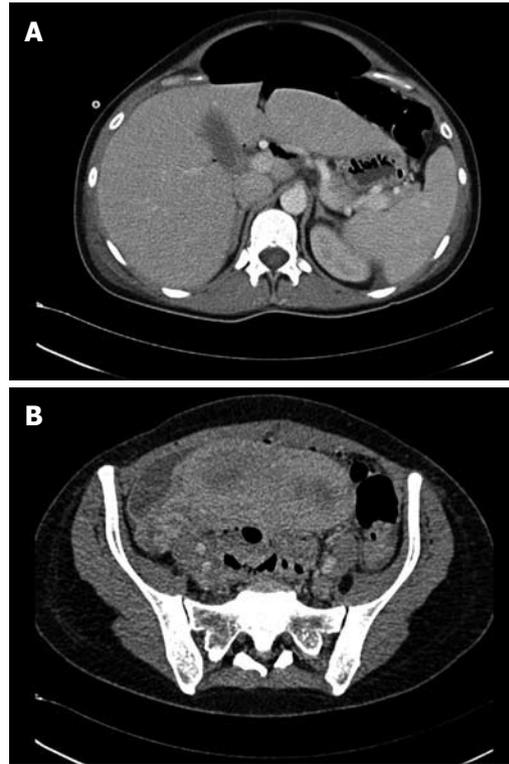

### INTRODUCTION

Endometriosis is defined by the presence of endometrium outside the uterus and usually affects pelvic structures including the bowel. Intestinal involvement occurs in 3%-37% of patients with endometriosis<sup>[1]</sup>. Intestinal endometriosis typically takes the form of asymptomatic serosal implants that occasionally result in intestinal obstruction with recurrent abdominal pain<sup>[2]</sup>. Transmural involvement is not as common, and spontaneous perforation of intestinal endometriosis is a rare complication that generally occurs in pregnancy<sup>[2-4]</sup>.

We report the case of a pregnant woman with spontaneous rectal perforation that originated from a decidualized endometriotic nodule, and we review all cases of intestinal perforation from endometriosis reported in the literature. To the best of our knowledge, this is the first report of spontaneous perforation of the rectal wall in an endometriotic area in pregnancy, which is an extremely rare cause of acute abdomen.

## CASE REPORT

In October 2008, a 37-year-old Caucasian woman was admitted to our hospital because of colicky pain in the right iliac fossa at 30 wk of pregnancy. She had a previous history of endometriosis that was surgically treated. In 2003, she underwent a laparotomy excision of an endometrioma of the left ovary. Later, she was submitted to three subsequent laparoscopies in which left salpingectomy for a sactosalpinx, diathermocoagulation of multiple endometriotic foci, excision of the posterior vaginal fornix, and adhesiolysis mainly between the uterus and sigmoid colon were performed. In 2007, the final laparoscopy showed no endometriosis in the Douglas cul-de-sac. At admission to our hospital, abdominal ultrasound revealed pelvicalyceal dilation on the right side, which improved after double J stent placement. However, symptoms suggestive of pyelonephritis persisted until 33 wk of gestation when delivery of a 1600 g premature male baby was performed through a cesarean section, because of the mother's worsening clinical condition that was caused by developing sepsis that was apparently related to pyelonephritis. Indeed, the clinical diagnosis of pyelonephritis was also supported by detection of pathological levels of *Escherichia coli* in the urine. However, during cesarean section, at the moment of peritoneal incision, a fecaloid smell came from the peritoneal cavity, but unfortunately, this finding was not correctly understood. On postoperative day 2, the patient was pyrexial (40°C), pale and shocked. Blood pressure and pulse rate were 90/50 mmHg and 95 beats/min, respectively. The abdomen was distended, with tenderness and rebound in the lower quadrants, where bowel sounds were absent. Laboratory data were as follows: white blood cell count,  $204 \times 10^9/L$ ; red blood cell count,  $370 \times 10^{12}/L$ ; hemoglobin, 10 g/L; thrombocyte count  $461 \times 10^9/L$ ; fibrinogen, 6.54 g/L. Chest X-ray revealed bilateral pleural effusion, while abdominal plain radiography showed free air in the peritoneal cavity. Enhanced abdominal computed tomography (CT) confirmed these findings (Figure 1A), as well as a low-density area with the features of a pelvic abscess on the right side of the enlarged uterus (Figure 1B). The patient underwent an emergency operation for a presumptive diagnosis of acute diffuse peritonitis. Explorative celiotomy revealed diffuse, severe fecaloid peritonitis that originated from a 3-cm wide rectal perforation in the deep cul-de-sac. Diffuse peritonitis was in an advanced stage and lasted for > 48 h. In addition, the sigmoid colon was adher-

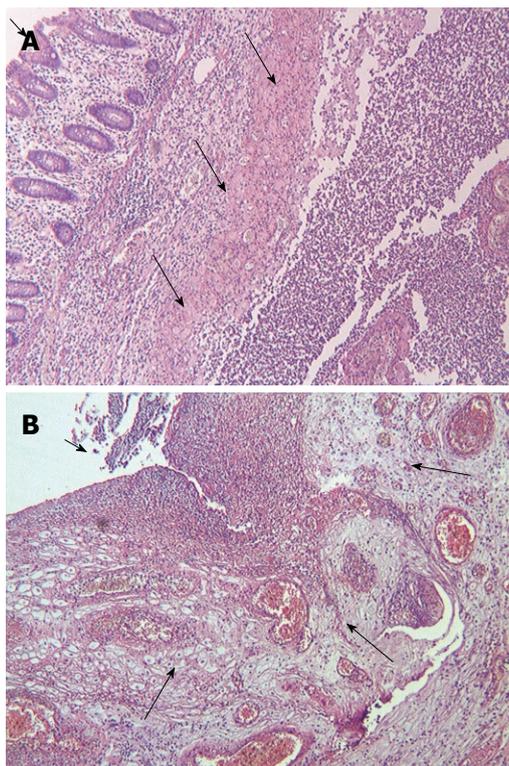

**Figure 1** Axial computed tomography (CT) scan. A: Free air in the abdominal cavity; B: Pelvic abscess at the right side of the enlarged uterus.

ent to the uterus. A Hartmann operation was necessary with end colostomy using the descending colon and closure of the rectal stump, and appendectomy was performed. Bilateral pleural effusion persisted for 14 d after the operation and the patient was finally discharged on postoperative day 19 as a consequence of abdominal wound infection. On gross examination, rectal perforation seemed to originate from an endometriotic nodule. Histopathological findings were consistent with decidualization of the rectal wall (Figure 2A) and vermiform appendix. Decidualized endometriosis was mainly found around the rectal perforation, which was the most likely explanation for this occurrence (Figure 2B). Nursery care was needed for 35 d until the infant reached a stable body weight and was able to feed by mouth. Afterwards, the patient was referred to the gynecologist for further therapy and she was readmitted 3 mo later for Hartmann reversal without any sequelae.

## DISCUSSION

Intestinal endometriosis may affect the ileum, appendix, sigmoid colon and rectum<sup>[4]</sup>. The most common non-genital manifestation is in the rectosigmoid<sup>[3,5]</sup>. The peritoneal implantation of endometrium by retrograde menstruation or the possible metaplasia of peritoneal cells are still the two most accepted etiological theories of endometriosis<sup>[1]</sup>.

Intestinal endometriosis may be found in every layer of the bowel wall but it is most commonly found within the

**Figure 2** The rectal wall. A: Decidualization of the rectal wall (long arrows); mucosa side of the rectal wall (short arrow) (HE, × 40); B: Decidualized endometriosis around the rectal perforation (long arrows); rectal perforation with necrosis at the peritoneal side of the rectal wall (short arrow) (HE, × 100).

subserosa as superficial serosal implants<sup>[2,6]</sup>. Under cyclical hormonal influences, these implants may proliferate and infiltrate the intestinal wall and cause a fibrotic reaction with formation of strictures and adhesions, which may lead to bowel obstruction and recurrent abdominal pain<sup>[4,7]</sup>. On the other hand, transmural bowel wall involvement is not so common and the intestinal mucosa usually remains intact, and perforation of the affected intestinal tract is a very rare complication<sup>[3,6]</sup>. Up till now and including the present report, only 21 cases of intestinal perforation from endometriosis have been reported and among these, nine cases (42.8%) occurred in pregnancy. Sigmoid colon turned out to be the most common site of perforation from endometriosis and accounted for 12 of 21 published cases. The current case is the first report of spontaneous perforation of the rectum (Table 1).

In those patients with perforation, the entire intestinal wall is replaced by endometriotic tissue. In pregnancy, under the effect of progesterone, the area of ectopic endometrium becomes decidualized with a progressive reduction in size<sup>[8,9]</sup>. In our patient, decidualized endometriosis was found mainly around the rectal perforation. Actually, the reduction in size of a transmural endometriotic nodule may lead to perforation, by weakening of the intestinal wall<sup>[2]</sup>, particularly in the third trimester, which is the time of perforation in most reported cases<sup>[2,8]</sup>, as in our patient who had rectal perforation at 33 wk of pregnancy. Moreover, decidualization causes a severe inflammatory response with an increased number of natural killer cells

and decidual changes, which are responsible for a higher risk of perforation<sup>[9,10]</sup>. In our case, we believe that perforation was also facilitated by the progressive traction of the enlarged uterus on the strictly adherent sigmoid colon, and consequently, on the decidualized and weakened area of the anterior rectal wall. Moreover, the absence of endometriotic foci in the cul-de-sac at final laparoscopy made rectal perforation unpredictable.

Although endometriosis improves during pregnancy, the current report shows the potential occurrence of serious and unexpected complications of the disease. Both the rareness of the perforation and the symptoms that are suggestive of pyelonephritis or diverticulitis may be misleading and delay the diagnosis. Indeed, the appropriate management of these patients may be challenging and a good outcome is absolutely dependent on a multidisciplinary approach.

### Abstract

Germ cell tumor (GCT) of the liver is extremely rare. Here, we describe a case of hepatic mixed GCT with significant sarcomatous components and elevated serum  $\alpha$ -fetoprotein (AFP) in a 34-year-old man. Histopathologically, the tumor was composed of two GCTs components: yolk sac tumor and immature teratoma. The predominant components of immature teratoma consisted of several types of tissue that represented different germinal layers (endoderm, mesoderm and ectoderm) and showed varying degrees of differentiation with significant sarcomatous components. The yolk sac component showed positivity for AFP and cytokeratin (AE1/AE3). The immature teratoma components showed positivity for varying differentiation markers. Interphase cytogenetic analysis revealed that the yolk sac tumor and immature teratoma were positive for i(12p) and 12p over-representation. In particular, the rhabdomyoblastic components also showed typical i(12p) and 12p overrepresentation. This suggested that sarcomatous components may be associated with dedifferentiation or malignant transformation of certain mesenchymal components within teratoma.

### INTRODUCTION

Germ cell tumors (GCTs) are a diverse family of neoplasms, and they are all presumed to arise from totipotent primordial germ cells<sup>[1]</sup>. This family of neoplasms includes tumors that arise from different anatomic sites, in different age groups, and that vary in clinical behavior. Most GCTs are gonadal in origin, others are extragonadal, which are located mainly along the midline of the body. GCT of the liver is extremely rare, and accounts for < 1% of all liver neoplasms<sup>[2]</sup>. Most of them are in children aged < 3 years old, and about half of these tumors are malignant. Approximately 20 cases of malignant GCTs have been reported in the English literature following presentation as teratoma<sup>[3-5]</sup>, choriocarcinoma<sup>[6,7]</sup> or yolk sac tumor<sup>[8,9]</sup> in patients over 21 years of age. The presence of sarcomatous components in gonadal or extragonadal GCTs is also an infrequent phenomenon<sup>[10]</sup>.

Here, we report the light microscopic and cytogenetic findings of a case of hepatic malignant mixed GCT with significant sarcomatous components in a 34-year-old Chinese man.

### CASE REPORT

A 34-year-old man presented with right upper quadrant

**Figure 1** Histological features of mixed GCT of the liver with sarcomatous components. A: Papillary structures resemble yolk sac tumor with Schiller-Duval bodies; B: Rhabdomyoblastic cells in primitive mesenchymal cell components; C: Intestinal-type epithelium embedded in neuroblastoma tissue; D: Acinar structures resembling pancreatic acinar tissue; E: Keratinizing epithelium embedded in primitive mesenchymal tissue; F: Neuroblastoma tissue with rosettes formation [Hematoxylin and eosin (HE) stain; A,  $\times 200$ ; B-F,  $\times 400$ ].

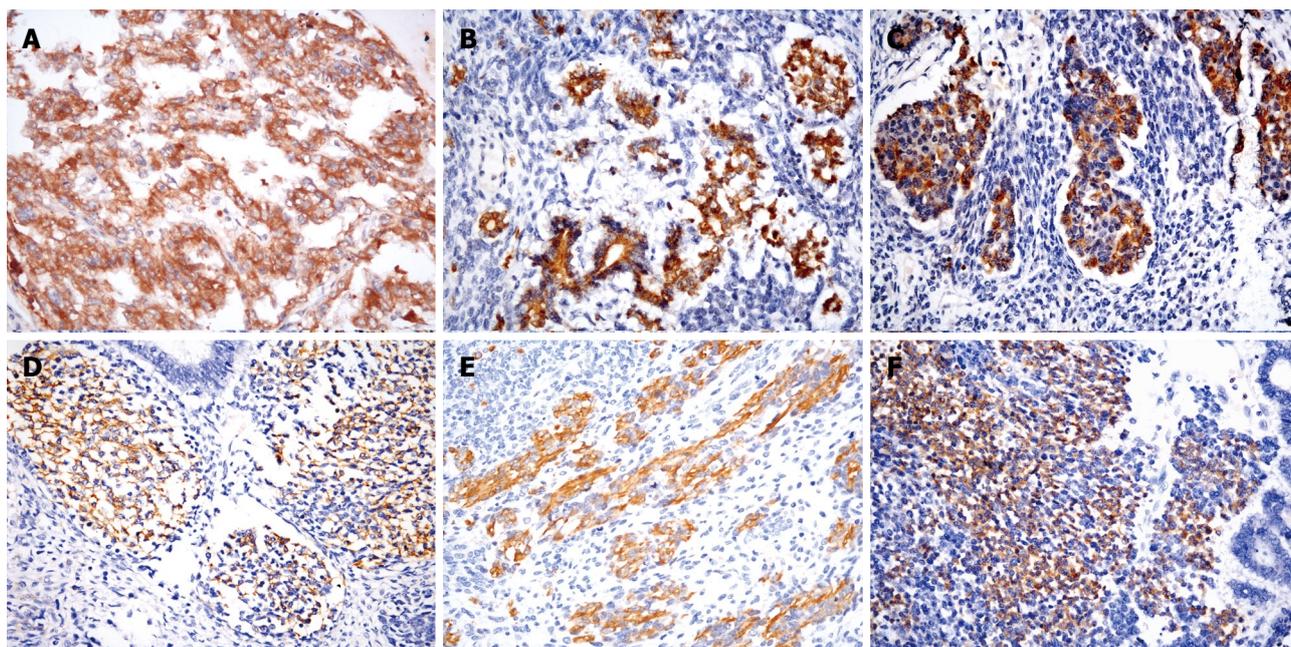

pain in 2006. Ultrasound, magnetic resonance imaging and computed tomography showed a 15 cm  $\times$  12 cm  $\times$  9 cm low density heterogeneous mass in the right liver lobe. Blood tests showed slightly elevated aspartate aminotransferase,  $\gamma$ -glutamyl transferase, alkaline phosphatase and a very high  $\alpha$ -fetoprotein (AFP: 56 500  $\mu$ g/L, normal level  $< 20$   $\mu$ g/L). Other biochemical parameters (renal and liver function) and tumor markers such as carbohydrate antigen 19-9, and carcinoembryonic antigen (CEA) were within normal limits. Results of serology testing showed that serum hepatitis B virus surface antigen and anti-hepatitis C virus antibody were negative. The patient had not received any treatment before operation. No other tumor site was detected by extensive preoperative staging. After the liver tumor was resected, the serum AFP level went down to 512  $\mu$ g/L.

Macroscopically, the partial liver resection specimen from the right lobe contained a single, firm mass with partially necrotic areas. It measured 16 cm  $\times$  12 cm  $\times$  8 cm. The cut surface was reddish-purple, whitish, gray to tan, slightly lobular with fibrous septa, and showed cystic spaces and areas of hemorrhage.

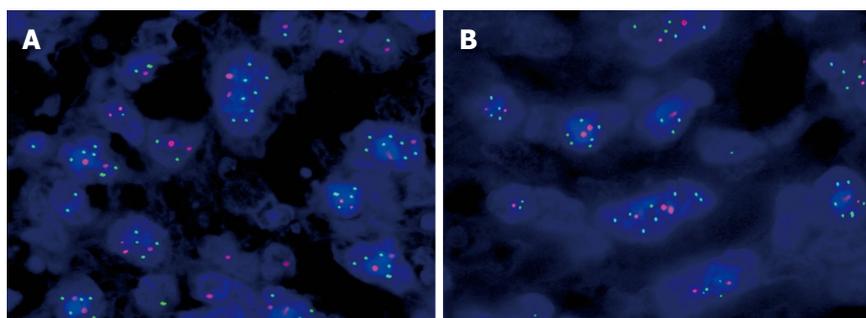

Histologically, the resected tumor was composed of two GCTs components: yolk sac tumor and immature teratoma. The morphological appearance of yolk sac tumor included endodermal sinus-like (with Schiller-Duval bodies), papillary and glandular components (Figure 1A). The predominant components of immature teratoma were composed of several types of tissue that represented different germinal layers (endoderm, mesoderm and ectoderm) and showed varying degrees of differentiation. The endoderm components were primitive mesenchyme

and various mesenchyme-derived tissues, which were composed predominantly of primitive to spindle cells with rhabdomyoblastic (Figure 1B), chondroid and osteoblastic differentiation. The mesoderm components were composed of respiratory, intestinal-type epithelium (Figure 1C), and glandular, ductal or acinar structures that resembled pancreatic acinar tissue (Figure 1D). The ectoderm components were composed of keratinizing or non-keratinizing epithelium (Figure 1E), which resembled neuroblastoma tissue that exhibited rosettes formation (Figure 1F), ganglion differentiation or embryonic neural tube. Mitotic figures were found frequently in various tumorous components. Areas of necrosis were also present. Hepatocellular differentiation was not found in the tumor. Uninvolved liver demonstrated no obvious cirrhosis but slight steatosis. The surgical resection margins were clear.

Immunohistochemically, the yolk sac tumor stained positively for AFP (Figure 2A) and cytokeratin (AE1/AE3). The cells of immature glandular or ductal structures were positive for pCEA, mCEA, AE1/AE3, CK7, CK18 and CK19. Focal hepatocyte marker (HepPar1) protein reaction was seen in the glandular epithelium. The acinar structures that resembled pancreatic acinar cells were positive for AFP (Figure 2B),  $\alpha$ -1-antitrypsin,  $\alpha$ -chymotrypsin (Figure 2C) and AE1/AE3. The primitive mesenchymal spindle cells were stained prominently with vimentin, and focally stained with smooth muscle actin, CD56 (Figure 2D), CD117 and CD34. Desmin and myoglobin were positive in the immature skeletal muscle tissue (Figure 2E). The cells of immature chondroid and osteoblastic components were positive for both vimentin and S-100 protein. The neuroblastoma-like areas and

**Figure 2 Immunohistochemical features of mixed GCT of the liver with sarcomatous components.** A: Strong staining for AFP in the yolk sac tumor component; B: Strong staining for AFP in acinar structures resembling pancreatic acinar tissue; C: Strong staining for α-chymotrypsin in acinar structures resembling pancreatic acinar tissue; D: CD56 positivity in primitive mesenchymal cells; E: Strong staining for desmin in rhabdomyoblastic cells in primitive mesenchymal cell components; F: Strong staining for synaptophysin in neuroblastoma tissue (EnVision Plus stain; A-F, × 400).

**Figure 3 Tumor cells possess isochromosome 12p and 12p overrepresentation, which are characteristic of tumors of germ cell origin.** FISH showing cells with 2-7 (green) 12p signals and 1-4 (orange) 12 centromere signals in yolk sac tumor (A), and rhabdomyoblastic cells (B). (green = 12p probe; orange = 12 centromere probe; magnification × 1000).

ganglion cells were positive for vimentin, synaptophysin (Figure 2F), neuron-specific enolase (NSE), glial fibrillary acid protein (GFAP), and focally stained with HMB45, CD99 and CD117. The immature glandular structures and neuroblastoma-like areas showed a high proliferative activity of Ki-67 positivity, whereas proliferative activity in the spindle cell areas was lower. P53 showed strong nuclear expression in all epithelial and rhabdomyoblastic cells. All tumor cells stained negatively for CD30, human chorionic gonadotropin or placental alkaline phosphatase (PLAP). The immunohistochemical profile of tumor in the differential diagnosis of GCT of the liver is shown in Table 1.

Interphase cytogenetic analysis using fluorescence *in situ* hybridization (FISH) revealed that the yolk sac tumor and immature teratoma components were positive for i(12p) and 12p overrepresentation (Figure 3A). In particular, the rhabdomyoblastic cell components also showed typical i(12p) and 12p overrepresentation (Figure 3B). The FISH ratios ranged from 1.21 to 3.30 in various tumor components (mean:  $2.1 \pm 0.8$ ).

Based on the clinical features, histological findings,

immunohistochemical stains and cytogenetic studies, the pathological diagnosis of hepatic mixed tumor with significant sarcomatous components was made. Gonads and retroperitoneal lymph nodes were examined, and did not reveal any abnormality. This patient was cured with a standard protocol of cisplatin, etoposide and bleomycin. Five months after surgery, the patient died of hepatic failure with tumor recurrence and thrombosis of the intrahepatic veins, which indicates that this tumor had the low chemosensitivity. Permission for an autopsy was not granted.

## DISCUSSION

GCTs are a diverse family of neoplasms, and they are gonadal and extragonadal in origin<sup>[1]</sup>. Mixed GCTs include mature/immature teratoma, and one or more malignant germ cell components. Sarcomatous differentiation has been observed previously in primary and metastatic GCTs<sup>[10,11]</sup>. We describe a hepatic mixed GCT with significant sarcomatous components and elevated serum AFP in an adult man. The tumor was composed of two GCT components: yolk sac tumor and immature

teratoma. The components of immature teratoma included epithelial (keratinizing or non-keratinizing, glandular, ductal or acinar), mesenchymal (rhabdomyoblastic, chondroid and osteoblastic differentiation) and neuroectodermal (neuroblastoma exhibiting rosettes formation, and ganglia) differentiation structures. GCTs in the liver may be primary or metastatic, therefore, it is important to exclude a gonadal tumor before making a diagnosis of malignant GCT. The present case was without any history of pretreatment, because no other tumor site was detected by extensive preoperative staging. This suggested that the tumor was primary to the liver. Therefore, malignant mixed GCT with significant sarcomatous components arising in the liver was diagnosed, based on the clinical features, histological findings, immunohistochemical stains and cytogenetic studies. To the best of our knowledge, this is the first report of hepatic malignant mixed GCT with significant sarcomatous components in adults.

Sarcomatous components are more common in mediastinal GCTs than those of other locations<sup>[10,11]</sup>. Although the pathogenesis of the development of sarcomatous components in GCTs has not been fully elucidated, it has

been proposed to include a dedifferentiation phenomenon; malignant transformation of certain mesenchymal components within teratomas; origin from primitive germ cells; and transformation of the blastematous stroma in yolk sac tumor<sup>[10,11]</sup>. In the present case, the rhabdomyoblastic cell components also showed typical i(12p) and 12p overrepresentation, which supports the origin of the sarcomatous components from malignant transformation of mesenchymal components within the teratoma, and GCTs have the potential to develop almost any type of sarcoma<sup>[10,11]</sup>.

Another interesting finding is the presence of focal pancreatic acinar differentiation, with positive staining for AFP,  $\alpha$ -1-antitrypsin, and chymotrypsin. AFP production is normally a feature of yolk sac, embryonal liver, and embryonal gastrointestinal tract, and it is recapitulated in neoplasms of these structures. Such a phenomenon has been described under the term hepatoid carcinoma in tumors at numerous sites<sup>[12]</sup>. The production of AFP by pancreatic acinar neoplasms is well recognized, and Cingolani *et al*<sup>[12]</sup> have reported a case of such a tumor arising in a mediastinal teratoma, similar to our case but lacking the sarcomatoid components. Therefore, our case

supports the hypothesis that AFP production in pancreatic neoplasms is related to acinar cell differentiation.

In the differential diagnosis, the tumor has to be compared with several entities, including carcinosarcoma, hepatocellular carcinoma or cholangiocarcinoma with sarcomatoid dedifferentiation, yolk sac tumor, mixed hepatoblastoma with teratoid features, lymphoma, and melanoma. The latter two are excluded by negativity of the tumor markers<sup>[13,14]</sup>. Carcinosarcoma of the liver is a malignant tumor that contains an intimate mixture of carcinomatous (either hepatocellular or cholangiocellular) and differentiated sarcomatous elements (such as osteosarcoma, angiosarcoma, rhabdomyosarcoma or malignant schwannoma). Unlike GCT, true carcinosarcoma consists of only a single malignant epithelial component and a single malignant mesenchymal component. They must be distinguished from sarcomatoid carcinoma or spindle-cell carcinoma, morphological variants of hepatocellular carcinoma and/or cholangiocarcinoma. The sarcomatoid part that consists of spindle cells is epithelial marker positive. HepPar1 and pCEA are useful markers for hepatocytes<sup>[15]</sup>. A true immature teratoma does not contain fetal and embryonal hepatoblastoma areas.

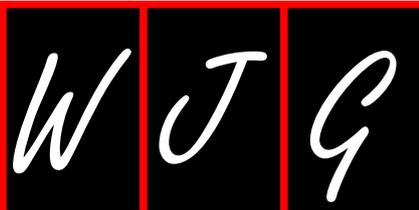

The role of chemotherapy remains speculative. Although the prognosis of GCTs depends on the site and clinical stage, the emergence of sarcomatous components in a GCT portends a worse prognosis, and appears to be highly resistant to the standard combination chemotherapy commonly employed for the treatment of GCT. However, numerous authors have administered chemotherapy to GCTs with sarcomatous differentiation, and some have achieved complete remission<sup>[10,11]</sup>. Our case was also treated with adjuvant chemotherapy after complete surgical excision according to sarcoma protocols, but the effectiveness did not appear to be obvious. Therefore, the role of chemotherapy needs to be clarified in this extremely rare tumor. Addition of sarcoma specific treatment modalities should be explored in such patients to increase the chances for survival.

In summary, primary mixed malignant GCT with sarcomatous components in the liver is extremely rare. The presence of sarcomatous components in GCT is a factor that portends a more aggressive behavior, and appears to be highly resistant to standard chemotherapy. As a result of the extreme rarity of this disease, it appears very important to add additional cases of this pathology to the literature. Further studies are needed to identify prognostic factors, and the role of chemotherapy in the management of GCT.

### Abstract

Wotton and Akoh in their previously reported case in this journal postulate that Permacol rejected. This letter provides a detailed critique of that claim and provides an alternative explanation for the histological data provided by the authors. It is also argued that Wotton and Akoh have misrepresented one of the papers in the discussion in their article and a clarification of that referenced paper is given.

Smart NJ. No evidence of Permacol rejection presented by Wotton and Akoh. *World J Gastroenterol* 2010; 16(5): 657-658 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i5/657.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i5.657>

### TO THE EDITOR

Wotton and Akoh<sup>[1]</sup> have misrepresented one of the cases published in a case series I co-authored<sup>[2]</sup> on the use of Permacol in abdominal wall closure in paediatric renal transplantation in a specious attempt to justify their conclusions.

It is true that one out of five children did suffer a dehiscence of their abdominal wound following the use of Permacol to close the abdominal wall in size mismatched renal transplants. In the particular case discussed, the 9-year-old male had steroid refractory nephrotic syndrome and underwent a bilateral nephrectomy for persistently low albumin levels. That the wound did not heal was much more likely due to chronic steroid use and hypoalbuminaemia than any reaction to the Permacol. It is misleading to use this case as supporting evidence for Wotton and Akoh's claims that Permacol may induce foreign body reaction or rejection.

I see no reliable evidence presented in this case report that Permacol was "rejected". Firstly, we are not told which suture material was used to suture the Permacol in place, but we are informed that the "histology revealed features of acute and chronic inflammation superficially and granulomatous inflammation in the deep layer consistent with a "stitch granuloma". Is it not possible that this "stitch granuloma" could well have been due to the suture material itself rather than Permacol? Secondly, the use of the term "rejection" implies a specific immunopathological entity. "Features of acute and chronic inflammation" is so non-specific that it could be due to any number of factors, but I hypothesize that it was most likely due to the contaminated field. No detailed pathological or immunological evidence (such as characterisation of lymphocytes present, immunofluorescence, immunostaining or electron microscopy) is presented to substantiate the claim of rejection of the Permacol. Since this is alleged to be the first report on rejection of Permacol in humans, the evidence needs to be

more substantial than that presented before the claim can be given credence.

 AIDS

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board

members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on the substantial advance and its importance in the fast-developing areas; (2) Frontier: To review the most representative achievements and comment on the current research status in the important fields, and propose directions for the future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide Guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To systematically review the most representative progress and unsolved problems in the major scientific disciplines, comment on the current research status, and make suggestions on the future work; (8) Original Article: To originally report the innovative and valuable findings in gastroenterology and hepatology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce Consensus and Guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

## Instructions to authors

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/1007-9327/Instructions-toAuthprs.asp>) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com), or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

## MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

### Title page

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. [montgomery.bissell@ucsf.edu](mailto:montgomery.bissell@ucsf.edu)

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

### Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g.  $6.92 \pm 3.86$  vs  $3.61 \pm 1.67$ ,  $P < 0.001$ ; CONCLUSION (no more than 26 words). Available from: <http://www.wjgnet.com/wjg/help/8.doc>; Writing requirements of abstract at: <http://www.wjgnet.com/1007-9327/links/Abstract.doc>.

### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the

main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: <http://www.wjgnet.com/wjg/help/instructions.jsp>.

### Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A...; B...; C...; D...; E...; F...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P* < 0.05 and <sup>d</sup>*P* < 0.01 are used. A third series of *P* values can be expressed as <sup>e</sup>*P* < 0.05 and <sup>f</sup>*P* < 0.01. Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>". If references are cited directly in the text, they should be put together within the text, for example, "From references<sup>[19,22-24]</sup>, we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### Electronic journal (list all authors)

- 15 Morse SS. Factors in the emergence of infectious diseases. *Emerg Infect Dis* serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

### Patent (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

### Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4  $\pm$  2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub>, not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum can be found at: <http://www.wjgnet.com/wjg/help/15.doc>.

### Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used

abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

### Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr-A*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E coli*, etc.

## RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

### Editorial Office

#### World Journal of Gastroenterology

Editorial Department: Room 903, Building D,

Ocean International Center,

No. 62 Dongsihuan Zhonglu,

Chaoyang District, Beijing 100025, China

E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)

<http://www.wjgnet.com>

Telephone: +86-10-5908-0039

Fax: +86-10-85381893

### Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

### Copyright assignment form

Please download a Copyright assignment form from <http://www.wjgnet.com/1007-9327/news/10.doc>.

### Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: <http://www.wjgnet.com/1007-9327/news/12.doc>.

### Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

### Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

### Publication fee

Authors of accepted articles must pay a publication fee.

EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

ISSN 1007-9327  
CN 14-1219/R

**AIM AND SCOPE**

*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1096 experts in gastroenterology and hepatology from 60 countries.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

### Abstract

Constipation is a significant manifestation of a number of psychological disorders. Published papers recommend using self-assessment questionnaires for discriminating psychological from non-psychological constipated patients before operating on them but reports from major surveys revealed that general practitioners failed to diagnose 70% of depressed patients using self-assessment questionnaires. Lower circulating concentrations of progesterone, 17-hydroxyprogesterone, cortisol, testosterone, androstenedione, and dehydroepiandrosterone sulfate (DHEAS) during the follicular phase in constipated young women compared with respective controls were found during the follicular phase of the menstrual cycles. During the luteal phase of the cycle, reductions were identified in estradiol, cortisol and testosterone in the constipated group. Likewise, circulating concentrations of DHEAS were found to be lower in depressed patients than comparable healthy controls. DHEAS/cortisol ratios in morning serum and salivary samples were lower than those retrieved during other times of the day in depressed patients. The idea of recognizing major depression in constipated patients by measuring DHEAS/cortisol ratios in saliva and serum may be plausible but this possibility needs to be confirmed in well-designed studies.

El-Tawil AM. Is the DHEAS/cortisol ratio a potential filter for non-operable constipated cases? *World J Gastroenterol* 2010; 16(6): 659-662 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v16/i6/659.htm> DOI: <http://dx.doi.org/10.3748/wjg.v16.i6.659>

### INTRODUCTION

Constipation is a prominent feature amongst patients with depression<sup>[1-5]</sup>, anorexia nervosa, weight loss, sleep disorders<sup>[6]</sup>, fatigue, and decreased sexual interest, particularly with menarche or after a stressful emotional experience<sup>[7,8]</sup> or surgical operation<sup>[9,10]</sup>.

The outcome of treatment in patients with chronic constipation is unpredictable. This may be a consequence of the lack of effectiveness of such treatment or may reflect heterogeneity within patient subgroups.

### IDIOPATHIC CHRONIC CONSTIPATION AND PSYCHOLOGICAL VARIABLES

A positive link was identified by Martelli *et al*<sup>[11]</sup> between various psychiatric variables and both outlet obstruction and colonic inertia. These results were further confirmed

by others<sup>[12]</sup>. Fisher *et al*<sup>[13]</sup> conducted a survey in 50 patients, 21 of whom complained of chronic severe constipation, 29 had fecal incontinence, and none were receiving psychiatric therapy or had a history of a relevant medical condition or drug therapy that could lead to the development of any of these ailments. The participants were asked to complete the Hospital Anxiety & Depression Scale (HAD) questionnaire and the General Health Questionnaire (GHQ) before and after surgery to assess the surgical outcome. Constipated patients had significantly higher HAD depression scores in comparison with respective controls. Constipated patients who had improvement after surgery had significantly lower pre-operative HAD scores compared with those who had no improvement. Using the same parameters, incontinent patients did not differ from respective controls, but those who had bad results after surgery had significantly higher HAD scores than those who benefited from surgery.

Later on, a similar study was conducted where Ghosh *et al*<sup>[14]</sup> reported the HAD scores determined from a physician-administered questionnaire in patients with chronic constipation, ulcerative colitis, and cancer of the colon, and found a link between the score and the examined clinical symptoms, such as abdominal pain, straining at stool and urgency. The HAD scores were higher in the constipated group in comparison with others, and were significantly higher in those who complained of straining at stool.

However, use of a self-assessment questionnaire as a parameter in patients suffering from chronic disease could not be relied on without other evidence<sup>[15]</sup>. Published reports revealed that general practitioners could not diagnose a significant percentage of psychological cases using self-assessment questionnaires in patients with chronic diseases<sup>[16,17]</sup>.

## PHYSIOLOGY OF STEROIDS HORMONES AND MENSTRUAL CYCLE

Adrenal androgens represent an important component (> 50%) of the circulating androgens in menstruating females<sup>[18-25]</sup>. In males, the adrenal contribution is much less because of the testicular production of androgens. Adrenal secretion of androgens in men is about the same as in women during the follicular phase.

The adult adrenal gland secretes dehydroepiandrosterone (DHEA) at approximately 4 mg/d, DHEA sulfate (DHEAS) at 7-15 mg/d, and androstenedione at 1.5 mg/d<sup>[26]</sup>.

## RELATIONSHIPS BETWEEN STEROID HORMONES AND BRAIN FUNCTIONS

The relationships between steroid hormones and brain functions have mostly been considered within the framework of endocrine mechanisms as genomic responses, elicited by secretory products from steroidogenic endocrine glands, transported through the

bloodstream, and exerting actions on the brain. Ever since the biosynthesis of steroid hormones in the brain<sup>[27]</sup> and their rapid non-genomic actions<sup>[28,29]</sup> were first reported, specific targets for so-called “neurosteroids” in plasma membranes have been postulated.

DHEA and its metabolites, DHEAS and androsterone, have been identified recently as having neurosteroid activity.

DHEAS modulates the actions of the gamma-aminobutyric acid type A (GABAA) receptor, the N-methyl-D-aspartate receptor, and the sigma subtype 1 (σ1) receptor<sup>[27,30-35]</sup> among others<sup>[36-38]</sup>. DHEA and DHEAS generally act as noncompetitive antagonists of the GABAA receptor. GABAA receptor-mediated regulation of 5-hydroxytryptamine (5-HT) neuronal firing was found to be sensitive to negative modulation by DHEA and DHEAS, and to positive modulation by androsterone. GABAA receptor-mediated regulation of 5-HT firing may be responsible for some of the reported behavioral and psychological effects of endogenous and exogenous DHEA<sup>[39]</sup>. An assessment of depression ratings in relation to plasma concentrations of several steroid hormones (estradiol, testosterone, estrone, androstenedione, cortisol, DHEA, and DHEAS) in 699 postmenopausal women (aged 50-90 years) who were not taking the contraceptive pill<sup>[40]</sup> found that only DHEAS concentrations were negatively correlated with ratings of depressed mood. Explicitly, higher DHEAS concentrations were associated with less depression, and this association was independent of age, physical activity and weight change. Furthermore, women with categorical diagnoses of depression had significantly lower plasma DHEAS concentrations compared to age-matched non-depressed women<sup>[41]</sup>. Similarly, in a large-scale study of 2855 well-functioning elderly men and women, serum DHEAS concentrations were inversely correlated with depressive symptoms<sup>[42]</sup>. Women whose first onset of major or minor depression occurred during the peri-menopause showed low morning plasma DHEA and DHEAS concentrations<sup>[43]</sup>. Lower plasma DHEA concentrations during pregnancy and during the postpartum period were associated with higher postpartum ratings of depression<sup>[44]</sup>.

## PATHOPHYSIOLOGY OF STEROID HORMONES IN SEVERELY CONSTIPATED PATIENTS

Levels of progesterone, 17-hydroxyprogesterone, cortisol, testosterone, androstenedione, and DHEAS were found to be lower during the follicular phase of the menstrual cycle in patients diagnosed with idiopathic chronic constipation compared with respective healthy controls<sup>[44]</sup>.

A lack of estradiol, cortisol and testosterone was identified during the luteal phase of the cycle in the constipated group<sup>[45]</sup>. The high prevalence of idiopathic constipation in pre-menopausal women is likely a result of the high affinity of progesterone for progesterone receptors together with the non-specific affinity for adrenal androgen receptors, and the lack of a stimulatory effect of estrogen on the wall of the bowel<sup>[45]</sup>.

## MEASUREMENT OF DHEAS/CORTISOL RATIO AND PSYCHOLOGICAL VARIABLES

A deficiency of DHEAS is thus identified in depression and constipation and it would be impossible to rely on it for distinguishing depressed, severely constipated patients. However, estimates of DHEA-to-cortisol ratios in serum and saliva, are likely to be more reliable than concentrations of either hormone alone, with lower morning ratios seen in depression<sup>[46-48]</sup>. The molar DHEAS/cortisol ratio was significantly lower in non-medicated depressed patients than in controls, and the evening salivary DHEA/cortisol ratio was inversely correlated with the length of the current depressive episode<sup>[49]</sup>. Morning salivary DHEA hyposecretion as well as evening cortisol hypersecretion were significantly and independently associated with major depression in young patients<sup>[49]</sup>.

## IMPLICATIONS IN RESEARCH AND IN CLINICAL PRACTICE

This review hypothesizes that measurement of the DHEAS/cortisol ratio in constipated patients could filter out those patients with a psychological disorder and improve the outcome after surgery.

For assessing the credibility of this measurement, a well-designed study needs to be conducted. The recruited constipated patients should have no personal or family background of a major psychological disorder. Participants should be asked to complete a stool diary. In this diary, they would be asked to report on the frequency, shape, consistency of stool, and whether they strained at defecation or not. The starting day would be their first menstruating day of the nearest menstruation cycle and the end would be the commencement of the next one. They would comment on the day and timing of defecation, stool consistency, stool form and the presence or absence of straining at stool.

They would also be asked to give 3 blood samples and 3 samples of saliva in any day during the mid-follicular period (days 7-10). The first samples would be collected early in the morning, the second on the afternoon and the third would be collected early in the evening.

Similarly, the same process would be repeated in any day during the mid-luteal period (days 18-20) to measure the DHEAS/cortisol ratio in serum and in saliva. The whole process would be repeated over the second consecutive menstrual cycle to obtain an average of each measurement. On these 2 d, participants would also be asked to fill in the Hospital Anxiety & Depression Scale questionnaire and General Health Questionnaire.

During the mid luteal period, the value of the DHEAS/cortisol ratio is supposed to be higher than that during the mid-follicular period in purely constipated patients. Because of ovarian secretions during the luteal phase, the concentration of DHEAS would be nearly normal but that of cortisol would still be low. However,

in mixed cases, the ratio would be low, and in particular in the early morning samples.

## CONCLUSION

The use of self-assessment questionnaires for excluding a psychological disorder in severely constipated patients seems insufficient, but the idea of measuring serum and salivary DHEAS/cortisol ratios before embarking upon invasive treatments appears to be more specific. This conclusion warrants confirmation in well-designed studies.

### Abstract

The carcinogenic potential of iron in colorectal cancer (CRC) is not fully understood. Iron is able to undergo reduction and oxidation, making it important in many physiological processes. This inherent redox property of iron, however, also renders it toxic when it is present in excess. Iron-mediated generation of reactive oxygen species *via* the Fenton reaction, if uncontrolled, may lead to cell damage as a result of lipid peroxidation and oxidative DNA and protein damage. This may promote carcinogenesis through increased genomic instability, chromosomal rearrangements as well as mutations of proto-oncogenes and tumour suppressor genes. Carcinogenesis is also affected by inflammation which is exacerbated by iron. Population studies indicate an association between high dietary iron intake and CRC risk. In this editorial, we examine the link between

iron-induced oxidative stress and inflammation on the pathogenesis of CRC.

### INTRODUCTION

Colorectal cancer (CRC) is the second most common cancer in developed countries. Apart from genetic mutations, environmental factors appear to play a role in intestinal carcinogenesis. Results from numerous population studies support the idea that dietary iron and/or elevated iron levels increase the risk of cancers including CRC, hepatocellular carcinoma (HCC) and lung cancer<sup>[1-6]</sup>. HCC occurs at a higher incidence in hereditary haemochromatosis (HH) patients with hepatic iron overload than in the normal population<sup>[7]</sup> and recently, an increased risk for CRC and breast cancer development in patients with HH has also been demonstrated<sup>[8,9]</sup>. Further support for a role of iron in carcinogenesis comes from animal studies. Multiple injections of iron compounds, such as iron dextran complex, ferric nitriloacetate and ferric saccharate in rodents result in the formation of sarcomas, renal cell carcinoma and mesothelioma, respectively<sup>[10-12]</sup>. Iron has also been implicated in intestinal carcinogenesis in rodent models of CRC<sup>[13,14]</sup>.

Iron, whilst indispensable for life, can cause tissue injury through the formation of reactive oxygen species (ROS) and the high oxidative potential of iron and its

participation in oxidative stress-related carcinogenesis have been reviewed in detail elsewhere<sup>[15-17]</sup>. The excessive generation of oxidative stress can lead to carcinogenic events, and this has been the premise for the hypothesis that high iron levels may potentiate the risk of cancer. In addition, iron is a source of sustenance for cancer cell growth and proliferation. Cancer cell growth is enhanced by iron administration and has been shown to be retarded by both dietary iron deprivation<sup>[18]</sup> and treatment with iron chelators<sup>[19,21]</sup>. It is thought that genetic modifications and continual activation of the signalling pathways of cell proliferation by ROS synergistically promote carcinogenesis<sup>[16,22]</sup>. Chronic inflammation also induces cell oxidative stress, which promotes the onset of dysplasia<sup>[23]</sup> and is accompanied by a dysregulation in iron metabolism<sup>[24]</sup>. Nonetheless, the mechanistic link among iron, oxidative stress, inflammation and colorectal carcinogenesis remains to be elucidated.

## CRC

The incidence of CRC varies among countries and this has been mainly attributed to environmental factors, although genetic factors are also important. Environmental risk factors for colorectal carcinogenesis include many dietary factors such as high red meat and alcohol consumption as well as low fibre and vegetable intake<sup>[25,26]</sup>.

The majority of CRCs originate from pre-existing adenomatous polyps of the colonic mucosa<sup>[27]</sup>. These are defined as well demarcated masses of epithelial mucosa with increased crypt proliferation. Eventually, neoplastic cells migrate through the muscularis mucosa and it is once the basement membrane surrounding these cells is breached that the lesions are classified as malignant. These morphological and histopathological changes are accompanied by sequential dysregulation of key molecular pathways of cell division and tissue homeostasis<sup>[28]</sup>. Several syndromes have been described in families with a history of CRC, which involve mutations in components of these pathways<sup>[29]</sup>. Affected persons with familial adenomatous polyposis (FAP) develop hundreds of adenomatous polyps throughout their lifetime, some of which inevitably progress to malignancy. Genetic studies in subjects with FAP led to the discovery of the adenomatous polyposis coli (*APC*) gene, a key gene in the regulation of mucosal epithelial maturation *via* the Wnt signalling pathway<sup>[30,31]</sup>. In contrast, hereditary non-polyposis colorectal cancer (HNPCC) is characterised by an increased risk for developing CRC in the absence of a germ line mutation in the *APC* gene and is typically accompanied by the loss of DNA mismatch repair genes which impacts on other signalling pathways<sup>[32,33]</sup>. Although there is currently no evidence that iron plays a role in the pathology of these syndromes, it is interesting to note that iron can increase Wnt signalling in the absence of *APC*<sup>[34]</sup> and that mutations in the haemochromatosis gene (*HFE*) act as a genetic modifier of HNPCC disease expression<sup>[35]</sup>.

Although there is a strong role for genes in the pathogenesis of CRC in the above-mentioned risk groups,

environmental factors seem to play a more significant role. Population based studies have shown that in immigrant groups, the incidence of CRC changes towards that observed in the host country<sup>[36,37]</sup>. Another indication of the importance of environmental factors is that in Japan, a country with a traditionally low incidence of CRC, the rate has rapidly increased in recent years, a circumstance that has been primarily attributed to changes in life-style in the recent decades<sup>[29]</sup>. It is also interesting to note, that one of the highest incidences of CRC in the United States can be found in Japanese Hawaiians, highlighting the significance of environment *vs* genes<sup>[38]</sup>.

Of the environmental risk factors, the diet is of particular interest since it impacts on the composition of the intestinal luminal contents, which are in direct contact with the colonic mucosa. Diets between countries vary significantly in their iron content and iron-rich food components, suggesting that iron intake could be one of the factors influencing CRC incidence in different populations. Dietary iron as an environmental modifier of CRC has been examined in population-based studies and there is evidence that both dietary iron<sup>[4,5,39]</sup> and/or increased body iron stores<sup>[1,2,40]</sup> enhance the risk of CRC.

## IRON METABOLISM

Iron is a vital trace element participating in numerous biological and cellular processes such as electron transfer, oxygen transport and DNA synthesis as well as cell cycle progression and growth<sup>[41]</sup>. Iron absorption from the diet occurs mainly in the duodenum by a tightly regulated process. Most of the absorbed iron is utilized for erythropoiesis and any excessive iron is stored mainly in the liver<sup>[42]</sup>. Dietary iron occurs in two forms, haem iron from red meat and non-haem iron from plants and dairy products. Both forms of iron are taken up from the intestinal lumen into the enterocyte by different pathways. Haem iron is taken up as an intact metalloporphyrin by a haem transporter, the identity of which has yet to be confirmed. After entering the enterocyte, haem is broken down by haem oxygenase into free iron, biliverdin that is rapidly converted to bilirubin and carbon monoxide<sup>[43,44]</sup>. In contrast, non-haem ferric iron is reduced to ferrous iron by a ferrireductase and is then taken up by divalent metal transporter 1 at the apical surface of enterocytes. The iron from both sources enters a common intracellular iron pool and is stored as ferritin or transferred across the basolateral membrane of the enterocyte into the circulation by ferroportin. Upon release, iron is oxidised by hephaestin and binds to plasma transferrin. Transferrin-bound iron is taken up by cells *via* transferrin receptors. Iron absorption is inversely regulated by body iron levels, increasing during iron deficiency and decreasing in conditions of iron excess. Iron metabolism is regulated by the hepatic hormone, hepcidin, and its expression is controlled by many factors including iron stores, hypoxia, inflammation, anaemia and erythropoiesis<sup>[45,46]</sup>. The regulation of cellular iron metabolism has been extensively reviewed elsewhere<sup>[42,47-49]</sup>.

### Iron and CRC risk

The association between dietary iron and CRC risk has been examined in many population-based studies. A meta-analysis of studies investigating dietary iron intake, body iron stores and CRC demonstrated a positive correlation between iron in the diet and CRC risk<sup>[50]</sup>. Notably, two large prospective cohort studies have found that high iron intake and CRC risk were associated with other factors such as a high fat diet or bile acids<sup>[4,5]</sup> and at least three other case control studies have corroborated the positive correlation between dietary iron and CRC<sup>[39,51,52]</sup>. Of the studies analysing body iron stores and CRC, one large cohort study observed an association between transferrin saturation and CRC risk<sup>[2]</sup> whilst three case control studies found a positive correlation between serum ferritin levels and the formation of colorectal adenomatous polyps<sup>[1,40,53]</sup>. Other studies, however, reported inverse correlations between transferrin saturation<sup>[54]</sup> or ferritin levels<sup>[5]</sup> and CRC risk. The role of body iron stores in CRC appears more complex than that of dietary iron and the influence of genetic factors on body iron stores will be discussed in more detail below.

The effect of high red meat consumption, as a dietary source of iron, on the pathogenesis of CRC has been of considerable interest. Red meat is a major component of the human diet in some societies and contains a high amount of myoglobin and haemoglobin. Both contain haem, a porphyrin structure that contains a central iron atom and it has been suggested that the haem content in red meat promotes colorectal carcinogenesis<sup>[55,56]</sup>. A meta-analysis of 48 studies specifically addressing red meat consumption showed a significantly increased risk of developing CRC in people with a high intake of red meat as well as processed meat in most of the studies<sup>[57]</sup>. Of interest is a recent very large prospective cohort study investigating nutrition and disease that described an increased risk of CRC in people who consumed red meat rich in haem, whilst no increased risk was identified for poultry and an inverse correlation was observed for fish, both of which have a lower haem content<sup>[58]</sup>. Another two prospective cohort studies also reported that haem iron was associated with a higher risk of CRC especially in those who consumed alcohol<sup>[59]</sup> or those with a low intake of chlorophyll<sup>[26]</sup>. It is, however, unclear whether the effects of red meat on colorectal carcinogenesis are due to haem, the iron bound to haem, or a combination of both.

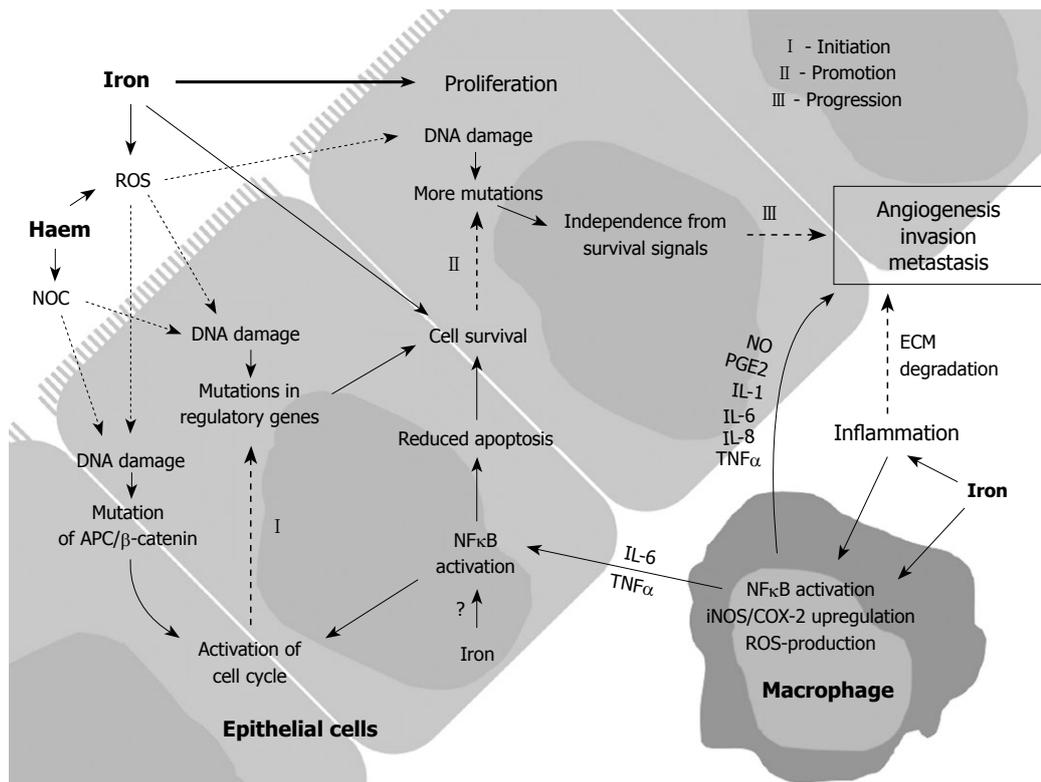

HH is a common disorder of iron metabolism that usually results from a homozygous C282Y mutation in the *HFE* gene. HFE protein is a key regulator of hepcidin, and in HH, the HFE-mediated regulation of hepcidin is impaired resulting in excessive absorption of iron and increased deposition of iron primarily in the liver<sup>[47,60]</sup>. As mentioned earlier, these individuals have an increased risk of developing CRC. This is exemplified by the recent findings that patients homozygous for the C282Y mutation have a 2.4-fold increased risk of developing CRC<sup>[9]</sup>. This is of particular significance considering that the C282Y mutation is one of the most abundant autosomal mutations in some Western

societies with homozygosity rates ranging from 1/102 in Northern Ireland to less than 1/100000 in Greece<sup>[61]</sup>. The homozygosity rate of 1/385 in the United States of America calculates as an estimated number of 718000 affected individuals with an increased risk of CRC<sup>[61]</sup>. Another study describing a 7.7-fold increased risk of developing CRC in patients with homozygous mutations in both *HFE* and *TFR1* genes, further implicates a dysregulation in iron metabolism as a possible mechanism contributing to colorectal carcinogenesis<sup>[62]</sup>. An increased risk for CRC has also been described for compound C282Y/H63D heterozygotes, single C282Y or H63D heterozygotes and H63D homozygotes<sup>[35,63-65]</sup>, but not all studies detected a significant correlation between *HFE* mutations and CRC<sup>[65-73]</sup>. Knekt *et al.*<sup>[2]</sup>, however, reported a 3-fold increased risk for CRC that was associated with a transferrin saturation level exceeding 60% in a large cohort from Finland, which may include subjects with mutations in the *HFE* gene. Furthermore, systemic iron reduction by phlebotomy decreases visceral malignancies and mortality in patients with peripheral arterial disease<sup>[74]</sup> and in blood donors the number of non-haematological malignancies is significantly reduced<sup>[75]</sup> indicating that reduction of iron levels might decrease CRC risk. The availability of mouse models of HH enables future studies to investigate the interaction of dietary iron, regulation of body iron stores and colorectal carcinogenesis.

### Role of luminal iron in colorectal carcinogenesis

There is evidence suggesting that significant iron absorption may occur in the colon<sup>[76,77]</sup>. Increased iron intake results in higher levels of iron in colonic epithelial cells in rats<sup>[78]</sup>, and although divalent metal transporter 1, ferroportin and hephaestin mRNA expression is highest in the duodenum and decreases along with the length of the small intestine<sup>[79]</sup>, their expression is still relatively high in the colon, especially hephaestin and ferroportin. These findings suggest that there may be significant colonic iron transport, which impacts on cell proliferation and cancer development. In a recent study, it was shown that there was increased iron staining in human colorectal tumours<sup>[80]</sup>. The expression of proteins involved in cellular iron uptake such as divalent metal transporter 1 and transferrin receptor 1 was also upregulated. The expression of the iron exporter, ferroportin, was increased but it was located intracellularly whilst hephaestin expression was decreased, suggesting decreased release of iron from the cells. These results suggest that the retention of iron by tumours may facilitate cell proliferation.

Further support for the concept of iron as a risk factor for CRC has been demonstrated in animal studies. Elevated dietary iron levels increased the incidence of tumours in rodent models of CRC induced by inflammatory or carcinogenic agents<sup>[13,14]</sup>. In these experiments, however, iron was supplemented with inorganic carbonyl iron, a form that does not constitute a major component of natural diets. Interestingly, in the inflammatory model, Seril and colleagues demonstrated that systemic iron supplementation did not increase tumour incidence. This

**Figure 1 Potential roles of iron in the development of colorectal cancer.** Luminal iron may cause DNA damage through the generation of reactive oxygen species (ROS) via the Fenton reaction. Haem may also stimulate the production of N-nitroso compounds (NOC) in the colon which are mutagenic. (I) In the initiation phase of tumorigenesis, DNA damage leads to mutations in key genes regulating cell proliferation and survival such as APC or β-catenin of the Wnt pathway; (II) In the promotion phase, the increase in cell proliferation and survival due to the deleterious effects of NOC and ROS leads to further genetic instability and an accumulation of more mutations. Iron is an important nutrient required for proliferation during this phase. Iron also increases intestinal inflammation and the pro-inflammatory cytokines, TNFα and IL-6 released from inflammatory cells increase cell survival through inhibition of apoptosis via the activation of NFκB; (III) In the progression phase, tumour cells gain independence from survival signals and progress towards a malignant phenotype. Iron has been shown to activate NFκB increasing inducible nitric oxide synthase (iNOS) and cyclo-oxygenase (COX)-2 expression in macrophages. Activated macrophages produce more ROS, increase infiltration through degradation of the extracellular matrix (ECM) and promote angiogenesis by release of nitric oxide (NO), prostaglandin E2 (PGE2), IL-1, -6 and -8 as well as TNFα, ultimately leading to tissue invasion and metastasis.

suggests that increased luminal iron but not systemic iron levels increase colorectal carcinogenesis in an inflammatory model of CRC<sup>[81]</sup>. In a carcinogen-induced CRC model, the number of preneoplastic lesions increased with the amount of haem in the diet<sup>[82]</sup>. Haem iron is more bioavailable than non-haem iron and has been shown to increase mucosal proliferation and cytotoxicity, indicating that haem may have a greater propensity for inducing malignancy compared with other forms of dietary iron<sup>[55,56]</sup>. Haem has been shown to stimulate the production of endogenous N-nitroso compounds in the large intestine after red meat ingestion, many of which are pro-carcinogenic<sup>[83]</sup>. The genotoxic effect of haem has also been demonstrated in human colonic cells, where DNA damage was induced by haemoglobin and haemin<sup>[84]</sup>. The exact mechanism by which luminal iron (haem and/or non-haem), iron transport, systemic iron levels and their regulation impact the pathogenesis of CRC, however, remains to be elucidated.

**Iron and molecular pathways of colorectal carcinogenesis**

Colorectal carcinogenesis is a multi-step process involving the formation of adenomatous polyps and their subsequent

progression to malignancy. At the molecular level, this process is reflected by sequential events of gene mutation and activation of key molecular pathways<sup>[85,86]</sup>. Some of these pathways may be altered by iron and iron-mediated generation of ROS (Figure 1). The APC gene was initially identified in patients with FAP and subsequently shown to be mutated in > 80% of human colorectal neoplasia<sup>[85]</sup>. APC mutations involved in carcinogenesis led to nuclear accumulation of β-catenin and constitutive activation of the wnt/β-catenin/T cell factor (TCF) signalling pathway. In rodent models of azoxymethane-induced CRC, the majority of colonic tumours harbour mutations in APC and/or β-catenin genes<sup>[87,88]</sup>. Activation of the wnt/β-catenin/TCF pathway results in increased expression of cyclin D1 and c-myc, both of which are positive regulators of cell proliferation<sup>[89,90]</sup>. Iron has been implicated in APC loss<sup>[34]</sup> and iron chelators decrease the expression of cyclin D1 and c-myc<sup>[41]</sup>.

The molecular pathogenesis of ulcerative colitis-associated colorectal carcinogenesis has been extensively studied<sup>[91]</sup>. Events such as chromosomal and microsatellite instability and alterations in tumour suppressor genes (p53 and APC mutations) and DNA mismatch repair genes have been documented<sup>[92,93]</sup>. The inhibitor of NFκB kinase

(IKK $\beta$ )/nuclear factor kappa B (NF $\kappa$ B) signalling pathway constitutes a key molecular link between inflammation and carcinogenesis. NF $\kappa$ B is activated in colorectal carcinogenesis and is influenced by both inflammation and oxidative stress<sup>[94]</sup>. NF $\kappa$ B targets the genes that control cell proliferation, apoptosis, angiogenesis and metastasis<sup>[94,95]</sup>. A direct stimulatory effect of iron on NF $\kappa$ B signalling has also been demonstrated in hepatic macrophages<sup>[96,97]</sup>.

Other pathways involved in colorectal carcinogenesis include cyclo-oxygenase (COX)-2 mediated prostaglandin E2 synthesis and inducible nitric oxide synthase (iNOS)-mediated generation of nitric oxide<sup>[98]</sup>. Prostaglandin E2 is involved in regulating angiogenesis and inhibiting apoptosis<sup>[99]</sup> whilst iNOS activity induces DNA damage and promotes microvascularisation<sup>[100]</sup>. Both COX-2 and iNOS are frequently over-expressed in human CRC<sup>[101,102]</sup> and inhibition of their activity has been shown to decrease tumorigenesis in rodent models of CRC<sup>[103,104]</sup>. Furthermore, iNOS is a target of the wnt/ $\beta$ -catenin/TCF pathway and its production of ROS through nitric oxide is catalysed by iron<sup>[105]</sup>.

## OXIDATIVE STRESS AND COLORECTAL CARCINOGENESIS

Oxidative stress occurs when the body or cell is unable to combat the deleterious effects of overproduction of oxidants or free radicals due to decreased anti-oxidant activity to counterbalance or eliminate them. Oxidative stress is related to many pathological conditions such as infection, inflammation, iron and other transition metal overload. It has also been implicated in carcinogenesis<sup>[15,106,107]</sup>. Although many reactive species and free radicals such as reactive nitrogen species contribute to oxidative stress, the role of ROS in colorectal carcinogenesis will mainly be discussed here. ROS is generated through the partial reduction of oxygen which results in superoxide anion, singlet oxygen, hydrogen peroxide and hydroxyl radical formation. ROS plays a dual role in biological systems. When the balance between oxidant and anti-oxidant activity is maintained, ROS can participate as secondary messengers in intracellular signal transduction cascades, whilst the presence of excessive ROS induces tissue damage.

Iron is a strong oxidant and when present at high levels, it generates ROS *via* the Haber-Weiss-Fenton reaction. Iron-mediated generation of ROS can cause oxidative damage to lipids, nucleic acids or proteins<sup>[86]</sup>. Oxidative damage to proteins and lipids can generate reactive intermediates that can couple to DNA bases resulting in DNA lesions<sup>[86]</sup>. DNA damage as a consequence of prolonged oxidative stress can result in mutation of proto-oncogenes and tumour suppressor genes, microsatellite instability and chromosomal rearrangements as well as a dysregulation in transcription, signal transduction and replication, all of which are associated with carcinogenesis<sup>[115,86,108]</sup>. Haem is also an oxidant<sup>[109]</sup>, and despite being essential for many biological processes and enzyme systems,

excessive free haem catalyses ROS production, resulting in oxidative stress<sup>[110]</sup>. The degradation of haem by haem oxygenase-1 alleviates oxidative stress<sup>[111]</sup> and bilirubin, a by-product of haem breakdown, is anti-oxidative and has been shown to scavenge peroxy radicals in plasma<sup>[112,113]</sup>. In mice lacking copper-and zinc-containing superoxide dismutase, oxidative damage is pervasive and the rate of liver cancer development is increased later in life<sup>[114]</sup> whilst, mice with decreased manganese-containing superoxide dismutase activity have an increased risk for lymphoma and adenocarcinoma<sup>[115]</sup>. These results suggest that reduced anti-oxidant activity can lead to cancer.

Oxidative stress is enhanced in neoplastic tissue from the colonic mucosa of CRC patients<sup>[116,117]</sup>. In these patients, lipid peroxidation is increased in colonic tumours compared with normal mucosa<sup>[116]</sup>. In addition, there is a greater extent of DNA strand breakage in colonic mucosal cells isolated from neoplastic tissues compared with normal tissues from cancer patients<sup>[117]</sup>. Oxidative damage is also more evident in the earlier stages of CRC than in the more advanced stages of cancer. The accumulation of iron in a human colon cancer cell line has been shown to correlate with increased oxidative protein and DNA damage<sup>[118]</sup>. In rodent studies, mice and rats fed a diet high in iron<sup>[119-122]</sup> and haem<sup>[82]</sup> exhibited greater lipid peroxidation activity in the colon and increased colonic aberrant crypt foci, which are pre-neoplastic lesions<sup>[82,123,124]</sup>. Oxidative damage markers are increased in the colons of *Hfe* knockout mice<sup>[125]</sup>, indicating an increased presence of ROS in these iron-loaded mice. Oxidative stress due to high iron and/or haem levels may, therefore, be instrumental in mediating colorectal carcinogenesis.

## INFLAMMATION AND CRC

The relationship between inflammation and tumour development has been a major focus in recent cancer research. Persistent inflammation as a result of infection promotes carcinogenesis; for example, infection with hepatitis B and C and human papilloma viruses are associated with HCC and cervical cancer, respectively, whilst *Helicobacter pylori* infection is linked to gastric cancer<sup>[126]</sup>. Furthermore, subjects with inflammatory bowel disease such as ulcerative colitis and Crohn's disease suffer from recurring inflammation in the colonic mucosa and are at an increased risk of developing CRC<sup>[127]</sup>.

Chronic inflammation and metabolites from phagocytic processes result in formation of excessive ROS and nitric oxide<sup>[98,128]</sup>, which as mentioned above, can directly cause damage to DNA, protein or lipids. Inflammatory cells active in chronic inflammation are also present within a tumour and its surrounding tissue. This suggests that the presence of oxidative stress and the network of inflammatory cytokines and chemokines in a tumour microenvironment may perpetuate carcinogenesis by promoting genotoxicity, proliferation and survival as well as angiogenesis, cell invasion and metastasis<sup>[129]</sup>. Cytokines that are frequently associated with carcinogenesis include TNF $\alpha$  and IL-6, which promote cell proliferation and

survival<sup>[130]</sup>. Angiogenesis, invasion and metastasis are influenced by the cytokines, TNF $\alpha$ , IL-1, -6 and -8<sup>[129]</sup>.

CRC occurs in approximately 4% of patients with ulcerative colitis<sup>[131]</sup> where the risk for CRC has been reported to be approximately 10-fold higher than in the normal population<sup>[127,132]</sup>. The risk for cancer increases with longer duration and the extent of colon affected by this disease, and how well the inflammation is controlled, indicating that it is the prolonged inflammatory stimulus that directly affects the pathogenesis of CRC in these patients. In addition to the blood loss and iron deficiency due to the chronic intestinal inflammation, patients with ulcerative colitis and Crohn's disease may also develop iron deficiency anaemia secondary to inflammation and reduced mobilization of bone marrow iron and are frequently treated with oral iron supplementation. Hence, the effects of iron on colitis-associated colorectal carcinogenesis have also been examined. Chronic inflammation induced in mice treated with dextran sodium sulphate resulted in colorectal tumorigenesis which became worse with dietary iron supplementation, indicating the tumour-promoting role of iron when inflammation was present<sup>[13]</sup>. This was accompanied by the increased presence of enhanced nitrotyrosine and iNOS expression, which implicates a role for oxidative stress in inflammation-associated carcinogenesis. Further evidence comes from experimental models where colitis is attenuated when anti-oxidant activity is increased<sup>[133,134]</sup>. In addition, the formation of pro-oxidants due to increased activity of phagocytic leukocytes in the colons of ulcerative colitis patients has been reported<sup>[135]</sup>. These findings suggest that oxidative stress induced by both inflammation and iron plays a major role in inflammation-associated colorectal carcinogenesis.

Better understanding about the relationship between inflammation and iron metabolism has been achieved since the identification of hepcidin. Inflammation affects iron homeostasis by inducing hepcidin through an IL-6-mediated pathway<sup>[45]</sup>. Increased hepcidin levels caused decreased iron absorption<sup>[136,137]</sup> as well as iron retention by reticulo-endothelial macrophages, which may result in hypoferraemia (low serum iron concentration)<sup>[138]</sup>. Hypoferraemia is associated with the anaemia of chronic disease, also known as anaemia of inflammation. Haem, like iron, is pro-inflammatory and increases the expression of inflammatory adhesion molecules in endothelial cells<sup>[109]</sup>. Haem oxygenase 1 knockout mice suffer from anaemia, tissue iron loading and severe inflammation, having enlarged spleens and lymph nodes, vasculitis and inflammatory cell infiltrates in the liver<sup>[139]</sup>. Carbon monoxide, a by-product of haem degradation, ameliorates inflammation in a mouse model of colitis<sup>[140]</sup>. High dietary iron and/or haem levels are likely to contribute to the pathogenesis of inflammation-associated colorectal carcinogenesis.

## FUTURE PERSPECTIVES

Population-based studies as well as animal studies point to a role for dietary and/or systemic body iron levels in

colorectal carcinogenesis. The effect of high iron levels on regulatory pathways of iron metabolism through HFE and hepcidin as well as the increased production of ROS in the presence of iron provide potential mechanisms. The interference of high iron levels with ROS and/or inflammation and their effects on pathways involved in colorectal carcinogenesis remains poorly understood. Future studies in mouse models of HH, dietary iron overload and colorectal carcinogenesis will provide valuable insights into this fascinating aspect of iron biology and CRC.

### Abstract

In spite of advances made in the management of the other more common cancers of the gastrointestinal tract, significant progress in the treatment of pancreatic cancer remains elusive. Nearly as many deaths occur from pancreatic cancer as are diagnosed each year reflecting the poor prognosis typically associated with this disease. Until recently, the only treatment with an impact on survival was surgery. In the palliative setting, gemcitabine (Gem) has been a standard treatment for advanced pancreatic cancer since it was shown a decade ago to result in a superior clinical benefit response and survival compared with bolus 5-fluorouracil. Since then, clinical trials have explored the pharmacokinetic modulation of Gem by fixed dose administration and the combination of Gem with other cytotoxic or the biologically "targeted" agents. However, promising trial results in small phase II trials have not translated into survival improvements in larger phase III randomized trials in the advanced disease setting. Two trials have recently reported modest survival improvements with the use of combination treatment with Gem and capecitabine (United Kingdom National Cancer Research GEMCAP trial) or erlotinib (National Cancer Institute of Canada

Clinical Trials Group PA.3 trial). This review will focus on the use of systemic therapy for advanced and metastatic pancreatic cancer, summarizing the results of several recent clinical trials and discuss their implications for clinical practice. We will also discuss briefly the second-line chemotherapy options for advanced pancreatic cancer.

### INTRODUCTION

Pancreatic cancer is responsible for approximately 5% of cancer-related deaths and is the eighth most common cause of cancer-related death for both genders combined worldwide<sup>[1]</sup>. Recent estimates indicate that approximately 42000 new cases and deaths are expected to occur in the United States during 2009. For all the stages combined, the 1- and 5-year survival rates are only 23% and 5%, respectively<sup>[2]</sup>.

The prognosis is even poorer for patients with advanced pancreatic cancer. At the time of diagnosis, approximately half of the patients have metastases, and their median overall survival (OS) with treatment is around 6 mo; whe-

reas approximately one third of patients diagnosed with locally advanced disease have an OS ranging between 6 and 9 mo<sup>[3]</sup>. Only 15%-20% of patients are eligible for surgery at diagnosis<sup>[3]</sup>. Only about 20% of surgically resected patients with localized disease will survive 5 years. There is a clear need for better systemic treatments.

This review will summarize and discuss the various clinical trials of chemotherapy for locally advanced and metastatic pancreatic cancer, including the more recent trials, which have investigated the novel targeted agents.

## PALLIATIVE CHEMOTHERAPY FOR ADVANCED PANCREATIC CANCER

Patients with metastatic or locally advanced inoperable pancreatic cancer are enrolled in clinical trials as a group, although these patients have different prognoses. The role of radiation therapy for patients with locally advanced disease remains controversial. In addition to a survival benefit, the palliative role of chemotherapy in addition to best supportive care compared to supportive care alone has been demonstrated in advanced pancreatic cancer<sup>[4-6]</sup>. Patients treated with 5-fluorouracil (5-FU) based chemotherapy had an OS of 6-10 mo compared with 2-3.5 mo in patients who did not receive chemotherapy. Glimelius *et al*<sup>[4]</sup> also reported that quality of life (QOL) was better, and quality-adjusted survival time was longer, for patients who were randomized to chemotherapy (median of 4 mo *vs* 1 mo,  $P = 0.01$ ) since gemcitabine (Gem) was established as a standard therapeutic agent.

### Single agent Gem

The improvement in survival with 5-FU-based chemotherapy compared to best supportive care, and of Gem compared to bolus 5-FU has established Gem as the standard treatment in advanced or metastatic pancreatic cancer<sup>[7]</sup>. In phase II studies, single-agent Gem has shown modest response rates (RR) of 6%-11% with disease stabilization occurring in a further 19%-32%<sup>[8]</sup>. The toxicities observed with Gem include bone marrow suppression, lethargy, a flu-like syndrome, nausea and vomiting, and peripheral edema. Several trials have attempted to improve upon the efficacy of Gem.

**Fixed dose Gem:** The administration of Gem usually involves a fixed dose rate (FDR) of 10 mg/m<sup>2</sup> per min. Gem is a pro-drug that is converted to its active tri-phosphate form intracellularly. FDR infusion maximizes the intracellular concentrations of the phosphorylated forms of Gem<sup>[9]</sup>.

In a randomized phase II trial<sup>[10]</sup>, Gem at FDR infusion led to a higher RR and better survival, although the primary end point of time to treatment failure (ITF) was similar for both arms. (2.1 mo for FDR Gem *vs* 1.8 mo,  $P = 0.09$ ). The median survivals were 8.0 and 5.0 mo, and the 1-year survivals were 28.8 and 9%, for both arms, respectively. The incidence of hematological toxicity, particularly grade 3-4 neutropenia, was higher in the FDR Gem arm (48.8% *vs* 26.5%).

However in a phase III trial by the Eastern Cooperative Oncology Group (ECOG)<sup>[11]</sup>, the FDR of Gem or

Table 1 Progression-free and overall survival analyses from the ECOG 6201 trial<sup>[11]</sup>

Parameter	PFS		OS	
	Median (mo)	Log-rank <i>P</i>	Median (mo)	Log-rank <i>P</i>
All eligible patients ( <i>n</i> = 824)	2.9		5.6	
Gem ( <i>n</i> = 275)	2.6		4.9	
FDR Gem ( <i>n</i> = 277)	3.5	0.09	6.2	0.15
GemOx ( <i>n</i> = 272)	2.7		5.7	

PFS: Progression-free survival; OS: Overall survival; ECOG: Eastern Cooperative Oncology Group; Gem: Gemcitabine; GemOx: Gem and oxaliplatin.

GemOx [Gem and oxaliplatin (Ox)] did not meet the survival superiority endpoint of the trial compared to standard infusion Gem. Table 1 shows the efficacy results from this trial.

### Gem-based combination chemotherapy

Despite promising phase II trials, the combination of Gem with other cytotoxic drugs has not been proved to be superior to Gem alone in survival (Table 2).

**Gem and FU:** Phase III trials of Gem plus FU compared with single-agent Gem in patients with advanced disease have not shown any benefit in terms of survival<sup>[12,13]</sup>. In a phase III ECOG trial, 322 patients with advanced pancreatic cancer were randomized to Gem alone *vs* Gem combined with FU. OS was 5.4 mo for Gem alone and 6.7 mo for Gem plus FU ( $P = 0.09$ ). Progression-free survival (PFS) for Gem alone was 2.2 mo, compared with 3.4 mo for Gem plus FU ( $P = 0.022$ ).

**Gem and capecitabine:** The combination of capecitabine and Gem (GemCap) has shown promising clinical activity in phase I and II clinical studies in advanced pancreatic cancer patients<sup>[14,15]</sup>. A phase III trial conducted by Herrmann *et al*<sup>[16]</sup> also showed positive results for good performance status (PS) patients. Of 319 patients in the study, median OS, the primary end point, was 8.4 and 7.2 mo in the combination and Gem alone arms, respectively ( $P = 0.234$ ). In addition, there was no statistically significant difference in PFS between the arms (4.8 mo *vs* 4.0 mo,  $P = 0.0207$ ). Only the subgroup analysis of patients with good performance status [Karnofsky performance status (KPS) score of 90-100] have shown significant prolongation of median OS in the GemCap group compared with the control group (10.1 mo *vs* 7.4 mo, respectively,  $P = 0.014$ )<sup>[16]</sup>.

In the more recently reported United Kingdom Phase III trial<sup>[17]</sup> (UK NCRI study), a higher dose intensity of Gem and capecitabine was used than in the previous trial. Capecitabine dose was approximately 44% higher, and the Gem dose in the combined arm was approximately 12% higher. The dose of Gem in the control arm was identical in the two trials. Median OS was shown to be significantly superior in the GemCap group compared with the Gem group (7.4 mo *vs* 6 mo, respectively,  $P = 0.014$ ), as were the ORR (14% *vs* 7%, respectively,  $P = 0.001$ ) and

Table 2 Phase III trials of gemcitabine doublets

Phase III trial	Combination	OS (mo)	P	PFS (mo)	P
Berlin <i>et al</i> <sup>[12]</sup> (n = 322)	Gem + FU	6.7	0.09	3.4	0.022
	Gem	5.4		2.2

	Gem	6.2		4.0	

FU: Fluorouracil.

the 1-year survival rates (26% and 19%, respectively). Although, higher doses of chemotherapy were used in this study, there was no significant difference in the frequency of grade 3 or 4 adverse events between the two trials. These data were presented in 2005. However, the final results of this trial have not been reported and a full manuscript has not been produced.

Additionally, Bernhard *et al*<sup>[18]</sup> assessed the clinical benefit response (CBR) and QOL in patients treated with GemCap or Gem alone. CBR was defined as improvement from baseline for 4 consecutive weeks in pain (pain intensity or analgesic consumption) and KPS, stability in one but improvement in the other, or stability in pain and performance status but improvement in weight. Of 319 patients, 19% of patients treated with the combination regimen and 20% of patients treated with Gem alone experienced a CBR, with a median duration of 9.5 and 6.5 wk, respectively ( $P = 0.02$ ). There was no treatment difference in QOL ( $n = 311$ ) between the two treatment arms. Regardless of their initial condition, some patients experienced an improvement in QOL on chemotherapy by symptom control; however, this was followed by a worsening 1-2 mo before treatment failure (all  $P < 0.05$ )<sup>[18]</sup>.

**Gem and platinum:** A recent randomized phase III trial evaluating Gem with or without cisplatin in patients with advanced pancreatic cancer demonstrated a trend toward increased OS (7.6 mo *vs* 6.0 mo,  $P = 0.12$ ) and PFS in the combination arm relative to the control arm but these differences were not statistically significant<sup>[19]</sup>. Also, there was no significant difference in QOL between the arms and only nausea and vomiting were significantly increased in the combination arm (22.2% *vs* 5.8%,  $P = 0.002$ ). Similarly, another randomized study did not show a benefit in survival for combination treatment (6.9 mo *vs* 4.6 mo,  $P = 0.48$ ) despite a marked improvement in response rate (26.4% *vs* 9.2%,  $P = 0.02$ )<sup>[20]</sup>.

On the basis of published preclinical *in vitro* synergy data between Gem and Ox<sup>[21]</sup>, the French Multidisciplinary

Clinical Research Group in Oncology (GERCOR) has conducted a phase II study in 64 patients with advanced or metastatic pancreatic cancer<sup>[22]</sup>. The encouraging results observed with GemOx in this phase II study has prompted the initiation of a phase III trial, conducted by both GERCOR and the Italian Group for the Study of Gastrointestinal Tract Cancer (GISCAD). In this phase III study, GemOx was superior in terms of PFS (5.8 mo *vs* 3.7 mo,  $P = 0.04$ ), RR (26.8% *vs* 17.3%,  $P = 0.04$ ) and clinical benefit (38.2% *vs* 26.9%,  $P = 0.03$ )<sup>[23]</sup> in both the metastatic and locally advanced population. The 1-year survivals observed in both arms of the study were impressive (34.7% and 27.8%, respectively,  $P = 0.22$ ). However, median OS did not significantly improve (9.0 mo *vs* 7.1 mo,  $P = 0.13$ ). For patients with locally advanced disease, median OS was identical in both arms (10.3 mo), whereas in patients with metastatic disease, median OS was 8.5 and 6.7 mo for GemOx and Gem alone, respectively ( $P = 0.17$ )<sup>[23]</sup>. The identical OS in patients with locally advanced disease and failure of this study to demonstrate the statistical significance of its primary end point has been attributed to the assignment of some patients to chemoradiotherapy after 3 mo of chemotherapy. Thirty percent and 32% of patients in the Gem and GemOx arms, respectively, presented with locally advanced disease. Chemoradiotherapy was recommended after 3 mo of chemotherapy in the case of stable disease or response, at the discretion of each investigator. Sixteen out of 40 (40%) and 11 out of 33 (33.3%) patients in the GemOx and Gem arms, respectively, received chemoradiotherapy. The incidence of grade 3-4 thrombocytopenia, vomiting and peripheral sensory neuropathy was increased in the combination arm<sup>[23]</sup>. An ECOG study<sup>[11]</sup> was designed to compare the survival impact of single-agent Gem *vs* Gem FDR or GemOx in metastatic or locally advanced pancreatic cancer, and performance status 0 to 2. Of 824 patients enrolled, there was no significant difference in median survival and PFS among the 3 treatment arms (Table 1). A meta-analysis of 5 randomized trials (two oxaliplatin-based and three

cisplatin-based Gem combinations) by Heinemann *et al*<sup>[24]</sup> demonstrated a significant improvement in ORR and PFS in 2 trials, while the level of significance was not reached in the other 3 trials. The platinum-based combination regimens consistently prolonged OS. However, none of the individual trials showed a statistically significant superiority compared to Gem alone. A significant improvement in OS was detected only when a combined analysis of the five trials was performed (HR = 0.85,  $P = 0.010$ ).

**Gem and topoisomerase inhibitors:** Irinotecan alone has a response rate of 9% in advanced pancreatic cancer<sup>[25]</sup>. In a phase II, multicenter, single-arm study with irinotecan and Gem (IRINOGEN), 11/45 patients (24%) had 50% or greater reductions in tumor area with a RR of 20% (95% CI, 8%-32%). CA 19-9 was found to decrease during therapy in 50% of patients and was reduced by  $\geq 50\%$  in 30% of patients<sup>[26]</sup>. There were significant ( $P < 0.001$ ) correlations between proportional changes in CA 19-9 and radiographic changes in the tumor area. Median TTP, median survival and 1-year survival rate were modest at 2.8 mo, 5.7 mo and 27%, respectively. Severe toxicities were uncommon and primarily limited to grade 4 neutropenia (2%), grade 4 vomiting (2%), and grade 3 diarrhea (7%)<sup>[26]</sup>. This phase II data was followed by a phase III randomized study conducted by Rocha Lima *et al*<sup>[27]</sup> to compare the OS of 180 patients randomly assigned to IRINOGEN ( $n = 173$ ) *vs* Gem ( $n = 169$ ). Unfortunately, the combination was not found to improve OS (6.3 mo *vs* 6.6 mo,  $P = 0.789$ ), although the combination had a significantly better tumor RR (16.1% *vs* 4.4%,  $P < 0.001$ )<sup>[27]</sup>. Median TTP was 3.5 mo for the IRINOGEN group *vs* 3.0 mo for the Gem group ( $P = 0.352$ ). However, subset analyses in patients with locally advanced disease suggested a TTP advantage with IRINOGEN *vs* Gem (7.7 mo *vs* 3.9 mo). CA 19-9 progression was positively correlated with tumor progression as shown in the previous phase II trial conducted by the same author. The incidence of grade 3 diarrhea was higher in the IRINOGEN group but grade 3 to 4 hematologic toxicities and QOL measures were similar<sup>[27]</sup>.

Another topoisomerase inhibitor exatecan (DX-8951f) was studied in a randomized phase III trial and was shown to be inferior to Gem in RR and improvement in QOL<sup>[28]</sup>. Furthermore, the combination of exatecan and Gem failed to show any significant survival benefit over Gem alone in a phase III study (6.7 mo *vs* 6.2 mo,  $P = 0.52$ )<sup>[29]</sup>. Patients in the combination treatment arm experienced significantly more grade 3-4 toxicity, in particular neutropenia (30% *vs* 15%,  $P = 0.001$ ), thrombocytopenia (17% *vs* 5%,  $P = 0.004$ ) and vomiting (11% *vs* 5%,  $P = 0.04$ )<sup>[29]</sup>.

The oral topoisomerase I inhibitor rubitecan (9NC) has also been tested in pancreatic cancer in phase I / II trials<sup>[30,31]</sup>. In the phase II trial of 19 enrolled patients, an objective response was documented in 4 of the 14 evaluable patients (28.6%). Overall median survival was 21 wk and the 1-year survival was 16.7%. Toxicity leading to temporary discontinuation of 9NC was encountered in seven patients (36.8%), all related to a prior dose increase, while milder toxicity was observed in eight patients (42.1%)<sup>[31]</sup>.

**Gem and taxanes:** Although the taxanes (docetaxel and paclitaxel) have both single-agent activity and activity in combination chemotherapy in advanced pancreatic cancer, they are associated with significant toxicity, particularly myelosuppression. In a phase I / II study of Gem with docetaxel, the dose-limiting toxicity was grade 3-4 neutropenia<sup>[32]</sup>. Subsequent phase II combination studies have reported RR of 12%-18% and median survivals of 4.7-8.9 mo<sup>[33-35]</sup>. The incidence of grade 3-4 neutropenia was improved by the addition of prophylactic G-CSF (31%) or ciprofloxacin (48%), although these studies still reported an incidence of febrile neutropenia in 12% of patients<sup>[33,34]</sup>.

**Gem with other agents:** Gem has also been investigated in a multidrug combination chemotherapy regimen. A very small randomized study comparing the combination of cisplatin, epirubicin, FU and Gem (PEFG regimen,  $n = 51$ ) to Gem alone ( $n = 46$ ) showed better 4-mo PFS (primary end point) (60% *vs* 28%) and RR (38.5% *vs* 8.5%,  $P = 0.008$ )<sup>[36]</sup> in the PEFEG group than in the control group. Both the 1-year OS (38.5% *vs* 21.3%,  $P = 0.119$ ) and the median OS (5.4 mo *vs* 3.3 mo,  $P = 0.0033$ ) were impressive in the PEFEG group. There was no significant difference in QOL between the treatment arms, although there was a higher CBR in the PEFEG arm (65% *vs* 25%,  $P = 0.0139$ ). However, grade 3-4 neutropenia (43% *vs* 14%,  $P = 0.0001$ ) and thrombocytopenia (30% *vs* 1%,  $P = 0.0001$ ) occurred more frequently in the PEFEG arm. Subsequently, this regimen was modified by increasing the dose intensity of cisplatin and epirubicin (both at 30 mg/m<sup>2</sup> every 14 d) and of Gem (at 800 mg/m<sup>2</sup> every 14 d) in an attempt to further improve activity and efficacy, to reduce toxicity and to yield a schedule more suitable to the patient<sup>[37]</sup>. When compared with 84 patients treated with classical PEFEG at the same institution, dose-intense PEFEG was not inferior in terms of PFS at 6 mo (63% *vs* 57%), 1-year OS (48% *vs* 42%) and RR (49% *vs* 49%); it allowed an increase in dose intensity for Gem of 32%, for cisplatin and epirubicin of 36% (FU reduced by 3%) which significantly reduced grade 3-4 hematological toxicity (neutropenia: 26% *vs* 86%,  $P < 0.00001$ ; thrombocytopenia: 4% *vs* 58%,  $P < 0.00001$ ) and reduced the number of outpatient accesses by one-third<sup>[37]</sup>.

### Emerging role of the novel targeted agents in pancreatic cancer

A better understanding of the biology of cancer has led to the development of novel agents targeting pathways of cancer cell survival. Since Gem has been considered a standard treatment for advanced pancreatic cancer for the past decade, clinical trials have explored the combination of Gem and biological "targeted" agents. However, despite their promise in preclinical studies, most of the clinical trials with the newer agents have not shown survival advantage when compared with standard Gem. A questionable exception is the combination of Gem and erlotinib which showed superiority in median survival compared to Gem alone, but only a net gain of two weeks

**Table 3 Phase I / III trials of gemcitabine in combination with novel targeted therapies**

	Combination	OS (mo)	P	PFS (mo)	P	ORR (%)	SD (%)
Phase II trial							
Xiong <i>et al</i> <sup>[41]</sup> (n = 61)	Gem + Cetuximab	7.1		3.8		12.2	63.4
Fogelman <i>et al</i> <sup>[47]</sup> (n = 50)	GemOx + BEV	12.1		NR		NR	39
Kim <i>et al</i> <sup>[48]</sup> (n = 82)	GemOx + BEV	8.1		5.7		11.3	NR
Ko <i>et al</i> <sup>[49]</sup> (n = 57)	Gem + Cetuximab + BEV	NR		3.5		10.7	29
	Cetuximab + BEV			1.8		0	24
Kindler <i>et al</i> <sup>[50]</sup> (n = 139)	Gem + BEV + Erlotinib	7.8		5.0		23	49
	Gem + BEV + Cetuximab	7.2		5.1		18	45
Phase III trial							
Moore <i>et al</i> <sup>[40]</sup> (n = 569)	Gem + Erlotinib	6.37	0.038	NR	0.004		
	Gem	5.91					
Philip <i>et al</i> <sup>[43]</sup> (n = 735)	Gem + Cetuximab	6.5	0.14	3.5	0.058		
	Gem	6.0		3.0			
Kindler <i>et al</i> <sup>[45]</sup> (n = 602)	Gem + BEV	5.7	NS	4.8	NS		
	Gem	6.0		4.3			
Vervenne <i>et al</i> <sup>[46]</sup> (n = 607)	Gem + BEV	7.1	NS	4.6	0.0002		
	Gem	6.0		3.6			

ORR: Overall response rate; SD: Stable disease; NR: Not reported; NS: Not significant; BEV: Bevacizumab; Gem: Gemcitabine; Gem FDR: Gemcitabine fixed-dose rate; GemOx: Gemcitabine 1000 mg/m<sup>2</sup> iv over 100 min on day 1 plus oxaliplatin 100 mg/m<sup>2</sup> on day 2 every 14 d.

was observed, questioning the true clinical significance of this superiority<sup>[3]</sup> (Table 3).

**Gem based chemotherapy with novel targeted agents**

**Gem and erlotinib:** Preclinical synergy with Gem and erlotinib in inducing apoptosis in pancreatic xenograft models was demonstrated<sup>[38]</sup>, and a phase I study established the dose of erlotinib for single-agent daily dosing to be 150 mg/d, with which the incidence of severe diarrhea and/or skin rash was unacceptably high<sup>[39]</sup>. In a phase III trial by Moore *et al*<sup>[40]</sup>, 569 patients with locally advanced and metastatic pancreatic cancer were randomly assigned to receive erlotinib plus Gem *vs* Gem alone. The study showed statistically significant improvements in OS (6.37 mo in the erlotinib arm and 5.91 mo in the control arm, *P* = 0.038) and PFS (*P* = 0.004). Median survival in the erlotinib group was 6.24 mo and the 1-year survival rate was 23% compared with 5.91 mo and 17% in the control arm. There was a slight increase in the incidence of grade 3-4 skin rash and diarrhea (6% *vs* 1%) in the group receiving erlotinib, although there was no overall difference in QOL between the arms. As in studies of anti-EGFR agents in colorectal cancer, the presence of rash was associated with a higher likelihood of achieving disease control<sup>[40]</sup> (*P* = 0.05). This study did not require EGFR positivity to be demonstrated prior to study entry and the overall rate of EGFR expression observed was 57%, which was lower than has been reported in previous studies<sup>[41,42]</sup>. A subgroup analysis by EGFR status suggested a trend towards benefit from erlotinib regardless of EGFR status, but there was inadequate power to show statistical significance.

**Gem and cetuximab:** In a phase II study<sup>[41]</sup>, 41 patients with EGFR expressing advanced pancreatic cancer were treated with the combination of Gem and cetuximab. A reasonable RR of 12.2% was reported, with a further 63.4% of patients achieving disease stabilization. These

results led to a randomized phase III trial<sup>[43]</sup> undertaken by The South Western Oncology Group (SWOG, S0205), the results of which were presented at the 43rd American Society of Clinical Oncology (ASCO) Annual Meeting in 2007 and did not show any survival benefit<sup>[43]</sup>. Seven hundred and thirty five patients were enrolled between January 2004 and April 2006. The median survival was 6 mo in the Gem arm and 6.5 mo in the Gem plus cetuximab arm for an overall HR of 1.09 (95% CI: 0.93-1.27, *P* = 0.14). The corresponding PFS was 3.0 and 3.5 mo, for the Gem and Gem-cetuximab arms, respectively (HR: 1.13; 95% CI: 0.97-1.30, *P* = 0.058). The unconfirmed responses yielded 14% in the Gem arm and 12% in the Gem-cetuximab arm.

**Gem and bevacizumab:** Another targeted agent with promising efficacy in pancreatic cancer is bevacizumab which was studied in combination with Gem in a phase II trial that resulted in a RR of 19%<sup>[44]</sup>. However, the results of the US Cancer and Leukemia Group B (CALBG) phase III randomized trial of Gem with or without bevacizumab did not reveal any improvement in survival upon addition of bevacizumab<sup>[45]</sup>. Median OS in the bevacizumab arm *vs* the control arm was 5.7 mo *vs* 6.0 mo (95% CI: 4.9-6.5 mo *vs* 5.0-6.9 mo) and PFS of 4.8 mo *vs* 4.3 mo, respectively (95% CI: 4.3-5.7 mo *vs* 3.8-5.6 mo). This result did not prevent completion of a similar, Roche sponsored trial, AVITA, in which 607 patients with metastatic pancreatic cancer were randomized to Gem and erlotinib with or without bevacizumab<sup>[46]</sup>. There was no significant prolongation of survival with the addition of bevacizumab, although disease-free survival (DFS) was statistically significantly improved (from 3.6 to 4.6 mo). Bevacizumab was reported to be safe in this combination, despite an increase in the incidence of epistaxis, hypertension and proteinuria. Interestingly, there was no reported increase in thrombotic events with bevacizumab<sup>[3]</sup>. The AVITA study suggests that antiangiogenic strategies may have merit in the treatment of

advanced pancreatic cancer, although the margin of benefit with bevacizumab is modest.

Two phase II trials were presented at the 2009 ASCO Gastrointestinal Cancer Symposium which evaluated the efficacy of Gem in combination with biologic agents. Fogelman *et al*<sup>[47]</sup> reported the final results of a 3-drug combination consisting of Gem, Ox and bevacizumab in 50 patients with advanced pancreatic cancer. This triple drug combination achieved 1 and 2-year survival rates of 40% and 16%, respectively with a high response rate of 39%<sup>[47]</sup>. In addition, this regimen demonstrated a higher RR and longer median survival compared to a previously reported Gem and Ox study<sup>[23]</sup>. Of note, there was a correlation between CA 19-9 levels and median survival. Another phase II trial<sup>[48]</sup> assessing the combination of GemOx plus bevacizumab included 82 patients with advanced pancreatic cancer. This study showed 6-mo survival of 65.0% (95% CI: 53.5%-75.3%), median survival of 8.1 mo (95% CI: 6.5-9.3 mo) and median TTP of 5.7 mo (95% CI: 4.4-6.4 mo).

On the other hand, Gem with a dual monoclonal antibody regimen was disappointing. Ko *et al*<sup>[49]</sup> designed a phase II trial to evaluate the efficacy of dual EGFR/VEGF monoclonal antibodies cetuximab and bevacizumab with or without Gem. Fifty-seven patients received dual antibodies. Overall RR was only 10.7% in the Gem arm and OS data has not been presented yet<sup>[49]</sup>. The above results were confirmed by another phase II trial by Kindler *et al*<sup>[50]</sup>. One hundred and thirty-nine patients with locally advanced pancreatic cancer received Gem, bevacizumab and erlotinib or Gem, bevacizumab and cetuximab<sup>[50]</sup>. Interestingly, a correlation between early hypertension and response to treatment was observed. There was no significant difference between the two arms in either OS or PFS. Therefore, cetuximab or bevacizumab is not recommended for the treatment of advanced pancreatic cancer in the current clinical setting outside of an investigational trial.

### Other combined regimens

There have been very few attempts to address the role of alternative cytotoxic agents other than Gem in the first-line setting which may represent better platforms for the addition of targeted therapies. One such study conducted by Ducreux *et al*<sup>[51]</sup> evaluated the efficacy of oxaliplatin alone (OXA), infusional FU alone (FU) and an oxaliplatin/infusional 5-FU combination (OXFU) in the phase II setting. 90% of patients had metastatic disease (81% with liver metastases) and 83% of patients had PS 0-1. Median TTP and OS were higher in the combination arm (4.2 and 9.0 mo, respectively) than either of the single-agent arms (OXA, 2.0 and 3.4 mo; FU, 1.5 and 2.4 mo, respectively). Response rate was 10% in the OXFU arm and the safety profile was encouraging<sup>[51]</sup>.

In the FFCD 0301 trial<sup>[52]</sup>, a large phase III trial presented in the first-line setting, 202 patients with advanced pancreatic cancer were randomized to either FU and leucovorin plus cisplatin followed by Gem or *vice versa*. Patients received therapy until progression after which they could cross to the opposite arm. After a median follow-up

of 44 mo, the majority of patients ( $n = 192$ ) died. There was no significant difference in survival between the two arms. One-year and two-year survival figures were also identical between the Gem and FU plus cisplatin arms. Although it is unlikely that FU and cisplatin will replace Gem due to toxicity concerns, these data provided the rationale for non-Gem containing regimens in the first-line setting. One may consider a pharmacogenomic profile in the future to select either therapy.

EndoTAG-1 is a novel cationic liposomal formulation of paclitaxel. It increases the microvascular permeability probably due to vascular damage. Manipulation of the blood-tumor barrier with EndoTAG-1 can increase the effectiveness of conventional chemotherapy. The combination of Gem plus liposomal paclitaxel at three different dose levels (11, 22, or 44 mg/m<sup>2</sup>) was compared to Gem alone in 200 patients with metastatic pancreatic cancer<sup>[53]</sup>. Preliminary results were presented at the 2009 ESMO meeting. This regimen achieved a disease control rate of 53%-69% depending on the dosage of paclitaxel. Median PFS was 18, 20, and 19 wk, respectively, in the Gem/EndoTAG-1 low, medium, and high dose groups, compared with 12 wk in the Gem monotherapy group. Median OS was 7.2 mo with Gem alone *vs* 8.4, 8.7, and 9.4 mo with Gem plus low, medium, and high dose EndoTAG-1. Twelve-month survival rates were 17% with Gem alone *vs* 22%, 36% and 33% for Gem plus low, medium and high dose EndoTAG-1.

The results of a randomized phase II trial of 3 different regimens in patients with advanced pancreatic cancer suggested that capecitabine plus Ox is comparable to Gem combined with either capecitabine or Ox<sup>[54]</sup>. A phase II trial conducted by Burtness *et al*<sup>[55]</sup> confirmed the activity of another non-Gem regimen. Ninety-two patients with advanced pancreatic cancer were randomly assigned to receive irinotecan/docetaxel (Arm A) or irinotecan/docetaxel/cetuximab (Arm B). Median OS were reported to be 6.5 (95% CI: 4.8-8.6 mo) and 7.4 mo (95% CI: 4.4-10.7 mo) in Arm A and B, respectively. However, this triple regimen was associated with high rates of grade 3-4 neutropenia and diarrhea<sup>[55]</sup>.

### Other agents

Numerous studies employing other novel targeted agents are currently being developed. The CALGB presented the results of a single-arm phase II study of sunitinib for patients with advanced pancreatic cancer who had previously been treated with Gem-based therapy. No responses were reported in 77 treated patients, and stable disease in only 7 patients<sup>[56]</sup>. The California consortium reported similar disappointing results with sorafenib when combined with Gem<sup>[57]</sup>. In this randomized study, chemo-naïve pancreatic cancer patients received sorafenib as a single agent or in combination with Gem. No responses resulted with sorafenib alone and the median survival in the Gem plus sorafenib arm was only 6 mo. Wolpin *et al*<sup>[58]</sup> treated 31 Gem-refractory pancreatic cancer patients with everolimus, an oral mTOR inhibitor. Although the agent was tolerable, there was no response and disease stability

was uncommon. These targeted agents do not merit further study in pancreatic cancer due to their insufficient anti-tumor activity. Other targeted agents, which have been tested in pancreatic cancer and not found to add any survival benefit, include the farnesyl transferase inhibitor tipifarnib<sup>[59,60]</sup> and the matrix metalloproteinase inhibitors marimastat<sup>[61-63]</sup> and BAY 12-9566<sup>[64]</sup>.

Another new agent, AMG 655, is a fully humanized monoclonal antibody that targets human death receptor 5 (DR5), activates caspases, and induces apoptosis in sensitive tumor cells. In pancreatic cancer xenografts, the anti-tumor activity of AMG 655 was enhanced by adding Gem. In a phase I trial<sup>[65]</sup>, patients with metastatic pancreas cancer were enrolled into sequential cohorts of 3- or 10-mg/kg AMG 655 iv on days 1 and 15 plus Gem 1000 mg/m<sup>2</sup> iv on days 1, 8, and 15 every 28 d. Best overall tumor response assessed by RECIST criteria showed that 3 (23%) patients had partial responses, 6 (46%) had stable disease (range 15-34+ wk), and 4 (31%) patients had progressive disease. Four of 7 patients (57%) with baseline CA19-9 > 100 U/mL had a  $\geq 70\%$  decrease on study. The median PFS was 5.3 mo and the 6-mo survival rate was 76.2% (42.7%-91.7%)<sup>[65]</sup>. A randomized phase II trial of 10 mg/kg AMG 655 every 2 wk plus Gem has been completed in patients with metastatic pancreatic cancer and the results are forthcoming.

## SECOND-LINE CHEMOTHERAPY FOR ADVANCED PANCREATIC CANCER

There is no standard second-line regimen for advanced pancreatic cancer after Gem failure and there is a paucity of trials in this setting. Gem may offer palliative benefits in the second-line setting in patients that have not been treated with Gem previously<sup>[66]</sup>, and results from a phase II study ( $n = 30$ ) suggest that FDR Gem and Ox may have activity in patients who become refractory to standard Gem therapy<sup>[67]</sup>. All patients received at least one cycle of GemOx (median 5). Response in 31 evaluable patients was as follows: Partial response: 7/31 (22.6%),  $\geq 8$  wk: 11/31 (35.5%), s.d. < 8 wk: 1/31 (3.2%), Progressive disease: 12/31 (38.7%). Median duration of response and TTP were 4.5 and 4.2 mo, respectively. Median survival was 6 mo (range 0.5-21 mo). The CONKO-3 study<sup>[68]</sup> randomized 168 patients who had Gem-refractory pancreatic cancer to 5-FU, LV and oxaliplatin (OFF) or 5-FU and LV (FF). The study showed an improved OS by 2 mo in the OFF arm (4.8 mo *vs* 2.3 mo respectively,  $P = 0.0077$ ). Both regimens were tolerable, with the exception of higher neuropathy in the OFF arm. There was also a significant prolongation of PFS in the treatment arm (13 wk *vs* 9 wk)<sup>[68]</sup>. After those significant results, this regimen has been regarded as an appropriate second-line regimen for Gem refractory pancreatic cancer patients.

In a phase III study patients with advanced pancreatic cancer who had failed at least one line of chemotherapy were randomized to rubitecan or physicians' choice of treatment<sup>[69]</sup>. Eighty-five percent of patients in both arms had previously received Gem; 70% and 73% had

received FU; 60% and 63% had received both drugs in combination, respectively. The study was unable to show a statistically significant improvement in OS (3.7 mo *vs* 3.1 mo,  $P = 0.626$ ), and PFS was only marginally improved (1.9 mo *vs* 1.6 mo,  $P = 0.001$ ).

In a phase II trial by Cartwright *et al*<sup>[70]</sup>, 42 patients were treated with oral capecitabine 1250 mg/m<sup>2</sup> administered twice daily in 3-weekly cycles consisting of 2 wk of treatment followed by 1 wk without treatment. Twenty-four percent of patients experienced a significant CBR as evidenced by improvement in pain intensity, analgesic consumption, and/or KPS. Three (7.3%) of the 41 patients with measurable disease had an objective partial response. The median time to objective response was 85 d (range, 47 to 91 d) and duration of response was 208, 260, and 566 d for the three responding patients. One patient with non-measurable but assessable disease had improved residual disease with a positive CBR. For a total of 4 responders among the 42 assessable patients, the OS rate was 9.5%<sup>[70]</sup>. Of note, the capecitabine dose (1000 mg/m<sup>2</sup> *po* twice daily) recommended in the guidelines was less than the dose described by Cartwright *et al*<sup>[70]</sup>, because the higher dose has been associated with increased toxicity (diarrhea, hand and foot syndrome).

In another phase II trial<sup>[71]</sup>, pancreatic cancer patients were administered capecitabine (1000 mg/m<sup>2</sup> twice daily for 14 d) combined with Ox (130 mg/m<sup>2</sup> given on day 1 for 14 d) every 21 d (patients aged > 65 years or with an ECOG PS of 2 received Ox 110 mg/m<sup>2</sup> on day 1 and capecitabine 750 mg/m<sup>2</sup> twice daily for 14 d). The treatment was repeated every 3 wk. Of the 39 evaluable patients, 1 patient had a partial response and 10 patients demonstrated stable disease. The median OS was 23 wk and PFS was 9.9 wk. The 6-mo and 1-year survival rates were 44% and 21%, respectively. The most common grade 3-4 non-hematologic toxicity was fatigue<sup>[71]</sup>.

Currently, it is recommended that physicians enroll their patients in a clinical trial if they progress on first-line therapy; however, when investigational therapy is not available, alternatives for good PS patients include capecitabine with or without Ox or OFF.

## CONCLUSION

In the first-line setting, Gem with or without erlotinib has been the standard treatment for pancreatic cancer since 1997, despite low response rates and short survival outcome. The recent introduction of targeted therapies in the therapeutic armamentarium against cancer raised hopes in the treatment of patients with advanced or metastatic cancers. Unfortunately, the target agents studied to date have fallen short of these expectations. Knowledge of the molecular events occurring in the malignant transformation processes should allow the development of more efficient targeted therapies. Metastatic and locally advanced pancreatic cancers have consistently been observed as independent predictors of outcome in randomized clinical trials. One should study these two different pancreatic cancer populations separately.

### Abstract

Congenital hepatic fibrosis (CHF) is an autosomal recessive inherited malformation defined pathologically by a variable degree of periportal fibrosis and irregularly shaped proliferating bile ducts. It is one of the fibropolycystic diseases, which also include Caroli disease, autosomal dominant polycystic kidney disease, and autosomal recessive polycystic kidney disease. Clinically it is characterized by hepatic fibrosis, portal hypertension, and renal cystic disease. CHF is known to occur in association with a range of both inherited and non-inherited disorders, with multiorgan involvement, as a result of ductal plate malformation. Because of the similarities in the clinical picture, it is necessary to differentiate CHF from idiopathic portal hypertension and early liver cirrhosis, for which a liver biopsy is essential. Radiological tests are important for recognizing involvement of other organ systems. With regards to our experience at Hacettepe University, a total of 26 patients have been diagnosed and followed-up between 1974 and 2009 with a diagnosis of CHF. Presentation with Caroli syndrome was the most common diagnosis, with all such patients presenting with symptoms of recurrent

cholangitis and symptoms related to portal hypertension. Although portal fibrosis is known to contribute to the ensuing portal hypertension, it is our belief that portal vein cavernous transformation also plays an important role in its pathogenesis. In all patients with CHF portal vein morphology should be evaluated by all means since portal vein involvement results in more severe and complicated portal hypertension. Other associations include the Joubert and Bardet-Biedl syndromes.

### INTRODUCTION

Congenital hepatic fibrosis (CHF) is an autosomal recessive inherited malformation defined pathologically by a variable degree of periportal fibrosis and irregularly shaped proliferating bile ducts. The hepatic manifestations of CHF were first described in 1856<sup>[1]</sup>. The term CHF, with its varied clinical manifestations, was recognized in 1960<sup>[2]</sup>, and later on elaborated in 1961<sup>[3]</sup>. CHF is one of the fibropolycystic diseases, which also include Caroli disease, autosomal dominant polycystic kidney disease (AD-PKD), and autosomal recessive polycystic kidney disease (ARPKD). Clinically it is characterized by hepatic fibrosis,

portal hypertension, and renal cystic disease.

The exact incidence and prevalence of CHF are not known, but it is a rare disease. By 1988, only 200 patients with CHF had been reported in the literature<sup>[4]</sup>. In most patients, the first manifestations of the disease are signs or symptoms related to portal hypertension, especially splenomegaly and varices, often with gastrointestinal bleeding<sup>[5]</sup>. The clinical manifestations of CHF are, however, nonspecific, making the diagnosis of this disorder extremely difficult. Onset of symptoms and signs is highly variable and ranges from early childhood to the 5th or 6th decade of life, although this disorder is diagnosed in most patients during adolescence or young adulthood<sup>[6]</sup>. The late appearance of symptoms and their clinical evolution suggest that CHF is a dynamic and progressive condition.

## ASSOCIATED SYNDROMES

CHF occurs in association with a range of both inherited and non-inherited disorders, with multiorgan involvement (Table 1). Several gene mutations have been established for more commonly encountered conditions that have been better investigated (e.g. Joubert syndrome, Bardet-Biedl syndrome). In these conditions, hepatic fibrosis has been reported to occur to varying degrees; however, in most cases, the main cause of morbidity and mortality is involvement of other organ systems, particularly the kidneys and central nervous system. Patients rarely reach adulthood, and in many cases death occurs intrauterine or in early childhood.

## PATHOPHYSIOLOGY

It has been established that congenital hepatic fibrosis, and indeed Caroli's disease closely resemble each other pathophysiologically, in that both occur as a result of ductal plate malformation. The ductal plate is a cylindrical layer of cells that surround a branch of the portal vein, and is the embryonic precursor of the intrahepatic bile ducts, as both interlobular and intralobular bile ductules develop from the ductal plate. Progressive remodeling starts at 12 wk of gestation, and full maturation is usually complete by 20 wk. Arrest of maturation and the lack of remodeling of the ductal plate that occurs as a result leads to the persistence of an excess number of immature embryonic duct structures. This abnormality has been termed the ductal plate malformation. The persistence of these immature duct elements stimulates the formation of portal fibrous tissue, and it is this periportal fibrosis that contributes to the clinical picture of recurrent cholangitis or portal hypertension and associated symptoms (Figure 1). Although long standing portal hypertension is known to result in secondary portal vein thrombosis, and eventually portal vein cavernous transformation (PVCT), it is firmly believed that PVCT is actually a component of the disorder, present at the onset rather than developing at a later stage. Embryologically speaking, the development of bile ducts and hepatic vasculature are closely related. The

ductal plate malformation has been shown to be associated with a "pollard willow" malformation of the portal vein, which results in too many small and closely branched portal veins, which supports the idea that PVCT may be congenital. Histologically, enlarged portal tracts containing immature ductal plates surrounding several hypoplastic or even obliterated portal vein branches are observed<sup>[7]</sup>. In one report, PVCT was observed in almost 50% of patients with congenital hepatic fibrosis, and such patients had relatively larger splenomegaly than those without PVCT, as well as suffering from more frequent bleeding episodes from esophageal varices<sup>[8]</sup>.

Furthermore, depending on the stage of arrest of maturation, either the small interlobular bile ducts (congenital hepatic fibrosis), or the medium intrahepatic bile ducts (Caroli's disease) may be involved. Involvement of both simultaneously results in what is known as Caroli's syndrome. In this context, the clinical picture of Caroli's disease (recurrent cholangitis) may be so predominant that co-existing congenital hepatic fibrosis may easily be overlooked. A liver biopsy is therefore warranted in all patients with suspected Caroli's disease to confirm the presence or absence of Caroli's syndrome<sup>[9,10]</sup>.

The hepatic stellate cell (HSC) is at the center of the hepatic fibrotic process associated with liver disease, and has also been shown to play a role in the progression of the disease in congenital hepatic fibrosis. It is widely accepted that transforming growth factor (TGF)- $\beta$  is a potent growth inhibitory and profibrotic cytokine which plays a pivotal role in the physiological process of wound healing as well as in the pathogenesis of organ fibrosis<sup>[11]</sup>. TGF- $\beta$  expression has been shown to be increased in a wide range of fibrotic diseases. Initiation of HSC activation is primarily induced by TGF- $\beta$ 1 derived from Kupffer cells. TGF- $\beta$ 1 mediates its profibrotic actions by stimulating fibroblasts and related cell types, including the HSC in the liver, to secrete a wide range of extracellular matrix proteins. In pathological conditions this leads to accumulation of fibrotic matrix or in a more physiological context to the efficient healing of wounds<sup>[12-14]</sup>. Latent TGF- $\beta$  is also activated by MMP-9, another product of Kupffer cells. TGF- $\beta$  has other important actions, namely its immunomodulatory properties and its antiproliferative effects on epithelial cells, including hepatocytes.

Several studies have attempted to establish the pathophysiological mechanism behind the abnormal and excessive fibrotic response associated with CHF. Degradation of the basement membrane and extracellular matrix (ECM) constituents, and the remodeling of the ECM are important processes of embryonic development. Basal laminar components such as laminin and type IV collagen along with the coordinated expression of proteolytic enzymes are thought to be essential for the normal development of intrahepatic bile ducts<sup>[15-18]</sup>. Most of the proteolytic enzymes involved in these processes belong to the matrix metalloproteinases (MMPs) and the serine proteinases, in particular the plasminogen activator (PA)/plasmin system<sup>[19,20]</sup>. Both tissue PA (tPA) and urokinase type PA have been shown to contribute to the plasminogen-

Table 1 Syndromes with associated congenital hepatic fibrosis

Associated disorder	Genetic anomaly [chromosome (gene)]	Characteristic clinical features
Caroli syndrome	6p21.1-p12 ( <i>PKHD1</i> gene)	Caroli's disease - ectasia or segmental dilatation of the larger intrahepatic ducts
Polycystic kidney disease	6p21.1-p12 ( <i>PKHD1</i> gene)	Progressive cystic dilation of the renal tubule (resulting in renal failure), hepatic cysts, cerebral aneurysms, cardiac valvular abnormalities
Joubert syndrome	9q34.3; 11p12-q13; 6q23 ( <i>AHI1</i> gene); 2q13 ( <i>NPHP1</i> gene); 12q21.32 ( <i>CEP290</i> or <i>NPHP6</i> gene); 8q21 ( <i>TMEM67</i> gene); 16q12.2 ( <i>RPGRIP1L</i> gene)	Cerebellar vermis hypoplasia retinitis pigmentosa, nystagmus, ataxia
Senior-Loken syndrome	2q13 ( <i>NPHP1</i> , <i>NPHP4</i> , <i>NPHP5</i> genes); 3q22 ( <i>NPHP3</i> gene)	Cerebellar ataxia and skeletal abnormalities, nephronophthisis, retinal dystrophy, sensorineural hearing loss
COACH syndrome	4p15.3 ( <i>CC2D2A</i> gene)	Cerebellar vermis hypo/aplasia, oligophrenia, ataxia, coloboma, polydactyly
Cogan syndrome	2q13 ( <i>NPHP1</i> gene)	Oculomotor apraxia, nephronophthisis, cerebellar ataxia
Arima syndrome	Not yet established	Cerebellar vermis hypoplasia, renal abnormalities, psychomotor retardation
Meckel syndrome	17q23 ( <i>MKS1</i> gene); 8q ( <i>TMEM67</i> gene); 12q ( <i>CEP290</i> gene); 16q12.2 ( <i>RPGRIP1L</i> gene); 4p15 ( <i>CC2D2A</i> gene); 11q	Microcephaly, renal cystic disease, hypoplastic or ambiguous genitalia, polydactyly, congenital heart defect, cleft palate, ocular defects
Bardet-Biedl syndrome	11q13; 16q21; 3p12-q13 ( <i>ADP-ribosylation factor</i> gene); 15q22.3; 2q31; 20p12 ( <i>MKKS</i> gene); 4q27; 14q32.11 ( <i>tetratricopeptide repeat domain-containing</i> gene); 7p14; 12q; 9q33.1; 4q27; 17q23 ( <i>MKS1</i> gene); 12q21.3 ( <i>CEP290</i> gene)	Rod-cone dystrophy (atypical retinitis pigmentosa), postaxial polydactyly, central obesity, mental retardation, hypogonadism, and renal dysfunction
Alstrom syndrome	2p13 ( <i>ALMS1</i> gene)	Childhood obesity congenital retinal dystrophy, sensorineural hearing loss, endocrinopathies, cardiomyopathy, renal failure
Oral-Facial-Digital type IV - Not yet established		Lobulated tongue, pseudo-cleft of lip, hyperplastic frenula, polydactyly, severe bilateral deafness
Mohr-Majewski syndrome		

dependent lysis of basement membrane laminin in human carcinoma cell lines. Furthermore, plasmin contributes to the activation of MMP-9 and MMP-13 which also play an important role in the degradation of basement membrane components including type IV collagen. In a recent study by Yasoshima *et al.*<sup>[21]</sup>, it was postulated that biliary overexpression of plasminogen and tPA leads to the generation of excessive amounts of plasmin, and subsequent plasmin dependent lysis of the ECM molecules which may contribute to biliary dysgenesis in CHF.

Overexpression of the osteopontin gene has also been implicated in the pathophysiology of biliary atresia, as well as congenital cholestatic syndromes such as CHF and Caroli's disease. Osteopontin is a stimulant of fibroinflammation, and its overexpression has been shown to be regulated by the presence of excessive amounts of regulatory factors such as NF- $\kappa$ B and TGF- $\beta$ 1<sup>[22]</sup>.

In an effort to establish how the presence of excessive immature bile ducts contributes to the process of fibrosis, Sato *et al.*<sup>[23]</sup> managed to demonstrate in a rat model that in the presence of TGF- $\beta$ 1, cholangiocytes acquire mesenchymal features, thus resembling fibroblasts. They speculated that excess production of extracellular matrix molecules by these transformed cells may contribute to the progressive periportal/hepatic fibrosis.

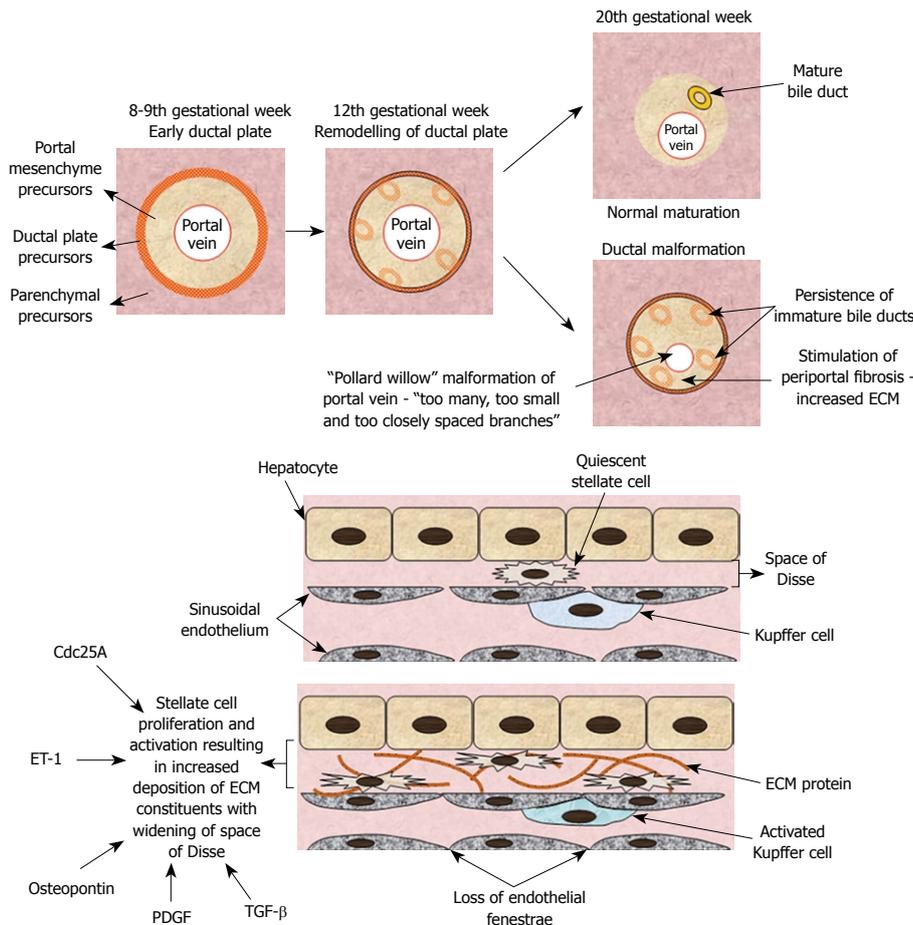

On a different note, a possible role of microRNA has been postulated in the pathogenesis of fibropolycystic disorders involving both the liver and the kidneys. Chu *et al.*<sup>[24]</sup> demonstrated decreases in the levels of the microRNA miR15a in the livers of patients with ARP-KD, ADPKD and CHF. They reported that this resulted in an increase in the expression of a cell-cycle regulator

known as cell division cycle 25A gene product (Cdc25A), which is directly responsible for cellular proliferation and cystogenesis *in vitro*.

## CLINICAL PICTURE

The age of onset of presentation and the severity of symptoms varies greatly, with patients usually being diagnosed in childhood or early adulthood, although presentations as late as in the fifth decade have been reported. Although patients usually present with symptoms involving other organ symptoms (e.g. renal, central nervous system, *etc.*), cases referred for gastroenterologic/hepatologic consultation generally have complaints attributed to CHF. Four clinical forms have been defined<sup>[25]</sup>: (1) Portal hypertension (most common; more severe in the presence of portal vein abnormality); (2) Cholangitic - cholestasis and recurrent cholangitis; (3) Mixed; and (4) Latent - presentation at a late age.

Most patients are asymptomatic, while some may complain of mild right upper quadrant pain. Patients with a predominant portal hypertensive picture may present with upper gastrointestinal variceal bleeding. Physical examination findings include hepatomegaly, with predominant involvement of the left lobe, splenomegaly and nephromegaly. The liver is firm, with a mildly nodular surface. Laboratory workup may reveal mild elevations in liver enzymes. Patients with a predominantly cholangitic clinical picture may have marked elevations in alkaline phosphatase (ALP),  $\gamma$ -glutamyl transpeptidase (GGT) and bilirubin. Varying cytopenias (leukopenia, thrombocytopenia) secondary to hypersplenism may be seen on a blood count. Abnormal renal func-

tions tests are associated with extensive cystic renal disease, which may even progress to end-stage renal failure<sup>[26]</sup>.

## COMPLICATIONS

### **Cholangiocellular carcinoma**

The association of cholangiocellular carcinoma (CCC) with congenital cystic malformation of the biliary tree, as seen in Caroli's disease and Caroli's syndrome, has been well established, ranging from 2.5%-16% of afflicted individuals. However, pure congenital fibrosis has also been reported to result in CCC<sup>[27,28]</sup>.

## DIAGNOSIS

### **Role of radiology**

Ultrasonography (US) is generally regarded as the first line modality used in the diagnostic process with its high utility, lack of radiation exposure and its capability of detecting the bile duct and liver parenchymal abnormality. In particular, its unique capability of detecting the parenchymal heterogeneity and the associated kidney abnormalities accentuates its role in the diagnosis. Findings include hypertrophy of the left lateral segment and caudate, normal or hypertrophic left medial segment, atrophic right lobe, presence of hepatosplenomegaly, dilatation of the intrahepatic and extrahepatic bile ducts with concomitant focal cystic or solid lesions such as regenerative liver nodules and periportal thickening, dilated intrahepatic bile ducts

and stones in the ducts (Caroli's disease), hepatic and renal cysts, and portal vein cavernous transformation (Figure 2).

Computed tomography (CT) offers an advantage to US in that it provides a better depiction of gross morphology of the liver with accurate volume measurements and imaging of liver vasculature, as well as demonstrating any changes in the biliary tree (Figure 3A and B). Periportal cuffing, indicative of the fibrotic process, may also be easily detected with CT. Moreover, imaging of the central nervous system, particularly by CT is essential in the differential diagnosis of syndromes with associated congenital hepatic fibrosis.

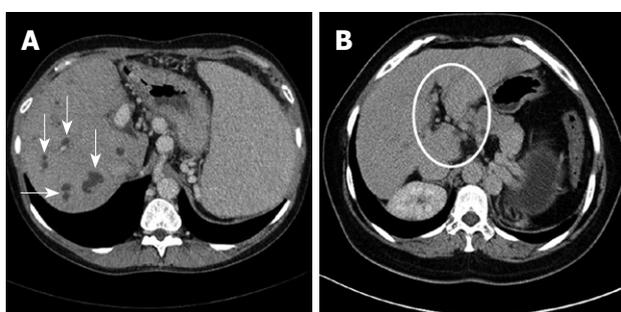

Magnetic resonance imaging (MRI), on the other hand, is an attractive alternative, especially since it does not involve the use of radiating energy. Magnetic resonance cholangiopancreatography (MRCP) allows for detailed and thorough evaluation of the biliary tree and renal abnormalities, where lesions that were missed by US may even be detected. Some authors advocate that with the advent of newer technologies like half-fourier-acquisition single-shot turbo spin-echo (HASTE) it may even be possible to quantify the extent of parenchymal fibrosis. Brain MRI is also essential to identify cerebellar malformations associated with disorders such as the Arima, Joubert and COACH syndromes (Figure 4).

### **Histopathological findings**

A unequivocal diagnosis of congenital hepatic fibrosis can only be made by a examination of a liver biopsy. The

**Figure 2** Ultrasound image of a patient with congenital hepatic fibrosis (CHF). Heterogenous appearance of hepatic parenchyma. The circled area depicts the presence of portal vein cavernous transformation.

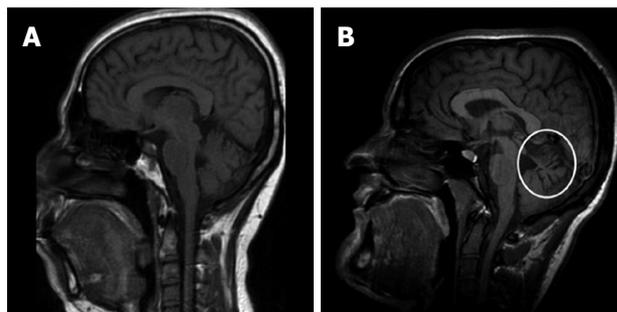

**Figure 3** Abdominal computerized tomography (CT) scans of two patients with CHF. A: White arrows depict cystic dilatations of the biliary tree associated with Caroli's syndrome; B: Circled area shows portal vein cavernous transformation in a patient with Bardet-Biedl syndrome.

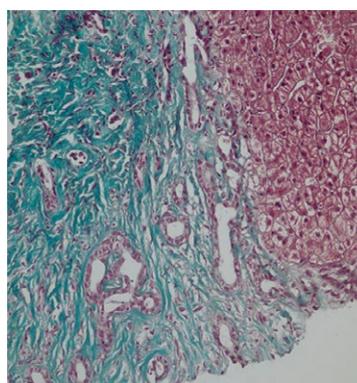

classical histological findings of this disorder are varying degrees of hepatic fibrosis with nodular formation, which may become extensive as the disease progresses. In the eyes of inexperienced pathologists, histopathological findings may easily be mistaken for cirrhosis. In CHF, widened fibrous bands may be encountered in the portal tract containing an increased number of irregularly shaped proliferating bile ducts lined by normal cuboidal epithelium. Unlike cirrhosis, hepatic lobules are usually normal with normal hepatocyte morphology, particularly in the early stages (Figure 5). Signs of cholestasis may be observed in the setting of associated cholangitis. Other findings include cystic dilatation of bile ducts (Caroli's disease), and hypoplasia of the portal vein branches in association with supernumerous hepatic artery branches. In fact, congenital absence of the portal vein has been reported in a pediatric patient with CHF<sup>[29]</sup>. Similarly, considering the close association of portal vein cavernous transformation with CHF, it has been postulated that such a portal vein anomaly may be a component of the disorder, rather than a consequence, since bile ducts and portal veins share embryonic origins<sup>[7]</sup>.

## TREATMENT

As yet, no treatment modality has been shown to actually stop or even reverse the pathological process in con-

**Figure 4** Brain magnetic resonance imaging (MRI) scans of two patients with congenital hepatic fibrosis. A: A patient with Bardet-Biedl syndrome with normal findings; B: The circled area depicts cerebellar vermis atrophy manifested by more prominent folds/sulci, associated with Joubert syndrome.

**Figure 5** Liver biopsy of a patient with CHF. The left side of the image depicts a portal area with extensive fibrosis and the presence of several bile ducts with cuboidal epithelium that have arrested at different stages of the maturation process. On the right, hepatocytes with normal morphology may be seen ( $\times 230$ , trichrome stain).

genital hepatic fibrosis, and it remains a progressive and debilitating condition. However, extensive research has been underway into the pathogenesis of fibrosis of the liver, particularly in the setting of chronic liver diseases, and some of the treatment options available may in fact be extended to CHF patients. Instead, for CHF, treatment is directed at the management of its complications.

### Anti-fibrotic therapy

Several agents have been studied, particularly in the setting of chronic liver disease. Although results have been promising, especially in animal studies, the clinical impact on humans has failed to live up to expectations. For example, colchicine is a plant alkaloid that inhibits polymerization of microtubules, and is believed to be antifibrotic, preventing collagen secretion and deposition. It had been shown to effectively inhibit collagen synthesis and fibrosis in experimental animal models, however almost all clinical trials, as well as several meta analyses, failed to show any benefits in humans, and current recommendations do not include colchicine as an antifibrotic agent<sup>[30]</sup>.

The angiotensin II system, on the other hand, represents an extremely attractive antifibrotic target, as overproduction of angiotensin II has been shown to stimulate stellate cell activation and fibrogenesis in the liver.

**Table 2** Several antifibrotic agents studied in the setting of hepatic fibrosis of different etiologies<sup>[33-43]</sup>

Authors	Antifibrotic agent studied	Patient group (n)	Dose used	Therapeutic efficacy
Kershenobich <i>et al</i> <sup>[33]</sup> , 1988	Colchicine	Cirrhosis - all causes (100)	0.6-1.8 mg/d	5-yr survival rates: colchicine 75%, placebo 34%; Histological improvement: colchicine 30%, placebo 0%
Pockros <i>et al</i> <sup>[34]</sup> , 2007	IFN- $\gamma$	Cirrhosis - HCV-related (488)	IFN- $\gamma$ 1b 100 mg and 200 mg	Histological improvement in select group with IFN-inducible T cell a chemoattractant (I-TAC),
Weng <i>et al</i> <sup>[35]</sup> , 2005	IFN- $\gamma$	Cirrhosis - HBV-related (99)	50 mg IFN- $\gamma$ intramuscularly on a daily basis for 3 mo	Histological improvement: treatment group 63%, control group 24.1%
Debernardi-Venon <i>et al</i> <sup>[36]</sup> , 2007	Angiotensin II receptor blockers (candesartan)	Cirrhosis - all causes (47)	8 mg/d	Has been shown to decrease hepatic venous pressure gradient in patients with cirrhotic portal hypertension; studies investigating histological improvement still underway
Neuschwander-Tetri <i>et al</i> <sup>[37]</sup> , 2003	PPAR ligands (rosiglitazone)	NASH associated fibrosis (30)	4-8 mg/d	Significant improvements in zone 3 perisinusoidal fibrosis
Armendáriz-Borunda <i>et al</i> <sup>[38]</sup> , 2006	Pirfenidone	HCV-related fibrosis (15)	1200 mg/d	Histological improvement in 30% of patients
Ferenci <i>et al</i> <sup>[39]</sup> , 1989	Silymarin	Cirrhosis - all causes (170)	140 mg three times daily	4-yr survival rate: silymarin 58%, placebo 39%; no histopathological studies available
Nelson <i>et al</i> <sup>[40]</sup> , 2003	Interleukin-10	HCV related fibrosis (30)	subcutaneously at a daily or thrice weekly dose of 8 pg/kg or a thrice weekly dose of 4 pg/kg	Significant improvements in histology
Poupon <i>et al</i> <sup>[41]</sup> , 2003	Ursodeoxycholic acid	PBC (367)	15-20 mg/kg per day	Significantly delayed progression of histopathological changes
Lieber <i>et al</i> <sup>[42,43]</sup> , 2003	Polyenyl-phosphatidylcholine	Chronic alcoholics (789)	1.5 g three times daily	No improvement in fibrosis; new study underway

HCV: hepatitis C virus; HBV: Hepatitis B virus; IFN- $\gamma$ : Interferon- $\gamma$ ; PPAR: Peroxisome proliferator-activated receptor; NASH: Non-alcoholic steatohepatitis; PBC: Primary biliary cirrhosis.

Angiotensin II may also play a role in the pathogenesis of portal hypertension, thus providing an added benefit to attempts inhibiting the system. The data in humans, however, has been mixed, with no conclusive evidence supporting the use of angiotensin receptor blockers for the prevention of liver fibrosis<sup>[30]</sup>.

Pirfenidone, another promising antifibrotic agent, whose mechanism of action is not clearly understood, was found to be useful in the management of idiopathic pulmonary fibrosis. Its benefit on liver fibrosis has yet to be sufficiently investigated. Other potential antifibrotic agents have been listed in Table 2<sup>[30]</sup>.

### Endoscopic therapy

Endoscopic treatment is the mainstay for primary and secondary prophylactic management of esophageal and gastric varices, as well as in the setting of acute bleeding. Similarly, for the management of recurrent cholangitis attacks associated with Caroli's syndrome, besides the use of antibiotics, drainage and stone extraction using endoscopic retrograde cholangiopancreatography (ERCP) may be indicated.

### Radiological intervention

Transjugular intrahepatic portosystemic shunts are considered for patients not amenable to sclerotherapy, and is particularly valuable in treating patients with refractory bleeding to buy time until liver transplantation.

### Surgery

Surgical shunts may also be indicated with the aim of portal decompression in patients with variceal bleeding not

satisfactorily managed endoscopically. Procedures of choice include nonselective total portosystemic shunts, nonselective partial portosystemic shunts that maintain some antegrade blood flow to the liver and selective portosystemic shunts, which decompress the gastroesophageal junction and the spleen through the splenic vein to the left renal vein. On the other hand, for Caroli's disease with recurrent bouts of cholangitis, partial liver resection may be indicated in case of extensive heterogenous involvement of a segment of the liver.

### Liver transplantation

Liver transplantation is the only known cure for CHF, and is indicated at the later stages of the disease, with the development of signs of liver failure. In Caroli's syndrome, frequent recurrence of cholangitis with diffuse involvement of the liver is also an indication for transplantation<sup>[9,10,31]</sup>. In 2008, Rossi *et al*<sup>[32]</sup> reported on three patients who had co-incidental hepatic failure due to CHF and end-stage renal failure as a result of polycystic kidney disease. All three underwent successful liver and kidney transplantation (1 simultaneous and 2 sequential) with excellent long term results.

## HACETTEPE EXPERIENCE

Throughout the 35 years between 1974-2009 in the history of the Department of Gastroenterology at Hacettepe University, Ankara, a total of 26 patients, 16 female and 10 male, with an average age of presentation of 28.4 years, have been diagnosed with congenital hepatic fibrosis. While up to the year 1985 only 3 patients were diagnosed,

the remaining 23 patients were diagnosed in the 1990s and particularly after the year 2000. This may be attributed to better recognition of the disorder by both clinicians and pathologists.

The most common presenting symptom was abdominal distention (11/26 - 42.3%) attributed to hepatosplenomegaly, with a history of recurrent cholangitis present in 6/26 (23%) of patients. In only two patients (7.7%) bleeding from esophageal varices was the presenting finding.

In 8/26 patients (31%) CHF was found to be in association with Caroli's disease (a combination otherwise known as Caroli syndrome). Incidentally, all patients who presented with signs of cholangitis suffered from Caroli's disease, where cholangitis is an expected manifestation. Joubert's syndrome with associated cerebellar vermis anomalies was diagnosed in 2 patients. In 2008, three siblings were referred to the department with common findings including mental retardation, blurred vision, nystagmus, truncal obesity, optic fundal and neurological abnormalities. Further investigation into the possible etiology of co-incident hepatosplenomegaly resulted in a diagnosis of CHF after liver biopsy. All three were diagnosed as suffering from Bardet Biedl syndrome.

All but three of the patients under follow-up in our department are alive and well. Two patients died after contracting cholangiocellular cancer, while the third patient with Caroli's disease who had undergone several endoscopic gall stone extraction procedures died of biliary sepsis in 2002. Three patients, all of whom had Caroli's syndrome, underwent successful liver transplantation.

## CONCLUSION

CHF is a very rare disorder usually occurring in association with other fibropolycystic disorders, including renal involvement. Thus, pure/isolated CHF is very rare. It is necessary to differentiate it from idiopathic portal hypertension and early liver cirrhosis. After a diagnosis of CHF is established, the physician must investigate other organ systems, particularly for neuromuscular or renal involvement. A liver biopsy is essential in the diagnosis and differential diagnosis of CHF, as the presence of small bile duct dilatation and proliferation would rule out other metabolic disorders of the liver.

### Abstract

It is essential in treating rectal cancer to have adequate preoperative imaging, as accurate staging can influence the management strategy, type of resection, and candidacy for neoadjuvant therapy. In the last twenty years, endorectal ultrasound (ERUS) has become the primary method for locoregional staging of rectal cancer. ERUS is the most accurate modality for assessing local depth of invasion of rectal carcinoma into the rectal wall layers (T stage). Lower accuracy for T2 tumors is commonly reported, which could lead to sonographic overstaging of T3 tumors following preoperative therapy. Unfortunately, ERUS is not as good for predicting nodal metastases as it is for tumor depth, which could be related to the unclear definition of nodal metastases. The use of multiple criteria might improve accuracy. Failure to evaluate nodal status could lead to inadequate surgical resection. ERUS can accurately distinguish early cancers from advanced ones, with a high detection rate of residual carcinoma in the rectal wall. ERUS is also useful for detection of local recurrence at the anastomosis site, which might require fine-needle aspiration of the tissue. Overstaging is more frequent than understaging, mostly due to inflammatory changes. Limitations of ERUS are operator and experience

dependency, limited tolerance of patients, and limited range of depth of the transducer. The ERUS technique requires a learning curve for orientation and identification of images and planes. With sufficient time and effort, quality and accuracy of the ERUS procedure could be improved.

### INTRODUCTION

Colorectal cancer is the most common gastrointestinal malignancy and the second most common cause of cancer-related deaths in Western countries<sup>[1]</sup>. Nearly 30% of these cancers arise in the rectum<sup>[2]</sup>. It is essential to determine prognostic factors in a patient before primary therapy is instituted. If examination has been delayed, it might be too late to influence the survival of a patient because of the lost opportunity to downstage the tumor before surgery. Primary surgery is no longer the only treatment due to recent advances in oncology and availability of therapeutic options. The potential advantages of preoperative treatment are to shrink the tumor size and thereby enhance the resectability rate

and facilitate sphincter-saving surgery, to reduce local recurrences, and possibly to improve long-term survival<sup>[3]</sup>. The prognosis of rectal cancer is closely related to several factors, including depth of tumoral invasion, number of metastatic lymph nodes, and involvement of the circumferential margin. Assessment of the cancer invasion through the bowel wall (T stage) remains the primary and most important factor in treatment of patients with rectal cancer<sup>[1-4]</sup>.

The TNM system for staging cancer of the colon and rectum to guide treatment and prognosis corresponds with the Dukes system: Stage I, Dukes A; stage II, Dukes B; and stage III, Dukes C. Stage IV corresponds to the presence of distant metastases<sup>[5]</sup>. Survival rates differ between T stages, and identifying poor prognostic groups within each stage has been the object of research. Early rectal cancers (T0) have a high, five-year survival rate of 95%. T3N0M0 and T4N0M0 lesions are stage II. Invasion of one or two lymph nodes but no distant metastasis (T1-4N1-2M0) with any T level represents stage III disease. Stage IV disease is the most severe, with distal metastasis (T1-4N1-2M1). The five-year survival rate for stage IV disease is poor (Table 1). There is a marked improvement in survival with early disease. A number of authors have shown a relationship between survival and the depth of extramural spread that is independent of other prognostic factors, including the circumferential margin status<sup>[6-8]</sup>.

The presence of lymph node (LN) involvement is important for the clinical decision, as early and locally advanced disease are managed differently. Endorectal ultrasound (ERUS) is a safe diagnostic method that allows both tumor invasion and lymph node metastatic involvement to be staged, and it contributes significantly to the selection of an adequate surgical strategy in patients with rectal cancer<sup>[7-9]</sup>.

Lesions confined to the wall may be resected by transanal excision or low anterior resection. Lesions involving, or in close proximity to, the anus might need abdominoperineal resection (APR). Patients with locoregionally-advanced lesions (extension onto the perirectal fat and/or perirectal or pelvic adenopathy) should be considered for neoadjuvant chemoradiotherapy. Neoadjuvant therapy has been shown to reduce local recurrence and permit an increased likelihood of a sphincter-sparing operation, with less toxicity compared with postoperative regimes. Thus, unlike more proximal colon cancers, the optimal method of management of rectal carcinoma is critically dependent on accurate preoperative staging of the disease<sup>[9,10]</sup>.

These therapeutic strategies appear to reduce local recurrence rates, increase sphincter-preserving surgeries, and possibly improve overall survival. Surgeries, and possibly improve overall survival. Therefore, staging of rectal cancer is important for selecting patients for adequate management prior to disturbing the tumor bed and potentially disseminating the disease. In daily practice we have been using newly developed and improved technologies that enable us to assess the extent of rectal cancer, which in turn influences choice of therapy. At

present, existing modalities for the preoperative staging of rectal cancer include computed tomography (CT); magnetic resonance imaging (MRI) with traditional body, endorectal, or phased-array coils; ERUS with rigid or flexible probes; and positron emission tomography (PET) with and without CT. The choice of modality is often influenced by local expertise and availability. This article reviews the current literature on the usefulness of ERUS in the staging of rectal cancer.

## ENDORECTAL SONOGRAPHY

Endorectal sonography was introduced to clinical practice in 1983 and has been successfully used in clinical practice for the evaluation of both the prostate and the rectum. In 1985, Hildebrant and Feifel introduced endorectal ultrasound as a means of staging rectal carcinoma<sup>[11]</sup>. In the last decade ERUS has become a widely accepted tool for staging of gastrointestinal cancers. Availability of ERUS in developing countries is limited, and there is a variation in availability and use of ERUS across Europe; the United Kingdom being the country in which ERUS is most widely used<sup>[12]</sup>. When ERUS is available, oncologists usually prefer to use it for staging of rectal cancer, which is the second most common cause of consultation with endosonographic examination indicated by surveyed oncologists. Most oncologists (89.5%) thought ERUS made an important impact on the management of patients with rectal cancer<sup>[13]</sup>.

Primary rectal adenocarcinoma is a common cause of a rectal mass on imaging. Other, less-common, lesions of the anorectum and perirectal tissues might resemble an adenocarcinoma. Transrectal sonography has proved to be a fast, safe, and accurate initial method for the staging of known rectal cancers or masses, although not for the screening of suspected rectum tumors, and is widely accepted as the diagnostic modality of first choice<sup>[14,15]</sup>. Imaging of the anorectum and perirectal tissues is technically challenging and can be difficult to interpret, as fecal material might be present, rectal lesions can be mobile or large, and general orientation is difficult<sup>[16]</sup>. The technique of transrectal sonography requires a learning curve for orientation and identification of ultrasound images and planes of rectal tumors. With sufficient effort, time, and meticulous technique, however, the rectum can be easily examined<sup>[15,16]</sup>.

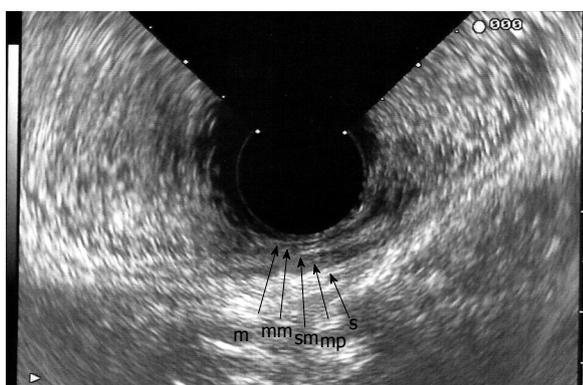

### Technique

To perform ERUS it is preferable to have an empty rectum, because fecal material can distort the images obtained. Laxative enemas are usually sufficient for rectal lesions, but standard colonoscopy preparation, even for rectal end sigmoid lesions, could optimize imaging so that it is free of artifacts. For endosonographic examination of proximal colonic lesions, such a preparation is a prerequisite. Pre-examination sigmoidoscopy should be routinely performed to ensure the lumen is clear of debris. The procedure is well tolerated and can be performed without sedation. Intraluminal rectal ultrasound examination of

**Table 1** Tumor stage on endorectal ultrasound to determine the management strategy, and corresponding survival rates<sup>[2,10]</sup>

Stage	T and N groups	Management	Five year survival
I	T 1-2, N0, M0	Snare polypectomy, EMR-	> 90%
II	T3 - 4, N0, M0	ESD, TAEX, LAR, APR	60%-85%
III	T1-4, N1, M0	LAR, RT followed by APR	25%-60%
IV	T1-4, N0-2, M1	RT-CT followed by APR	5%-7%

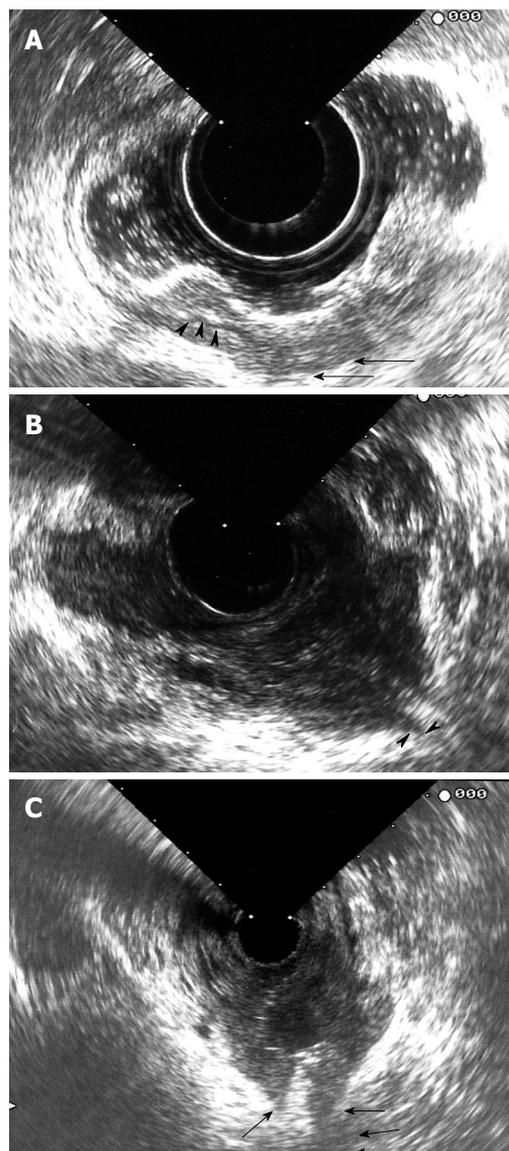

N0: No regional lymph node metastasis; N1: Metastasis in one to three regional lymph nodes; N2: Metastasis in four or more regional lymph nodes; EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; TAEX: Transanal excision; LAR: Low anterior resection; APR: Abdominoperineal resection; RT: Neoadjuvant radiotherapy; RT-CT: Neoadjuvant radiochemotherapy.

**Figure 1** Normal endorectal sonogram image acquired by flexible echoendoscope. The layers of the rectum are as follows: hyperechoic mucosa (m), hyperechoic muscularis mucosa (mm), hyperechoic submucosa (sm), hypoechoic muscularis propria (mp), and hyperechoic serosa (s).

rectal lesions can be done with a rigid probe or a flexible echoendoscope with a radial transducer. At our institution, we use a front-viewing upper echoendoscope, which can be advanced under direct vision to the level of the lesion. Linear echoendoscopes are normally used for fine-needle aspiration in case tissue sampling is needed, but could be used for routine ERUS<sup>[9]</sup>. For the purpose of this discussion, both techniques are considered as ERUS. Commonly, a dedicated blind rectal probe is used for ERUS. The probe is inserted and advanced into the rectum, where a water-filled balloon at the tip of the probe is inflated for evaluation of the rectum. High-frequency miniprobe are available and can be used with standard endoscopes to image the gastrointestinal wall and focal lesions under endoscopic vision. ERUS accurately visualizes the layers of the rectal wall and the precise localization of the layers of the rectal wall disrupted by the tumor, and the presence of perirectal lymph node metastases can be established<sup>[17]</sup>.

Endosonographically, the bowel wall is seen as five alternating hyper- and hypoechoic layers (Figure 1)<sup>[9,17-19]</sup>, as a result of differences in acoustic impedance, corresponding to histological layers. The first (hyperechoic) layer is the interface between the superficial mucosa and water or a water-filled balloon; the second (hypoechoic) layer represents the mucosa and muscularis mucosae; the

**Figure 2** Endorectal ultrasound (ERUS) image. A: A rectal carcinoma that appears to be T1 (penetration into submucosa) in one part (arrowheads show intact muscularis propria) and T2 (penetration into muscularis propria-arrows) in another part; B: A T3 rectal adenocarcinoma. Arrowheads show that the lesion penetrated into perirectal fat; C: A locally invasive cervical cancer, which invaded the rectum (arrows show tumor breach).

third (hyperechoic) layer denotes the submucosa and its interfaces; the fourth (hypoechoic) layer represents the muscularis propria; and the fifth (hyperechoic) layer is the interface between the serosa and perirectal fat.

Carcinomas are hypoechoic, and the degree to which they disrupt and penetrate the rectal wall layers suggests the local stage<sup>[4]</sup>. Ultrasonographic staging of tumor depth is denoted by the prefix “u”. The ultrasonographic staging corresponds to the TNM classification<sup>[5]</sup>. A uT1 tumor does not penetrate the muscularis propria. A uT2 tumor penetrates the muscularis propria (Figure 2A). A uT3 tumor proceeds beyond the muscularis propria, infiltrating the perirectal fat to a variable degree (Figure 2B). A uT4 tumor infiltrates surrounding organs<sup>[10,18]</sup>. As the tumor stage is advanced, a marked decrease in survival is

observed. ERUS, however, cannot reliably visualize the mesorectal fascia and thus cannot indicate whether the planned surgical circumferential resection margin will be successful<sup>[1-5]</sup>.

The sonographic criteria for identifying involved lymph nodes consist of size greater than 5 mm, mixed signal intensity, irregular margins, and spherical rather than ovoid or flat shape. ERUS can distinguish the different anatomic layers of the bowel, and thus it appears to have advantages over both CT and MRI in assessing mural penetration, and is invaluable in assessing patients considered for local resection<sup>[10,20]</sup>.

Indications for ERUS in rectal cancer are as follows<sup>[21]</sup>:

(1) to choose endoscopic mucosal resection or transanal excision in case of a large polyp or small rectal cancer (lesion is T1 by ERUS); (2) to determine whether preoperative chemotherapy and radiation is needed; and (3) surveillance after surgery for rectal cancer.

### T and LN staging

As outlined above, appropriate staging guides the treatment. Many other modalities, including CT and MRI of the abdomen, have been utilized to correctly determine the TNM stage. In 80 consecutive patients with newly diagnosed rectal cancer who were prospectively evaluated, Harewood *et al.*<sup>[22]</sup> reported T staging accuracy of 91%, compared to 71% for CT, and N staging accuracy of 82%, compared to 76% for CT.

The accuracy of ERUS for assessing local depth of invasion of rectal carcinoma (T stage) ranges from 80% to 95%, compared to 65%-75% for CT and 75%-85% for MRI<sup>[20]</sup>. ERUS has been demonstrated to be very accurate for staging superficial rectal tumors, with accuracy in evaluating tumor ingrowth into rectal wall layers ranging from 69% to 97%<sup>[23,24]</sup>.

A recent meta-analysis evaluating all ERUS studies from 1980 to 2008 showed that accuracy was high (88%-95%). The sensitivity and specificity of ERUS to diagnose stage T1 cancer were 87.8% and 98.3%, respectively. For stage T2, ERUS had a sensitivity and specificity of 80.5% and 95.6%, respectively. For stage T3, ERUS had a sensitivity and specificity of 96.4% and 90.6%, respectively. In diagnosing stage T4 cancer, ERUS had a sensitivity of 95.4% and specificity of 98.3%<sup>[25]</sup>. One common finding is a lower accuracy for T2 tumors. Several reasons have been suggested, including the difficulty in distinguishing those tumors that have deep invasion into the muscularis propria from those with microscopic invasion into the perirectal fat. This could raise problems with sonographic T3 cancers that have been overstaged, because there is an increased tendency to give preoperative radiotherapy to T3 cancers.

Zorcolo *et al.*<sup>[26]</sup> evaluated the accuracy of ERUS for the distinction of early *vs* advanced rectal lesions before transanal endoscopic microsurgery and they found ERUS differentiated early and advanced rectal lesions with 96% sensitivity, 85% specificity, and 94% accuracy. Similarly, another retrospective series reached 89.2% accuracy for staging of early rectal carcinomas<sup>[27]</sup>.

ERUS is also helpful in determining the presence of residual cancer in the rectal wall. A retrospective series with 63 patients showed the presence of residual cancer in patients who underwent surgery ( $n = 30$ ) with 54% accuracy. Authors stated that ERUS was more useful than morphological or histological criteria for determining residual cancer<sup>[28]</sup>.

Transanal endoscopic microsurgery (TEM) and endoscopic submucosal dissections have been becoming more popular because of they offer function-preserving resections. An important problem that has arisen in this setting is the assessment of the tumor breach to the submucosa, which changes the mode of surgery. Other imaging modalities are known to be poor at staging in early cancers. According to a prospective study involving 156 patients, of whom 62 underwent TEM, no understaging was observed with an accuracy of 95%, and only 5% were overstaged. ERUS is accurate at predicting early disease<sup>[29]</sup>.

ERUS was useful in detecting cancer recurrence at the anastomosis site. This often requires serial examination to differentiate postoperative scars from local recurrences. In sonographically equivocal cases, tissue characterization and sampling *via* FNA make ERUS very accurate; although the surveillance period was not assessed, a recommendation was made of every 3-6 mo during the first two years after low anterior resection<sup>[20]</sup>.

Assessment for nodal metastases is less accurate than that for tumor depth. According to a recent meta-analysis of 35 studies by Puli *et al.*<sup>[30]</sup>, which involved more than 2700 patients, the sensitivity of ERUS in diagnosing nodal involvement in rectal cancer was 73.2% and it had a specificity of 75.8%.

Discrepancies in accuracies could be partly due to the variable criteria used for defining nodal metastases. For rectal cancer in particular, over half of the metastatic nodes secondary to rectal cancer are  $\leq 5$  mm and are located within 3 cm of the primary tumor<sup>[31]</sup>. In a large trial, lymph node metastatic disease was shown to predict local recurrence. There is a wide variation in accuracy for metastatic nodal detection with ERUS (62%-87%), CT (22%-73%), and MRI (39%-95%)<sup>[32]</sup>. ERUS criteria are a lack of ovoid morphology and central echogenic nidus, but its limited field of view is a major limitation<sup>[4]</sup>. Data from pooled analyses, as well as from recent smaller studies, reveal that the sensitivity of ERUS in detecting LN metastasis ranges from 50% to 83%, which is comparable with that of MRI (sensitivity 45% to 79%)<sup>[9,10]</sup>. Assessment of nodal metastases is difficult because most small lymph nodes are not easily observed with ERUS, and 18% of lymph nodes less than 5 mm harbor metastases<sup>[17]</sup>. More recent studies suggest that multiple criteria should be used to improve accuracy. Gleeson *et al.*<sup>[20]</sup> conducted a study with ERUS guided FNA to identify nodal echo characteristics and size for prediction of malign infiltration, and to determine if any combination of standard nodal criteria had sufficient predictive value to preclude FNA. Nodal hypoechogenicity and short axis  $\geq 5$  mm were independent factors for malignancy. If all four

malignant nodal echo features of node were present, it distinguished the malignant from the benign node. These US features were node size, echogenicity, shape, and the border. A long axis length greater than 9 mm was 95% specific for the presence of malignancy.

Accuracies of ERUS might vary with different tumor stages. Overstaging is more frequent than understaging. As with MRI, overstaged T2 lesions are the most common causes of inaccuracy. ERUS cannot reliably or precisely differentiate an irregular outer rectal wall due to peritumoral inflammation or real transmural tumor extension<sup>[7-9,33]</sup>. Staging of the stenotic lesions might also be difficult; they are probably suboptimally staged because of the inability of the probe to traverse the lesion. This problem is greater with rigid probes. Flexible probes have the ability to evaluate the iliac region for adenopathy, which is clinically important because these nodes are retained in standard resection with total mesorectal excision. In one study, up to 28% of lymph node-positive distal tumors showed iliac adenopathy, with 6% of patients having only iliac adenopathy. Thus, failure to evaluate this region could lead to inadequate surgical margins in up to 6% of patients with low rectal lesions. Lymph nodes > 5 mm in size have a 50% to 70% chance of being malignant compared with only 20% of nodes < 4 mm. ERUS-guided FNA allows confirmation of malignancy in suspicious nodes during the same examination, as long as the primary tumor does not lie in the path of the needle<sup>[33]</sup>.

Preoperative chemoradiation is a main reason for lower staging accuracy rate. Napoleon *et al.*<sup>[34]</sup> found a variation in the accuracy of T staging from 86% (in patients referred directly to surgery) to 46% (in patients after neoadjuvant radiation therapy).

Overstaging is mainly caused by inflammatory and associated reactive changes in the rectum wall after preoperative radiotherapy. They are presented as hypo-echoic lesions and can be confused with carcinoma. However, radiotherapy affects the wall thickness but does not change the five-layered image. In one particular study, comparison of postradiation ERUS correlated with histopathology findings revealed that ultrasound was actually assessing the fibrosis that had replaced the tumor; therefore, after radiotherapy, what is staged by ERUS is no longer the tumor but the extent of fibrosis in the rectal wall. A histopathological examination showed that the residual tumor, when present, was always within the fibrosis, never outside or separate from it<sup>[33,35]</sup>.

In general, ERUS is better at detecting lymph nodes in the distal and middle thirds of the rectum<sup>[21,33]</sup>. The overstaging of lymph node status is primarily caused by the presence of reactive swollen lymph nodes that could be considered as malignant. The small blood vessels, urethra, and seminal vesicle are known to be mistaken for metastatic lymph nodes. Blood vessels can simulate malignant nodes, but they can be differentiated by moving the transducer to outline the linear or branching course of the vessel and by power Doppler. The main reasons for nodal status understaging are difficulty in

detecting very small involved nodes (less than 2 mm) and nodes outside the perirectal tissue<sup>[21,33]</sup>.

The three-dimensional reconstruction is also thought to improve visualization of subtle protrusions of tumors infiltrating into adjacent tissues and organs, allowing for improved T and N staging. A study of 25 patients undergoing three-dimensional ERUS, two-dimensional ERUS, and MRI showed no significant difference in T- or N-stage accuracy, but it was thought that MRI and three-dimensional ERUS improved understanding of the spatial relationship of the tumor due to their ability to obtain multiplanar images<sup>[36]</sup>.

The limitations of ERUS are that it is heavily operator dependent; it has poor patient acceptability; it has limited depth of penetration; it cannot be performed in stenotic tumors<sup>[16,21]</sup>; and it is unable to visualize tumors located in the upper rectum with a rigid probe, detect lymph nodes outside the range of the transducer, or visualize mesorectal fascia because of its limited field of view. In addition, accuracy is affected by postbiopsy peritumoral inflammation, hemorrhage, and villous or pedunculated tumors<sup>[22,31]</sup>. Overstaging of tumor depth frequently occurs as a result of paraneoplastic inflammation, as ultrasound cannot clearly differentiate between inflammatory and neoplastic tissue<sup>[22,31]</sup>.

Several authors suggest that obstructive tumors interfere with accurate staging. In such tumors, inadequate probe contact perpendicular to the tumor makes it more likely to be mis-staged. Some authors reported better accuracy rates for high compared to low rectal tumors, while others found the opposite<sup>[32]</sup>.

The tumor margin cannot be assessed accurately, which in turn causes mis-staging, because of inadequate bowel preparation and bulky tumors that lie outside the focal length of the transducer.

There is a learning curve with operator variability<sup>[33]</sup>. Badger *et al.*<sup>[37]</sup> found that experience does not affect the T and N staging accuracy, suggesting that there was no learning curve. Others supported the effect of experience and appropriate training for accurate staging<sup>[38]</sup>. Inexperience has been cited as contributing to many of the poor accuracies in tumor depth infiltration<sup>[17]</sup>.

Orrom *et al.*<sup>[39]</sup> reported an increase in diagnostic accuracy of ultrasound from 59.3% to 95% over a period of three years when ERUS was performed by several operators and a single skilled operator performed the later exams. More time and meticulous training are required for improvements in the accuracy of ERUS, a statement supported by different studies showing a progress from 50% to over 90%<sup>[39-42]</sup>. It has also been suggested that centralization of ERUS could provide more caseloads to experienced operators and result in a high-quality service<sup>[41]</sup>.

Studies suggest a learning curve of up to 50 cases for tumor depth and more than 75 cases for accurate node status assessments<sup>[41]</sup>. Interpretation is often more difficult after a partial excision or neoadjuvant chemoradiation, which can result in a hematoma or local inflammation with obliteration of sonographic layers of the rectal wall.

Presence of inflammatory changes, desmoplastic changes, and hypervascularity could lead to overstaging because the echogenicity of tumors is similar to that of muscularis propria and inflammatory infiltrate<sup>[42]</sup>.

## OTHER MALIGNANCIES OF THE RECTUM

Transrectal sonography is useful to differentiate extramural lesions, extrinsic compression, vascular lesions, and solid tumors. Other types of malignancies resembling rectal adenocarcinoma include neuroendocrine tumors, which usually manifest as small, mobile, submucosal nodules or focal areas of submucosal thickening, and primary squamous cell carcinomas, which seem to be frequently locally invasive and involve regional lymphatic vessels. Lymphomas are rare, and can be a primary lesion or a secondary infiltration of the large intestine, which characteristically involves the deeper layers of the intestinal wall. Anorectal melanoma is another rare rectal tumor. Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor that originates in the alimentary tract, but it rarely involves the anorectal region. The tissue of origin is the muscle layer of the bowel wall, and the size can be variable. On sonography, a GIST appears as a hypoechoic mass<sup>[15]</sup>. ERUS is also helpful for determining local invasion of the rectum by other pelvic malignancies (Figure 2C).

## CONCLUSION

ERUS is a safe and accurate technique for the local staging of rectal carcinoma with reported high accuracy rates for T and N staging. Although availability is limited, it has been implemented into clinical practice in clinical decision making regarding treatment modality. A growing body of expertise has confirmed the clinical impact. ERUS is also helpful in assessing recurrence of rectal cancer and evaluation of subepithelial masses. Technological improvements in ultrasound might improve accuracy and reduce the overstaging problem.

### Abstract

*Capillaria hepatica* (*C. hepatica*) is a parasitic nematode causing hepatic capillariasis in numerous mammals. Ecologic studies showed that the first hosts of *C. hepatica* were rodents, among which rats had relatively high infection rates, which explains why *C. hepatica* spreads globally. Anatomical studies showed that the liver was the principal site of colonization by these parasites and physical damage tended to occur. Although *C. hepatica* might lead to serious liver disorders, relevant clinical reports were rare, because of the non-specific nature of clinical symptoms, leading to misdiagnosis. This review mainly focuses on the biological characteristics and epidemiology of *C. hepatica* in China and histopathologic changes in the liver, with expectation of gaining a better understanding of the disease and seeking more effective treatment.

### INTRODUCTION

*Capillaria hepatica* (*C. hepatica*) is a nematode parasite of wild rodents and other mammals and has worldwide distribution<sup>[1-8]</sup>. Adult worms colonize the liver of the host<sup>[6,9-11]</sup>. They can cause hepatic capillariasis, a serious liver disorder, which may be found both in humans and animals<sup>[11-14]</sup>. These parasites could be accidentally transmitted to humans by ingestion of embryonated eggs. Up to the year 2000, 37 cases of human infections had been documented<sup>[15]</sup>. However, there are few reports of the pathology of the infection, which results in serious effects in subjects because of the special anatomic area in which *C. hepatica* congregates. Clinical symptoms of hepatic capillariasis were non-specific with manifestations of persistent fever, hepatomegaly, eosinophilia and, more seriously, death.

### MORPHOLOGY AND BIOLOGICAL FEATURES

#### Morphology

A typical adult *C. hepatica* takes the shape of a slender nematode, with the anterior part of the body narrow, and the posterior part gradually swelling. The females measure about 53-78 mm × 0.11-0.20 mm, but males are approximately 24-37 mm × 0.07-0.10 mm. The esophagus is long, occupying half of the body of the female and a third of the male body. The cauda of *C. hepatica* bears a copulatory spicule and sheath. The eggs of *C. hepatica* resemble those of *Trichuris trichiura*, but differ in size. The *C. hepatica* egg is about 48-66 μm × 28-36 μm, and numerous micropores can be seen in the outer shell<sup>[16]</sup>.

#### Biological features

*C. hepatica* parasites live in liver parenchyma, where they

Tung et al <sup>[38]</sup>	2009	Taichung	Various species of rodents	49.50

become biologically mature, then lay eggs in this site. Eggs are immature when produced in the first 4 wk, and these eggs will develop into larvae under favorable conditions of appropriate temperature and moisture. When embryonated, eggs can be ingested by a predator, their larvae then hatch and invade the intestinal mucosa, transporting themselves *via* the mesenteric vein and portal vein to the liver. The first ecdysis takes place 3–4 d after their arrival in the liver, followed by the second, third (5–7 d) and fourth (9–16 d) larval stages. In the fourth stage, sexual differentiation starts. After sexual differentiation (male, 18 d; female, 20 d), they will experience their final ecdysis and become fifth-stage larvae. The life-span of the female lasts about 59 d, with 40 d for males<sup>[17]</sup>. It is worthy of note that eggs produced by females in the liver are metabolically active for a prolonged period of time, but remain immature. The host which has ingested these immature eggs displays a “spurious infection”. In contrast, “true infection” occurs when the host ingests embryonated eggs, which will result in the production of larvae that can invade the intestine wall and lead to hepatica capillariasis.

## EPIDEMIOLOGY IN CHINA

### *Epidemiology in the human population*

Reports of the 37 cases of hepatica capillariasis indicate they were scattered predominantly in Japan, India, America, Canada, Brazil, Germany, Italy, Korea and Czechoslovakia<sup>[15,18–26]</sup>. While only 3 cases of “true infection” had been confirmed in China<sup>[27–29]</sup>, those few cases found in China do not necessarily encompass the overall actual morbidity, as the final diagnosis would have to rely on biopsy or necropsy<sup>[30,31]</sup>, so both the rate of misdiagnosis and missed diagnosis could be higher. Table 1 shows the 3 cases with detailed clinical symptoms.

### *Epidemiology in the animal population*

The chief hosts of *C. hepatica* are various rodents, including more than 70 species, and the principal hosts include *Tamias striatus*, squirrel, mole, shrew, opossum, weasel and skunk<sup>[32]</sup>. In mainland China, the total infection rate of hepatica capillariasis in rodent species ranges widely. Table 2 highlights the infection rate in distinct areas with different rodent species<sup>[33–41]</sup>.

## PATHOLOGY OF HEPATICA CAPILLARIASIS

*C. hepatica* primarily invade the sinus hepaticus, where they experience maturation and egg-laying. Both the worms and their eggs cause focal chronic inflammation in the liver, and around these worms and eggs appear diverse inflammatory cells, including macrophages, eosinophils, and some multinucleate giant cells. Inflammatory infiltration may persist until the final formation of encapsulation or calcification of dead worms. After the focal parasitic necroinflammatory lesions, septal fibrosis occurs. Although the pathological course of the formation of fibrosis has not been well established, it was speculated that the slow and continuous release of disintegrated products from encapsulated parasitic lesions activated the Kupffer cells, which then promoted the development of fibrosis in the liver<sup>[42]</sup>. Whether there is a relationship between the focal parasitic hepatic lesions and septal fibrosis remain to be resolved. In the experiment of Gomes *et al.*<sup>[12]</sup>, rats were first infected with 600 embryonated eggs, and then injected with a corticoid and *C. hepatica* antigen. After treatment, focal inflammation ceased, but there was no evident alteration in the formation of septal fibrosis. These findings indicated that, although focal lesions and septal fibrosis were both caused by *C. hepatica* infection, they played different roles in the pathological course of the infection. Further studies should be conducted to explore the pathological course of hepatic fibrosis.

## DIAGNOSIS

Hepatica capillariasis is an exceptionally rare infection in humans with non-specific clinical manifestations, and frequent misdiagnoses have been made<sup>[43]</sup>. More importantly, the main difficulties interfering with correct diagnosis were related to the unique biological characteristics of the parasite. Apart from those cases of “spurious infection”, both worms and eggs could not be detected in the peripheral blood and stools of infected hosts, so routine laboratory tests of blood and stools invariably showed negative results. Although liver biopsy was a precise and quick method in confirming *C. hepatica* infection, it was not the most appropriate one, as biopsy was a traumatic diagnostic approach. With introduction of immuno-techniques, the detection of *C. hepatica* became more convenient and efficient. Assis and colleagues<sup>[12]</sup> employed an indirect immunofluorescence test to diagnose hepatica capillariasis successfully. Huang *et al.*<sup>[44]</sup> developed a diagnostic test for experimental rat hepatica capillariasis using an enzyme-linked immunosorbent assay, with high sensitivity and specificity, which was specific for *C. hepatica* infection. The tests described above have been considered practical, reliable and sensitive. A sensitive immunological test is useful for particular clinical situations, but it is essential to take account of the epidemiological surveys in local areas, which may help lead to a more comprehensive diagnosis.

The differential diagnosis should include accidental tissue infection by nematodes, including *Toxocara cati*, *Toxocara canis*, *Fasciola hepatica*, and *Schistosoma japonicum*, hepatitis B virus, hepatitis C virus and visceral larva migrants<sup>[45-48]</sup>.

## TREATMENT

Pereira *et al.*<sup>[30]</sup> reported a case of hepatica capillariasis in Brazil where the male subject with massive *C. hepatica* infection survived after treatment with prednisone, disophenol, and pyrantel tartrate. Thanks to marked eosinophilia in the peripheral blood and hepatic lesions, the patient underwent initial therapy with prednisone (60 mg/d) for a session of 10 d and sequential maintenance by 10 mg every other 10 d. To kill the parasites, or at least to prevent the production of eggs, the patient was treated with disophenol (2-6-diiodo-4-nitrophenol) intramuscularly in a single dose of 7.5 mg/kg body weight and with pyrantel tartrate orally in a single dose of 30 mg/kg body weight. Three years after the treatment, a needle biopsy of the liver, showed sparse portal fibrosis but it was otherwise normal, and the patient remained well during an 8-year follow-up. Also, medication with albendazole was generally effective<sup>[31]</sup>.

Other than chemical treatment, partial hepatectomy or some distinct surgical intervention proved therapeutically effective in animal experiments in rats. The results revealed morphologically that the fibrosis was unaffected, but its relative quantity within the microscopic field appeared significantly decreased, as a consequence of the increased liver tissue mass following regeneration<sup>[49]</sup>.

## RESEARCH ACHIEVEMENTS

While prevalence of *C. hepatica* is dominant in rodents, other mammalian species showed slight resistance to this infection even in laboratory conditions. Yang *et al.*<sup>[50]</sup> examined the predisposition to *C. hepatica* between rats and cats by injecting each animal with embryonated eggs at high density. The long-term investigation revealed that every rat became infected with *C. hepatica*, while, as was expected, the liver biopsy from cats showed negative results. To further confirm whether there were some differences between rats and mice in the course of the formation of hepatic fibrosis, Andrade *et al.*<sup>[13]</sup> infected both rats and mice with embryonated eggs, and he found that, although rats and mice both had the same pathological changes in the first stage, there were distinct features in the development of hepatic fibrosis. Researching into the immunological mechanisms of hepatica capillariasis, Kim *et al.*<sup>[51]</sup> measured cytokine mRNA expression in mice spleen cells and mesenteric lymph node cells. In the earlier stages, expression of T-helper, Th1 and Th2, cells were at a high level, as well as the expression of immunoglobulin G1 and G2. Expression in functional cells in the spleen was relatively higher than in mesenteric lymph node cells, which indicated that the spleen was the main location of the

response to the infection rather than the mesenteric lymph node. With the density of egg production, expression of interferon- $\gamma$  became stronger, suggesting that it had significant importance in the defense against infection.

## CONCLUSION

*C. hepatica* can cause a serious liver disorder in its hosts including humans and animals. More simple and accurate diagnostic methods and more effective treatment measures need to be further developed. A better understanding of *C. hepatica* and hepatic capillariasis would help humans to better combat the disease.

### **Abstract**

**AIM:** To investigate the therapeutic effect of *Schistosoma mansoni* (*S. mansoni*) soluble worm proteins on gastrointestinal motility disturbances during experimental colitis in mice.

**METHODS:** Colitis was induced by intrarectal injection of trinitrobenzene sulphate (TNBS) and 6 h later, mice were treated ip with *S. mansoni* proteins. Experiments were performed 5 d after TNBS injection. Inflammation

was quantified using validated inflammation parameters. Gastric emptying and geometric center were measured to assess *in vivo* gastrointestinal motility. Peristaltic activity of distal colonic segments was studied *in vitro* using a modified Trendelenburg set-up. Cytokine profiles of T-lymphocytes isolated from the colon were determined by real time reverse transcriptase-polymerase chain reaction.

**RESULTS:** Intracolonic injection of TNBS caused severe colitis. Treatment with *S. mansoni* proteins significantly ameliorated colonic inflammation after 5 d. TNBS did not affect gastric emptying but significantly decreased the geometric center and impaired colonic peristaltic activity 5 d after the induction of colitis. Treatment with *S. mansoni* proteins ameliorated these *in vivo* and *in vitro* motility disturbances. In addition, TNBS injection caused a downregulation of effector T cell cytokines after 5 d, whereas a *S. mansoni* protein effect was no longer observed at this time point.

**CONCLUSION:** Treatment with *S. mansoni* proteins attenuated intestinal inflammation and ameliorated motility disturbances during murine experimental colitis.

## INTRODUCTION

Crohn's disease and ulcerative colitis, the two most common forms of inflammatory bowel diseases (IBD), are idiopathic inflammatory disorders of the intestine. The current hypothesis states that IBD results from an uncontrolled immune response against intraluminal bacterial antigens in genetically predisposed individuals<sup>[1,2]</sup>. Genetic factors as well as environmental factors contribute to the development of the inappropriate immune response<sup>[3]</sup>.

The incidence of Crohn's disease is highest in well-developed countries<sup>[4]</sup>. According to the hygiene hypothesis, this is directly related to the higher hygienic standards in these countries<sup>[5]</sup>. It is suggested that the lack of exposure to intestinal parasites (e.g. helminths) contributes to the susceptibility to Crohn's disease<sup>[6-8]</sup>. Several experimental and clinical studies showed the beneficial effect of helminth infections in IBD<sup>[9-12]</sup>. Current research is focusing on identifying helminth molecules with immunomodulatory function that exert this protective effect<sup>[13]</sup>.

Patients with Crohn's disease often suffer from disturbed gastrointestinal motility leading to symptoms such as abdominal pain, cramps, diarrhea, weight loss, rectal bleeding and malnutrition<sup>[14,15]</sup>. It is well established that inflammation of the gut results in functional and structural changes of the enteric nervous system<sup>[16,17]</sup> and changes in smooth muscle contractility<sup>[18,19]</sup>. For instance, patients with ulcerative colitis have increased propagating contractions with lower peak amplitudes coupled with variable transit<sup>[20]</sup>, whereas delayed gastric emptying and prolongation of orocecal transit time have been reported in patients with Crohn's disease<sup>[21-23]</sup>. Dysmotility can also occur in non-inflamed sites of the gastrointestinal tract. Gastroparesis often occurs in patients with inflammation restricted to the small or large intestine<sup>[14,24]</sup>. Motility disturbances may also persist in the period following an episode of gastrointestinal inflammation, resulting in the development of irritable bowel syndrome or functional dyspepsia<sup>[14,25]</sup>.

The aim of this study was to investigate the therapeutic potential of *Schistosoma mansoni* (*S. mansoni*) soluble worm proteins (SmSWP) on gastrointestinal motility disturbances 5 d after induction of experimental colitis in mice both *in vivo* and *in vitro*. In addition, the inflammatory reaction was quantified and the balance between different T cell subsets was investigated based on their cytokine profile to elucidate the underlying immunological pathways.

## MATERIALS AND METHODS

### TNBS-induced colitis

Colitis was induced by intraluminal injection of 2,4,6-

trinitrobenzene sulfonic acid (TNBS) as previously described<sup>[26]</sup>. Briefly, male Swiss mice (weight 26-28 g, Charles River, France) were fasted for 24 h and subsequently anesthetized by ketamine (90 mg/kg, ip) and xylazine (10 mg/kg, ip). Next, 100  $\mu$ L of a 10 mg TNBS in 30% ethanol solution was injected intrarectally. Ethanol is required to break the intestinal epithelial barrier, whereas TNBS is a haptening agent that immunogenizes autologous proteins. Control animals received an intrarectal injection of 100  $\mu$ L saline. Afterwards, mice were held upside-down for 1 min to prevent leakage of TNBS solution. The Medical Ethical Committee on animal experimentation of the University of Antwerp, Belgium, approved all experiments.

### Preparation of antigen mixtures

SmSWP were prepared as described previously<sup>[27]</sup>. Briefly, *S. mansoni* adult worms were recovered from mice (housed at the Queensland Institute of Medical Research, Brisbane, Australia), washed and homogenized in PBS and soluble proteins were extracted by centrifugation. Mice were treated with 25  $\mu$ g SmSWP ip. Proteins were diluted to a final volume of 100  $\mu$ L in PBS. Control animals were injected ip with 100  $\mu$ L PBS.

### Experimental protocol

In a previous study we investigated the time course of inflammation during TNBS colitis and found that inflammation peaked at day 3 and that colitis was self-limiting with near complete remission after 1 wk. In the present study, we wanted to evaluate the effect of helminth protein treatment after the peak of inflammation but when overt signs of colitis were still present.

In a first set of experiments, we scored the therapeutic effect of SmSWP on colonic inflammation 5 d after the induction of colitis. Six hours after TNBS injection, mice were treated once ip with 25  $\mu$ g *S. mansoni* proteins or phosphate-buffered saline (PBS). Five days later, mice were sacrificed and inflammation was scored based on 5 parameters: clinical disease activity, macroscopic and microscopic inflammation score, extent of colonic inflammation and myeloperoxidase activity. Two different groups were studied: TNBS mice treated with PBS (TNBS-PBS) after 5 d and TNBS mice treated with 25  $\mu$ g SmSWP (TNBS-SmSWP) after 5 d ( $n = 8-10$  in each group).

In a second set of experiments, we investigated the effect of SmSWP treatment on *in vivo* gastrointestinal motility and *in vitro* colonic peristalsis 5 d after induction of colitis. Four different groups were studied: control-PBS mice, control mice treated with 25  $\mu$ g SmSWP (control-SmSWP), TNBS-PBS mice and TNBS-SmSWP mice ( $n = 7-10$  in each group). In preliminary experiments we also investigated the effect of colitis on gastrointestinal motility disturbances 3 d after the induction of colitis, and the effect of SmSWP treatment as these experiments were not performed previously.

In a third set of experiments, we investigated the

cytokine profile of colonic T cells 5 d after induction of colitis. Cytokine profiles were studied in 4 different groups: control-PBS, control-SmSWP, TNBS-PBS, TNBS-SmSWP ( $n = 5-8$  in each group, for each  $n$ , colonic tissue of 3 mice was pooled).

### Inflammatory scores

Briefly, the clinical disease score (0-8) was based on the following characteristic parameters (0-2 score each): weight loss, piloerection, immobility and blepharitis<sup>[27]</sup>.

After sacrifice, the colon was removed and opened to score colonic damage macroscopically. Four parameters were taken into account: presence of adhesions, degree of colonic ulcerations, wall thickness, and degree of mucosal edema. The total score ranged from 0 to 12<sup>[28]</sup>. The extent of inflammation in the colon was also measured and expressed in cm. Tissue samples were harvested for histological assessment of the inflammatory infiltrate and for myeloperoxidase (MPO) assay. Colonic segments were fixed in 4% formaldehyde and embedded in paraffin for hematoxylin-eosin staining. Microscopic inflammation score ranged from 0 to 10 based on the following parameters: inflammatory infiltrate, number of gut wall layers infiltrated, loss of mucosal architecture, and edema<sup>[27]</sup>. MPO activity was measured to monitor the degree of myeloid cell infiltration in the colon. Colonic MPO activity was assayed according to published methods<sup>[29]</sup> and expressed as units MPO per gram tissue.

### In vivo measurement of gastrointestinal motility: Evans blue technique

Mice were fasted for 18 h and *in vivo* semi-liquid meal motility was assessed according to published methods<sup>[30]</sup>. Briefly, mice received an intragastric injection of 0.1 mL Evans blue (50 mg/mL + 0.5% methylcellulose) *via* an orogastric cannula. Fifteen minutes later, mice were anesthetized and a laparotomy was performed. The stomach and small intestine were resected and the small intestine was divided into 5 segments of equal length. The amount of Evans blue in the segments was measured spectrophotometrically to assess gastric emptying (GE) and geometric center (GC):  $\%GE = [\Sigma A_{565} (\text{intestine 1-5}) / \Sigma A_{565} (\text{stomach} + \text{intestine 1-5})] \times 100$ ;  $GC = \Sigma (A_{565} \text{ of Evans blue per segment} \times \text{segment number}) / \text{total } A_{565}$ .

### In vivo measurement of gastrointestinal motility: Solid beads technique

Mice were fasted for 18 h and *in vivo* solid meal motility was assessed as previously described<sup>[31]</sup>. Mice received an intragastric gavage of 25 green glass beads (0.4-0.5 mm in diameter) together with 0.5 mL H<sub>2</sub>O solution *via* an orogastric cannula and were transferred to a wired bottom cage to prevent coprophagy<sup>[32]</sup>. Subsequently, 30, 120 and 360 min after gavage, mice were anesthetized, the gastrointestinal tract was resected and divided into

different segments: stomach, 5 small intestinal segments, cecum, 2 colonic segments and feces. The number of beads in each segment was counted under a stereomicroscope and GE and GC were calculated by the following equations:  $\%GE = [\text{number of beads (small intestine 1-5} + \text{cecum} + \text{colon 1-2} + \text{feces}) / \text{total number of beads}] \times 100$ ;  $GC = \Sigma (\text{beads per segment} \times \text{segment number}) / \text{total number of beads}$ .

### In vitro evaluation of colonic peristaltic activity

Assessment of colonic peristalsis was performed as previously described<sup>[31]</sup>. Briefly, mice were anesthetized, the colon was removed, flushed and put in cold aerated Krebs-ringer solution. The distal colon segment (3 cm in length) was mounted horizontally in an organ bath. For each segment, the oral end was connected to a perfusion pump for intraluminal infusion of Krebs solution and the other end was attached to a pressure transducer and a vertical tube of which the outlet could be raised in height. After 30 min of equilibration, the outlet was increased from 0 to 7.5 cm. Under these circumstances, spontaneous peristaltic contractions occurred. This activity was associated with regular pressure increases which were recorded by the pressure transducer and analyzed by a data-acquisition system (CED 1401, Cambridge Electronic Design, Cambridge, UK). After an equilibration period of 20 min, the mean amplitude (cmH<sub>2</sub>O) of 3 consecutive peristaltic contractions as well as the mean time interval(s) between 4 subsequent peristaltic contractions were calculated and compared.

### Investigation of T cell cytokine profiles

Colonic lamina propria mononuclear cells were isolated based on a 30%:70% gradient Percoll column as previously described<sup>[27,33]</sup>. Colonic lamina propria T cells were subsequently isolated by positive selection using the EasySep enrichment procedure employing antibody-coated, magnetic particles as described by the manufacturer (Stem Cell Technologies, Vancouver, Canada). Total RNA was extracted from isolated colonic T cells by using the Absolutely RNA microprep kit as described by the manufacturer (Stratagene, La Jolla, CA, USA).

Using real time reverse transcriptase-polymerase chain reaction (RT-PCR), we performed a quantitative analysis of the mRNA expression of different cytokines to determine the balance between T helper (Th) 1, Th17, Th2 and Treg (regulatory T) cells in colonic tissue. TaqMan Gene Expression assays (Applied Biosystems, Lennik, Belgium) specific for IFN $\gamma$  produced by Th1 cells, IL17 produced by Th17 cells, IL-5 produced by Th2 cells and IL-10 produced by Treg cells were performed on a ABI Prism 7300 sequence detector system (Applied Biosystems, Lennik, Belgium) in 25  $\mu$ L reaction volumes containing One step Universal PCR master mix (Applied Biosystems, Lennik, Belgium) as previously described<sup>[27]</sup>.

**Drugs**

NaCl 0.9% (Plurule®, Baxter, Lessines, Belgium); 2,4,6 trinitrobenzene sulfonic acid solution (Fluka, Neu-Ulm, Germany); PBS (GIBCO BRL, Merelbeke, Belgium); diethyl ether, ethanol absolute, 30% hydrogen peroxide, methanol absolute, potassium dihydrogen phosphate, dipotassium hydrogen phosphate trihydrate (Merck, Darmstadt, Germany); xylazine (Rompun®, Bayer, Brussels, Belgium); ketamine (Ketalar®, Pfizer, Brussels, Belgium); hexadecyltrimethylammonium bromide, *o*-dianisidine dihydrochloride, FCS, collagenase, Percoll, Evans blue (Sigma Chemical, St. Louis, Missouri, USA); RPMI 1640, EDTA, HBSS, HEPES, L-glutamine,  $\beta$ -mercaptoethanol, sodium pyruvate, penicillin, streptomycin (Invitrogen, Merelbeke, Belgium), glass beads (0.4-0.5 mm in diameter) (VWR international, Leuven, Belgium) were purchased from the respective companies mentioned in parentheses. Helminth protein preparation was described earlier.

**Presentation of results and statistical analysis**

Data are presented as mean  $\pm$  SE. Statistical analysis was performed in SPSS 16.0 for Windows. Analyses of the non-parametric data (clinical disease score, macroscopic and microscopic inflammation score) were performed by Mann-Whitney *U* tests. Parametric data (extent of inflammation, MPO, GE, GC, amplitude, interval and RT-PCR results) were analyzed by Student's *t*-tests or by two-way ANOVA (with TNBS colitis as factor 1 and protein treatment as factor 2). When the interaction was significant one-way ANOVA and Student-Newman-Keuls post hoc analysis was performed. *P* values  $\leq$  0.05 were considered to be significant.

**RESULTS**

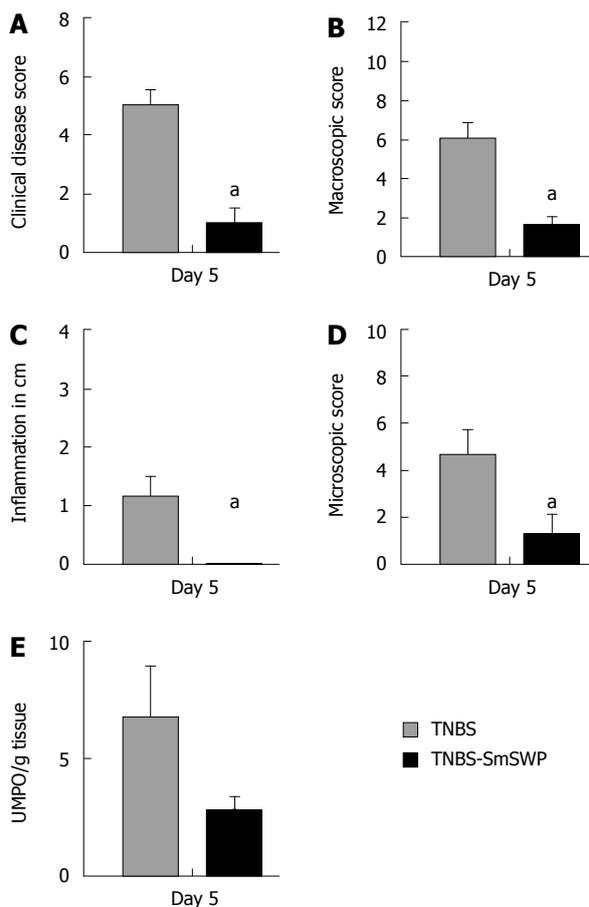

**Effect of SmSWP on TNBS-induced colitis after 5 d**

The injection of TNBS caused an increase in all inflammatory parameters (Figure 1A-E) as compared to control mice that did not show any signs of inflammation (data not shown).

Treatment of TNBS-injected mice with SmSWP caused a significant decrease in clinical disease score (Figure 1A), macroscopic inflammation score (Figure 1B), extent of colonic inflammation (Figure 1C), microscopic inflammation score (Figure 1D) and a tendency to decrease the MPO activity (Figure 1E) as compared to TNBS-PBS mice.

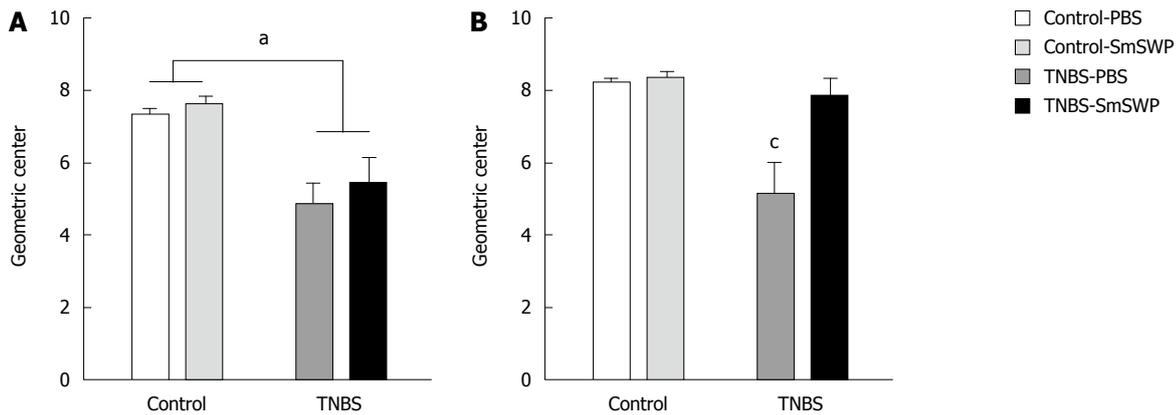

**Effect of TNBS-induced colitis per se on gastrointestinal motility**

In preliminary experiments, 3 d after the induction of colitis, GE and GC of a semi-liquid Evans blue solution were not significantly different between control and TNBS mice: GE was 43%  $\pm$  9% in controls and 48%  $\pm$  10% in TNBS colitis mice and GC was 2.1  $\pm$  0.3 in controls and 2.2  $\pm$  0.3 in TNBS colitis mice (*n* = 7-9). We also evaluated

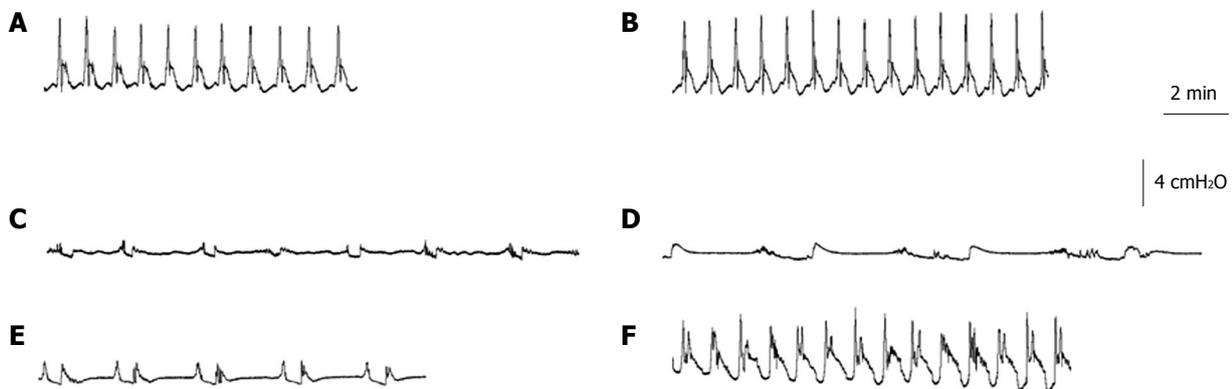

**Figure 1** Effect of 25  $\mu$ g *Schistosoma mansoni* soluble worm (SmSWP) proteins on clinical disease score (A), macroscopic score (B), extent of inflammation (C), microscopic score (D) and myeloperoxidase (MPO) activity (E) 5 d after trinitrobenzene sulphate (TNBS)-induced colitis. Grey bars represent phosphate-buffered saline (PBS)-treated TNBS mice; black bars represent SmSWP-treated TNBS mice. Data are presented as mean  $\pm$  SE. Non-parametric data (A, B, D) were analyzed by the Mann-Whitney *U* test, parametric data (C, E) were analyzed by the Student's *t*-test; *n* = 8-10; \**P*  $\leq$  0.05, significant effect of SmSWP treatment.

the effect of colitis on gastrointestinal motility after intragastric gavage of 25 glass beads 3 d after the injection of TNBS. Experiments were performed 30 min, 120 min and 360 min after intragastric gavage of the marker: GE progressed over time in control mice (from 32%  $\pm$  12% to 61%  $\pm$  14% and 100%  $\pm$  0%, respectively) and in TNBS mice (from 42%  $\pm$  13% to 81%  $\pm$  9% and 97%  $\pm$  2%, respectively) but no significant differences between the control and TNBS groups were observed. The GC also increased over time from 1.5  $\pm$  0.2 (30 min) to 3.2  $\pm$  0.7 (120 min) and to 7.3  $\pm$  0.2 (360 min) in control mice. This time-dependent increase in GC was also observed in mice with colitis (from 1.7  $\pm$  0.3 to 2.9  $\pm$  0.5 and 5.5  $\pm$  0.6). When measured 360 min after gavage of the beads, GC in mice with colitis (5.5  $\pm$  0.6) was significantly lower as compared to control mice (7.33  $\pm$  0.2). Based on these preliminary results, further measurements studying the effect of worm protein treatment on GC were performed 360 min after intragastric gavage of 25 glass beads.

**Figure 2** Effect of 25  $\mu$ g *S. mansoni* proteins on geometric center 3 d (A) and 5 d (B) after the induction of colitis. Data were analyzed by two-way ANOVA with the Student-Newman-Keuls (SNK) post hoc test;  $n = 7-10$ ; <sup>a</sup> $P \leq 0.05$ , significant colitis effect; <sup>c</sup> $P \leq 0.05$ , post hoc analysis showed a statistically significant difference from the other 3 groups.

**Figure 3** Peristaltic tracings as recorded in the control-PBS group (A), the control-25  $\mu$ g SmSWP group (B), the TNBS-PBS group on day 3 (C), the TNBS-PBS group on day 5 (D), the TNBS-25  $\mu$ g SmSWP group on day 3 (E) and the TNBS-25  $\mu$ g SmSWP group on day 5 (F).

**Effect of SmSWP treatment on delayed gastrointestinal transit during TNBS colitis**

Experiments were performed 3 d (Figure 2A) and 5 d (Figure 2B) after TNBS injection. Treatment of control mice with SmSWP had no effect *per se* on GC at both time points (Figure 2A and B). TNBS-colitis significantly reduced GC 360 min after intragastric gavage of the beads both at day 3 and at day 5 (Figure 2A and B). Treatment of colitis mice with SmSWP had no effect on GC 3 d after the injection of TNBS (Figure 2A). However, treatment of colitis mice with SmSWP reversed the TNBS-induced decrease in GC at day 5 (Figure 2B).

**Effect of SmSWP treatment on colonic peristalsis**

Distention-induced peristaltic contractions were recorded (Figure 3) and, subsequently, the amplitude and the interval between the peristaltic waves were measured.

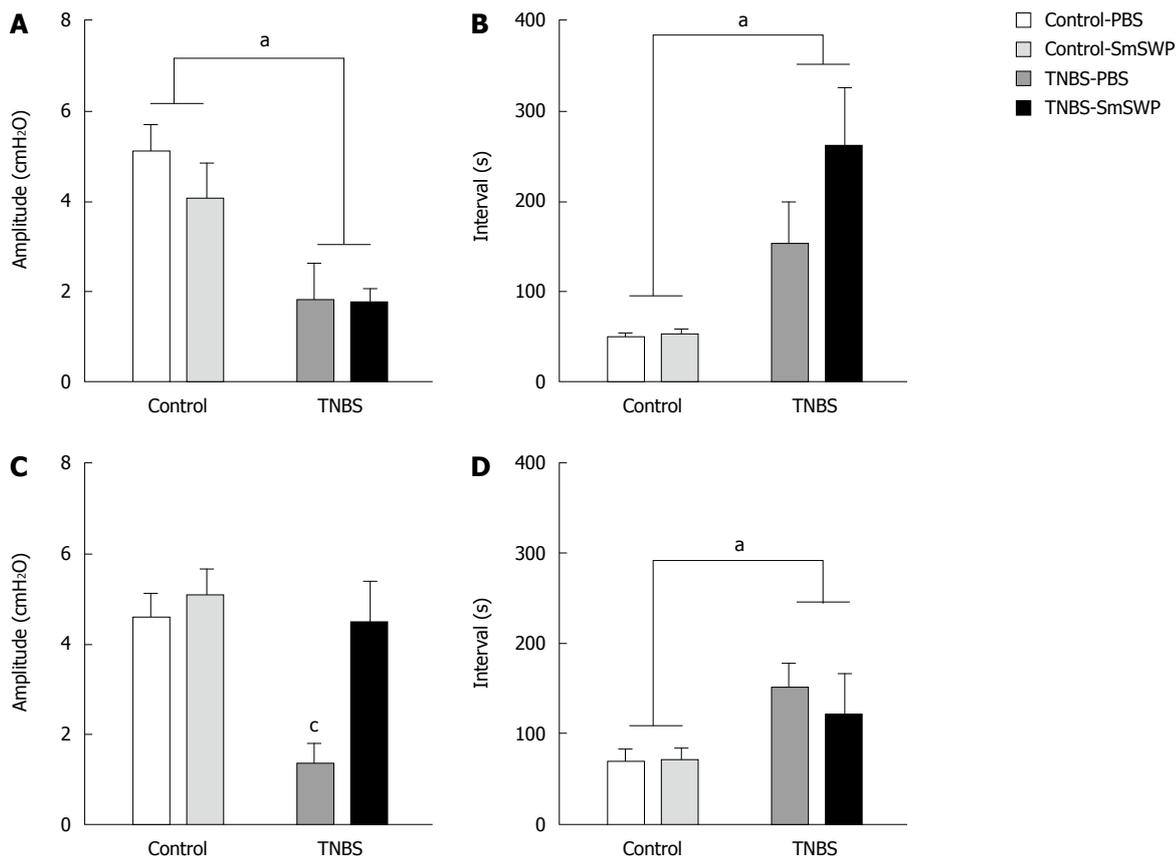

Peristaltic activity of distal colonic segments was measured 3 d (Figure 4A and B) and 5 d (Figure 4C and D) after TNBS enema. Treatment of control mice with SmSWP had no significant effect on colonic peristaltic activity at the two different time points (Figure 3B and Figure 4A-D). The induction of colitis caused significant impairment of peristaltic activity as shown by a significant

decrease in amplitude and an increase in interval between the waves. These TNBS-induced disturbances in peristalsis were significant both on day 3 and on day 5 (Figure 3C and D, Figure 4A-D). Furthermore, it is important to note that in 4 of 8 TNBS-PBS mice on day 3 we were not able to measure any peristaltic activity whereas this was only the case in 1 of 8 TNBS-SmSWP mice.

Treatment with SmSWP did not ameliorate the disturbed peristaltic activity caused by intestinal inflammation after 3 d (Figure 3E, Figure 4A and B). However, 5 d after the induction of colitis the amplitude of the distention-induced peristaltic contractions was significantly increased to normal control values when mice were treated with SmSWP (Figure 3F and Figure 4C). At this time point, the mean interval between the waves remained increased after treatment with SmSWP as compared to control animals (Figure 4D).

**Measurement of cytokine profiles in colonic T cells**

We recently showed the importance of the differential roles of Th1, Th17, Th2 and Treg cells in colonic tissue 3 d after the induction of TNBS colitis and the effect of SmSWP treatment on these T cell subsets<sup>[27]</sup>. In this study we investigated the cytokine profiles of

**Figure 4** Effect of 25 µg *S. mansoni* proteins on the amplitude and interval of peristaltic waves 3 d (A, B) and 5 d (C, D) after the induction of colitis. Data are presented as mean ± SE. Data were analyzed by two-way ANOVA with SNK post hoc test; *n* = 7-9 (except for the TNBS-PBS group on day 3 *n* = 4); <sup>a</sup>*P* ≤ 0.05, significant colitis effect; <sup>c</sup>*P* ≤ 0.05, post hoc analysis showed a significant difference from the other 3 groups.

T cells isolated from colonic tissue on day 5 after the induction of colitis. As shown in Figure 5A, interferon (IFN)-γ mRNA expression was not significantly altered in colonic T cells 5 d after the induction of colitis. On the other hand, we found a significant downregulation of interleukin (IL)-17 and IL-5 expression 5 d after the induction of colitis in both PBS- and SmSWP-treated mice (Figure 5B and D). Investigating the Treg response, we found that injection of TNBS and treatment with SmSWP had no significant effect on IL-10 mRNA expression 5 d after TNBS injection (Figure 5C).

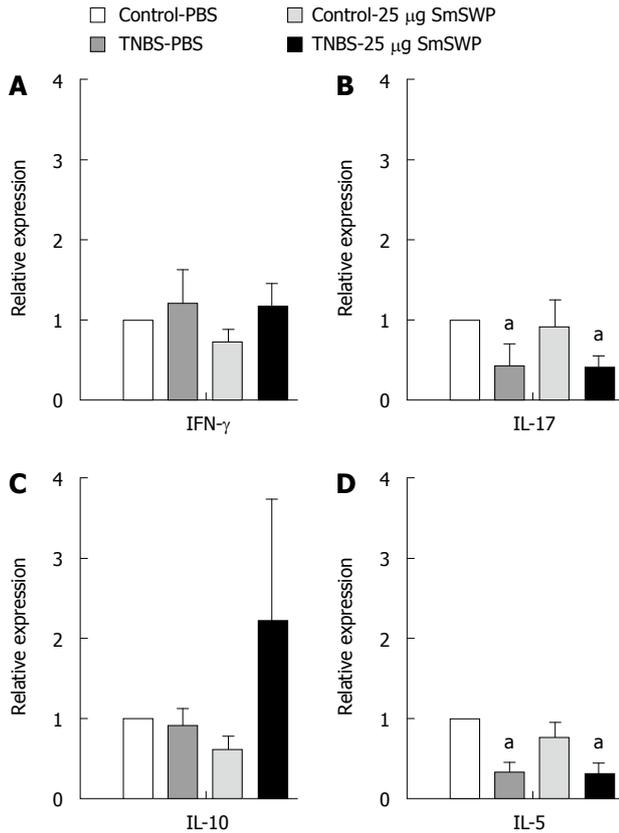

## DISCUSSION

In this study we showed that treatment with SmSWP ameliorated *in vivo* and *in vitro* motility disturbances in a murine model of TNBS-induced colitis after 5 d.

Experimental and clinical data support the idea that helminths provide protection against IBD<sup>[34]</sup>. To avoid the possible disadvantages of a therapy with living parasites, current research is now focusing on the identification and characterization of helminth-derived immunosuppressive molecules that contribute to the protective effect<sup>[13]</sup>. Furthermore, it is well established that gut inflammation leads to disturbed gastrointestinal motility<sup>[14]</sup>. The model of TNBS-induced colitis is widely

used to investigate motility disturbances occurring in the inflamed colon. We previously showed that contractility of colonic longitudinal smooth muscle strips was time-dependently decreased during TNBS colitis in rats and concurrent infection with *S. mansoni* abrogated these TNBS-induced contractility disturbances<sup>[10]</sup>.

In a previous study we showed that TNBS colitis caused clear signs of inflammation 3 d after the induction of colitis and that our model of TNBS colitis was self-limiting with near complete remission after 1 wk<sup>[27]</sup>. In this study we focused on a later phase during murine TNBS-induced colitis. We showed that 5 d after TNBS injection, treatment with SmSWP also caused a significant decrease in clinical disease score, macroscopic inflammation score, extent of colonic inflammation and microscopic inflammation score at this later time point along the course of colitis. There was however no significant difference in MPO activity between TNBS-PBS and TNBS-SmSWP mice at this time point although a clear tendency of inhibition was observed. Taken together, these results indicate that treatment with helminth proteins ameliorated colonic inflammation leading to accelerated healing of colitis. A similar beneficial effect has been described previously by our group: rats with TNBS colitis showed spontaneous and complete healing of inflammation 4 wk after the induction of colitis and this was reduced to 2 wk

**Figure 5** Interferon (IFN) and interleukin (IL) mRNA expression of T helper (Th) 1 (A), Th17 (B), regulatory T (Treg) (C) and Th2 (D) cells isolated from colonic tissue at day 5. Data are expressed as relative expression and the control-PBS group was chosen as calibrator. Data are presented as mean ± SE. Data were analyzed by two-way ANOVA with SNK post hoc test when appropriate; *n* = 5-8 (except for IL-17 *n* = 2-5); \**P* ≤ 0.05, significant colitis effect, no significant effect of worm protein treatment was shown at day 5.

in rats infected with *S. mansoni*<sup>[10]</sup>.

Investigation of the effect of TNBS colitis on gastrointestinal motility failed to show an effect on gastrointestinal transit of a semi-liquid meal. In other words, colitis did not affect gastric emptying in our murine model. Nevertheless, delayed gastric emptying has been described in a clinical setting<sup>[21,23]</sup> as well as in the rat TNBS model<sup>[35]</sup>. Literature on TNBS-induced motility disturbances in mice is scarce and gastric emptying disturbances have not been reported so far. In addition to species differences, this lack of effect of colitis on gastric emptying in mice might be linked to the type and severity of inflammation induced and to the time point chosen to perform motility experiments.

On the other hand, assessment of gastrointestinal transit of a solid meal showed that the geometric distribution of solid beads in the gastrointestinal tract was significantly decreased 3 d after the induction of colitis and this decrease was still evident after helminth protein treatment by day 3. Five days after the induction of colitis, the geometric distribution was still significantly altered in mice with colitis but treatment with worm proteins significantly reversed transit to normal values at this time point. These results indicate that although the

healing process of intestinal inflammation is ongoing in untreated TNBS mice by day 5, gastrointestinal motility of the gastrointestinal tract remains disturbed. Only when inflammatory signs are almost completely absent, as in the SmSWP-treated TNBS mice on day 5, was *in vivo* gastrointestinal motility of the distal gastrointestinal tract restored.

Comparable results were found on *in vitro* colonic peristalsis. The amplitude of distension-induced pressure waves as well as the interval between the waves were significantly altered in the colon of mice with TNBS-induced colitis, both at day 3 and day 5. Treatment with SmSWP did not have any ameliorating effect after 3 d whereas the amplitude was significantly increased to normal control values after 5 d. The interval between the waves was nevertheless still significantly augmented as compared to controls at day 5. This suggests that some signs of disturbed peristalsis persisted although inflammation is resolving and that the disturbed interval of *in vitro* peristaltic waves 5 d after colitis and worm treatment did not have any repercussion on *in vivo* colonic motility which, at that time point, was normalized in these mice.

With regard to the clinical setting, treatment of IBD patients with *Trichuris suis* ova caused clinical amelioration of both Crohn's disease activity index and ulcerative colitis disease activity index<sup>[11,12]</sup>. This decrease in clinical disease scores might indicate that symptoms such as diarrhea and abdominal pain are less frequent after treatment with helminths. It is well known that infection with intestinal helminths can alter gastrointestinal motility thus contributing to worm expulsion<sup>[36]</sup>. The role of T cells in those circumstances was previously investigated, leading to the understanding that infection-induced intestinal muscle hypercontractility is CD4+ T cell-dependent<sup>[37]</sup>.

Cytokines produced by mucosal leucocytes can also mediate neurogastrointestinal function. We previously showed that the pro-inflammatory cytokine IL-1β modulates gastrointestinal neuromuscular function<sup>[38]</sup>. In addition, Th2 cytokines IL-4 and IL-13 contribute to intestinal muscle hypercontractility<sup>[39]</sup>. Treatment with exogenous IL-10 has been shown to abrogate the delayed gastrointestinal transit during postoperative ileus<sup>[40]</sup>. Gastrointestinal inflammation during Crohn's disease is mediated *via* Th1 lymphocytes as well as through the recently described Th17 cells<sup>[41]</sup>. On the other hand, it is well established that helminths have the potential to evoke strong regulatory T cell responses with immunosuppressive properties<sup>[42]</sup>. In this way, we might hypothesize that infection with helminths induce Th2 and Treg immune responses that contribute to the amelioration of motility disturbances during colitis.

As such, we measured the cytokine profile of colonic T cells. We previously showed that a Th1 response (upregulation of IFN-γ) in the colon was evident 3 d after induction of TNBS colitis. This Th1 response

was significantly suppressed after administration of *S. mansoni* proteins. Treatment with SmSWP also caused an upregulation of regulatory T cell cytokines in the colon after 3 d<sup>[27]</sup>. In this study we identified the balance between the different T cell subsets in the colon at a later time point along the course of colitis, 5 d after the injection of TNBS. Our results showed there was no longer a significant effect on IFN- $\gamma$  mRNA expression after the induction of colitis, indicating that the Th1 response seen on day 3 in the colon of TNBS-PBS mice had subsided by day 5. Furthermore, injection of helminth proteins decreased the expression of IL-17 after 3 d, both in control mice and in TNBS mice<sup>[27]</sup>. After 5 d we found decreased IL-17 mRNA expression due to a colitis effect instead of a protein effect. These differential results on IL-17 mRNA expression at both time points are interesting: at day 3 the effect on IL-17 expression was related to helminth protein, whereas it was colitis mediated at day 5. Although we did not detect a significant effect of colitis or worm protein treatment on IL-5 expression after 3 d, a significant downregulation of IL-5 expression on day 5 was apparent both in the PBS treated group and in the helminth protein treated group. One might hypothesize that the naturally occurring healing response leads to the production of regulatory cytokines which are able to suppress cytokines produced by T effector cells including IL-17 and IL-5. This coincides with the attenuation of inflammatory parameters at this time point as described above.

Experiments performed 3 d after the induction of colitis showed a significant upregulation of the mRNA expression of regulatory cytokines IL-10 and transforming growth factor- $\beta$  after treatment with SmSWP that had subsided by day 5. Our results showed that the immunological effect of helminth protein treatment on Th1 and Treg cells, which is present after 3 d as shown previously<sup>[27]</sup>, has diminished after 5 d. This might be explained by the fact that proteins were only injected once 6 h after TNBS or PBS injection and not repeatedly until day 5. Nevertheless, this single injection with helminth proteins evoked a protective effect that was almost immediate, leading us to assume that these proteins might also have an effect on innate immunity. It was previously reported that infection with *S. mansoni* prevented experimental colitis in mice by a mechanism dependent on macrophages<sup>[43]</sup>. Furthermore, dendritic cells are key regulators in the immune defence of the gut and are also influenced by helminth infections<sup>[44,45]</sup>. Investigation on how helminth proteins affect cells of the innate immune system might contribute to a better understanding of the immunological pathways by which helminth proteins suppress ongoing colonic inflammation.

In this study, we provide evidence that treatment with helminth proteins contributes to amelioration of gastrointestinal motility disturbances. Inhibition of inflammation and amelioration of motility disturbances

after treatment with helminth proteins both appear at the same time. However, whether the beneficial effect of helminth protein treatment on gastrointestinal motility is directly or indirectly related to amelioration of inflammation needs to be further established. If helminth proteins provoke a reaction that not only leads to a reduction in inflammation but also influences the enteric nervous system and/or smooth muscle cells directly, these proteins might be useful in the treatment of gastrointestinal motility disturbances.

Taken together, we showed that treatment with *S. mansoni* proteins significantly attenuated the course of TNBS-induced colitis leading to reversal of *in vivo* gastrointestinal motility disturbances and amelioration of *in vitro* colonic peristalsis 5 d after induction. We conclude that SmSWP have therapeutic potential in gut inflammation leading to a marked reduction in inflammation and in gastrointestinal motility disturbances, accelerating the natural course of remission.

## COMMENTS

### Background

Gastrointestinal inflammation during inflammatory bowel diseases (IBD) results from an uncontrolled immune response against intraluminal antigens in genetically predisposed persons and might lead to motility disturbances with related symptoms. The lack of exposure to helminth infections, as a result of improved living standards and medical conditions, has contributed to the increased incidence of IBD in the developed world.

### Research frontiers

Epidemiological, experimental and clinical data support the idea that helminths provide protection against IBD. However, treatment with living helminths may have serious drawbacks such as infection and/or invasion of the parasite to other tissues in the human host where they might cause pathology. Therefore, in this study the authors evaluated the therapeutic potential of helminth-derived proteins on inflammation and associated motility disturbances.

### Innovations and breakthroughs

This study investigates the effect of TNBS colitis and exposure to *Schistosoma mansoni* proteins on murine gastrointestinal motility. This is a novel pursuit. The effects of inflammation and therapeutic interventions on gastrointestinal motility are largely ignored but critically important. The authors showed that treatment of experimental colitis with helminth proteins restored gastrointestinal motility.

### Applications

Treatment with helminth soluble proteins attenuates inflammation and ameliorates motility disturbances during experimental colitis. These results suggest that helminth soluble proteins represent an attractive therapeutic option in the management of IBD.

### Peer review

This is an interesting study dealing with the effect of *Schistosoma mansoni* proteins on inflammatory and motility response in a rat model of inflammatory bowel disease. The experimental methods are described comprehensively and the interpretations and conclusions justified by the results.
