Abstract

AIM: To evaluate survival and recurrence after radiofrequency ablation (RFA) for the treatment of small hepatocellular carcinoma (HCC) using a meta-analysis.

METHODS: Literature on RFA *vs* surgical resection for the treatment of small HCC published between January 1990 and December 2008 was retrieved. A meta-analysis was conducted to estimate pooled survival and recurrence ratios. A fixed or random effect model was established to collect the data.

RESULTS: The differences in overall survival at 1-year, 3-years and at end of follow-up were not statistically significant between the RFA and surgery groups ($P > 0.05$). There were no differences in 1-year and 3-year recurrences between the RFA and surgery groups ($P > 0.05$). However, recurrence in the RFA group was lower than that in the surgery group up to the end of follow-up ($P = 0.03$). Survival was not significantly different. There was a significant difference in recurrences at the end of follow-up after RFA compared with surgical resection.

CONCLUSION: RFA did not decrease the number of overall recurrences, and had no effect on survival when compared with surgical resection in a selected group of patients.

INTRODUCTION

The preferred treatment for hepatocellular carcinoma (HCC) is surgical resection which has a good long-term effect. In recent years, radiofrequency ablation (RFA) has emerged as the latest oriented treatment, especially for HCC, and has become an important treatment following surgical resection and has established its place in the treatment algorithm of liver tumors. The treatment of HCC in patients with chronic liver disease is a major challenge. With the intention of avoiding hepatic failure which can appear after hepatic resection, percutaneous ablative treatments have been proposed. RFA ablation has progressively reached consensus due to its efficacy, tolerability and low-risk[1]. RFA is much less invasive, involves a short hospital stay and has an extremely low associated mortality; however, long-term results are difficult to ascertain, because the majority of reports concern evaluation of the percentage of success in terms of tumor necrosis and few data are available on the overall

and disease-free survival of patients[2-6]. Clear evidence is still needed for RFA to be accepted as an alternative to surgery for resectable HCC on cirrhosis. Few studies have focused on a comparison between the results of surgery and RFA. In order to reduce research bias and differences, we used a meta-analysis to compare survival and recurrences following RFA compared with surgical resection for the treatment of small HCC. This article may provide a reference for clinical practice.

MATERIALS AND METHODS

Data accrual

We carried out an exhaustive Medline, PubMed, CBM and CNKI search of the world literature comparing survival and recurrences following RFA compared with surgical resection for the treatment of small HCC, between the period January 1990 to December 2008 using the key words (radiofrequency, radio-frequency or radio frequency), (surgical resection or hepatectomy) and (liver or hepatic or hepatocellular) in English, French, German, Italian, Spanish, Danish, Dutch, Korean and Chinese. All abstract supplements from published literature were searched manually. Relevant papers were also identified from the reference lists of previous papers which were obtained through the search, and from abstracts from recent international meetings.

In the case of overlap between 2 reports, only the most detailed report was included. Only series with a minimum follow-up of 12 mo were included. Reports about treatments obtained with noncommercial electrodes and treatments with palliative intent (intentional partial debulking) were excluded. When appropriate, authors were contacted to obtain more details about the cases they reported.

In addition, we chose some Chinese articles, as there are many patients with small HCC in China. A good meta-analysis requires these data.

Data extraction and quality assessment

Data were extracted by two or three independent observers using standardized forms. The recorded data included the number of patients, overall survival and recurrence. The quality of all selected articles was ranked in accordance with the score of the non-randomized controlled clinical trial quality evaluation standard (Table 1).

Study selection criteria

Inclusion criteria for this study were as follows: (1) A solitary HCC smaller than 5 cm in diameter or multiple (no more than three) HCC smaller than 5 cm in total diameter; (2) No extrahepatic metastasis; (3) No radiologic evidence of invasion into the major portal/hepatic vein branches; (4) Good liver function with Child-Pugh Class A or B, with no history of encephalopathy, ascites refractory to diuretics or variceal bleeding; (5) No previous treatment of HCC; (6) Patient should be suitable for treatment with either surgical resection or RFA; and (7) No recurrences where no tumor was found by spiral computed tomography and serum α-fetoprotein level when assessed every 3 mo after treatment during the follow-up period.

Statistical analysis

Meta-analysis was performed using fixed-effect or random-effect methods, depending on the absence or presence of significant heterogeneity. Statistical heterogeneity between trials was evaluated by the Cochran χ^2 test and was considered significant when $P < 0.10$. In the absence of statistically significant heterogeneity, the Mantel-Haenszel method in the fixed-effect model was used for the meta analysis. Otherwise, the DerSimonian and Laird method in the random-effect model was selected.

The odds ratio (OR) with 95% confidence interval (CI) was used to assess treatment efficacy. The combined result was an average OR and 95% CI weighted according to the standard error of the OR of the trial. $P < 0.05$ was considered statistically significant. We used funnel plots to assess the publication bias, and tested for funnel plot asymmetry using Egger's test and Begg's test. All analyses were performed with STATA version 9.0 (Stata Co., College Station, TX, USA) and Review Manager version 4.2.2 (RevMan, Cochrane Collaboration, Oxford, England).

RESULTS

Description of included trials in the meta-analysis

According to exclusion and selected criteria of historical data, 10 studies were selected for the meta analysis, including 787 cases of RFA and 735 cases of surgical resection. However, one publication[7] was removed, because the number of cases continued to expand in another publication[8]. Among the 10 articles selected, 4 (40%) were from China, and corresponded to the high incidence of Hepatitis B virus-associated HCC in China. The characteristics of the 10 clinical trials included are shown in Table 1.

Meta-analysis

The comparison of survival and recurrence following RFA *vs* surgical resection for the treatment of small HCC using the meta-analysis is shown in Figures 1-3 [8-17].

Survival during follow-up 1 year after treatment: The χ^2 test of heterogeneity was highly significant ($P = 0.95$). Accordingly, a fixed-effect model was used. There was no difference in the 1-year overall survival rate between the RFA group (87.9%) and the surgical resection group (88.6%) with a combined OR of 0.94 (95% CI: 0.65 to 1.36, $P = 0.75$, Figure 1).

Survival during follow-up 3-year after treatment: The χ^2 test of heterogeneity was highly significant ($P = 0.0002$). Accordingly, a random-effect model was used. There was no difference in the 3-year overall survival rate between the RFA group (62.5%) and the surgical resection group (63.6%) with a combined OR of 0.92 (95% CI: 0.56 to 1.51, $P = 0.73$, Figure 2A).

[1]The score from the non-randomized controlled clinical trial quality evaluation standard. RFA: Radiofrequency ablation.

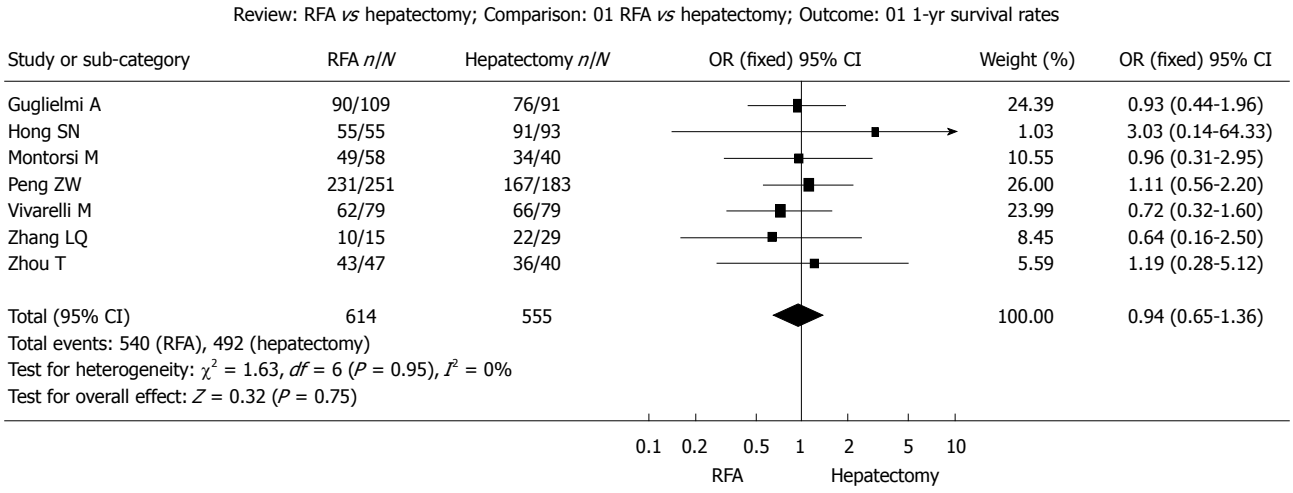

Figure 1 Fixed effect model of odds ratio for survival during follow-up 1-year after treatment: Radiofrequency ablation *vs* hepatectomy. RFA: Radiofrequency ablation.

Survival up to the end of the follow-up period: The χ^2 test of heterogeneity was highly significant ($P < 0.0001$). Accordingly, a random-effect model was used. There was no difference in overall survival rate at the end of follow-up after treatment with RFA (57.4%) compared with surgical resection (60.9%) with a combined OR of 0.82 (95% CI: 0.48 to 1.39, $P = 0.46$, Figure 2B).

Recurrence during follow-up 1-year after treatment: The χ^2 test of heterogeneity was highly significant ($P = 0.07$). Accordingly, a fixed-effect model was used. There was no difference in recurrence rate during follow-up 1-year after treatment between the RFA group (20.6%) and the surgical resection group (20.9%) with a combined OR of 0.96 (95% CI: 0.69 to 1.33, $P = 0.80$, Figure 3A).

Recurrence during follow-up 3-year after treatment: The χ^2 test of heterogeneity was highly significant ($P < 0.0001$). Accordingly, a random-effect model was used. There was no difference in recurrence rate during follow-up 3-years after treatment between the RFA group (59.4%) and the surgical resection group (60.4%) with a combined OR of 1.19 (95% CI: 0.63 to 2.27, $P = 0.59$, Figure 3B).

Recurrence up to the end of the follow-up period: The χ^2 test of heterogeneity was highly significant ($P = 0.0005$). Accordingly, a random-effect model was used. The recurrence rate up to the end of the follow-up period was significantly higher in the RFA group (66.7%) than in the surgical resection group (52.9%) with a combined OR of 1.73 (95% CI: 1.04 to 2.87, $P = 0.03$, Figure 3C).

Sensitivity analysis and publication bias

Publication bias may exist when no significant findings remain unpublished, thus artificially inflating the apparent magnitude of an effect.

Survival and recurrences following RFA or surgical resection for the treatment of small HCC were calculated by the fixed-effect model and random-effect model, respectively. The results were similar and the combined results were highly reliable.

Funnel plots of the study results are shown in Figure 4A-F. The funnel plots on survival and recurrence following RFA or surgical resection for the treatment of small HCC showed basic symmetry, which suggested no publication bias.

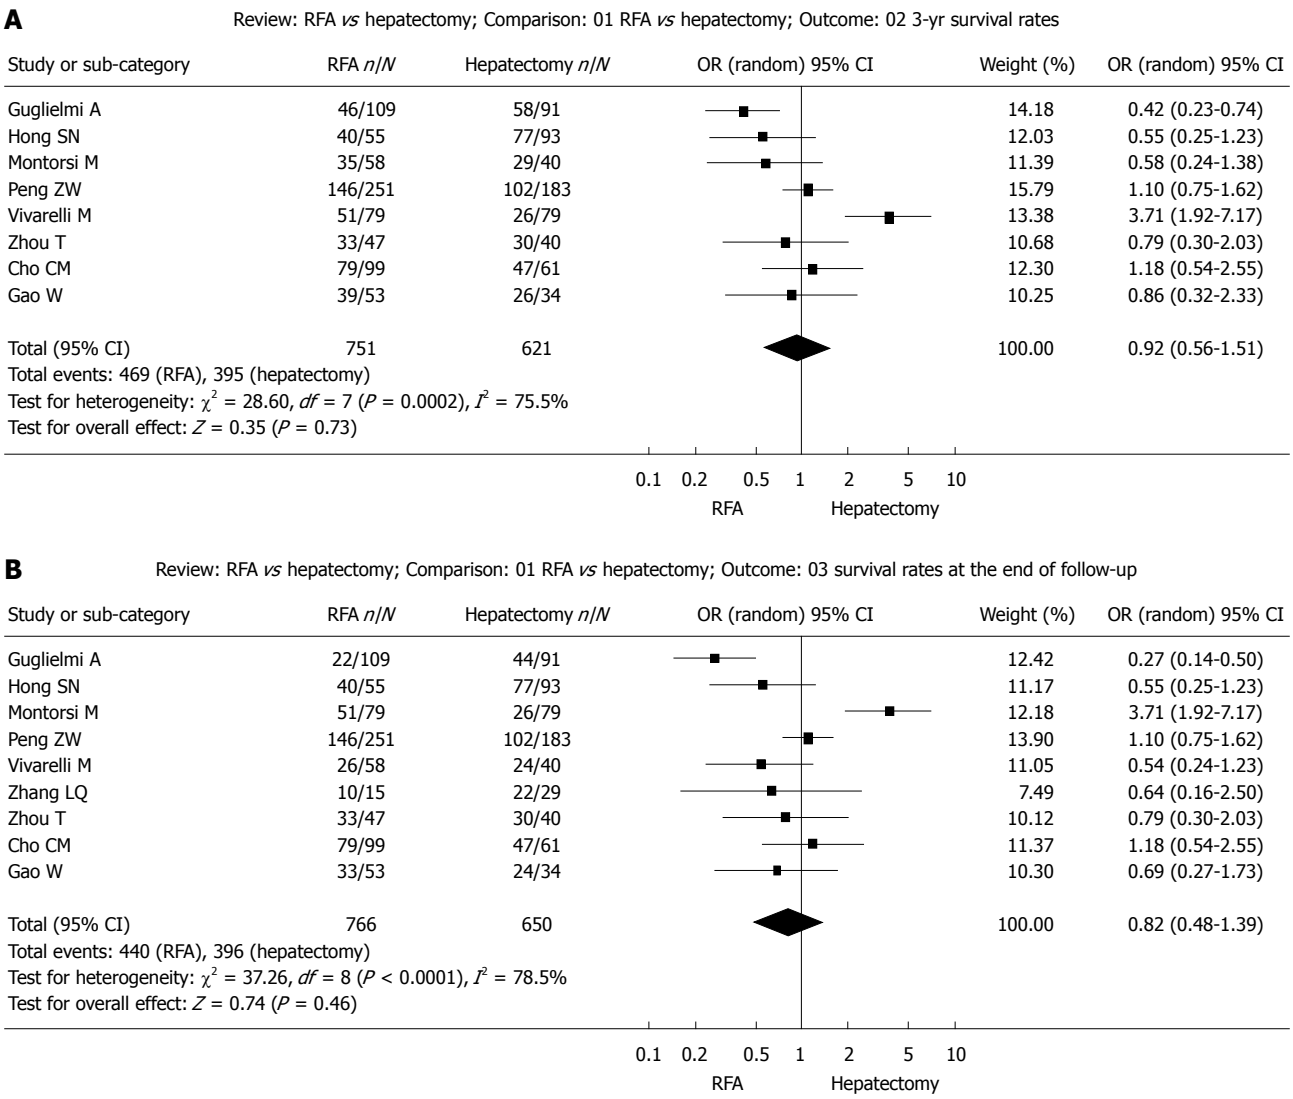

Figure 2 Random effect model of odds ratio for survival of follow-up 3-year (A) and at the end of follow-up (B) after treatment: Radiofrequency ablation *vs* hepatectomy. RFA: Radiofrequency ablation.

DISCUSSION

Hepatocellular carcinoma (HCC) is one of most common malignant tumors of the liver. According to the general condition of patients, tumor location and size and liver function status, surgery can include radical tumor resection, or liver surgery such as local excision. However, there are factors that limit the use of surgical resection. RFA is a relatively new treatment and is now performed more widely, because it results in large coagulated necrosis of the tumor, requires fewer treatment sessions, and achieves higher survival rates[18,19].

RFA has the potential to enhance the long-term survival rate of liver cancer patients worldwide and is of significant importance[20]. Research has indicated that more than 90% of the tumor can be completely destroyed and tumor recurrence *in situ* is effectively inhibited following RFA, which also achieved satisfactory short-term efficacy[21]. Long-term survival following RFA treatment was satisfactory in liver cancer patients as was liver function in those with A-class[22]. The efficacy of RFA was also shown to be related to Child-Pugh grading[23]. Compared with surgery, RFA did not cause significant liver function damage, had a lower rate of complications and was more affordable in terms of treatment costs. The results of this study showed that RFA did not decrease overall recurrences, but had no effect on survival in comparison with surgical resection (i.e. compared with surgical resection, RFA showed no significant difference in the short-term survival rate).

This review has some limitations. Funnel plots can be suggestive of publication bias with lack of negative small RCTs. However, a firm conclusion about bias is difficult to reach as the asymmetry of the funnel plot is minimal. In addition, funnel plots can show asymmetry for reasons other than publication bias. Therefore, our pooled OR might be an overestimate of the true effect. Due to data constraints, this meta-analysis could not analyze the quality of life score and was unable to carry out stratified analyses of other possible confounding factors. If the method is to be more effective, then larger samples and randomized controlled studies with longer

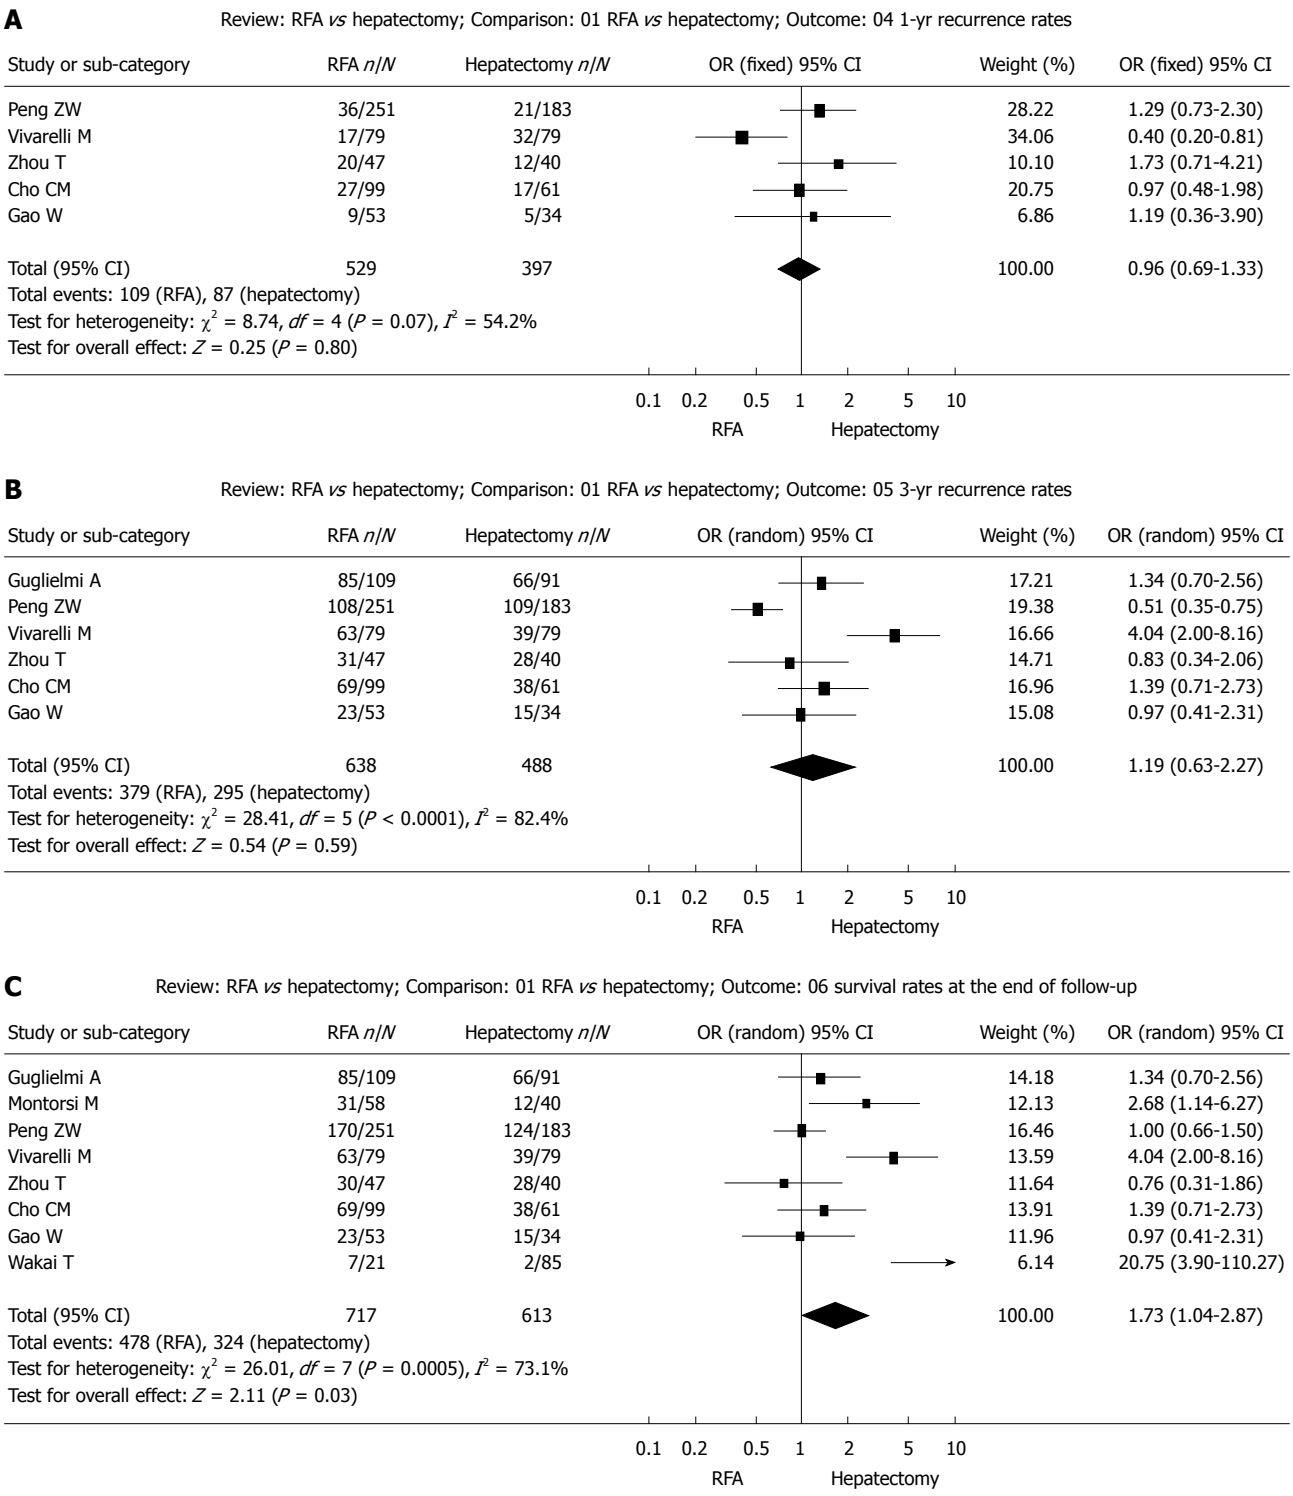

Figure 3 Random effect model of odds ratio for Recurrence of follow-up 1-year (A) and 3-year (B) and the end of follow-up (C) after treatment: Radiofrequency ablation *vs* hepatectomy. RFA: Radiofrequency ablation.

follow-up are required[24]. Chinese article should also be chosen, because there are many patients with small HCC in China. A good meta-analysis requires these data. However, the conclusions of this study also need more detailed data to confirm the results. The search language was limited. The integrity of the data was affected to a certain extent.

In conclusion, with the development of RFA, when conditions permit and under technically assured circumstances, RFA can be performed percutaneously, laparoscopically or during laparotomy, and can partially replace surgical resection. For patients who do not have the opportunity or are unwilling to accept surgical treatment, RFA is an acceptable means of palliative care.

A: 7 articles in the meta-analysis of survival during follow-up 1-year after treatment; B: 8 articles in the meta-analysis of survival during follow-up 3-years after treatment; C: 9 articles in the meta-analysis of survival up to the end of follow-up; D: 5 articles in the meta-analysis of recurrence during follow-up 1-year after treatment; E: 6 articles in the meta-analysis of recurrence during follow-up 3-years after treatment; F: 8 articles in the meta-analysis of recurrence up to the end of follow-up.

COMMENTS

Background

Over the last decade, radiofrequency thermal ablation (RFA) has established its place in the treatment algorithm of liver tumors. This meta-analysis was designed to evaluate survival and recurrence following RFA for the treatment of small hepatocellular carcinoma (HCC).

Research frontiers

The study evaluated survival and recurrence following RFA for the treatment of HCC using a meta analysis of all relevant controlled studies.

Innovations and breakthroughs

The authors made a comprehensive search of studies dealing with small HCC treated with RFA. The studies were analyzed to determine survival and recurrence after RFA in these patients.

Applications

RFA is an effective technique for the treatment of small HCC and offers an alternative treatment method. This meta-analysis shows that RFA did not decrease overall recurrences, but had no effect on survival in comparison with surgical resection in a selected group of patients. Larger samples and randomized controlled studies with longer follow-up are required.

Peer review

This is an interesting report of RFA *vs* surgical resection for HCC.

Abstract

AIM: To assess the effect of human leukocyte antigen (HLA) mismatching on liver graft outcome and acute rejection from a meta-analysis of available cohort studies.

METHODS: Articles in PubMed/MEDLINE, EMBASE and the Cochrane database from January 1970 to June 2009, including non-English literature identified in these databases, were searched. Only studies comparing HLA or sub-phenotype matching with mismatching were extracted. The percentage of graft survival was extracted by "Engauge Digitizer" from survival curves if the raw data were not displayed. A meta-analysis was performed when at least 3 studies provided data.

RESULTS: Sixteen studies met the inclusion criteria. A lower number of HLA mismatches (0-2 *vs* 3-6) did reduce the incidence of acute rejection (relative risk: 0.77, $P = 0.03$). The degree of HLA mismatching (0-2 *vs* 3-6) had no significant effect on 1-year [hazard ratio (HR): 1.04, $P = 0.68$] and 5-year (HR: 1.09, $P = 0.38$) graft survival. In sub-phenotype analysis, the degree of HLA-A, B and DR mismatching (0 *vs* 1-2) had no significant effect on 1-year and 5-year graft survival, either. The HRs and *P*-values were 0.95, 0.71 (HLA-A, 1-year); 1.06, 0.60 (HLA-A, 5-year); 0.77, 0.16 (HLA-B, 1-year); 1.07, 0.56 (HLA-DR, 1-year); 1.18, 0.23 (HLA-DR, 5-year), respectively.

CONCLUSION: The results of this systematic review imply that good HLA compatibility can reduce the incidence of acute rejection in spite of having no influence on graft outcomes. To obtain a short recovery time and minimize rejection post transplantation, HLA matching studies should be considered before the operation.

INTRODUCTION

In the past 2 decades, deaths and other complications of organ transplantation have decreased significantly as a re-

sult of improvements in anesthesiology and surgical techniques. In addition, development of immunosuppressive agents and new organ preservation solutions have been shown to play a role in the improved survival rate. However, acute or chronic rejection remains the most important reason of graft failure, especially for patients who suffer from mismatching of human leukocyte antigen (HLA).

The role of HLA matching between donor and recipient in organ transplant rejection and survival has been widely studied and proven to increase graft survival after kidney, heart, and other organ transplantation and to reduce the incidence of acute or chronic rejection[1-6]. In contrast, major histocompatibility complex analysis is not routinely performed in liver transplantation because its importance remains controversial, with different groups reporting disparate results. It was reported that some populations of patients gained benefit from high degrees of HLA matching[7-14]. Concern has been voiced about possible increased likelihood of recurrence of primary disease with good HLA compatibility[15-25].

We therefore performed a systematic review and meta-analysis on the efficacy of HLA mismatching in all published controlled clinical trials on the outcomes of liver transplantation.

MATERIALS AND METHODS

Search strategy

Relevant articles that were published between January 1970 and June 2009 in PubMed/MEDLINE, EMBASE and the Cochrane database, including the non-English literature were identified. The search strategy used the following single text words and combinations: living donor liver transplantation (LDLT), liver transplantation (LT), orthotopic liver transplantation (OLT), human leukocyte antigen (HLA), major histocompatibility complex (MHC), histocompatibility, matching and mismatching. Reference lists of relevant articles were cross checked for other potentially relevant articles.

Selection of trials and quality of the studies

Three separate authors (Lan X, Pu CL and Guo CB) independently reviewed and evaluated all articles for inclusion, which were classified as randomized control trial (RCT), controlled trial (CT), or descriptive study. After the initial article selection, the article dataset was reviewed and updated to capture any articles published between the final consensus review and the final data analysis (Zhang MM). Only cohort studies were indentified because of a lack of RCT.

The scoring system was adapted from Stahl, the Cochrane Collaboration and others[26-29]. This system suits not only RCT but CT or other studies well: (1) Was the trial design clearly stated? (2) Selection bias questions: Was the Patient selection process clearly stated? If the trial was an RCT, were patients randomly allocated to the therapeutic intervention? Were patients and clinicians blinded to the intervention? If the trial was not an RCT, were confounders controlled for? If the trial design was case control were matching procedures clearly described and implemented? Were patient recruitment procedures clearly described? Were the intervention and control groups selected similarly? (3) Performance bias questions: Was the intervention clearly described? Was intervention clearly measured? (4) Attrition bias questions: Were patients followed up? Were they followed up for 2 or more explicitly defined intervals? If patients were lost/dropped out other than because of death, were they accounted for? Were all outcome measures captured at the declared follow-up intervals? (5) Detection bias questions: Were the outcome measures clearly described? Was measurement of the outcome measures blinded? (6) Were appropriate statistical methods used? Were *P*-values clearly stated? Was life table analysis provided, *etc*.; and (7) Was the presentation of data adequate, for example, in the article were endpoints clearly defined i.e. graft survival, patient survival, duration of follow-up, re-transplantation rate, *etc*.? Were survival curves provided or were sufficient data to construct survival curves provided, were donor and recipient variables clearly defined and presented?

These questions were placed on a 3 point scale: unclear/inadequate (0), adequate (1), good (2). Articles were considered for inclusion if their summary score exceeded 30.

Data extraction

Graft loss was measured by hazard ratio (HR) and rejection was measured by relative risk (RR) at 1-year and 5-year in every study by 2 independent reviewers, reconciling any differences by consensus or when in doubt referring it to a third reviewer (Zhang MM) for arbitration. Graft survival rate was extracted for calculating corresponding HR using the formula recommended by Parmar *et al*[30]. Data was extracted by the software "Engauge 4.0" from survival curves if it was not shown in articles directly. Donor/recipient HLA compatibility for HLA class Ⅰ (A and B), and HLA class Ⅱ (DR) was measured as the number of mismatches, locus-specific (0 to 2 mismatches) and overall for the A, B, and DR loci (0 to 6 mismatches).

Meta-analysis

Both HR and RR were compared between 0 with 1-2 mismatches for each locus (mismatches of the HLA-A, B and C loci respectively) and 0-2 with 3-6 mismatches for overall HLA-A, B and DR loci. Comparability of the studies included in each pooled analysis was confirmed by examination of the $\chi^2 Q$ (expressed as a *P*-value) and I^2 statistics of heterogeneity. Statistical heterogeneity was defined as $P < 0.10$ or $I^2 > 50\%$. Lack of over-influence of one individual study to pooled estimates was confirmed by serial omission of each study and examination of the resulting estimate. To account for potential differences that were evident clinically but not identified by statistical tests, random effects models were used for each outcome measure. All statistical analyses were performed using Review Manager 5.0 which was a new program for determining HR.

Table 1 Contents of included studies

Author	Location	Immunosuppression	Number of patients	Contents
Meyer *et al*[9]	France	Cyclosporine, methylprednisolone and azathioprine	162	HLA-A, B and DR (5-yr graft survival); HLA-DR (1- and 5-yr graft survival)

RESULTS

Results of the article selection are described in Figure 1. 1568 potentially relevant articles were identified in the search. The abstracts of these studies were reviewed by 2 independent investigators. One thousand four hundred and forty-two did not meet inclusion criteria as their summary score was less than 30. Publications eligible for analysis included 16 articles: 2 prospective studies[7,8] and 14 retrospective cohort studies[9-22]. Non RCTs were included in our studies. In 4 studies acute rejection rates were compared clearly between 0-2 mismatches and 3-6 mismatches of HLA[8,12-14]. That is too say, specific data could only be extracted in these 4 articles. In 10 and 8 studies 1-year and 5-year survival rates, respectively, were compared between 0-2 mismatches and 3-6 mismatches of HLA[7-10,12,13,15,17,19,21,22]. In 6 and 5 studies 1-year and 5-year survival rates, respectively, were compared or could be extracted from survival curves between 0 mismatches and 1-2 mismatches of the HLA-A epitope[7,8,10,17-22]. In 9 and 5 studies 1-year and 5-year survival rates, respectively, were compared or could be extracted from survival curves between 0 mismatches and 1-2 mismatches of the HLA-DR epitope[8,9,16-22]. In 6 studies 1-year survival rates were compared between 0 mismatches and 1-2 mismatches of the HLA-B epitope[8,17-19,21,22]. Although 0 mismatches of the HLA-B epitope were compared with 1-2 mismatches in 5-year survival rates in 3 articles, the statistical heterogeneity was $P = 0.004$ and $I^2 = 82\%$ in the meta-analysis. Hence, the HR of the HLA-B epitope in 5-year survival rates was not included in our discussion. Details of these studies are described in Table 1.

RCS: Retrospective cohort studies; NS: Not specified.

The methodological quality of the studies was assessed using a validated tool as described above (Table 2).

Meta-analysis of HLA epitope

HLA-A, B and DR (0-2 mismatches *vs* 3-6 mismatches): In the studies included in the meta-analysis, a total of 4260 patients were included in 10 articles (1-year graft survival) and 3180 patients were included in 8 articles (5-year graft survival). No differences between 0-2 mismatches and 3-6 mismatches of HLA-A, B, and DR epitopes were seen in terms of 1-year graft survival [HR: 1.04, 95% confidence interval (CI): 0.86-1.25, $P = 0.68$] and 5-year graft survival (HR: 1.09, 95% CI: 0.90-1.32, $P = 0.38$, Figure 2).

HLA-A epitopes (0 mismatch *vs* 1-2 mismatches): Of the studies included in the meta-analysis, there were a total of 2049 patients in 6 articles (1-year graft survival) and 2138 patients in 5 articles (5-year graft survival). No differences between 0 mismatch and 1-2 mismatches of the HLA-A epitopes were seen in terms of 1-year graft survival (HR: 0.95, 95% CI: 0.72-1.25, $P = 0.71$) and 5-year graft survival (HR: 1.06, 95% CI: 0.85-1.34, $P = 0.60$, Figure 2).

HLA-B epitopes (0 mismatch *vs* 1-2 mismatches): A total of 1969 patients were included in 6 articles (1-year graft survival). No differences between 0 mismatch and 1-2 mismatches of the HLA-B epitopes were seen in terms of 1-year graft survival (HR: 0.77, 95% CI: 0.53-1.11, $P = 0.16$, Figure 2).

HLA-DR epitopes (0 mismatch *vs* 1-2 mismatches): A total of 2688 patients were included in 9 articles (1-year graft survival) and 2175 patients were included in 5 articles (5-year graft survival). No differences between 0 mismatch and 1-2 mismatches of the HLA-DR epitopes were seen in terms of 1-year graft survival (HR: 1.07, 95% CI: 0.84-1.37, $P = 0.56$) and 5-year graft survival (HR: 1.18, 95% CI: 0.90-1.54, $P = 0.23$, Figure 2).

HLA epitopes and acute rejection

A total of 1268 patients were included in 4 articles (acute rejection within 3 mo after transplantation). Significant differences between 0-2 mismatches and 3-6 mismatches of HLA-A, B and DR epitopes were seen in terms of acute rejection (RR: 0.77, 95% CI: 0.61-0.97, $P = 0.03$, Figure 2).

DISCUSSION

This is the first systematic review and meta-analysis on the effect of HLA mismatching in short and long term liver graft outcome and acute rejection. We identified and analyzed 16 unique cohort studies and all HLA locus-specific analyses were performed by standard lymphocytotoxicity tests with confirmation by polymerase chain reaction, with HLA-A, B and DR locus mismatches being compared. The results clearly showed that a lower number of HLA mismatches (0-2 *vs* 3-6) did reduce the incidence of acute rejection. The degree of HLA mismatching (0-2 *vs* 3-6) had no significant effect on 1-year and 5-year graft survival. Furthermore, we found no difference between 0 mismatches and 1-2 mismatches in 1-year and 5-year graft survival of HLA-A, HLA-B and HLA-DR on subgroup analysis.

The role of HLA matching between donor and recipient in liver transplant rejection and graft survival has been determined in some cohort studies and there still is no consensus view[7-15,31]. This systematic review analyzed the different data of various studies and has given our own results. However, the main objective in performing this analysis was to assess the necessity of donor-recipient HLA matching before liver transplantation.

As the role of HLA matching between donor and recipient in organ transplant rejection and survival had been proven to increase graft survival after kidney and heart transplantation, it has been debated whether these matches affected the outcomes of the liver graft similarly. In liver transplantation, organ allocation relies mostly on ABO blood group, recipients' body weight, and clinical urgency, and the outcome of liver grafts relies mostly on complications after transplantation; HLA matching is usually not taken into account and the literature is inconsistent on the role of this parameter. In fact, any complications after transplantation are associated with graft outcome and rejection. Liver artery thrombosis, venous thromboembolic complications, seventh-day syndrome, primary graft nonfunction, and serious infection can decrease survival[32-36]. Compared to HLA mismatching, these complication are more important for long term graft survival.

Although the liver graft was considered to be a kind of immune-free organ, in our meta-analysis a lower number of HLA mismatches (0-2 *vs* 3-6) did reduce the incidence of acute rejection. It has become clear in recent years that mismatching of HLA in liver grafts led to endothelialitis induced by the recipient's natural killer cells and so rejection was instigated. The association of acute rejection with

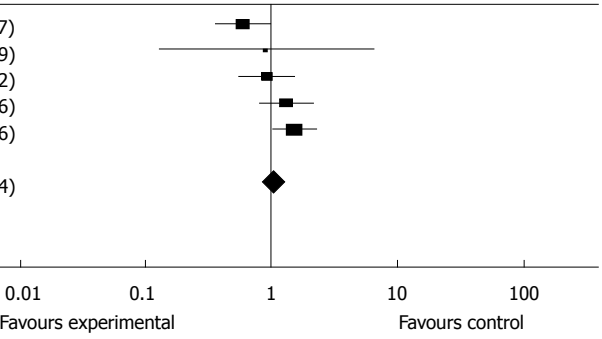

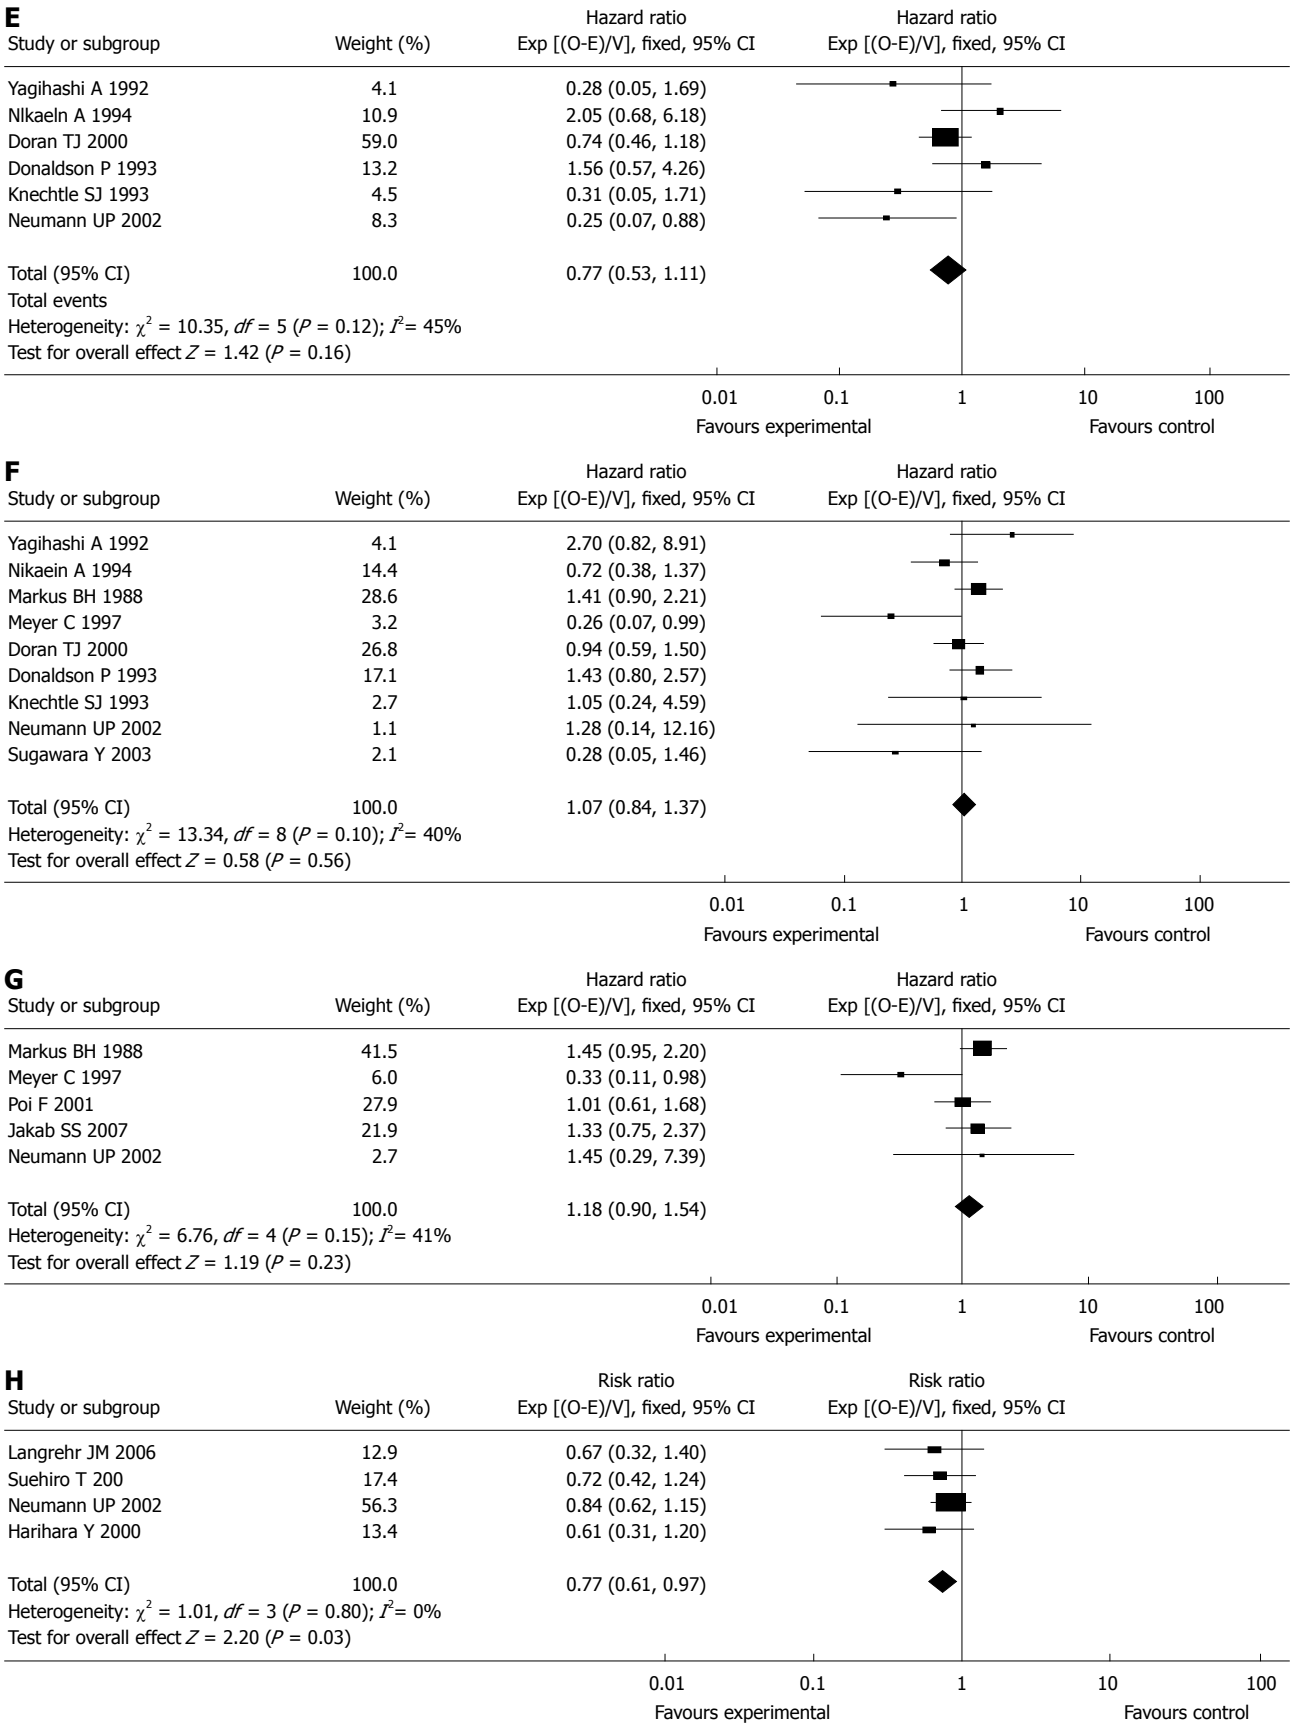

Figure 2 Meta-analysis of cohort trials comparing the effect of different mismatches of human leukocyte antigen epitopes on graft survival and acute rejection. A: 0-2 *vs* 3-6 mismatches of human leukocyte antigen (HLA)-A, B, DR epitopes on 1-year graft survival; B: 0-2 *vs* 3-6 mismatches of HLA-A, B, DR epitopes on 5-year graft survival; C: 0 *vs* 1-2 mismatches of HLA-A epitopes on 1-year graft survival; D: 0 *vs* 1-2 mismatches of HLA-A epitopes on 5-year graft survival; E: 0 *vs* 1-2 mismatches of HLA-B epitopes on 1-year graft survival; F: 0 *vs* 1-2 mismatches of HLA-DR epitopes on 1-year graft survival; G: 0 *vs* 1-2 mismatches of HLA-DR epitopes on 5-year graft survival; H: 0-2 *vs* 3-6 mismatches of HLA-A, B and DR epitopes on acute rejection.

3 other risk factors (cold ischemia time greater than 15 h, pretransplantation elevation of aspartate transaminase, and older donor age) are less readily explained, but suggest that nonallogeneic and allogeneic immunological injury may be related. Both a long cold ischemia time and older donor age predispose an allograft liver to injury shortly after transplantation, which evokes immunological reactions that are not necessarily triggered by allogeneic differences.

Although a meta-analysis may provide a high level of scientific evidence, it is important to realize the limitations of interpreting results of meta-analyses. One major limitation to the meta-analysis is that inferences are based on aggregate analysis of relatively heterogeneous studies. We acknowledge the potential heterogeneity of combining studies from different centers in different geographic locations with different treatment protocols. In our systematic review, results obtained from each study were considered to be homogeneous (heterogeneity test was $P > 0.10$ and $I^2 < 50\%$ in all available studies) in spite of there being no RCTs in this meta-analysis. Although we did not investigate through meta-regression any differences in the use of immunosuppressants or differences in study centers, the treatment protocols were nearly the same: cyclosporine or tacrolimus, azathioprine and prednisolone and no mycophenolate mofetil were used (Table 1).

Additionally, some studies did not report results with the measures that we chose for data extraction. It is the second limitation we must deal with. Survival rates under 1-year or 5-year were extracted by special software from survival curves if they was not shown in articles directly. We did not even obtain any data from some cohort studies, but including or excluding these articles also did not affect our conclusions.

The length of post transplantation follow-up was another limitation of many of the trials that we analyzed. Although most trials reported follow-up of some patients up to 5 years or even longer, some reported follow-up only to 1 year or 6 mo. Long-term graft survival, including HBV, HCV and hepatocellular carcinoma recurrence, may only become apparent or more pronounced after many years of post liver transplantation follow-up, and hence we may have underestimated the mortality in our study. In other words, we may have overestimated the role of HLA mismatching in liver graft loss.

Despite these limitations, our meta-analysis suggests that a lower number of HLA mismatching did reduce the incidence of acute rejection. The degree of HLA mismatching had no significant effect on 1-year and 5-year graft survival. Performing good donor-recipient HLA matching appears to be associated with a reduction in the incidence of acute rejection. Thus to obtain a shorter recovery time and avoid more rejection post transplantation, HLA matching examinations should be considered before surgery.

COMMENTS

Background

The role of human leukocyte antigen (HLA) matching between donor and recipient in organ transplant rejection and survival has been widely studied and proven to increase graft survival and to reduce the incidence of acute or chronic rejection. In contrast, major histocompatibility complex analysis is not routinely performed in liver transplantation because its importance remains controversial.

Research frontiers

Different groups have reported disparate results on the effect of HLA matching: some patients acquired benefit from high degrees of HLA matching but concern has been voiced about a greater likelihood of recurrence of primary disease with good HLA compatibility.

Innovations and breakthroughs

This is the first systematic review and meta-analysis on the effect of HLA mismatching in short and long term liver graft outcome and acute rejection. Importantly, the authors have some different conclusions compared to traditional views. Good donor-recipient HLA matching appears to be associated with a reduction in the incidence of acute rejection although there is no effect on 1-year and 5-year survival rates.

Applications

The percentage of graft survival was extracted by "Engauge Digitizer" from survival curves if the raw data was not presented. All statistical analyses were performed using Review Manager 5.0 which was a new program for determining HR.

Peer review

The authors aimed to assess the effect of HLA mismatching in liver graft outcome and acute rejection from available cohort studies by a systematic review and meta-analysis. The design of the study is rational and reliable, and the statistical methods used are appropriate. The article is also well organized. The conclusion may provide reliable and valuable information for clinical practice.

Abstract

AIM: To establish a predictive algorithm which may serve for selecting optimal candidates for interferon-α (IFN-α) treatment.

METHODS: A total of 474 IFN-α treated hepatitis B virus e antigen (HBeAg)-positive patients were enrolled in the present study. The patients' baseline characteristics, such as age, gender, blood tests, activity grading (G) of intrahepatic inflammation, score (S) of liver fibrosis, hepatitis B virus (HBV) DNA and genotype were evaluated; therapy duration and response of each patient at the 24th wk after cessation of IFN-α treatment were also recorded. A predictive algorithm and scoring system for a sustained combined response (CR) to IFN-α therapy were established. About 10% of the patients were randomly drawn as the test set. Responses to IFN-α therapy were divided into CR, partial response (PR) and non-response (NR). The mixed set of PR and NR was recorded as PR+NR.

RESULTS: Stratified by therapy duration, the most significant baseline predictive factors were alanine aminotransferase (ALT), HBV DNA level, aspartate aminotransferase (AST), HBV genotype, S, G, age and gender. According to the established model, the accuracies for sustained CR and PR+NR, respectively, were 86.4% and 93.0% for the training set, 81.5% and 91.0% for the test set. For the scoring system, the sensitivity and specificity were 78.8% and 80.6%, respectively. There were positive correlations between ALT and AST, and G and S, respectively.

CONCLUSION: With these models, practitioners may be able to propose individualized decisions that have an integrated foundation on both evidence-based medicine and personal characteristics.

Key words: Chronic hepatitis B; Interferon-α; Patient selection; Predictive model; Scoring system; Treatment outcome

INTRODUCTION

Chronic hepatitis B (CHB) is one of the most refractory diseases that mankind faces and is a serious global public health problem. Hepatitis B virus (HBV) infection often leads to acute or chronic hepatitis B, hepatocellular carcinoma (HCC) and other complications. Of approximately 350 million carriers of HBV worldwide, about 1 million die from chronic complications, such as cirrhosis, HCC or both every year[1]. According to Liu *et al*[2], there is a 9% rate of HBV surface antigen (HBsAg) in the general population in China. In the United States, there are an estimated 1.25 million HBV carriers[3]. Currently, available antiviral options can be divided into 2 types, interferon-α (IFN-α) and nucleoside/nucleotide analogues, including conventional IFN-α, pegylated IFN-α (PEG-IFN), lamivudine, adefovir dipivoxil, entecavir, telbivudine, *etc*. IFN-α is one of the major choices; however, some factors greatly hinder its wide range of applications. First of all, the expense of antiviral therapy is considerable in either underdeveloped or developing countries; in addition, there are several side effects, such as fatigue, flu-like syndrome and others; ultimately, the most important aspect is that only a proportion of patients may achieve a response after therapy[4,5]. Thus, antiviral therapy is not generally accepted by patients.

Predicting the efficacy of IFN-α is crucial before attempting treatment for CHB patients. Some factors, such as HBV genotype A or B, lower viral load, higher serum alanine aminotransferase (ALT) levels, higher grading (G) of intrahepatic inflammation, and lower staging (S) of liver fibrosis, have been identified to be the predictors of the outcome of IFN-α therapy in HBV e antigen (HBeAg)-positive patients[3,6,7]. Female gender, short course of disease, having mild liver fibrosis, having good compliance with therapy, absence of co-infection and an early virological response at the 12th wk also indicate a good therapeutic outcome[8]. Sometimes, however, patients do not have all the "positive" predictors. They may also have one or more "negative" predictors. For example, a patient infected by HBV of genotype C, has a high viral load, accompanied by high ALT and high G. Is he suitable for IFN-α treatment? As pointed out by the European Association for the Study of the Liver, the HBV genotype has a poor individual predictive value, and currently, genotype alone should not define the choice of treatment[7]. These types of issues may be challenging for both practitioners and patients. Owing to the trials that had rigorous designs, many patients have benefited from evidence-based medicine developed in the last several decades. However, evidence-based medicine aims at the resolution of issues which came from individuals with a common background whereas individual information is not always taken into account. The current research aims at making a sensible decision that has an integrated foundation in both evidence-based medicine and personal characteristics.

We therefore conducted the present study to determine (1) baseline predictive factors for the response to IFN-α; (2) what was the relationship between these predictive factors; (3) whether a predictive algorithm for IFN-α treatment of CHB can be derived from these factors; and (4) what was the efficacy of the model.

MATERIALS AND METHODS

Patients

During the period between July 2005 and November 2008, all HBeAg-positive CHB patients were followed up for their response to IFN-α if they initially started IFN-α treatment in our Liver Division, the 174th Hospital of the PLA, the Traditional Chinese Medicine Hospital of Xiamen, Zhongshan Hospital Xiamen University, Xiamen, or Macheng Hospital, Hubei. Patients were recruited according to the guidelines in China[8], and were administrated with 5 MU of conventional IFN-α every other day for 24 wk or longer. The patients' baseline information was collected, including age, gender, blood tests, G, S, HBV DNA, genotype, *etc*. Several studies have indicated the potential benefits of extended duration of IFN-α or PEG-IFN therapy regarding a sustained response[9,10] or suppression of chronic complications[11]. Thus, duration was also recorded for balancing the effect of therapy span. Patients were excluded if they had HCC on presentation or other concomitant diseases including hepatitis A, C or D virus infection, autoimmune hepatitis, Wilson's disease, primary biliary cirrhosis and alcoholic liver disease. Patients with the following conditions were also excluded: pregnancy, mental disorders (such as severe depression), uncontrolled epilepsy, alcohol abuse, narcotic abuse, uncontrolled autoimmune disorders, decompensated liver cirrhosis, symptomatic heart disease, neutrophil count below 1.0×10^9/L and/or platelet count below 50×10^9/L before treatment, had received or were receiving any other form of established treatment for CHB. Finally, 474 patients were included in the current study. For the treatment of HBeAg-positive CHB, a combined response (CR) was defined as ALT levels returning to normal, undetectable HBV DNA, and HBeAg seroconversion; partial response (PR) was defined as ALT levels returning to normal, HBV DNA $< 10^5$ copies/mL, but no seroconversion; whereas non-response (NR) refers to no CR or PR observations[8]. The mixed set of PR and NR was recorded as PR+NR. A sustained response was defined as the response at the 24th wk after cessation of IFN-α treatment.

Monitoring of patients

Patients were followed up every 1-2 mo by monitoring HBsAg status, HBeAg/anti-HBe status, HBV DNA level,

ALT, aspartate aminotransferase (AST), α-fetoprotein (AFP), complete blood count and mental status. Complete blood counts were taken once every 1-2 wk for the first month, then once per month until cessation of treatment. Other tests, such as thyroid function, blood glucose, routine urinalysis, were taken once every 3 mo. For patients who had abnormal thyroid function at baseline, appropriate therapy was initiated, and thyroid function was closely monitored during antiviral therapy. If there was evidence of a depressive disorder or suicidal tendency, treatment was stopped and patients were closely monitored. Ultrasound of the liver was scheduled for patients with AFP levels greater than 20 ng/mL. Patients were suggested to stop IFN-α administration if CR or NR occurred after therapy for 24 wk, or if severe side effects developed during the course of treatment. Patients' choices were also taken into account.

Determination of HBV genotypes and HBV DNA levels

Sera from patients on presentation were taken for the following tests: (1) HBV genotyping performed by the polymerase chain reaction (PCR)-fluorescence detection kit for HBV genotype B, C according to the manufacturer's instructions (Bioselex, Hangzhou, China); and (2) HBV DNA levels were determined by quantitative fluorescence PCR on the ABI 7000 (Applied Biosystems), with a lower limit of detection of 1000 copies/mL. HBV DNA levels below the lower detection limit were regarded as negative for statistical calculations.

Statistical analysis

Statistical analyses were performed using version R 2.8.1 (a language and environment for statistical computing, Vienna, Austria, ISBN 3-900051-07-0, http://www.R-project.org). The inter-variable correlation was determined by the Spearman rank correlation coefficient. The Gini index based on random forest methodology was used to determine whether the identified variables were associated with therapy outcomes. In the present study, the response to IFN-α treatment (dependent variable) was ordinal data. If the independent variable was ordinal data (such as ALT, AST, G, S, *etc.*), Kendall's *tau-b* test was adopted to test the statistical significance between independent variable and dependent variable. For the nominal independent variable (gender, genotype, *etc.*), the Pearson χ^2 test was used.

About 10% of patients were randomly selected as the test set, and the remaining patients were employed as the training set. The predictive model was constructed with a support vector machine (SVM) package for the R platform. Accuracies for CR and PR+NR in the training set and test set were calculated. The above process was repeated 300 times and mean accuracy was calculated. Performance of the constructed predictive algorithm was evaluated by the mean accuracies for CR and PR+NR for the training set and test set. The scoring system for sustained CR (SCR) was derived from our observations (Table 1) with computer-aided minor adjustment according to other data[3,7,12,13]. The weight for every level in each factor was rounded to the nearest integer.

Table 1 Baseline demographic and virological data of the study population

Factor	*n* (range)
Sex (M:F)	345:129
Age (yr)	29.8 (10-58)
ALT (U/L)	250 (16-1908)
AST (U/L)	146 (24-1304)
Genotype (A:B:C)[1]	51:212:211
HBV DNA (log copies/mL)	7.35 (5.00-9.83)
Fibrosis staging, S (0:1:2:3:4)	10:154:157:114:39
Histology activity index, G (1:2: 3:4)	39:215:169:51

Continuous variables are expressed as median (range). [1]B, C refers to genotype B, C, respectively; genotype B and C co-infection and other genotypes were named as A. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; HBV: Hepatitis B virus.

The area under the curve (AUC) was then calculated for measuring the overall prediction accuracy. A 95% confidence interval (CI) for an AUC was obtained by sampling the 474 patients for 1000 bootstrap samples with the confidence limits calculated as the 2.5th and 97.5th percentiles. The scoring system was assessed by the leave-one-out cross-validation in order to assess the performance of new data[14]. To ease clinical employment of the SCR score, cut-off values were determined by maximizing the Youden index, i.e. sensitivity + specificity - 1, calculated from the receiver operating characteristic curves analysis. Accuracy of using the optimal cut-off values was assessed by the sensitivity, specificity, predictive values and likelihood ratios. Their 95% CIs were obtained from 1000 bootstrap samples. The cut-off values were also cross-validated by the leave-one-out method.

RESULTS

Demographics

A total of 474 CHB patients were enrolled. The baseline demographics, liver function tests, liver biochemistry, histology data and virological data are listed in Table 1. As shown in Table 2, the ratios of CR, PR and NR at the 24th wk after cessation of IFN-α therapy were 34.4%, 45.1% and 20.5%, respectively. It should be pointed out that genotype A in the current research refers to co-infection of genotype B and C, and other genotypes beside B and C.

Patients' factors and treatment factor for the response to IFN-α therapy

As shown in Table 2, female patients had a higher chance of a CR compared to male patients (41.1% *vs* 31.9%, $P < 0.001$; Kendall's *tau-b* test). Genotype B had a preferential effect on CR (45.3% and 25.1% for genotype B and genotype C, respectively, $P < 0.001$, Pearson χ^2 test). ALT and AST had a positive reciprocal relationship with treatment response ($P < 0.001$; Kendall's *tau-b* test) (Table 2).

Table 2 Individual factors of patients with diverse responses at the 24th week after cease of interferon-α therapy

	CR	PR	NR
Sex (M:F)	110:53	163:51	72:25

[a]$P < 0.05$, [b]$P < 0.01$; [1]log copies/mL; [2]Response after 6 mo of follow-up. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase.

Inter-variable correlations

The correlations between variables were determined by the Spearman rank correlation coefficient. As shown in Table 3, there were positive reciprocal relationships between G and S (0.74, $P < 0.01$), ALT and AST (0.73, $P < 0.01$). Baseline ALT (0.39, $P < 0.01$), AST (0.35, $P < 0.01$) and genotype (0.25, $P < 0.01$) had a substantial predictive effect on the sustained response. The correlations between G and S, ALT and AST are illustrated in Figure 1A and B.

Multivariate analysis for factors associated with the response to IFN-α therapy

Stratified by duration of IFN-α therapy, Gini index analysis showed that baseline predictors, from highly significant to least significant, were ALT, HBV DNA in log copies/mL, AST, genotype, S, G, age and gender (Table 4).

Predictive algorithm for the SCR to IFN-α therapy

Based on SVM, a predictive model was developed for the SCR to IFN-α therapy. According to the established model, the accuracies for SCR and PR+NR respectively were 86.4% and 93.0% for the training set, 81.5% and 91.0% for the test set.

Predictive scoring system for the SCR to IFN-α therapy

Based on our data provided in Table 2 with computer-aided minor adjustment according to other data[3,7,12,13], a predictive scoring system was developed for the SCR to IFN-α therapy. The odds ratio of SCR score was 15.25 (95% CI: 9.65-24.68, $P < 0.001$) indicating that the scoring system had an excellent prediction performance. By optimizing with the Youden's index, the optimal cut-off for the prediction of SCR was 169. This cut-off had good sensitivity and specificity and had been accurately validated by the leave-one-out validation (Table 5). The AUCs were as high as 0.797 (95% CI: 0.773-0.812) for SCR prediction (Figure 2A). The odds ratio of SCR according to the scoring system is depicted in Figure 2B.

Table 4 Significance of baseline factors for sustained combined response to interferon-α therapy

Variable	CR	PR	NR	Mean decrease accuracy	Mean decrease Gini
ALT	2.242	0.860	2.611	1.363	42.806

AUC	0.79	0.779-0.807

AUC: Area under the curve.

DISCUSSION

In summary, the main findings and results of the current research include: (1) development of an accurate predictive model for the SCR to IFN-α therapy; (2) deduction of a scoring system for SCR as the data mining method may be unavailable to most the clinicians; (3) identification of positive reciprocal relationships between G and S, ALT and AST; (4) a predictive role of baseline ALT, AST and genotype for SCR; and (5) baseline predictive factors, listed from the greatest to the least significant, are ALT, HBV DNA, AST, genotype, S, G, age and gender.

The predictive factors for the response to IFN-α therapy have been extensively investigated; however, response prediction for individual patients remains uncertain. First, evidence-based medicine aims at a therapeutic strategy for patients with a similar background rather than a given patient. Additionally, a given individual may have "positive" predictive factors and "negative" predictive factors at the same time. Thus, patients or even clinicians may be perplexed by the probability estimation of therapy outcome. This leads to significant profligacy of health resources and a delay in treating patients who need an appropriate antiviral intervention. Fortunately, the present study may facilitate the management of these difficulties. One of the limitations of the current study is that most of the genotypes are B and C, or co-infection of B and C, which is in accordance with the report by Zeng *et al*[15]. There are not enough patients infected by other genotypes of HBV for statistical analysis. Another limitation is that treatment with conventional IFN-α rather than PEG-IFN was evaluated in the present research. Although PEG-IFN was extensively prescribed in developed countries, its application was greatly hindered by its high cost in developing countries. In China, there is great disparity in the prescription costs of IFN-α and PEG-IFN. We cannot recruit enough patients administrated with PEG-IFN for statistical analysis. However, IFN-α and PEG-IFN share the same bioactive molecule *in vivo* and similar baseline predictors[16]. Therefore, using our scoring system, which was easily employed in clinical practice, the response to PEG-IFN therapy may be predicted with reasonable accuracy. If statistical packages were available, higher predictive accuracy could be achieved.

In line with several studies[12,17], genotypes B or C have dramatically different effects on treatment response. Apart from genotypes, the present study also found that increasing HBV DNA levels were associated with a stepwise decrease in the response, which was similar to that of S; in contrast, increasing ALT, AST and G played an opposite role. Patients with higher ALT, AST and G tended to have better outcomes. According to the inter-variable correlation analysis, there were significantly positive reciprocal relationships between ALT and AST, G and S, respectively. The correlation between ALT and AST sounds reasonable, which may be a result of parallel release of intracellular contents after immune injury.

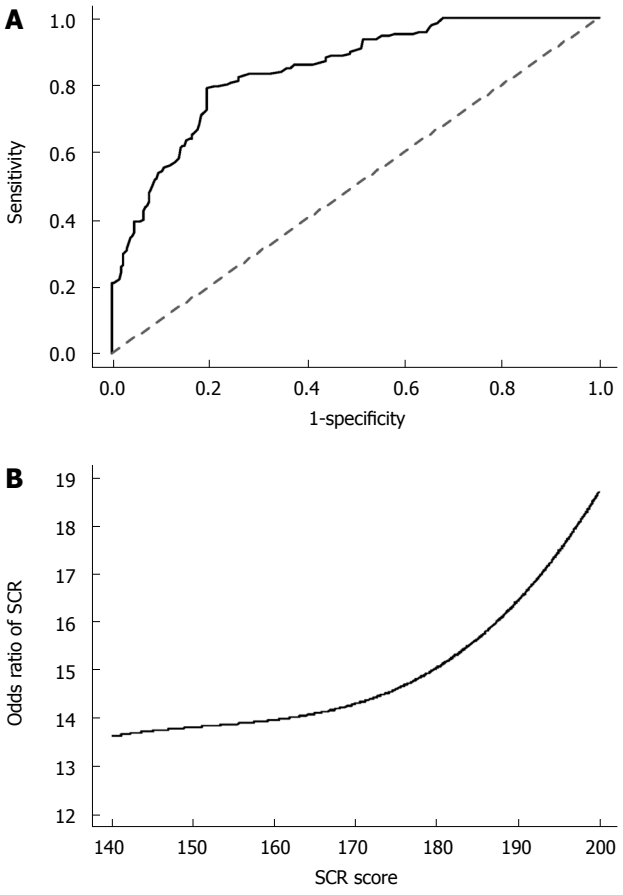

Figure 2 Predictive performance of the scoring system for sustained combined response. A: Receiver-operator characteristics curve of the scoring system for sustained combined response (SCR); B: Odds ratio of the scoring system for SCR.

Repeated intrahepatic immunologic inflammation triggers fibrinogen secretion from hepatic stellate cells and eventually leads to cirrhosis, which may partly explain the correlation between G and S. The performed study indicated the most important predictive factor was baseline ALT, followed by HBV DNA level, AST, genotype, S, G, age and gender. Interestingly, the Gini index of S was slightly higher than that of G, which may be due to the higher variation of G than that of S though they have a high correlation as mentioned before. Baseline AST also had a considerable predictive role for SCR. Although ALT is regarded as a specific index for HBV-induced inflammation, AST rather than ALT manifests a correlation with fibrosis stage[18]. Data by Brook *et al*[19] also indicated AST > 85 U/L is a predictive factor for the response to IFN-α therapy.

We developed a predictive model that was shown to have parallel accuracies for both a training set and test set by adjusting kernel parameters, which ensured that satisfactory sensitivity may be achieved for samples out of the observation pool. In other words, the established model would have a reasonable predictive accuracy for patients who were not enrolled in the current research. In addition, a scoring system for SCR was developed to identify patients who may have SCR if the score was greater or equal to the optimal cut-off value of 169. This score was validated by the stringent leave-one-out statistical analysis with high sensitivity and specificity of 78.2% and 79.9%, respectively, for the prediction of SCR. Using these SCR scores, the practitioner can calculate the prognosis of a patient on presentation, which is important for devising individual management of the patient. The practitioner can also identify very high-risk patients who should be recommended for treatment by nucleoside/nucleotide analogues to obtain good results.

In clinical practice, we are not aware of any predictive score for the SCR to IFN-α therapy in HBeAg-positive CHB patients with the integration of potential predictive factors. Our novel predictive algorithm and SCR score may serve as an excellent reference for clinicians to decide who should undergo IFN-α therapy. With these models, practitioners would be able to propose individualized treatment paradigms that have an integrated foundation in both evidence-based medicine and personal characteristics. It has extensive potential clinical use to identify CHB patients who have a high potential of a SCR to IFN-α therapy. These patients should be suggested to be treated by IFN-α to delay or prevent lethal complications of CHB such as liver cirrhosis and HCC.

ACKNOWLEDGMENTS

We are much indebted to Professor Bayasi Guleng and Miss Qi Li for discussion and comments on the manuscript.

COMMENTS

Background

Predicting the efficacy of interferon-α (IFN-α) is crucial before attempting treatment of chronic hepatitis B (CHB) patients. Though predictors of the responses to IFN-α have been well identified, patients frequently have "positive" and "negative" predictors at the same time. Therefore, it is very difficult to predict the treatment response before IFN-α therapy for a specific patient.

Research frontiers

Evidence-based medicine aims at the resolution of issues which came from individuals with a common background whereas individual information can not always be taken into account. The current research aims at sensible decision-making that has an integrated foundation on both evidence-based medicine and personal characteristics.

Innovations and breakthroughs

The current research successfully integrated the patients' personal characteristics into the foundations of evidence-based medicine. A precise prediction model and a simplified scoring system for a sustained combined response (SCR) to IFN-α were generated.

Applications

It has extensive clinical use to identify CHB patients who have a high potential of a SCR to IFN-α therapy. With these predictive models, practitioners would be able to propose individualized treatments that have an integrated foundation in both evidence-based medicine and personal characteristics.

Peer review

This is an interesting report of a prediction model and simplified scoring system for SCR to IFN.

Abstract

Postoperative intussusception is an unusual clinical entity in adults, and is rarely encountered as a complication following gastric surgery. The most common type after gastric surgery is retrograde jejunogastric intussusception, and jejunojejunal intussusception has been rarely reported. We report a case of anterograde jejunojejunal intussusception after radical subtotal gastrectomy with Billroth Ⅱ anastomosis in a 38-year-old Korean woman with early gastric cancer, and include a review of the literature on this unusual complication.

Key words: Intussusception; Postoperative complications; Gastrectomy

INTRODUCTION

Postoperative intussusception is an unusual clinical entity in adults, and is rarely encountered as a complication following gastric surgery. The reported incidence is under 0.1% in patients who undergo gastric surgery[1]. The most common type after gastric surgery is jejunogastric intussusception[2]. Jejunojejunal intussusception has been rarely reported, and all previously reported cases have been observed after Roux-en-Y gastro- or esophagojejunostomy. Here, we report a case of anterograde jejunojejunal intussusception that developed at the efferent limb after subtotal gastrectomy with Billroth Ⅱ reconstruction in a woman with early gastric cancer. We also include a review of the literature on this unusual complication. To the best of our knowledge, this is the first case report of jejunojejunal intussusception after partial gastrectomy with Billroth Ⅱ type gastrojejunostomy.

CASE REPORT

A 38-year-old woman was referred to our outpatient clinic for biopsy-proven adenocarcinoma of the stomach. The patient had no significant medical history. On gastroduodenoscopic examination, type Ⅱc early gastric cancer was found at the lesser curvature of the body. Moderately differentiated adenocarcinoma was confirmed by performing a biopsy of the lesion. Staging work-up including abdominal computed tomography (CT) revealed no metastasis.

Radical subtotal gastrectomy with Billroth Ⅱ reconstruction, including complete dissection of the perigastric nodes plus the lymph node along the left gastric and hepatic arteries, was performed. The lesser curvature of the stomach and the duodenal stump were closed with staples. Antecolic, isoperistatic gastrojejunostomy was performed using Albert-Lembert sutures. A nasogastric tube was placed in the remnant stomach.

On the first postoperative day (POD), the patient did not complain of abnormal symptoms. However, on POD 2, she started to complain of recurrent episodes of abdominal colicky pain, which did not subside for over 5 d,

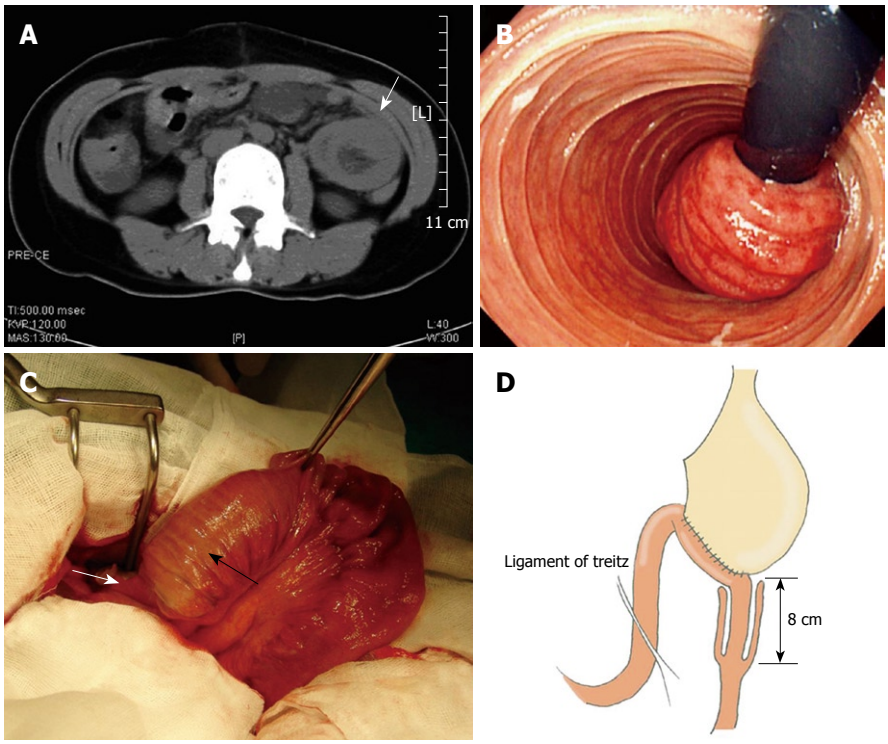

Figure 1 Radiologic, endoscopic and intraoperative findings of anterograde jejunojejunal intussusception. A: Abdominal computed tomography showed a non-homogeneous mass (arrow) in the left upper quadrant of the abdomen; B: A J-turn view of gastrofibroscopic examination demonstrated a congested jejunal mass (intussusceptum); C: Intraoperative findings revealed that the intussusception started just below the gastrojejunostomy anastomosis. The black arrow indicates the intussuscipiens, and the white arrow indicates the intussusceptum; D: Schematic diagram of the intussusception at the efferent-loop.

without a definite cause. During that time, 500-900 mL bile-containing gastric juice was drained *via* the nasogastric tube daily. Serial plain abdominal radiography and laboratory tests showed no remarkable findings. The blood tests were unremarkable except for elevated white blood cell count up to 16000/μL. On POD 6, the patient complained of intermittent abdominal cramping, and abdominal tenderness in the left upper quadrant of the abdomen on physical examination. Non-enhanced CT was carried out and revealed a non-homogeneous jejunal mass below the anastomosis site (Figure 1A). Gastrofibroscopic examination was performed subsequently. The entrance of the efferent loop was narrow and edematous, but the gastrofibroscope was able to pass through the efferent loop. A congested jejunal mass was observed on the J-turn image (Figure 1B). Emergency laparotomy was performed, on suspicion of a jejunojejunal intussusception.

On exploration, an anterograde jejunojejunal intussusception was found at about 5 cm distal to the gastrojejunostomy anastomosis line (Figure 1C and D). Manual reduction was performed carefully and the intussusception came loose subsequently. The proximal jejununal segment (intussusceptum), about 8 cm in length, did not recover from ischemia. The primary gastrojejunostomy anastomosis, which was non-viable, was removed, and a Roux-en-Y gastrojejunostomy was formed. On pathological examination, no identifiable leading point for the intussusception was present. She was discharged without further complications or abnormal symptoms on POD 11 after the second operation.

DISCUSSION

Intussusception is primarily a disease of infancy and childhood, and only about 5% of cases occur in adults[3]. Although childhood intussusception is idiopathic in 90% of cases, adult intussusception has an organic lesion as a leading cause in 70%-90% of cases, and > 50% of the lesions have been reported to be malignant[4,5].

Although postoperative intussusception is a rare clinical entity in both age groups, it is also more common in the pediatric population than in adults. It accounts for 5%-10% of cases of postoperative ileus in infancy and childhood[6], and only 1% of cases in adults[7].

Intussusception is an extremely rare complication after gastric surgery; the incidence is reported to be < 0.1%[1]. Since the first case of jejunogastric intussusception after gastrojejunostomy was reported by Bozzi[8] in 1914, a large number of isolated cases have been reported, and fewer than 200 cases of postoperative intussusception after gastric surgery have been reported in the English-language literature[2]. Retrograde jejunogastric intussusception is the most common type after gastric surgery[9]. Rarer cases of jejunojejunal[10-14], jejunoduodenal[15] or duodenogastric intussusception[16], or intussusception through a Braun anastomosis[17] also have been reported after gastric surgery.

All cases of jejunojejunal intussusception have been observed after Roux-en-Y gastro- or esophagojejunostomy. To the best of our knowledge, this is the first case report of jejunojejunal intussusception after partial gastrectomy with Billroth II type gastrojejunostomy. However, it should be pointed out that jejunojejunal intussusception might not be such a rare problem after Roux-en-Y gastric bypass for morbidly obese patients[18]. Simper *et al*[18] recently have reported 22 cases (0.15%) of postoperative jejunojejunal intussusception after more than 15000 Roux-en-Y gastric bypasses.

In the present case, neither functional nor mechanical causes were identified as leading causes of intussusception. Although most adult intussusceptions are caused

by a definable structural lesion[5], definite anatomical or pathological causes are rarely found in cases following gastric surgery[2]. A variety of postoperative conditions, such as adhesions around the suture lines[3,19], a long intestinal tube[20], increased intra-abdominal pressure[1], shortening of the jejunal mesentery[21], and reverse peristalsis[19,22], have been proposed as possible mechanisms of intussusception after gastric surgery, but none has been confirmed. Functional causes include reverse peristalsis, which is triggered by an anastomosed jejunal loop being irritated by hydrochloric acid, and atonic stomach, which is caused by vagotomy[2].

Diagnosis of postoperative intussusception is difficult in adults. The classic symptom triad of intussusception (pain, palpable mass, and currant-jelly stool) rarely occurs in adults[3]. Furthermore, usual symptoms encountered in acute postoperative intussusception are easily confused with postoperative ileus or adhesion[23,24]. For these reasons, diagnosis was delayed in our case, which rapidly progressed to incarceration and strangulation of the involved efferent limb. Thus, a high index of clinical suspicion is necessary for early diagnosis of this potentially lethal complication. Upper gastrointestinal endoscopy and abdominal CT are highly diagnostic in the setting of urgent, high-level intestinal obstruction[25].

Endoscopic reduction of jejunogastric intussusception has been suggested in a few selected cases[26]; however, this is associated with a significant risk of recurrence[27]. Surgery is the mainstay of treatment in jejunojejunal intussusception, and should be individualized for each patient. Surgical procedures include reduction, resection, and revision of the intussusception and takedown of the previous anastomosis with construction of a new anastomosis, depending on the operative findings. If the affected segment loses viability, resection of the non-viable segment is inevitable. Ozdogan *et al*[13] have suggested that the operation should be conservative, provided that the bowel is viable; manual reduction is the only required treatment, and other preventive measures are not necessary.

We report a case of anterograde jejunojejunal intussusception that caused acute efferent loop syndrome after partial gastrectomy. Acute jejunojejunal intussusception after gastric surgery is an extremely rare clinical entity that requires a high index of clinical suspicion for early diagnosis and prompt surgical management. Thus, intussusception should be considered as one of the possible causes of high-level intestinal obstruction in the immediate postoperative period after partial gastrectomy.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in tahe field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case

report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

AIM AND SCOPE		*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries. The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Abstract

The incidence of colorectal carcinoma is increasing in young patients, in contrast to the well established wisdom that it is exclusively diagnosed in patients older than 40 years. In this survey, we examined all possible risk factors, and we recommend a number of measures for early detection in young patients who are at risk of developing this malignant tumor.

Key words: Colorectal adenocarcinoma; Food contamination; Pesticides; Young patients; Free radicals

Peer reviewer: Kam-Meng Tchou-Wong, Assistant Professor, Departments of Environmental Medicine and Medicine, NYU School of Medicine, 57 Old Forge Road, Tuxedo, New York, NY 10987, United States

INTRODUCTION

Colorectal cancer continues to be one of the most common human malignancies, afflicting nearly one million individuals worldwide every year. The disease can be considered endemic in all western and industrialized countries, but there are indications that, in the near future, colorectal neoplasms will become frequent also in populations that at present show a low incidence of the disease[1]. Reports from Asian and African countries have demonstrated that annual diagnosis of colorectal cancer is increasing[2-5] and cases have been identified in those aged < 40 years old[6]. However, hereditary factors could not be recognized as risk factors in these cases[6] and high dietary intake of meats and fats could not be blamed as risk factors in these developing countries because of a lack of supply of either to the majority of the population[6-8]. Therefore, this phenomenon requires further investigation. It is likely to be due to chemical contamination of food and drink.

CHLORINATION OF DRINKING WATER AND DEVELOPMENT OF BOWEL CANCER

It is likely that chlorination of drinking water plays a role in the above phenomenon. During the chlorination process, chlorine reacts with organic materials in the water to produce a complex mixture of halogenated and non-halogenated by-products, the concentration and distribution of which vary with characteristics of the raw water and the treatment process[9]. A large number of halogenated chemical species have been identified, including trihalomethanes, halogenated acetonitriles, halogenated acids, haloketones, and haloaldehydes[10]. Trihalomethanes are the most frequently occurring by-products[11,12] and are routinely measured in public water supplies, thus making them a useful marker for the level of chlorination by-products in treated water. Chronic exposure to disinfected surface waters is considered one of the contributing factors to the development of urinary bladder and colon cancer[13-15]. Mutagenic activity of chlorinated water may be due to the presence of chemicals produced from reactions of chlorine with natural substances released by the breakdown of vegetation in the source water[16]. The chlorinated hydroxyfuranone [e.g. 3-chloro-4-(dichloromethyl)-5-hydroxy-2(5H)-

furanone], for example, has been shown to be responsible for a majority of this mutagenic activity[5,12]. 3-chloro-4-(dichloromethyl)-5-hydroxy-2(5H)-furanone has been reported to occur at much lower concentrations in drinking water than other disinfection by-products, yet it might be a significant public health concern because it is the most potent mutagen currently identified in drinking water[17]. Two years of treatment with this compound in drinking water resulted in a multi-organ carcinogenic response in male and female Wistar rats[18]. Moreover, reliable evidence from epidemiological studies has suggested an increase in the risk of urinary bladder, colon, and rectal cancer among people using disinfected drinking water that contains high levels of trihalomethanes[15,19]. King *et al*[20] have reported that increasing exposure to different drinking water constituents is associated with increasing risk of colon cancer in men. In this population, several halogenated chemical species have shown a tendency for increasing colon cancer risk across different exposure categories due to increasing exposure, which reached at least a 53% elevation in risk for the highest exposure categories. Long-term (approximate 35 years) exposure to trihalomethanes at a level of approximate 75 mg/L was associated with a doubled colon cancer risk among men (OR: 2.10, 95% CI: 1.21-3.66). The highest quartile of cumulative trihalomethanes-years exposure was associated with an OR of 1.74 (95% CI: 1.25-2.43)[20]. The continuous representation of cumulative trihalomethanes exposure was associated with a 17% increase in risk for each 1000 mg/L-years (95% CI: 6-29)[20].

FOOD CONTAMINATION AND DEVELOPMENT OF BOWEL TUMORS

Polychlorinated biphenyls are possible sources of food contamination. They are synthetic organochlorine compounds that are used in industrial and commercial processes[19,21]. However, dioxins, commonly referred to as dibenzodioxins and dibenzofurans, are organochlorine by-products of waste burning, paper lightening, pesticide production, and production of polyvinyl chloride plastics[21,22]. In the United States, major dietary sources of polychlorinated biphenyls and dioxins are beef, chicken, and pork, dairy products, vegetables, fish and shellfish, and eggs[23]. Animal experiments and some evidence in humans have indicated that polychlorinated biphenyls and dioxins are carcinogenic. This is likely to be related to effects on the aryl hydrocarbon receptor, a transcription factor that affects gene expression[24,25].

Food contamination with pesticides is another example. High levels of different types of pesticides in the collected serum samples from patients with colorectal carcinoma and their relatives have been reported[26-29]. However, no significant correlation between these chemicals and development of this neoplasm has been recognized. Also, higher concentrations of these chemicals in the samples from the healthy relatives[29] might have precluded any possibility of any significant link. Nevertheless, there is increasing evidence that systemic oxidative stress plays an important role in the development and progression of cardiovascular disease and cancer[30].

Oxidative stress is defined as a state in which the level of toxic reactive oxygen intermediates (free radicals) overcomes the endogenous antioxidant defenses of the host, such as the lipid-soluble antioxidants. Oxidative stress can result, therefore, from either an excess of free radical production or depletion of antioxidant defenses. For example, in the absence of adequate levels of lipid-soluble antioxidants, increased free radical production may cause functional and structural damage by reacting with lipoproteins, thus resulting in lipid peroxidation with the formation of degradation products, such as malondialdehyde, which are themselves carcinogenic. The mechanism by which overproduction of free radicals can lead to development of a chronic non-infectious disease has been fully described previously[31].

Recent studies have reported that various pesticides can induce oxidative stress in different tissues[32-35]. The significantly reported positive correlation between different tumor stages, concentrations of lipid peroxidation products, and lack of antioxidants in the serum of patients with colorectal cancer[36-38] gives hope for screening those patients who are at risk for development of these tumors, and for detecting these malignancies at an early stage.

The failure to link measurements of pesticides in the serum of patients with diagnosed colorectal adenocarcinoma to other measurements of lipid peroxidation products, (e.g. malondialdehyde) antioxidants, (e.g. vitamin C, zinc) and copper/zinc ratio in the blood likely explains the confusing outcome of the published reports.

IMPLICATIONS IN CLINICAL PRACTICE AND IN RESEARCH

Well-structured studies need to be designed to assess a possible link between levels of pesticides in those at risk of developing bowel tumors with the levels of lipid peroxidation products for early tumor detection.

Abstract

Radiofrequency ablation (RFA) of pancreatic neoplasms is restricted to locally advanced, non-resectable but non-metastatic tumors. RFA of pancreatic tumors is nowadays an ultrasound-guided procedure performed during laparotomy in open surgery. Intraoperative ultrasound covers the mandatory role of staging, evaluation of feasibility, guidance and monitoring of the procedure. Different types of needle can be used. The first aim in the evaluation of RFA as a treatment for locally advanced pancreatic ductal adenocarcinoma, in order of evaluation but not of importance, is to determine the feasibility of the procedure. The second aim is to establish the effect of RFA on tumoral mass in terms of necrosis and cytoreduction. The most important aim, third in order of evaluation, is the potential improvement of quality of life and survival rate. Nowadays, only a few studies assess the feasibility of the procedure. The present paper is an overview of RFA for pancreatic adenocarcinoma.

Key words: Radiofrequency ablation; Pancreatic adenocarcinoma; Intraoperative ultrasound; Contrast-enhanced ultrasound; Perfusion computed tomography

INTRODUCTION

Ductal adenocarcinoma is the most common primary malignancy of the pancreas, and represents 80% of malignant pancreatic tumors[1-3]. Pain, anorexia and weight loss are common symptoms, even in early stages. Tumors of the pancreatic head frequently cause obstruction of the common bile duct and present with jaundice. Tumors of the body/tail of the pancreas may grow to a large size before obvious symptoms appear[4]. Macroscopically, pancreatic ductal adenocarcinoma is a white/yellow and firm mass with infiltrating epithelium that recapitulates ductal struc-

tures. Microscopically, it is composed of infiltrating glands surrounded by dense and reactive fibrous tissue[4]. Highly aggressive adenocarcinomas are characterized by the presence of intratumoral fibrosis and necrosis, typically with a reduction of the microvascular density and perfusion[5].

Diagnostic imaging aims to correctly detect and characterize the tumor, thus playing an important role in the management of pancreatic ductal adenocarcinoma[6]. Conventional ultrasonography (US) is often the initial noninvasive imaging modality chosen for the first evaluation of the pancreas, as it is inexpensive, easy to perform and widely available[7]. The detection of a solid hypoechoic mass should be considered to be a ductal adenocarcinoma until proven otherwise. Contrast-enhanced US can better characterize and stage pancreatic tumors already detected by US[8], thus differentiating between solid and cystic lesions and influencing the choice of further examinations. A solid hypovascular pancreatic mass has to be considered a ductal adenocarcinoma until proven otherwise and requires computed tomography (CT) confirmation and staging. more than 95% of cases, pancreatic ductal adenocarcinoma is diagnosed at an advanced stage[5], with locally advanced (presence of perineural and vascular invasion) or metastatic disease (commonly in the liver, lungs, peritoneum and adrenal glands)[2,3,6,7]. Prognosis and treatment approach depend on the resectability or non-resectablility of the lesion at presentation[6]. Thus, only 10%-20% of patients are candidates for surgery[4], whereas in most cases, there is worse survival[8,9] and only palliative therapies are feasible.

Palliative therapies for advanced pancreatic adenocarcinoma consist of chemotherapy to give both local and systemic effect and radiotherapy for local effect. Endo-prosthesis positioning, biliary and pancreatic anastomosis, or ethanol ablation of the celiac plexus for pain relief represent further palliative procedures.

Radiofrequency ablation (RFA) of pancreatic ductal adenocarcinoma builds on its positive experiences in the liver. In fact, ablation therapy performed on the liver, usually minimally invasive through a percutaneous approach, provides extremely favorable results[10,11]. Thus, the first aim in the evaluation of RFA as a treatment for locally advanced pancreatic ductal adenocarcinoma, in order of evaluation but not of importance, is to determine the feasibility of the procedure. Nowadays, only few studies that are mainly concerned with the feasibility and complications of the procedure have been reported[12,13]. The second aim is to establish the effect of RFA on tumoral mass in terms of necrosis and cytoreduction. This is the same endpoint of radiotherapy, but with a possible better effect in terms of extent and type of tumor necrosis for RFA, even if performed during open surgery. The most important aim, third in order of evaluation, is the improvement of quality of life and survival rate.

INDICATIONS

RFA of pancreatic neoplasms is restricted to locally advanced, non-resectable but non-metastatic tumors. The resectability of a lesion represents an absolute exclusion criterion, because surgical resection is the treatment of choice. The presence of metastatic spread again represents an exclusion criterion. At preoperative imaging, the eligibility is related to the presence of a locally advanced, non-resectable pancreatic solid mass in the absence of any sign of metastatic spread, including ascites.

The anatomical complexity of the pancreatic and peripancreatic regions in which the pancreatic ductal adenocarcinoma grows makes the procedure of RFA different from that in other regions. In fact, independent from tumor size, the necrotic area must not overcome the lesion owing to the required safety margins in respect to the contiguous main vascular and digestive structures. Therefore, RFA has become a palliative treatment and could be included in a combined therapeutic plan.

The indications depend on the different clinical presentations related to the site of the obstructive or non-obstructive tumors. Non-obstructive tumors are usually located in the body/tail of the pancreas. These neoplasms do not need immediate surgical treatment and neoadjuvant chemotherapy represents the first choice. The absence of distant metastases and a good local response to therapy are expected at the post-treatment restaging evaluation. Resectable masses are treated surgically, whereas RFA can be performed in cases of non-resectable tumor. Obstructive tumors are usually located in the pancreatic head and frequently cause obstructive jaundice that promptly requires endoprosthesis positioning or derivative treatment and subsequent neoadjuvant chemotherapy. The presence of a resectable mass leads to surgical treatment, whereas RFA can be performed in cases of inveterate non-resectable tumor.

RFA TECHNIQUE

RFA of pancreatic tumors is nowadays an ultrasound-guided procedure that is performed during laparotomy in open surgery (Figure 1). Intraoperative ultrasound (IOUS) covers the mandatory role of staging, evaluation of feasibility, guidance and monitoring of the procedure (Figure 2).

The malignant nature of the lesion has to be confirmed pathologically before the procedure. Then, presurgical imaging staging needs confirmation. In particular, metastatic spread in the peritoneum (under inspection and extemporary histology of suspicious lesions, eventually present) and liver (under IOUS with extemporary cytology of doubtful lesions, eventually present) must be excluded. RFA will not be performed if the lesion is found resectable at IOUS, or if metastatic liver lesions are detected. The occurrence of very small lesions or those that envelop the main vessels without a true mass is a contraindication for the procedure. However, the possibility of RFA must be at first evaluated at preoperative imaging.

IOUS has to confirm the safety and feasibility of the RFA procedure without any risk of damage to the contiguous vascular and digestive structures, especially the duodenum. Tumor shape and diameters technically influence the procedure (approach, choice of needle and opening of the electrodes).

Two main types of needle are now available. In a needle with expandable electrodes, the electrodes can be opened from the top (Figure 3A) or the back (Figure 3B)

Figure 1 Radiofrequency ablation procedure. Ultrasound-guided radiofrequency ablation performed during laparotomy in open surgery.

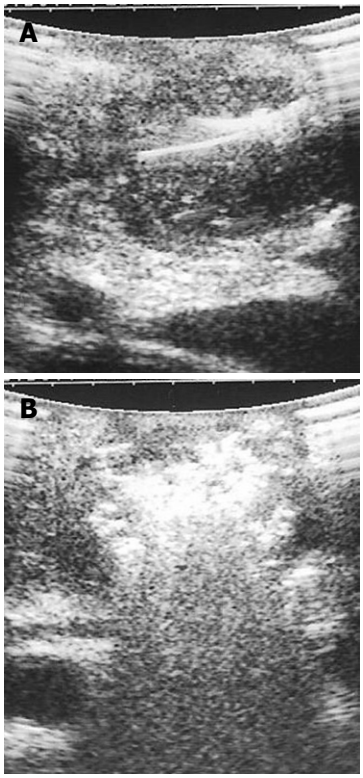

Figure 2 Intraoperative ultrasound monitoring. A: Needle with expandable electrodes is opened in the pancreatic hypoechoic mass under intraoperative ultrasound guidance; B: During radiofrequency ablation, the ablation zone becomes hyperechoic.

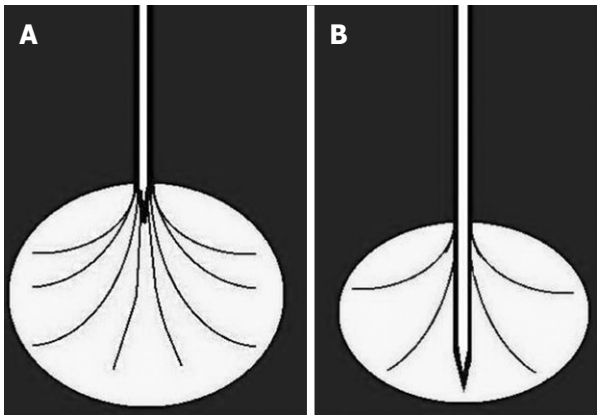

Figure 3 Needle with expandable electrodes. The electrodes can be opened into the lesion from the top (A) or from the back (B) of the needle.

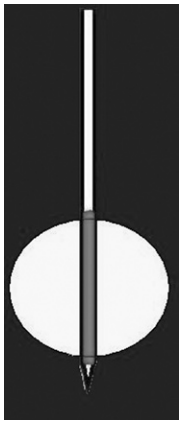

Figure 4 Needle with single electrode. Single electrode of the needle in the lesion.

of the needle. In the first case, the tip of the needle has to stop immediately prior to the lesion and electrodes (up to nine) open up and widen into the lesion. It is also possible to treat small tumors because the device can be opened at different degrees in relation to the size of the requested ablation zone. However, the flexibility of the electrode is not a negligible disadvantage in the treatment of very hard tumors. In the second case, by using a needle with electrodes coming from the back during the opening procedure, the electrodes (usually four) open up at about 2 cm behind the tip and move towards the outside. After complete opening, the electrodes arrive at the same level as the central needle tip. As a consequence, for correct positioning, the needle has to pass completely through the lesion, and the presence of the central needle for at least 2 cm within the mass assures the electrodes enter the neoplastic tissue. The central needle crossing throughout the mass and the stiffer electrodes guarantee excellent stability, even in the presence of hard tumor. On the other hand, the required introduction of the needle throughout the lesion for at least 2 cm can represent a disadvantage with respect to the dimensions and location of the tumor.

In a needle with a single electrode (Figure 4), the length of the area that has to be treated depends on the uncovered portion of the electrode. The width of the treated area depends on both the length of the uncovered portion and the time of ablation. The first type of needle produces a spherical/ovoid necrotic area, with a diameter ranging from 2 to 5-6 cm, depending on the needle and the electrode opening. The second type produces a cylindrical necrotic area ranging from 1 to 3 cm, depending on the extension of the uncovered metallic portion of the needle.

As reported above, the shape and dimension of the tumor influence the choice of the needle. For example, in the case of rounded lesions, even if located in the head of the pancreas, the first type have to be chosen, whereas, to treat ovoid lesions, the second type of needle is preferred. The latter is also preferable for very small lesions with particularly difficult access and/or location; choosing the needle with a lower caliper (17 rather than 14 gauge) and

taking advantage of the cool tip for safer placement.

After laparotomy, the gastrocolic ligament is divided to access the pancreas. For most tumors localized in the pancreatic head, after Kocher maneuver a cold wet gauze is placed over the inferior vena cava to protect it from heat, to reduce maximally the risk of complications. The duodenum is continuously perfused with cold saline solution through a nasogastric tube. Simultaneously, instillation of cool water to the areas around the tumor has to be performed during ablation.

IOUS guides the ablation procedure, mainly during the needle positioning and opening of the electrodes into the lesion (Figure 2A). During treatment, the tip of the needle and the electrodes must be kept at almost 5 mm from the sensitive structures such as the duodenum and peri-pancreatic vessels, as previously reported[13-15]. The correct needle positioning and electrode opening are followed by setting of the parameters for the procedure. These parameters differ depending on the system used. The time setting usually ranges from 5 to 10 min. The power supply affects the temperature directly, and the treated volume indirectly. Some systems also allow evaluation of impedance, which increases with the development of necrosis during the procedure. The temperature at the tip of each electrode can be monitored, thus assuring a more uniform distribution of the temperature in the mass. The temperature setting depends on the treatment aims. Since protein denaturation begins at 50-60℃, the higher temperatures used during the procedure achieve homogeneous necrosis. On the other hand, the use of too high temperatures (105℃) increases the risk of complications, without a favorable effect. Hence, during the ablation procedure of a pancreatic mass, middle-range temperatures are usually applied (90℃). During the procedure, monitored with ultrasound, the tumor gradually becomes hyperechoic owing to the gas produced inside the treated lesion (Figure 2B). This sign can be used to confirm the radiofrequency effect that monitors the integrity of the sensitive surrounding structures, as described previously[10]. At the end of the procedure, the electrodes have to be closed and the needle removed.

The post-treatment IOUS evaluation has to assess the volume of the resultant hyperechoic treated area. The presence of incomplete necrosis with a significant hypoechoic neoplastic remnant can be treated again. When technically possible, a biliary and gastric bypass is required for pancreatic head tumors[12]. In particular, Siriwardena *et al*[16] have recommended that no patient should undergo laparotomy simply for ablation, but the procedure should be used only in patients in whom palliative bypass is required or non-resectable disease is found at surgery. As a consequence, intraoperative RFA of tumor of the pancreatic body, which is non-resectable at imaging, seems unacceptable at this time, but it could be justifiable if positive survival results in large populations are found.

Moreover, in the future, endoscopic or percutaneous approaches for ablation of these tumors, under local anesthesia with sedation, are expected, as occurs in other regions.

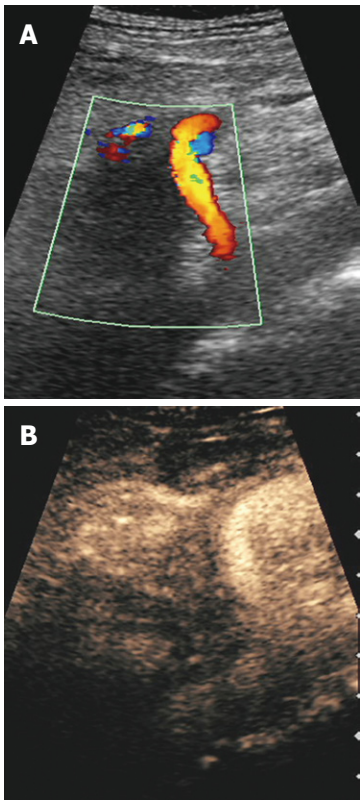

Figure 5 Pancreatic ductal adenocarcinoma after radiotherapy. A: Longitudinal color Doppler scan of the lesion, with hypoechoic infiltration of the superior mesenteric artery; B: Longitudinal contrast-enhanced ultrasonography scan of the hypovascular lesion.

FEASIBILITY AND COMPLICATIONS

Only a few studies have focused on the feasibility and complications of RFA, and none of these have reported major intraoperative complications[12,13,16,17]. Hadjicostas *et al*[17], based on results obtained in four patients, have concluded that RFA seems to be a feasible, potentially safe and promising option in patients with advanced and non-resectable pancreatic cancer. Girelli *et al*[12], based on results obtained in 50 patients, showed that RFA of locally advanced pancreatic cancer is feasible and relatively well tolerated, with a 24% complication rate. In a previously published series of 16 patients, however, a mortality rate of 25% was reported, with all deaths in patients treated for pancreatic head tumor and complicated with massive gastrointestinal hemorrhage[13]. However, the temperature applied exceeded 90℃ and no protective/refrigeration practices were utilized. On the contrary, in the Girelli series in which the procedure was performed with protective/refrigeration practices, the reported mortality rate was 2%. Moreover, in the same series in the second part of the study, by using a temperature of 90℃, the complication rate decreased to 8%[12].

Postoperative observation (clinical surveillance, laboratory tests and imaging studies) is mandatory because of the potential for major or minor, early or later complications. The most frequent complications encountered in the earlier postoperative period (within 1 wk) are fluid

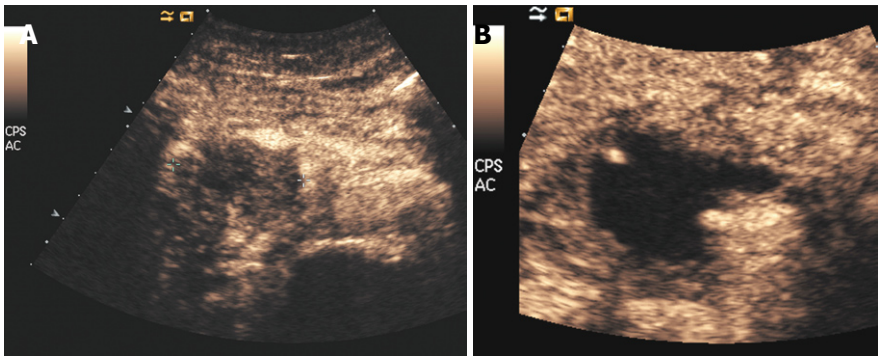

Figure 6 Pancreatic ductal adenocarcinoma before and after radiofrequency ablation. A: Axial contrast-enhanced ultrasonography (US) scan of the hypovascular lesion; B: Axial contrast-enhanced US scan of the avascular lesion after radiofrequency ablation.

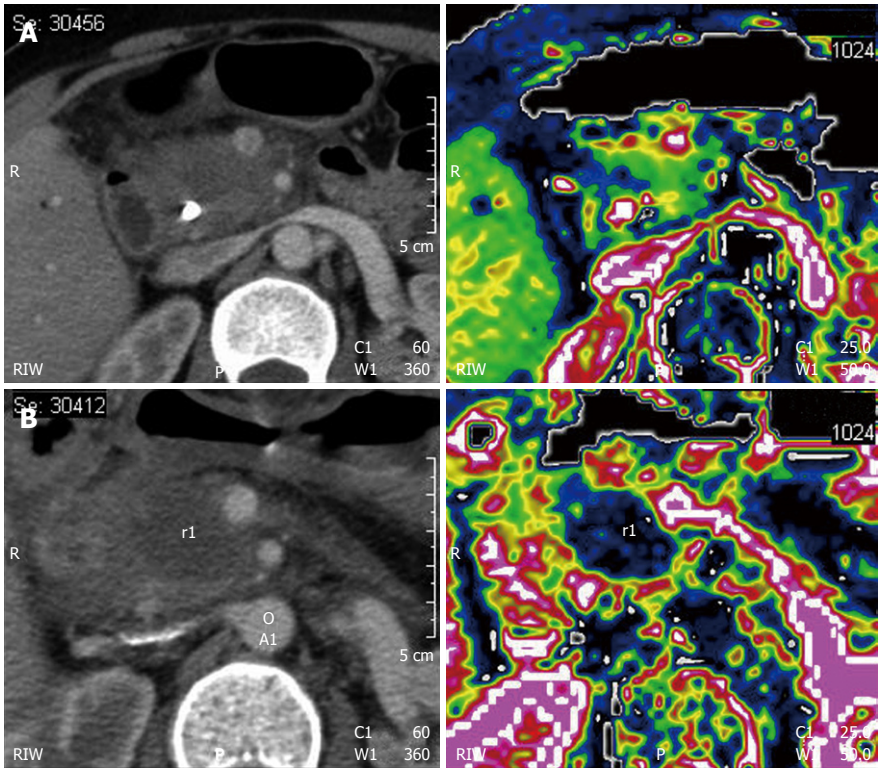

Figure 7 Pancreatic ductal adenocarcinoma before and after radiofrequency ablation. A: Contrast-enhanced computed tomography (CT) of pancreatic head lesion that appears hypodense and vascularized at perfusion CT (right side); B: Contrast-enhanced CT of the lesion after radiofrequency ablation, which appears hypodense and avascular at perfusion CT (right side).

collection, pancreatic fistula, duodenal perforation and vascular damage. At later times, digestive or abdominal bleeding, infections or abscesses are more common. Severe acute pancreatitis is a rare complication[17]: in Girelli's study, there was only one case, and none was reported in Wu's study[12,13]. Major complications frequently are present with RFA of pancreatic head tumors, mainly owing to the closeness of the duodenum. These lesions are more difficult to treat, as reported previously[13].

TECHNICAL RESULTS AND POSTOPERATIVE IMAGING

The necrotic area obtained by RFA is complete. In comparison with radiotherapy (Figure 5), the RFA-treated area (Figure 6) is completely avascular at perfusion imaging. Immediate ultrasound evaluation is useful for identification of possible fluid collections. In the presence of clinical suspicion of major complications, CT is mandatory. Dynamic studies after the administration of contrast agents, usually starting 1 mo after the procedure, are performed to detect the intratumoral necrotic area produced by RFA.

Postoperative imaging of RFA of the pancreas differs from that of the liver. With hepatocellular carcinoma, detection of the ablated area after treatment is immediate because of the hypervascular nature of the tumor. On the contrary, ductal adenocarcinoma is markedly hypovascular, such that after the procedure, the identification of the necrotic area with respect to residual viable tumor tissue can be difficult (Figure 7). It is more important to assess the type and extent of the post-ablation necrotic area, rather than the presence of remnant tumor. In treating pancreatic tumors, the presence of residual viable tumor at the periphery of the treated area is an intrinsic aspect of the procedure. This is the other important difference in comparison with RFA of the liver, in which the lesion must be covered by the necrotic area. On the contrary, in RFA of the pancreas, the necrotic area must be included in the tumor (Figure 8).

All these particular features of pancreatic RFA have to be considered during postoperative imaging. Precise and

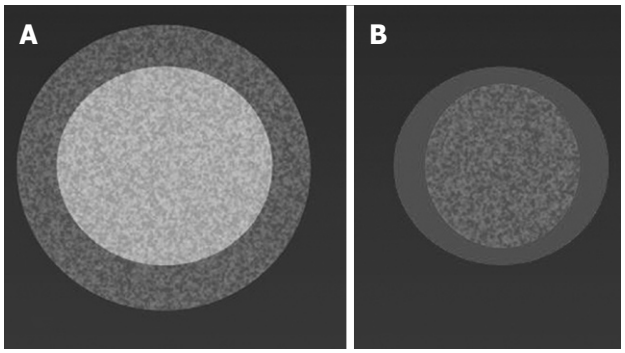

Figure 8 Ablation zone on target lesion. A: Necrotic ablation zone (dotted grey) must covered the hepatocellular carcinoma (white); B: Necrotic ablation zone (dotted grey) must be included in the pancreatic ductal adenocarcinoma (grey).

accurate dynamic imaging evaluation, such as contrast-enhanced US or perfusion CT (Figures 6 and 7), is necessary.

CLINICAL RESULTS AND FUTURE VIEW

RFA of locally advanced pancreatic neoplasms is currently performed under ultrasound guidance in open surgery during laparotomy, with the palliative aim of tumor reduction in a combined therapeutic plan. Minimally invasive laparoscopic or percutaneous approaches, as in other regions, are expected.

The primary endpoint, represented by improvement in quality of life, has been achieved, given that the treatments obtain excellent pain relief[12,13,17]. In particular, in the series of Wu *et al*[13], pain relief was reported in 50% of cases, and in 68% in the series of Girelli[12]. Pain relief seems not to be related to ablation necrotic volume. Girelli *et al*[12] have reported a decreased of CA 19-9 concentration 7 d after surgery.

Regarding the more ambitious clinical endpoint, significant results about improved survival are still missing. At this time, only one study has investigated survival in a group of 25 consecutive patients, which showed a significant difference in survival between RFA and control groups in patients with stage Ⅲ disease[18]. Further studies are needed to validate the reported preliminary results, to evaluate a possible correlation with tumor markers eventually expressed during the preoperative period, and particularly, to validate the technique.

CONCLUSION

RFA of locally advanced, non-resectable but non-metastatic, pancreatic tumors is a feasible palliative treatment that leads to tumor reduction and improved quality of life. Further studies are needed to validate therapeutic strategies and associations for the best possible results on survival.

Abstract

As colorectal cancer and colorectal liver metastases become a serious public health problem, new treatment modalities are needed in order to achieve better results. In the last decade there has been very important progress in oncology, with new and more effective chemotherapeutic agents administered alone or in combination improving the resectability rate in up to 40% of patients with colorectal liver metastases. Advances in interventional radiology, in particular, with the use of portal vein embolization and radiofrequency thermal ablation are new strategies allowing major liver resections and treatment of small liver metastases or early recurrences. Surgery, however, remains the gold standard strategy with intention to treat. In this review article we will describe the advanced role of surgery in the multidisciplinary approach to colorectal liver metastases, and the clinical problems the liver surgeon has to deal with, such as the resectability of the metastases, the presence of bilobar liver lesions and extrahepatic disease, the impact of chemotherapy in already resectable liver metastases, the problem of vanishing metastases after chemotherapy and the dilemma of staged or combined liver and colon operations and which organ first in the clinical scenario of synchronous colorectal liver metastases.

Key words: Metastases; Liver metastases; Colorectal cancer; Surgery

INTRODUCTION

Colorectal cancer (CRC) is an important public health problem: there are nearly one million new cases diagnosed worldwide each year and half a million deaths. Recent reports show that CRC is the third most frequent cancer in the Western world while in the USA it is the most frequent form of cancer among persons aged 75 years and older[1]. Approximately 25% of these patients have liver metastases at the time of diagnosis [colorectal liver metastases (CRLM)] and 25% will develop, CRLM during the course of the disease. Eventually two-thirds of patients

with CRLM will die because of liver metastases[2]. Given that the majority of malignancies occur in elderly people and with ageing of the population in mind the above epidemiological observations make the need for prevention and improved treatment strategies very urgent.

In the last decade there has been very important progress in 3 different fields regarding the treatment of CRLM: new and more effective chemotherapeutic agents in oncology administered alone or in combination; an advanced role of interventional radiology with portal vein embolization and radiofrequency ablation; and last, but not least, new strategies and manipulation techniques for safer hepatic resections. The combination of these improvements makes the role of a multidisciplinary approach in the patient with CRLM the only therapeutic modality, which has gradually but effectively improved the resectability rate of metastases to 20%-30% of cases and has resulted in 5-year survival of 35%-50% for selected cases[3,4].

In this review we will discuss the improvement in chemotherapy and interventional radiology as well as the new and advanced role of surgery in this multidisciplinary approach in order to establish treatment strategies and to gain better results in disease-free and overall survival in patients with CRLM.

CHEMOTHERAPY-ONCOLOGY

Chemotherapeutic agents have substantially changed over the last decade. Two new agents, irinotecan and oxaliplatin are used in combination with the traditional regimen of 5-fluorouracil (5-FU) and leucovorin (LV). Irinotecan is an inhibitor of topoisomerase I and its combination with 5-FU and LV is called Folfiri while oxaliplatin is a non-nephrotoxic platinum complex which in combination with 5-FU and LV is called Folfox. While traditional chemotherapy was of limited efficacy, with response rates not exceeding 25%, the new combinations allowed a tumor response in approximately 40%-50% of patients[5,6]. Another very important issue is that the new chemotherapeutic combinations have been reported to facilitate the resection of 9%-40% of initially unresectable metastases, with data emerging from randomized trials suggesting that the addition of targeted agents and a third cytotoxic drug might improve these results even more[7,8]. The use of a triple combination of irinotecan, oxaliplatin and 5-FU or LV seems to further increase the efficacy of systemic chemotherapy, as 3 different studies described a response rate of up to 70% and improvement in the overall survival of up to 26 mo[9-11]. All these studies showed that patients who can undergo surgical resection for their CRLM have better survival rates compared to patients treated only with chemotherapy.

Besides oxaliplatin and irinotecan, the introduction of two new targeted agents opens a new era in the oncological treatment of colorectal liver metastases. Cetuximab is a monoclonal antibody against the epithelial growth factor receptor and bevacizumab is a humanized antibody against the vascular endothelial growth factor (VEGF). The use of the above-mentioned targeted agents in combination with Folfox or Folfiri has increased the resectability rate in patients whose tumors were previously considered unresectable and has also improved the overall survival rate in patients with CRLM as mentioned above. Hurwitz *et al*[12] published a randomized controlled trial where 813 patients with CRLM were allocated to either Folfiri or Folfiri plus bevacizumab. The addition of bevacizumab was associated with a statistically significant increase in median survival, progression-free survival and overall tumor response rate. There were also other studies where the addition of bevacizumab to Folfox was associated with an increased tumor response rate and median overall survival[13]. However, these studies were not randomized.

However, apart from these positive effects of chemotherapy on resectability and survival rates, there were also some severe adverse effects on the liver, as histological lesions are known to occur in the liver parenchyma following chemotherapy, with the type of lesion being specific for the agent used. Sinusoidal obstruction syndrome is characterized by erythrocytic congestion and can be accompanied by perisinusoidal fibrosis and fibrotic venous occlusion. This syndrome has been described in association with oxaliplatin, and the incidence of these histological changes is between 20% and 29%[14,15]. The administration of oxaliplatin-based chemotherapy can also be associated with vascular lesions in the liver such as hemorrhagic centrilobular necrosis, and carry a higher risk of operative bleeding and transfusion requirement, as well as impaired liver regeneration and increased post-hepatectomy mortality[16,17]. The second adverse effect is a form of steatohepatitis that has been related to irinotecan administration. Chemotherapy-associated steatohepatitis is characterized by the simultaneous presence of severe steatosis, lobular inflammation and ballooning of the hepatocytes[18]. Analysis of the impact of steatosis on surgical outcome suggests that morbidity is increased and that there is also an increased rate of infectious complications[19,20]. Steatohepatitis linked to irinotecan treatment is associated with increased 90-d mortality because of liver failure after surgery[18,21].

At this point there is an important question raised whether the above-mentioned chemotherapy-linked liver damage is related to the duration of treatment or not. There are 2 pertinent studies in the literature which clearly showed that the morbidity rate was related to the number of cycles of chemotherapy administered[17,21]. More recent data on postoperative complications in the EORTC 40983/EPOC study show that 3 mo of preoperative chemotherapy with Folfox-4 had a relatively mild impact on surgical outcome[22]. Another issue regarding the safety of preoperative chemotherapy is the potent effect of the monoclonal antibody bevacizumab, as targeting VEGF could augment hepatic damage and diminish regeneration after resection. One study showed that there was no major effect of bevacizumab on the incidence of postoperative complications if stopped at least 5 wk prior to surgery[23]. Data from another study described that the use of this agent may even reduce the

incidence of liver failure after hepatic resection[24]. One can conclude that neoadjuvant chemotherapy can induce liver injury but with little clinical impact if patients are not overtreated and if a proper time interval is maintained between chemotherapy and surgery[25].

INTERVENTIONAL RADIOLOGY

Advances in interventional radiology have contributed to the treatment of patients with CRLM, in particular the use of portal vein embolization (PVE) and radiofrequency thermal ablation (RFA). Since 1982 when Makuuchi *et al*[26] first used PVE in order to provoke compensatory hypertrophy of the future remnant liver in patients planned for major hepatic resections, much experience has been gained and this technique is today available in every specialized hepatobiliary center[27,28]. In patients planned for major hepatectomy and with an otherwise normal liver, preoperative PVE is recommended when the ratio of the remnant liver to total liver volume is estimated to be less than 30%, whereas in patients with neoadjuvant chemotherapy this ratio is considered to be 40%[29,30]. PVE is a safe procedure, but movement of the embolic material to the main portal vein or into branches that supply the future remnant liver remains a risk.

RFA was initially and widely used for local treatment of hepatocellular carcinoma and recently has gained popularity for the management of CRLM, where its indications are still under debate. Critical review of the results of RFA shows that RFA must be restricted in cases with a maximum of 3 lesions with the size of the biggest lesion less than 3 cm[31]. Another limitation for the use of RFA in the management of CRLM is the anatomic location of the lesion. When the metastases are near big vessels the risk of incomplete ablation is increased as the heat effect is minimized[32]. Because of the above-mentioned limitations there is still no place for RFA in patients with resectable CRLM. The use of RFA is actually limited in cases with early recurrence after resection, detected as small lesions, because it is not mandatory to stop chemotherapy[33].

THE ROLE OF SURGERY

The liver surgeon of the multidisciplinary team for the treatment of CRLM will face some clinical problems and scenarios such as the resectability of the metastases, the presence of bilobar liver lesions or extrahepatic disease, the impact of neoadjuvant chemotherapy in the case of resectable metastases, the problem of vanishing metastases after chemotherapy, and the dilemma of staged or combined liver and colon resections in the clinical scenario of synchronous CRLM. For historical reasons we mention that liver metastases were classified as unresectable if they were large in size, bilobar or there were more than 4[34,35]. Today there has been substantial progress in liver surgery owing to improved preoperative diagnosis and intraoperative and postoperative care, and new strategies are being developed in order to achieve larger and

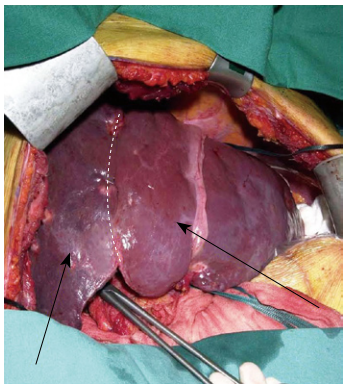

Figure 1 Atrophy of the right hemiliver (right arrow) and hypertrophy of the left hemiliver (left arrow) after right portal vein ligation.

safer resections. Many tumors that were previously considered unresectable are now amenable to complete resection. In 2007, Figueras *et al*[36] published a study where no predefined criteria of resectability were mentioned with regard to number, size, location of the tumor or presence of extrahepatic disease. The only prerequisite is that the resection was possible and that the potential liver remnant was able to sustain metabolic, synthetic and detoxifying functions[37]. It is in general accepted that where possible it is better to remove a metastasis than to leave it and that even R1 resections might become an acceptable clinical strategy provided that they confer meaningful patient benefit[25].

The presence of bilobar CRLM is a challenging issue for the liver surgeon as this problem requires extended resections. As mentioned above, interventional radiology with PVE is an important preoperative tool in order to increase the volume of the remnant liver after an extended resection. However, the legitimate concern that metastases in the non-embolized hemiliver might grow more rapidly after right PVE[38] has led to the proposal of a 2-stage procedure. In the first stage all visible metastases in the left hemiliver are removed in association with right portal vein ligation. In the second stage, which takes place between 2 and 4 wk after the first stage, an extended right hemihepatectomy is performed[37] (Figure 1).

Despite the great effort that has been made both in preoperative liver volume manipulation and in intraoperative and postoperative care there are still many patients who present to the liver surgeon with initially unresectable metastases. Current treatment practice for these patients is a combination of classical chemotherapy with the targeted agents cetuximab and bevacizumab, which facilitates resection in 9%-40% of lesions initially considered unresectable[7]. As a consequence, 5-year survival rates of 50% after combined treatment are becoming increasingly common[36]. The next step is to define the most effective chemotherapeutic regimen for this treatment strategy. Currently, data from randomized trials are beginning to show the added benefit conferred by the targeted agent cetuximab on response and resection rates achieved with standard first-line therapies in patients with advanced CRC[39,40]. The rate of surgery with curative intent was higher in patients who received Folfiri plus cetuximab in comparison with Folfiri alone and the R0 resection was also increased[40]. In this setting the requirement for a

delay between the end of chemotherapy treatment and the planning of surgery, as well as the presence of K-ras mutation in the primary tumor are 2 very important considerations for the management of these complex cases[41-43]. Mutations in this gene have been shown to be predictive of reduced disease-free and overall survival. Furthermore, it has been demonstrated that those with K-ras mutations do not benefit in the same manner from the traditional chemotherapeutic regimens as those with the wild type. Analysis of recent data show that patients with wild type K-ras had a significant advantage in terms of tumor response with the addition of bevacizumab compared to standard Folfiri treatment. Further studies are needed in the era of biomarkers in order to achieve better tumor response rates and increased survival[44,45]. At this point it is important to mention that the presence of extrahepatic disease is no longer considered in the criteria for unresectability, provided that it is also resectable[46].

The conventional way of thinking in patients with resectable synchronous CRLM is to offer an upfront operation, and the reason for this attitude is the fear that the CRLM will not respond to chemotherapy and that during the time of chemotherapy the tumors will grow beyond the possibility of surgical cure. However, chemotherapy before surgery, even in patients with resectable CRLM, can increase the complete resection rate, facilitate limited hepatectomies, improve postoperative recovery, treat micrometastases, provide a test for chemoresponsiveness, identify aggressive disease and spare ineffective chemotherapy. All the above parameters are supported by the results of the EORTC 40983 study where the progression-free survival rate at 3 years was increased by 8.1% in those patients who received perioperative chemotherapy when compared with surgery alone. Furthermore, single-center non-randomized studies support the use of neoadjuvant protocols for resectable CRLM[47]. A specific problem that has emerged with the use of effective neoadjuvant chemotherapy regimens is known as the "missing" or "vanishing" metastases. This terminology reflects lesions that were present on initial radiological examinations and can no longer be identified by imaging performed after chemotherapy. Because these lesions are very difficult to localize and resect during surgery the situation is well characterized by the sentence "when the dream of the oncologist becomes the nightmare of the surgeon". While a publication suggested that missing metastases are cured in 70% of cases[48], another study showed persistent microscopic or macroscopic residual disease or very early recurrence in 83% of cases with a complete radiological response[49]. Thus a complete radiological response does not mean a complete histological response and some authors suggest that when the detailed intraoperative ultrasound examination fails to detect missing metastases, the corresponding parenchymal region should be resected in the basis of vascular landmarks[33].

The final but very important issue that the liver surgeon has to deal with is whether to proceed to combined (liver and colon) or staged surgery and if he chooses a staged procedure which organ first. The ideal solution for this complicated problem would be a simultaneous colon and liver operation. The advantage of the combined procedure is that we have one operation with less psychological considerations for the patient, less financial costs and shorter hospitalization time. On the other hand the advantages of the staged procedure are that there is no accumulation of the risks of liver and bowel resections at the same time, a neoadjuvant chemotherapy may be given before liver resection, and an extended hepatectomy or difficult bowel resection can be performed with the full attention of the surgical team focused on the liver or bowel disease. However, the critical issue for decision-making is the patient's safety. Considering the initial experience with simultaneous *versus* staged resections, a French multicenter study showed an operative mortality of 7% for simultaneous *vs* 2% for staged surgery[50], while in a single center US study the mortality was 12% for simultaneous *vs* 4% for staged resections[51]. It was also shown in several studies that simultaneous operations can be performed without death[52-55]. These studies, however, were retrospective and patients for simultaneous resection were selected by experienced hepatobiliary surgeons. In conclusion, simultaneous liver and bowel operations can be performed on selected patients but should be avoided in cases of major hepatectomies, in elderly patients, and in difficult rectal surgery.

In the case of a staged operative procedure, the standard treatment recommendations in the pertinent literature until now were resection of the primary tumor followed by chemotherapy for 3-6 mo and then liver surgery. Given that liver metastases rather than the primary tumor determine survival the above-mentioned standard approach has some disadvantages. Firstly, chemotherapy which is effective against liver metastases cannot be given during the treatment of the primary tumor, especially if complications of colorectal surgery are encountered as the risk for an anastomotic leak in rectal surgery varies from 6% to 12%[56,57]. Even if the colon surgery runs uneventfully the recommended treatment for locally advanced rectal cancer is a long course of radio-chemotherapy (5 wk). Surgery is usually planned 6-10 wk after finishing neoadjuvant therapy. During these 3 mo no treatment is given to hepatic metastases and these may progress beyond cure[58]. The second disadvantage is that there rapid growth of metastases described after removal of the primary tumor in several mouse models[59,60]. The underlying mechanism for these experimental data seems to be the loss of primary tumor-induced inhibition of angiogenesis in the metastases. It was also demonstrated in human CRLM that vascular density increased after resection of the primary tumor[61]. However, the clinical significance of these experimental demonstrations is still unknown.

These two major disadvantages gave impetus to a new approach for the treatment of CRLM. This new approach is the "liver first" approach, where, after initial treatment with chemotherapy, the liver metastases were operated first followed by removal of the primary tumor. The new reverse approach includes the risk that during the period

between chemotherapy and liver resection the primary tumor might become obstructive. This rare possibility can easily be solved by performing Hartmann's procedure. There have already been pertinent studies published in the literature showing that the "liver first" approach is a safe procedure and brings excellent results[58,62]. The results of these studies suggest that patients with advanced synchronous CRLM and non-obstructive primary tumors can be safely and effectively treated with highly effective neoadjuvant chemotherapy towards the metastases, followed by liver surgery and, finally, colorectal resection.

CONCLUSION

Many changes have occurred in the treatment of CRLM in the last decade. Progress in neoadjuvant chemotherapy, new targeted agents and improvement of interventional radiology with PVE and RFA as well as diagnostic imaging provide useful tools. However, since surgery is still the only treatment modality that has curative potential on its own, this may appear the most attractive approach in some situations, even if resistance to medical treatment generally means an unfavorable prognosis. The 2-stage hepatectomy as well as the "liver first" approach seem to create new treatment strategies and improve the rate of survival of patients in whom an R0 resection can be achieved with curative intention. The multidisciplinary treatment modality in these complex cases of patients with CRLM helps to make the best treatment selection for patients in order to offer each of them the best strategy.

Abstract

Recent studies indicate that the process of liver regeneration involves multiple signaling pathways and a variety of genes, cytokines and growth factors. Protein-protein interactions (PPIs) play a role in nearly all events that take place within the cell and PPI maps should be helpful in further understanding the process of liver regeneration. In this review, we discuss recent progress in understanding the PPIs that occur during liver regeneration especially those in the transforming growth factor β signaling pathways. We believe the use of large-scale PPI maps for integrating the information already known about the liver regeneration is a useful approach in understanding liver regeneration from the standpoint of systems biology.

Key words: Liver regeneration; Protein-protein interaction; Protein-protein interaction maps; Transforming growth factor β

INTRODUCTION

Liver has the capacity to regenerate by a process of compensatory growth following injury and various molecular and cellular pathways are involved in this process[1-4]. It is still difficult to understand precisely how the process of liver regeneration is regulated. Previous studies of liver regeneration have been made at the functional, cellular, molecular or gene level[5]. It is generally believed that most cellular processes are determined by protein-protein interactions (PPIs)[6,7] and, therefore, PPIs maps provide a valuable framework for a better understanding of the functional organization of the proteome during liver regeneration[2,8,9]. Various methods have been used to study the functions of specific proteins during liver regeneration. In this review, we describe the use of high-throughput experimental methods and algorithmic predictions to unravel the complex processes of liver regeneration through the use of PPI maps.

LIVER REGENERATION

Source of liver cells and genes analysis in liver regeneration processes

Liver regeneration can be seen as a timely sequence of

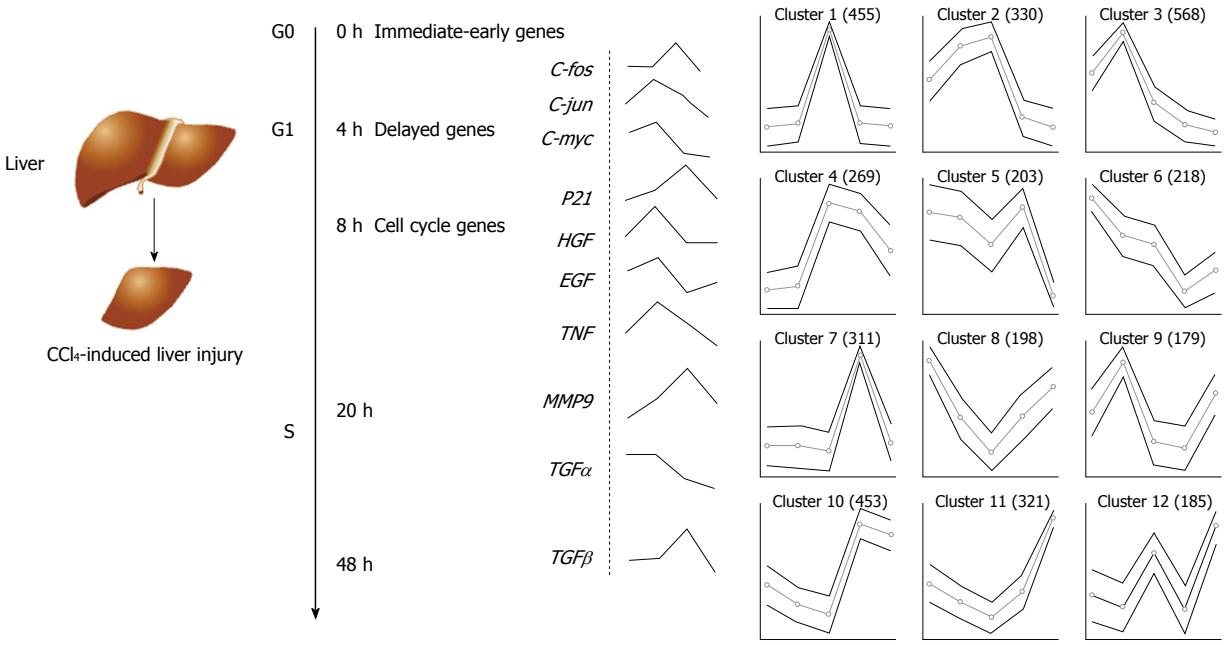

Figure 1 Hepatocyte cell cycle during liver regeneration and clustering algorithm of gene expressions in gene chip during mouse liver regeneration following CCl_4-induced liver injury. Some important genes are activated in the regenerating liver after partial hepatectomy or hepatocellular injury induced by CCl_4. Liver regeneration can be divided into four phases: G0: Corresponds to approximately the first 4 h; G1: Quiescent cells enter the cell cycle during production of hepatocyte growth factor (HGF), epidermal growth factor (EGF), tumor necrosis factor (TNF), *etc.*; S: Chromosomal DNA is replicated and peak DNA production occurs at approximately 24 h; then, after 48 h or more, the process of regeneration is terminated. The curves following the gene products and the dashed line represent the changes in gene expressions measured in our lab using Gene Chip® mouse 430 2.0 during liver regeneration following CCl_4-induced liver injury. Changes on the level of gene expression were log2-transformed using signal value at 0 h time-point as baseline. Genes with their expression levels varying at least 2-fold between any two time-points were subjected to hierarchical clustering analysis. TGF: Transforming growth factor; MMP9: Matrix metalloproteinase 9.

Table 1 Liver cell types and their functions during liver regeneration

Cell types	Functions
Hepatocytes	Organized in single cell plates; perform metabolic and detoxification function; can secrete HGF, IL-6, proteases and protease inhibitors
Sinusoidal endothelial cells	Involved in endocytosis and metabolism of molecules; can produce TGFβ, HGF, IL-6 and nitric oxide
Biliary epithelial cells	Can promote fibrogenesis by attraction of hepatic stellate cells and can secrete cytokines such as MCP-1 and IL-6
Kupffer cells	Major producers of cytokines such as TNF and IL-6
Hepatic stellate cells	Store vitamin A and secrete laminins, collagens and growth factor: HGF, EGF, TGFβ and cytokines IL-6; also produce MMPs
Oval cells	Can differentiate to biliary and hepatocytes lineage

HGF: Hepatocyte growth factor; IL-6: Interleukin-6; EGF: Epidermal growth factor; TGF: Transforming growth factor; MCP: Monocyte chemotactic protein; MMP: Matrix metalloproteinase; TNF: Tumor necrosis factor.

morphological events; resulting in the reconstitution of the lost liver mass following surgical resection or carbon tetrachloride (CCl_4) induced injury. Depending on the nature of the regenerative processes, several sources of liver cells are involved[4,10,11] (Table 1).

After partial hepatectomy (PH) or toxic forms of liver injury, some immediate early genes are expressed simultaneously in the liver. C-fos, c-jun and c-myc are up-regulated immediately and they activate hepatic non-parenchymal cells. Then tumor necrosis factor α, epidermal growth factor, hepatocyte growth factor and transforming growth factor α (TGFα) are released to provide the cooperative signals for the hepatocytes cell cycle to move from G0 through G1 to S phase, leading to DNA synthesis, and hepatocyte proliferation. TGFβ, which controls hepatocyte DNA synthesis, is blocked during the proliferative phase, but is again restored at the end of the process of regeneration. TGFβ is believed to be a key factor in returning hepatocytes to the quiescent state and ending liver regeneration[1,3,4,12].

Our laboratory has used a mouse model of CCl_4-induced liver injury to investigate changes of gene expression during the process of liver regeneration (Figure 1). Changes in the expression of 3642 genes were detected during the process of liver regeneration by microarray analysis[13] (Figure 1). Genes whose expression levels varied at least 2-fold at any time-point were subjected to self-organizing analysis, using Cluster 3.0 (Stanford University). Their specific functions of each cluster were analyzed and will be described elsewhere (manuscript in preparation).

Termination response during liver regeneration

Many research studies have focused on the regulation of the initiation and proliferation phases of liver regeneration. Although the molecular mechanisms for termination of liver regeneration are still not completely understood, TGFβ and activins, which belong to the TGFβ superfam-

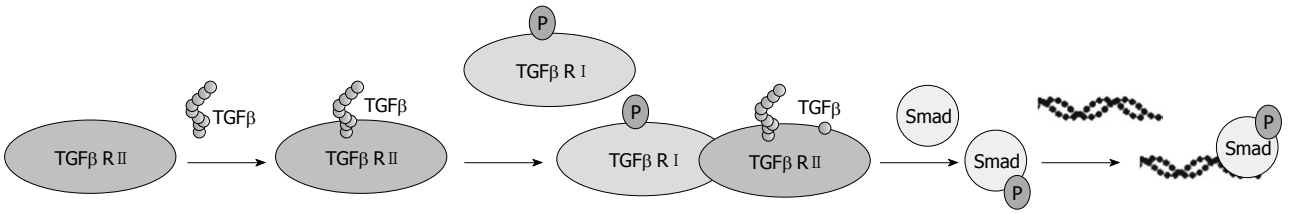

Figure 2 The classical and basic view of transforming growth factor β signaling pathway during liver regeneration. Generally speaking, transforming growth factor β (TGFβ) superfamily ligands bind to a type Ⅱ receptor (RⅡ), which recruits and phosphorylates a RⅠ. The RⅠ then phosphorylates receptor-regulated Smads. Then complexes accumulate in the nucleus where they act as transcription factors and participate in the regulation of target gene expression.

ily, appear to be important[14]. TGFβ and activin A may bind to their high-affinity cell surface type Ⅱ receptor (TGFβRⅡ) and ActRⅡ or ActRⅡb, respectively and TGFβ inhibits G1 to S phase transition in hepatocytes. TGFβ levels rise rapidly after CCl_4-induced injury and, therefore, TGFβ is known to have growth inhibitory effects on liver regeneration. So, at its simplest, the basic TGFβ signals through its Type Ⅰ and Type Ⅱ receptors (TGFβRⅠ and TGFβRⅡ) cause phosphorylation of Smad proteins and activate the Smads complex that controls transcription (Figure 2). Dierssen *et al*[15] demonstrated that gp130-dependent Stat3 activation and concomitant suppressor of cytokine signaling 3 (Socs3) is involved in timing of DNA synthesis during liver regeneration. Also, Riehle *et al*[16] showed that Socs3 modulates several signaling pathways and involved in physiological proliferative processes and protects hepatocyte proliferation in liver regeneration. Therefore, there is more to be understood about the TGFβ signaling pathway and its effects in termination of regeneration, but this still should underscore the complexity of other related pathways and their contribution to the process of termination of liver regeneration[17]. Further studies need to be conducted on understanding the mechanism of liver regeneration.

PPIs AND CORRESPONDING MAPS

PPIs refer to the association of protein molecules and PPI maps/networks summarize large amounts of PPI data, both from experiments and prediction.

There are a multitude of methods to detect PPI including biochemical, physical/biophysical and theoretical methods. The yeast two-hybrid (Y2H) technology is one of the most reliable and feasible experimental biochemical methods to detect PPI since it was established in 1989[18]. The improvement of Y2H techniques can provide high-throughput methods which are widely used in proteome studies of PPIs. Co-immunoprecipitation (CoIP) is also considered to be the gold standard assay for PPIs, especially when it is performed with endogenous proteins. Pull-down assays are a common variation and immunoprecipitation and immunoelectrophoresis are used identically, although this approach is more amenable for an initial screening of interacting proteins[19]. Fluorescence resonance energy transfer is a common biophysical technique used for observing the interactions of two different proteins[20]. There are many ways to detect PPI and each of the approaches has its own strengths and weaknesses, therefore, it is wise to determine the specific method after weighing the advantages and disadvantages.

Visualization of PPI is a popular application and already, the map of PPI among *Saccharomyces cerevisiae*[21], *Drosophila melanogaster*[22], *Caenorhabditis elegans*[6], constructed through a series of experiments and algorithmic predictions, has proved its usefulness for analyzing complex gene regulation and cellular behavior[23]. Similar efforts for PPI maps for human are ongoing and the first human PPI map was constructed from more than 3000 PPIs[24] (Table 2). Recently, the size of PPI maps in different organisms were estimated (with the PPI map for humans being nearly 650 000 PPIs) and the size is strongly believed to have correlation with the organism's apparent biological complexity[25].

Although the PPI maps are still far from complete, whether its deciphered from DNA parts are molecules, cells, or living organisms, a PPI map provides an insight into the systems biology. Our current challenge is to know how large-scale PPI maps possible functions and to understand how cells operate in an integrated manner to carry out phenotypic functions, besides increasing the coverage and accuracy of the existing and novel PPI data sets[39,40].

PEELING THE PPI MAPS DURING LIVER REGENERATION

During liver regeneration, cytokine, growth factors and metabolic pathways were both active after PH or CCl_4-induced liver injury, and the pathways interacted with each other[2]; although, there is indeed a flow of information *via* interactions between DNA, RNA and proteins on which this review will mainly focus. More research about PPI maps is on the level of proteome (Table 2), and these PPI maps will reveal the connectivity of the proteome. If we construct a PPI map during liver regeneration, it will reflect the particular cellular or unique signaling pathway status. As to the PPI map analysis, the so called small-word and scale-free behavior are considered, which indicated that in the maps only few nodes (stand for proteins) are highly connected with others (hub protein) and most of the nodes are connected with only a few nodes (low degree)[41]. In this processes, to capture the changes in protein connectivity and find the key signaling pathways, especially those that interact, is most attractive. For the mechanisms of liver regeneration to be completely understood, a multitude of PPI maps must be coordinated[37].

PPI maps and TGFβ signaling pathway

Understanding the processes and mechanisms of liver regeneration involves recognizing components in liver regeneration system, the dynamic change of these components and their interactions[42].

In this review, it is pointed out that PPI maps (or PPI data) are closely correlated with TGFβ regulated Smad signaling pathways during liver regeneration. Colland *et al*[31] have used Y2H technique identified 755 interactions, mainly in a focused analysis of TGFβ signaling pathways and have constructed the PPI maps. They used this method to analyse LMO4, HYPA, KIAA1196 and LAPTm5 proteins, which are additional proteins involved in regulation of TGFβ signaling pathways. Also, they present an integrated approach for the identification of new factors implicated in TGFβ signaling pathway involved in several human pathologies and in the termination of liver regeneration. From this point of view, we can apply this strategy to study liver regeneration.

This review focuses on PPI maps and liver regeneration, and pays attention to the TGFβ signaling pathway. The PPI maps were constructed containing proteins related to the TGFβ signaling pathway and some of these proteins may have potential functions on the termination of liver regeneration (Figure 3). It can be easily used to find the key proteins in this process and additional experiments should be done to validate this hypothesis. Regardless, it is confirmed that the PPI map is an effective tool to study liver regeneration.

A PPI maps acting during liver cell proliferation

Gao *et al*[37] constructed a PPI map of transcription factors acting during liver regeneration which contains 32 regulatory proteins. Among them, 27 transcription factor genes that might have roles in the control of liver regeneration and five other genes that encode signal transducers might modulate transcription. After using a matrix mating Y2H technique, a PPI map in which all the components are related with liver cell proliferation was constructed (Figure 4) and some of the interactions were validated by α-glutathione S-transferase pull-down and CoIP assays. From this PPI map, Gao *et al*[37] pointed out that ATF3, a member of the mammalian activation transcription factor/cAMP responsive element-binding protein family of transcription factors, interacts with FHL2 which may be an important interaction during liver regeneration, especially for liver cell proliferation. When it comes to the termination response during liver regeneration, FHL2 and ATF3 may form a complex which abolishes its function on DNA synthesis and might terminate the liver regeneration. Also, it is possible that FHL2 may interact with Stat3 to inhibit its function in activating downstream gene expression that is necessary to terminate the liver regeneration. Nearly all the interactions in this map are growth repressors during liver regeneration and this is one of the ways in which the termination of hepatocyte proliferation and liver regeneration is regulated. Although this is one hypothesis for termination of liver regeneration, there is still growing evidence which shows that it is feasible to understand liver regeneration.

This PPI map is only a small-scale map and already can make sense of termination of liver regeneration. It would be no exaggeration to say that if large-scale, more complicated PPI maps are constructed it will greatly help us to know more about mechanism of liver regeneration.

FUTURE PROSPECTS

During the last decade, several efforts had been made to demonstrate the mechanism of liver regeneration. But unfortunately, an important gap is the lack of understanding of liver regeneration and therefore, some difficulties appear in liver cancer treatments or liver transplantation and drug development, which remain to be

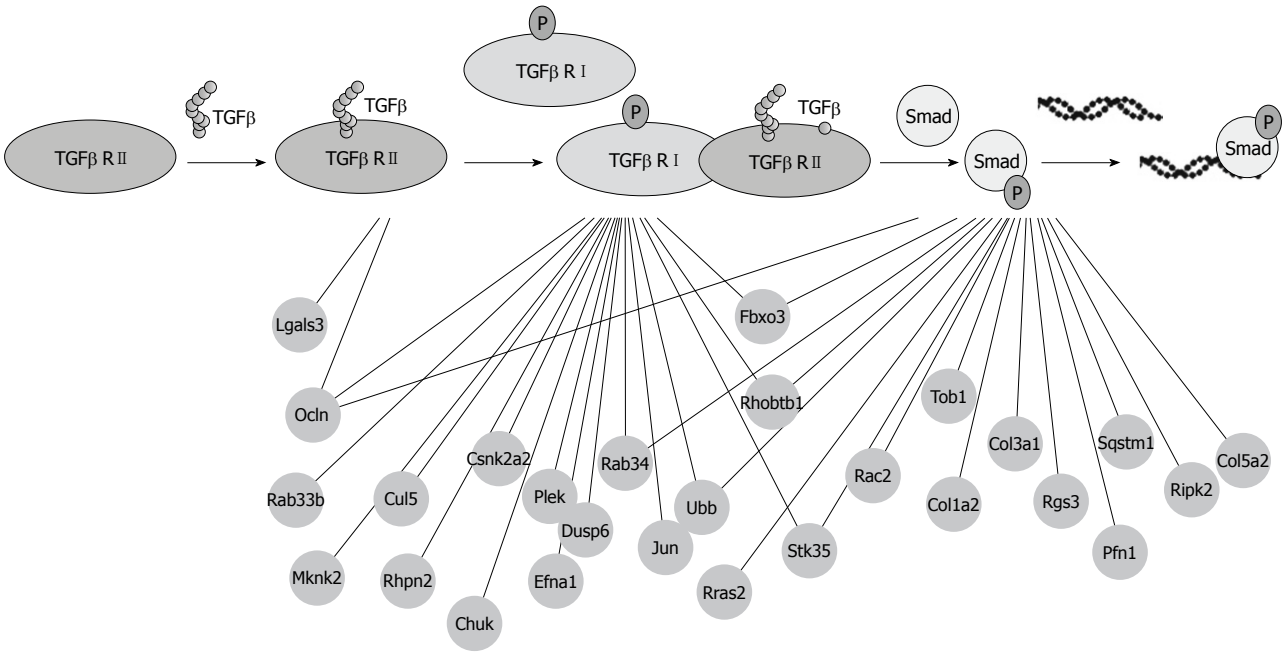

Figure 3 A protein-protein interaction comprising the transforming growth factor β signaling pathway. This figure just lists the protein-protein interactions which correlated with transforming growth factor β type Ⅰ receptor (TGFβ R Ⅰ), TGFβ R Ⅱ and Smads and all the proteins that directly interact with these three proteins which indicate that additional partners are not represented in this figure.

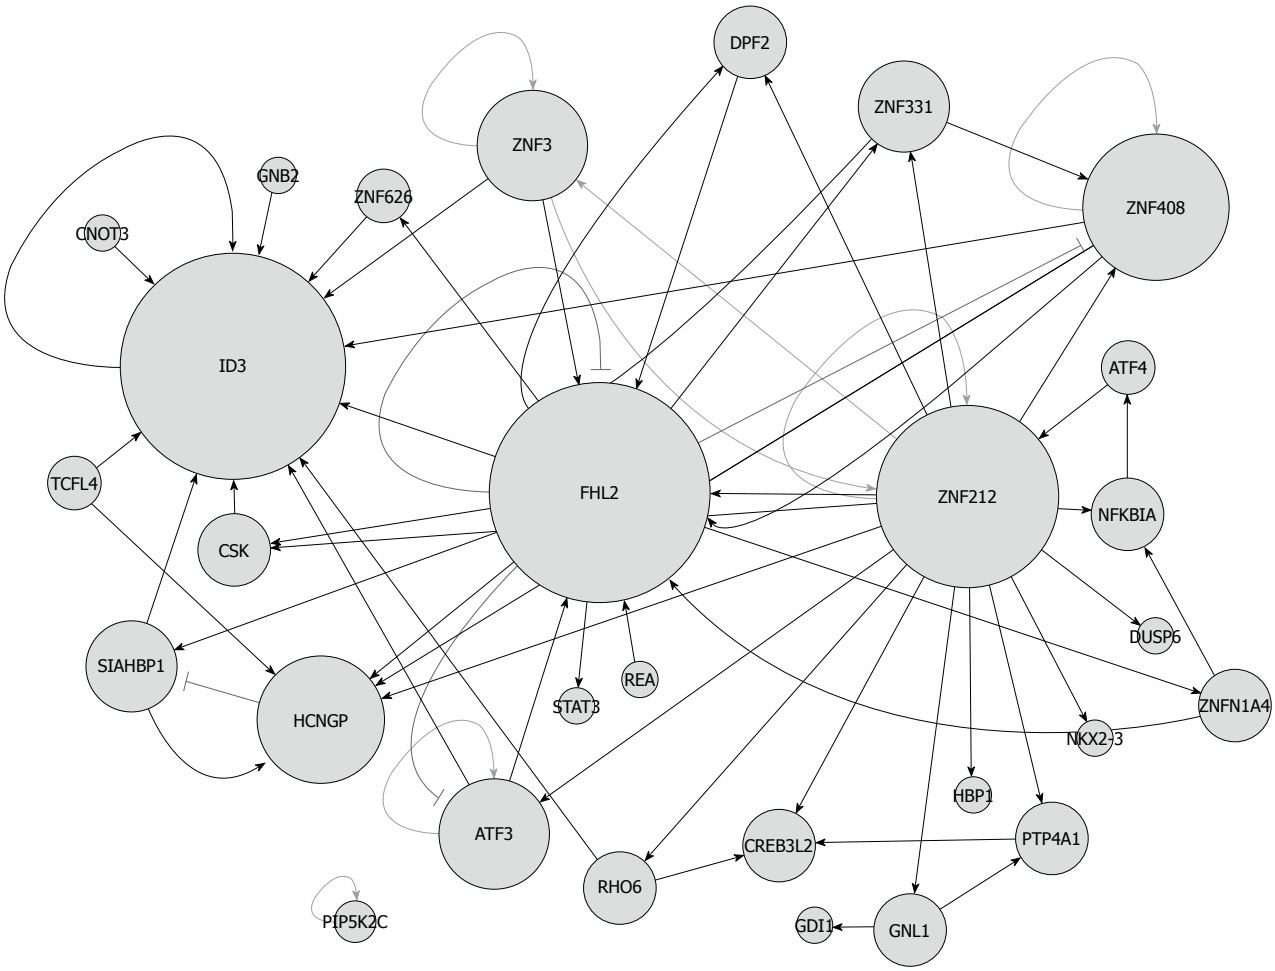

Figure 4 Protein-protein interaction maps comprising the transforming growth factor β signaling pathway of transcription factors associated with liver cell proliferation. The protein-protein interaction maps consist of different stages of liver regeneration (0 d, 0.5 d, 1.5 d, 4.5 d and 7 d after CCl_4-induced liver injury).

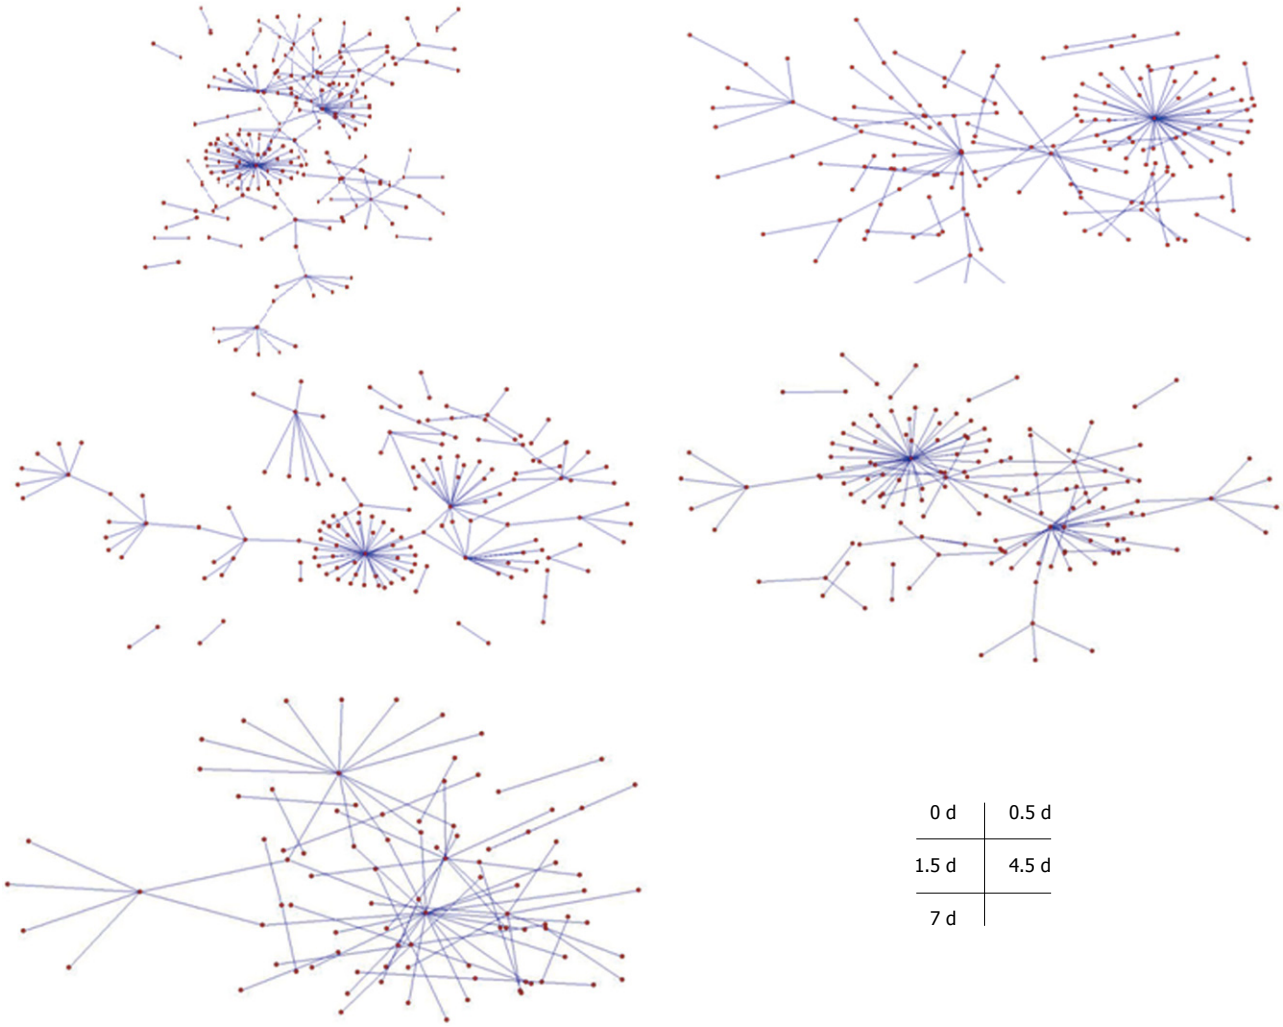

Figure 5 A protein-protein interaction map of transcription factors associated with liver cell proliferation. Node stands for protein and the edge means the two proteins are interactive; the node size symbolizes the degree of this protein (the more highly connected with others, the bigger node); the edge target arrow shape and color: delta and blue, interactions are only validated by yeast two-hybrid (Y2H); diamond and green means validated by Y2H and α-glutathione S-transferase pull-down; T and black means validated by Y2H and co-immunoprecipitation.

solved. Constructing PPI maps is a powerful step toward addressing these challenges. The most important profiles shall be discussed.

Integration of PPI data druing liver regeneration

Different high-throughput PPI data are difficult to cover even if in the same species, also, it has a higher rate of false positives than that of small-scale data[44]. However, it may be useful to increase the capacity of false positive identification in order to find out the real PPI from the noise data. The first step is to collect the correct and reliable PPI data and find several criteria which can be used to evaluate the PPI data sets. By integrating small-scale and large-scale PPI data, PPI databases have emerged and it is generally believed that a PPI database is a symbol of the level of PPIs. Although a series of PPI databases such as BIND (http://bind.ca), MIPS (http://mips.gsf.de) and DIP (http://dip.doe-mbi.ucla.edu) are popular and helpful, there are still no PPI databases for liver cells, liver regeneration or specific liver diseases, such as liver cancer. PPI data should be collected, evaluated, retrieved and systemically stored (including the detailed information for PPIs).

With liver regeneration PPI data which is integrated into the databases and is made readily accessible through the internet, researchers will be able to quickly locate the PPIs for their proteins of interest during liver regeneration, also, they will get the interpretation of PPIs in detail, which means any type of available information on proteins or protein domains can be verified. Meanwhile, we should also explore a tool that allows easy navigation in this complex of PPI databases especially for liver regeneration.

Already, the Y2H system has increasingly been applied in high-throughput applications intended to map genome-scale PPI for liver regeneration and is definitely believed to be an effective way to construct large-scale PPI maps during liver regeneration. Also, the low coverage and experimental bias call for development of computational methods to predict PPIs[45], and mining of existing inter-

action data to infer additional interactions is also a trend to enlarge the PPI database. Nowadays, lots of PPI data are obtained from different organisms and we can get PPI from interacting proteins to exhibit similar phylogenetic trees[46]. As to PPIs during liver regeneration, much more computational methods and algorithms must be fixed in order to predict PPIs during liver regeneration, also it may from signaling pathways level or proteome level.

Static and dynamic architecture of PPI maps during liver regeneration

Static PPI maps during liver regeneration, especially the PPI maps on signaling pathways, will help us to understand the different phases and different gene changes of liver regeneration. In order to understand the mechanism of liver regeneration, the PPI map furthered the understanding of the architecture of cellular machinery and revealed fundamental properties[47]. The large-scale and static PPI maps show us some information and they are quite important to understand the spatiotemporal existence of PPIs. Obviously, PPI maps are dynamic and not static, but unfortunately nearly all the PPI maps are static and do not consider the PPI strength and spatiotemporal existence let alone the types of PPI maps and do not reflect the actual situation in liver cells. Therefore, dynamic PPI maps are of more importance for cell signaling and dictate timing and intensity of map outputs. Our lab has also tried to construct dynamic PPI maps during mouse liver regeneration.

We picked up 5 major time points (0 d, 0.5 d, 1.5 d, 4.5 d and 7 d) during the mouse liver regeneration process after CCl_4-induced liver injury, in which all the proteins are transcription factors associated with TGFβ signaling pathway and constructed 5 PPI maps (Figure 5). It is easy to identify the PPIs change in the whole process of liver regeneration including numbers and the protein category. The numbers of PPIs increased at the beginning and then decreased. A detailed analysis of these PPI maps are in progress, which is a mark of the beginning of dynamic PPI maps construction.

Though no large-scale data sets are yet available on liver PPI map dynamics, the time dimension can be added by projecting time series of liver regeneration mRNA expression data onto transcription factors, allowing one method to interpret dynamic PPI maps. Researchers also need to consider addressing where and when interactions take place in different phases of liver regeneration and how they regulate the process. It will be a great help for us to know about liver regeneration if we know the full range of PPIs, from static to dynamic, and this is a useful method for studying liver regeneration over the next few years which will hopefully improve our ability to understand the PPI maps during liver regeneration.

Liver regeneration remains a fascinating project and the exact cellular and molecular mechanisms are still a mystery to us. In order to understand this phenomenon, many methods must integrate and we are just beginning to appreciate the relationship between PPIs and liver regeneration. We strongly believe that PPI maps from systems biology is a key gateway for deciphering liver regeneration. Certainly, like the sequencing of the human genome, the construction of a PPI map during liver regeneration will represent a major step along the path towards understanding the mechanisms of liver regeneration.

Abstract

AIM: To examine the relevance of hypoxia inducible factor (HIF-1) and nitric oxide (NO) on the preservation of fatty liver against cold ischemia-reperfusion injury (IRI).

METHODS: We used an isolated perfused rat liver model and we evaluated HIF-1α in steatotic and non-steatotic livers preserved for 24 h at 4℃ in University of Wisconsin and IGL-1 solutions, and then subjected to 2 h of normothermic reperfusion. After normoxic reperfusion, liver enzymes, bile production, bromosulfophthalein clearance, as well as HIF-1α and NO [endothelial NO synthase (eNOS) activity and nitrites/nitrates] were also measured. Other factors associated with the higher susceptibility of steatotic livers to IRI, such as mitochondrial damage and vascular resistance were evaluated.

RESULTS: A significant increase in HIF-1α was found in steatotic and non-steatotic livers preserved in IGL-1 after cold storage. Livers preserved in IGL-1 showed a significant attenuation of liver injury and improvement in liver function parameters. These benefits were enhanced by the addition of trimetazidine (an anti-ischemic drug), which induces NO and eNOS activation, to IGL-1 solution. In normoxic reperfusion, the presence of NO favors HIF-1α accumulation, promoting also the activation of other cytoprotective genes, such as heme-oxygenase-1.

CONCLUSION: We found evidence for the role of the HIF-1α/NO system in fatty liver preservation, especially when IGL-1 solution is used.

INTRODUCTION

During the last decade, the dramatic shortage of organs has obliged physicians to consider the transplantation of liver grafts with moderate steatosis[1-3]. Liver steatosis results from the abnormal accumulation of fat in the cytoplasm of hepatocytes. This causes alterations in the microcirculation with a higher risk of graft dysfunction or primary nonfunction. Steatotic liver grafts thus show poor tolerance to ischemia-reperfusion injury (IRI) associated with transplantation[3-5]. The composition of preservation solutions is critical for the quality of liver grafts during cold ischemia. Although University Wisconsin solution (UW) is the gold standard for abdominal organs, its use has been questioned because it contains hydroxyl-ethyl starch (HES), and a high concentration of K^+ ions[6-9]. It is has been reported that HES could be responsible for red blood cell aggregation[10-12].

Recently, IGL-1 solution has been proposed as an effective alternative to UW for steatotic liver preservation[12]. It has a lower concentration of K^+ ions and contains polyethylene glycol as osmotic support instead of HES. The benefits of IGL-1 are due in part to its capacity to increase the levels of nitric oxide (NO)[12], which protects the liver against IRI[13], and thus mitigates the alterations to hepatic microcirculation[12].

Cold ischemia graft preservation is characterized by a lack of oxygen supply to the liver. In these conditions, hypoxia inducible factor 1 (HIF-1) regulates the adaptive response of the organ to the changes in oxygenation induced during preservation[14]. HIF-1 is a heterodimer formed by α and β subunits which are constitutively expressed. The β subunit is independent of O_2, whereas the protein stability of the α subunit depends on the cellular levels of O_2[15]. Under normoxic conditions, the α subunit is degraded by a complex process involving the prolyl-hydroxylases, the Von Hippel Landau protein and the 26 S proteasomes[15,16]. It is well established that NO impairs normoxic degradation of HIF-1α by inhibition of HIF-1 prolyl-hydroxylases and contributes to its stabilization[17].

HIF-1α confers protection against IRI by activating others genes such as heme oxygenase-1 (HO-1)[18-20] which plays an important cytoprotective role in liver graft preservation against cold IRI[21,22].

Recently, it has been demonstrated that anti ischemic drugs such as trimetazidine (TMZ) protect heart mesenchymal stem cells against hypoxic insult by increasing HIF-1α expression[23]. Similar results were reported by Jayle *et al*[14] in TMZ-treated pig kidneys subjected to warm IRI. In addition, the benefits of TMZ seem to be associated with its capacity to generate NO[24] and the activation of endothelial NO synthase (eNOS) when it was used as an additive in UW solution[25].

As HIF-1α is involved in cell survival during IRI, we examined how hypoxic adaptations can be exploited to protect fatty livers in preservation solutions. We hypothesized that the HIF-1α accumulation during cold ischemia would be hepato-protective in normoxic reperfusion as a result of the NO-stabilizing action induced by IGL-1.

To test this hypothesis, we added TMZ to IGL-1 solution, and examined the effects of various protocols on the preservation of livers excised from rats. We found that the addition of TMZ to IGL-1 solution has a synergistic effect on NO generation and thus favors HIF-1α accumulation during normothermic reperfusion. Preserved HIF-1α levels contribute to the increase in the over-expression of HO-1 in fatty liver grafts.

The results reported here reveal the importance of the HIF-1α/NO system in the prevention of liver cold IRI, especially when moderate steatosis is present.

MATERIALS AND METHODS

Homozygous obese (Ob) Zucker rats and heterozygous lean (Ln) Zucker rats (reference group), aged 16-18 wk, were obtained from Iffa-Credo (L'Abresle, France)[12,25].

An isolated perfused rat liver model was used to evaluate hepatic function separate from the influence of other organ systems, undefined plasma constituents, and neural/hormonal effects. Hepatic architecture, microcirculation, and bile production are preserved in this experimental model[26,27]. All procedures were performed under isoflurane inhalation anesthesia. This study adhered to European Union regulations (Directive 86/609/CEE) for animal experiments.

Liver procurement and experimental groups

The surgical technique was performed as described elsewhere[12,28]. After cannulation of the common bile duct, the portal vein was isolated and the splenic and gastroduodenal veins were ligated. All animals were randomly distributed into groups as described below.

Protocol Ⅰ: induction of HIF-1α in steatotic livers after 24 h of cold ischemia in IGL-1 preservation solution: In order to evaluate the potential generation of HIF-1α during liver graft storage (24 h, 4℃) in IGL-1 preservation solution, and the benefits of the addition of TMZ, the following experiments were carried out: (1) Cont 1: Control livers from 16 Zucker rats (8 Ln and

8 Ob) were flushed with Ringer's lactate solution immediately after laparatomy *via* the portal vein without cold storage; (2) UW: Livers from 16 Zucker rats (8 Ln and 8 Ob) were preserved for 24 h in UW solution; (3) IGL-1: Livers from 16 Zucker rats (8 Ln and 8 Ob) were preserved for 24 h in IGL-1 solution; and (4) IGL-1 + TMZ: Livers from 16 Zucker rats (8 Ln and 8 Ob) were preserved for 24 h in IGL-1 with TMZ at a concentration of 10^{-6} mol/L, as previously described[25,28].

Aliquots of the effluent flush corresponding to groups 1, 2, 3 and 4 were sampled for measurements of cumulative transaminases. Liver tissue samples were used for HIF-1α activity determination after prolonged ischemia.

Protocol Ⅱ: effect of NO on HIF-1α stabilization and HO-1 induction after cold IRI: To examine the role of NO in stabilizing HIF-1α formed during cold ischemia, and the subsequent effect on HO-1 generation, fatty livers were subjected to 2 h-normoxic reperfusion, in the following groups: (5) Cont 2: Control livers from 16 Zucker rats (8 Ln and 8 Ob) were flushed with Ringer's lactate and immediately perfused *ex vivo* without ischemic preservation; (6) UW: Livers from 16 Zucker rats (8 Ln and 8 Ob) were preserved for 24 h in UW solution and then inserted into an isolated perfused rat liver system for 2 h; (7) IGL-1: Livers from 16 Zucker rats (8 Ln and 8 Ob) were preserved in IGL-1 solution and then inserted into an isolated perfused rat liver system for 2 h; (8) IGL-1 + TMZ: Livers from 16 Zucker rats (8 Ln and 8 Ob) were preserved for 24 h in IGL-1 with the addition of 10^{-6} mol/L TMZ and then inserted into an isolated perfused rat liver system for 2 h[25,28]; and (9) IGL-1 + TMZ + NAME: Livers from 16 Zucker rats (8 Ln and 8 Ob) were preserved for 24 h in IGL-1 with the addition of 10^{-6} mol/L TMZ and Nω-nitro-L-arginine methyl ester hydrochloride (L-NAME), an inhibitor of NO synthesis, at a dose of 60 μg/g liver before cold ischemia, and then inserted into an isolated perfused rat liver system for 2 h[28].

In order to account for the period of rewarming during surgical implantation *in vivo*[28], after 24 h of cold preservation livers from groups 5, 6, 7, 8 and 9 (Protocol Ⅱ) were exposed to 22℃ for 30 min prior to reperfusion. Livers were then connected *via* the portal vein to a recirculating perfusion system for 120 min at 37℃[12,25]. Time 0 was the point at which the portal catheter was connected to the circuit. As previously reported[12,28], during the first 15 min of perfusion (initial equilibration period), the flow was progressively increased in order to stabilize the portal pressure at 12 mmHg (Pression Monitor BP-1; Pression Instruments, Sarasota, FL, USA). The flow was controlled using a peristaltic pump (Minipuls 3, Gilson, France)[12,25]. The reperfusion liquid consisted of a cell culture medium (William's medium E; Bio Whitaker, Barcelona, Spain) with a Krebs-Heinseleit-like electrolyte composition enriched with 5% albumin osmotic support. The buffer was continuously ventilated with 95% O_2 and 5% CO_2 gas mixture. The buffer was subsequently passed through a heat exchanger (37℃) and a bubble trap prior to entering the liver[25]. During 120 min of normothermic reperfusion, the effluent was collected at 30-min intervals to measure liver transaminases. After the initial equilibration period of 15 min, flow rate and vascular resistance were assessed continuously throughout the reperfusion. Bile output, hepatic clearance [expressed as percentage of sulfobromophthalein (BSP) in bile samples], HIF-1α activity, and NOS proteins were evaluated at 120 min of reperfusion.

Biochemical determinations

Liver injury: Hepatic injury was evaluated according to transaminase levels using a commercial kit from Boehringer Mannheim (Munich, Germany).

Liver function: Liver function was assessed by measuring bile production[12,25]. Bile was collected through the cannulated bile duct and output is reported as μL/g liver.

Hepatic clearance: As with bile output, hepatic clearance was considered as another parameter of hepatic function[27,28]. Thirty minutes after the onset of the perfusion (t_{30}), 1 mg of BSP (Sigma, Spain) was added to the perfusate. The concentration of BSP in bile samples (t_{120}) was measured at 580 nm with a UV-visible spectrometer. Bile BSP excretion was expressed as a percentage of perfusate content (t_{120} bile/t_{30} perfusate × 100)[28,29].

Vascular resistance: Liver circulation was assessed by measuring perfusion flow rate and vascular resistance[26,28]. Perfusion flow rate was assessed continuously throughout the reperfusion period and expressed as mL/min × g. Vascular resistance was defined as the ratio of portal venous pressure to flow rate and expressed in mmHg × min × g/mL[26,28].

Glutamate dehydrogenase activity: Glutamate dehydrogenase (GLDH) is a mitochondrial enzyme and was used as an indirect measure of mitochondrial damage[25,28]. GLDH activity was determined in perfusates as described elsewhere[25,28].

Determination of nitrite and nitrate: NO production in liver was determined by tissue accumulation of nitrite and nitrate, as previously reported[25,28].

eNOS immunohistochemistry: Frozen liver sections (18 μm thick) were fixed in pre-cooled acetone for 10 min at room temperature. After washing with phosphate-buffered saline (PBS), permeabilization was performed with 0.5% Triton X-100 for 15 min each. Antibody non-specific binding was blocked for 1 h in PBS with 10% normal goat serum, 3% bovine serum albumin, 1.5% NaCl and 0.5% Triton X-100 for 1 h. The primary eNOS antibody (Polyclonal IgG anti-NOS-3, Santa Cruz Biotechnology, Santa Cruz, CA, USA) was applied at a dilution of 1:100 in the blocking solution and incubated for 1 h at room

temperature in a moist chamber. After rinsing with PBS, permeabilization was performed again with 0.5% Triton X-100, 3 times for 10 min each. The secondary antibody goat anti-rabbit Alexa488 Fluor labeled (Invitrogen) was applied at a dilution of 1:400 in the blocking solution for 50 min at room temperature. After washing with PBS, the slides were mounted with ProLong Gold antifade (with DAPI) mounting medium, and eNOS immunohistochemistry images were obtained by fluorescence microscope.

Western blottings of eNOS and HO-1

Liver tissue was homogenized as previously described[28] and proteins were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis and transferred to polyvinylidene fluoride membranes. Membranes were immunoblotted with antibodies against anti-eNOS (transduction laboratories, Lexington, KY, USA), against anti-HO-1 (Sigma Chemical, St Louis, MO, USA) and β-actin (Sigma Chemical, St. Louis, MO, USA). Signals were detected by enhanced chemiluminescence and quantified by scanning densitometry.

Preparation of nuclear fraction: Nuclear fractions were prepared from frozen liver tissues which were suspended in a hypotonic buffer that contained 10 mmol/L HEPES (pH 7.6), 15 mmol/L KCl, 2 mmol/L $MgCl_2$, 0.1 mmol/L EDTA, 1 mmol/L dithiothreitol, and 0.2% Nonidet P-40 with protease inhibitor (1 mmol/L phenylmethylsulfonyl fluoride, 1 μg/mL aprotinin, 1 μg/mL leupeptin and 1 μg/mL pepstatin) and homogenized for 40 s with a polytron homogenizer. After centrifugation at 850 *g* the supernatant that contained cytoplasmic and membrane protein was collected. Nuclear proteins were extracted at 4℃ by gently resuspending the nuclear pellet in hypertonic buffer that contained 25 mmol/L HEPES (pH 7.8), 50 mmol/L KCl, 0.1 mmol/L EDTA, 1 mmol/L dithiothreitol, 10% glycerol, 0.4 mol/L NaCl and protease inhibitor, followed by 30 min incubation at 4℃ with occasional vortexing. After centrifugation at 18 000 *g* for 15 min at 4℃, the supernatant that contained nuclear protein was collected and protein concentration was measured by the Bradford Protein method (Bio-Rad, Hercules, CA, USA).

HIF-1α measurement: HIF-1α translocation to nuclei was assessed by Western blotting and was also quantified by specific binding of HIF-1α to its specific oligonucleotide recognition hypoxia responsive element, using the Trans AM HIF-1α kit (Active Motiv, Carlsbad, CA, USA). Membranes were incubated with an antibody against anti-HIF-1α (Santa Cruz Biotechnology, Santa Cruz, CA, USA). Signals were detected by enhanced chemiluminescence and quantified by scanning densitometry. For the quantitative method, samples were run in duplicate in microtiter plates coated with an oligonucleotide for HIF-1α following manufacturer's instructions. Results are expressed as μg HIF-1α/mg protein of nuclei extract[30,31].

Statistical analysis

Data are expressed as mean ± SE, and were compared statistically by variance analysis, followed by the Student-Newman-Keuls test (Graph Pad Prism software). $P < 0.05$ was considered significant.

RESULTS

Induction of HIF-1α in non-steatotic and steatotic livers after 24 h of cold ischemia

As indicated in Figure 1A and B, cumulative HIF-1α levels were determined in non-steatotic and steatotic livers preserved in IGL-1 + TMZ solutions and compared to levels observed in IGL-1 and UW alone. HIF-1α accumulation was significantly increased by the addition of TMZ to IGL-1 solution in both types of liver. Although steatotic livers showed slightly lower HIF-1α levels than non-steatotic livers, these differences were not significant (Figure 1A and B).

Liver ischemic damage was assessed by alanine transaminase (ALT) and aspartate transaminase (AST) levels after 24 h of cold storage as shown in Figure 1C and D. A significant reduction in release of ALT and AST occurred in non-steatotic and steatotic livers preserved in IGL-1 + TMZ when compared to IGL-1 and UW, respectively. This reduction correlated with the significant accumulation of HIF-1α observed for the IGL-1 + TMZ and IGL-1 solutions (Figure 1A and B).

Stabilization of HIF-1α in non-steatotic and steatotic livers after cold ischemia-reperfusion: role of NO

In order to evaluate whether HIF-1α could be stabilized by NO after hepatic reperfusion, we measured HIF-1α accumulation in steatotic and non-steatotic livers preserved in UW, IGL-1 and IGL-1 + TMZ solutions (24 h, 4℃) and then subjected to 2 h normoxic reperfusion (37℃). NO generation was inhibited by the addition of L-NAME to IGL-1 + TMZ solution (IGL-1 + TMZ + NAME).

Figure 2 shows the HIF-1α levels after 2 h of normothermic reperfusion in steatotic and non-steatotic livers preserved in IGL-1, IGL-1 + TMZ and UW solutions, respectively. HIF-1α levels were higher in the non-steatotic and steatotic livers stored in IGL-1 + TMZ solution than in those stored in IGL-1 and UW respectively. In all cases, the greatest increases were for the non-steatotic and steatotic livers preserved in IGL-1 enriched with TMZ (IGL + TMZ), and were significantly prevented by L-NAME (Figure 2A and B).

eNOS activity and nitrite/nitrate levels were higher in the steatotic and non-steatotic livers preserved in IGL-1 + TMZ when compared to UW and IGL-1 alone (Figure 2C, D and Figure 3). This enhanced eNOS activity and nitrite/nitrate levels were more evident when TMZ was added to IGL-1. In contrast, the addition of L-NAME to IGL-1 + TMZ solution reduced both.

In order to evaluate the benefits of HIF-1α and NO in livers preserved in IGL-1 and IGL-1 + TMZ after reperfusion, we evaluated liver injury (AST/ALT) and function (bile production, vascular resistance), as indicated in Figure 4.

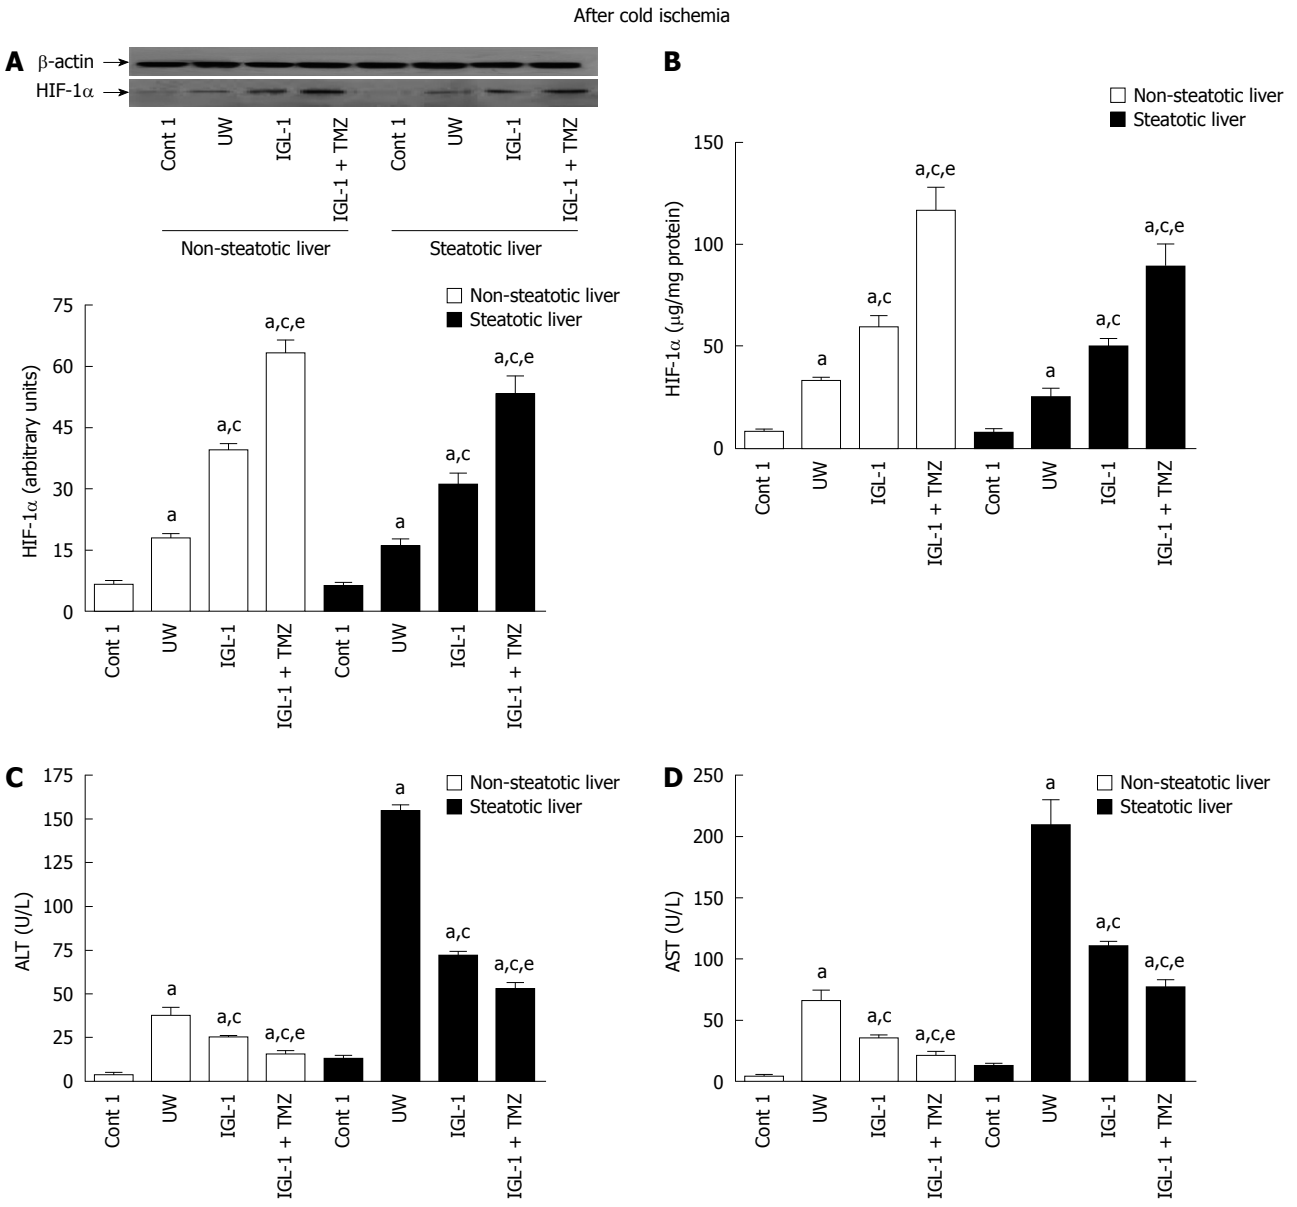

Figure 1 Hypoxia-inducible factor-1α protein levels in liver after 24 h of cold storage. A: Representative Western (top) and densitometric analysis (bottom); B: Hypoxia-induced factor-1α (HIF-1α) protein levels quantified by Trans AM HIF-1α kit; Alanine transaminase (ALT) (C) and aspartate transaminase (AST) (D) levels in flushing effluent after 24 h of cold storage. University Wisconsin (UW): Liver preserved in UW solution; IGL-1: Liver preserved in IGL-1 solution; IGL-1 + trimetazidine (TMZ) (trimetazidine): Liver preserved in IGL-1 solution with TMZ; Cont 1: Liver flushed without cold preservation. $^{a}P < 0.05$ *vs* Cont 1; $^{c}P < 0.05$ *vs* UW; $^{e}P < 0.05$ *vs* IGL-1.

At 2 h reperfusion release of ALT and AST was significantly lower in non-steatotic and steatotic livers preserved in IGL-1 + TMZ solution than in IGL-1 and UW solutions (Figure 4A and B). In contrast, the inhibition of NO by L-NAME showed significantly increased in AST/ALT release, in both kinds of liver. In all cases, the AST/ALT profiles were consistent with those obtained for HIF-1α accumulation during reperfusion (Figure 2).

TMZ also had beneficial effects on bile production and %BSP clearance in bile (Figure 4C and D). It also promoted a significant reduction in vascular resistance (Figure 4E), when compared to IGL-1 and UW solutions. The greatest reduction in vascular resistance occurred when TMZ was added to IGL-1. This finding is consistent with highest increases in eNOS activity and nitrite/nitrate levels as shown in Figures 2 and 3.

Mitochondrial damage was evaluated by measuring GLDH activity levels in perfusate at the end of the reperfusion period. Steatotic livers preserved in UW solution showed greater GLDH activity than did non-steatotic livers (Figure 5A). Livers stored in IGL-1 as well as in IGL-1 + TMZ solution reduced GLDH levels in both type of livers (Figure 5).

Finally, we examined the effect of HIF-1α accumulation during liver reperfusion on the induction of other cytoprotective agents, such as HO-1. HO-1 expression was exacerbated in both kinds of liver preserved in IGL-1 + TMZ solution when compared to IGL-1 and UW alone (Figure 5B). As with HIF-1α, HO-1 was inhibited by the presence of L-NAME in both livers. The HO-1 pattern profiles were similar to those obtained for HIF-1α (Figure 2).

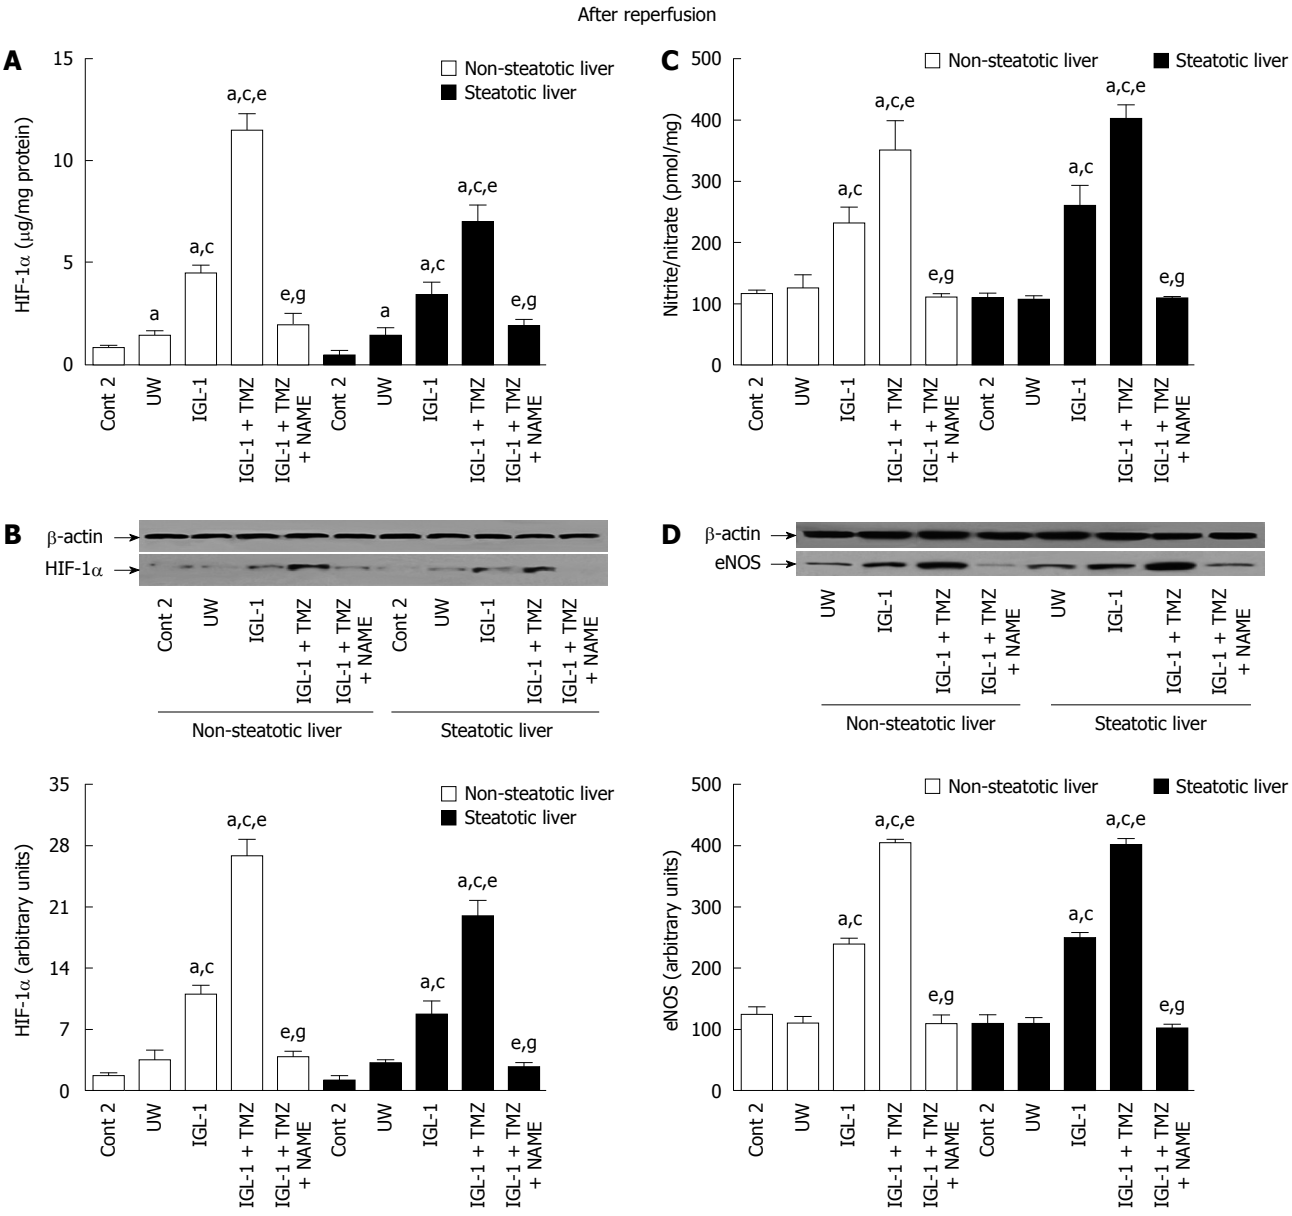

Figure 2 Hypoxia-inducible factor-1α, nitrite/nitrate and endothelial nitric oxide synthase. A: Hypoxia-induced factor-1α (HIF-1α) protein levels quantified by Trans AM HIF-1α kit after 24 h of cold storage and 120 min of normothermic reperfusion; B: Representative Western blotting of HIF-1α (top) and densitometric analysis (bottom) after 24 h of cold storage and 120 min of normothermic reperfusion; C: Nitrite/nitrate levels after 120 min of normothermic reperfusion; D: Endothelial nitric oxide synthase (eNOS) protein levels in liver after 120 min of normothermic reperfusion. Representative Western blotting (top) and densitometric analysis (bottom). Cont 2: Liver flushed and perfused *ex vivo* without cold preservation; University Wisconsin (UW): Liver preserved in UW solution; IGL-1 + trimetazidine (TMZ) + NAME: Liver preserved in IGL-1 solution with TMZ and an nitric oxide synthesis inhibitor, L-NAME. $^{a}P < 0.05$ *vs* Cont 2; $^{c}P < 0.05$ *vs* UW; $^{e}P < 0.05$ *vs* IGL-1; $^{g}P < 0.05$ *vs* IGL-1 + TMZ.

DISCUSSION

HIF-1 is the main factor involved in the regulation of transcriptional responses to hypoxia[32,33]. HIF-1α levels accumulate and trigger an increase in expression of genes involved in glycolysis, glucose metabolism, mitochondrial function, cell survival and resistance to oxidative stress[20], in response to oxygen deprivation, and during organ cold storage. For this reason, we have explored new pharmacological strategies to promote the highest accumulation of cytoprotective factors such as HIF-1α to protect fatty livers against cold ischemia and reperfusion injury.

Here, we demonstrate for the first time that significant activation of HIF-1α occurs after 24 h of cold storage in both types of liver when TMZ is added to IGL-1 solution. This improves liver protection, as evidenced by the reduction in transaminase levels. This is of particular interest in clinical practice, since numerous pharmacological strategies that are effective in non-steatotic livers may not be useful in the presence of steatosis[34,35]. These results agree with the protective effects observed when TMZ was added to UW preservation solution[14,25].

Significant HIF-1α accumulation was also found after 2 h of liver reperfusion. This is consistent with the finding that mesenchymal stem cells pre-treated with TMZ were

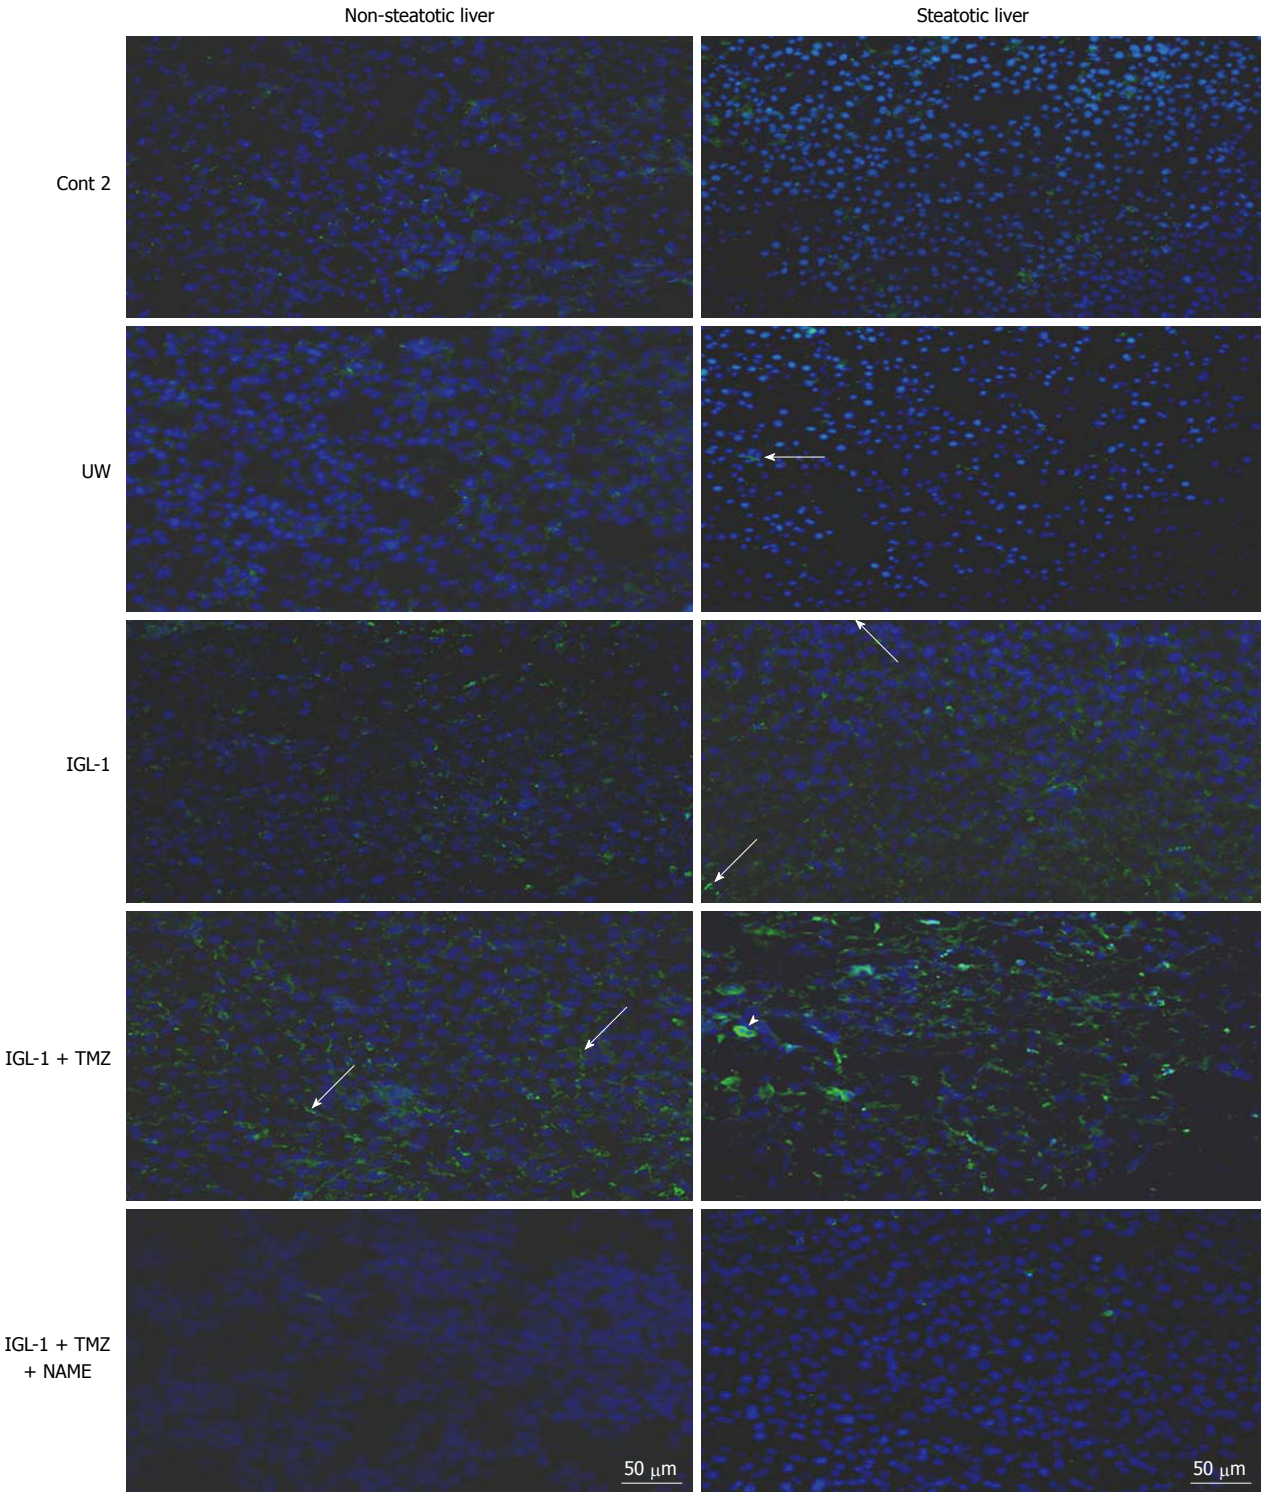

Figure 3 Endothelial nitric oxide synthase immunohistochemistry in steatotic and non-steatotic livers. Control livers and livers stored in University Wisconsin (UW) solution show only a little positivity for endothelial nitric oxide synthase (eNOS), localized typically in a few sinusoidal endothelial cells (arrows). The positivity increases when the livers are submitted to cold storage with IGL-1 solution and even more when trimetazidine (TMZ) is added to IGL-1 solution. When TMZ is added to IGL solution, some positive Kupffer cells (arrowhead) can be observed also. The addition of L-NAME to IGL-1 + TMZ solution reduced eNOS activity.

protected against H_2O_2 induced loss of cellular viability and membrane damage, with a concomitant increases in HIF-1α[23]. Similar observations were reported by Jayle *et al*[14] when pig kidneys were subjected to warm ischemia reperfusion.

Cumulative HIF-1α levels contributed to liver protection but they were abolished by the addition of L-NAME, an inhibitor of NO synthesis. This demonstrates by the first time in fatty liver preservation, the relevance of NO in HIF-1α accumulation during normoxic liver reperfusion.

NO is an intracellular and/or intercellular and dif-

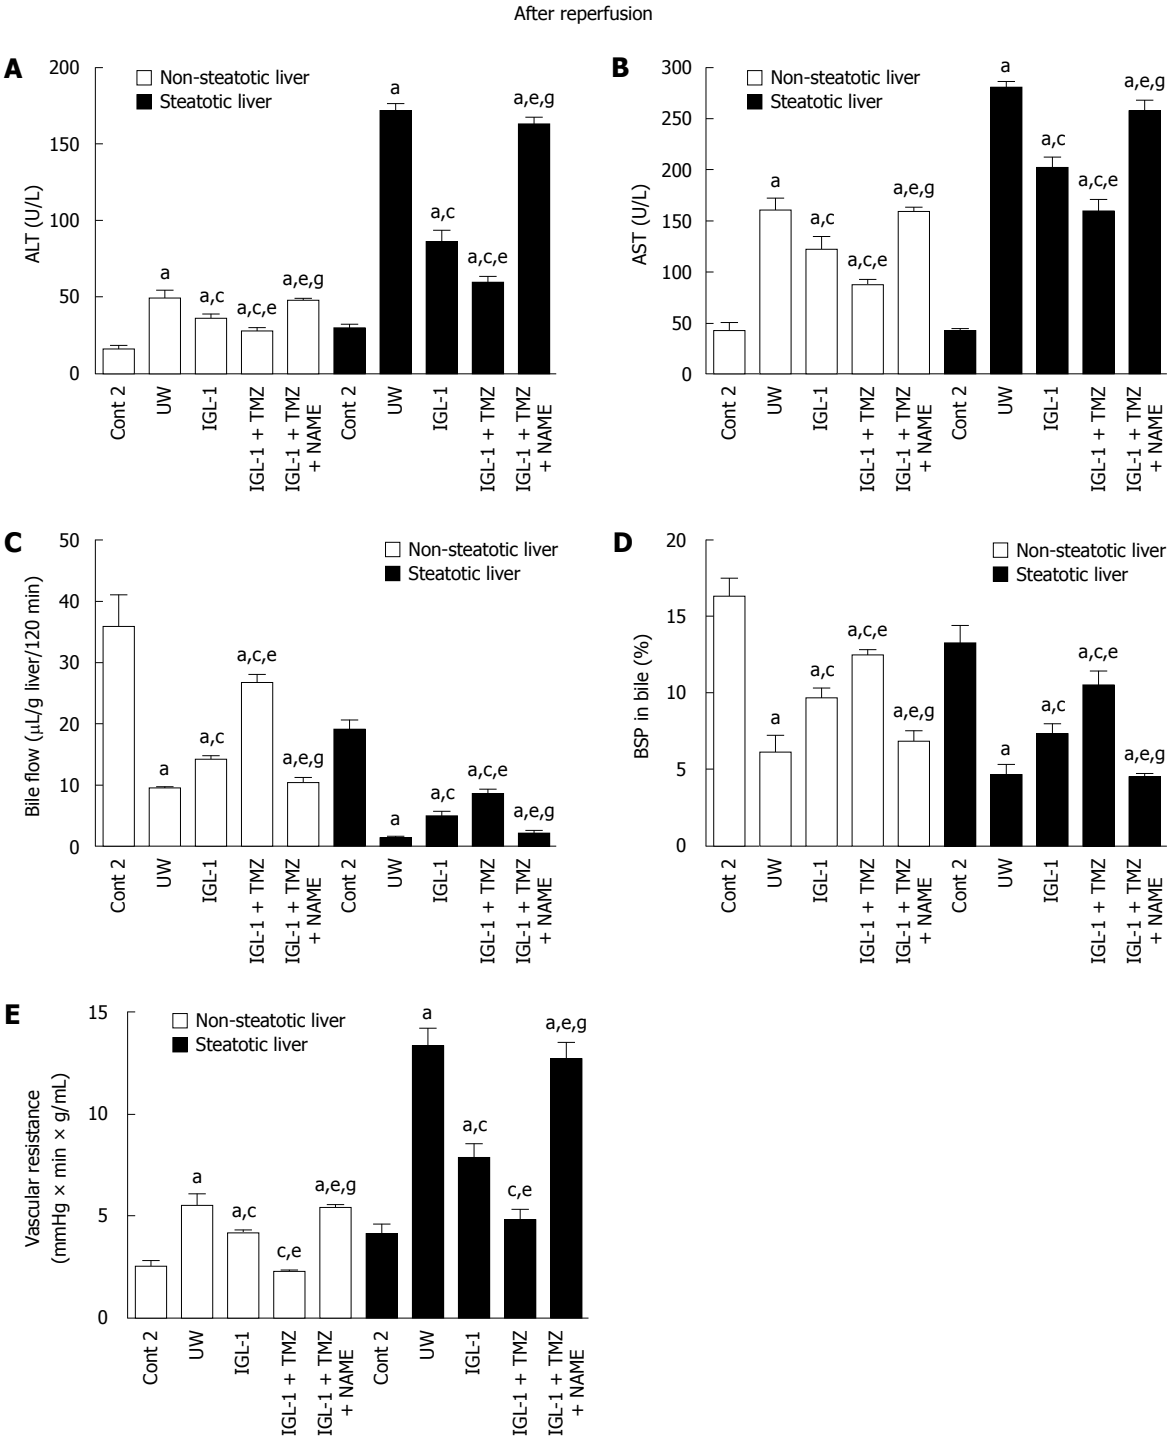

Figure 4 Alanine transaminase (A), Aspartate transaminase (B) levels in perfusate, bile flow (C), percentage of sulfobromophthalein in bile (D), and vascular resistance (E) of steatotic and non-steatotic livers after 120 min of normothermic reperfusion. fusible mediator whose role on hepatic IRI is controversial[28,36-38]. Overall, the important factors in determining the beneficial *vs* harmful effects of NO are the amount, duration, and site of NO production[39,40]. A low concentration eNOS-derived NO serves to maximize blood perfusion, promote cell survival and protect the liver against IRI[41]. However, a sustained presence of iNOS-derived NO might become detrimental by increasing toxic reactive oxygen species leading to liver injury[37,40-42]. The results reported here show that the NO benefits were derived mainly from eNOS and that they did not originate from iNOS activation (data not shown).

NO vasodilator properties prevent the alterations of microcirculation observed during liver reperfusion, which are exacerbated in the presence of steatosis[12,28]. The addition of NO donors to UW solution preserves livers against cold ischemic injury[13]. Thus, the benefits of the use of IGL-1 solution for fatty liver preservation are as-

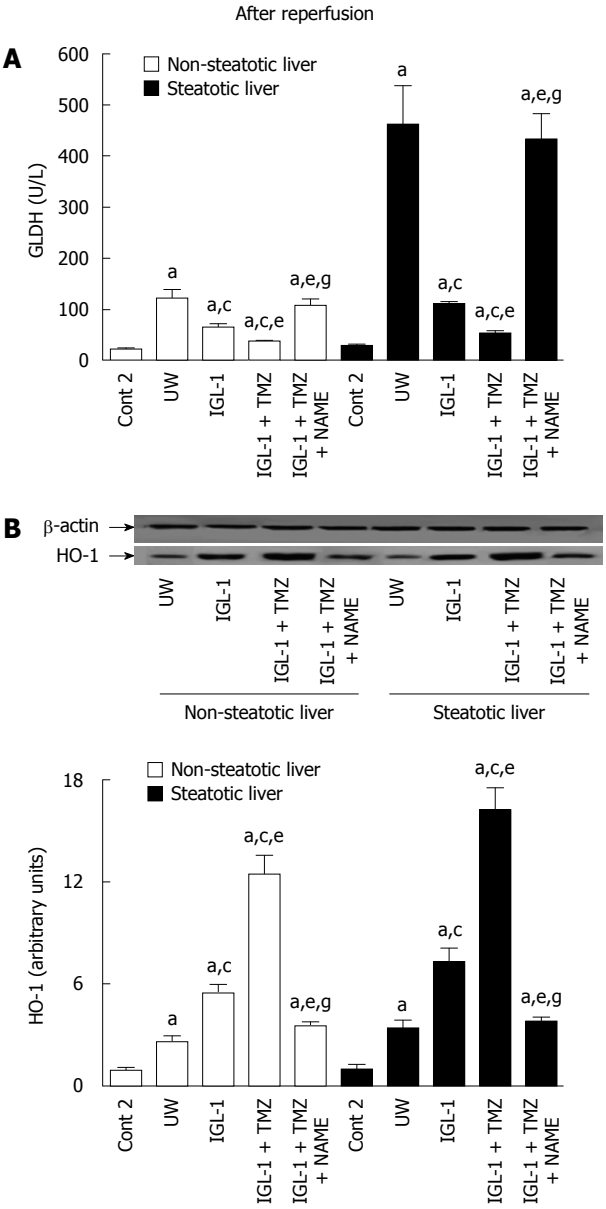

Figure 5 Glutamate dehydrogenase and heme oxygenase-1. A: Glutamate dehydrogenase (GLDH) levels after 120 min of reperfusion; B: Heme oxygenase-1 (HO-1) protein levels in liver after 120 min of normothermic reperfusion. Representative Western blotting at (top) and densitometric analysis at (bottom). [a]*P* < 0.05 *vs* Cont 2; [c]*P* < 0.05 *vs* University Wisconsin (UW); [e]*P* < 0.05 *vs* IGL-1; [g]*P* < 0.05 *vs* IGL-1 + trimetazidine (TMZ).

sociated with the capacity of generating NO[12]. However, the relevance of NO and it relationship with HIF-1α accumulation for increasing fatty liver graft protection against cold IRI is demonstrated here for the first time.

In recent years, there has been increasing interest in the relationship between HIF-1α and NO. NO profoundly affects the HIF-1α signaling pathway[43,44]. In normoxia, NO inhibits the prolyl-hydroxylases responsible for HIF-1α degradation, thus contributing to its stability[17].

Our results demonstrate that HIF-1α also accumulate during reperfusion in the presence of NO in liver grafts preserved in IGL-1 + TMZ or IGL-1 alone. Beneficial effects on HIF-1α accumulation are confirmed by the increased constitutive eNOS activity and nitrite/nitrate levels in liver grafts preserved in both solutions. In addition, these data confirm the synergism between IGL-1 solution and TMZ, responsible for the increased NO production by the activation of constitutive eNOS[24,28]. NO levels generated from the synergistic action of TMZ in IGL-1 solution are determinant of effective HIF-1α accumulation and subsequent protection of the liver graft against IRI. This differs from the effects observed when TMZ was added to UW, where the induction of eNOS activity was lower (data not shown).

Previous studies from our group showed that bile production is higher when livers are preserved in IGL-1than when they are preserved in UW[12]. Similarly, TMZ increased bile secretion when added to UW solution[25]. Our results show a synergistic action when TMZ is added to IGL-1 solution, which enhances the increase in bile production.

Fat accumulation in the cytoplasm of the hepatocytes is associated with an increase in cell volume, which may result in the partial or complete obstruction of the hepatic sinusoidal space[45,46]. Our results demonstrate that NO generated from the synergistic action mentioned above contributes to the reduction in vascular resistance. In fact NO inhibition by L-NAME increased vascular resistance, confirming the role of NO in fatty liver preservation.

Fatty degeneration, which induces a series of ultrastructural and biochemical alterations in mitochondria[47,48] may render these organelles intrinsically more susceptible to I/R injury. Mitochondrial injury is a common pathway of cell necrosis and apoptosis in IRI. Recent studies have shown that activation of HIF-1α prevents mitochondrial injury after mouse liver ischemia reperfusion[49]. Our results indicate that the HIF-1α accumulation after normoxic reperfusion prevented mitochondrial injury.

Finally, we measured the expression of HO-1 after 2 h of normothermic reperfusion, as a potential gene target induced by HIF-1α activation[18,19]. HO-1 is activated during cellular stress: its over-expression is a requisite for increasing organ cytoprotection against IRI, especially when steatosis is present[20,21,45,50].

We confirmed increased HO-1 expression in livers preserved in IGL-1 and IGL-1 + TMZ solutions. This is in line with the better protection against reperfusion injury in livers stored in IGL-1 + TMZ solution than in IGL-1 or UW alone. The abolition of HIF-1α stabilization by NO inhibition with L-NAME reversed HO-1 levels and increased liver injury after reperfusion.

In conclusion, we report by the first time the importance of NO in fatty liver reperfusion in stabilizing HIF-1α which is generated during liver cold storage.HIF-1α accumulation determines, in part, the increase in HO-1, a cytoprotective factor which improves the outcome of grafts after transplantation.

COMMENTS

Background

Steatosis is a major risk against cold ischemia-reperfusion injury (IRI). Hypoxia inducible factor-1α (HIF-1α) is a cytoprotective factor generated in response to lack of oxygen, as occurs during cold storage of liver grafts in preservation solutions. IGL-1 solution has been proposed as an effective alternative to University Wisconsin for steatotic liver preservation. The benefits of IGL-1 solution are due in part to its capacity to increase the levels of nitric oxide (NO).

Research frontiers

NO impairs normoxic degradation of HIF-1α by inhibition of prolyl-hydroxylases and contributes to its stabilization. HIF-1α confers protection against IRI by activating genes such as heme oxygenase-1 which plays an important cytoprotective role in liver graft preservation against cold IRI. In this study, the authors focused on the importance of HIF-1α and NO in fatty liver preservation.

Innovations and breakthroughs

The authors provide evidence that the enrichment of IGL-1 solution with trimetazidine (an anti-ischemic drug) increases NO generation and prevents HIF-1α degradation during steatotic liver graft reperfusion.

Applications

The use of modified IGL-1 solutions should be a useful strategy for increasing steatotic liver graft preservation through HIF-1α accumulation in normothermic reperfusion.

Peer review

In essence, the paper demonstrates that the HIF/NO system is important in fatty liver preservation following ischemia reperfusion injury. The study is well designed and the interpretation of the data is adequate.

Abstract

AIM: To identify and assess studies reporting the diagnostic performance of ultrasound imaging for identifying chronic liver disease (CLD) in a high risk population.

METHODS: A search was performed to identify studies investigating the diagnostic accuracy of ultrasound imaging for CLD. Two authors independently used the quality assessment of diagnostic accuracy studies (QUADAS) checklist to assess the methodological quality of the selected studies. Inter-observer reliability of the QUADAS tool was assessed by measuring the degree of agreement (percent agreement, κ statistic) between the reviewers for each assessment prior to a consensus meeting. The characteristics of each study population, sensitivity and specificity results for the index tests, and results of any testing for observer agreement were extracted from the reports. Receiver Operator Characteristic plots were generated using Microsoft Excel 2003 software and used to graphically display the diagnostic performance data and to explore the relationships between the reported ultrasound techniques and study characteristics, and methodology quality.

RESULTS: Twenty-one studies published between 1991 and 2009 were retained for data extraction, analysis and assessment for methodological quality. Assessment of methodology quality was performed on the 21 selected studies by two independent reviewers (RA & KT) using the QUADAS assessment tool. Across all studies the mean number of responses within the QUADAS assessment tool was 10 (range 7-13) for "Yes", 1 (range 0-3) for "No" and 3 (range 0-6) for "unclear". Inter-rater agreement for assessment of methodology quality was significantly greater than chance when assessing for representative spectrum, clear selection criteria, appropriate delay between reference and index tests, adequate descriptions of the index and reference tests, reference and index test blinding, and if relevant clinical information was provided. Seven studies reported moderate to high observer agreement for ultrasound techniques. Studies which clearly reported blinding performed better than the other studies for diagnostic accuracy, and lower diagnostic accuracy was evident for populations with lower prevalence of disease. Assessment of the liver surface using ultrasound consistently had moderate diagnostic accuracy across studies which demonstrated good research methodology. Other techniques demonstrated variable or poor to fair diagnostic accuracy.

CONCLUSION: Ultrasound of the liver surface is a useful diagnostic tool in patients at risk of CLD when assessing whether they should undergo a liver biopsy.

Key words: Chronic liver disease; Liver surface; Systematic review; Ultrasonography

INTRODUCTION

Chronic liver disease (CLD) is a significant cause of morbidity and mortality in developed nations. It is commonly caused by viral hepatitis and alcohol abuse with significant contributions from metabolic disorders[1]. Accurate diagnostic testing for CLD to identify asymptomatic patients in a high risk population has become more important due to recent advances in management and treatment options that provide better patient outcomes if the diagnosis of fibrosis or cirrhosis can be made before cirrhosis becomes clinically apparent[2]. In some cases, liver fibrosis has been demonstrated to be reversible[3], a phenomenon that was previously not considered possible.

The standard method for determining, staging and grading CLD is liver biopsy[4]. The invasiveness of this method, and its associated morbidity and mortality has led to the emergence of less invasive methods which include medical imaging techniques (computed tomography, magnetic resonance imaging and ultrasound), serum markers (both direct and indirect markers of fibrosis) and transient elastography[2]. All of these techniques have the potential to reduce the number of biopsies performed in a high risk population.

Ultrasound can identify the manifestations of CLD such as liver fibrosis and cirrhosis which are characterized by the presence of vascularized fibrotic septa and regenerating nodules[1,5-7]. Ultrasound is an attractive diagnostic tool because it is readily available, inexpensive, well tolerated and is already extensively used in the diagnostic work-up of patients with CLD. The diagnostic accuracy of ultrasound needs to be established to inform clinicians of its role in patients at high risk of CLD.

The aim of the following systematic review was to identify and assess studies reporting the diagnostic performance of ultrasound imaging for identifying CLD in a high risk population.

MATERIALS AND METHODS

Search strategy

A search of electronic databases in November 2009 was performed by one author (RA) to identify studies reported in English, investigating the diagnostic accuracy of ultrasound imaging for CLD. MEDLINE, EMBASE, CINAHL and Science Citation Index databases were searched using the terms "chronic liver disease", "cirrhosis", "fibrosis", "liver biopsy". The truncated terms "sonograph*" and "ultraso*" were also used in the search for alternate terms used for ultrasound such as sonography, sonographic, ultrasonic, ultrasound and ultrasonography. A Boolean search strategy was employed for the above terms in the following form: (sonograph* OR ultraso*) AND (chronic liver disease OR cirrhosis OR fibrosis) AND liver biopsy. No search filters were used. "Pearling" of the reference lists of all selected studies was also performed.

Eligibility and study selection

One author (RA) determined the eligibility of studies for inclusion in this review. Inclusion and exclusion criteria were created to identify studies that were likely to conform to the highest level of evidence for studies of diagnostic tests using the National Health and Medical Research Council of the Australian Government Level Ⅱ criteria[8].

The inclusion and exclusion criteria for the systematic review are described in Table 1. Initially, abstracts of all identified studies were assessed to determine if the study met the inclusion and exclusion criteria. Studies were retained if they clearly met the inclusion criteria, did not meet the exclusion criteria, or if it was unclear from the abstract if the study met the exclusion and inclusion criteria. The full text reports of all retained studies were then re-assessed for inclusion. All studies clearly meeting any of the exclusion criteria were excluded, and all studies meeting all the inclusion criteria were retained for assessment of methodological quality, data extraction and analysis.

Assessment of methodological quality

Two authors (RA, KT) independently used the quality assessment of diagnostic accuracy studies (QUADAS)[9] checklist to assess the methodological quality of the selected studies. The QUADAS checklist (Table 2) contains 14 assessment items, each assessing an aspect of the study that impacts on methodological quality. Each author assessed the selected studies by rating each assessment item for each study as "yes", "no" or "unclear". The studies were not given an overall score, nor were they stratified into high or low quality groups. Inter-observer reliability of the QUADAS tool was assessed by measuring the degree of agreement (percent agreement, κ statistic) between the reviewers for each assessment prior to a consensus meeting. A consensus meeting was held to resolve any discrepant scores between the two assessors. A third independent assessor (MP) reviewed the discrepant scores and acted as a final adjudicator if a consensus could not be reached.

Data extraction

The characteristics of each study population were extracted from the reports and included country of origin, sample size, gender, aetiology, age (mean, range and SD),

Table 1 Inclusion and exclusion criteria for studies

Inclusion criteria	Exclusion criteria
Evaluated diagnostic accuracy	Did not evaluate diagnostic accuracy
Quantitative results of diagnostic performance presented in a format that enabled a 2 × 2 contingency table to be extracted OR results presented as sensitivity, specificity and prevalence	2 × 2 contingency table could not be extracted from results of diagnostic performance OR sensitivity, specificity and prevalence results not presented
Index test of study was an ultrasound imaging technique	Index test included was not an ultrasound imaging technique OR included a non-ultrasound imaging technique as part of the index test
Studies were conducted prospectively	Studies were not conducted prospectively
The reference test for all subjects in the study was liver biopsy	The reference test for the study was not liver biopsy OR liver biopsy was not used for all subjects
The sample population described were adults at risk of chronic liver disease	The sample population described included children OR sample population included adults not at risk of chronic liver disease
	The study was published as a case study, review or editorial

Table 2 Quality assessment of diagnostic accuracy studies assessment items

Item	Question	Guidelines for assessment	Aspect of study assessed
1	Was the spectrum of patients representative of the patients who will receive the test in practice?	Patients who receive the test in clinical practice will be suspected of having chronic liver disease but not yet have decompensated cirrhosis Sample populations should fit this general characteristic. Samples may be a mixed population or may be restricted to one disease type if this is a common and clinically important disease, in this case alcohol abusers or viral hepatitis Score "yes" if clearly stated and meet the above definitions, "no" if the spectrum is clearly outside this definition and "unclear" if there is insufficient information	Generalisability
2	Were selection criteria clearly described?	Clear definitions of the inclusion and exclusion criteria should be included. "Yes" if clearly stated, "no" if not stated and 'unclear" if only partially stated	Quality of reporting
3	Is the reference standard likely to correctly classify the target condition?	Liver biopsy must be used as the reference standard. "Yes" if biopsy used, "no" if not and "unclear' if not stated	Presence of bias
4	Is the time period between reference standard and index test short enough to be reasonably sure that the target condition did not change between the two tests?	The time period must be no more than one month for all cases to avoid discrepancies between the index and reference test due to disease progression. The order in which the tests are done is not relevant. Score "yes" if one month or less, "no" if more than one month and "unclear" if not clearly stated	Presence of bias
5	Did the whole sample or a random selection of the sample, receive verification using a reference standard?	All patients should receive a biopsy unless some form of randomisation was used. Score "no" if some patients were excluded. Score "unclear" if this information is not reported by the study	Presence of bias
6	Did patients receive the same reference standard regardless of the index test result?	If it is clear all patients received a liver biopsy, score "yes". If some received laparoscopy (or other test), score "no". If it is not stated, score "unclear"	Presence of bias
7	Was the reference standard independent of the index test (i.e. the index test did not form part of the reference standard)?	Score 'yes" if the index test did not form part of the reference test, "no" if it did and "unclear" if not stated or there is doubt	Presence of bias
8	Was the execution of the index test described in sufficient detail to permit replication of the test?	Studies should describe equipment and techniques in sufficient detail to enable replication. Ultrasound criteria for identifying fibrosis or cirrhosis must be clearly stated and be able to be replicated (e.g. clear and easily reproducible system for assessing grey scale appearances or Doppler measurements or indices) Score "yes" if the above is true, "no" if these details are not stated or if the technique described is not able to be replicated and "unclear" if an incomplete description is given	Quality of reporting
9	Was the execution of the reference standard described in sufficient detail to permit its replication?	A clear description of the biopsy technique sufficient to enable replication. Ideally this should include information about the needle technique used and the minimum size of the sample. A recognised staging system for fibrosis or a description with sufficient detail to enable replication must be provided Score "yes" if the above are true, "no" if no description of technique is given OR no staging system used and "unclear" if a partial description is given from which conclusions cannot be reached	Quality of reporting
10	Were the index test results interpreted without knowledge of the results of the index test?	Score "yes" if the ultrasound was performed and reported without knowledge of the biopsy. Score "no" if this is not the case and "unclear" if it is not stated	Presence of bias
11	Were the reference standard results interpreted without knowledge of the results of the reference test?	Score "yes" if the biopsy was performed and reported without knowledge of the ultrasound. Score "no" if this is not the case and "unclear" if it is not stated	Presence of bias

12	Were the same clinical data available when test results were interpreted as would be available when the test is used in practice?	Score "yes' if pre-test clinical data was available for the ultrasound and biopsy. Score "no" if it was not available. Score "unclear" if it is not stated	Presence of bias
13	Were uninterpretable/intermediate results reported?	Score "yes" if all test results, including uninterpretable or indeterminate results, are accounted for. Score "no" if some data is missing and not explained or has been excluded from analysis. Score "unclear" if it is not clear whether all results have been included	Quality of reporting
14	Were withdrawals from the study explained?	A flow chart or matching numbers in a 2 × 2 table can help assess this item If it is clear what happened to all participants, score "yes". If some patients are not accounted for, score "no". Score "unclear" if interpretation is difficult	Quality of reporting

Table 3 Inter-rater reliability for quality assessment of diagnostic accuracy studies items

QUADAS item	Agreement (%)	κ
Representative spectrum?	90	0.462[1]
Selection criteria clear?	81	0.632[1]
Appropriate reference standard?	100	1.000[1]
Appropriate delay between tests?	100	1.000[1]
Partial verification avoided?	95	-[2]
Differential verification avoided?	95	-[2]
Incorporation avoided?	100	1.000[1]
Adequate index test description?	86	0.468[1]
Adequate reference test description?	76	-[2]
Index test blinded?	86	0.704[1]
Reference test blinded?	95	0.901[1]
Relevant clinical information available?	86	0.712[1]
Uninterpretable results reported?	29	0.022
Withdrawals explained?	33	0.033

[1]Agreement significantly greater than chance ($P < 0.05$); [2]A κ statistic could not be calculated because one reviewer responded "yes" for all studies on this item. QUADAS: Quality assessment of diagnostic accuracy studies.

exclusion and inclusion criteria, severity of disease, prevalence, staging system of liver biopsy, and the ultrasound technique(s) used. Sensitivity and specificity results for the index tests were extracted from the reports or from constructed contingency tables. The results of any testing for observer agreement were also extracted.

Statistical analysis

Receiver Operator Characteristic (ROC) plots were generated using Microsoft Excel 2003 software and used to graphically display the diagnostic performance data and to explore the relationships between the reported ultrasound techniques and study characteristics[10]. To demonstrate any patterns and relationships between methodology quality and diagnostic quality, plots were also produced for items on the QUADAS checklist.

RESULTS

Search results

No previous systematic reviews addressing the diagnostic accuracy of ultrasound in liver fibrosis or cirrhosis were identified. A total of 1355 separate studies were revealed from the following databases: MEDLINE (n = 464), EMBASE (n = 1155), CINAHL (n = 18) and Science Citation Index searches (n = 639). Attrition of studies after an initial assessment of the abstracts against the inclusion and exclusion criteria resulted in a residual of 38 studies [MEDLINE (n = 33), EMBASE (n = 3), Science Citation Index (n = 2)]. An additional 8 studies were revealed after pearling of the residual 38 studies (n = 46). After assessment of the full text reports of these 46 studies against the selection criteria, there was further attrition of 25 studies resulting in a total of 21 studies retained for data extraction, analysis and assessment for methodological quality.

Methodology quality assessment results

Assessment of methodology quality was performed on the 21 selected studies by two independent reviewers (RA & KT) using the QUADAS assessment tool. Inter-rater agreement for each item, across all studies, was assessed by calculating the percentage agreement and kappa value (κ) (Table 3). For items where there was disagreement between the reviewers, consensus was achieved without the need for an independent adjudicator.

Across all studies the mean number of responses within the QUADAS assessment tool was 10 (range 7-13) for "Yes", 1 (range 0-3) for "No" and 3 (range 0-6) for "unclear".

Characteristics of study populations

The studies included in this review were published between 1991 and 2009. The characteristics of the study populations are reported in Table 4.

The method for staging the histology obtained at liver biopsy was either not reported or unclear in 5 studies, all of which were published prior to the year 2000. Across the other 16 studies a total of seven staging systems were used. METAVIR[11] (n = 7), Ishak[12] (n = 3), Desmet[13] (n = 2) and four other systems which were each used once[14-17].

Measurements of observer agreement

Seven studies reported observer agreement assessment of the ultrasound technique[18-24]. When reported, results for observer agreement were acceptable, with κ values ranging from 0.51-0.93, coefficient of variation values ranging from 2%-8%, and correlation coefficients ranging from 0.82-0.9.

Ultrasound techniques

Diagnostic accuracy was determined for a range of ultra-

Table 4 Characteristics of included studies

Author	Country	Sample	Males (%)	Mean age in years (range)	Prevalence of disease (%)	Aetiology (largest disease type)	Inclusion criteria	Exclusion criteria	Severity of disease

sound techniques across all studies. There were 48 reports of diagnostic accuracy for specific ultrasound techniques within the 21 included studies. Thirty different ultrasound techniques were reported of which 23 were reported once. Seven techniques were reported multiple times. The ultrasound techniques could be broadly described according to four main categories: (1) low frequency grey scale imaging, where an assessment of the liver parenchyma, liver shape and size, spleen size and hepatic vessel appearance or calibre was made from an ultrasound examination using a low frequency (≤ 5 MHz) convex or sector transducer (n = 14 reports); (2) high frequency grey scale imaging, where the liver surface was assessed using a high frequency linear (> 5 MHz) array transducer (n = 8 reports); (3) Doppler techniques, where a Pulsed Wave (PW) Doppler study of the portal, hepatic and splenic veins and/or the hepatic artery was performed to determine measurements of maximum or mean velocities, ratios and/or indices of resistance and/or pulsatility, and/or subjective assessments of haemodynamic waveforms (n = 19 reports); and (4) Scoring system using a combination of techniques, where more than one technique and/or parameter described in categories 1-3 provided a quantitative or qualitative assessment (n = 7 reports).

The diagnostic accuracy of the ultrasound techniques by group are demonstrated in Table 5.

Statistical analysis

A ROC plot (Figure 1A) was generated for all 48 reports of diagnostic accuracy according to the predetermined broad group categories. One scoring system achieved perfect results[25], while one report of high frequency liver surface technique[26] indicated a performance no better than chance.

A ROC plot (Figure 1B) was generated for ultrasound techniques that were reported more than once.

PV: Portal vein; SA: Splenic artery; PI: Pulsatility index; Vtam: Time averaged mean velocity; Vmax: Maximum velocity; HA: Hepatic artery; HV: Hepatic vein; RI: Resistive artery; BF: Blood flow.

The ROC plots demonstrate that results for liver echogenicity were consistent but had poor diagnostic accuracy[27,28], results for hepatic vein pulsatility were highly variable[18,29,30], results for liver parenchyma[17,23,31], portal vein maximum velocity[23,30,32], and spleen size[16,23,30] were variable, results for caudate to right lobe ratio were consistent but fair in diagnostic accuracy, and results for liver surface consistently had moderate diagnostic accuracy[18,19,23,31,33,34] except for two outlying reports[26,35].

Reference test blinding (QUADAS item 11) was the only item of methodology quality which demonstrated an obvious trend when plotted on a ROC for diagnostic accuracy; most studies which clearly reported blinding performed better than the other studies (Figure 1C).

ROC plots of diagnostic accuracy across disease characteristics (histology staging definition, prevalence, disease aetiology and severity of disease) demonstrated no obvious patterns except that diagnostic accuracy was generally lower for populations with lower prevalence of disease (Figure 2).

DISCUSSION

The aim of this review was to assess the results and quality of studies reporting the diagnostic accuracy of ultrasound imaging techniques used to identify patients with CLD in a high risk population. The search was restricted to techniques that used ultrasound imaging techniques. Transient elastography, which has demonstrated good diagnostic performance[36] and is becoming more widely used in hepatology practice, was not included because it is a non-imaging technique and currently is not an option on standard ultrasound equipment. A review to establish the performance of stand alone ultrasound is useful because ultrasound scans are often provided by medical imaging departments that do not have access to elastography.

The search strategy was optimized for sensitivity rather than precision, as recommended by the Cochrane Collaboration[37] with no filters used which could potentially restrict the search. Efforts to identify as many relevant studies as possible included expanding the search to databases beyond MEDLINE and EMBASE, reading the abstracts of all identified studies and "pearling" of reference lists. Pearling was particular valuable with an additional eight studies identified, however, it is possible that relevant studies may have been missed because the search strategy did not include the grey literature and was restricted to English. Across the studies in this review there was a wide

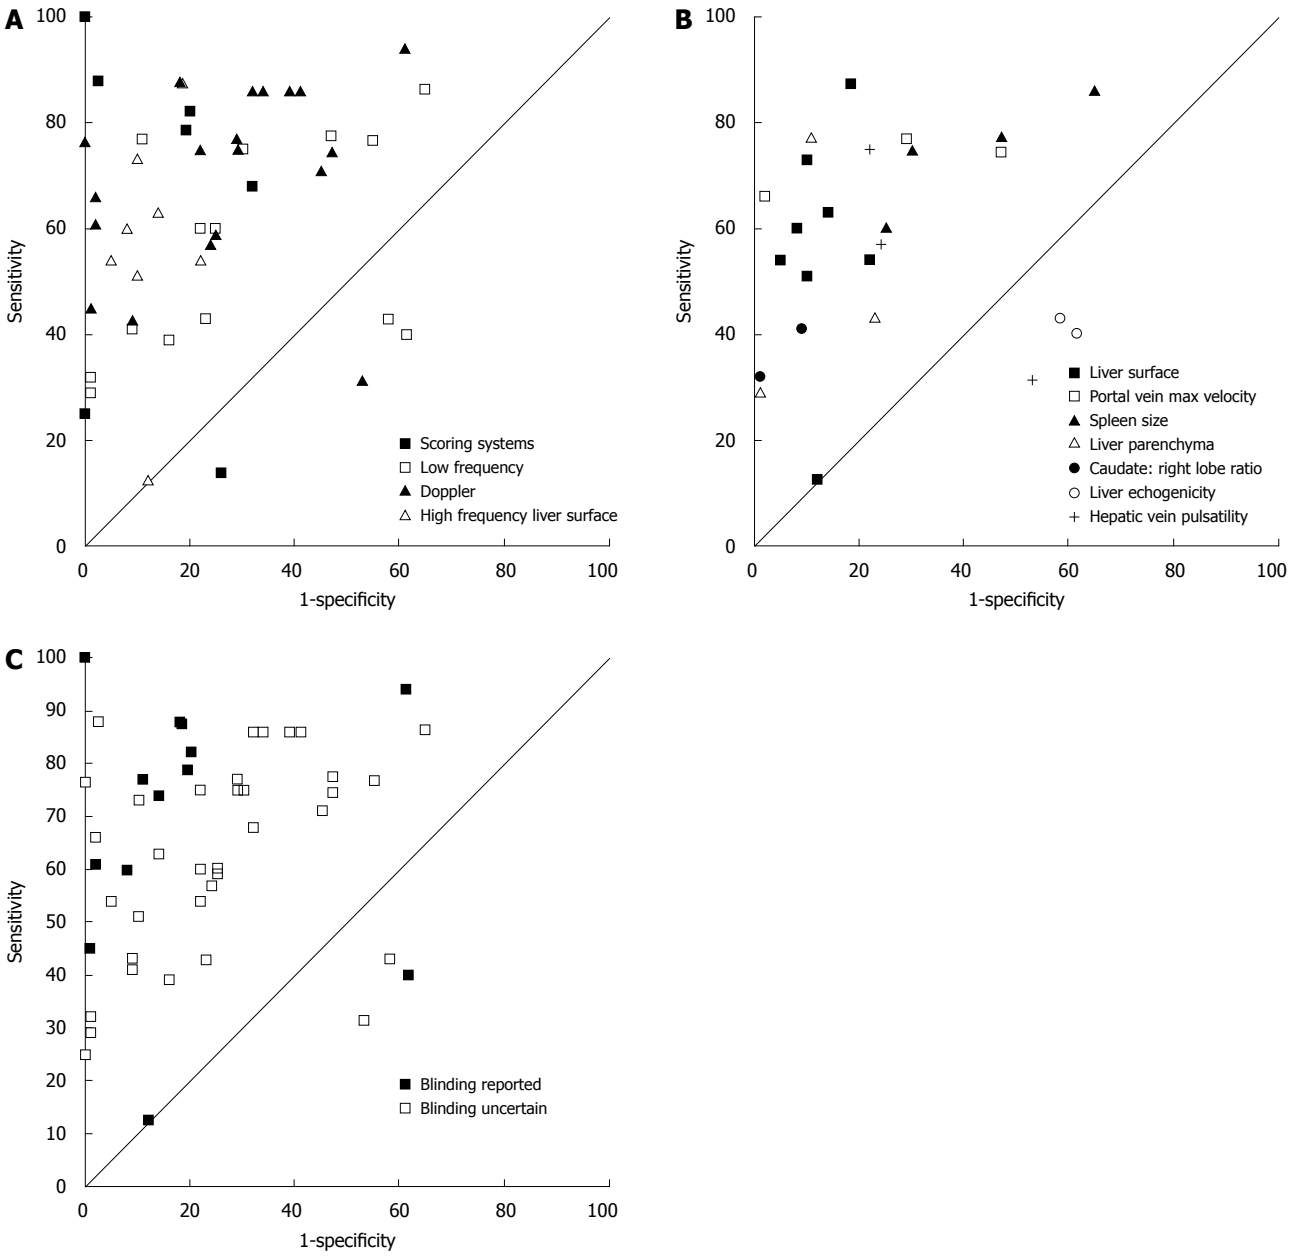

Figure 1 Receiver operator characteristic plot. Diagnostic performance data for categories of ultrasound techniques (A), ultrasound techniques reported multiple times (B) and relating to reference test blinding (C).

range of complexity and clarity of the described ultrasound techniques.

Methodology quality of the included studies was assessed with the QUADAS quality assessment tool, an independently validated method recommended by the Cochrane Collaboration[37]. As recommended[9] the QUADAS tool was modified for the specific needs of the review. Inter-rater variability testing of QUADAS showed good agreement over most of the QUADAS items with nine of 14 having substantial or almost perfect agreement. At the consensus meeting addressing differences in QUADAS ratings it was found that differences tended to relate to differing interpretations of item guidelines. Involving both reviewers in the formulation of the guidelines may have resulted in clearer guidelines and more consistent interpretations.

There was no identifiable group of studies that were clearly superior to the rest nor was there a group of studies that was markedly inferior; therefore all studies in the review were assessed for diagnostic accuracy. Blinding was the only item of methodology quality which demonstrated a relationship with diagnostic accuracy results. Studies reporting blinding for the reference test also reported higher diagnostic accuracy than studies which did not report reference test blinding. This finding further endorses the studies reporting higher diagnostic accuracy, because the chance of bias in these reports is reduced.

The only study characteristic that showed a relationship to diagnostic accuracy was prevalence, with studies reporting low prevalence also tending to have lower diagnostic accuracy. Whilst this may seem surprising, as sensitivity and specificity should be independent of prev-

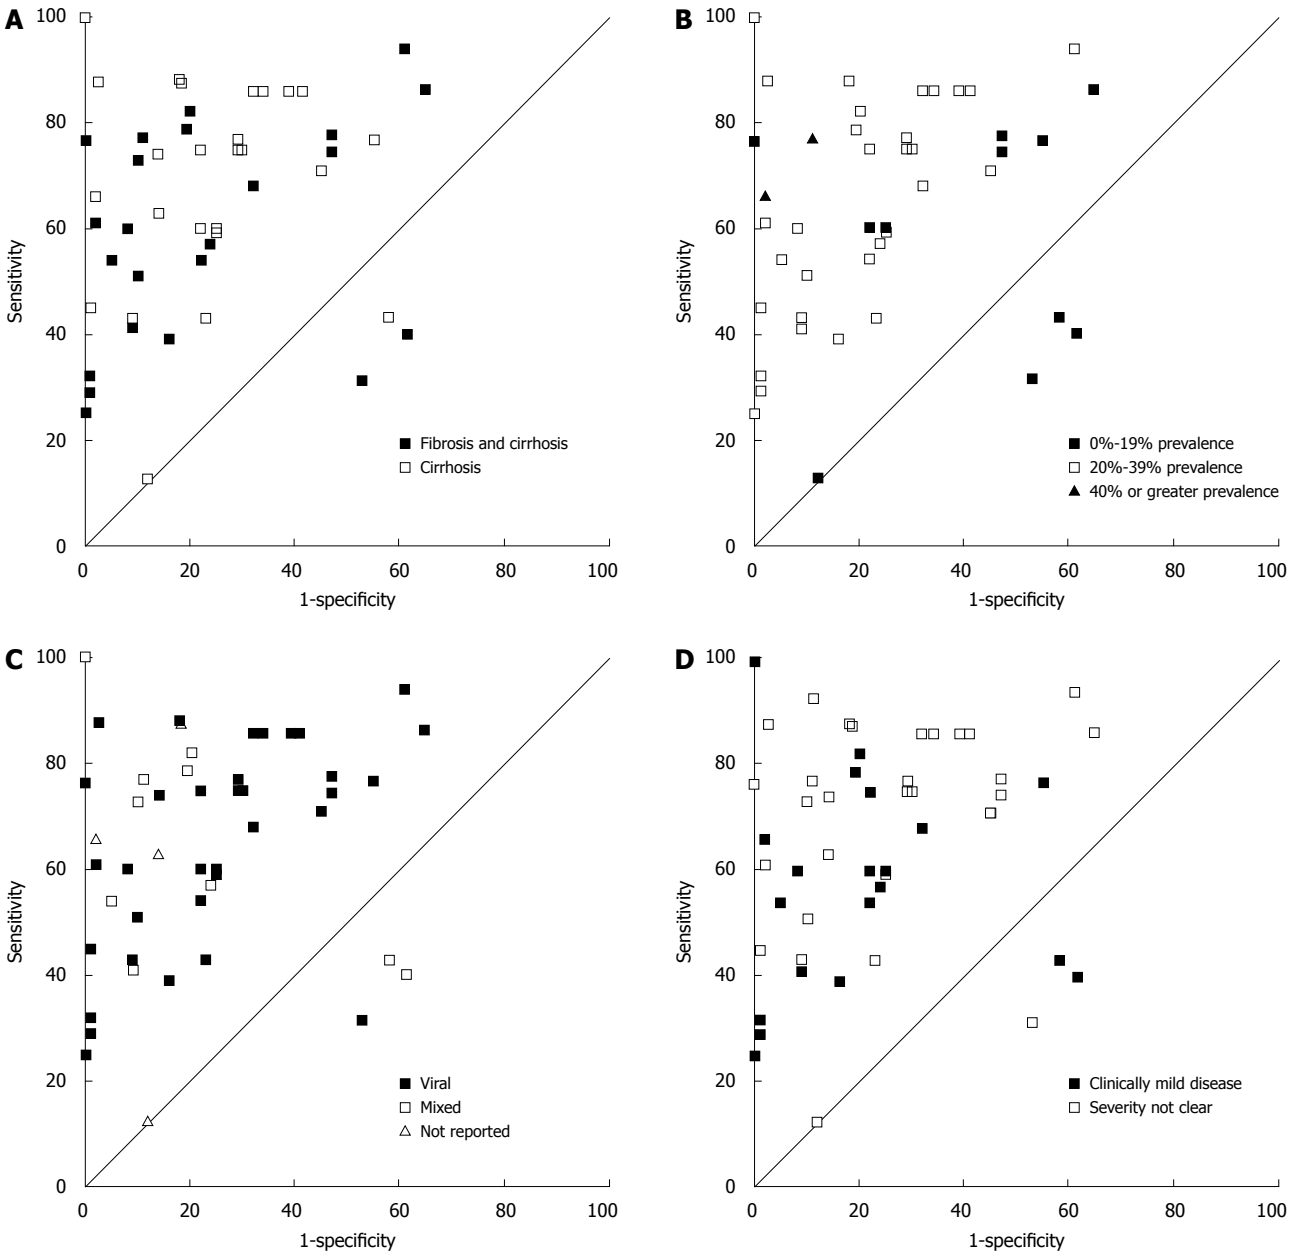

Figure 2 Receiver operator characteristic plot displaying diagnostic accuracy across disease characteristics. A: Histology staging definition; B: Prevalence; C: Disease aetiology; D: Severity of disease.

alence, it has recently been shown that prevalence can affect diagnostic accuracy due to clinical or artefactual variability in studies[38].

Liver biopsy was chosen as the reference test in this review although it has a significant false negative rate due to difficulties with the biopsy technique and sampling error which make it a less than ideal reference test. We justify our choice because it is the test used in clinical practice and is the only practical choice for a reference test. Whilst laparoscopy may be more accurate, it is much more invasive, with significantly more risk, and generally not used in normal clinical practice. Studies using laparoscopy as the reference test were excluded as including more than one reference test has the potential to introduce differential verification bias[9].

Studies were included if the diagnostic accuracy results were either given as true positive (TP), false positive (FP), true negative (TN) and false negative (FN) data or simply in the form of sensitivity and specificity. Restricting studies to those that expressed results in full (TP, FP, TN, FN) would have reduced the range of studies included. Whilst potentially this would have enabled the use of forest plots and meta-analysis to assess the diagnostic accuracy, this was not performed because the numbers of studies of techniques similar enough to enable comparison was too small to provide meaningful results. Instead all studies included in this review were analysed visually using the ROC plot technique. This provided an effective method for comparing data and exploring the relationship between diagnostic accuracy and the quality and characteristics of

the studies[10]. The area under the ROC for the various ultrasound techniques was not calculated due to the lack of reported raw data to make this possible.

Across all studies there was wide variation in both the ultrasound techniques used and in the reported diagnostic sensitivities and specificities for liver fibrosis and cirrhosis. For ultrasound to be clinically useful as a test that can reduce the number of patients requiring liver biopsy it needs to accurately confirm chronic liver disease. To be effective it should have a low false positive rate resulting in high specificity and a high positive predictive value. In this way patients with positive ultrasound results may be able to avoid the risks of liver biopsy. Two studies[22,25] stand out as having very high specificity (100% and 97.6%, respectively) and very high sensitivity (100% and 87.8%, respectively). Both of these studies used scoring systems and this suggests that this may be the best method of identifying severe fibrosis and cirrhosis; however, these results need to be treated with caution. The scoring systems used in both studies were complex, subjective and relied on the compounding of several ultrasound techniques. The use of multiple techniques[20,22,25,31,39] raises concerns regarding reproducibility, as variations may occur with each of the methods used and become magnified with compounding of methods. It is also a concern that in one of these studies[22] it was unclear if blinding had been used, if there were any subject withdrawals, how the selection criteria were applied, how the reference test was applied and how the scoring system was applied. In contrast, the other study[25] scored very well for methodological quality excepting that observer agreement was not reported.

The reporting of observer agreement was poor in many of the reviewed studies despite it being an important consideration when assessing the usefulness of a diagnostic test. We made an assessment of consistency of results across studies which reported similar techniques as a proxy method to determine the reproducibility of a technique in the absence of agreement reporting. Confidence in the results of a study's results can be increased if the technique has been reported over multiple studies with consistent results. We could make this assessment for the following ultrasound techniques; liver echogenicity, caudate lobe to right lobe ratio, portal vein maximum velocity, hepatic vein pulsatility, liver parenchyma echo-pattern, spleen size and liver surface.

The results for portal vein maximum velocity, hepatic vein pulsatility, liver parenchyma echo-pattern and spleen size were inconsistent between studies.

Consistently poor results of diagnostic accuracy were demonstrated between the two studies which tested measurements of liver echogenicity[27,28]. Liver echogenicity is known to be associated with liver steatosis but not with fibrosis[40] so this result is not surprising. Consistent results of diagnostic accuracy were demonstrated for the caudate lobe to right lobe ratio across two studies[18,31] with high specificity (> 90%) and low sensitivity (41% and 32%, respectively). The liver surface technique was the most frequently reported technique (n = 8 reports). Diagnostic accuracy was consistent across six of these studies, with high specificities (78%-95%) and moderate sensitivities (51%-73%)[18,19,23,30,32,34]. These studies were also of reasonable or good methodological quality. There were two studies reporting the liver surface technique[26,34] which produced results that were outliers compared to the other six and contained methodological flaws that were serious enough to not accept their findings. The flaws included an unclear description of patient spectrum or selection criteria in one study[26] together with a reported low prevalence of CLD which does not represent a high risk population which was the population of interest in this review. The other study[35] scored poorly for verification and differential bias and had a significant number of unexplained withdrawals.

The findings of consistent results of diagnostic studies that are methodologically sound make the assessment of liver surface appealing to apply in the clinical environment. This technique also appeared simple to implement, was defined clearly in the reports, and used a simple dichotomous categorical classification technique to interpret definitions of normal and abnormal. Three of these studies[18,19,23] also reported substantial inter and/or intra-observer agreement. Although these studies did not demonstrate high sensitivities, the high specificity and therefore high positive predictive value indicate this technique should be accurate for identifying patients who have a high likelihood of severe fibrosis or cirrhosis and who may benefit by avoiding the risks associated with liver biopsy.

In conclusion, a wide range of ultrasound techniques have been reported in the literature and investigated for their diagnostic accuracy to identify CLD in a high risk population. The most robust ultrasound technique for assessment of CLD appears to be the assessment of liver surface. The studies investigating the liver surface technique consistently demonstrated good observer agreement and high specificity. This review has revealed that an assessment of the liver surface is a useful screen for patients at risk of CLD to assist in determining who should undergo a liver biopsy.

COMMENTS

Background

Chronic liver disease (CLD) is a significant cause of morbidity and mortality. Accurate diagnostic testing to identify early CLD in asymptomatic patients at high risk is advantageous due to recent management and treatment advances. Biopsy, which is the current method of choice, is invasive and carries a significant risk. Less invasive techniques have the potential to reduce biopsy numbers. Ultrasound is one such technique which is readily available, inexpensive and well-tolerated. However, there are several ultrasound techniques in current practice. For an ultrasound study to be clinically useful it has to demonstrate accuracy in confirming CLD. This systematic review informs clinicians of the usefulness of ultrasound in early diagnosis of CLD in high risk patients, in particular, which method is shown to be the most specific and sensitive.

Research frontiers

There have been no identified published systematic reviews addressing diagnostic accuracy in ultrasound of CLD.

Innovations and breakthroughs

This rigorous systematic review identifies methodological and/or reporting flaws in several of the selected papers. It also highlights the variety and range of

diagnostic ultrasound techniques for liver examination in CLD in current usage. This review demonstrates that the most robust ultrasound technique for assessment of CLD appears to be high frequency ultrasound assessment of the liver surface.

Applications

The high specificity of ultrasound of the liver surface provides a clinician with confidence that if signs of CLD are evident then the condition is present. The moderate sensitivity means that if ultrasound signs of CLD are not present, a liver biopsy may be performed to confirm the presence of CLD. Performing high frequency ultrasound of the liver surface in high risk patients has the potential to reduce the number of biopsies in patients at high risk of CLD.

Terminology

Pulse-wave Doppler: A technique by which the ultrasound machine can determine the velocity of blood flowing in vessels. In addition, it allows evaluation of the direction and character of the blood flow. Pulse-wave Doppler is displayed as a spectral waveform on the screen. Maximum velocity: The velocity of blood cells flowing along a vessel will vary according to the position within the blood vessel. The maximum velocity is the greatest velocity detected in a particular vessel in a selected area; pulsatility and resistance indices and the spectral waveform allows quantification of the pulsatility of the blood flow by calculations using the maximum, minimum and mean velocities displayed. The indices are an indication of resistance to blood flow in the vessel and variation from normal may be an indication of disease, either in the vessel itself or the organ it supplies.

Peer review

This is a well written review on the quality and accuracy of ultrasound imaging techniques for identifying patients with chronic liver disease.

Abstract

AIM: To clarify the association of glypican-3 (GPC3) expression with Wnt and other growth signaling molecules in hepatocellular carcinoma (HCC).

METHODS: Expression of GPC3, Wnt, matrix metalloproteinases (MMPs), sulfatase (SULF)1, SULF2, and other growth signaling molecules was analyzed in HCC cell lines and tissue samples by real-time reverse transcription-polymerase chain reaction, immunoblotting, and/or immunostaining. Expression of various genes in *GPC3* siRNA-transfected HCC cells was analyzed.

RESULTS: GPC3 was overexpressed in most HCCs at mRNA and protein levels and its serum levels were significantly higher in patients with HCC than in non-HCC subjects ($P < 0.05$). Altered expressions of various *MMPs* and growth signaling molecules, some of which were correlated with *GPC3* expression, were observed in HCCs. Down-regulation of GPC3 expression by siRNA in GPC3-overexpressing HCC cell lines resulted in a significant decrease in expressions of MMP2, MMP14, fibroblast growth factor receptor 1, insulin-like growth factor 1 receptor. GPC3 expression was significantly correlated with nuclear/cytoplasmic localization of β-catenin.

CONCLUSION: These results suggest that GPC3, in conjunction with MMPs and growth signaling molecules, might play an important role in the progression of HCC.

Key words: Glypican-3; Wnt; Matrix metalloproteinases; Sulfatase; Hepatocellular carcinoma

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most com-

mon cancers in the world[1]. HCC is associated with well-defined viral and non-viral etiological factors. Chronic infection with hepatitis B virus (HBV) or hepatitis C virus (HCV), chemical carcinogens (i.e. aflatoxins), and other environmental and host factors causing liver injury have etiologically been linked to HCC[2,3]. Various genetic and epigenetic abnormalities have been identified in HCC, suggesting a multi-step nature of hepatocarcinogenesis[3,4].

The pathogenesis of HCC has been known to involve *p53*[5], *β-catenin*[6], *TGFβ*[7] and the retinoblastoma gene[8]. *p53* gene mutation occurs in one-third of HCC[5,9]. Activating mutations in *β-catenin* have been reported in 18% of HCC patients and *axin* mutations in 6%[6,10]. HCCs are also known to express various Wnt family members[11] and the activation of the canonical Wnt signaling pathway occurs in 18% of HCC[10].

Glypican-3 (GPC3) is a member of the glypican family of glycosylphosphatidylinositol-anchored cell-surface heparan sulfate proteoglycans. GPC3 is highly expressed in HCC cells and tissues[12-19]. It is thought that GPC3 stimulates the growth of HCC cells by upregulating autocrine/paracrine canonical Wnt signaling[20]. GPCs have been reported to stimulate both the canonical and non-canonical pathways[20]. GPC3 reportedly regulates migration, adhesion, and actin cytoskeleton organization in mammary tumor cells through Wnt signaling modulation[21].

Matrix metalloproteinases (MMPs) also play an important role in HCC[22]. It has been reported that GPC3 may regulate MMP activity in breast cancer[23]. It has also been demonstrated that secreted MMP-9 associates with glypican-like proteoglycans through their heparan sulphate chains, and plays a crucial role in cell motility of murine colon cancer cell line LuM1 cells[24].

GPC3 has been shown to bind to fibroblast growth factor (FGF)2 and may function as a coreceptor for FGF2[25]. Two recently identified human heparin-degrading endosulfatases, named sulfatase 1 (SULF1) and SULF2, have been found to be involved in liver carcinogenesis[26,27]. Interestingly, SULF2 reportedly up-regulates GPC3, promotes FGF signaling, and decreases survival in HCC[27].

Moreover, GPC3 reportedly confers oncogenicity through the interaction between insulin-like growth factor (IGF)-Ⅱ and its receptor, and the subsequent activation of the IGF signaling pathway[28]. Specific interactions both between GPC3 and IGF-Ⅱ and between GPC3 and IGF 1 receptor (IGF1R) have been reported[28].

These results suggest that GPC3 joins a multiprotein complex, which is composed of the ligand, receptor, GPC3, and probably other proteins[28]. However, the association of GPC3 with Wnt, MMPs, SULF1, SULF2, and other growth signaling molecules has not been systematically analyzed in HCC. In this study, we analyzed expression of these molecules in HCC cell lines and tissue samples by real-time reverse transcription-polymerase chain reaction (RT-PCR), immunoblotting, and/or immunostaining. Expression of various genes in *GPC3* siRNA-transfected HCC cells was analyzed.

MATERIALS AND METHODS

Cell lines

HCC cell lines, HepG2, Hep3B, JHH-4, HuH-7, HLE, HLF, PLC/PRF/5, Li-7, huH-1, HT17, CHC4, and CHC32, were obtained from the Japanese Cancer Research Resources Bank (Tokyo, Japan), Riken Cell Bank (Tokyo), or the American Type Culture Collection (Rockville, MD, USA), and cultured as recommended. Cells were maintained at 37℃ in an atmosphere of humidified air with 5% CO_2.

Tissue samples

All tissue and serum samples were obtained from Japanese patients. Informed consent was obtained from each patient. Tissue microarray of HCC tissues was purchased from SuperBioChips Laboratories (Seoul, Korea). Each tissue specimen was divided into two pieces. One sample was used for total RNA extraction. The other sample was processed for pathological examination using hematoxylin and eosin staining for the evaluation of the tumor cell content. Only specimens containing more than 80% tumor cells were used for analysis. The tumor-node-metastasis (TNM) system of the American Joint Committee on Cancer and the International Union against Cancer was used for the pathologic diagnosis and classification of variables.

Semiquantitative RT-PCR and real-time RT-PCR

Semiquantitative RT-PCR was performed as described previously[29]. The primer sequences used were 5'-AGGTAGCTGCGAGGAAAC-3' and 5'-AGGTCACGTCTTGCTCCTC-3' for *GPC3* and 5'-TGGACATCAATGAGTGCCTC-3' and 5'-CACATTCT GGTGAGCATTCG-3' for *GAPDH*. Real-time RT-PCR was performed by using TaqMan real-time PCR system as described previously[30]. The following genes were analyzed: *GPC3*, *WNT* (*WNT1*, *WNT2*, *WNT2b*, *WNT3a*, *WNT4*, *WNT5a*, and *WNT7b*), *MMP* (*MMP2*, *MMP3*, *MMP7*, *MMP9*, and *MMP14*), *SULF1*, *SULF2*, *FGF2*, *FGF receptor* (*FGFR*) *1*, *FGFR2*, *FGFR3*, *FGFR4*, *epidermal growth factor receptor* (*EGFR*), *erb-b2* (*ERBB2*), *IGF2* and *IGF1R*. A comparative threshold cycle was used to determine gene expression relative to the no-tissue control (calibrator).

Immunoblotting

Immunoblotting using total cell lysates was performed as previously described[29]. The antibodies used were MMP2 (Santa Cruz Biotechnology, Santa Cruz, CA, USA), MMP14 (Abcam, Cambridge, UK), FGFR1 (Abcam), and IGF1R (Santa Cruz Biotechnology). The protein was visualized using the enhanced chemiluminescence plus detection system (Amersham Biosciences, Piscataway, NJ, USA), and the membranes were stripped and reprobed with mouse anti-actin monoclonal antibody (Chemicon, Temecula, CA, USA).

Gelatin zymography

Gelatinase activity of conditioned media of siRNA-trans-

fected HepG2 was measured using SDS-polyacrylamide gels containing 0.1% gelatin as described previously[22]. Gels were washed in 2.5% Triton X-100 for 30 min prior to incubation in 20 mmol/L glycine, 10 mmol/L $CaCl_2$, 1 μmol/L $ZnCl_2$ (pH 8.3) for 48 h at 37℃, before staining with Commassie Brilliant Blue.

siRNA transfection

siRNAs for the *GPC3* gene were purchased from Ambion (Silencer® Pre-designed siRNA, Austin, TX, USA). Unrelated nonspecific siRNAs (Silencer® Negative Control siRNA) were used as a control. siRNA transfection was performed following the manufacturer's instructions[29]. After incubation for 72 h, siRNA-transfected HepG2 cells were analyzed by real-time RT-PCR and immunoblotting to validate knockdown effect on GPC3. These cells were used for real-time RT-PCR.

Immunohistochemistry

Immunohistochemistry with an anti-human GPC3 mouse monoclonal antibody (Clone 1G12 used at 5 mg/mL, BioMosaics, Burlington, VT, USA) and an anti-human β-catenin monoclonal antibody (Santa Cruz Biotechnology) was performed as described previously[29]. A case was considered negative for GPC3 if < 5% of the carcinoma cells exhibited immunoreactivity[31]. Cancer cases were categorized into the following 4 groups corresponding to immunostaining patterns of β-catenin as previously described: membranous, membranous staining pattern similar to that in normal; weak, no staining or weaker staining than normal; cytoplasmic, staining in the cytoplasm or cytoplasm/cell membrane; accumulated, staining in the nucleus or nucleus/cytoplasm.

Serum GPC3 levels by ELISA

Serum GPC3 levels were measured using a commercially available sandwich ELISA kit (Biomosaics) following the manufacturer's protocol[16]. The subjects were 6 healthy volunteers, 6 healthy HBV carriers, 8 patients with chronic hepatitis, 11 patients with cirrhosis, and 64 patients with HCC.

Statistical analysis

The results were assessed for associations with clinicopathological parameters using the following statistical tests: Student's *t* test for age, the Mann-Whitney test for lymph node metastasis and pTNM stage, and the χ^2 test or Fisher's exact test for the remaining parameters. To explore relationships between the variables selected for the models, Spearman's correlation coefficients were calculated. A *P* value of less than 0.05 was considered significant. A *P* value between 0.05 and 0.10 was considered as trend toward an association.

RESULTS

Expression of GPC3 mRNA in HCC cell lines

GPC3 expression was detected in 7 (58%) of 12 HCC cell lines (Figure 1). *GPC3* mRNA was detected in HT17, PLC/PRF/5, HuH-1, HepG2, Hep3B, and HuH-7 at a high level and HLE at a low level. *GPC3* mRNA was positive in well differentiated HuH7 and poorly differentiated HT17 cell lines. There was no correlation between *GPC3* positivity and histopathology. Concordant results were obtained by real-time RT-PCR (Figure 2). There was no correlation between quantitative *GPC3* mRNA levels and histopathology.

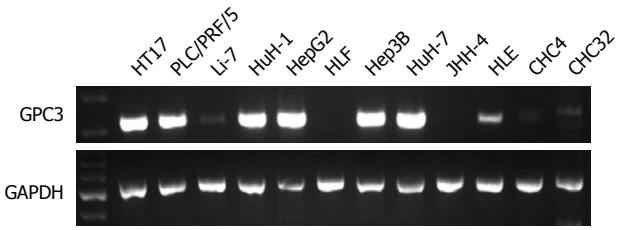

Figure 1 Semiquantitative reverse transcription-polymerase chain reaction analysis of glypican-3 in hepatocellular carcinoma cell lines. Expression of glypican-3 (GPC3) mRNA was analyzed in hepatocellular carcinoma cell lines by semiquantitative reverse transcription-polymerase chain reaction. GAPDH served as a control.

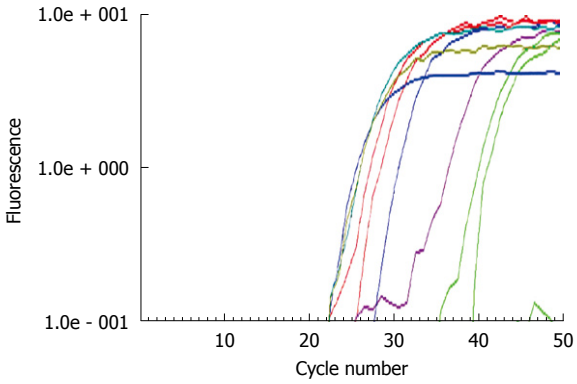

Figure 2 Real time reverse transcription-polymerase chain reaction analysis of glypican-3 in hepatocellular carcinoma cell lines. cDNA was used for quantitative polymerase chain reaction (PCR). The amount of PCR products was determined by reading the midpoint of the linear portion of the S-shaped real-time curves, called the Ct point or threshold cycle. The Ct refers to the number of cycles it takes a sample to reach a specific fluorescence threshold.

mRNA expression of WNT, MMPs, SULF1, SULF2, and other growth signaling molecules in HCC cell lines

WNT1, *WNT2*, *WNT2b*, *WNT3a*, *WNT4*, *WNT5a*, *WNT7b* expression was detected in 0 (0%), 7 (58%), 0 (0%), 0 (0%), 5 (41%), 9 (75%), 4 (33%) of 12 HCC cell lines. Thus, *WNT2* and *WNT5a* were frequently detected compared with other *WNTs*. *MMP2*, *MMP3*, *MMP7*, *MMP9*, *MMP14* expression was detected in 7 (58%), 2 (16%), 8 (67%), 2 (16%), 11 (92%) of 12 HCC cell lines. Thus, the positivity was considerably different among *MMPs*. *SULF1* and *SULF2* expression was detected in all of the 12 HCC cell lines. *EGFR*, *ERBB2*, *FGF2*, *FGFR1*, *FGFR2*, *FGFR3*, *FGFR4* expression was detected in 12 (100%), 12 (100%), 12 (100%), 12 (100%), 6 (50%), 2

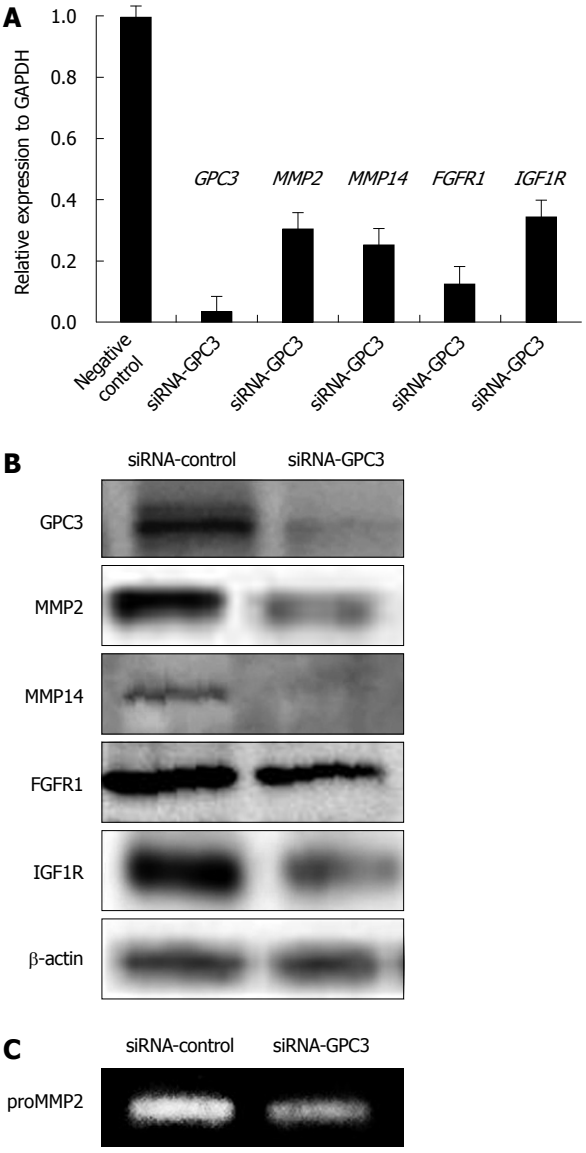

Figure 3 Down-expression of various molecules in glypican-3 siRNA-transfected hepatocellular carcinoma cell line. A: mRNA levels analyzed by real-time reverse transcription-polymerase chain reaction. The mRNA expressions of matrix metalloproteinase (MMP)2, MMP14, fibroblast growth factor receptor 1 (FGFR1), and insulin-like growth factor 1 receptor (IGF1R) were significantly down-regulated in HepG2 cells treated with glypican-3 (GPC3) specific siRNA ($P < 0.05$). Bar: SE; B: Protein levels analyzed by immunoblotting. The protein expressions of MMP2, MMP14, FGFR1, and IGF1R were significantly down-regulated in HepG2 cells treated with GPC3 specific siRNA; C: MMP2 activity analyzed by gelatin zymography. Conditioned media of siRNA-transfected HepG2 were used for gelatin zymography.

(16%), 12 (100%) of 12 HCC cell lines. Thus, growth factor receptors were frequently detected in HCC cell lines. *GPC3* expression was significantly correlated with expression of *MMP14*, *ERBB2*, *FGFR3*, and *FGFR4*.

Overexpression of GPC3 mRNA in HCC tissue

In 18 (78%) of 23 cases, mRNA expression of *GPC3* was upregulated in cancer tissue compared with non-tumor tissue samples. There was no significant difference in *GPC3* mRNA levels among non-tumor liver tissue, including from chronic hepatitis and liver cirrhosis cases. Overexpression of *GPC3* was not related to HBV or to HCV infection. Overexpression of *GPC3* was not significantly correlated with other clinicopathological characteristics (data not shown).

mRNA expression of WNT, MMPs, SULF1, SULF2, and other growth signaling molecules in HCC tissue

mRNA expression of *SULF1* was downregulated in 17 (74%) and *SULF2* was upregulated in 7 (30%) of 23 HCC tissue samples compared with non-tumor tissue. Overexpression of *GPC3* was significantly correlated with *MMP2* ($P = 0.0460$), *FGF2* ($P = 0.0001$), *FGFR1* ($P = 0.0417$), *FGFR2* ($P = 0.0023$), *SULF1* ($P = 0.0202$), and *SULF2* ($P = 0.0081$).

Knockdown effect of GPC3 on expression of various molecules in HCC cells

To assess the effect of GPC3 expression on gene expression in HCC, mRNA expression of *WNT*, *MMPs*, *SULF1*, *SULF2*, and other growth signaling molecules was analyzed by real-time PCR after treatment with specific siRNA for the *GPC3* gene. Transfection with siRNA resulted in over 80% inhibition of mRNA and protein expression of GPC3 (Figure 3). Among the genes analyzed, mRNA expression of *MMP2*, *MMP14*, *FGFR1*, and *IGF1R* was downregulated in *GPC3* siRNA-transfected cells compared with control siRNA-transfected counterparts (Figure 3A). Down-expression of MMP2, MMP14, FGFR1, and IGF1R was confirmed at protein levels analyzed by immunoblotting (Figure 3B). Down-regulation of MMP2 activity was further confirmed by zymography (Figure 3C).

Immunohistochemical expression of GPC3 and β-catenin in HCC tissue

Figure 4 shows representative results of immunohistochemistry for GPC3 in HCC tissue samples. GPC3 protein was strongly expressed in the cytoplasm and/or membrane of carcinoma cells, when compared with adjacent non-tumor cells. GPC3 expression was positive in 54 (75%) of the 72 cases. GPC3 positivity was not significantly correlated with clinicopathological characteristics. Figure 5 shows representative results of immunohistochemistry for β-catenin in HCC tissues. Membranous, weak, cytoplasmic, and accumulated pattern was observed in 18 (64%), 0 (0%), 6 (22%), and 4 (14%), respectively. Nuclear/cytoplasmic localization of β-catenin was observed in a significantly higher percentage of carcinomas with GPC3 expression (9 of 18, 50%) than in those without (1 of 10, 10%, $P = 0.040$).

Serum GPC3 levels

Serum GPC3 levels were under cut-off levels in healthy volunteers, HBV carriers and chronic hepatitis patients (Figure 6). One patient with liver cirrhosis and 32 (50%) of the 64 patients with HCC showed elevated serum GPC3 levels. Serum GPC3 levels in patients with HCC were significantly higher than in non-HCC subjects ($P < 0.05$). There was no correlation in positivity between

GPC3, α-fetoprotein (AFP) levels and vitamin K absence or antagonist-Ⅱ (PIVKA-Ⅱ) levels (data not shown).

DISCUSSION

In this study, we found overexpression of *GPC3* mRNA in HCC cell lines and tissue samples. The overexpression of GPC3 in HCC was also observed at protein level analyzed by immunohistochemistry. These results further support the notion that GPC3 plays an important role in hepatocarcinogenesis.

We analyzed the association of GPC3 with WNT, MMPs, SULF1, SULF2, and other growth signaling molecules, in HCC cell lines and tissue samples. *GPC3* expression was correlated with expression of *MMP14*, *ERBB2*, *FGFR3*, and *FGFR4* in HCC cell lines. Overexpression of *GPC3* was significantly correlated with *MMP2*, *FGF2*, *FGFR1*, *FGFR2*, *SULF1*, and *SULF2* in HCC tissue. To assess the effect of GPC3 expression on gene expression in HCC cells, expression of WNT, MMPs, SULF1, SULF2, and other growth signaling molecules was analyzed in HCC cell lines after treatment with specific siRNA for the *GPC3* gene. Down-expression of MMP2, MMP14, FGFR1, and IGF1R was observed at mRNA and

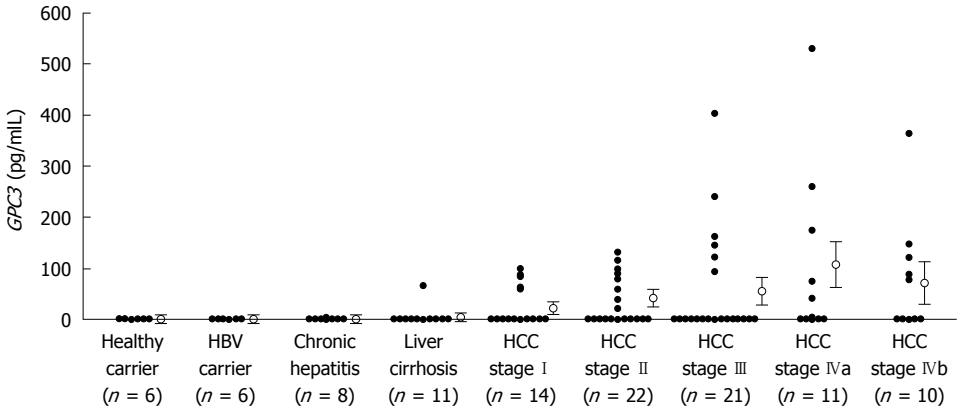

Figure 6 Serum glypican-3 levels. Serum glypican-3 (GPC3) levels were measured using a commercially available sandwich ELISA kit. Bar: Standard error. Serum GPC3 levels were significantly higher in patients with hepatocellular carcinoma (HCC) than in non-HCC subjects ($P < 0.05$). HBV: Hepatitis B virus.

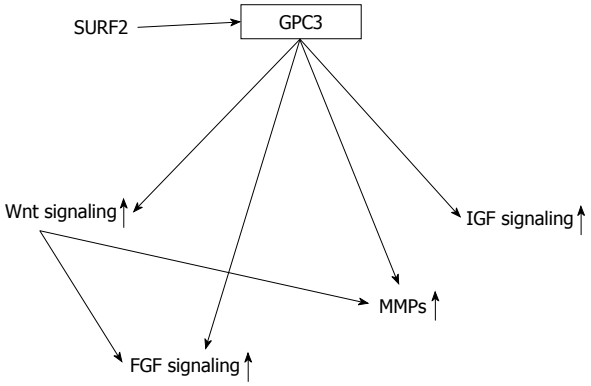

Figure 7 Associations of glypican-3 expression with matrix metalloproteinases and growth signaling molecules in hepatocellular carcinoma. A summary diagram is shown. MMPs: Matrix metalloproteinases; SULF2: Sulfatase 2; GPC3: Glypican-3; FGF: Fibroblast growth factor; IGF: Insulin-like growth factor.

protein levels, and that of MMP2 was also observed at gelatinolytic activity levels.

MMP2 and its activator MMP14 play an important role in HCC progression[22]. Therefore, down-regulation of both MMP2 and MMP14 by GPC3 suppression is interesting. It has been reported that GPC3 may regulate MMP activity[23]. FGF-FGFR signaling plays an important role in hepatocarcinogenesis[27,32]. GPC3 has been shown to bind to FGF2 and may function as a coreceptor for FGF2[25]. SULF2 reportedly up-regulates GPC3, and promotes FGF signaling in HCC[27]. Moreover, GPC3 reportedly confers oncogenicity through the interaction between IGF-Ⅱ and IGF1R, and the subsequent activation of the IGF signaling pathway[28]. Specific interactions both between GPC3 and IGF-Ⅱ and between GPC3 and IGF-IR have been reported[28]. Therefore, the association of GPC3 expression with expressions of these molecules found in this study is interesting (Figure 7).

Nuclear/cytoplasmic localization of β-catenin was observed in a significantly higher percentage of HCCs with GPC3 expression than in those without. GPC3-induced accumulation of cytoplasmic β-catenin has been reported in HCC cells[20]. Therefore, in addition to *β-catenin* mutation or deletion, *axin* mutations, and other alterations of molecules in the canonical WNT signaling pathway, GPC3 may play a role in nuclear/cytoplasmic localization of β-catenin in HCC. These results may explain, in part, the association between GPC3 and growth signaling molecules in HCC. Further studies are necessary to clarify the direct and/or indirect interactions between GPC3 and growth signaling molecules in HCC.

The implication of a part played by GPC3 in HCC was further substantiated by the fact that serum GPC3 levels were significantly higher in patients with HCC than non-HCC subjects. However, there was a discrepancy between GPC3 overexpression in HCC tissues (75%) and GPC secretion (50%). The discrepancy was also reported in previous studies[14,16]. The sandwich ELISA kit used in this study used a polyclonal antibody and a monoclonal antibody, both raised against the last 70 amino acids of the COOH-terminal portion of GPC3, to detect glycanated GPC3[16,19]. This may be one of the reasons why serum GPC3 positivity was lower than GPC3 positivity in HCC tissue[17]. Comparison of our results with those analyzed by a kit using antibody against the NH_2-terminal portion of GPC3 will further strengthen the notion that GPC3 is a useful serum marker for HCC[17]. There was no correlation between GPC and AFP levels. Therefore, detection of both glycanated and NH_2-terminal truncated GPC3, as well as AFP, may provide additional useful markers for HCC.

Taken together, our results suggest that GPC3 overexpression plays an important role in HCC. As a target gene for molecular therapy, its expression in normal adult tissues is important. Considering the expression pattern of GPC3 together with its oncogenic function, GPC3 could be an attractive target for molecular therapy. Antitumor effects of the anti-GPC3 antibody have been reported[33]. Interestingly, we have recently reported the tumor suppressive effect of tyrosine kinase inhibitor of IGF1R, NVP-AEW541, on GPC-3-expressing HCC cell line PLC/PRF/5[34]. Combination of the anti-GPC3 antibody and molecular therapy targeting GPC3-related molecules, such as FGFR, found in this study will be a promising new cancer therapy in the future.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the most common cancers in the world. Understanding the molecular biological features of HCC is necessary for early diagnosis and better prognosis. The potential role of glypican-3 (GPC3) in human HCC is receiving increasing attention.

Research frontiers

GPC3 is highly expressed in HCC cells and tissues. However, little is known about the association of GPC3 expression with Wnt and other growth signaling molecules. In this study, the authors demonstrate that GPC3, in conjunction with matrix metalloproteinases (MMPs) and growth signaling molecules, might play an important role in the progression of HCC.

Innovations and breakthroughs

GPC3 was overexpressed in most HCCs at mRNA and protein levels and its serum levels were significantly higher in patients with HCC than in non-HCC subjects. Altered expressions of various MMPs and growth signaling molecules, some of which were correlated with GPC3 expression, were observed in HCCs. This is the first study to report an association of GPC3 expression with MMPs and growth signaling molecules in HCC.

Applications

Considering the tumor specific expression pattern of GPC3 together with its oncogenic function, GPC3 could be an attractive target for molecular diagnosis and/or therapy in clinical settings. Understanding of the direct and/or indirect interactions between GPC3 and growth signaling molecules may represent a future strategy for therapeutic intervention in the treatment of patients with HCC.

Terminology

GPC3: GPC3 is a member of the glypican family of glycosylphosphatidylinositol-anchored cell-surface heparan sulfate proteoglycans. Sulfatase (SULF): Two recently identified human heparin-degrading endosulfatases, named SULF1 and SULF2, are extracellular neutral-pH SULFs. SULFs modulate several signaling pathways, including the promotion of Wnt signaling.

Peer review

This paper reports an association of GPC3 expression with MMPs and growth signaling molecules in HCC. The authors showed that GPC3, in conjunction with MMPs and growth signaling molecules, might play a key role in the progression of HCC. The study sounds interesting and significant in a potentially important area involving HCC.

Abstract

AIM: To investigate the immune response of peripheral blood mononuclear cells (PBMCs) and dendritic cells (DCs) that were stimulated by probiotic preparations.

METHODS: PBMCs were isolated, cultured, and stimulated with Bio-Three (a mixture of *Bacillus mesentericus*, *Clostridium butyricum* and *Enterococcus faecalis*; 10^5, 10^6 and 10^7 CFU/mL for 24 h). Cytokine production of (1) circulating PBMCs; (2) PBMCs stimulated by probiotic preparation; (3) monocyte-derived DCs; and (4) DC and T cell co-culture was determined by enzyme-linked immunosorbent assay. Phenotypic analysis of circulating PBMCs was also investigated by flow cytometry. Blood was obtained from individuals who consumed Bio-Three (10^9 CFU/d *B. mesentericus*, *C. butyricum* and *E. faecalis*) for 2 wk, or those who did not take probiotics orally.

RESULTS: In culture supernatants, interferon-γ (IFN-γ) and interleukin (IL)-10 production increased, but IL-4 and tumor necrosis factor-α (TNF-α) production by PBMCs decreased after 1 and 2 wk of probiotic treatment. Flow cytometry was also performed on day 14 and detected enhanced expression of CD11b, HLA-DR, CD4, CD45RA, CD25, CD44 and CD69 in response to Bio-Three. Furthermore, IL-10 and IL-12 were upregulated in supernatants of monocyte-derived DCs, and IFN-γ and IL-10 were enhanced in supernatants of $CD4^+$ T cells co-cultured with DCs.

CONCLUSION: Bio-Three appeared to stimulate the Th1 immune response, downregulate pro-inflammatory cytokines (TNF-α) and upregulate anti-inflammatory cytokine (IL-10). Probiotics could be effective in activation of PBMCs and DCs.

INTRODUCTION

The use of probiotics to promote human health has been proposed for many years. Mechanisms of probiotic actions include effects on luminal microbial ecology and immune modulation, particularly through balance control of pro-inflammatory and anti-inflammatory cytokines[1-4]. Currently, species of lactobacillus and bifidobacteria are most widely used to prevent and treat allergy and intestinal disorders; other strains such as *Bacillus*, *Clostridium*, *Streptococcus*, *Escherichia coli* and *Saccharomyces have received* increased attention.

To date, the most extensively studied and best documented probiotic application is for the treatment of acute infectious diarrhea, prevention of antibiotic-associated diarrhea, and allergic diseases[5-7]. Many other benefits are largely unproven, including therapeutic use in necrotizing enterocolitis, irritable bowel syndrome, constipation, inflammatory bowel diseases, pouchitis, and *Helicobacter pylori* infection[5-7].

It has been proposed that many effects of probiotics are mediated *via* immune modulation[3]. There are host-specific and strain-specific differences in the activities of probiotic bacteria. Some strains can enhance or eliminate the activity of other strains *in vivo*[1,2,8]. Previously, most studies that have reported the beneficial effect of probiotics have been on single strain preparations. Few have examined the effect of multiple strain preparations (e.g. VSL#3)[9,10]. Our study was undertaken to investigate whether Bio-Three (a mixture of *Bacillus mesentericus*, *Clostridium butyricum* and *Enterococcus faecalis*) affects immune regulation in human peripheral blood mononuclear cells (PBMCs).

The primary effectors of the human gut are antigen-presenting cells [APCs, including monocytes, macrophages, and dendritic cells (DC)], which provide nonspecific innate immune protection. APCs are responsible for detecting microbes through Toll-like receptors (TLRs) and presenting their antigenic structures to T cells. This triggering process of APCs initiates a signal transduction cascade that leads to the release of cytokines and initiation of the acquired immune response[2,11,12]. Among the APCs, DCs are the most potent. These differentiate from CD14+ monocytes *in vitro* in response to granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukin (IL)-4[10,13,14]. DCs activated by microbes further stimulate the development of T helper type 1 (Th1) and T helper type 2 (Th2) cells or regulatory T cells[1,15].

Several cytokines are involved in immune modulation. Tumor necrosis factor-α (TNF-α) and IL-6 are pro-inflammatory cytokines that are involved in systemic inflammation and the acute phase reaction[12]. IL-12 together with interferon-γ (IFN-γ) causes a shift towards a Th1 response, which favors the development of cell-mediated and cytotoxic immunity[2]. Prostaglandin E_2 (PGE_2), together with IL-4, causes a shift towards a Th2 immune response, which favors the production of antibodies and the induction of IgE and allergic responses[2]. IL-10 (an anti-inflammatory cytokine) enhances the generation of regulatory T (Treg) cells[1,2]. Treg cells seem to suppress or regulate effector T cell function through production of cytokines such as IL-10 and transforming growth factor-β (TGF-β).

The purpose of this study was to determine whether a probiotic combination (Bio-Three) had immunomodulatory effects (altered the phenotype of circulating lymphocytes or monocytes) in human PBMCs. We observed the expression of specific cytokines and changes in PBMC phenotypes.

MATERIALS AND METHODS

The study protocol was approved by the Institutional Review Board of Chang Gung Memorial Hospital, Taiwan, China.

PBMC preparation

Blood cells were separated from platelet-rich plasma and suspended in RPMI 1640 medium. Human PBMCs were isolated by centrifugation of buffy coats on Lymphoprep (Nycomed, Oslo, Norway) gradients. After washing, cells were resuspended at a concentration of 1×10^6 cells/mL in RPMI 1640 medium that contained 10% heat-inactivated fetal bovine serum.

Source of blood donors

All experiments were performed with cells obtained from 14 blood donor volunteers. Subjects were eligible if they were in good general health and were not currently taking medications, probiotics, and other supplements. These blood donors were divided randomly into two groups: group A ($n = 7$) consumed the probiotic preparation Bio-Three 5×10^8 CFU/dose twice daily (total 10^9 CFU/d) for 2 wk, and group B ($n = 7$), the negative control, did not consume probiotics. Peripheral blood samples were obtained from each subject by venipuncture on day 7 (week 1) and day 14 (week 2).

Probiotic preparation for stimulation experiments

The probiotic preparation Bio-Three was a lyophilized mixture that consisted of three different bacteria (*B. mesentericus*, *C. butyricum* and *E. faecalis)*, at a concentration of 3×10^8 live bacteria/packet. 3×10^8 live bacteria were reconstituted in 3 mL sterile PBS without additives, and serial dilutions (1:10) were made in sterile PBS for addition to cell cultures.

PBMC cultures and stimulation experiments

The concentration of PBMCs (obtained from groups A and B) was adjusted to 10^5 cells/mL in complete medium, and the cells were transferred to 24-well plates. Some wells were collected for cytokine detection [by enzyme-linked immunosorbent assay (ELISA)] after 12 h culture at 37℃. The remaining wells were then stimulated with Bio-Three for 24 h at 37℃ in an atmosphere that contained 5% CO_2. Initial dose-response experiments were performed by co-culturing 10^5 (1:1), 10^6 (1:10), and 10^7 CFU (1:100) of bacteria per mL (host cells: bacteria ratio), respectively. Culture supernatants were collected, and triplicates were pooled and kept at -20℃ until analyzed by ELISA. The remaining cells in the culture plates were mixed with

TRIzol Reagent (Gibco Life Technologies, Carlsbad, CA, USA) and stored at -20℃ for gene expression analysis. Repeated thawing and freezing were avoided.

Cytokine determination

Concentrations of IFN-γ, IL-4, TNF-α, IL-10, and IL12 p70 in the supernatants of cell cultures were determined by ELISA. All antibodies and standards were purchased from Pharmingen (San Diego, CA, USA). Costar plates (Invitrogen, San Diego, CA, USA) were coated with the following capture monoclonal antibodies (mAbs): anti-IFN-γ (MQ2-13A5), anti-IL-4 (8D4-8), anti-IL-12 p70 (20C2), anti-TNF-α (MAb1), and anti-IL-10 (JES3-9D7). Standard curves were generated using recombinant human IFN-γ, IL-4, IL-12 p70, TNF-α, and IL-10, respectively. The following biotinylated antibodies were used for detection: anti-IFN-γ (MQ2-39C3), anti-IL-4 (MP4-25D2), anti-IL-12 p40/p70 (C8.6), anti-TNF-α (MAb11), and anti-IL-10 (JES3-12G8). Samples, standards, biotinylated antibodies, and streptavidin-horseradish peroxidase were diluted in high-performance ELISA dilution buffer (Sanquin, Amsterdam, Netherlands).

Detection of PBMC cytokine mRNA expression

Cytokine mRNA expression in PBMCs was evaluated by real-time polymerase chain reaction (PCR). Total cellular RNA was isolated from frozen cultured PBMCs using TRIzol (Gibco Life Technologies) according to the manufacturer's instructions. cDNA was synthesized and used as templates for PCR using specific primers for human IFN-γ (forward: 5'-GCATCGTTTTGGGTTCTCTTGGCTGTTACTGC; reverse: 5'-CTCCTTTTTCGCTTCCCTGTTTTAGCTGCTGG), IL-4 (forward: 5'-TCTCACCTCCCAACTGCTTCC; reverse: 5'-CGTTTCAGGAATCGGATCAGC), TNF-α (forward: 5'-AGCCAGTAGCTCATGTTGTAGCAA; reverse: 5'-GGCACTATCAGCTGGTTGTCTGT), IL-10 (forward: 5'-GCTGGAGGACTTTAAGGGTTACCT; reverse: 5'-CTTGATGTCTGGGTCTTGGTTCT), IL-12 (forward: 5'-TGGATGCTATTCACAAGCTCAAGT; reverse: 5'-TGGTTTGATGATGTCTCTGATGAAG), and β-actin (forward: 5'-GCATGGAGTCCTGTGGCAT; reverse: 5'-CTAGAAGCATTTGCGGTGG). All experimental samples were amplified in duplicate. The results were normalized to β-actin expression.

Phenotypic analysis by flow cytometry

Flow cytometry was performed on day 14 after enrollment and detected the expression of immune phenotype distributions. White blood cells were stained using a panel of mAbs directed against surface antigens expressed by PBMCs, lymphocytes, monocytes and the appropriate species-specific IgG isotype controls. After blocking with FCγⅢ/ⅡR antibody (CD16/CD32; Pharmingen), the cells were stained with mAbs directed against CD4, CD45RA, CD45RO, CD14 fluorescein isothiocyanate, together with one of the activation markers: CD3, CD8, CD19, CD25, CD44, CD69, or CD11b, HLA-DR (all phycoerythrin-conjugated; Pharmingen). We analyzed 10000-20000 cells using a FACSCalibur system (Becton-Dickinson, Franklin Lakes, NJ, USA) equipped with CellQuest software (San Jose, CA, USA).

Generation of monocyte-derived DCs

CD14-positive monocytes were then purified from the mononuclear cells by magnetic cell sorting by using positive selection according to the manufacturer's protocol (Miltenyi Biotec, Bergisch Gladbach, Germany). Monocytes (10^6 cells/mL) were cultured in six-well plates in endotoxin-free RPMI 1640 medium supplemented with 250 U/mL recombinant IL-4 (R&D Systems, Abingdon, UK) and 250 U/mL recombinant GM-CSF (R&D Systems). The cells were cultured in the presence of 5% CO_2 at 37℃ for 7 d. Fresh medium that contained IL-4 and GM-CSF was added every second day. This procedure resulted in generation of immature DCs that were positive for CD11b but negative for CD14.

Isolation of human $CD4^+$ T cells and co-culture with DCs

PBMCs were isolated by centrifugation of buffy coats on Lymphoprep gradients. $CD4^+$ T cells were separated using negative selection affinity columns (R&D Systems), according to the manufacturer's instructions. After separation, the T cells were washed and resuspended in RPMI 1640 culture medium supplemented with 5% heat-inactivated human AB serum, 100 IU/mL penicillin, 100 μg/mL streptomycin, and 2 mmol/L L-glutamine. Purified $CD4^+$ T cells (1×10^6/mL) were stimulated by the combination of immobilized anti-CD3 (1 μg/mL) and soluble anti-CD28 (5 μg/mL) mAbs (Pharmingen). Subsequently, purified $CD4^+$ T cells were incubated with the above DCs at a ratio of 2.5×10^5/mL DCs to 10^6/mL T cells. After 48 h of co-culture, concentrations of IFN-γ, IL-4, IL-10, and IL12 p70 in the culture supernatants were determined by ELISA.

Statistical analysis

Statistical analysis was performed using a paired samples *t* test to reveal significant between-group differences in cytokine production. In all cases, $P < 0.05$ was considered as significant. Statistical calculations were performed using the GraphPad Software Prism 3.03 (San Diego, CA, USA) and SPSS for Windows 12.0 (Chicago, IL, USA).

RESULTS

Effects of Bio-Three on PBMCs isolated from blood donors

To determine the cytokine production of PBMCs, we examined the supernatants of cells isolated from blood donors. Group A consumed Bio-Three and group B was a negative control. In Figure 1, IFN-γ, IL-10 and IL-12 levels were upregulated in group A, but IL-4 and TNF-α levels were downregulated at 1 and 2 wk after Bio-Three consumption. This indicates that this probiotic preparation enhances cytokines associated with Th1 (IFN-γ, IL-12) and anti-inflammatory (IL-10) responses. In contrast, it might reduce cytokine production associated with Th2 (IL-4) and pro-inflammatory (TNF-α) responses.

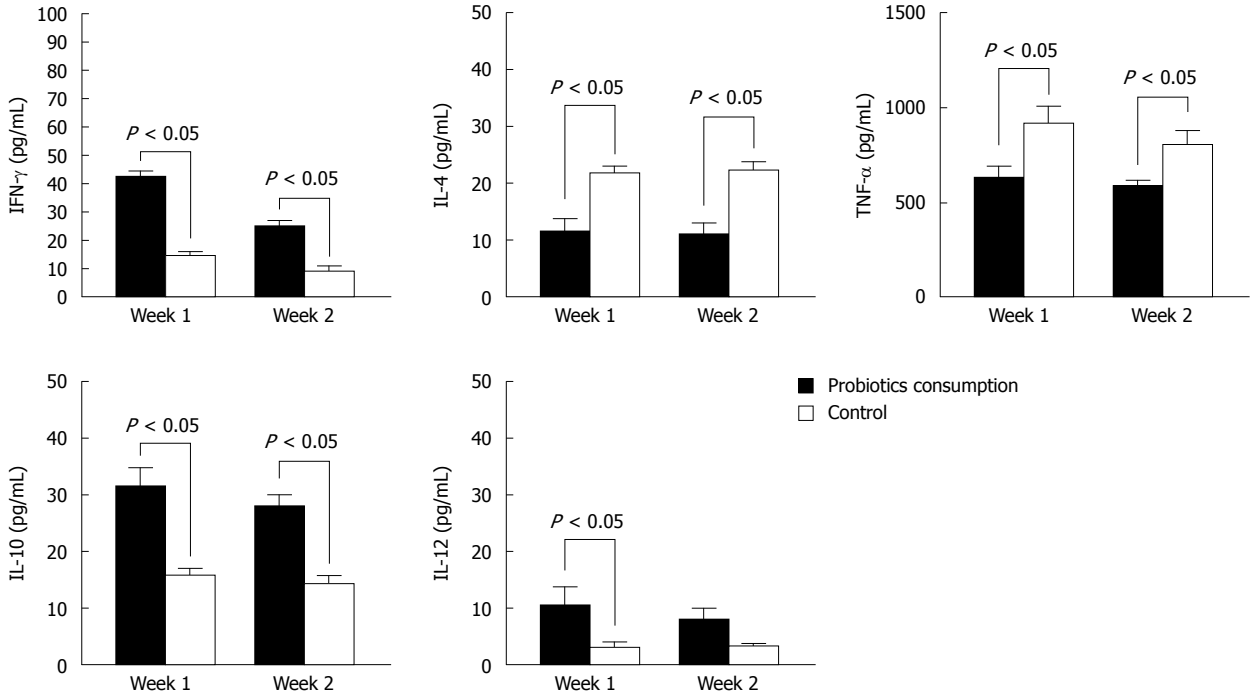

Figure 1 Effects of Bio-Three on peripheral blood mononuclear cells isolated from blood donors. Concentrations of interferon-γ (IFN-γ), interleukin (IL)-4, tumor necrosis factor-α (TNF-α), IL-10, and IL-12 p70 in the supernatants of peripheral blood mononuclear cells (PBMCs) (10^5 cells/mL) incubated for 12 h were determined by enzyme-linked immunosorbent assay. The data shown are the values of different cytokines in the supernatants of PBMCs, which were collected at 1 and 2 wk after Bio-Three consumption, compared with controls. The results are presented as the mean ± SD.

Enhancement of IFN-γ and IL-10 levels, but inhibition of TNF-α production in bacterial stimulation experiments

To explore the effects of probiotic bacteria on PBMCs, we performed stimulation experiments with different bacteria at concentrations of 10^5, 10^6 and 10^7 CFU/mL.

The level of IFN-γ was significantly higher in group A (probiotics) than group B (negative control) (Figures 2 and 3). Moreover, the level of IFN-γ revealed a dose-dependent effect of Bio-Three. There was no significant effect on IL-4 level, although it seemed slightly lower in the probiotic group. In contrast, TNF-α level was decreased at weeks 1 and 2 in the probiotic group (Figures 2 and 3). TNF-α level was significantly lower in response to restimulation with 10^7 CFU/mL probiotic bacteria after 2 wk of Bio-Three consumption. The probiotic group showed increased IL-10 production, which was maximal following restimulation with 10^6-10^7 CFU/mL probiotic bacteria at week 2. The level of IL-12 was low in both groups, which suggested that Bio-Three had no significant effect on IL-12 production (Figures 2 and 3). After stimulation with Bio-Three and co-culture *in vitro*, the IL-12 level in supernatants of PBMCs was upregulated (Figures 2 and 3). PBMCs can be activated by *in vivo* stimulation (probiotic consumption) and probiotic bacteria re-stimulation *in vitro*, which enhanced IFN-γ and IL-10 production, as well as downregulated TNF-α production.

Initial cytokine levels and immune phenotype distribution in PBMCs from blood donors

Initial concentrations of IFN-γ, IL-4, TNF-α, IL-10, and IL12 p70 in the supernatants of isolated human PBMCs were determined (Figure 4A) by ELISA. To determine the effect of probiotics (Bio-Three) on PBMCs, phenotypic analysis of immune responses was also studied. Figure 4B shows that probiotics might alter the expression of some T cell and DC surface phenotypes compared with controls, such as $CD4^+$ (54.2% ± 3.6% *vs* 43.4% ± 3.0%), $CD45RA^+$ (69.1% ± 4.2% *vs* 43.3% ± 3.6%), $CD25^+$ (15.1% ± 2.6% *vs* 9.8% ± 2.3%), $CD44^+$ (48.3% ± 3.8% *vs* 40.1% ± 3.2%), $CD69^+$ (45.6% ± 2.4% *vs* 34.3% ± 2.7%), $CD11b^+$ (63.6% ± 4.5% *vs* 51.8% ± 2.8%) and HLA-DR (29.9% ± 2.7% *vs* 22.3% ± 2.3%). Probiotics can enhance expression of CD4, CD45RB, CD44, CD69, CD25, CD11b and HLA-DR, which indicates alternation of co-stimulation with markers of Th cells and DCs.

Effect of probiotics on expression of CD14, CD 11b and HLA-DR

To determine the effect of Bio-Three on circulating monocytes and APCs (such as DCs), phenotypic analysis of CD14, CD 11b and HLA-DR was also studied. Probiotics can also enhance the expression of CD11b, and HLA-DR in gating monocytes and granulocytes (Figure 5), which indicates alternation of co-stimulation with marker of DCs. However, the expression of CD14 was similar in the probiotics and control groups.

Enhancement of CD4, CD45RA, CD44, CD69 and CD25 expression

To determine the effect of Bio-Three on circulating lymphocytes, phenotypic analysis of T cells and B cells was also studied. Figure 6 shows that probiotics can alter the

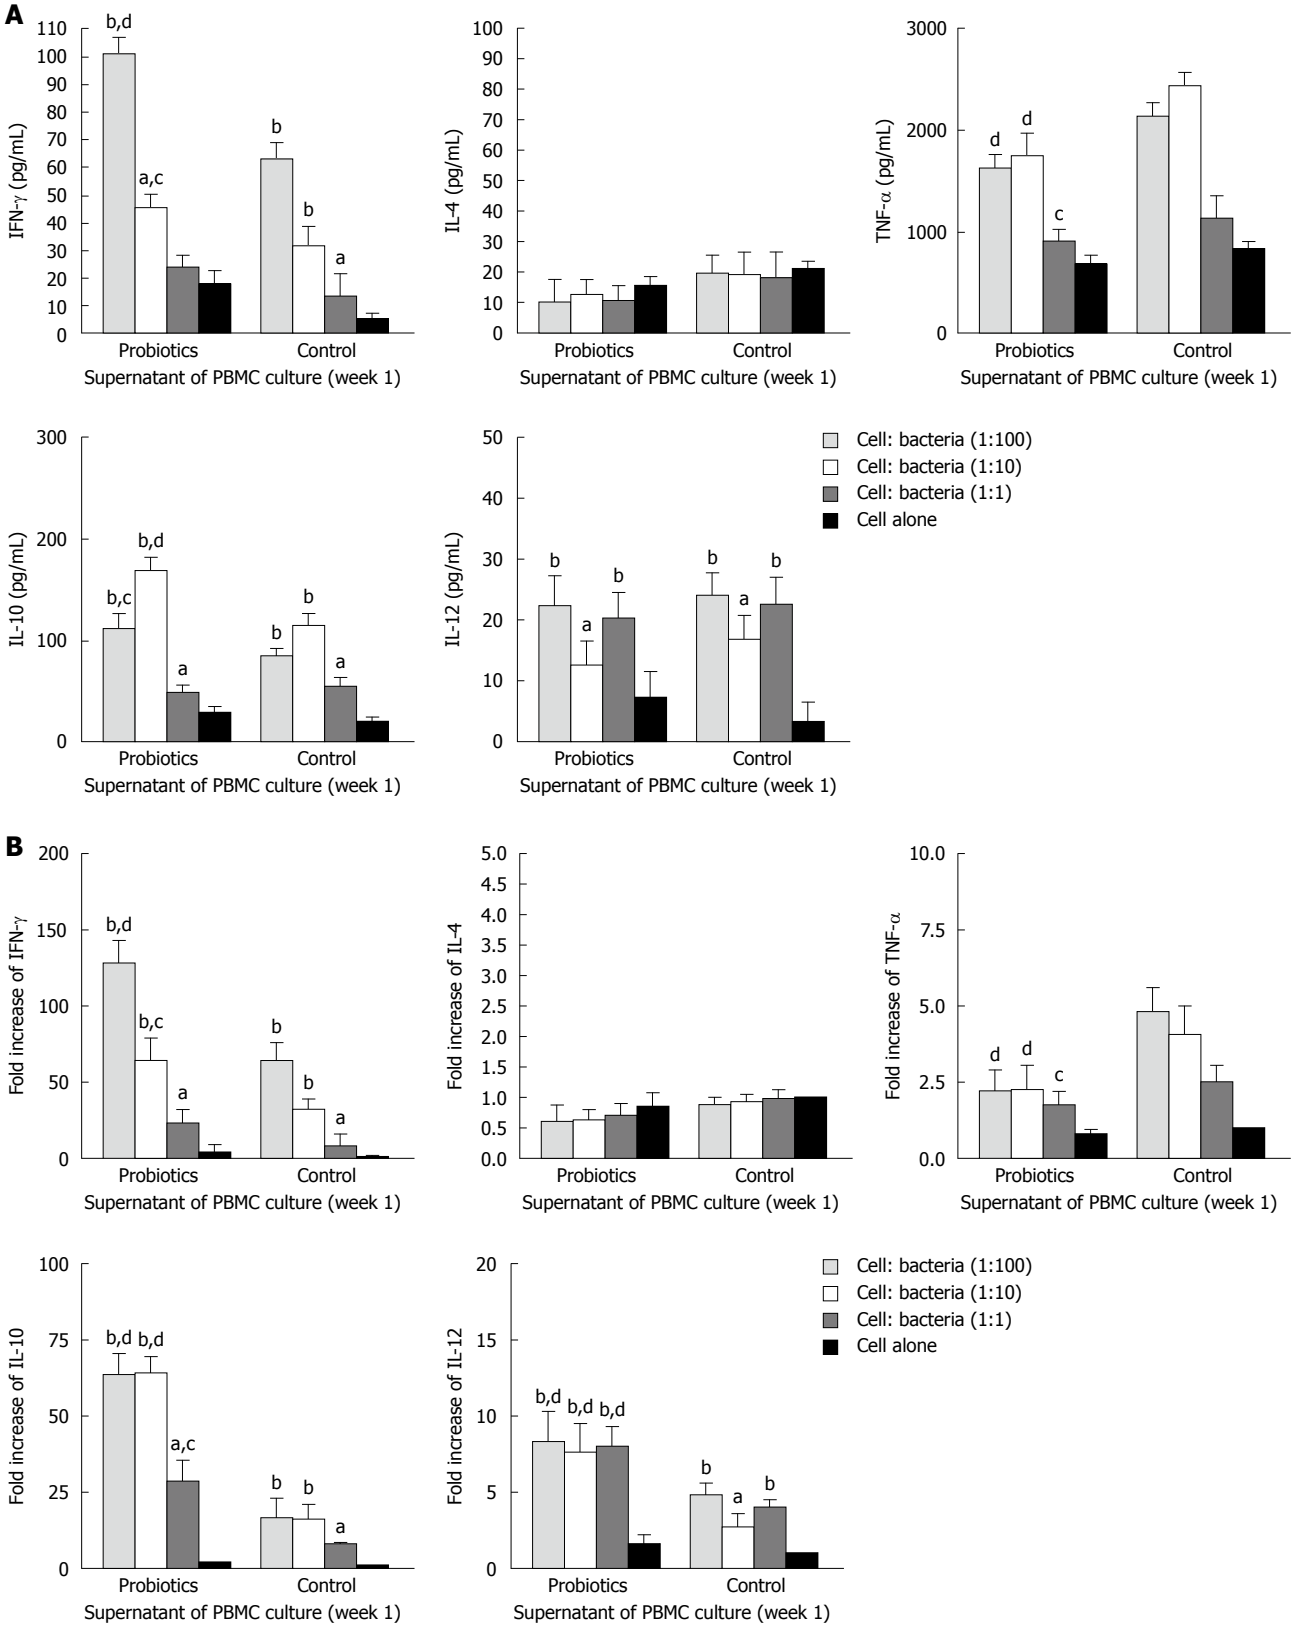

Figure 2 Effects of Bio-Three re-stimulation on cytokine production of peripheral blood mononuclear cells isolated at 1 wk after consumption, compared with controls. Peripheral blood mononuclear cells (PBMCs) (10^5 cells/mL) were stimulated at a host cell: bacteria ratio of 1:1, 1:10 and 1:100. A: At 24 h after bacterial stimulation, cell culture supernatants were collected and cytokine levels were determined by enzyme-linked immunosorbent assay; B: The remaining cells in the culture plates were mixed with TRIzol Reagent, and cytokine mRNA expression was analyzed by real-time polymerase chain reaction. The fold increases were compared to that of control cells, which was set at 1. The columns represent the means and the error bars indicate the SD. $^aP < 0.05$, $^bP < 0.01$ *vs* control cells; $^cP < 0.05$, $^dP < 0.01$ *vs* controls at the same host cell:bacteria ratio. IFN-γ: Interferon-γ; IL-4: Interleukin-4; TNF-α: Tumor necrosis factor-α.

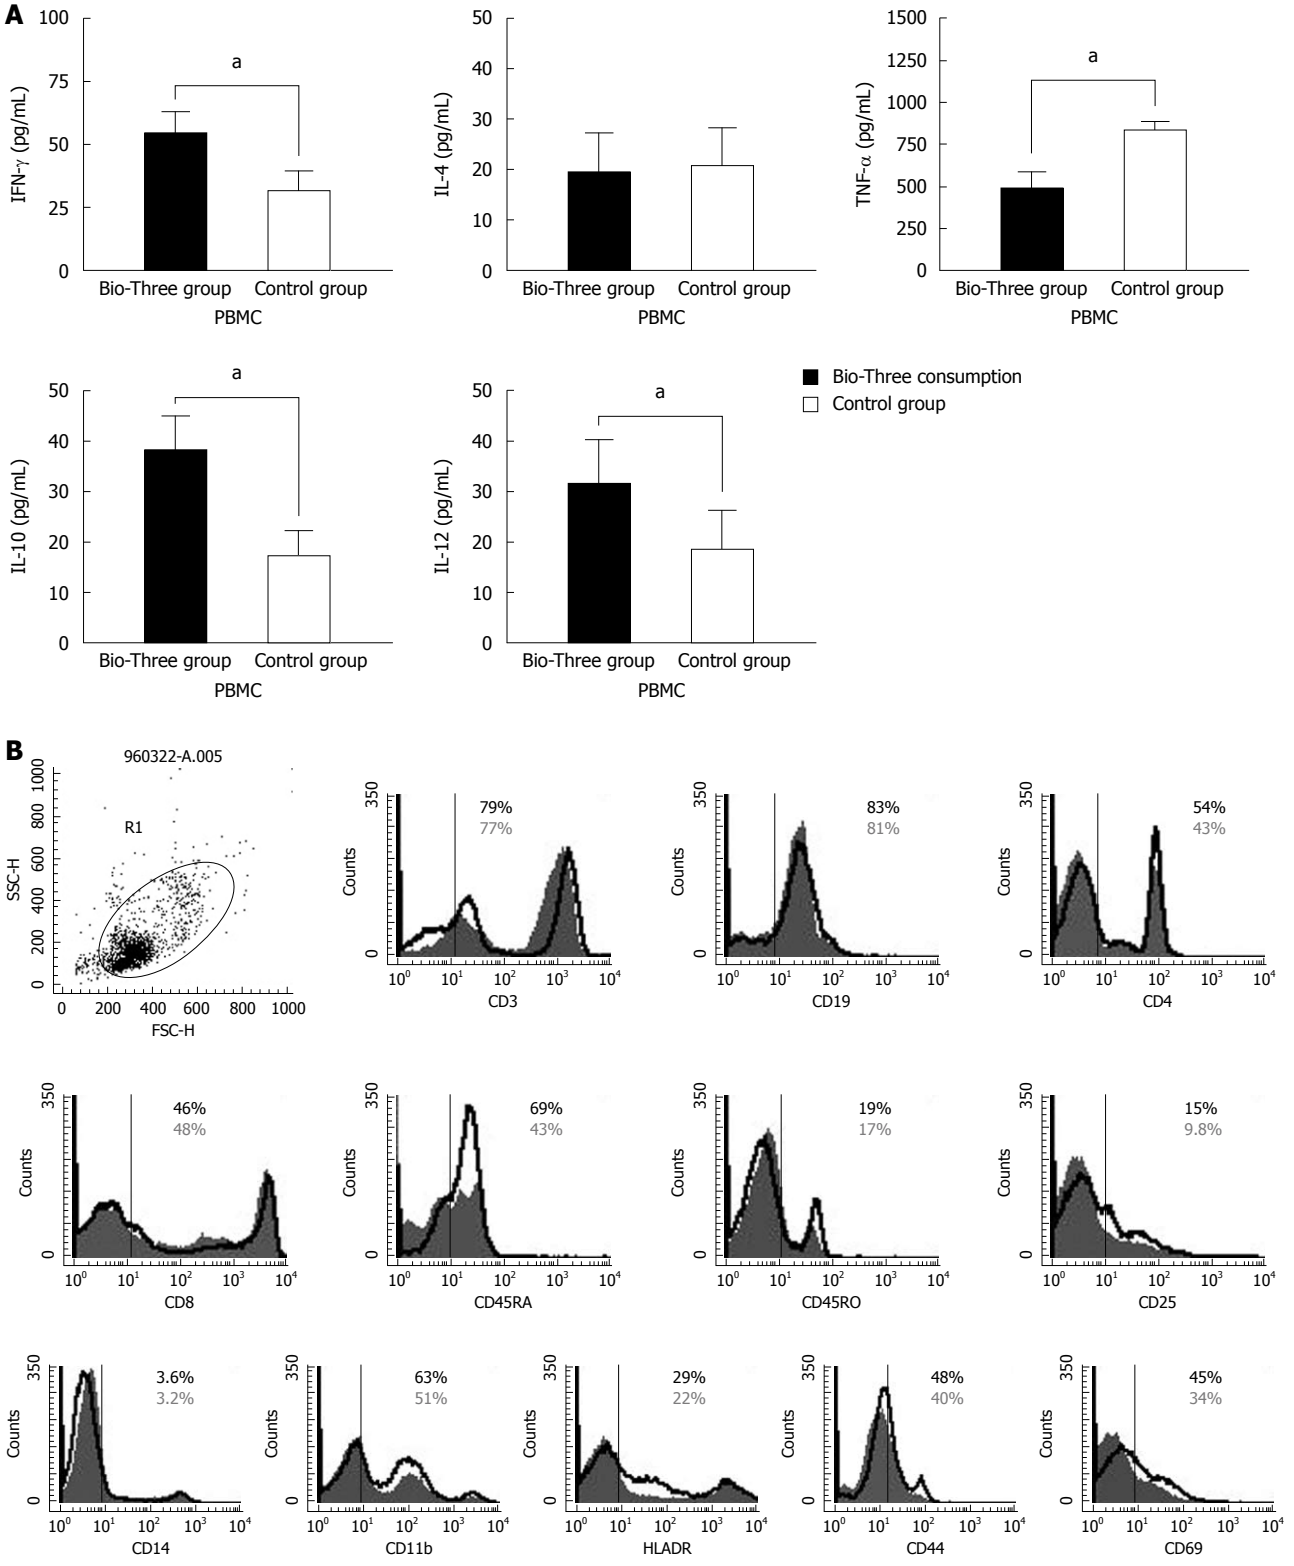

Figure 4 Measuring initial cytokine levels and determining immune phenotype distributions in peripheral blood mononuclear cells isolated from blood donors. A: Initial concentrations of interferon-γ (IFN-γ), interleukin (IL)-4, tumor necrosis factor-α (TNF-α), IL-10, and IL-12 p70 in the supernatants of human peripheral blood mononuclear cells (PBMCs) were determined by enzyme-linked immunosorbent assay. The results are presented as the mean ± SD. Statistically significant differences compared with the controls ($^aP < 0.05$); B: To determine the effect of Bio-Three on PBMCs, phenotypic analysis of the immune response was studied. The solid histogram shows the control results, and the unshaded area shows the level of expression of co-stimulatory molecules after Bio-Three consumption. The data shown are representative of three experiments performed. Probiotics might enhance expression of CD4, CD45RB, CD44, CD69, CD25, CD11b and HLA-DR, which indicates alternation of co-stimulatory markers of T helper cells and dendritic cells.

expression of some T-cell surface phenotypes compared with controls, such as $CD4^+$ (63.2% ± 4.6% *vs* 45.6% ± 3.1%), $CD45RA^+$ (69.2% ± 3.9% *vs* 42.3% ± 2.6%), $CD25^+$ (13.2% ± 2.5% *vs* 8.7% ± 2.1%), $CD44^+$ (47.3%

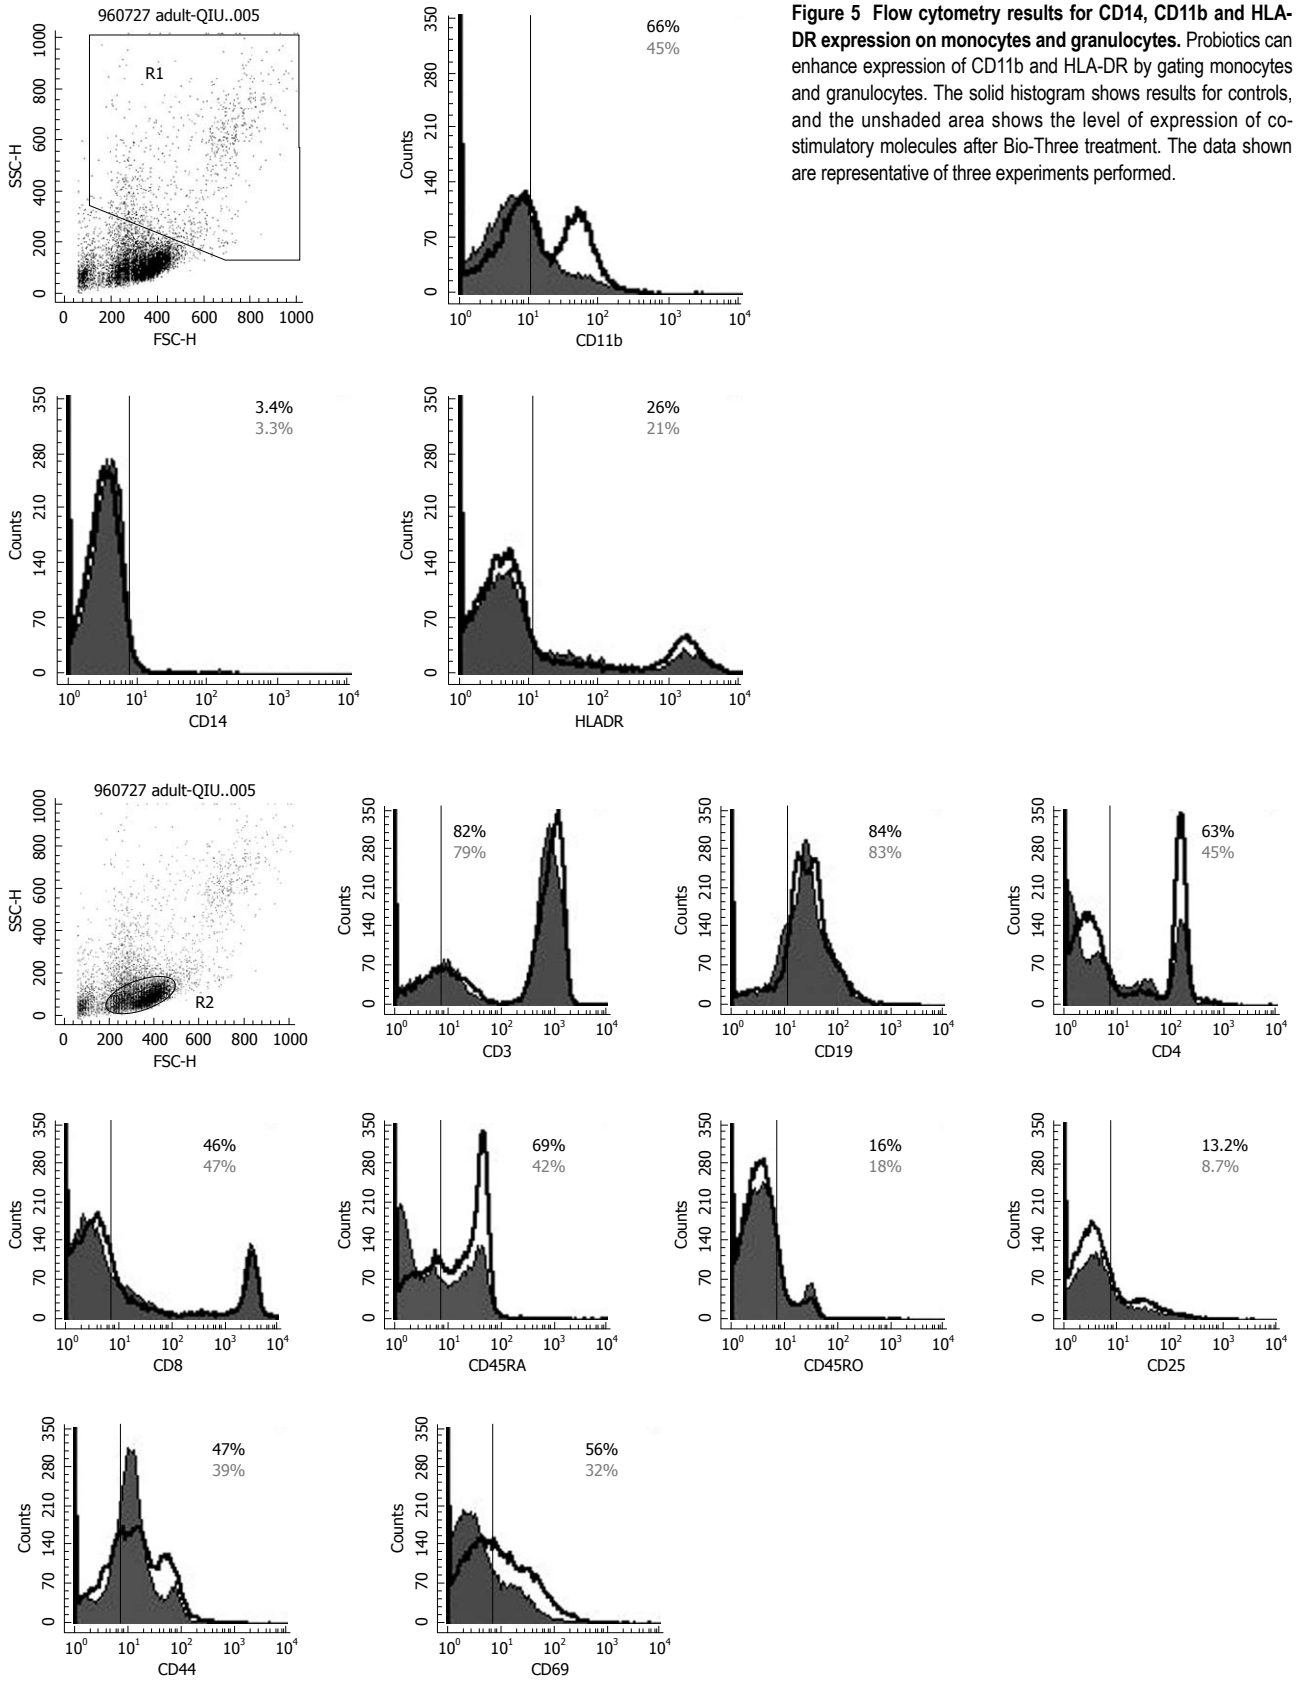

Figure 5 Flow cytometry results for CD14, CD11b and HLA-DR expression on monocytes and granulocytes. Probiotics can enhance expression of CD11b and HLA-DR by gating monocytes and granulocytes. The solid histogram shows results for controls, and the unshaded area shows the level of expression of co-stimulatory molecules after Bio-Three treatment. The data shown are representative of three experiments performed.

Figure 6 Flow cytometry results for CD3, CD4, CD45RA, CD45RO, CD8, CD19, CD25, CD44, CD69 expression on peripheral lymphocytes. The solid histogram shows the results for controls, and the unshaded area shows the level of expression of co-stimulatory molecules after Bio-Three treatment. The data shown are representative of three experiments performed. Bio-Three might alter the expression of T-cell surface phenotype, such as CD4, C45RA, CD44, CD69, and even CD25.

± 3.6% *vs* 39.8% ± 3.8%) and $CD69^+$ (56.6% ± 2.3% *vs* 32.1% ± 2.6%). Flow cytometry showed that probiotic treatment was associated with altered expression of CD4 (Th cells), CD45RA (naïve T cells), CD25 (Treg cells),

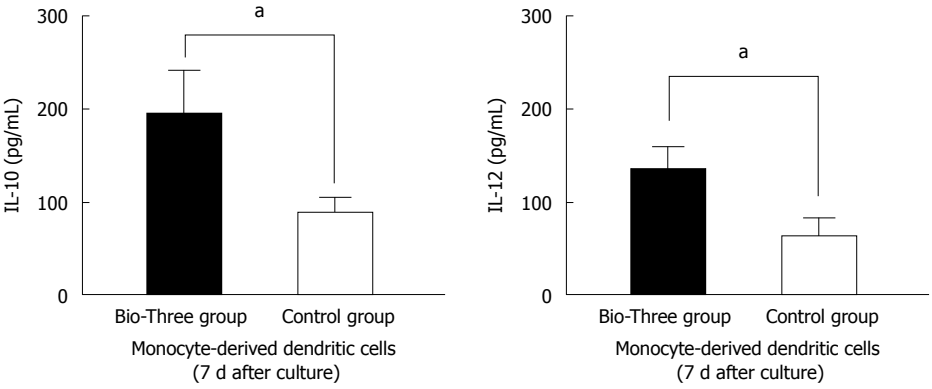

Figure 7 Interleukin-10 and interleukin-12 p70 levels in the supernatants of monocyte-derived dendritic cells. The data shown are the levels of cytokines in the probiotic group (black bar), and control group (white bar) collected on day 7 after Bio-Three consumption. Bio-Three upregulated interleukin (IL)-10 and IL-12 p70 levels in the supernatants of monocyte-derived dendritic cells. The results are presented as the mean ± SD. Statistically significant differences compared with the controls ($^aP < 0.05$).

CD44 and CD69 (T-cell activation markers) on lymphocytes, but there was no significant effect on the expression of CD3, CD8 or CD45RO.

Effect of probiotics on monocyte-derived DCs

To determine the effect of probiotics on DCs, we isolated monocytes and cultured them at 37℃ for 7 d. In the culture supernatants from monocyte-derived DCs, IL-10 and IL-12 levels were upregulated in the probiotic group compared to the control group (Figure 7). This indicates that Bio-Three can stimulate monocyte-derived DCs to produce more IL-10 and IL-12.

Probiotics enhance cytokine levels associated with Th1 and Treg cells in CD4$^+$ T cells co-cultured with DCs

To explore the effect of probiotic consumption on DC and CD4$^+$ T cell differentiation, we use a cell culture model to study cytokine levels in the supernatants of CD4$^+$ T cells co-cultured with monocyte-derived DCs. Bio-Three upregulated IFN-γ (associated with Th1) and IL-10 (associated with Treg cells) levels in the supernatants of DCs and CD4$^+$ T cells co-cultured for 48 h (Figure 8).

DISCUSSION

The role of intestinal microflora as a modulator of the immune response has been studied intensively in recent years. *Lactobacillus* species are the most well-studied both *in vitro* and *in vivo*, and could have clinical importance in inducing phagocytosis and IgA secretion, modifying T-cell responses, enhancing Th1 responses, and attenuating Th2 responses[2,15-17]. However, how intestinal microbes interact with the mucosal immune system remains unclear[15]. The ability of different strains of *Lactobacillus* to induce production of key cytokines such as IL-12 and IL-10 varies markedly[2,8].

The functionally different CD4$^+$ Th cell subsets known as Th1 and Th2 have different cytokine profiles. The Th1/Th2 paradigm is relevant to the pathogenesis of several pathological conditions and provides the rationale for the development of new strategies for treating and preventing diseases. The development of polarized Th1 or Th2 responses depends on environmental factors [e.g. dose of antigen, nature of the immunogen, and cytokines (IL-4, IL-12 or interferons) at the time of antigen presentation], or on other undefined factors that mainly affect so-called natural immunity[18]. Th1-dominated responses are potentially effective in eradicating infectious agents, including those hidden within the host cells.

In our study, probiotics upregulated IFN-γ levels and moderately downregulated IL-4 in the supernatant of cultured PBMCs, which suggests that probiotics enhance the Th1 immune response and suppress the Th2 immune response.

The effects of consuming probiotics other than lactic acid bacteria are relatively unexplored. *Bacillus* strains are used in the treatment of diarrhea[19]. Additionally, they have antimicrobial activities, induce secretory IgA, IFN-γ, IL-12, IL-10 and TGF-β production, stimulate CD4$^+$ T cell proliferation, and suppress IL-4 levels[20,21]. The clinical and immunomodulatory effects of *Clostridium* and *Enterococcus* species are well documented in animal models. Heat-inactivated *C. butyricum* enhanced IFN-γ production, polyclonal antibody formation, and phagocytosis in a mouse model[22,23]. Moreover, culture supernatants of *C. butyricum* TO-A downregulate TLR4 expression in human colonic epithelial cells[24]. Feeding *E. faecium* SF68 to mice has been documented to antagonize *Giardia intestinalis* infection and increase the percentage of CD4$^+$ T cells in the Peyer's patches and spleen[25]. It has also been suggested that adequate *E. faecium* after antibiotic treatment improves the intestinal ecosystem, and thereby prevents the shift to Th2 immunity in neonatal mice[26].

The present study focused on the probiotic mixture Bio-Three of *B. mesentericus*, *C. butyricum* and *E. faecalis*. We speculated that each species of Bio-Three would modify the immune function differently, thus leading to more complex effects. To date, few studies have examined the clinical effects of Bio-Three. One study has found that Bio-Three prevents enterohemorrhagic *Escherichia coli* O157: H7 infection in rabbits[27]. Another has found that Bio-Three is effective in patients with ulcerative colitis that is refractory to conventional therapy[28]. Administration of Bio-Three to infants changes the composition of

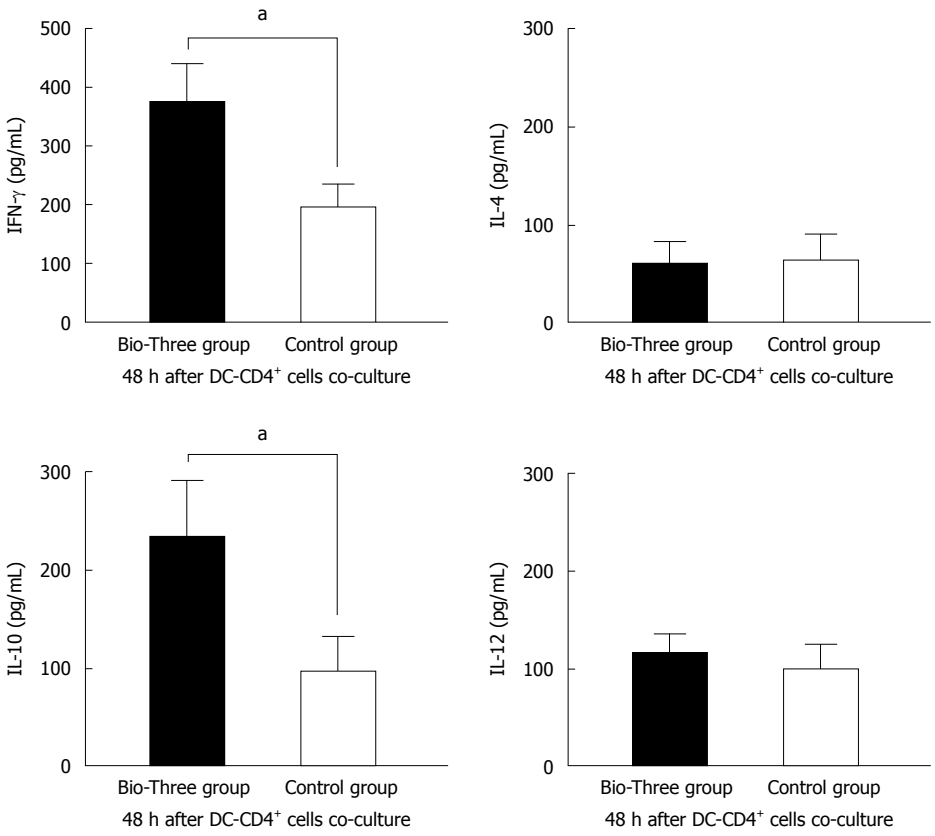

Figure 8 Interferon-γ, interleukin-4, interleukin-10, and interleukin-12 p70 cytokine profile of supernatants of human CD4$^+$ T cells co-cultured with dendritic cells. The data shown are the levels of cytokines in the probiotic group (black bar), and control group (white bar). Bio-Three upregulated interferon-γ (IFN-γ) and interleukin (IL)-10 levels in the supernatants of CD4$^+$ T cells co-cultured with dendritic cells at a ratio of 1:4 for 48 h. The results are presented as the mean ± SD. Statistically significant differences compared with the controls ($^aP < 0.05$).

intestinal flora and decreases serum endotoxin produced by potentially pathogenic microorganisms[29], and probably reduces infectious complications after pancreaticoduodenectomy[30].

In the present study, Bio-Three induced IL-10 production and increased the number of Treg cells (CD4$^+$ and CD25$^+$ T lymphocytes). IL-10 modulates immune responses by probiotic bacteria[2,15,31] by inhibiting synthesis of IL-2, IL-12 and TNF-α produced by cells such as APCs and Th1 cells[10,12,32]. Increased IL-10 production might explain why Bio-Three inhibits TNF-α production, which can be harmful at high levels[3,33].

IL-12 plays a central role in promoting the Th1 response[2,10]. Specific strains of *Lactobacillus* enhance IL-12 production by human mononuclear cells[34,35]. However, in our study, this effect was limited probably because of strains in Bio-Three were not stimulatory. Other explanations include inhibition by IL-10, shorter time of stimulation *in vitro* (24 h), and inadequate dose (around 10^9 organisms/d). In previous studies, daily doses of 10^{10}-10^{11} (but not < 10^9) organisms of probiotic lactic acid bacteria conferred physiological benefits[36,37]. In the present study, IL-12 level in both groups was low, therefore, the influence of Bio-Three dose on IL-12 production should be further investigated. Notably, not all probiotics species can induce IL-12 production.

We used a previously published method (10^5, 10^6 and 10^7 CFU/mL bacteria co-cultured with PBMCs (10^5/mL) for 1 d (the ratio of bacteria:PBMC was 1:1, 10:1 and 100:1) to investigate how the concentration of bacteria affects cytokine production[35,38,39]. A prior study has demonstrated that *Lactobacillus* dose-dependently stimulates PBMC expression of cytokines[39]. In our system, the optimum dose was around 10^6-10^7 CFU/mL, which was almost statistically significant ($P < 0.05$). However, cytokine production was less at the highest concentration (10^8 CFU/mL bacteria, data not shown), which suggested that stimulation of PBMCs was not fully dose-dependent. This inconsistency between the responses to Bio-Three and *Lactobacillus* may have been due to species differences. Moreover, the possibility that highly concentrated cell debris induces apoptosis, deletion, or cell death of PBMCs should be considered.

In our experiment, CD4$^+$, CD45RA$^+$ and CD25$^+$ T lymphocytes were upregulated, whereas CD14$^+$ cells showed no significant change. DCs are CD11b$^+$ cells that can differentiate from CD14$^+$ monocytes[10,40]. The expression of CD11b$^+$ cells in our study suggested that they were increased by exposure to Bio-Three. DCs regulate the development of T cell responses, especially the polarization of such responses[1,2]. It has been demonstrated that exposure to probiotic bacteria upregulates markers of DC maturation, such as HLA-DR and members of the B7 family (CD80, CD86)[10,31,41-44]. High but not low doses of probiotic organisms induce DC maturation, which suggests that different intracellular signal-

ing pathways are activated by high doses[10,45].

As described above, the level of HLA-DR (a marker of immune stimulation), which participates in DC signaling, is usually enhanced. In the present study, Bio-Three had an enhancing effect on expression of HLA-DR. Furthermore, co-culture with DCs and $CD4^+$ T cells, showed upregulation of IFN-γ (associated with Th1 cells) and IL-10 (regulatory cytokine) in the supernatants.

To date, the real pathways of probiotic immunomodulatory effects are not fully understood, and some types of immune cells that are primed by probiotics might be the connection between *in vivo* and *in vitro* stimulation. We proposed that PBMCs are involved in the *in vivo* sensitizing effect of Bio-Three and further *in vitro* stimulatory effects. The monocyte-derived DC transformation might play a key role in the mechanism of probiotic immunomodulation. DCs are the most potent APCs that are primed by probiotic bacteria, and they are the principal stimulators of naïve T cells to drive further immune responses.

In conclusion, we found that probiotics (Bio-Three) increased expression of IFN-γ (associated with Th1 cells), increased IL-10 production (anti-inflammatory cytokine), and decreased TNF-α level. The optimum concentration of Bio-Three for cytokine production was around 10^6-10^7 CFU/mL. It is reasonable to speculate that Bio-Three redirected the immune system toward an anti-inflammatory phenotype, rather than an aggressive immune response, even at a relatively low dose (10^9 organisms/d for 2 wk). Furthermore, the short term *in vivo* (2 wk) and *in vitro* (24 h) exposure was probably sufficient to promote a Th1 cell response and HLA-DR expression on DCs.

COMMENTS

Background

There is increasing evidence that probiotic bacteria influence host immune function, but the immune response in human peripheral blood after probiotic consumption is little known. Probiotic products, however, are usually consumed by the general population, but not much is known about the effects that they have on the immune system in healthy adults.

Research frontiers

It is not fully clarified how probiotics exert their beneficial effects, but one of the most probable mechanisms is the modulation of host immune responses. The possible action mechanism could be the ability to induce cytokines that further regulate innate and adaptive immune responses.

Innovations and breakthroughs

The present study was designed to explore the immune response of peripheral blood mononuclear cells (PBMCs) *in vivo* after stimulation by a probiotic preparation, such as cytokine production and phenotypic analysis of circulating PBMCs. The authors also investigated cytokine production of (1) PBMCs stimulated by probiotic preparation; (2) monocyte-derived dendritic cells (DCs); and (3) co-cultured DCs and T cells.

Applications

The authors found that the probiotic preparation Bio-Three (*Bacillus mesentericus*, *Clostridium butyricum* and *Enterococcus faecalis*) could direct immune responses to either a Th1 or anti-inflammatory response. More detailed information on the cytokine patterns elicited by probiotic bacteria could help in designing probiotic preparations for specific preventative or therapeutic purposes.

Peer review

This is a well-written paper with promising results that could be the basis of forthcoming new research on the therapeutic and immunomodulatory effects of probiotics.

Abstract

AIM: To study the role of hepcidin in hereditary hyperferritinemia cataract syndrome (HHCS).

METHODS: Six patients from two families with HHCS, confirmed by genetic analysis showing A to G mutation at position +40 in the L-ferritin gene, were recruited to undergo serum hepcidin and prohepcidin measurements using radioimmunoassay and enzyme linked immunoassay, respectively, and measurements were compared with levels in serum from 25 healthy volunteers (14 females), mean age 36 ± 11.9 years.

RESULTS: The serum hepcidin and prohepcidin levels in patients with HHCS were 19.1 ± 18.6 and 187 ± 120.9 ng/mL, respectively. Serum ferritin was 1716.3 ± 376 μg/L. Liver biopsy in one patient did not show any evidence of iron overload. Serum hepcidin and prohepcidin values in healthy controls (HCs) were 15.30 ± 15.71 and 236.88 ± 83.68 ng/mL, respectively, while serum ferritin was 110 ± 128.08 μg/L. There was no statistical difference in serum hepcidin level between the two cohorts (19.1 ± 18.6 ng/mL *vs* 15.30 ± 15.71 ng/mL, P = 0.612) using two-tailed t-test.

CONCLUSION: Serum hepcidin levels in HHCS patients is similar to that in HCs. Our study suggests that circulating ferritin is not a factor influencing hepcidin synthesis and does not have a role in the iron-sensing mechanism in hepatocytes.

INTRODUCTION

The iron-sensing mechanism has been widely studied but is not yet fully defined. In iron-replete states, circulating transferrin carrying iron to hepatocytes competes with hemochromatosis-Fe protein (HFE-protein) to bind to transferrin receptor-1 (TfR-1)[1]. Transferrin loaded with iron has greater affinity with TfR-1 than does HFE-protein. When transferrin binds to TfR-1, HFE-protein is freed up to bind to transferrin receptor-2 (TfR-2). This complex is thought to operate as an iron sensor mechanism and functions as an inducer of hepcidin production *via* SMAD (small mothers against decepentaplegic homologue) pathway[2]. Under normal circumstances, hepcidin expression and subsequent release into plasma prevents further absorption of iron from the duodenal enterocytes by preventing the efflux of iron by ferroportin channels and hence reduced amounts of iron delivery *via* transferrin to hepatocytes[3].

Ferritin is an iron storage protein and its synthesis is controlled at the level of transcription[4] and mRNA translation by an iron response mechanism. The control process depends on a highly conserved motif at the 5' non-coding region of ferritin mRNA. Studies have shown that ferritin is synthesized in the liver and has two subunits, L (19 kDa, Light) and H (21 kDa, Heavy)[5]. Different proportions of component L and H subunits give rise to isoferritins with tissue specific distributions, with H-ferritin as the major iron storage protein. The L-ferritin and H-ferritin genes are based in chromosomes 19 and 11, respectively.

Regulation of ferritin synthesis involves an interaction between an iron binding protein, termed as the iron regulatory protein (IRP), and ferritin mRNA[6,7]. The translational regulation of ferritin mRNA involves two IRPs, IRP-1 and IRP-2. Only IRP-1, but not IRP-2, contains an iron-sulphur complex and is bifunctional, registering intracellular iron status mainly through an iron-sulphur switch mechanism and alternating between an active cytosolic aconitase form and an apoprotein that binds iron responsive elements (IREs). Although IRP-2 is homologous to IRP-1, IRP-2 activity is regulated primarily by iron-dependent degradation through the ubiquitin-proteasomal system in iron-replete cells. Targeted deletions of IRP-1 and IRP-2 in animals suggest that IRP-2 is the chief physiologic iron sensor[8]. A constant region of the ferritin mRNA molecule, termed the IRE, binds with IRP. The resultant IRE-IRP complex inhibits ribosomal binding to mRNA and prevents translation of the ferritin coding sequence[6]. A critical CAGUGU sequence within IRE is important for binding with IRP.

In iron overload, as in hereditary hemochromatosis, the IRE-IRP inhibitory system is suppressed and ferritin synthesis is increased. When this form of iron storage is saturated, iron is deposited as hemosiderin in tissue[9]. Thus ferritin is a sequel of intracellular iron metabolism and not a part of the iron sensor mechanism itself.

Hereditary hyperferritinemia cataract syndrome (HHCS) is an autosomal dominant disorder characterized by premature cataract formation and raised serum L-ferritin in the absence of iron overload[10,11]. We have earlier described this syndrome in a family with 11 members, six members from three generations having genetic mutation at +40 (A to G mutation) corresponding to the critically conserved nucleotide motif in L-ferritin mRNA IRE on chromosome 19[12]. We have recently discovered another family with five members from two generations; two members confirmed as having the genetic mutation as described above. In this manuscript, we describe serum levels of hepcidin and prohepcidin in HHCS and discuss the iron-sensing mechanism in hepatocytes.

MATERIALS AND METHODS

A prospective study was performed with approval of our Regional Ethics Committee and written consent was obtained from all patients and healthy volunteers in accordance with the Declaration of Helsinki. Patients and healthy volunteers were recruited from a single hospital with mixed ethnicity mainly comprising Caucasians and South Asians living in West London.

Healthy controls

The serum study comprised of 25 healthy controls (HCs); 14 were females, mean age was 36 ± 11.9 years (age range 21-62 years), who were hospital colleagues recruited to measure serum hepcidin-25, prohepcidin and ferritin as well as routine biochemical profile. HCs on supplemental vitamins and oral iron were excluded. None of the participants had received any blood products in the past. A morning fasting venous blood sample was collected and serum stored at -20℃ for analysis.

Patients

Six patients from two families with HHCS were recruited for serum hepcidin, prohepcidin and ferritin analysis. All six patients had cataracts with limited reduction in visual acuity and all had hyperferritinemia but normal transferrin saturation. Venous blood samples were obtained and serum separated and stored at -20℃ until analysis. None of the recruited patients had chronic inflammatory disease and none were on oral iron supplementation.

Liver biopsy was performed on one of the affected individuals (A Ⅱ-1) to determine tissue iron status using Perl's Prussian blue staining. Blood samples from family members were analyzed for genetic mutation within the L-ferritin IRE.

Genetic analysis

Polymerase chain reaction amplification and DNA sequencing were carried out as described previously[12,13]. Direct cycle sequencing of the 5' untranslated region of the L-ferritin gene from three affected members from Family A (A Ⅰ-2, A Ⅱ-1 and A Ⅱ-5) revealed that all three patients were heterozygous for A to G point mutation at position +40. Family B (B Ⅱ-1 and B Ⅱ-3) underwent genetic analysis and revealed the same mutation as mentioned above. This corresponds to position 2 of the CAGUGU motif within the L-ferritin IRE mRNA.

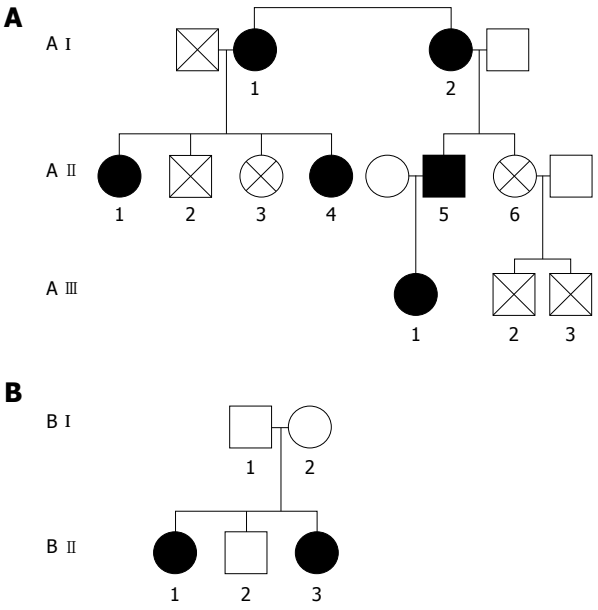

Figure 1 Family tree of two families Family A (A) and Family B (B) with hyperferritinemia. Solid symbols indicate those with ferritin in excess of 800 μg/mL; symbols with crosses indicate ferritin concentrations within the normal range; clear symbols indicate spouses in whom the ferritin concentrations have not been measured.

Hepcidin and prohepcidin analysis

We have earlier described development of a radioimmunoassay for measurement of serum hepcidin-25[14]. Serum prohepcidin was measured by enzyme linked immunoassay (DRG Diagnostics, UK). Serum ferritin was measured using a standard solid phase, two site chemiluminescent immunometric assay (Immulite).

Statistical analysis

Quantitative variables were compared using unpaired *t*-test. A value of $P < 0.05$ was considered significant. All statistical analyses were carried out using the statistical package GraphPad Prism, version 5.00 for Windows, (GraphPad Software, San Diego California USA, www.graphpad.com).

RESULTS

The serum hepcidin and transferrin saturation values for all six patients with HHCS were similar to HCs. Figure 1 describes the relationship between the various family members and Table 1 describes the relation of serum ferritin to cataract. The mean ± SD serum hepcidin in patients with HHCS was 19.1 ± 18.6 ng/mL as compared to an HC mean value of 15.68 ± 15.7 ng/mL, and there was no statistically significant difference between cohorts ($P = 0.612$). However, there was a highly significant difference ($P < 0.0001$) in serum ferritin level between the two cohorts; mean serum ferritin for HHCS patients was 1716 ± 376 μg/L, as compared to mean value of 110 ± 128 μg/L for HCs (Table 2). Liver biopsy performed on one patient did not reveal iron overload.

Table 1 Relation between serum ferritin concentrations and cataracts

Family member	Serum ferritin (μg/L)	Transferrin saturation (%)	Cataract
A I 1	1542	18	Yes
A I 2	1581	17	Yes
A II 1	2049	22	Yes
A II 4	988	17	Yes
A II 5	1855	26	Yes
A III 1	902	37	Yes

Albumin (g/L)	46.2 ± 2.4	42.7 ± 4.2	34-50

Reference range as followed by Department of Biochemistry, Ealing Hospital NHS Trust, University of London, United Kingdom. HHCS: Hereditary hyperferritinemia cataract syndrome; Hb: Hemoglobin; MCV: Mean corpuscular volume; TIBC: Total iron binding capacity; Tsat %: Transferrin saturation; ALP: Alkaline phosphatase; ALT: Alanine transaminase; NA: Not available.

DISCUSSION

HHCS is now a well recognized entity[15,16]. The only clinical manifestation in these patients appears to be early onset cataracts. Further studies on other family members who have undergone cataract extraction have confirmed that the cataracts represent deposits of L-ferritin subunits[17]. To our knowledge, this is the first ever study of hepcidin and prohepcidin levels in patients with HHCS. Our patients had normal transferrin saturation with liver biopsy on one patient ruling out tissue iron overload. Serum hepcidin levels in HHCS patients were similar to those in HCs.

The iron-sensing mechanism in hepatocytes is poorly understood. Unlike the ferritin mRNA, there is no iron regulatory element sequence in the hepcidin gene that is directly influenced by cellular iron[18]. Kemna *et al*[19] have put forward the hypothesis that several pathways are involved in hepcidin regulation. Three of these are active regulation pathways (erythropoietic activity derived regulation, iron store based regulation, and inflammation induced regulation) and one is an independent mandatory signaling pathway.

Hemojuvelin (HJV)-controlled transcription factors, such as the bone morphogenic protein (BMP)/SMAD signaling pathway, appears to be a mandatory signaling process for the influence of iron stores and erythropoiesis derived hepcidin regulation[19,20]. Any direct influence of intracellular iron on hepcidin regulation is not well elucidated. It is known that iron activates BMP-6, an upstream regulator of hepcidin. Moreover, it has also been suggested that hepcidin responds to increases in transferrin saturation. Recent reports suggest that a transmembrane protease (matriptase-2) inhibits hepcidin activation by cleaving membrane HJV[21,22].

The inflammation regulatory pathway for hepcidin regulation is mainly induced by interleukin-6 (IL-6) with a cascade involving IL-6 receptor Janus kinase, signal transducer and activator of transcription (STAT 3)[23].

A syndrome of non-hereditary liver iron overload in patients with modestly raised serum ferritin but normal transferrin saturation has also been reported. This disorder is distinct from both hereditary hemochromatosis and HHCS and seems to be associated with hyperlipidemia and impaired glucose tolerance[24]. The metabolic syndrome candidate genes, upstream stimulating factor (*USF*) *1* and *2* in chromosome 19, are in direct control of the hepcidin anti-microbial peptide gene (*HAMP* gene, chromosome 19 q13), suggesting a link between lipid, glucose, and iron metabolism.

Our study confirms that L-ferritin in patients with HHCS is not a factor in the regulation of hepcidin synthesis. It is therefore most likely that iron saturation of transferrin plays a key role in the iron-sensing mechanism in hepatocytes. The iron overload reported in patients with congenital atransferrinemia also supports this hypothesis[25].

ACKNOWLEDGMENTS

We would like to thank Dr. Bharati Bhatkal for helping us with the recruitment of patients and Dr. Frank Geoghegan, Department of Biochemistry, Ealing Hospital NHS Trust, for his helpful advice and discussion.

COMMENTS

Background

Hereditary hyperferritinemia cataract syndrome (HHCS) is an autosomal dominant disorder characterized by L-ferritin hyperferritinemia and premature cataract formation. The defect is due to a point mutation or deletion in the L-ferritin iron responsive element (IRE) and the resultant changes in the structure of the L-ferritin IRE preventing its interaction with the iron regulatory protein. Hepcidin is an iron regulatory peptide predominantly formed in the liver. Hepcidin has been shown to be low in the various types of hereditary hemochromatosis such as hemochromatosis-Fe-related C282Y/C282Y, hemojuvelin- and transferrin receptor-2-related hemochromatosis. No data has been available on the levels of hepcidin in HHCS to date. This research study examined serum levels of hepcidin in two families with HHCS and set out to explain the iron-sensing mechanism in the liver.

Research frontiers

Hepcidin and its role in iron metabolism has been a topic of intense research recently. The initial hurdle to measure hepcidin in serum has partly been resolved with the development of assays to measure the peptide in serum, e.g. radioimmunoassay and enzyme-linked immunosorbent assay. HHCS is a benign disorder of iron metabolism and we report for the first time serum levels of hepcidin in this disorder. This should help in further understanding the regulation of hepcidin in various disorders.

Innovations and breakthroughs

The authors report for the first time the level of serum hepcidin in patients with HHCS. Results prove that circulating ferritin has no role in the iron-sensing mechanism.

Applications

The authors used radioimmunoassay to measure serum levels of hepcidin in patients and healthy controls. Use of this assay would help explore the role of hepcidin in various iron disorders.

Peer review

In this work Arnold *et al* measure the iron regulatory hormone hepcidin (and its precursor pro-hepcidin) in sera from patients with HHCS. They report that levels of hepcidin are within the normal range in these patients and conclude that serum ferritin is not involved in body iron sensing. These findings are not surprising, but are nevertheless interesting and worthy of publication.

Abstract

AIM: To investigate the effectiveness of *Clostridium novyi* (*C. novyi*)-*NT* spores for the treatment of established subcutaneous pancreatic tumor in the syngeneic, immunocompetent Panc02/C57Bl/6 model.

METHODS: *C. novyi-NT* spores were applied intravenously to animals carrying established pancreatic tumors of three different sizes. Systemic immune responses in peripheral blood and spleen were examined by flow cytometry. Supplementary, cytotoxic activity of lymphocytes against syngeneic tumor targets was analyzed.

RESULTS: Application of spores identified, that (1) small tumors (< 150 mm^3) were completely unaffected (n = 10); (2) very large tumors (> 450 mm^3) responded with substantial necrosis followed by shrinkage and significant lethality most likely due to tumor lysis syndrome (n = 6); and (3) an optimal treatment window exists for tumors of approximately 250 mm^3 (n = 21). In this latter group, all tumor-bearing animals had complete tumor regression and remained free of tumor recurrence. In subsequent tumor rechallenge experiments a significant delay in tumor growth compared to the initial tumor cell inoculation was observed (tumor volume at day 28: 197.8 ± 87.3 mm^3 *vs* 500.1 ± 50.9 mm^3, $P < 0.05$). These effects were accompanied by systemic activation of immune response mechanisms predominantly mediated by the innate arm of the immune system.

CONCLUSION: The observed complete tumor regression is encouraging and shows that immunotherapy with *C. novyi-NT* is an interesting strategy for the treatment of pancreatic carcinomas of defined sizes.

Key words: Bacteriolytic immunotherapy; *Clostridium novyi-NT*; Immune response; Pancreatic carcinoma

INTRODUCTION

Spontaneous regression of tumors in patients with concurrent bacterial infections was described for the first time over 300 years ago[1]. Two centuries later, it was William Coley who developed pioneering work on a treatment strategy using bacteria. He applied-with remarkable results-a combination of *Streptococcus pyogenes* and *Serratia marcescens* to patients suffering from inoperable tumors[2,3]. With the emergence of modern chemotherapy, bacteriological therapy of cancer fell more and more into oblivion. However, in 1976 Morales *et al*[4] reintroduced the principle into the clinic with the development of a treat-

ment regimen for superficial bladder cancer using bacillus Calmette-Guerin. Remarkably, this therapy is still in use today.

It is well known that hypoxic zones in poorly vascularised or necrotic tumors are a major handicap in cancer therapy preventing effective delivery of therapeutic medications to tumor cells or limiting radiation efficacy. On the other hand, these zones of severe hypoxia offer the opportunity for tumor-specific colonization with anaerobic bacteria along with subsequent tumor destruction[5]. Anaerobic bacteria are strictly limited to growth in oxygen-deprived areas and have several advantages compared to viruses such as (1) ease of production and storage stability; (2) no interference with the genome of the recipient; and (3) the possibility of complete eradication of bacteria with antibiotics[5]. In the 1960's several reports described the lytical effects of specific clostridial strains targeting tumors by colonization of hypoxic tumor areas[6,7]. In the past few years, several *Clostridium* species have been studied for their antitumor potential[8]. In 2001, the Vogelstein group investigated a variety of anaerobic bacteria, including several *Clostridium* strains[9]. They found *Clostridium novyi* to be the best at colonizing tumors. A detoxified strain of *C. novyi* [*C. novyi non-toxic* (*NT*)] was shown to germinate and grow within the avascular regions of xenografted human cancer and to destroy surrounding tumor cells in immunodeficient mice. Similar results were obtained for the treatment of experimental murine cancer in syngeneic, immunocompetent animals. They showed complete tumor regression in up to 30% of treated animals with renal and colorectal tumors[10]. Successfully treated animals even rejected rechallenged tumors and remained disease free. The authors presumed a substantial participation of immune mechanisms in order to explain their results[10].

So far, there are no experimental data regarding the antitumoral effects of *C. novyi-NT* against pancreatic carcinomas. Our study therefore examines the efficacy of *C. novyi-NT* treatment in a syngeneic pancreatic carcinoma mouse model. These experiments demonstrated that bacteriolytic therapy is effective in eradication of pancreatic tumors, although strictly dependent on the initial tumor size. We found that (1) small tumors (< 150 mm^3) were completely unaffected; (2) very large tumors (> 450 mm^3) responded with substantial necrosis followed by shrinkage accompanied by significant lethality; and (3) an optimal treatment window exists for tumors of approximately 250 mm^3 finally resulting in long-term tumor-free survival.

MATERIALS AND METHODS

Animals and tumor cell line

Experiments were performed on female 8-10-wk-old C57Bl/6N mice (Charles River, Fa. Wiga, Sulzfeld, Germany) weighing 18-20 g. All animals were fed standard laboratory chow and given free access to water. Experiments were performed in accordance with the German legislation on protection of animals and the Guide for the Care and Use of Laboratory Animals (Institute of Laboratory Animal Resources, National Research Council; NIH Guide, vol.25, no.28, 1996).

The pancreatic tumor model using Panc02 cells was originally described in 1984 by Corbett *et al*[11]. Panc02 cells were cultivated in Dulbecco's modified Eagle's medium/Ham's F12 medium, supplemented with 10% FCS and 200 mmol/L Glutamine and were incubated at 37℃ in an atmosphere of 5% CO_2 under humidity of 95%. All media and supplements were from PAA unless stated otherwise (Cölbe, Germany).

Bacteria

Clostridium novyi-NT spores were kindly provided by Bert Vogelstein (Oncology Center, Johns Hopkins University, Baltimore, USA). Obtained spores were first cultivated on reinforced clostridial medium (Difco, Le Pont de Claix, France). About three to five days after cultivation in an anaerobic atmosphere, colonies of vegetative bacteria were transferred into cooked meat medium (Difco) for sporulation. Spores settled in the cooked meat particle layer and were purified from contaminating vegetative forms on a discontinuous Percoll gradient (70%, 55%). Aliquots of 7.5 × 10^7 spores were preserved in phosphate buffered saline (PBS) until injection.

Tumor model and treatment regimen

Under brief ether anaesthesia 1 × 10^6 Panc02 cells were injected subcutaneously (s.c.) into the right hind leg. Tumor growth was routinely controlled at least twice a week and tumor volume was estimated according to the formula: V = $width^2$ × length × 0.52.

Three groups with different tumor volumes were defined (150 mm^3, n = 10, 250 mm^3, n = 21 and 450 mm^3; n = 6). After reaching the predetermined tumor volumes, 7.5 × 10^7 spores were injected intravenously (i.v.) *via* tail vein injection in 50 μL PBS. As controls, one tumor-carrying group and one group without tumor received PBS (vehicle) alone.

Animals were euthanized at day 28 post-treatment or when they became moribund due to extensive tumor growth. Subsequently, complete tumor, spleen, mesenteric lymph nodes, femur bone marrow and blood samples were collected for further analysis.

Rechallenge experiment

After successful treatment (defined as macroscopic tumor disappearance), respective animals (n = 5) received a second dose of 1 × 10^6 Panc02 tumor cells into the left hind leg contralateral to the initial tumor cell injection site. Tumor volumes were evaluated twice a week as described above.

Flow cytometry

Flow cytometry was performed with leukocytes from peripheral blood, spleen and bone marrow. Leukocytes from spleens were isolated after homogenization and subsequent lysis of erythrocytes in lysis buffer (0.17 mol/L Tris, 0.16 mol/L NH_4Cl). Purified bone marrow cells were obtained after washing in PBS.

Whole blood cells and isolated leukocytes from spleens

and bone marrow were labelled using the following fluorescein-isothiocyanate (FITC)- and phycoerythrin (PE)-conjugated rat anti-mouse monoclonal antibodies (mAbs): CD3ε FITC (1 μg, ImmunoTools, Friesoythe, Germany), CD11b FITC, CD11c FITC, CD19 FITC, CD4 PE, CD8 PE, CD62L PE, Gr1 PE (1 μg, Miltenyi Biotec, Bergisch-Gladbach, Germany) and NK1.1 FITC (0.5 μg BD Pharmingen) followed by lysis of erythrocytes in the case of whole blood cells (FACS Lysing Solution, BD Pharmingen, Heidelberg, Germany). Negative controls consisted of lymphocytes stained with the appropriate isotypes (BD Pharmingen). Samples were analyzed on a FACSCalibur Cytometer (BD Pharmingen). Data analysis was performed using CellQuest software (BD Pharmingen).

Flow cytometric cytotoxicity assay

Lytic activity of lymphocytes (spleen) from treated animals against target cells (Panc02, CMT-93, and MC3T3-E1) was determined by flow cytometry. Prior to co-culture, target cells were labelled with CFDA-SE (carboxyfluorescein diacetate succinimidyl ester, final concentration: 2 μmol/L). Target cells without effector cells were used as negative controls. Following co-incubation for five hours at an effector to target cell ratio of 30:1 and 10:1, propidium iodide (PI) was added to measure death of target cells based on carboxylfluorescein diacetate/propidium iodide (CFDA/PI) double positive cells. Cytotoxicity was calculated according to the following formula: % cytotoxicity = experimental release-spontaneous release of target cells.

Statistical analysis

All values are expressed as mean ± SE. After proving the assumption of normality, differences between tumor control and treated animals were determined by using the unpaired Student's *t*-test. If normality failed, the nonparametric Mann-Whitney *U*-Test was applied. The tests were performed by using Sigma-Stat 3.0 (Jandel Corporation, San Rafael, CA, USA). The criterion for significance was set to $P < 0.05$.

RESULTS

Therapeutic effectiveness of C. novyi-NT is related to tumor size

Earlier experiments described complete eradication of tumors subsequent to intravenous injection of *C. novyi* spores. However, there is a lack of experimental data for the treatment of pancreatic carcinomas. This has prompted the investigation of whether bacteriolytic therapy is also applicable for this tumor entity. Different sizes of the tumor were chosen to establish an effective treatment regimen (Figure 1A).

In the first series of experiments, animals with small tumors below 150 mm^3 were treated. Macroscopically, tumor growth was completely unaffected, with tumor sizes remaining comparable to controls until the endpoint (day 21: 1036.6 ± 232.9 mm^3 *vs* 1079.1 ± 164.3 mm^3). This was most likely due to the absence of intratumoral hypoxia and necrotic areas, thereby prohibiting germination of bacteria within the tumor. To overcome this, animals with large tumors (> 450 mm^3) were employed. All tumors responded with substantial necrosis and subsequent shrinkage within a few hours ($P < 0.05$ *vs* tumor control).

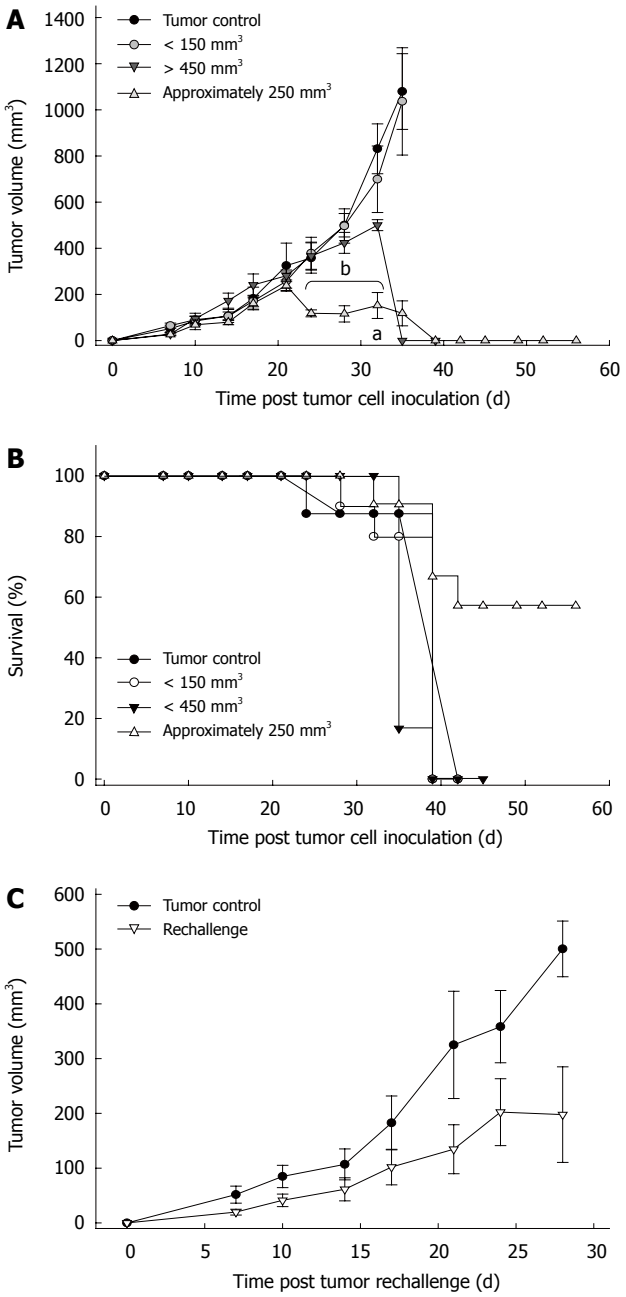

Figure 1 Data of *in vivo*-analyses of s.c. Panc02 tumors treated with *Clostridium novyi-NT* spores. A: Growth kinetics of s.c. Panc02 tumors; B: Survival curve of tumor-carrying mice after i.v. injection of *Clostridium novyi-NT* spores. For evaluation of the optimal therapeutic dose, different groups of tumor carrying mice were employed. These included tumor sizes below 150 mm^3 (n = 10), of about 250 mm^3 (n = 21) and larger than 450 mm^3 (n = 6). Experiments identified a tumor-size dependent toxicity and response rate. Small tumors were completely unaffected and remained comparable to controls. In contrast, larger tumors responded with substantial necrosis followed by shrinkage and subsequent complete regression; C: Growth kinetics of tumors after rechallenge. Successfully treated animals (n = 5) received a second tumorigenic dose of Panc02 cells at day 28 post therapy. Naïve animals were used as controls. As can be depicted from the graph, bacteriolytic therapy mediated partial protection from re-exposure to tumor cells. Values are given as the mean tumor volume (mm^3) ± SE; $^aP < 0.05$ vs tumor control; $^bP < 0.001$ *vs* tumor control; Mann-Whitney *U*-test.

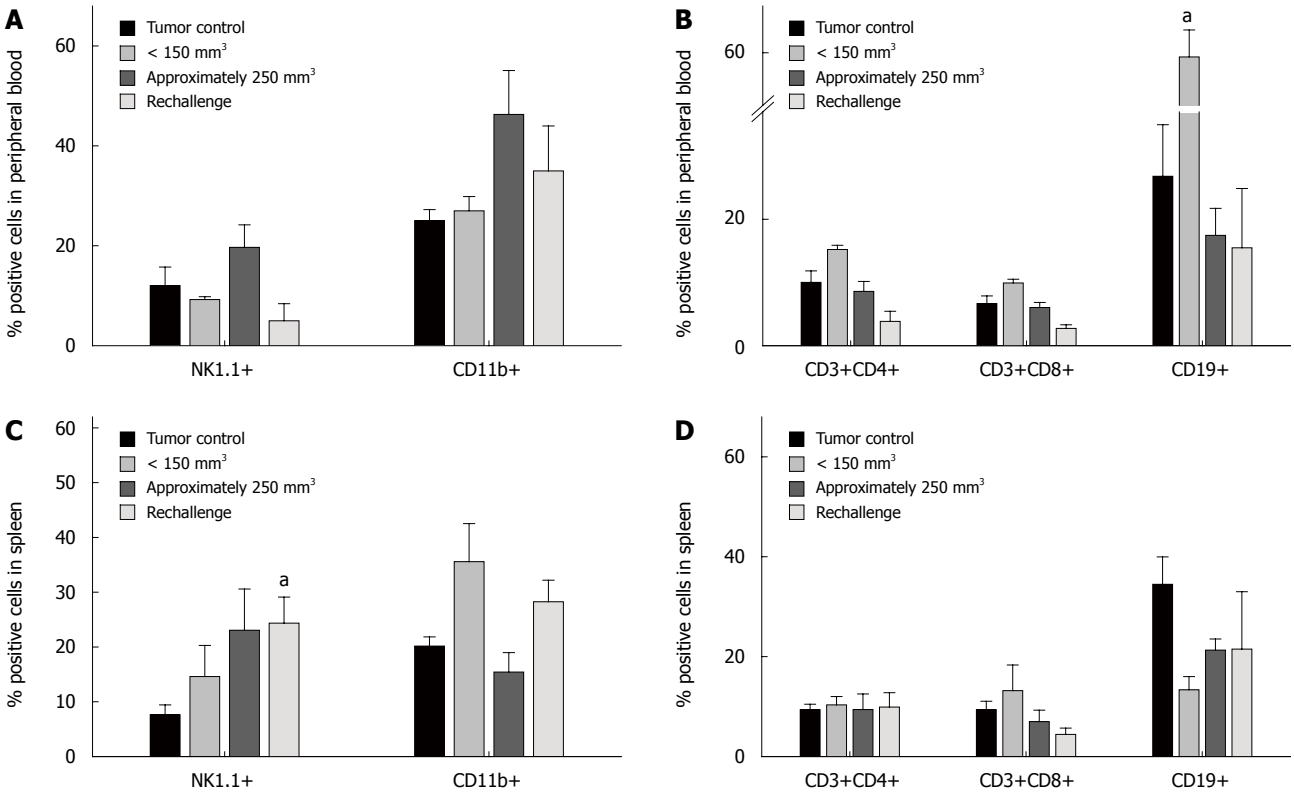

Figure 2 Flow cytometric analyses of leukocytes from peripheral blood (A, B) and spleens (C, D) in tumor control animals, of *Clostridium novyi-NT* treated animals (< 150 mm^3, approximately 250 mm^3) and after rechallenge. Bacteriolytic therapy predominantly activated the innate arm of the immune system. Values are given as mean ± SE. $^aP < 0.05$ *vs* tumor control; Mann-Whitney *U*-test.

Another group consisted of animals carrying tumors of about 250 mm^3. This tumor size was found to be optimal for *C. novyi* treatment. Tumors displayed rapid necrosis within 48 h and macroscopically disappeared 10-14 d later ($P < 0.05$ *vs* tumor control). There was no tumor regrowth until the experimental endpoint (day 31), indicative of complete tumor regression.

Toxicity of spores correlates with tumor size

Toxicity of *C. novyi-NT* spores is thought to be dependent on germination of bacteria within hypoxic regions of tumors. Accordingly, tumor-free control animals only receiving a single intravenous injection of spores displayed no clinical symptoms such as weight loss, lethargy or anorexia. Macroscopic examination of the inner organs revealed no abnormalities. Toxicity was also low in tumor-carrying animals where germination did not occur (Figure 1B). However, toxicity appeared to be greater when larger tumors were employed. We observed up to 40% lethality in mice carrying tumors of about 250 mm^3. Death was observed predominantly in the post-acute phase of infection between days 10-18. In this time, mice were cured of their tumors. Toxicity is thus related to germination of the bacteria within tumors. This finding is reinforced by the massive lethality post-treatment of larger tumors. All animals ($n = 6$) died within 24 h after spore administration.

Tumor rechallenge demonstrates partial protection

Next, we analyzed to what extent the bacteriolytic therapy not only led to tumor regression but also induced protective immunologic memory towards a re-exposure to Panc02 tumor cells. To perform these rechallenge experiments, successfully cured animals (approximately 250 mm^3) received a tumorigenic dose of Panc02 cells into the contralateral flank. Slowly growing tumors (197.8 ± 87.3 mm^3, $P < 0.05$ *vs* tumor control) developed in 4/5 mice four weeks after tumor inoculation, with one animal remaining tumor-free until the end of the experiment (Figure 1C). However, when compared with untreated, naïve mice (500.1 ± 50.3 mm^3), tumor development was significantly sustained (Figure 1C). Taken together, this indicates, that *C. novyi* therapy mediates potent antitumor reactivity *in vivo*. However, complete protective immunity was obtained in only 20% of the animals.

Immunologic effects by C. novyi NT treatment

Regression of tumors subsequent to *C. novyi-NT* treatment is thought to be, at least in part, due to the stimulation of immune response mechanisms. We therefore examined the influence of spore application on immune cells. Flow cytometric analysis of circulating leukocytes identified increased numbers of monocytes, granulocytes (CD11b$^+$) and NK cells (NK1.1$^+$) after treatment (250 mm^3 tumors), while levels of T (CD3$^+$/CD4$^+$, CD3$^+$/CD8$^+$) and B cells (CD19$^+$) were similar to controls (Figure 2A and B). Therapy of small tumors (< 150 mm^3), however, resulted in considerably elevated levels of CD19$^+$ B cells ($P < 0.05$ *vs* tumor control), but again, numbers of T cells remained

unchanged. Likewise, monocytes and NK cells showed no alteration (Figure 2B).

In spleens, *C. noyvi* mediated increases in NK cells (Figure 2C). Elevation of this cell population was highest after treatment of 250 mm^3 tumors. As well as in peripheral blood, levels of T and B cells were not affected by the application of bacteria (Figure 2D). This was also seen post-bacterial exposure in small tumors. Here, numbers of NK1.1 and CD11b positive cells were only slightly induced, while CD19 positive B cells were found to be down-regulated. Other analyzed cell populations, such as $CD11c^+$ dendritic cells and $Gr1^+$ granulocytes were also not induced (data not shown).

To sum up these findings, bacteriolytic treatment predominantly induced the innate arm of the immune system.

Functional immune responses evoked by C. novyi-NT treatment

We next examined whether immune cells isolated from treated animals were able to react against tumor cells. In a functional cytotoxicity assay, splenocytes were used as effectors. Panc02 tumor cells were lysed by immune cells from successfully treated mice. Similar results were obtained with the syngeneic colorectal cell line CMT-93 (Figure 3). However, this reaction was not restricted to tumor cells. Reactivity of splenocytes to the non-cancerous MC3T3-E1 fibroblasts was also observed, indicative of non-specific stimulation of immune cells. Thus, these effects were more likely mediated by activated NK cells than by tumor-antigen specific T cells.

DISCUSSION

The cure of cancer by severe bacterial infections was reported by W.B. Coley over a century ago. These historical observations have provided a basis for active microbial immunotherapy, which has been extensively studied in recent years. In 2001, the Vogelstein group demonstrated in pioneering work that spores of *C. noyvi-NT* are very efficient in eradicating established solid tumors[9]. These effects could be boosted when combined with standard chemotherapy[9], resulting in long-term protective immunologic memory. Similarly, other bacteria such as *Salmonella* and *Mycobacteria* have been shown to stimulate an inflammatory response with neutrophil-directed cytokines leading to a potent cellular antitumoral immune response[12-14].

Among the more frequent tumors, pancreatic cancer has an outstandingly poor prognosis. Recent treatment regimens have so far failed to substantially improve the clinical outcome of this tumor entity. Moreover, immunotherapeutic approaches aiming to specifically stimulate the host's immune system against tumor cells are rare in pancreatic malignancies. Here, we investigated the effectiveness of *Clostridium* spores for the treatment of established Panc02 tumors in the syngeneic, immunocompetent C57Bl/6 model. We found that (1) small tumors (< 150 mm^3) were completely unaffected; (2) very large tumors (> 450 mm^3) responded with substantial necrosis

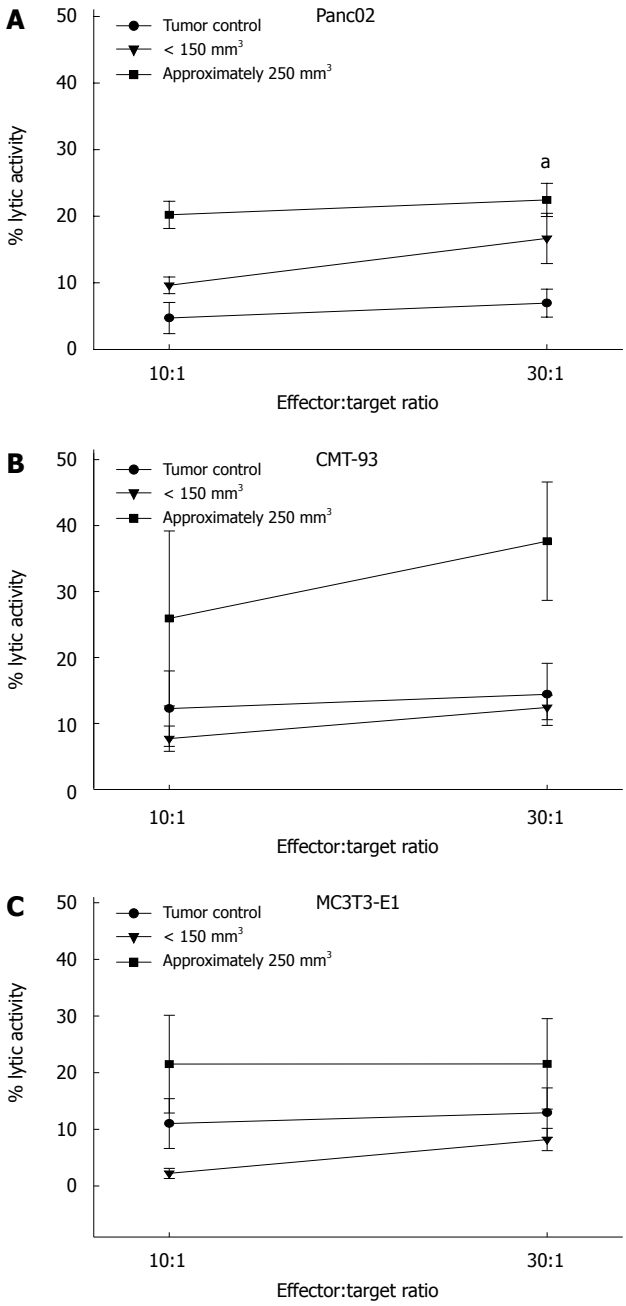

Figure 3 Quantitative analysis of cytotoxicity using flow cytometric carboxylfluorescein diacetate/propidium iodide staining. Lymphocytes were isolated from spleens and co-cultured with targets for five hours at E:T cell ratios of 10:1 and 30:1. Lymphocytes from successfully treated animals showed lytic activity against (A, B) syngeneic tumor cells with highest reactivity against CMT-93 cells at an E:T ratio of 30:1. However, cytotoxicity was found to be non-tumor specific, as reactivity was also observed against (C) non-malignant fibroblasts MC3T3-E1. Values are given as mean ± SE; $^aP < 0.05$ *vs* tumor control; *t*-test.

followed by shrinkage but accompanied by significant lethality (80%); and (3) an optimal treatment window exists for tumors of approximately 250 mm^3. These findings are, in part, consistent with previous studies in other tumor entities, where therapeutic effectiveness and toxicity were also found to be related to the size of the tumor. However, lethality was predominantly observed after combined bacteriolytic therapy, but not after administration of spores or chemotherapeutics alone even when large tu-

mors were employed[9]. In 2005, Diaz *et al*[15] described the relationship between toxicity, spore dose and tumor size. They found an increased mortality at higher spore doses injected into Balb/c mice carrying large tumors and concluded a germinating-dependent toxic effect of *C. novyi*. In our study, we also observed massive toxicity only after treatment of mice with large tumor burdens. On the other hand, mortality was absent in animals carrying no tumors or only small tumors, where anoxic areas allowing for bacterial germination were missing. It is therefore conceivable that toxicity was related to germination of the bacteria within tumors. This germination occurred rapidly in larger Panc02 tumors which contained extended areas of necrosis resulting from inadequate oxygenation and nutrition. As a consequence, massive destruction of neoplastic cells occurred, accompanied by the release of intracellular ions and metabolic by-products into the systemic circulation that may lead to metabolic complications and death. This phenomenon is recognized in the clinic as "tumor lysis syndrome" usually occurring in patients with bulky, rapidly proliferating tumors responding to treatment. Clinically, the syndrome is characterized by the development of hyperuricaemia, hyperkalaemia, hyperphosphataemia, hypocalcaemia, and acute renal failure[16]. Nevertheless, the tumor lysis syndrome appeared not to be the lethal cause in our experimental setting since clinical parameters, such as levels of serum uric acid and calcium were not altered (data not shown).

Another important fact of bacterial therapy is the activation of immune response mechanisms. It has been reported that *C. novyi* infection is associated with inflammation and subsequent development of a potent immune response. Consistent with these data, we also observed raised numbers of circulating NK cells, granulocytes and monocytes even four weeks post-infection. Of note, this immune stimulation was paralleled by additional signs of systemic inflammation like reactive splenomegaly. In subsequent rechallenge experiments, a growth retardation of tumors was observed. However, in a functional *in vitro* cytotoxicity assay, these effects were found not to be tumor specific as reactivity was also observed towards non-malignant syngeneic cells like fibroblasts. Thus, in our study, the bacterial treatment predominantly activated the innate arm of the immune system. Most likely, NK cells are the main cytotoxic cell type involved in recognition of Panc02 tumor cells. These observations are to some extent contrary to those described by Agrawal and coworkers, who achieved prevention of tumor growth subsequent to adoptive transfer of $CD8^+$ lymphocytes from tumor-carrying mice cured by *C. novyi-NT* application.

Recently, we provided convincing data that experimental pancreatic tumors can be successfully treated with the facultative anaerobic bacterium *S. pyogenes*. Living bacteria as well as bacterial lysates mediated regression of established tumors in the very same syngeneic mouse model[17,18]. Compared to these results, we found here that despite their ability to induce substantial tumor necrosis even after application of only small numbers into large tumors, *C. novyi* spores are substantially more toxic, and most importantly from the immunological point of view, are a less potent inducer of tumor-reactive T cells.

ACKNOWLEDGMENTS

We thank Professor B. Vogelstein for kindly supplying us with *C. novyi-NT* spores.

COMMENTS

Background

Pancreatic carcinoma has an outstandingly poor prognosis. This has prompted research on alternative treatment approaches that may complement conventional anticancer strategies. In this context, the therapeutic application of bacteria is equally simple and promising.

Research frontiers

Immunotherapy has repeatedly been shown to have a very strong antitumoral potential. Most groups focus on tumor antigens together with dendritic cell vaccination. Recently, several groups have developed novel antitumoral approaches using tumor-therapeutic bacterial strains.

Innovations and breakthroughs

Vogelstein and coworkers proved that anaerobic bacteria such as *Clostridium noyvi* (*C. noyvi*)-*NT* selectively germinate and grow within hypoxic regions of tumors. However, they always combined the i.v. administration of lethal toxin-free spores of *Clostridium novyi* with standard chemotherapy. This is the first report on the therapeutic effectiveness of *Clostridium novyi*-spores as a single agent for the treatment of pancreatic carcinoma. Additionally, the study showed that this effect is due to an immunological response dominated by the innate immune system.

Applications

The observed complete tumor regression is encouraging and shows that immunotherapy with *Clostridium novyi*-spores is an interesting strategy for the treatment of pancreatic carcinomas of defined sizes.

Peer review

The study investigates a novel approach for pancreatic cancer treatment through applying anaerobic bacteria. The idea behind this approach is that anaerobic bacteria which are strictly limited to growth in oxygen-deprived areas would colonize in tumors which have hypoxic areas but not in normal organs. The study investigates the effectiveness of *C. novyi-NT* spores on the established tumor in a subcutaneous model of pancreatic cancer. The authors show that the effects of *C. novyi-NT* on the pancreatic tumor depend on the size of the tumor.

Abstract

AIM: To investigate aberrant DNA methylation of CpG islands and subsequent low- or high-level DNA microsatellite instability (MSI) which is assumed to drive colon carcinogenesis.

METHODS: DNA of healthy individuals, adenoma (tubular or villous/tubulovillous) patients, and colorectal carcinoma patients who underwent colonoscopy was used for assessing the prevalence of aberrant DNA methylation of human DNA mismatch repair gene mutator L homologue 1 (*hMLH1*), Cyclin-dependent kinase inhibitor 2A (*CDKN2A/p16*), and O-6-methylguanine DNA methyltransferase (*MGMT*), as well as their relation to MSI.

RESULTS: The frequency of promoter methylation for each locus increased in the sequence healthy tissue/adenoma/carcinoma. *MGMT* showed the highest frequency in each group. *MGMT* and *CDKN2A/p16* presented a statistically significant increase in promoter methylation between the less and more tumorigenic forms of colorectal adenomas (tubular *vs* tubullovillous and villous adenomas). All patients with tubulovillous/villous adenomas, as well as all colorectal cancer patients, showed promoter methylation in at least one of the examined loci. These findings suggest a potentially crucial role for methylation in the polyp/adenoma to cancer progression in colorectal carcinogenesis. MSI and methylation seem to be interdependent, as simultaneous *hMLH1*, *CDKN2A/p16*, and *MGMT* promoter methylation was present in 8/9 colorectal cancer patients showing the MSI phenotype.

CONCLUSION: Methylation analysis of *hMLH1*, *CDKN2A/p16*, and *MGMT* revealed specific methylation profiles for tubular adenomas, tubulovillous/villous adenomas, and colorectal cancers, supporting the use of these alterations in assessment of colorectal tumorigenesis.

INTRODUCTION

Chromosomal instability and microsatellite instability (MSI) are two well-known pathways of colorectal carcinogenesis[1,2]. Recently, the CpG island methylation phenotype has been added to these two pathways. This novel pathway is characterized by the concordant methylation of the promoter regions of multiple genes that play a role in carcinogenesis[3], an alteration that has also been associated with the process of aging. CpG island DNA methylation, the most extensively studied epigenetic alteration in neoplasms, represses gene transcription by excessive and aberrant methylation of CpG-rich regions, called "CpG islands", in the 5' region of genes, leading to transcriptional silencing of the promoter and therefore inactivation of the gene[4,5].

Aberrant DNA methylation of CpG islands (CpG island methylator phenotype, CIMP) is also linked with subsequent low- or high-level DNA MSI[6-8]. Methylation of the human DNA mismatch repair gene mutator L homologue 1 (*hMLH1*) is the principal mechanism underlying the pathogenesis of sporadic high-level MSI (MSI-H) colorectal cancer (CRC)[6] and methylation of another DNA repair gene, O-6-methylguanine DNA methyltransferase (*MGMT*), is linked with low-level MSI (MSI-L)[7,8]. Moreover, epigenetic inactivation of the cyclin-dependent kinase inhibitor 2A (*CDKN2A/p16*) by methylation has been observed in both adenomas and CRC[9,10]. These hypermethylated genes are not only probable pathogenic events in the polyp to cancer progression sequence, but are also neoplasm-specific molecular events that have the potential to be used as molecular markers for pre-malignant tumors in the colon.

In this study, we used high-sensitivity methylation-specific polymerase chain reaction (PCR) (MSP) assays for *hMLH1*, *CDKN2A/p16*, and *MGMT*, three genes previously shown to be aberrantly methylated in pre-malignant neoplasms in the colon[6-10]. We have applied these assays to DNA extracted from blood, normal tissue, adenomas (tubular, villous, or tubulovillous), and colon cancer of patients who underwent first time colonoscopy at the University Hospital of Ioannina, Greece. We assessed the prevalence of aberrant DNA methylation and its correlation to MSI status, as well as the temporal order and the time of their appearance during the different steps of adenoma to carcinoma progression, in an attempt to identify their possible use as molecular markers of colon carcinogenesis and furthermore their pathogenic role in the transformation of colon neoplastic adenomas to carcinoma.

MATERIALS AND METHODS

Study design

The study was designed to include patients undergoing first time colonoscopy for routine clinical indications, organized in four different groups, on account of their colonoscopic and histopathological data. Patients without colonoscopic findings and histologically normal mucosa consisted group I (normal individuals - G I). Patients with tubular adenomatous polyps comprised group II (G II). Patients with polyps of increased tumorigenic potential (tubulovillous or villous adenomatous polyps) formed group III (G III), and, finally, patients with colonoscopic findings and histological evidence of CRC comprised group IV (G IV).

Patients

Seventy nine patients (44 males and 35 females, mean age: 62.5 ± 13.9 years) who underwent colonoscopy for routine clinical indications or for colon cancer screening at the Hepatogastroenterology Unit of the University Hospital of Ioannina, were included in this study, after approval from the Review Board of the University Hospital of Ioannina. Each group consisted of approximately 20 consecutive patients defined by histopathological analysis. Thus, we obtained 18 patients with tubular adenomas (10 M/8 F), 21 patients with tubulovillous or villous adenomas (12 M/9 F), and 20 colon cancer cases (11 M/9 F). Finally, 20 adenoma-free patients matched by sex and age (11 M/9 F) formed the control group.

The study was performed on freshly obtained lesions from adenomas or cancerous tissue that were resected at the time of colonoscopy. Matched normal colorectal mucosa was obtained from the resection margin that was furthest from any malignant lesion. Blood samples withdrawn at the time of colonoscopy were also included in this study. Patients with a prior history of inflammatory bowel disease, genetic CRC syndromes, or any other cancers, were excluded from our study.

Collection of tissue and blood DNA samples

DNA from the blood, fresh normal, and abnormal tissue of patients who underwent colonoscopy was extracted using the QiaAmp DNA Mini Kit (Qiagen GmbH, Hilden, Germany).

Methylation-specific PCR

Methylation of the CpG promoter region of the three genes *hMLH1*, *CDKN2A/p16*, and *MGMT* was determined by MSP after bisulfite-modification of DNA samples (blood, cancerous, and non-cancerous tissue) as previously described[11,12]. These three genes have been

employed in several earlier methylation studies of CIMP and CRC. In brief, the procedure was as follows: The extracted DNA underwent bisulfite modification (2 μg DNA is necessary for each experiment) using the EZ DNA methylation Gold kit (Zymo Research, Orange, CA) according to the manufacturer's instructions. The modified DNA was used immediately for MSP or stored at -20℃ for further analysis. The bisulfite-treated DNA was subject to MSP in a blinded manner using primer pairs designed to specifically amplify the methylated or unmethylated alleles for the respective genes (Table 1). Each PCR reaction mix consisted of a total volume of 50 μL containing: 3.5 mmol/L of $MgCl_2$ (2 mmol/L for the methylated reaction); 1 × PCR Gold Buffer (Applied Biosystems, Weiterstadt, Germany); 250 μmol/L deoxynucleotide triphosphates mixture (Promega, Madison, USA); 0.1 μmol/L of forward and reverse primers (Invitrogen GmbH, Karlsruhe, Germany); 2.5 Units of AmpliTaq Gold DNA polymerase (Applied Biosystems, Weiterstadt, Germany), and the appropriate amount of bisulfite-treated DNA. The thermocycler conditions were in general as follows: 95℃ for 10 min; 55 cycles of 30 s each at 95℃, specific annealing temperature for 30 s, and 1 min at 72℃; and a final extension of 10 min at 72℃. The PCR products were then subjected to horizontal gel electrophoresis on a 25 g/L agarose gel, stained with ethidium bromide, and visualized under UV transillumination. All MSP assays were repeated at least twice to validate the results. A set of known methylated and unmethylated control DNA samples was included in each round of bisulfite treatment.

The specificities of the MSP assays were confirmed by sequence analysis of aberrant methylation bands using the Thermo Sequenase Cy5.5 Dye Terminator Cycle Sequencing Kit (Amersham Biosciences, Piscataway, USA), in a LI-COR 4200 DNA sequencer (LI-COR Inc., USA), in parallel with the corresponding normal DNA samples, as described previously[12].

MSI testing

The MSI status of the 79 patients was assessed using the reference panel of five pairs of microsatellite primers: BAT25, BAT26, D2S123, D5S346, and D17S250, known as Bethesda markers[13]. PCR reactions and primer sequences have been described previously[14]. The 5'-labelled PCR products are loaded onto a 66 cm denaturing 6 mol/L urea-acrylamide gel and analyzed in a LI-COR 4200 DNA sequencer. Each PCR was run twice to ensure reproducibility of results in case the band shifts were not clearly informative in the first attempt. The MSI phenotype was identified by the presence of abnormal bands in the polyp/adenoma or carcinoma tissue DNA that were not present in blood or normal tissue DNA. MSI high (MSI-H) polyps/adenomas or carcinomas were defined as those where two of the five Bethesda markers were unstable. MSI low (MSI-L) samples were defined as a shift in only one of the five markers. Samples showing no allelic shifts were termed as MSI stable (MSS).

RESULTS

MSP for hMLH1, CDKN2A/p16 and MGMT

Table 2 shows the methylation patterns of the four distinct patient groups for the promoters of the genes examined. Promoter methylation was detected even in the G Ⅰ group (healthy individuals). In this case, only patients aged over sixty showed methylation of some promoters (with one exception for MGMT concerning a 28-year-old woman). This indicates that methylation in normal patients is correlated to the age. By contrast,, in the patients of the G Ⅱ, G Ⅲ, and G Ⅳ groups, the frequency of methylation is similar in older and younger patients (> 60 years and $\leqslant 60$ years respectively, statistical data not shown), indicating that factors other than age are probably responsible for promoter methylation in these groups (Figure 1).

Among all samples investigated, promoter methylation of *hMLH1* or *CDKN2A/p16* was detected only in tissue samples and not in blood (indicating that methylation of these promoters is somewhat tissue/site specific). *MGMT* methylation was detected in tissue as well as in blood samples. The frequency of *MGMT* methylation was similar in blood and tissue samples only for the G Ⅰ patient group (46% in tissues *vs* 40% in blood, $P = 0.704$), as has been reported before and is also age related. However, in patient groups G Ⅱ, G Ⅲ, and G Ⅳ a significantly increased ratio in tissue samples *vs* blood samples (39% in tissues *vs* 6% in blood, $P = 0.022$; 76% *vs* 41%, $P = 0.035$ and 90% *vs* 64%, $P = 0.043$ for G Ⅱ, G Ⅲ and G Ⅳ, respectively) was observed. This implies that methylation of *MGMT* is

[1]Statistically significant in comparison to the previous group. M: Methylated; U: Unmethylated.

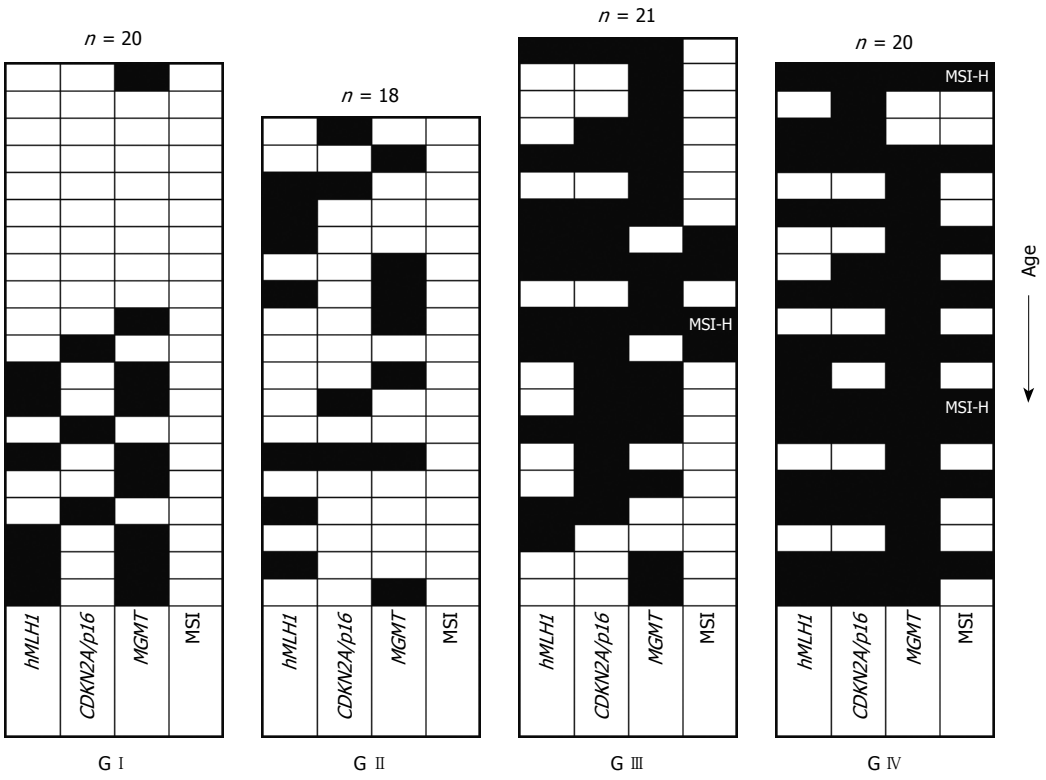

Figure 1 CpG island methylation at three loci and the microsatellite instability phenotype in G I (n = 20), G II (n = 18), G III (n = 21) and G IV (n = 20). The rows represent individual cases and the dark boxes indicate methylation or microsatellite instability (MSI) phenotype; the three high-level MSI (MSI-H) cases are also indicated.

also in part tissue/site specific. Another explanation for this could also be a low incidence of circulating cells having methylated promoters. In any case, this will require further investigation. The frequency of promoter methylation for each locus, as well as the number of methylated loci, increased from group G I to G IV (Table 2 and Figure 1), with *MGMT* showing a higher ratio. All of the methylated tissue samples also displayed evidence of unmethylated *hMLH1*, *CDKN2A/p16*, and *MGMT*, indicating that only one of the alleles is methylated or that only a part of the tissue contained cells that carried the methylated allele of the examined promoters (Figure 2).

It must be noted that *hMLH1* showed similar levels of promoter methylation between groups G II and G III (39% *vs* 48%, P = 0.576) in contrast to *CDKN2A/p16* and *MGMT*, which showed clearly increased levels of methylation in group G III (22% *vs* 67%, P = 0.008, and 39% *vs* 76%, P = 0.025, respectively), suggesting that *hMLH1* promoter methylation is an early phenomenon in comparison to polyp formation, while methylation of *CDKN2A/p16* and *MGMT* is correlated to the progression of polyps to more tumorigenic cases.

CDKN2A/p16 methylation was usually accompanied by methylation of another locus in tumorous and highly tumorigenic tissues (13/14 for G III and G IV), in contrast to the normal and low tumorigenic tissues (0/3 for GI and 2/4 for G II respectively). *MGMT* follows a rather different pattern, being in many cases the only methylated locus (5/7, 6/16, and 5/18 for G II, G III and G IV, respectively). The pattern for *hMLH1* is even more complicated (Figure 1).

Of the 18 tubular adenoma patients examined 14 (77%) showed methylation in at least one of the three tested loci, while four (22%) showed no evidence of pro-

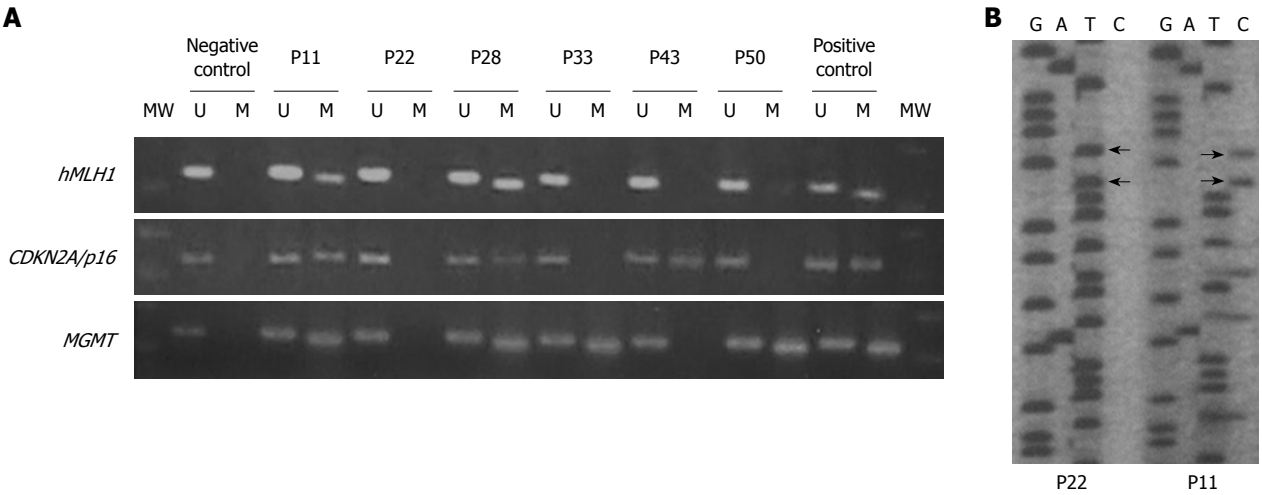

Figure 2 Methylation-specific polymerase chain reaction and sequence analysis. A: Methylation specific polymerase chain reaction (PCR) for *hMLH1*, *CDKN2A/p16* and *MGMT* promoter methylation. In this panel, the MSI-H patients P11 and P28 show promoter hypermethylation for *hMLH1*, *CDKN2A/p16*, and *MGMT*. The low-level MSI (MSI-L) patient P33 shows promoter hypermethylation for *MGMT*. The MSI stable (MSS) patient P22 does not show promoter hypermethylation for any gene, whereas the MSS patient P43 shows promoter hypermethylation only for *CDKN2A/p16*.The healthy MSS patient P50 shows promoter hypermethylation only for *MGMT*; B: Sequence analysis of methylation-specific PCR (MSP) PCR products of *hMLH1* promoter. The sequence analysis of MSP products for patients P22 (unmethylated) and P11 (methylated) reveals the complete transition of non-methylated cytosines to thymine (indicated by arrows) after bisulfite treatment. There also cytosines that are partially methylated, as indicated from the co-existence of T and C. The sequence from the bottom to top: 5'-TGG tGT TTG AtG TtG TGT TtG tGG GTA GT-3' P22 (unmethylated); 5'-TGG t(C)GT TTG At(C)G Tt(C)G TGT TCG CGG GTA GT-3' P11 (methylated); 5'-TGG CGT TTG ACG TCG TGT TCG CGG GTA GT-3' (wild type). Lower case letters represent thymines derived from unmethylated cytosines, the letters in parenthesis represent partially methylated cytosines and the bolds the CpG islands. MW: Molecular weight; M: Methylated promoter; U: Unmethylated promoter.

moter methylation, and only one (6%) showed methylation in all loci (Figure 1). All 21 G Ⅲ, as well as the 20 G Ⅳ patients (100%), showed promoter methylation in at least one locus. In particular, 6/21 (28%) and 11/20 (55%) for group G Ⅲ and G Ⅳ, respectively, were methylated in all loci, suggesting a potentially crucial role of methylation in the progression of CRC.

MSI status and hMLH1, CDKN2A/p16, and MGMT promoter methylation

According to our introductory remarks concerning the linkage between methylation status and MSI phenotype, we analysed the MSI status using the five Bethesda markers recommended by the NCI workshop[13]. Of the 79 samples examined, 66 (83%) were MSS, 10 (13%) were MSI-L and three (4%) were MSI-H (Figure 1). Only the G Ⅲ and G Ⅳ patients showed MSI, which reached 14% (3/21) for MSI-L and 5% (1/21) for MSI-H for the patient group G Ⅲ, whereas the corresponding percentages were 35% (7/20) and 10% (2/20) for MSI-L and MSI-H, respectively, in the G Ⅳ patient group.

Of the five Bethesda markers used for MSI analysis, BAT25 and BAT26 showed instability only in the MSI-H patients. On the other hand, the MSI-L phenotype was exclusively restricted to dinucleotide markers D2S123, D5S346, and D17S250 (3, 4 and 3 cases respectively). In the 13 cases with MSI-H or MSI-L, the following positive rates were obtained: 23% (3/13) in BAT26, 23% (3/13) in BAT25, 46% (6/13) in D2S123, 54% (7/13) in D5S346, and 46% (6/13) in D17S250, which is in accordance with previous references for cancer patients[15], as well as for patients with adenomatous polyps[16,17]. In a larger cohort of MSI-H cancer patients, Arnold *et al*[18] showed that the specificity of Bethesda markers was best for BAT26 and BAT25, with 99% and 95%, respectively. It is important to note that simultaneous *hMLH1*, *CDKN2A/p16*, and *MGMT* promoter methylation was present in 8/9 G Ⅳ patients, with the MSI phenotype as also being present in 2/4 patients of group G Ⅲ. All MSI-H patients showed methylation in all loci. From the remaining three patients, the two in group G Ⅲ showed methylation in two promoters (*hMLH1* and *CDKN2A/p16*) and the one G Ⅳ patient only in the *MGMT* promoter. The latter case also showed instability for the D2S123 marker. In the previous work of Arnold *et al*[18], all Bethesda markers, except the dinucleotide repeat D2S123, had a high detection rate (up to 90%) for the combination of MSI-H cancers and *hMLH1* methylation. This suggests that MSI-H cancers might originate from different pathways, e.g. one being caused by silencing the *hMLH1* gene and others by as yet unrecognized mechanisms.

DISCUSSION

The transformation of normal colon epithelial cells to adenomas, and then to cancer, is believed to be an evolutionary process in which neoplastic cells acquire heritable genetic and epigenetic alterations that drive the process of carcinogenesis[19]. Gene promoter hypermethylation is increasingly recognized to play an important role in cancer development through silencing gene transcription. It is also likely that the genetic and epigenetic alterations co-operate to promote tumor formation, and that the detection of colon polyps or adenomas that present aberrant promoter methylation might identify colonic epithelium that is at significant risk of acquiring genetic alterations

that will lead to colon tumor formation[20].

A number of studies have investigated the concordant methylation of multiple genes in colon adenoma[10,21,22]. Recently, aberrant promoter methylation found in different polyp forms[23,24] serves for a better understanding of aberrant CpG island methylation in the polyp/adenoma/carcinoma sequence of colorectal tumorigenesis. Thus, CIMP has been identified during several key stages in colon tumorigenesis, including aberrant crypt foci (ACF, the earliest identifiable neoplastic lesions in the colon), hyperplastic, tubular and tubulovillous/villous polyps, sporadic serrated adenomas, and tumors[3,10,22,25,26], suggesting that DNA methylation might be a pivotal event in the development of CRC. Furthermore, the aberrant methylation of *MGMT* and *hMLH1* has been shown to silence some genes and to result in cancer promoting events, such as an MSI phenotype or *k-RAS* mutation[27,28].

The molecular genetics of colorectal neoplasms have been studied extensively, but few studies have addressed the clinical and pathological associations in prospectively defined patient populations. Therefore, we studied specific promoter-methylation in a cohort that underwent colonoscopy including healthy individuals, polyp-bearing patients (more or less tumorigenic), as well as CRC patients.

Although we employed the MSP assay to detect methylated *hMLH1*, *CDKN2A/p16*, and *MGMT* DNA in the blood samples of patients of our cohort, we were able to detect methylated DNA in blood samples only for the *MGMT* promoter in all patient groups, including those with CRC. We note that Grady *et al*[11] used MSP in a study of 20 patients, detected methylated *hMLH1* DNA in the serum in 30% of patients with sporadic MSI colon cancer. This difference with our results might be attributed to the small number of MSI cancer patients of our cohort or to a different methylation site on the promoter.

We also observed increasing frequencies of promoter methylation as well as an increased number of methylated loci moving from group G Ⅰ to group G Ⅳ, for the three genes examined, which is in accordance with the data of Lee *et al*[29]. They also observed a stepwise increase in the number and frequency of methylated genes through the stages of multistep colorectal carcinogenesis in a study including twelve loci.

Adenomas with a villous component are generally larger than tubular adenomas and have been associated with a higher risk of CRC[30-32]. A number of studies have reported higher rates of methylation in adenomas with tubulovillous or villous histology (TVAs and VAs)[10,23,24,33,34] as compared to tubular adenomas (TA). Our study also demonstrated that methylation occurs more frequently in patients with TVAs/VAs (G Ⅲ) in comparison to patients with TAs for *MGMT* and *CDKN2A/p16* (statistically significant). By contrast, for *hMLH1,* the two groups showed a similar ratio. An increase in *MGMT* methylation has been demonstrated by other studies: 38% to 61% by Petko *et al*[23], 30% to 65% by Kim *et al*[33], and 37% to 87% by Kakar *et al*[24]. The higher rates of *MGMT* methylation in our study in comparison to previous ones could be attributed in part to the use of fresh tissue samples instead of paraffin-embedded tissue samples. Our results also showed an increased frequency of CDKN2A/p16 comparable with that of Petko *et al*[23], who found a ratio of 10% in the methylation of *CDKN2A/p16* for HPs and up to 30% for the adenomatous cases.

Furthermore, in our study, methylation, at least in one locus, reached 100% for TVAs/VAs and cancer patients, which is a higher value than that shown by Rashid *et al*[10].

It is likely that several different methylation pathways operate in CRC progression. Methylation of *MGMT* and *CDKN2A/p16* loci that are found to increase from TAs to TVA/VA could be a result of the adenoma to carcinoma progression, whereas methylation of *hMLH1* might be an initial step strongly associated with MSI-mediated carcinogenesis. The higher frequency of methylation in all loci for cancer patients compared to TVAs/VAs patients, as well as the increase in methylation from TAs to TVAs/VAs for *MGMT* and *CDKN2A/p16* supports this hypothesis.

The fact that MSI is evident in TVAs/VAs and that MSI and aberrant promoter methylation are observed simultaneously, suggests that MSI and hypermethylation are dependent on each other. As it has been shown before, that among 10% to 15% of the patients with colon cancer who have MSI, approximately 70% to 80% exhibit epigenetic gene silencing of the mismatch repair gene, *hMLH1*[6,27,35]. Moreover, a minor fraction of MSI-L and MSS cancers also appear to be methylated at the *hMLH1* promoter[36]. In our study, all MSI-H patients and 9/10 MSI-L patients showed simultaneous promoter methylation of *hMLH1,* while the remaining one MSI-L patient showed methylation of *MGMT*. However, not all MSI-L patients show inactivation of *MGMT* by promoter methylation, as we demonstrated for two of the G Ⅲ patients with the MSI-L phenotype (Figure 2).

The present study used MSP for detecting methylated alleles. MSP is a qualitative assay and does not provide quantitative information. Thus, the methylation detected by the MSP assay might not reflect gene expression, because the assay can detect only one methylated allele among 1000 unmethylated ones, and thus the vast majority of tumor cells may not harbor CpG island methylation of the given gene. The present study also shows that the methylated alleles of certain genes are present at an early stage of tumorigenesis, and that the number of genes with methylated alleles increases along the polyp/adenoma/carcinoma sequence, with *MGMT* being the most methylated gene.

In conclusion, our data indicates that aberrant CpG island hypermethylation occurs early and accumulates during multistep colorectal carcinogenesis, and that a temporal order exists in the methylation of tumor related genes. Furthermore, MSI is tightly connected to *hMLH1* as well as to *MGMT* promoter methylation, indicating that inactivation and/or overloading of the mismatch repair system might have a crucial role in driving CRC progression.

COMMENTS

Background

Colorectal carcinogenesis is a multistep process in which the progressive accumulation of genetic and epigenetic changes leads to a malignant transformation of normal epithelial cells to adenoma and, moreover, to cancer of the colon. CpG island DNA methylation, the most extensively studied epigenetic alteration in neoplasms, is characterized by the concordant methylation of the promoter region of many tumor suppressor and DNA repair genes, such as *hMLH1*, *CDKN2A/p16*, and *MGMT*, although their influence on disease progression remains inconclusive.

Research frontiers

Epigenetic changes usually begin very early in carcinogenesis, they are potentially reversible, and they can be thought of as one hit of the two-hits required for inactivation of carcinogenesis-related genes. For this reason, detection of aberrant methylation is important for early diagnosis, prognosis, and subsequent treatment of patients affected by this disease.

Innovations and breakthroughs

The frequency of promoter methylation for each promoter locus increases in the healthy tissue/adenoma/carcinoma sequence. *MGMT* shows the highest frequency in each group. *MGMT* and *CDKN2A*/*p16* present a statistically significant increase in promoter methylation between the less and more tumorigenic form of colorectal adenomas (tubular *vs* tubullovillous and villous adenomas). All tubulovillous/villous adenomas bearing patients, as well as all colorectal cancer patients, showed promoter methylation in at least one of the examined loci. These findings suggest a potentially crucial role for methylation in the polyp/adenoma to cancer progression in colorectal carcinogenesis. Microsatellite instability (MSI) and methylation seem to be dependent on each other, as simultaneous *hMLH1*, *CDKN2A*/*p16*, and *MGMT* promoter methylation was present in 8/9 colorectal cancer patients showing the MSI phenotype.

Applications

The results presented here show that a series of genetic and epigenetic molecular changes drives the next step during tumorigenesis in colorectal cancers, which results in a different molecular profile for each step. This underlines the need for a detailed record of the molecular situation, in order to establish the most efficient treatment for the patient. Prospective studies supplemented by the conventional study of prognostic factors, could improve the quality and accuracy of patients' prognosis and aid design of more efficient treatments.

Terminology

Epigenetic changes: Heritable changes in gene structure that do not include the changes in DNA sequence. CpG islands: CpG rich areas located in the promoter regions of many genes. CpG island methylation: The addition of a methyl group to a cytosine residue that lies next to guanine within CpG dinucleotides. Aberrant *de novo* methylation of CpG islands within the promoter region might lead to silencing of gene transcription through a complex process involving chromatin condensation and histone deacetylation. MSI is a change in the length of DNA microsatellites due to the insertion or deletion of repeating units (usually 1-5 nucleotides long), caused by defects in mismatch repair genes (*MLH1*, *MSH2*, or *MSH6*, and others) or methylation of the *MLH1* promoter.

Peer review

In this study, Psofaki *et al* investigated promoter methylation of *hMLH1*, *p16* and *MGMT*, as well as MSI, in a cohort of samples from patients underwent colonoscopy. They found accumulation of promoter methylation events during colorectal tumor progression. Promoter methylation and MSI seem to be dependent on each other. These results confirm that epigenetic inactivation is an important mechanism of tumor suppressor gene silencing. The study was well designed and the results are interesting. The manuscript is well written and includes potentially interesting findings.

Abstract

AIM: To investigate survival in patients treated with FOLFOX followed by primary site resection or palliative surgery for incurable metastatic colorectal cancer.

METHODS: Between 2001 and 2009, a total of 98 patients with colorectal adenocarcinoma and non-resectable metastases were diagnosed and treated with the new systemic agent chemotherapy regimen FOLFOX. Primary site resection was carried out in 38 patients, creation of a colostomy or bypass without resection was carried out in 36 patients, and 23 were not operated on because of advanced disease. The survival times of patients in different groups were analyzed.

RESULTS: There were no differences between the patients regarding their general condition, concurrent disease, or tumor stage according to AJCC classification. The median survivals of the three groups were 30.6, 20.8, and 12.7 mo (log-rank *P* value < 0.05), respectively. The postoperative complication rate was higher in the primary site resection group than in the palliative surgery group.

CONCLUSION: The results indicate that there are benefits from primary site resection for incurable metastatic colorectal cancer with systemic chemotherapy.

Key words: Colorectal cancer; Chemotherapy; Primary resection; Palliative surgery; FOLFOX; FOLFIRI

INTRODUCTION

Colorectal cancer (CRC) is the most common cancer worldwide. The estimated 5-year survival rate ranges from 90% in patients with stage 1 disease to 10% in those with metastatic CRC (mCRC). Approximately 20% of patients with primary CRC present with stage 4 metastatic disease. For many years, the standard treatment for patients with mCRC has been systemic chemotherapy with fluorouracil (FU) and combination therapy. The standard treatment remains 5-FU based. In the past five years, chemotherapy has progressed dramatically and shifted from FU to the newer agents irinotecan, oxaliplatin, bevacizumab, and cetuximab. Patients treated with oxaliplatin, 5-fluorouracil, and leucovorin (FOLFOX) displayed a median survival of 19.5 mo which is the longest survival reported in a phase 3 trial[1]. Data from this and other trials suggest that patient survival might be prolonged with adjuvant chemotherapy; therefore the role of surgical treatment in these patients is controversial.

In localized (non-metastatic) disease, surgery is the primary treatment and can be curative. On the other hand, surgical resection of the primary lesion for patients with mCRC is indicated mainly to manage symptoms such as obstruction, perforation, or bleeding, but is of uncertain

benefit in the absence of these symptoms. Patient-dependent factors, such as age, medical comorbidity, extent of distant metastases, and localized invasion are among the factors that influence the decision to perform elective resection. The possible benefit of chemotherapy in conjunction with surgical management is unproven.

This study was designed to compare long-term survival and perioperative outcome in patients with incurable metastatic CRC treated with FOLFOX followed by either primary lesion resection, or palliative surgical management (colostomy or bypass).

MATERIALS AND METHODS

Patients

This retrospective, observational study was done using our hospital cancer database. From 2005 to 2009, all patients who underwent systemic treatment with FOLFOX for CRC at our hospital were identified and reviewed. Patients with non-resectable CRC at the time of diagnosis or operation were included in the study. Patients were excluded if they had metachronous metastasis from previous completely resected CRC, or they could not undergo any operation due to severe comorbidity, progression of cancer, or unwillingness to accept surgery. The remaining patients were stratified into two groups. In addition to chemotherapy, patients undergoing resection of their primary lesion were included in the primary site resection group, whereas those who underwent a bypass or stoma operation without resection for relief of obstruction or bleeding were included in the palliative surgery group. Demographics, comorbidity, and cancer-specific information were evaluated for each patient, including tumor location, grade, lymph node metastasis, liver, lung and peritoneal metastasis, survival, and mortality. Comorbidity was graded using the Charlson index. The location and volume of metastatic disease were evaluated by computer tomography and by direct visualization during surgery. Each tumor stage was coded according to the TNM classification as described in the AJCC. Patients with hepatic metastatic disease were further classified according to the volume of hepatic parenchymal replacement: < 25% (H1), 25 to 50% (H2), and > 50% replacement (H3). Patients with pulmonary and peritoneal involvement were stratified according to the appearance of their CT scan's (Table 1).

The FOLFOX4 protocol of systemic chemotherapy is as follows: Leucovorin (LV; 200 mg/m^2 per day in a 2-h infusion), followed by bolus 5-FU (400 mg/m^2 per day), and 600 mg/m^2 5-FU daily in a 22-h infusion, day 1 and 2 every 2 wk, plus oxaliplatin, 85 mg/m^2 (2-h infusion) on day 1, were administered through an implantable port and a disposable or electronic pump. Treatment was continued until progressive disease occurred (PD) or unacceptable toxicity occurred, or until the patient chose to discontinue treatment.

Statistical analysis

The principal outcome was survival. Survival was defined as the time from initiation of treatment, either chemotherapy or surgical operation, to the time of death. For patients who were alive at the time of analysis, data on survival were censored at the time of the last contact. The primary statistical analysis compared survival times between the two groups. Secondary analysis was conducted by comparing subgroups after excluding T4 patients. The Kaplan-Meier method was used to estimate actual control and survival curves. The log-rank test was used to evaluate the survival difference between two groups. All the *P* values were 2-sided and the level of significance was set at 0.05. The statistical analysis was conducted using JMP version 6.

RESULTS

Patient characteristics

Between 2005 and 2009, 172 patients were treated with FOLFOX in our hospital. Of these, 98 patients had

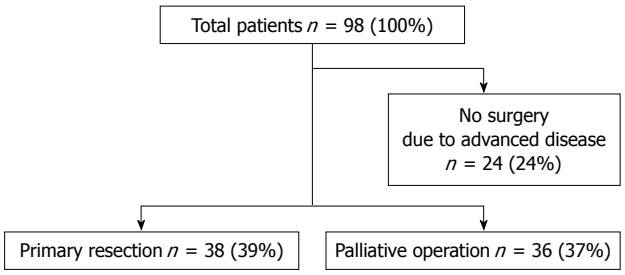

Figure 1 Breakdown of cohort by primary resection or palliative operation.

metastatic, locally advanced non-resectable CRC. Of these, 38 patients underwent initial resection of only their primary lesion without concomitant hepatic or pulmonary metastasectomy. Thirty-six patients did not undergo resection of their primary lesion, but had a palliative operation to alleviate symptoms of bleeding and obstruction, and 24 patients were excluded because they were not surgical candidates. This last group had a poor prognosis, with a median survival of 12.7 mo (Figure 1). Median age of the primary site resection group was 61 years (range 50-79 years) compared to 61 years (range 31-83 years) in the palliative surgery group. Primary tumor sites in both groups are shown in Table 1. There were no significant differences in the distribution of age, sex, primary site location, comorbidity, and metastatic disease, except for the T factor. Patients in the palliative surgery group were found to have more invasive and higher T factor lesions compared with the primary site resection group.

Chemotherapy

All patients were initially treated with FOLFOX4. The median duration of FOLFOX was 10 courses in primary site resection group and 11 courses in the palliative surgery group. The corresponding rates of response were 23% and 22%, respectively (P = 0.48). A total of 26 patients changed treatment to FOLFIRI (Irinotecan, Folinic acid, and 5-FU), 12 primary site resection patients and 14 palliative surgery patients. Bevacizumab and cetuximab were available from 2008. Four patients in each group were candidates for this new agent, and received the treatment without serious complications.

Survival time

Median survival time for the primary site resection group was 30.6 ± 7.8 mo, whereas in the palliative surgery group was 20.8 ± 10.2 mo. These median survival times were significantly different (P = 0.0094, log-rank test). The two-year actuarial survival in the primary site resection group was 67.2%, compared to 31.9% in the palliative surgery group (Figure 2A). We re-examined the mortality of the two groups to exclude the influence of localized invasion. After excluding all T4 patients, we found longer survival and higher rate of two-year survival in the primary site resection group. The median survival time was 30.6 ± 10.3 mo *vs* 17.3 ± 8.5 mo (P = 0.0149, log-rank test). Figure 2B shown the overall survival curves by treatment of primary resection or palliative surgery with FOLFOX (Modified group of T2-3 patients).

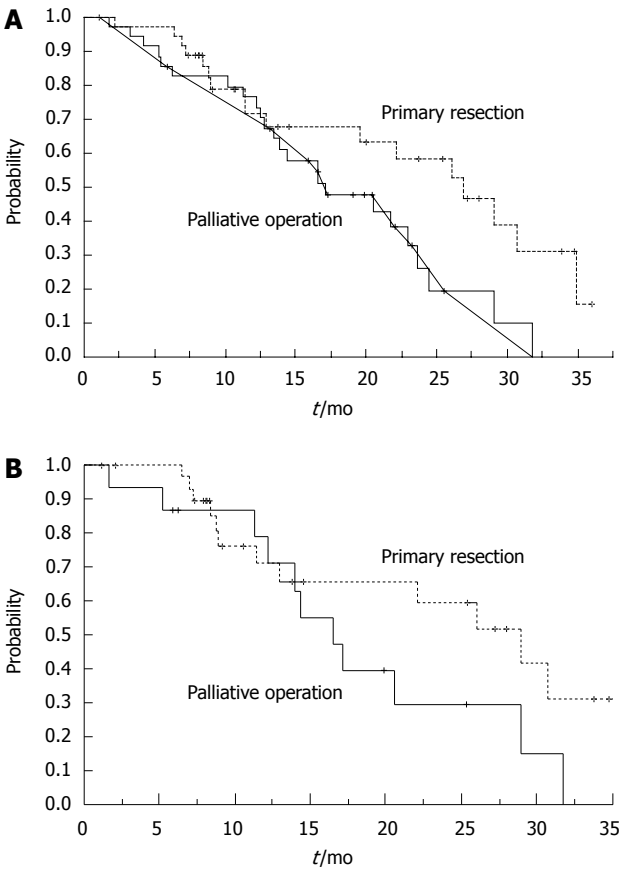

Figure 2 Overall survival curves by treatment of primary resection or palliative operation with FOLFOX (A), modified group of T2-3 patients (B).

Surgery

The operations performed are listed in Table 2. Of these, eight (21%) were emergent surgery in the primary site resection group and 10 (27%) in the palliative surgery group. In the primary site resection group, 16 of 38 patients experienced one or more postoperative complications *vs* 12 of 36 patients in the palliative surgery group. This relatively higher complication rate resulted in longer hospitalization (22.7 ± 12.9 d *vs* 18.1 ± 7.9 d) in the primary site resection group (Table 3). The two most common complications were wound infection and prolonged ileus, followed by urinary tract infection, pneumonia, catheter infection, gastric hemorrhage, and liver failure. In the primary site resection group, two patients (5.3%) developed anastomotic leaks and required reoperation for drainage and diversion. Among the patients who had undergone palliative surgery, two complications (5.5%) related to the primary tumor (one perforation and one bleeding) were observed. Both were managed conservatively.

DISCUSSION

The treatment of patients who present with mCRC is controversial. Although resection has often been advocat-

Table 2 Surgical procedure performed

Group	Procedure	*n*

ed to eliminate the source of symptoms such as bleeding, perforation and obstruction, management of asymptomatic patients has not been well defined. The purpose of our study was to define optimal primary tumor management in this subset of patients with metastatic disease. Our study demonstrated that the resection of the primary site significantly extends the median survival time in incurable CRC patients. Previous authors have addressed similar issues focusing in appropriate selection of surgical candidates, potential benefits of resection, and rates of operative morbidity and mortality. Some authors recommended resection to potentially improve survival[1-4].

Ruo *et al*[2] found a median survival of 16 mo in those undergoing resection and 9 mo in those never resected. Liu *et al*[3] also presented a retrospective series of 68 cases with longer mean survival of 10.6 mo in the resection group compared with 3.4 mo in patients who had a bypass. These findings are in agreement with our results. Others have reported similar results in terms of mortality between primary site resection and non-operative management, and recommend non-operative management of patients with metastatic CRC with synchronous metastases[5-7].

Charles *et al*[5] suggested that appropriately selected patients with incurable stage 4 CRC can be safely managed without primary tumor resection, with a median survival of 16.6 mo for the non-resection group. Johnson *et al*[7] found that in patients with rectal cancer and non-resectable liver metastases, there was no significant difference in cancer-specific survival after palliative resection or colostomy. Supporters of non-operative management argue that as metastatic tumor burden is the life-limiting factor, protracted postsurgical recovery might delay initiation of therapy targeting the disseminated disease, resulting in decreased survival. However, these studies have not addressed the effects of adjuvant chemotherapy including FOLFOX and FOLFIRI. In the study of George *et al*[2] of 233 patients with synchronous stage IV CRC treated by FOLFOX and FOLFIRI, 93% were managed non-operatively with 18 mo median overall survival. In comparison with our results, they might have obtained better outcomes using primary tumor resection, despite the patients' symptoms.

We believe that the role of primary resection in mCRC in the new era of chemotherapy and in the setting of incurable metastatic disease should be re-examined. We thought that new chemotherapies, including FOLFOX and FOLFIRI, would improve patients' prognosis and provide additional treatment options, including surgical resection. Indeed, the combination of oxaliplatin or irinotecan with 5-FU and leucovorin has proved to significantly increase response rates, prognosis, and survival compared with previous chemotherapies, such as 5-FU+LV[8-10], oxaliplatin alone[11] and IFL[1]. To compare the efficacy of FOLFOX and FOLFIRI, Tournigand *et al*[12] and Colucci *et al*[13] performed randomized trials in which patients received either FOLFOX followed by FOLFORI, or *vice versa*. Both investigators concluded that the regimens had similar efficacy when used as first-line therapy (median progression-free survival of 8 mo). Therefore FOLFOX followed by FOLFORI was chosen as the main chemotherapy in this study.

This study showed a significant difference in overall survival between the group of patients who underwent primary tumor resection without concomitant metastasectomy and the group of patients who underwent palliative surgery. However, patients with severe comorbidities or progressive metastasis who could not undergo an operation were excluded. We thought it was reasonable to separately compare patients who could undergo surgery. The two groups were well matched in terms of population and extent of tumor metastasis, but differed in their T factor. Thus, this observational survival benefit might be the result of patient selection. Therefore we additionally analyzed modified groups in which patients with T4 invasive CRC were excluded. Even in this analysis, the benefit of primary lesion resection was clearly shown. Postoperative complications in this study occurred in 28% of patients, which was similar to other reports[14]. Postoperative complications occurred more often after primary resection than after palliative surgery. This resulted in a significantly (P = 0.05) longer hospital stay in the primary resection group. A laparoscopic approach, when possible, might decrease morbidity[15]; however, we did not address this in our study. Laparoscopic surgery, as an alternative to open surgery, is safer with no added morbidity. In our study, two of 36 patients who were initially managed with palliative surgery developed perforation or significant gastrointestinal bleeding from their intact primary lesions and were successfully treated with no additional

surgical management. Such patients should be closely observed, because recent studies suggest that up to one-third of patients without resection will require subsequent intervention for symptoms related to an intact primary lesion[4,6,16]. Mild events can be managed medically, but life-threatening events require immediate surgical intervention. The issue of these tumor-dependent complications is still important. Until now it has been thought that most patients would succumb to systemic disease before developing a complication, based on high mortality and a poor 5-year survival of patients with stage 4 CRC. However, improved multidrug regimens such as FOLFOX and FOLFIRI would probably raise the incidence of severe complications indirectly by prolonging survival. Surgical treatment of primary disease to control severe complications including bleeding, perforation, and obstruction might also become increasingly important. Furthermore, whether perforation of the primary tumor is the result of tumor progression or a side effect of chemotherapy remains to be evaluated. Bevacizumab, a monoclonal antibody against vascular endothelial growth factor, is recognized to improve survival with chemotherapy but also has serious complications, such as gastrointestinal perforation. Hedrick *et al*[17] and Sugrue *et al*[18] found that 1.7% of patients who used bevacizumab experienced GI perforation. Intra-abdominal inflammation due to tumor necrosis was thought to be the common feature of these GI perforations. In addition, both the BRiTE[14] study and the First BEATrial[17] suggested that incidence of GI perforation was higher in patients with intact primary tumors. Therefore, perforation of the primary lesion is a severe problem and requires protective treatment for patients with invasive CRC. To gain a benefit from bevacizumab treatment without concern for perforation and bleeding from the primary tumor, resection of the primary tumor, if possible, is definitely favorable. In our study, eight patients have been treated with bevacizumab without severe toxicities since 2008. However, caution must be exercised in the management of the patients requiring surgery and receiving adjuvant treatment with bevacizumab.

In conclusion, this study supports the view that resection of the primary lesions in patients with non-resectable, metastatic colorectal cancer is advisable, as there is a significant improvement in survival with primary site resection over non-resected palliative surgery. We believe that all suitable patients should undergo this combined approach to avoid primary cancer complications and improve prognosis.

COMMENTS

Background

Colorectal cancer (CRC) is the most common cancer worldwide. Although chemotherapy has progressed dramatically, the role of surgical treatment in patients with incurable metastasis CRC is controversial. The resection of the primary lesions in these patients is recommended due to a significant improvement in survival.

Research frontiers

Previous studies have mentioned the comparison of primary site resection and palliative surgery. However, they have not addressed the effects of new adjuvant chemotherapy, including FOLFOX and FOLFIRI. In this study, the authors proved the superiority of primary site resection combined with FOLFOX.

Innovations and breakthroughs

This is the first study to report the combined effect of primary site resection and new chemotherapy. Furthermore, this study suggests that primary site resection might be associated with survival in patients with metastatic CRC.

Applications

This study might represent a future strategy for combined therapies for patients with CRC.

Peer review

This is an institutional experience that reviews the outcomes of patients with synchronous presentation of metastatic colorectal cancer who were treated with systemic chemotherapy for which subsequent management included a resection of the primary tumor or palliative surgical procedure to manage the primary tumor.

Abstract

AIM: To evaluate the adequacy of surgical treatment of T2 gallbladder carcinoma (GBCa) according to tumor spread in the subserosal layer.

METHODS: A series of 84 patients with GBCa were treated at Saga University Hospital, Japan between April 1989 and October 2008. The tumor stage was graded according to the TNM staging for GBCa from the American Joint Committee on Cancer Manual 6th edition. Tumor staging revealed 30 patients with T2 tumors. T2 GBCa was divided into three groups histologically by the extent of tumor spread in the subserosal layer, using a score of ss minimum (ss min), ss medium (ss med) or ss massive (ss mas).

RESULTS: For ss min GBCa, there was no positive pathological factor and patient survival was satisfactory with simple cholecystectomy, with or without extra-hepatic bile duct resection. For ss med GBCa, some pathological factors, h-inf (hepatic infiltration), ly (lymphatic invasion) and n (lymph node metastasis), were positive. For ss mas GBCa, there was a high incidence of positive pathological factors. The patient group with extra-hepatic bile duct resection with D2 lymph node dissection (BDR with D2) and those with S4a5 hepatectomy had significantly better survival rates.

CONCLUSION: We suggest that radical surgery is not necessary for ss min GBCa, and partial hepatectomy and BDR are necessary for both ss med and ss mas GBCa.

Key words: Hepatectomy; Bile duct resection; Gallbladder carcinoma; Tumor spread

INTRODUCTION

Gallbladder carcinoma (GBCa) is a relatively rare tumor[1-3], however, its mortality has increased worldwide over the past few decades[4], and the prognosis still remains poor[1,2]. There is no effective therapy for GBCa, except for surgical resection. However, the overall 5-year survival rate is 5%-42.3%, even after radical resection of the tumor[1,2,5,6]. The prognosis for patients with early GBCa, defined as pT1a/b lesions, shows a 5-year survival rate of 82%-100%[6-9]. Due to the anatomical proximity to important organs, surgery for advanced gallbladder cancer requires an aggressive approach. For pT2 or more advanced tumors, many authors advocate radical resection with lymph node dissection[10-14]. Previous reports have shown a second radical resection to be associated with significantly better survival than cholecystectomy alone in pT2 GBCa

patients whose cancers were incidentally found after cholecystectomy[15-18], whereas, Wakai *et al*[19] have reported that 40.5% of patients with unapparent pT2 tumors survived > 5 years after cholecystectomy alone. S4a5 hepatectomy combined with extra-hepatic bile duct resection (BDR) and D2 lymph node dissection is a highly recommended operation for the treatment of T2 and T3 GBCa[6], although, in T2 GBCa, the surgical procedure remains controversial, and there is no standard operation.

Recent reports have shown improved survival in patients with bile duct cancer who were treated with newly developed chemotherapy agents, gemcitabine and S-1. Several studies of single-agent gemcitabine have reported response rates of 8%-60%, and a median survival time ranging from 6.5 to 11.5 mo[20-25]. S-1 is an oral anticancer drug that contains two biochemical modulators, 5-chloro-2,4-dihydroxypridine and potassium oxonate, which improve the tumor-selective toxicity of 5-fluorouracil (5-FU)[26]. A phase Ⅱ study of S-1 has shown promising results with response rates ranging from 21% to 35% in biliary tract cancer[27,28].

The present retrospective study evaluated the limits of extended resection, such as hepatectomy, extra-hepatic BDR, and pancreatoduodenectomy (PD), especially for T2 GBCa, according to the extent of tumor spread in the subserosal layer, and to the characteristics of the clinicopathological or the prognostic factors. The good candidates were therefore recommended to receive adjuvant chemotherapy in T2 GBCa to obtain better survival.

MATERIALS AND METHODS

Between April 1989 and October 2008, 84 consecutive patients, 27 men and 57 women, with GBCa underwent surgical resection at Saga University Hospital, Japan. The mean age was 67.6 years, with a range of 45-87 years. The clinical and histopathological staging was based on the 6th edition of the American Joint Committee on Cancer Manual[29]. Nine (10.7%) patients were classified as T1a, eight (9.5%) as T1b, 30 (35.7%) as T2, 31 (36.9%) as T3, and six (7.1%) as T4. We evaluated the 30 patients with T2 GBCa who were treated with resection. These patients were divided into three groups histologically, according to the extent of tumor spread in the subserosal layer, using resected specimens. The pathological sections were examined and diagnosed using the most invaded slice.

In Table 1, the subserosal cancer invasion score (ss score) was histologically determined by dividing the vertical and horizontal tumor spread in the subserosal layer into three groups according to the ss score. Finally the extent of the subserosal invasion was divided subjectively into three categories: namely, ss minimum (ss min), ss medium (ss med), and ss massive (ss mas). As a result, the tumors were classified as ss min in four specimens, ss med in 10, and ss mas in 16.

Our fundamental strategy of S4a5 hepatectomy for T2 GBCa was indicated for highly suspected subserosal or serosal invasion preoperatively, and BDR for highly suspected lymph node metastases along the hepatoduodenal ligament. PD or pylorus-preserving PD (PPPD) was added for highly suspected retro-pancreatic lymph node metastases or direct invasion to the duodenum.

Table 1 Extent of tumor spread by ss score

Vertical invasion	< 1/3 in depth	α: score 1
	⩾ 1/3 and < 2/3	β: score 2
	⩾ 2/3	γ: score 3
Horizontal invasion	< 5 mm	A: score 1
	⩾ 5 mm and < 10 mm	B: score 2
	⩾ 10 mm	C: score 3

The sum total of ss score was calculated. ss minimum (ss min): 2; ss medium (ss med): 3-4; ss massive (ss mas): 5-6.

Table 2 ss score and clinicopathological factors *n* (%)

	ss min (*n* = 4)	ss med (*n* = 10)	ss mas (*n* = 16)
h-inf (+)	0	5 (50.0)	2 (12.5)
b-inf (+)	0	0	1 (6.3)
ly (+)	0	6 (60.0)	15 (93.8)
v (+)	0	0	5 (35.7)
pn (+)	0	1 (10.0)	6 (37.5)
n (+)	0	3 (30.0)	4 (25.0)

h-inf: Hepatic invasion; b-inf: Bile duct invasion; ly: Lymphatic invasion; v: Venous invasion; pn: Peri-neural invasion; n: Lymph node metastasis.

Statistical analysis

The clinicopathological factors and patient survival were statistically analyzed. The χ^2 and Fisher's exact tests were used to compare the two groups, and the Mann-Whitney *U* test was used for differences between the means. The survival was calculated according to the Kaplan-Meier method and compared between the groups by the log-rank test. Cox proportional hazards models were applied for the multivariate analysis. A value of $P < 0.05$ was considered to be statistically significant.

RESULTS

Relationship between ss score and pathological factors

Table 2 describes the relationship between ss classification and clinicopathological factors. The ss min group had no positive pathological factors. In the ss med group, pathological factors of h-inf (hepatic infiltration), ly (lymphatic invasion), pn (perineural invasion) and n (lymph node metastasis) were positive in 50%, 60%, 10%, and 30% of the patients, respectively. All pathological factors were positive at a high rate in the ss mas group. The positive rate of pathological factors increased along with the degree of the ss score.

Survival according to ss score

Figure 1A shows the disease-specific survival curve of the patients with T2 GBCa by ss classification. All the patients with ss min and ss med survived until the end of the follow-up period and the 5-year survival rate was 100% in

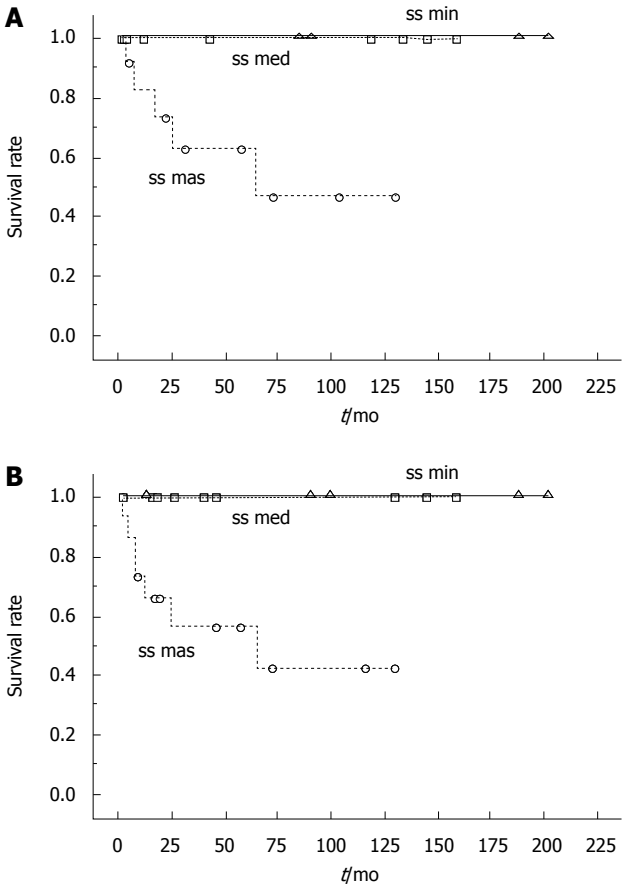

Figure 1 Kaplan-Meier survival analysis of patients with T2 gallbladder carcinoma by ss score. A: Disease-specific survival; the 5-year survival rate for ss min and ss med was 100%. In ss mas gallbladder carcinoma (GBCa), the 5-year survival rate was 59.7%; B: Disease-free survival; the 5-year survival rate for ss min and ss med was 100%. In ss mas GBCa, the 5-year survival rate was 56.6%.

the ss min and ss med groups. In ss mas GBCa, the survival was significantly worse than for ss min and ss med GBCa, and the 5-year survival rate was 59.7%. Figure 1B shows the disease-free survival curve. The 5-year survival rate in the ss min and ss med groups was 100%. In ss mas GBCa, the disease-free 5-year survival rate was 56.6%. There were seven patients with cancer recurrence in the ss mas group. The pattern of recurrence was three patients with lymph node recurrence, two with local recurrence, one with liver metastasis, and one with peritoneal dissemination.

Evaluation of surgical procedures in T2 GBCa

Table 3 summarizes the surgical procedures in each ss group. The procedure in ss min GBCa was based on simple cholecystectomy, and there was no hepatectomy, PD or PPPD. Six of 10 (60.0%) patients with ss med GBCa underwent S4a5 hepatectomy. In ss mas GBCa, the surgical procedures varied from simple cholecystectomy to extended right hepatectomy or PD, according to the mode of cancer spread.

Surgical procedures and survival in ss mas GBCa

To evaluate the appropriate surgical procedure for ss mas

Table 3 Surgical procedures in T2 gallbladder carcinoma

Surgical procedure	ss min (n = 4)	ss med (n = 10)	ss mas (n = 16)
Cx	3	2	3
Cx + Liver bed resection + D2ex			1
Cx + BDR + D2ex	1	2	1
S4a5 hepatectomy + D2ex		2	3
S4a5 hepatectomy + BDR+ D2ex		2	5
S4a5 hepatectomy + PD or PPPD		2	1
Extended right hepatectomy			1
PD alone			1

BDR: Bile duct resection; PD: Pancreatoduodenectomy; PPPD: Pylorus-preserving PD.

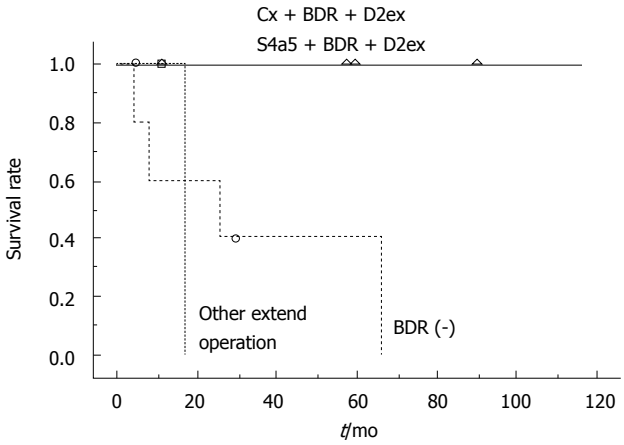

Figure 2 Kaplan-Meier survival analysis by surgical procedure for T2 gallbladder carcinoma. BDR: With extra-hepatic BDR; BDR (-): Without extra-hepatic BDR; S4a5: S4a5 hepatectomy; Cx: Simple cholecystectomy; D2ex: D2 lymph node dissection with para-aortic lymph node sampling. BDR: Bile duct resection.

GBCa, survival was analyzed according to the surgical procedures: simple cholecystectomy + extra-hepatic BDR + D2 lymph node dissection (Cx + BDR + D2ex); S4a5 hepatectomy + BDR + D2ex; S4a5 hepatectomy + PD (HPD); and cholecystectomy without BDR [Cx BDR (-)]. In ss mas GBCa, the Cx + BDR + D2ex and S4a5 + BDR + D2ex groups showed significantly better survival than the other groups (Figure 2). The 5-year survival of the Cx BDR(-) group was 33.3%, which was worse than for the Cx + BDR + D2ex group. Other extended operations, including HPD, PD, and extended hepatectomy, showed a dismal outcome. Surgery in these patients revealed massive lymph node metastasis during the operation.

DISCUSSION

In spite of the recent progress in diagnostic modalities, GBCa still tends to be found at an advanced stage[30], and only 15%-40% of patients who present with GBCa are candidates for surgical intervention[31]. Surgical management of T1 GBCa reveals almost no lymph node involvement and shows a relatively sufficient 5-year survival rate of 82%-100% with simple cholecystectomy[8,9,19].

The surgical management of T2 GBCa remains controversial. In these patients, the appropriateness of simple cholecystectomy versus radical resection remains the subject of debate. Some groups believe that most T2 lesions require only simple cholecystectomy, thus contending that radical resection is unnecessary and should be reserved for only a small subset of patients who meet certain pathological criteria[32-34]. On the other hand, proponents of radical resection believe that all T2 lesions should be treated with radical resection, because 40% of these patients will have residual lymphatic disease after resection. Radical cholecystectomy is associated with a significant survival benefit when liver surgery can be performed with minimal mortality and acceptable morbidity[35-37]. Radical surgery consisting of partial hepatectomy around the gallbladder fossa, and regional lymphadenectomy with or without resection of the extra-hepatic bile duct, yields 50%-86% 5-year survival rates[38-41]. Wakai *et al*[33] have reported the significance of the depth of subserosal invasion in patients with pT2 GBCa. The incidence of lymph node metastasis is significantly higher in patients with subserosal invasion > 2 mm (63%) than in patients with invasion < 2 mm (27%). Sasaki *et al*[42] have reported that lymph node involvement is seen in 33.3% of ss1, the upper third of subserosal invasion, 37.5% of ss2, middle third of subserosal invasion, and 85.7% of ss3, lower third of subserosal invasion. In the current study, the 5-year survival rate for T2 GBCa was 78.3%, including patients who underwent whole surgical procedures (data not shown). No positive pathological factors were observed in the ss min patient group, and simple cholecystectomy with or without extrahepatic BDR was associated with good survival (Table 3 and Figure 1). These data indicate that radical surgery, such as a hepatectomy or PD, is not necessary for ss min GBCa. For ss med GBCa, there were some positive pathological factors, h-inf, ly, pn, and n (Table 1). Partial hepatectomy, such as S4a5 hepatectomy or liver bed resection, and complete lymphadenectomy including BDR might therefore be necessary for ss med GBCa. For ss mas GBCa, a high incidence of multiple pathological factors was observed. Figure 2 shows that patients without BDR had a dismal outcome. To achieve better survival for ss mas GBCa, partial hepatectomy, such as S4a5 hepatectomy or liver bed resection, and complete lymphadenectomy including BDR, are the minimum requirement. However, radical surgery, such as major hepatectomy or hepatectomy with PD, had no survival benefit. In addition, the importance of S4a5 hepatectomy and BDR for T2 and T3 GBCa has also been previously reported[6].

To avoid unnecessary surgery, such as extended resection for ss min GBCa, the actual depth of GBCa in the subserosal layer should be determined pre- or intraoperatively. No report has previously described an effective pre- or intraoperative method to determine the actual extent of subserosal invasion. In addition, previous studies have employed intraoperative ultrasonography and frozen section histology to detect the actual depth of subserosal invasion, but it is still not sufficiently accurate, as well as being very difficult to determine the actual depth of invasion intraoperatively. A new method for the pre- or intraoperative determination of the actual extent of subserosal invasion is necessary to avoid unnecessary operation.

There is no current standard chemotherapy in advanced gallbladder cancer. In previous studies that have used chemotherapeutic agents, 5-FU, mitomycin C, methotrexate, etoposide, doxorubicin, or cisplatin, against biliary tract tumors, only 10%-20% revealed a partial response[43-46]. However, gemcitabine has shown remarkable biological activity against biliary tract cancers in some clinical studies. Several reports have described the efficacy of single-agent gemcitabine, with a response rate of approximately 30% and a median survival time of approximately 15 mo, and phase Ⅱ investigations into a gemcitabine-based combination have increased[47,48]. Gemcitabine is a novel nucleoside analog that demonstrates biological activities in a broad spectrum of solid tumors[49]. The ribonucleotide reductase subunit M1 (RRM1) plays an important role in gemcitabine resistance for biliary tract carcinomas. The expression of RRM1 has been investigated as a drug sensitivity marker for gemcitabine therapy of biliary tract carcinoma, through *in vitro* study and clinical analysis[50]. These results indicate that ss mas cancer with low RRM1 expression is therefore a good candidate for gemcitabine adjuvant chemotherapy to achieve better survival after surgical resection. S-1 has greater inhibition of thymidylate synthase (TS) and pemetrexed is classified as a multi-targeted antifolate. Orotate phosphoribosyl transferase (OPRT), dihydropyrimidine dehydrogenase (DPD) and TS play a critical role in the efficacy of antifolates. A low level of DPD and TS activity, and a high level of OPRT activity enhance the antitumor effect of S-1[51]. A phase Ⅱ study of S-1 in biliary tract cancer has shown promising results with a response rate of 21%-35%[27,28], and S-1 can be expected to have a good effect on gallbladder cancer. In T2 GBCa, ss mas cancers showed a high rate of recurrence, regardless of the radical surgical approach. Therefore, patients with ss mas cancer are thus considered to be good candidates for gemcitabine or S-1 adjuvant chemotherapy. Further studies of adjuvant chemotherapy against gallbladder cancer are necessary. The current algorithm of therapeutic strategy for T2 GBCa is shown in Figure 3.

In conclusion, the surgical management of T2 GBCa remains controversial. Radical surgery is not necessary for ss min GBCa. Furthermore, BDR may be necessary to complete lymphadenectomy for the hepato-duodenal ligament to achieve better survival for ss med and ss mas GBCa. S4a5 hepatectomy also contributed to better survival for ss med and ss mas GBCa. S4a5 hepatectomy with extra-hepatic BDR and lymphadenectomy should therefore be a standard operation for the treatment of ss med and ss mas GBCa. However, new methods for the pre- or intraoperative detection of the actual extent of subserosal invasion are still necessary to avoid unnecessary operations. In ss mas GBCa, survival remains unsatisfactory. Patients with ss mas GBCa are therefore

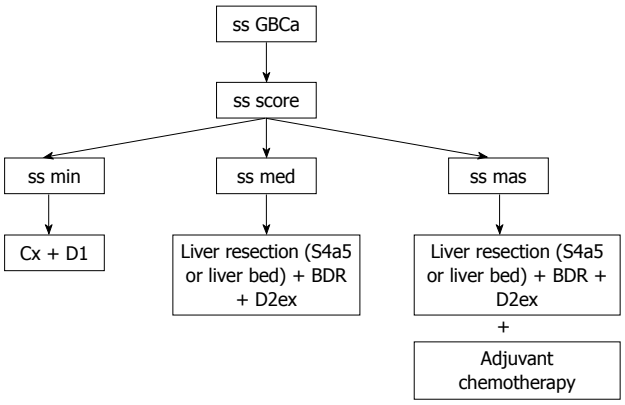

Figure 3 Algorithm of therapeutic strategy for T2 gallbladder carcinoma. Cx: Simple cholecystectomy; BDR: With extra-hepatic BDR; S4a5: S4a5 hepatectomy; D2ex: D2 lymph node dissection with para-aortic lymph node sampling.

considered to be good candidates for gemcitabine or S-1 adjuvant chemotherapy to achieve better survival.

COMMENTS

Background

Gallbladder carcinoma (GBCa) is a relatively rare tumor, however, the mortality of this tumor has increased worldwide over the past few decades, and the prognosis still remains poor. There is no effective therapy for GBCa, except for surgical resection. The prognosis for patients with early GBCa is good even with only cholecystectomy, but that for patients with advanced GBCa is poor even after radical surgery. The surgical management of T2 GBCa remains controversial.

Research frontiers

T2 GBCa was divided into three groups histologically by the extent of tumor spread in subserosal layer using the ss score. The ss score was histologically determined by dividing the vertical and horizontal tumor spread in the subserosal layer. Finally the extent of the subserosal invasion was divided subjectively into three categories: ss minimum (ss min), ss medium (ss med) and ss massive (ss mas).

Innovations and breakthroughs

For ss min GBCa, there was no positive pathological factor and survival was satisfactory after simple cholecystectomy. For ss med GBCa, some pathological factors were positive. For ss mas GBCa, there was a high incidence of positive pathological factors.

Applications

After surgical procedure analysis of T2 GBCa, the patient group with extra-hepatic bile duct resection with D2 lymph node dissection, and the group with S4a5 hepatectomy had significantly better survival rates. In ss mas GBCa, the survival of the patients remains unsatisfactory. Patients with ss mas GBCa are therefore considered to be good candidates for chemotherapy to achieve better survival.

Terminology

S4a5 hepatectomy is a type of hepatectomy for advanced GBCa. S4 is the lower half of the left medial segment of the liver, and S5 is the anterior medial segment of the liver, according to the Couinaud classification of liver segments. D2 lymph node dissection is based on the method described in the General Rules for Surgical and Pathological Studies on Cancer of the Biliary Tract from the Japanese Society of Biliary Surgery, 5th edition, 2003.

Peer review

This study investigated an important subject, namely, the best therapeutic approach for GBCa.

Abstract

AIM: To investigate the risk factors for *Clostridium-difficile*-associated diarrhea (CDAD) recurrence, and its relationship with proton pump inhibitors (PPIs).

METHODS: Retrospective data of 125 consecutive hospitalized patients diagnosed with CDAD between January 2006 and December 2007 were collected by medical chart review. Collected data included patient characteristics at baseline, underlying medical disease, antibiotic history before receiving a diagnosis of CDAD, duration of hospital stay, severity of CDAD, concurrent treatment with PPIs, laboratory parameters, response to CDAD therapy, and recurrence of disease within 90 d of successful treatment. Various clinical and laboratory parameters were compared in patients in whom CDAD did or did not recur.

RESULTS: Of the 125 patients (mean age, 67.6 ± 13.9 years) that developed CDAD, 98 (78.4%) did not experience recurrence (non-recurrent group) and 27 (21.6%) experienced one or more recurrences (recurrent group). Prior to the development of CDAD, 96% of the 125 patients were prescribed antibiotics, and 56 (44.8%) of the patients received PPIs. Age older than 65 years (P = 0.021), feeding *via* nasogastric tube (NGT) (P = 0.045), low serum albumin level (P = 0.025), and concurrent use of PPIs (P = 0.014) were found to be risk factors for CDAD recurrence by univariate analysis. However, sex, length of hospital stay, duration and type of antibiotics used, severity of disease, leukocyte count and C-reactive protein (CRP) were not associated with risk of CDAD recurrence. On multivariate analysis, the important risk factors were advanced age (> 65 years, adjusted OR: 1.32, 95% CI: 1.12-3.87, P = 0.031), low serum albumin level (< 2.5 g/dL, adjusted OR: 1.85, 95% CI: 1.35-4.91, P = 0.028), and concurrent use of PPIs (adjusted OR: 3.48, 95% CI: 1.64-7.69, P = 0.016).

CONCLUSION: Advanced age, serum albumin level < 2.5 g/dL, and concomitant use of PPIs were found to be significant risk factors for CDAD recurrence.

INTRODUCTION

Clostridium difficile is a spore-forming Gram-positive anaerobic bacillus and is the most common cause of hospital-acquired diarrhea[1]. *C. difficile* infection occurs when a susceptible host ingests spores, which then colonize the large bowel and release endotoxin. Specific antibiotic treatments with metronidazole or vancomycin show high levels of efficacy and reduce morbidity and mortality[2]. However, although initial response rates to antibiotic therapy exceed 90%, 10%-30% of patients experience *C. difficile*-associated diarrhea (CDAD) recurrence[3], which increases the cost of medical care, and causes re-hospitalization, complications, and mortality[4]. The complications of recurrent CDAD included toxic megacolon, septicemia, and C. *difficile*-associated arthritis. Furthermore, the average length of stay due to admission for recurrent CDAD among outpatients has been reported to be 8.8 d (range, 3-26)[5,6]. It has been reported that the elderly, and patients with chronic renal failure, multiple previous CDAD episodes, or a high level of white blood cell count ($\geqslant 15 \times 10^9$/L), and those that continue to use systemic antibiotics after a diagnosis of CDAD, are at high risk of recurrence[7,8].

Gastric acid inhibits the germination of ingested spores and the survival of *C. difficile*, and recent studies have found that gastric acid suppressive agents, such as PPIs, increase the risk of CDAD development in hospitalized patients[9,10]. However, relatively few studies have attempted to determine whether the use of gastric acid suppressive agents is associated with an elevated risk of CDAD recurrence[11,12].

The purpose of this study was to determine the risk factors of CDAD recurrence in hospitalized patients, and to investigate the relation between PPIs use and CDAD recurrence.

MATERIALS AND METHODS

Identification of subjects and collection of clinical data

This retrospective study was performed at Seoul National University Boramae Hospital, a 500-bed teaching hospital, between January 1, 2006 and December 31, 2007.

The medical records of all patients diagnosed with CDAD based on typical symptoms, that is, three or more bowel movements per day, abdominal pain, fever, leukocytosis at least 3 d after admission, and a positive ELISA result for *C. difficile* toxins A and B (Wampole TOX A/B Quic Check, Techlab, Blacksburg, VA, USA). The exclusion criteria applied were: age < 18 years, CDAD during the previous 3 mo, failure to complete at least 7 d of antibiotic therapy, a diagnosis of CDAD within 3 d of admission, or the presence of any other cause of diarrhea, such as, laxative use, the presence of another infectious pathogen, and inflammatory bowel disease.

Medical records included the following information: age; sex; type of underlying disease; duration, number and type of antibiotics prescribed before diagnosis of CDAD; hematological and biochemical parameters; CDAD severity; PPI use; specific therapy used to treat CDAD; time to resolution of CDAD symptoms; and disease recurrence within 90 d of cure. CDAD was considered severe if two or more of the following factors were present: (1) a frequency of stool of > 10/d; (2) fever (> 38.3℃); and (3) a leukocyte count of > 15000 cells/mm^3. PPI use was defined as at least 3 d treatment before the development of CDAD and continuous use thereafter.

In the majority of patients, oral metronidazole for 10-14 d was initially administered. Vancomycin was reserved for those that did not respond to metronidazole or had severe CDAD. The main causes of antibiotic prescription were pneumonia, urinary tract infection, postoperative wound infection, osteomyelitis, and cellulitis. Patients were classified into two groups based on recurrence within 90 d of cure (the recurrent and non-recurrent groups). Patients were regarded as cured when stool frequencies and consistencies were normal for at least three consecutive days. Recurrence was defined as diarrhea recurrence with a positive ELISA result for cytotoxin A, within 90 d after therapy completion, and the complete resolution of signs and symptoms. Patients were monitored for recurrence throughout this 90-d period.

Statistical analysis

SPSS 12.0 software (SPSS Inc., Chicago, IL, USA) was used for the statistical analysis. Patients were divided into recurrent and non-recurrent groups. Data are presented as mean ± SD or percentage frequencies. Student's *t* test, χ^2 test and Fisher's exact test were used to analyze continuous and categorical variables. Logistic regression analysis was used to determine the effects of continuous variables on recurrence. For all analyses, $P < 0.05$ was considered significant. This study was approved by the institutional review board of Seoul National University Boramae Hospital.

RESULTS

A total of 125 patients who received full course therapy for CDAD were included in this study. There were 57 (45.6%) men and 68 (54.4%) women, and mean patient age was 67.6 years (range 35-92). One hundred and twenty (96%) were prescribed antibiotics before CDAD was diagnosed. The most common antibiotics administered were cephalosporins (80.8%), clindamycin (25.6%), penicillin analogues (20%), and quinolones (19.2%). Five patients (4%) did not receive antibiotics prior to diagnosis of CDAD, and 81 (64.8%) were treated with more than one antibiotic. Forty-eight (38.4%) patients had diabetes, 41 (32.8%) had malignant disease, and 17 patients (13.6%) had chronic renal failure. Thirty-five patients (28%) were fed *via* an NGT before diagnosis. Of the

[a]*P* < 0.05. CDAD: *Clostridium-difficile*-associated diarrhea; WBC: White blood cells; NGT: Nasogastric tube.

125 subjects, 56 (44.8%) received PPIs for ≥ 3 d. One hundred and thirteen (90.4%) were initially treated with metronidazole, and 12 (9.6%) with vancomycin.

Of the 125 study subjects, 27 (21.6%) experienced disease recurrence within 90 d after cure, and the remaining 98 (78.4%) did not experience recurrence. The recurrence rate among patients treated with metronidazole was no different from that among patients treated with vancomycin (21.2% *vs* 16.7%). Univariate analysis showed that five parameters were significantly associated with recurrence (Table 1). Patients aged ≥ 65 years were found to be more likely to develop recurrence than those < 65 years (59.3% *vs* 31.6%, *P* = 0.021). Patients fed *via* an NGT were also more likely to develop recurrence (48.1% *vs* 23.5%, *P* = 0.045). The mean serum albumin level at the time of CDAD diagnosis was lower in patients with recurrence than in patients without recurrence (2.3 ± 0.5 g/dL *vs* 3.1 ± 0.4 g/dL, *P* = 0.028). Furthermore, significantly more patients in the recurrent group received concurrent PPIs therapy (63.0% *vs* 39.8%, *P* = 0.014). However, sex, length of hospital stay, duration of antibiotics used before diagnosis of CDAD, the presence of diabetes mellitus or renal failure, severity of CDAD, leukocyte count, hemoglobin and CRP levels were not found to be associated with an increased risk of recurrence.

Multivariate analysis showed that age > 65 years (OR: 1.32, 95% CI: 1.12-3.87, *P* = 0.031), serum albumin level of < 2.5 g/dL (OR: 1.85, 95% CI: 1.35-4.91, *P* = 0.028), and concurrent use of PPIs (OR: 3.48, 95% CI: 1.64-7.69, *P* = 0.016) were associated with the risk of recurrence (Table 2).

Table 3 summarizes antibiotic use before CDAD was diagnosed. The mean number of antibiotic types prescribed to patients was not found to be a risk factor for recurrence (2.58 in the recurrent group *vs* 2.43 in the non-recurrent group, *P* = 0.56). Furthermore, the two study groups were similar in terms of exposure to high-risk antibiotics, such as, clindamycin, cephalosporins, or quinolones.

CDAD: *Clostridium-difficile*-associated diarrhea.

DISCUSSION

Recurrent CDAD is one of the most difficult problems related to *C. difficile* infection. Despite an initial successful response in more than 90% of patients, CDAD recurs in 15%-30%[13,14]. In a previous study of 124 CDAD patients, 24% experienced recurrence[15], which concurs with the 20.8% observed in the present study. Patients treated with metronidazole (21.2%) had a greater tendency to recur than patients treated with vancomycin (16.7%), but this was not significant (*P* = 0.09). Studies have shown that the rates of treatment failure and recurrence are greater for patients treated with initial metronidazole than for patients treated with vancomycin, especially since 2000[16]. Because of its low cost and of concerns about vancomycin-resistant enterococci, metronidazole is recommended as first-line therapy. However, our finding that 21% of patients initially treated with metronidazole experienced recurrence suggests that vancomycin might be helpful as a first-line treatment in patients with multiple risk factors for recurrent CDAD. Although the pathogenesis of recur-

rence is poorly understood, several risk factors have been described. The important risk factors were advanced age, longer hospital stay, continued use of antibiotics for the treatment of non-*C. difficile* diarrhea after a first episode of CDAD, inadequate antitoxin antibody response, persistent disruption of colonic flora, and concomitant receipt of antacid medications[17-19].

Several studies have reported that agents that suppress gastric acid secretion, especially PPIs, increase the risk of CDAD development[20-22]. According to one study, the adjusted risk ratios for CDAD development for PPIs and H2-receptor antagonist (H_2RA) usage are 2.9 (95% CI: 2.4-3.4) and 2.0 (95% CI: 1.6-2.7), respectively. However, another study on the relationship between CDAD development and exposure to acid suppressive therapy in hospitalized patients has revealed an association with PPIs (OR: 3.6, 95% CI: 1.7-8.3) but not with H2RAs. In the present study, we found that PPI use was a significant risk factor of CDAD recurrence, which is in line with previous reports. In one study of 140 CDAD patients treated between 2004 and 2005, those receiving PPIs were found to be 4.17 times more likely to recur, which is greater than the OR found in the present study[11]. This result may be due to differences between study populations. In the study conducted by Cadle *et al*[11], most patients (98.6%) were men and the proportion of patients who received PPIs was greater than in the present study (69% *vs* 55%). In a recent meta-analysis, continued use of non-*C. difficile* antibiotics after a diagnosis of CDAD (OR: 4.23, 95% CI: 2.10-8.55), concomitant receipt of antacid medication (OR: 2.15, 95% CI: 1.13-4.08), and older age (OR: 1.62, 95% CI: 1.11-2.36) were found to be significantly associated with the risk of CDAD recurrence[12]. However, in this meta-analysis, PPIs and H2RAs were not differentiated, and thus, their specific effects on CDAD recurrence could not be evaluated.

The mechanisms by which acid suppressive agents increase the risk of CDAD development and recurrence are poorly understood[23]. However, although the spores of *C. difficile* are resistant to gastric acid, it has been suggested the survival and germination of *C. difficile* spores are greater at lower acidity, and that higher gastric pH increases vegetative bacteria counts in the small and large intestine[24]. Previous studies have found that gastric acid suppression increases stomach and small bowel colonization by bacteria and *C. difficile*[25,26]. Alternatively, it is also possible that PPIs directly affect host immune function, and thus, increase susceptibility to CDAD recurrence[27].

In the present study, age was found to be a risk factor for recurrence. A retrospective study of hospitalized patients in Quebec also has shown that patients aged > 65 years have a higher risk of CDAD recurrence after metronidazole and vancomycin therapy[28]. The reason why advanced age increases the risk of recurrence may be that these patients have comorbidities and are likely to be administered additional antibiotics for concomitant infections. A low serum albumin level was also found to be a significant risk factor for recurrence in our study. Hypoalbuminemia reflects a poor nutritional status, and may compromise immune response by diminishing antibody response to *C. difficile*. In one study, patients with recurrent disease were found to have significantly lower levels of IgG to toxin A than patients that did not recur[29]. Later increased serum levels of IgM and IgG to toxin A are known to be associated with a substantial reduction in the risk of CDAD recurrence[16].

In contrast to previous reports, we found no relationship between renal failure, leukocytosis, or CDAD severity and recurrence. However, we defined renal failure based on creatinine level alone, rather than on creatinine clearance, and this does not reflect the range of renal failure. With regard to leukocytosis and disease severity, a significant proportion of our study subjects were elderly, due to a failure to increase leukocytes in response to infection in some elderly patients, which may have influenced our results. Previous reports have shown that clindamycin, penicillin and cephalosporin use is an important risk factor for CDAD development, and recently, ciprofloxacin use also has been found to be a significant risk factor for CDAD in hospitalized patients[30-32]. In the present study, however, antibiotic use prior to CDAD was similar in our two patient groups, and this suggested that type and number of antibiotics used prior to CDAD might have influenced CDAD development, but not CDAD recurrence.

This study had several limitations that should be considered. First, the study was inherently limited by its retrospective nature, and in particular, stool cultures were not conducted, which prevented our determining whether recurrent CDAD was due to reinfection or relapse. Second, the confidence interval regarding the use of PPIs as a risk factor for recurrent CDAD was relatively large, which was probably due to the small number of patients enrolled in this study. Third, actual compliance to PPIs could not be assessed beyond the prescription data contained in medical charts.

In conclusion, older age (> 65 years) and a low serum albumin level (< 2.5 g/dL) were identified as risk factors for CDAD recurrence. The concomitant use of PPIs further enhanced the risk of recurrence. Of these risk factors, the use of PPIs is modifiable, and thus, it is appropriate to review constantly the necessity for concomitant use of PPIs in patients with CDAD. Prevention of unwarranted PPI therapy may be helpful in reducing the risk of recurrence, and additional larger studies are necessary in order to understand better the relationship between PPI use and CDAD recurrence.

COMMENTS

Background

The incidence and severity of *Clostridium-difficile*-associated diarrhea (CDAD) is increasing worldwide due to increased use of antibiotics and the introduction of hypervirulent strains. After successful initial therapy, approximately 10%-30% of patients experience symptomatic recurrence. Recurrence of CDAD causes increasing cost of medical care, re-hospitalization and complications. It is known that older patients, patients with chronic renal failure and multiple episode of previous CDAD are high risk groups for disease recurrence. Recent reports have suggested that the use of proton pump inhibitors (PPIs) is associated with CDAD recurrence in hospitalized patients, although the results appear to be conflicting. The objective of this study was to evaluate the risk factors for CDAD recurrence and to investigate the relationship of PPI use and recurrence of CDAD.

Research frontiers

Risk factors that are associated with CDAD recurrence and the association between use of PPIs and CDAD recurrence have been hot topics in recent studies. Of the 125 patients that developed CDAD, 98 did not experience recurrence and 27 experienced one or more recurrences. The important risk factors for CDAD recurrence were age > 65 years, low serum albumin level < 2.5 g/dL, and use of PPIs.

Innovations and breakthroughs

This study showed that advanced age, low serum albumin level and use of PPIs were associated with increased risk of CDAD recurrence.

Applications

This retrospective analysis of the risk factors for CDAD recurrence imply that avoidance of unwarranted PPI therapy may be helpful in reducing the risk of CDAD recurrence.

Peer review

This is a timely study extending present knowledge that PPIs are a risk factor for *C. difficile* reinfection.

Abstract

AIM: To investigate the association between *pre-miR-146a* C/G polymorphism and gastric cancer risk.

METHODS: We performed a hospital-based, case-control study using polymerase chain reaction-restriction fragment length polymorphism method in 608 individuals (304 gastric cancer patients and 304 age and sex matched cancer-free controls).

RESULTS: The frequencies of *pre-miR-146a* C/G genotypes in the case group were significantly different from those in the control groups (P = 0.037). Compared with CC genotype carriers, subjects with the variant genotypes (GC + GG) had a 58% increased risk of gastric cancer (adjusted OR = 1.58, 95% CI: 1.11-2.20, P = 0.009). Moreover, a higher gastric cancer risk was especially evident in younger individuals aged ⩽ 58 years, nonsmokers, and males (adjusted OR = 1.76, 95% CI: 1.08-2.87, P = 0.024; adjusted OR = 1.55, 95% CI: 1.06-2.28, P = 0.025; adjusted OR = 1.53, 95% CI: 1.04-2.27, P = 0.033; respectively).

CONCLUSION: *Pre-miR-146a* C/G polymorphism might be associated with an elevated risk of gastric cancer in Chinese population.

Key words: Pre-miR-146a; miR-146a; Gastric cancer; Polymorphism; Genotype

INTRODUCTION

MicroRNAs (miRNAs) are endogenous 19- to 25-nt noncoding RNAs, which could negatively regulate gene expression through suppressing translation or degrading mRNA[1]. Bioinformatic data identified that a single miRNA could bind to a large number of mRNA targets,

which could be implicated in disease development[2-8]. Interestingly, recent evidences indicated that miR-146a can play a role of mediator in a wide spectrum of biological processes, such as cell proliferation, differentiation, apoptosis, immune response and tumorigenesis[9-15]. Aberrant expression of miR-146a has been reported as a signature in breast cancer, pancreatic cancer, prostate cancer, and cervical cancer[16-18].

Single nucleotide polymorphism (SNP) is the most common type of genetic variation in the human genome. Polymorphisms in human pre-miRNA genome lesion modify the processing and/or target selection of human miRNAs, which are implicated in cell cycle regulation, and thereby play critical roles in carcinogenesis[19,20]. Calin *et al*[21] found that the *pre-miR-206* precursor mutation was associated with the risk of chronic lymphocytic leukemias (CLL). They also found a germ-line mutation in the miR-16-1-miR-15a primary precursor, which caused low levels of miRNA expression *in vivo* and *in vitro*[21].

Pre-miR-146a C/G polymorphism designated rs2910164 is located on chromosome 5, in the stem region opposite to the mature miR-146a sequence[22]. Several epidemiological studies have examined the role of the *pre-miR-146a* polymorphism in many human cancers, such as hepatocellular carcinoma (HCC), prostate cancer, breast cancer and papillary thyroid carcinoma (PTC)[22-26]. However, the results of these studies were inconsistent. Furthermore, no data are available concerning the association between *pre-miR-146a* C/G polymorphism and the risk of gastric cancer. Therefore, we have conducted a hospital-based case-control study to investigate the potential link between this polymorphism and gastric cancer in Chinese population.

MATERIALS AND METHODS

Subjects

This is a hospital-based case-control study, which comprised 304 gastric cancer patients and 304 cancer-free controls, consecutively recruited at the Affiliated Hospital of Nanjing Medical University. All the participants were genetically unrelated Han Chinese and were from Jiangsu Province or its surrounding regions. The diagnoses of gastric cancer were all confirmed by endoscopic biopsy or surgical specimens. Patients with secondary or recurrent tumors were excluded. Control subjects matched to gastric cancer cases by gender and age (within 5 years), were selected from patients hospitalized because of a variety of nonmalignant diseases during the time of case collection. Patients with previous histories of cancer or severe clinical symptoms and genetic disease were excluded. A structured questionnaire was administered by interviewers to collect information on demographic information and personal medical history. Those who formerly or currently smoked $\geqslant$ 10 cigarettes per day on average were defined as smokers. Pathologic variables were obtained after histopathological investigation. Depth of tumor invasion and local lymph node status were classified according to the tumor-node-metastasis (TNM) classification system of the International Union Against Cancer (UICC)[27]. Differentiation grade was classified according to WHO classification. The study was approved by the Ethics Committee of the First Affiliated Hospital, Nanjing Medical University and informed consent was obtained from each participant.

Genotyping

The protocol for genomic DNA extraction was described in our previous study[28]. The polymorphism was genotyped using a polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) assay. To control the quality of genotyping, the RFLP assay was performed without knowing the status of the cases or controls. The 372-bp DNA fragment containing the polymorphic site was amplified using two primers 5'-CATGGGTTGTGTCAGTGTTAGA-3' and 5'-CCAAGAGTCTCGTATAACAGCA-3'. PCR was done in 20 reaction mixtures containing 2 μL of 10 × PCR buffer (MBI Fermentas), 1.375 mmol/L $MaCl_2$, 0.1 mmol/L dNTPs, 1 unit Taq polymerase (MBI Fermentas), 200 ng genomic DNA, and 0.25 μmol/L of each primer. The PCR conditions were 95℃ for 8 min, followed by 35 cycles of 30 s at 95℃, 30 s at 54℃, and 30 s at 72℃, with a final elongation at 72℃ for 10 min. PCR product was digested with *HPY188*I (New England BioLabs), 5 units for 12 h at 37℃, followed by electrophoresis on a 3% agarose gel. The CC genotype yielded three bands at 211, 134 and 27 bp, and GG had two bands at 211 and 161 bp, while the GC produced four bands at 211, 161, 134, and 27 bp. Two research assistants independently examined the gel pictures and performed the repeated assays until they reached a consensus on the tested genotype.

In addition, 10% of the samples were randomly selected for retest, and the results were 100% concordant.

Statistical analysis

All the statistical analyses were performed using Stata Version 8.0 (STATA Corporation, College Station, TX). The Shapiro-Wilk statistics were used to estimate the normality of distribution. Quantitative variables departing from the normal distribution were summarized as median and estimated by the Mann-Whitney rank sum test. Pearson χ^2 test was used to investigate the difference in the distribution of categorical variables and genotype frequencies between the cases and controls. Hardy-Weinberg equilibrium of the *pre-miR-146a* genotypes was analyzed by the goodness-of-fit χ^2 test. Odds ratio (OR) and 95% confidence interval (CI) were calculated to evaluate the association between the polymorphism and the risk of gastric cancer. CC homozygotes were used as the reference. Crude OR was assessed by the Woolf approximation method, and the adjusted OR was computed using unconditional logistic regression with adjustment for age, gender, smoking status, residence, hypertension and diabetes. All statistical tests were two-tailed and considered statistically significant at a value of $P < 0.05$.

RESULTS

Demographic information

The demographic characteristics of the study partici-

Table 1 The characteristics of cases and controls *n* (%)

Characteristics	Cases	Controls	*P* value
Overall	304	304	
Gender (male)	228 (75)	228 (75)	1.000
Age[1] (yr)	59 (51-66)	58 (50-66)	0.865
Hypertension	54 (17.76)	59 (19.41)	0.602
Diabetes	17 (5.59)	27 (8.88)	0.118
Smoking	73 (24.01)	58 (19.08)	0.111
Residence			
Rural	158 (51.97)	165 (54.46)	0.540
Urban	146 (48.03)	138 (45.54)	

[1]Median (25th-75th percentiles).

pants are listed in Table 1. Cases and controls were well matched in terms of gender and age (within 5 years). Moreover, the two groups were similar with regard to smoking status, residence, history of hypertension, and diabetes. The number of patients with cancer of the gastric cardia and noncardia was 85 and 219, respectively. Most of the cases were adenocarcinoma (96.05%). Among those 304 gastric cancers with available clinicopathologic data, 52, 36, 142 and 67 were T1, T2, T3, and T4, respectively and 41, 165, and 91 were reported to be well, moderately, and poorly differentiated. Positive lymph nodes were identified in 190 cases.

Distributions of pre-miR-146a C/G genotype in cases and controls

Table 2 presents the genotype frequency and the association between *pre-miR-146a* C/G polymorphism and the risk of gastric cancer. The genotype distributions complied well with Hardy-Weinberg equilibrium in cases and controls (P = 0.7993 and P = 0.1223, respectively), indicating that there was no genetic drift or any selective advantage for particular *pre-miR-146a* alleles. A significantly different distribution of the *pre-miR-146a* genotypes was demonstrated between the cases and controls (χ^2 = 6.5768, P = 0.037). Furthermore, a higher frequency of G allele frequency was found in cases compared with the controls (χ^2 = 5.1232, P = 0.024).

Risk estimates for the variant pre-miR-146a genotypes

The association between gastric cancer risk and the polymorphism is presented in Table 2. With the CC genotype as reference, the OR for the variant genotypes (GG + GC) was 1.58 (95% CI: 1.12-2.22, P = 0.009) after adjusting for age, sex, smoking status, residence, hypertension, and diabetes. Moreover, the GG homozygotes had a 62% elevated risk (adjusted OR = 1.62, 95% CI: 1.01-2.58, P = 0.045), and the GC heterozygotes had a 55% increased risk (adjusted OR = 1.55, 95% CI: 1.07-2.22, P = 0.019).

Stratified analyses for the variant genotypes in cases and controls

Table 3 shows the results of stratified analyses by the median age of controls (58 years), sex, smoking status, and residence with the *pre-miR-146a* variant genotypes. A significantly increased risk associated with the variant genotypes was observed in only subjects aged ⩽ 58 years (adjusted OR = 1.76, 95% CI: 1.08-2.87, P = 0.024). In males, possession of the variant genotypes was associated with a 53% increased risk of gastric cancer (adjusted OR = 1.53, 95% CI: 1.04-2.27, P = 0.033), whereas the association was not statistically significant in females. In addition, stratification by smoking status revealed a significant cancer risk for nonsmokers (adjusted OR = 1.55, 95% CI: 1.06-2.28, P = 0.025) but not in smokers. However, no statistically significant difference was observed in rural and urban areas in the association between the polymorphism and susceptibility to gastric cancer.

We also evaluated the correlations of the variant genotypes with clinicopathologic features of gastric cancer, including tumor differentiation, depth of tumor infiltration, lymph node status and tumor location, however, no statistically significant association was observed (Table 4).

DISCUSSION

Recent genome-wide SNP polymorphisms are encouraging and widely performed to help in developing more accurate diagnostic and therapeutic strategies of various kinds of human disorders[29]. In the present study, we for the first time found that the C to G variant in *pre-miR-146a* conferred an increased risk of gastric cancer in Chinese population. We also found that the elevated gastric cancer risk was especially evident in the individuals aged ⩽ 58 years, nonsmokers and males.

The human miR-146a is located on chromosome 5[22]. In general, one miRNA targets thousands of mRNAs and one mRNA is regulated by many miRNAs. Therefore, it is very hard to understand the precise mechanisms of the miRNA in the pathogenesis of human disorders. Nevertheless, various studies have suggested that miR-146a is a NF-κB-dependent gene[30,31]. Upon processing, it could down-regulate levels of IRAK1 and TRAF6 proteins, reducing the activity of the NF-κB signaling pathway, which has been implicated as an important causal link between inflammation and carcinogenesis[9,10,32-34]. To date, aberrant miR-146a expressions have been described in several diseases[16-18,35-38]. Recent reports have indicated that miR-146a levels were increased in the tissues associated with chronic inflammatory diseases such as rheumatoid arthritis and psoriasis, whereas there was no increase of miR-146a levels in tissues obtained from patients with other chronic inflammatory diseases such as the skin from atopic eczema or lung biopsies from mild asthmatics[35-37]. Moreover, elevated miR-146a levels have been reported in PTC, cervical cancer, breast cancer and pancreatic cancer, whereas decreased miR-146a expression is associated with prostate cancer[16-18,38].

A C/G polymorphism (rs2910164) resides at position + 60 relative to the first nucleotide of *pre-miR-146a*, placing it in the passenger strand[22]. Compared with the major C allele, the minor G allele causes mispairing in the hairpin and a higher dG from -40.3 to -43.1 kcal/mol, suggesting

Table 2 The *pre-miR-146a* C/G genotype distribution in cases and controls and risk estimates for variant genotypes

	Cases (%)	Controls (%)[1]	Crude OR (95% CI)	*P* value	Adjusted OR[2] (95% CI)	*P* value

a more stable secondary structure for the G allele[39]. The genetic variant might have an impact on processing the pre-miRNA into the mature microRNA. The mutation in *pre-miR-146a* gene has been reported to modulate cancer risks, although the results are inconsistent[22-26]. Xu *et al*[23] showed that male individuals with GG genotype were 2-fold more susceptible to HCC (OR = 2.016, 95% CI: 1.056-3.848, P = 0.034) compared to those with CC genotype. In a case-control study, Xu *et al*[24] suggested that CC homozygotes exhibited an association with prostate cancer with a 65% decreased risk (95% CI: 0.43-0.99, P = 0.03). Findings by Jazdzewski *et al*[22] demonstrated that the GC

heterozygous state was associated with an increased risk of acquiring PTC (OR = 1.62, P = 0.000007), and both homozygous states were protective with OR = 0.42 for the CC genotype and OR = 0.69 for the GG genotype. Although one study showed that this polymorphism did not appear to be linked with an increased risk of breast cancer[26], another indicated that those breast and ovarian cancer patients who had at least one C allele were diagnosed at an earlier age (median age: 45 *vs* 56, P = 0.029 for breast cancer; median age: 45 *vs* 50, P = 0.014 for ovarian cancer)[25]. We noted that, compared with the CC genotype, the G allele carriers had a 55% increased risk of gastric cancer. After adjustment for age, sex, smoking status, residence, hypertension and diabetes, the difference still existed, confirming that the polymorphism was related to the risk of gastric cancer in China. Although the precise mechanisms of miRNA expression regulation are largely unknown and the inconsistent effect of miRNA SNP for cancer diagnosis and prognosis is ambiguous, those results may imply that miRNA expression patterns are associated with the biological and clinical behavior of human cancers.

Our data showed that the polymorphism was associated with the increased risk of gastric cancer among subgroups of the subjects aged ≤ 58 years, whereas not among older subjects. Overwhelming accumulated exposure to environmental carcinogens and weak immune system in older individuals may account for the age difference we observed[28]. An old age is related to an increased risk for gastric cancer, which is more likely due to the age effect rather than the direct genetic effect. Therefore, the polymorphism in the *pre-miR-146a* may be more evident in early-onset gastric cancer, although this age-specific association needs to be further replicated.

Tobacco smoking is a known cause of gastric cancer[40]. The association between the polymorphism and gastric cancer risk may be masked by the relatively high-level exposure to tobacco carcinogens in smokers so that it is more influential in nonsmokers.

Subsequently, a positive correlation between *pre-miR-146a* genotype and sex was found. A significantly elevated risk of gastric cancer was observed for the GG + GC genotypes among males but not among females. Xu *et al*[23] also concluded that male individuals with GG genotype were more susceptible to HCC compared to those with CC genotype. Based on the findings, it would therefore be plausible to expect that the sex-specific effect of *pre-miR-146a* may be responsible for the different results between males and females, although the exact mechanism remains unclear.

Further stratified analyses by clinicopathologic parameters of gastric cancer showed no significant association between the *pre-miR-146a* genotypes and clinical pathological parameters of gastric cancer. Gastric cancer is considered to be a complex, multi-step and multi-factorial process. Although our data did not support a causal link between the variant genotypes and gastric cancer progression, we could not exclude the possibility that other factors might impact the interaction between them. Moreover, the size of cases in the subgroups was relatively small; our findings from the stratified analyses should be interpreted with caution before confirmed in further studies.

Several limitations should be addressed in the study. First, lack of information on *Helicobacter pylori* (*H. pylori*) infection status did not allow us to analyze the interaction between the polymorphism and *H. pylori* infection status, because it was unethical to do *H. pylori* test in every subject. Second, the sample size was relatively small. This may have been underpowered to detect small but real gene-environment associations. Finally, the study was conducted in Chinese population, data should be extrapolated to other ethnic groups cautiously. Nevertheless, our initial data presented valuable insights and interesting information to guide future studies in this area.

In summary, our results suggested that *pre-miR-146a* C/G polymorphism is associated with the increased risk of gastric cancer in Chinese population, especially in younger individuals, nonsmokers, and males. Further studies are required to elucidate the mechanism underlying the polymorphism and gastric cancer progression.

COMMENTS

Background

MiR-146a is a small non-coding regulatory RNA supposed to regulate innate immune, inflammatory response and antiviral pathway negatively. Polymorphism in human *pre-miR146a* has been recently implicated in human cancers.

Research frontiers

Using polymerase chain reaction-restriction fragment length polymorphism method in 608 individuals, this study explored the relationship between *pre-miR-146a* C/G polymorphism and gastric cancer risk.

Innovations and breakthroughs

The results suggest that the polymorphism is associated with the elevated risk of gastric cancer in Chinese population, especially in younger individuals, males and nonsmokers.

Applications

The results of this study could be helpful in further understanding the genetic determinants of gastric cancer.

Peer review

This manuscript describes the association of a single nucleotide polymorphism in the *hsa-miR-146a* with gastric cancer, which is novel for this particular type of cancer, but biologically plausible owing to the associations reported by other authors for different types of tumors.

Abstract

AIM: To investigate whether tumor debris created by high-intensity focused ultrasound (HIFU) could trigger antitumor immunity in a mouse hepatocellular carcinoma model.

METHODS: Twenty C57BL/6J mice bearing H22 hepatocellular carcinoma were used to generate antitumor vaccines. Ten mice underwent HIFU ablation, and the remaining 10 mice received a sham-HIFU procedure with no ultrasound irradiation. Sixty normal mice were randomly divided into HIFU vaccine, tumor vaccine and control groups. These mice were immunized with HIFU-generated vaccine, tumor-generated vaccine, and saline, respectively. In addition, 20 mice bearing H22 tumors were successfully treated with HIFU ablation. The protective immunity of the vaccinated mice was investigated before and after a subsequent H22 tumor challenge. Using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay, the cytotoxicity of splenic lymphocytes co-cultured with H22 cells was determined *in vitro* before the tumor challenge, and tumor volume and survival were measured *in vivo* after the challenge in each group. The mechanism was also explored by loading the vaccines with bone marrow-derived dendritic cells (DCs).

RESULTS: Compared to the control, HIFU therapy, tumor-generated and HIFU-generated vaccines significantly increased cytolytic activity against H22 cells in the splenocytes of the vaccinated mice ($P < 0.001$). The tumor volume was significantly smaller in the HIFU vaccine group than in the tumor vaccine group ($P < 0.05$) and control group ($P < 0.01$). However, there was no tumor growth after H22 rechallenge in the HIFU therapy group. Forty-eight-day survival rate was 100% in mice in the HIFU therapy group, 30% in both the HIFU vaccine and tumor vaccine groups, and 20% in the control group, indicating that the HIFU-treated mice displayed significantly longer survival than the vaccinated mice in the remaining three groups ($P < 0.001$). After bone marrow-derived DCs were incubated with HIFU-generated and tumor-generated vaccines, the number of mature DCs expressing MHC-Ⅱ$^+$, CD80$^+$ and CD86$^+$ molecules was significantly increased, and interleukin-12 and interferon-γ levels were significantly higher in the supernatants when compared with immature DCs incubated with mouse serum ($P < 0.001$). However, no differences of the number of mature DCs and cytokine levels were observed between the HIFU-generated and tumor-generated vaccines ($P > 0.05$).

CONCLUSION: Tumor debris remaining after HIFU can improve tumor immunogenicity. This debris releases tumor antigens as an effective vaccine to develop host antitumor immune response after HIFU ablation.

INTRODUCTION

As a non-invasive thermal ablation, high-intensity focused ultrasound (HIFU) therapy has received increasing attention for the clinical management of patients with solid tumors, including those of the prostate, liver, pancreas, breast, kidney, uterus, bone and soft tissue[1-3]. Under real-time imaging guidance, this technique uses ultrasound energy locally to ablate a targeted tumor at depth, with no damage to overlying tissues. In addition, it has been shown that HIFU ablation can enhance host antitumor immune response[4-13], which may be of benefit in local recurrence and metastasis control in cancer patients who have previous dysfunction of antitumor immunity.

Selective recognition and destruction of tumor cells by the host immune system is a major role of antitumor immunity, and tumor antigens expressed by tumor cells are essential to achieve this antitumor immune response specific to tumor cells. After HIFU ablation, large amounts of tumor debris remain *in situ,* and the host gradually reabsorbs them as a normal process of the healing response. Our previous findings revealed a variety of tumor antigen expressions on HIFU-ablated breast cancer cells[15]. Some tumor antigens disappeared completely, others remained in their entirety such as heat shock protein (HSP) 70, while most remained partially in the tumor debris after HIFU ablation. However, it is still unknown whether the remaining tumor debris may be a potential antigen source available for the induction of host antitumor immunity. To test HIFU effects on the inherent immunogenicity of the tumor debris, we performed HIFU to ablate *in vivo* hepatocellular carcinoma (HCC), and then used the tumor debris to inoculate naïve animals against subsequent tumor challenge. The purpose of this study was to investigate whether the remaining tumor debris created by *in situ* HIFU ablation could be strongly immunogenic as an effective tumor vaccine to stimulate host antitumor immunity, and to provide potential benefit in long-term survival in a murine tumor model.

MATERIALS AND METHODS

Animals

The animal study was approved by the Chongqing Experimental Animal Committee (Chongqing, China). Male and female C57BL/6J mice (6-8 wk old) were obtained from the Experimental Animal Center of Chongqing Medical University (Chongqing, China), and housed in microisolator cages in a laminar flow unit under ambient light in the same animal center. All animal experiments adhered to the Animal Welfare Committee guidelines.

Tumor and vaccine generation

The H22 HCC cell line was provided by the Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences (Shanghai, China). 2×10^6 H22 cells (0.02 mL) were injected subcutaneously into the right flank of syngeneic C57BL/6J mice to establish a tumor model. Palpable tumors started to develop after 3 d, and reached the size of 5-7 mm after 7 d.

Twenty C57BL/6J mice bearing H22 tumors were used to generate antitumor vaccines at day 7 after tumor implantation. Under general anesthesia 10 mice underwent HIFU ablation, and the remaining 10 mice received a sham-HIFU procedure with no ultrasound irradiation. HIFU energy was produced by a 2-cm diameter transducer with a focal length of 8 mm, operating at a frequency of 9.5 MHz. Acoustic power was 5 W, and median exposure time was 220 s (range: 180-240 s). All mice were sacrificed 1 d after treatment, and tumor samples were harvested. The tissues were brought up to the same weight in both treated and untreated tumors, and they were respectively minced and homogenized. Repetitive freeze-thaw cycles were performed for the preparation of cellular lysate. Using the Bradford assay (Bio-Rad, Hercules CA, USA), the same protein concentration (0.5 mg/mL) was also achieved in both lysates, where the treated and untreated tumor tissues had the milligram per milliliter protein concentration in RPMI 1640.

Immunization

Sixty C57BL/6J mice were randomly divided into three groups: control group, tumor vaccine group and HIFU vaccine group. Each group had 20 mice, including 10 for cytotoxic T lymphocyte (CTL) assay 15 d after vaccination and 10 for long-term follow-up after tumor challenge. By using subcutaneous injection, the mice in the tumor group and HIFU group received either 10 μg untreated H22 vaccine or 10 μg HIFU-treated H22 vaccine in the left flank of each mouse. Those in the control group received only injection with same amount of saline solution. The vaccination times were 2 sessions, once a week for 2 consecutive weeks.

Cytotoxicity assay of CTL

Ten mice were sacrificed 7 d after the final vaccination in each group, and spleens were harvested to assess the activity of splenic CTL. Single cell suspensions were generated by passage through a metallic mesh. Erythrocytes were lysed with 0.87% ammonium chloride for 1 min, and macrophages were removed by exposure to plastic plates for 2 h. The nonadherent lymphocytic population was collected, washed, and resuspended at 2×10^6 cells/mL as CTL

effectors. H22 and B16 (a mouse melanoma cell line) cells were used as targeted cells, and the effector/target cell ratio was 10:1, which was the best cellular ratio in our pre-experimental study. The splenic lymphocytes were then co-cultured with either H22 or B16 cells in 96-well plates for 24 h. The 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay was performed to determine the cytotoxicity of the CTLs in each group. This is a standard colorimetric assay for determining *in vitro* cytotoxicity of CTLs against tumor cells in experiments[16,17]. As negative control groups, an equal number of target cells were cultured alone and an equal number of effector cells were cultured without target cells in a total of 200 μL. Using a multiwell spectrophotometer reader (Molecular Devices, Menlo Park, California, USA), the optical intensity at 570 nm was measured. Each assay was performed in triplicate, and RPMI 1640 medium was used as a blank control. According to the optical intensity in each group, the cytotoxicity calculation was determined by the following equation: Cytotoxicity (%) = (Effector spontaneous + Target spontaneous - Experimental)/(Target spontaneous - Target maximal) × 100%.

Tumor challenge

Seven days after the final vaccination, 10 mice were challenged in each group by subcutaneous injection of 2×10^6 H22 cells (0.02 mL) in the right flank of each mouse. The tumor growth was detected every 3 d by measuring its diameter with a Vernier caliper. Tumor volume was calculated using the following formula: tumor volume (mm^3) = $d^2 \times D/2$, where d and D are the shortest and longest diameters of the measured tumor, respectively. All mice were followed up for 48 d to observe the survival data.

Immune response after HIFU

Twenty C57BL/6J mice bearing H22 tumors were treated with HIFU at day 7 after tumor implantation to determine whether specific antitumor reactivity could be detected directly after HIFU ablation. These mice were classified as the HIFU therapy group in this study, and HIFU therapeutic parameters were similar to those used in generating the HIFU-related tumor vaccine. Fifteen days after HIFU ablation, 10 mice were sacrificed for the assessment of *in vitro* CTL cytotoxicity as described above, and the remaining 10 were rechallenged with 2×10^6 H22 tumor cells to follow long-term survival.

Isolation and culture of bone marrow-derived dendritic cells

Bone marrow-derived dendritic cells (DCs) were isolated from C57BL/6J mice, as described by Inaba and colleagues[18]. Briefly, DCs were obtained from bone marrow precursors by flushing mouse femur and tibia bones with cold PBS. After erythrocytes were lysed with ammonium chloride, erythrocyte-depleted bone marrow cells (4×10^6/2 mL per well) were cultured in 6-well plates (Nunc, Roskilde, Denmark) in complete medium (RPMI 1640 supplemented with 10% FBS, L-glutamine, 5 mmol/L 2-mercaptoethanol, and antibiotics) at 37℃ in a humidified atmosphere with 50 mL/L CO_2. The culture medium also contained 20 ng/mL mouse recombinant granulocyte macrophage colony-stimulating factor (mrGM-CSF; PeproTech, London, UK) and 20 ng/mL mouse recombinant interleukin-4 (mrIL-4; PeproTech, London, UK). The cultures were fed every 2 d with fresh medium containing 10 ng/mL mrGM-CSF and 10 ng/mL mrIL-4. On day 7, nonadherent and loosely adherent cells were collected, washed, and resuspended in PBS at 1×10^6/mL. These cells presented the typical morphological characteristics of immature DCs, and flow cytometry analysis showed that a majority (75%-80%) of them had positive expression of CD11c and CD205 molecules.

DCs loaded with vaccines

2×10^6/mL immature DCs were primed with either 5 μg H22 tumor vaccine (tumor vaccine group) or 5 μg HIFU-generated vaccine (HIFU vaccine group) in complete medium at 37℃. DCs co-cultured with the same amount of mouse serum alone were classified as the control group. These cells were incubated for 5 d in a humidified atmosphere with 50 mL/L CO_2. Using flow cytometry (FACSCalibur™ Flow Cytometer, BD Biosciences, San Jose, CA, USA), the cells in each group were then analyzed for the expression of MHC class Ⅱ, CD80, and CD86 molecules. Culture supernatants were harvested in each group, and cytokine production was determined in the supernatants by enzyme-linked immunosorbent assay using murine kits from R&D Systems (Minneapolis, MN, USA) for interleukin (IL)-12 and interferon (IFN)-γ, according to the manufacturer's recommendations. Each assay was performed in triplicate with separate DC preparations.

Statistical analysis

All observed data are displayed as mean ± SD. Statistical analysis was performed using the Student's *t* test. A cumulative survival rate was calculated by using the Kaplan-Meier method, and the statistical significance of any survival difference was evaluated by the log-rank test. Differences were considered statistically significant when the *P* value was less than 0.05.

RESULTS

HIFU-generated vaccine induces CTL cytotoxicity against H22 Cells

As shown in Figure 1 and Table 1, HIFU therapy, tumor- and HIFU-generated vaccines significantly increased cytolytic activity against H22 cells in the splenocytes of the vaccinated mice when compared with the activity in mice vaccinated with saline alone ($P < 0.001$). None of the vaccines elicited CTL cytotoxicity to control target B16 cells ($P > 0.05$), suggesting that HIFU therapy and the HIFU-generated vaccine could induce specific antitumor immunity. The splenocytes isolated from the HIFU-treat-

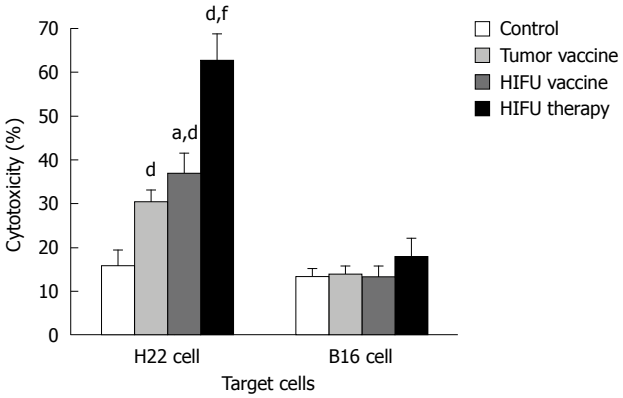

Figure 1 Cytotoxic activity of cytotoxic T lymphocytes against either H22 or B16 tumor cells *in vitro* at 10:1 effector:target ratio in the vaccinated and high-intensity focused ultrasound-treated mice. Naïve mice were vaccinated with high-intensity focused ultrasound (HIFU)-generated and tumor-generated vaccines, and saline alone once a week for 2 wk. The mice bearing H22 tumors were also treated with HIFU ablation. The vaccinated animals were sacrificed 7 d after the 2nd vaccination, and the HIFU-treated mice were sacrificed 15 d after HIFU therapy. The spleens were harvested, and single cell suspensions were generated. The splenic lymphocytes were then co-cultured with either H22 or B16 cells for 24 h. The cytotoxicity of the cytotoxic T lymphocytes was determined with a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay in each group after 2 h co-incubation. [a]$P < 0.05$ *vs* the tumor-generated vaccine; [d]$P < 0.001$ *vs* the control; [f]$P < 0.001$ *vs* the HIFU- and tumor-generated vaccines.

ed mice produced significantly stronger anti-H22 CTL activity than that of either the HIFU vaccine or tumor vaccine group ($P < 0.001$). The HIFU-generated vaccine was significantly better than the tumor-generated vaccine at increasing the cytotoxicity of CTLs ($P = 0.013$).

HIFU-generated vaccine mediates inhibition of tumor growth

The tumors were monitored with the caliper for 4 wk until mean tumor size was too variable due to death of the mice. As shown in Figure 2 and Table 2, vaccination with HIFU-treated tumor had a marked inhibitory effect on tumor growth in the 3rd and 4th wk of the tumor challenge when compared with the control (saline) ($P < 0.01$) and tumor-generated groups ($P < 0.05$). The strongest inhibition was observed in the HIFU therapy group because after H22 rechallenge no tumor growth was detected during the follow-up period. An inhibition of tumor growth was

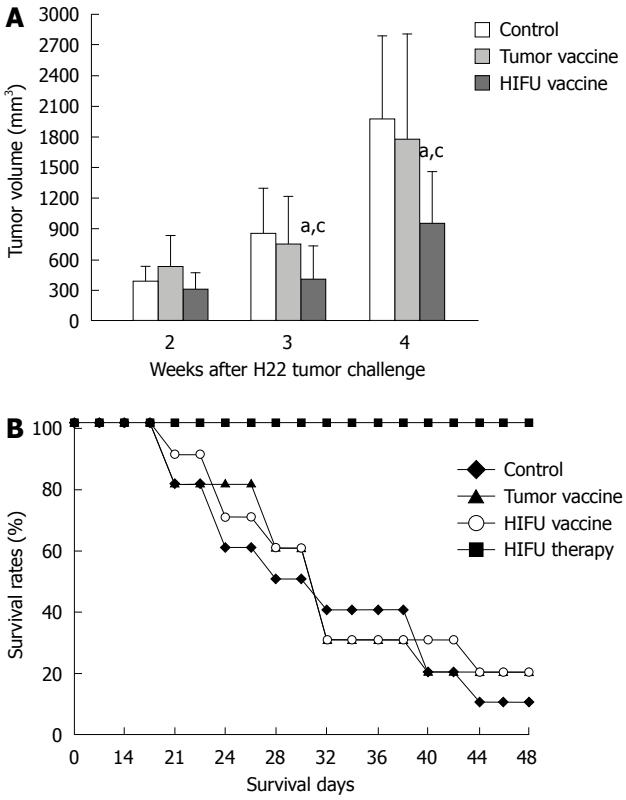

Figure 2 High-intensity focused ultrasound-generated vaccine inhibits tumor growth after a subsequent tumor challenge in a mouse H22 tumor model. Naïve mice were vaccinated with high-intensity focused ultrasound (HIFU)-generated and tumor-generated vaccines, and saline alone once a week for 2 wk. The mice bearing H22 tumors were also treated with HIFU ablation. 7 d after the 2nd vaccination, the vaccinated animals were challenged with 2×10^6 viable H22 cells, and the HIFU-treated mice received a second tumor challenge with the same number of H22 cells 15 d after HIFU therapy. Tumor diameters were measured for 3 wk, and the results were reported as the tumor volume. All mice were followed up for 48 d, and a cumulative survival rate was calculated in each group. A: The tumor volume, measured with a Vernier caliper, in the vaccinated and HIFU-treated mice after a subsequent tumor challenge. [a]$P < 0.05$ *vs* the control; [c]$P < 0.05$ *vs* the tumor-generated vaccine; B: Cumulative survival curves, calculated with the Kaplan-Meier method, in the vaccinated and HIFU-treated mice. Compared to the other groups, HIFU therapy shows a significant increase in survival ($P < 0.001$, the log-rank test).

observed in the tumor-generated vaccine group. However, there was no statistical difference between the control and tumor-generated vaccine groups ($P > 0.05$).

HIFU therapy results in better survival than tumor or HIFU vaccines

Survival of the vaccinated mice and HIFU-treated mice was also recorded for up to 48 d after tumor challenge with H22 cells. Survival curves (Figure 2) showed that 100% of HIFU-treated mice, 30% of HIFU vaccinated mice, and 30% of tumor vaccinated mice survived for 48 d, whereas 20% of saline vaccinated mice (control) survived 48 d. The HIFU-treated mice displayed significantly longer survival than the vaccinated mice in the remaining three groups ($P < 0.001$). The mice inoculated with either the HIFU-generated vaccine or tumor-generated vaccine survived a little longer than the mice vaccinated with saline (control). However, no statistical differences were observed among them.

HIFU-generated vaccine activates immature DCs

The expression of MHC class Ⅱ, CD80 and CD86 molecules on DCs was determined by flow cytometry after incubation for 5 d. As shown in Figure 3 and Table 3, incubation with either the HIFU-generated vaccine or tumor-generated vaccine significantly increased the number of mature DCs (MHC-Ⅱ$^+$, CD80$^+$ and CD86$^+$) when compared with incubation with mouse serum ($P < 0.001$), suggesting both vaccines could induce phenotypic maturation of DCs. However, no differences in the expression of MHC-Ⅱ, CD80 and CD86 were observed between the HIFU- and tumor-generated vaccines ($P > 0.05$).

HIFU-generated vaccine induces IL-12 and IFN-γ secretion by DCs

As shown in Figure 3 and Table 4, after immature DCs were incubated with HIFU- and tumor-generated vaccines, IL-12 and IFN-γ levels were significantly higher in the supernatants compared to DCs incubated with mouse serum ($P < 0.001$). However, there was no statistical difference in IL-12 and IFN-γ secretion between the HIFU and tumor vaccine groups ($P > 0.05$). These results demonstrated that both HIFU- and tumor-generated vaccines could induce the functional maturation of DCs.

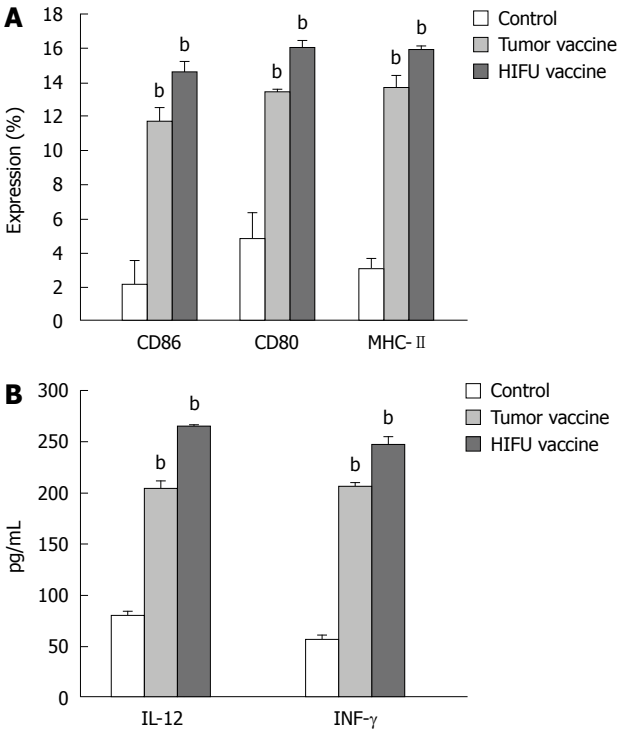

Figure 3 High-intensity focused ultrasound-generated and tumor-generated vaccines activate dendritic cells. Immature dendritic cells (DCs) were isolated from C57BL/6J bone marrow cultures, and then incubated for 5 d with the high-intensity focused ultrasound (HIFU)-generated vaccine, tumor-generated vaccine, and mouse serum alone. After incubation the cells were subjected to flow cytometry. Culture supernatants were harvested, and the enzyme-linked immunosorbent assay method was used to determine the production of interleukin (IL)-12 and interferon (IFN)-γ in the supernatants. [b]$P < 0.001$ *vs* the control. A: HIFU-generated vaccine induces the maturation of bone marrow-derived DCs. Results are reported as percentage of MHC-Ⅱ$^+$, CD80$^+$ and CD86$^+$ cells in the total population; B: HIFU-generated vaccine induces IL-12 and IFN-γ secretion by mature DCs.

DISCUSSION

The concept of HIFU as a noninvasive therapy for the local destruction of diseased tissue dates back more than 60 years. Much of the clinical application is recent, where clinical results are very promising in the treatment of solid malignancies[1-3]. It is obvious that large amounts of *in situ* tumor debris remain after HIFU ablation, however, little is known about whether this debris may be a potential antigen source for triggering host antitumor immune response. Using a newly developed tumor destruction model, we demonstrated that the remaining tumor debris can be immunogenic as an effective vaccine to elicit tumor-specific immune responses, including induction of CTL cytotoxic activity in the spleen, protection against a lethal tumor challenge in naïve mice, activation of immature DCs, and secretion of Th1-associated cytokines

by mature DCs for the development of cell-mediated immune response. To our knowledge, this is the first report of the use of HIFU ablation to generate an *in situ* tumor vaccine, and the first report of the use of this crude tumor vaccine which is functional in stimulating tumor-specific immunity in naïve animals in the absence of immune adjuvant. Our findings may contribute greatly to the understanding of how *in situ* HIFU ablation triggers the host antitumor immune response. However, with the use of flow cytometry, peptide MHC tetramers analysis is needed in the future to measure the number of antigen-specific CD8+ T lymphocytes.

Thermal and nonthermal effects are two major mechanisms related to HIFU-induced coagulation necrosis. During HIFU exposure, the absorption of ultrasound energy in a targeted tumor leads to a rapid temperature rise above 56℃ within the focal volume[19], and thus induces complete coagulation necrosis of the targeted cancer, with no direct evidence of apoptotic cells detected by the TUNEL method in the treated tumors[20].

It is postulated that antitumor immunity enhanced by the ultrasound thermal effect would be similar to those observed in other thermal therapies such as radiofrequency[21-23]. Cavitation is the most important nonthermal mechanism for HIFU-induced tissue destruction. It can cause membranous organelles, including mitochondria, endoplasmic reticulum, cell and nuclear membranes to collapse instantaneously, and thus lead to tumor cells breaking up into small pieces, on which the tumor antigens may remain intact[24]. Recent studies have revealed that acoustic cavitation can upregulate expression of tumor antigens such as heat shock proteins[4,5,8,14,15]. If heat shock proteins (HSPs) remain and upregulate as intracellular molecular chaperones in the tumor debris after HIFU ablation, they may bind tumor peptide antigens, and act as tumor vaccines to produce a potent cellular immune response[25,26]. However, as overexpression of HSPs may have deleterious effects on antitumor immunity after heat treatments such as hyperthermia, further studies are needed to evaluate whether HSPs could play an important role in the induction of host antitumor immune response after HIFU therapy.

Although the mechanism behind this enhanced immune response is still unknown, our findings reveal that it should be specific antitumor immunity. We have demonstrated that the HIFU-generated tumor vaccine can significantly elicit cytotoxicity of CTLs to H22 cells, whereas cytolytic activity against control target B16 cells was not observed in the splenocytes of vaccinated mice. Compared to tumor lysate, *in vitro* anti-H22 CTL activity was stronger in mice receiving the HIFU-generated tumor vaccine. Similar results were also observed in a mouse H22 tumor model after the vaccinated mice were challenged with H22 cells. Vaccination with HIFU-treated tumor caused a stronger inhibition of tumor growth than the control and tumor-generated vaccine groups, indicating the involvement of a tumor-specific immune response. However, this immune protection was still weak, because no significant survival benefit was observed after a lethal H22 challenge in the HIFU-generated vaccine group when compared with the control and tumor-generated vaccine groups.

We have found that the mice bearing H22 tumors, which were treated by HIFU previously, had the strongest protection against a second H22 cell challenge. The most potent cytotoxicity of CTLs against H22 cells *in vitro* was detected in mice who received previous HIFU ablation. Compared to the HIFU- and tumor-generated vaccine groups, *in situ* HIFU ablation of H22 tumors resulted in complete protection against a subsequent H22 tumor rechallenge. All mice survived during the follow-up period, with no evidence of tumor growth. These data suggest that once mice bearing H22 tumors are cured by HIFU treatment, a bona fide systemic memory response may be generated. In addition, tumor debris remaining after *in situ* ablation may continuously stimulate the host immune system during the reabsorption of dead tissue, leading to a stronger antitumor immune response. However, to support our speculation, further studies are needed to investigate the mechanisms behind this. Furthermore, as follow-up time was limited in this study, a longer period is necessary in future studies to observe the survival benefit and tumor development after tumor rechallenge in the HIFU-treated mice. Both the HIFU- and tumor-generated vaccine groups developed a relatively weak immune response, because the vaccination times were very limited, only performed once a week for 2 consecutive weeks. Therefore, further studies are necessary in this mouse H22 tumor model to optimize the vaccination method including the number of sessions, dosage and interval time. In order to induce a stronger immunological response, a longer vaccination time with the HIFU-treated tumor will be investigated, and immunoadjuvants will be used in combination with HIFU therapy.

Similar to other thermal therapies, a marked inflammatory reaction, with abundant leukocytic infiltration, has been histologically observed at the margins of coagulation necrosis in HIFU ablation[27-30]. We have recently found that HIFU ablation can significantly induce local infiltration of activated DCs within the marked inflammatory reaction in patients with breast cancer[31]. DCs are the most potent antigen-presenting cells for induction of adaptive immunity against cancer[32]. They infiltrate local tumors and present tumor antigens to naïve T lymphocytes in a MHC restricted fashion. Activating signals, delivered directly or indirectly by tumor cells including apoptotic and necrotic tumor cells, can induce the progression of infiltrating DCs from an immature to a mature stage[33]. During maturation DCs increase the expression of costimulatory molecules such as CD80 and CD86, and mature DCs secrete Th1-associated cytokines to induce cell-mediated immunity[34]. This study produced direct evidence that with no immune adjuvant, the remaining tumor debris can activate immature DCs, and thus induce secretion of IL-12 and IFN-γ by mature DCs for the development of cellular antitumor immune response. However, it is still

unknown whether the activated DCs could induce an *in situ* antitumor immune response by presenting tumor antigens directly to lymphocytes. Further studies are necessary to investigate the potential role of activated DCs in the induction of specific antitumor immunity *in vivo*.

Our findings indicate that a weak but tumor-specific immune response was produced by the HIFU-generated tumor vaccines after *in situ* tumor destruction. Therefore, active immunological stimulation such as immunoadjuvants, in combination with HIFU, could augment the efficacy of HIFU-induced antitumor immunity specifically against the targeted tumors, if the destruction of tumors releases tumor antigens or improves tumor immunogenicity.

HCC is one of the most common malignancies worldwide. Local tumor recurrence and metastasis are usually the cause of failure of multidisciplinary treatments of HCC in clinical practice. Using a mouse HCC model, we found that HIFU ablation can trigger host tumor-specific immune response. This may decrease or perhaps even eliminate residual and metastatic tumor cells in HCC patients who have had original antitumor immunity dysfunction.

In summary, this study demonstrated that tumor debris remaining after *in situ* HIFU ablation may improve tumor immunogenicity. This debris may release tumor antigens as an effective vaccine to elicit tumor-specific immune responses. However, further studies are needed to explore the nature of the "activation" factors in HIFU-generated tumor debris.

COMMENTS

Background

As a non-invasive thermal ablation, high-intensity focused ultrasound (HIFU) therapy has received increasing attention for the clinical management of patients with hepatocellular carcinoma (HCC). After HIFU ablation, large amounts of tumor debris remain *in situ*, and the host gradually reabsorbs them as a normal process of the healing response. However, it is still unknown whether the remaining tumor debris may be a potential antigen source available for the induction of host antitumor immunity.

Research frontiers

In the present study, the authors investigated whether tumor debris created by *in situ* HIFU could be an effective tumor vaccine to stimulate antitumor immunity in a mouse HCC model.

Innovations and breakthroughs

This study demonstrated that the remaining tumor debris after HIFU can be immunogenic as an effective vaccine to elicit tumor-specific immune responses, including induction of cytotoxic T lymphocyte cytotoxic activity in the spleen, protection against a lethal tumor challenge in naïve mice, activation of immature dendritic cells (DCs), and secretion of Th1-associated cytokines by mature DCs for the development of cell-mediated immune response. These findings may contribute greatly to the understanding of how *in situ* HIFU ablation triggers the host antitumor immune response.

Applications

These findings contribute greatly to the understanding of how *in situ* HIFU ablation triggers the host antitumor immune response. In addition, they suggest that HIFU ablation combined with subsequent immunotherapy such as immunoadjuvants may augment the efficacy of HIFU-induced antitumor immunity specifically against the targeted tumor, leading to a decrease of local recurrence and metastasis in HCC.

Peer review

It is a very interesting paper with adequately described and written all necessary parts of a manuscript.

Abstract

The overall survival for patients with advanced hepatocellular carcinoma (HCC) is still limited. Although the multi-kinase inhibitor sorafenib has recently been approved for this disease, response rates are still low and patients often face dose-limiting toxicities which lead to a reduction in prognosis and treatment success. We here report a patient with metastasized HCC who shows a sustained response for more than 30 mo to sorafenib therapy after failure of a first line therapy with gemcitabine, oxaliplatin and bevacizumab.

Key words: Hepatocellular carcinoma; Sorafenib; Bevacizumab; Angiogenesis

INTRODUCTION

Hepatocellular carcinoma (HCC) belongs to the most common malignancies worldwide and shows a rising incidence in Western countries due to high prevalence of chronic viral hepatitis, alcoholic liver damage and metabolic disorders associated with fatty liver degeneration[1-3]. Surgical and loco-regional approaches provide satisfying results for patient with early stage HCC, while advanced diseases with underlying cirrhosis have an unfavourable prognosis[4].

Angiogenesis and neo-vascularization are considered "hallmarks" of malignant tumors and several strategies have been established to interfere with the underlying signalling cascade[5], e.g. the anti-vascular endothelial growth factor (VEGF) antibody bevacizumab or the small molecule tyrosine kinase inhibitor sorafenib. HCC represents a highly vascularised tumor[6] and various anti-angiogenic treatment strategies have therefore been applied to this disease[7]. So far, only the multi-kinase inhibitor sorafenib provided a significant patient benefit in this setting and has therefore been approved as the first-line therapy for advanced HCC in patients with good metabolic liver capacity (Child-Pugh A)[8,9]. Although sorafenib showed a good tolerability in the study populations, most patients in clinical practice suffer from underlying liver cirrhosis with impaired metabolic function and experience dose-limiting toxicities with the need to reduce the overall dose of sorafenib subsequently[10].

We herein report a case of advanced metastatic HCC which was treated with a reduced dose of sorafenib for more than 30 mo after failure of a first-line therapy with gemcitabine, oxaliplatine and bevacizumab and intermittent radiation therapy.

CASE REPORT

In January 2007, a 56-year-old man presented in our hospital for clinical diagnosis of elevated liver enzymes with suspicion of ethyltoxic liver cirrhosis due to regular alcohol consumption of 60-80 g/d. Blood tests and ultrasonic investigation confirmed liver cirrhosis of Child-Pugh B (score 7) with elevated bilirubin (2.3 mg/dL) and acquired coagulation deficiency (INT 1.39). Ascites or hepatic encephalopathy were not present. Other aetiologies, e.g. chronic viral or autoimmune hepatitis, haemochromatosis or α_1-antitrypsin deficiency were excluded by corresponding blood tests. Moreover, multilocular (n = 6), extended lesions (diameter > 1 cm) were detected by contrast enhanced ultrasound and magnetic resonance imaging scan (largest lesions in segments Ⅱ: 1.2 cm × 1.5 cm; Ⅳa: 4.9 cm × 3.7 cm × 5.6 cm; Ⅷ: 1.9 cm × 2.9 cm). Portal vein thrombosis or invasion were not identified. High levels of α-fetoprotein (1900 ng/mL) substantiated the diagnosis of HCC according to AASLD guidelines[4,11]. Biopsy proved a well differentiated HCC (Figure 1).

For treatment of multifocal HCC, based on AASLD practice guidelines, neither systemic chemotherapy nor therapy options for a better overall survival were established in spring 2007. Locoregional methods like high frequency thermotherapy (HFTT) or radiofrequency ablation as well as transarterial chemoembolization could not be applied in this patient due to the multifocal disease[12]. It was not possible to perform selective internal radiotherapy (SIRT) representing an experimental therapy option in multilocular hepatic cancer[13]. Extrahepatic tumor manifestation was detected by positron emission tomography/computed tomography (CT) presenting a single thoracic metastasis of the 2nd rib at the right side of 8.8 cm × 7.7 cm. Consequently, SIRT was not performed. No histological analysis of this lesion was obtained as osseous metastases are typical extrahepatic manifestations of advanced HCC[14-16]. According to the Barcelona Clinic Liver Cancer staging system, our patient was classified as stage C (advanced stage) with good ECOG performance (status 1-2)[17]. We therefore considered the patient for new agents or randomized controlled trials[6].

Off-label use of systemic drug therapy seemed to offer the best option to sustain this patient at this time. A review of the literature available in January 2007 disclosed a phase Ⅱ trial with moderate response rates in palliative HCC treatment by a combination of gemcitabine, oxaliplatin (GemOx) and the angiogenesis inhibitor bevacizumab[18]. After informed consent of the patient, an individualized chemotherapy with this regimen was started in May 2007. The patient received 10 mg/kg bevacizumab on day 1 together with 1000 mg/m^2 gemcitabine followed by oxaliplatin at 85 mg/m^2 on day 2. First staging was performed after four cycles (14 d/cycle) resulting in a moderate tumor progression on thoracic CT scan and ultrasound but showed a good overall tolerability and stable primary tumors in the liver. Therapy was continued based on a good overall tolerability, the strong wish of the patient for continuing and the fact that no other therapy option was available at this time. The ongoing systemic chemotherapy induced a moderate pancytopenia, slight renal dysfunction and weight loss (8 kg in 8 mo). Yet, discontinuation of the therapy regimen was not necessary until 2nd staging in September 2007. Here, further progression of the thoracic metastasis with stable disease of hepatic lesions was demonstrated by CT and ultrasound scans (Figure 2).

At this time, a significant benefit for advanced HCC was proven in a randomized controlled phase Ⅲ trial using the novel raf-kinase inhibitor sorafenib as a single agent[8] which lead to the approval of sorafenib for the first-line therapy of advanced HCC in December 2008[9]. Treatment was started in October 2007 with the recommended dose of 800 mg/d. Known side effects (e.g. diarrhea, hand-foot-reaction, oral ulceration) developed during the first 2 wk of treatment and were handled symptomatically (e.g. loperamide, oily creams, mucositis solutions) and with a concomitant dose-reduction of sorafenib to 400 mg/d. Staging after 12 mo revealed an extraordinary regression of both hepatic and thoracic tumor masses (Figure 3). To avoid potential tumor progression by drug resistance, the patient underwent local radiation of the osseous metastases with a total of 66 Gy in November 2008. In March 2009 and 18 mo after initiation of sorafenib therapy, a single remaining calcifying lesion of hepatic segment Ⅳa was ablated by ultrasound-controlled HFTT (Figure 4). Facial and cleavage erythema, dry cough and hoarseness remained under continued sorafenib therapy, but were at a tolerable level. Liver function was stabilized at Child-Pugh A after treatment of a temporarily acquired coagulation deficiency with vitamin K. Now, 36 mo after first diagnosis of advanced HCC, the patient still consults our outpatient ward for regular surveillance in excellent general condition.

Histological aspects

Histological examination of both the primary biopsy and the biopsy material following treatment revealed essentially similar findings (Figure 1). The liver parenchyma showed micronodular cirrhosis with moderate steatosis without significant necroinflammatory activity. The tumor was composed of large polyhedral tumor cells with centrally located vesicular nuclei and prominent nuclei, arranged in trabeculae and pseudo-acinar structures. The cytoplasm was eosinophilic to pale or clear. Immunohistochemistry revealed a prominent vascularisation. In addition, tumor cells at the periphery expressed the VEGFR1, but were negative for VEGFR2/3. The proliferative index (Ki67) was well below 5%. The cytological features were consistent with a well differentiated

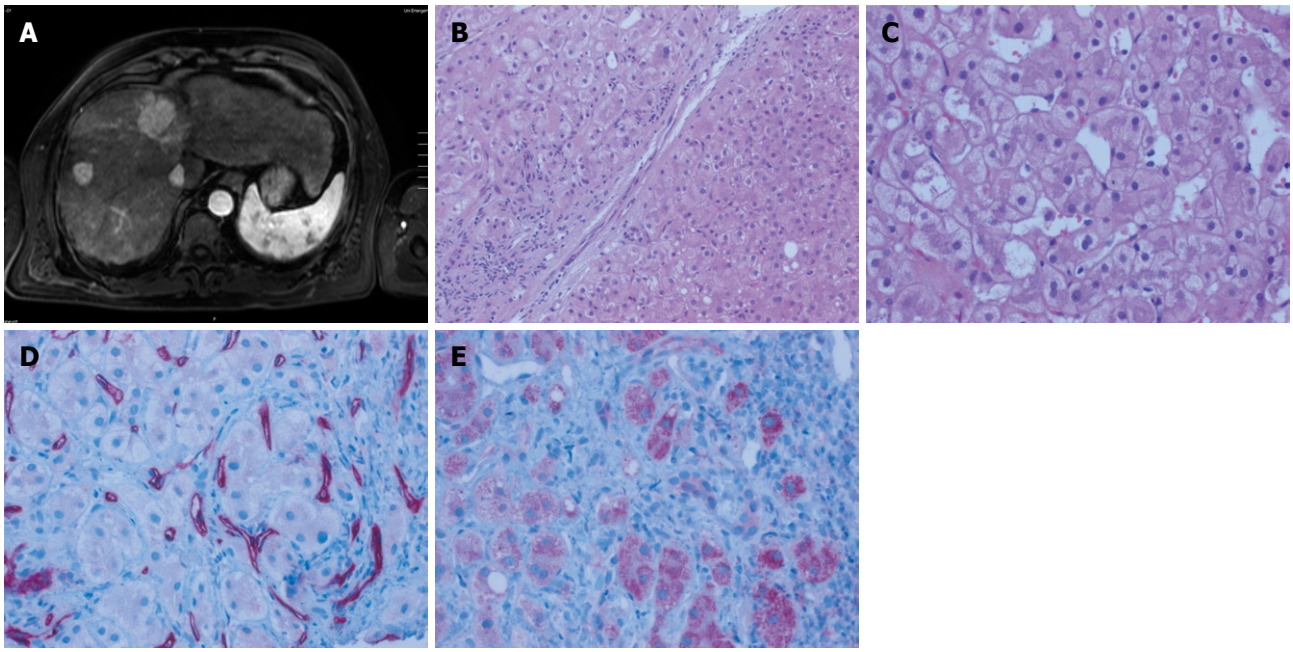

Figure 1 Baseline radiologic and pathologic assessment of the patient in late 2006 before initiation of therapy. A: Initial magnetic resonance imaging (MRI) scan revealing multiple hepatocellular carcinoma (HCC) nodules; B: Regenerative nodule (lower right) juxtaposed to well circumscribed HCC (upper left) separated by a fibrous septum with a sparse lymphocytic infiltrate (magnification, × 100); C: Representative high power magnification of the HCC showed large tumor cells with occasional vacuoles and microvesicular fatty degeneration of hepatocytes (magnification, × 200); D: Abnormally increased microvessel density within the HCC as demonstrated by CD34 immunohistochemistry (magnification, × 200); E: Tumor cells express VEGFR1 at the tumor front (right) contrasting with weak expression towards to the tumor centre (left; magnification, × 200).

HCC in a background of cirrhosis.

DISCUSSION

We here report the extraordinary success in treating metastatic HCC by a sequential therapy with gemcitabine,

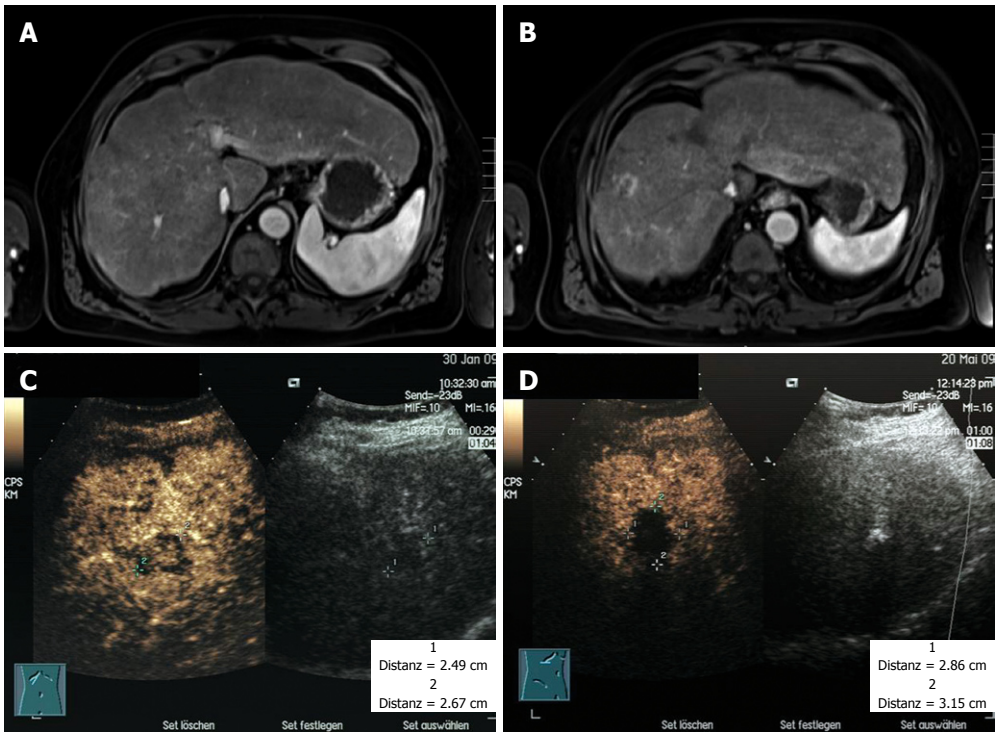

Figure 4 Magnetic resonance imaging scans of the liver in spring 2009, 18 mo after initiation of sorafenib therapy (A, B) and the contrast-enhanced ultrasound investigation of a single calcifying lesion of segment IVa before (C) and after (D) ablation by ultrasound controlled high frequency thermotherapy in spring 2009.

oxaliplatin, bevacizumab, internal radiation and treatment with the novel multi-kinase inhibitor sorafenib in a single patient with a survival time of more than 40 mo since the initial time of diagnosis and more than 30 mo since beginning sorafenib therapy (Figure 5).

Although sorafenib was established as first-line therapy for advanced HCC and approximately 70% of patients showed a stable disease in the initial trials[8,9], the overall response rate is below 3% and it does not therefore provide a significant survival benefit compared to other recently established experimental therapies[7]. Interestingly, the initial report on GemOx and bevacizumab in advanced HCC showed an overall response rate of 20% as well as progression free survival and overall survival rates comparable to the SHARP trial[7,9,18]. The tumor of our patient was well differentiated which indicates a good metabolic and detoxifying capacity of the tumor cells. In addition, the proliferation index was below 5% which indicates that drugs with a strong S-phase effect like pyrimidine-analogues are ineffective in this case.

Several recent studies highlighted the importance of anti-angiogenesis in HCC[19]. As angiogenesis-inhibitory effects represent the main mechanisms of action for both sorafenib and bevacizumab, additive effects are therefore conceivable. This concept has been proven successfully by Azad *et al*[20] in a phase I trial with advanced solid tumors and in a phase II trial in epithelial ovarian cancer[21], although enhanced toxicities were observed. In contrast to this study where both agents were applied simultaneously, we used a sequential approach of GemOx and bevacizumab before applying sorafenib, which may explain the good tolerability of this regime in our case. We started sorafenib therapy 26 d after the last application of bevacizumab, which is still in the range of bevacizumab's half-life in humans (approx 20 d, range 11-50 d)[22,23].

Preclinical data suggest that radiation therapy ameliorates the effect of anti-angiogenic therapeutics in rectal cancer, non-small cell lung cancer or malignant glioma[24]. Several mechanisms are discussed for this effect, e.g. increasing vascular permeability with improved delivery of cytotoxic agents to the tumor, and further investigations on determining the optimal biological dose as well as drug sequencing are therefore urgently needed. Yet, several studies showed that radiation therapy can sensitize human tumors, including HCC, for sequential sorafenib therapy[25-27].

Our patient experienced a rapid need for dose reduction of sorafenib which was accompanied by a good response of the tumor lesions. As dose reductions for sorafenib are usually not associated with the here observed rapid response, we conclude that the combination therapy and not sorafenib monotherapy is responsible for the observed therapeutic effect.

Based on these findings from the literature and our own experience, we assume that the sequential therapy with bevacizumab and sorafenib inhibits angiogenetic signalling pathways from both upstream at the receptor level and downstream at the level of signalling kinases and that this dual effect is further supported by the influence of radiation therapy. This strategy should therefore be validated in a larger series of patients with advanced HCC and other solid malignancies.

Abstract

Postoperative biliary strictures are the most common cause of benign biliary stricture in Western countries, secondary to either operative injury or bile duct anastomotic stricture following orthotopic liver transplantation (OLT). Surgery or endoscopic interventions are the mainstay of treatment for benign biliary strictures. We aim to report the outcome of 2 patients with refractory anastomotic biliary stricture post-OLT, who had successful temporary placement of a prototype removable covered self-expandable metal stent (RCSEMS). These 2 patients (both men, aged 44 and 53 years) were given temporary placement of a prototype RCSEMS (8.5 Fr gauge delivery system, 8 mm × 40 mm stent dimensions) in the common bile duct across the biliary stricture. There was no morbidity associated with stent placement and removal in these 2 cases. Clinical parameters improved after the RCSEMS placement. Long-term biliary patency was achieved in both the patients. No further biliary intervention was required within 14 and 18 mo follow-up after stent removal.

INTRODUCTION

Endoscopic intervention has emerged to become the first line treatment for benign biliary strictures (BBS) following orthotopic liver transplantation (OLT)[1,2]. The current endoscopic approach involves repetitive dilatation of the stricture and placement of multiple large-diameter parallel plastic stents with frequent stent exchange to prevent cholangitis.

Self-expandable metal stents (SEMS) have been used for malignant biliary strictures, however SEMS placement for BBS has not been widely accepted owing to tissue ingrowth leading to long-term complications[3-5]. A removable covered SEMS (RCSEMS) has not been extensively studied in the context of BBS but shows promise in early reports[6]. We report our preliminary experience with a prototype RCSEMS in 2 patients with refractory benign post-OLT anastomotic biliary strictures in Royal Prince Alfred Hospital, Sydney.

CASE REPORT

Two patients in our department with post-OLT anas-

Table 1 Patient characteristics

Case No.	Age (yr)	Gender	Etiology	Location of stricture	Interventions prior to RCSEMS placement	Duration of RCSEMS placement (d)
1	53	Male	Post-OLT anastomotic stricture Hepatitis C cirrhosis	Mid-CBD	3 ERCPs with balloon dilatation and multiple stent insertions	70
2	44	Male	Post-OLT anastomotic stricture Hepatitis C and alcoholic cirrhosis	Mid-CBD	5 ERCPs with balloon dilatation and multiple stent insertions One session of PTC with biliary dilatation and stent placement	42

RCSEMS: Removable covered self-expandable metal stent; OLT: Orthotopic liver transplantation; CBD: Common bile duct; PTC: Percutaneous transhepatic cholangiography; ERCP: Endoscopic retrograde cholangiopancreatography.

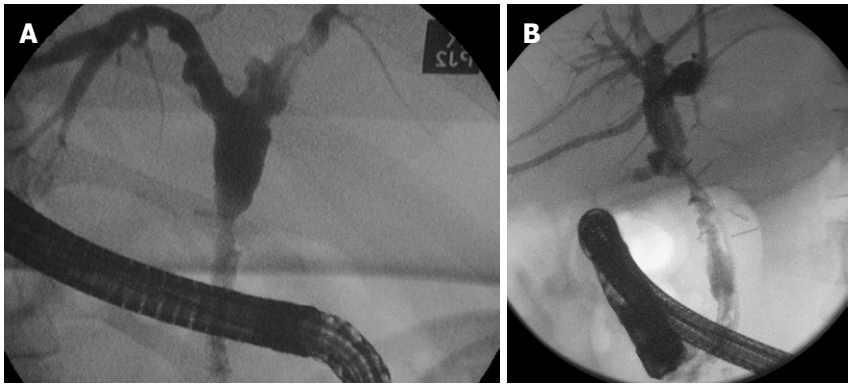

Figure 1 Stricture at mid-common bile duct. A: Case 1; B: Case 2.

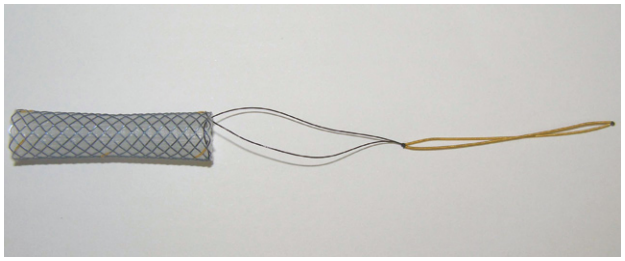

Figure 2 Removable covered self-expandable metal stent with characteristic waist at mid-portion and a radio-opaque string attached to its distal end.

Figure 3 Deployed removable covered self-expandable metal stent with radio-opaque string extending into the duodenum (Case 1).

tomotic stricture refractory to conventional endoscopic and/or surgical interventions were treated with RCSEMS and prospectively followed. They both had similar clinical scenarios: recurrent cholangitis secondary to post-OLT anastomotic stricture, and failure of conventional placement of plastic stent in the common bile duct (CBD) to alleviate biliary stricture.

The clinical presentations of these 2 patients are described in Table 1. Their cholangiograms prior to stenting are shown in Figure 1A and B.

The prototype RCSEMS is a Niti-S biliary stent (Figure 2) which consists of an implantable metal stent and a flexible introducer system (Taewoong Medical Co Ltd., South Korea). The stent is a semi-rigid, flexible and expandable tubular device made of nitinol (nickel titanium alloy) wire. Upon deployment, RCSEMS imparts an outward radial force on the luminal surface of the biliary duct to establish patency. RCSEMS is available in one diameter (8 mm mid-portion and 10 mm at either ends) and one length (40 mm). There are 2 characteristic features of this prototype stent. Firstly, a 10 cm radio-opaque nylon string is incorporated into the distal end of the stent to facilitate endoscopic retrieval. Secondly, it has a waist which is 2 mm narrower than each end. RCSEMS is approved by Australian Therapeutic Goods Administration for use in biliary strictures.

Side-viewing duodenoscopes (TJF-Q160R, and TJF-160VR; Olympus, Japan) were used for all procedures. All procedures were performed under general anesthesia. Sphincterotomy was performed in both cases prior to RCSEMS insertion. Over a guidewire and with fluoroscopic control, the RCSEMS was placed in the CBD across the stricture. Once the outer sheath was retracted and the stent deployed the catheter sheath was further retracted to release the 10 cm-long removal string. Figure 3 shows the cholangiogram with the RCSEMS *in situ*.

The removal of the RCSEMS was performed using a standard endoscopy biopsy forceps by grasping the

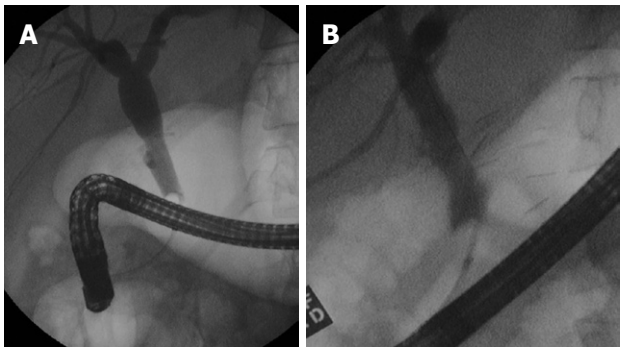

Figure 4 Common bile ducts of cases 1 (A) and 2 (B) after removal of the stent.

string attached at the distal end of the RCSEMS and then pulling it *via* the working channel of the duodenoscope. A cholangiogram was performed at the end of the procedure to confirm the patency of CBD after RCSEMS removal (Figure 4A and B). All procedures were performed by a single dedicated endoscopist.

An RCSEMS was successfully placed in both patients as outpatient day procedures. The immediate post-RCSEMS placement period was uneventful. Liver biochemistry improved. The stent remained *in situ* for 42 and 70 d and no stent migration was observed.

RCSEMS removal was performed as an outpatient day procedure and was straightforward. Endoscopic retrograde cholangiopancreatography images of CBD post-RCSEMS removal demonstrated good patency (Figure 4A and B) with an improvement in diameter of more than 50% at the strictured area.

Patients were followed up after the RCSEMS removal for 14 and 18 mo. During follow-up, liver function tests remained stable. No further episode of jaundice and cholangitis and no further procedure was indicated.

DISCUSSION

In Western countries, postoperative BBS are usually secondary to intraoperative injury, most commonly during laparoscopic cholecystectomy. BBS following OLT can be anastomotic secondary to local ischemia or non-anastomotic, which are usually related to hepatic artery ischemia and often result in complex hilar structuring.

Historically, surgery was considered the treatment of choice for refractory BBS, offering 70% to 90% long term success[7,8]. However, endoscopic intervention has proven to be as effective as surgical intervention in the management of BBS in recent years[9-12]. This was best shown by treatment protocols usually consisting of insertion of increasing numbers of parallel plastic stents with or without biliary dilatation. Despite these endoscopic approaches, significant failure rates in stricture resolution have been encountered. In a study by Alazmi *et al*[13] on 143 post-OLT patients who were followed for 28 mo, the recurrence rate of stricture following endoscopic treatment was estimated to be 18%.

The use of SEMSs in malignant biliary stricture has been studied by many large, well-designed, randomized, controlled trials[14,15] and is accepted as standard practice. Vakil *et al*[16] examined human tissue responses to endoluminal metallic stents, and observed that the presence of foreign stent material could evoke granulation tissue formation and extensive fibrosis. A systemic appraisal of 400 cases of BSS treated with uncovered SEMSs with a median follow-up of 31 mo revealed a 35% rate of stent occlusion[17]. These authors therefore cautioned against long-term use of SEMSs in BBS.

Several groups have studied the temporary placement of covered SEMSs with planned retrieval and obtained promising results. Gwon *et al*[18] studied a total of 36 temporary bile duct stent-grafts and found a primary patency rate of 90.6% but migration in 11%. One large series of 79 cases using covered SEMSs in BBS was published by Kahaleh *et al*[6] in 2008, who reported 90% resolution of BBS and stent migration in 14%. These studies offered some promise but clearly significant problems remained.

In designing the ideal metal stent for a post-OLT stricture, there are several important considerations. The actual stricture length is usually short (0.5-1.0 cm) and the rest of the bile duct is usually of normal caliber. Using a long SEMS across the stricture and extending into the duodenum in this situation would impart pressure over a large area of normal duct, potentially risking pressure necrosis and fibrosis. Conversely, using a short SEMS would result in the stent being high up the CBD, making removal challenging. Stent migration is another well-recognized problem with covered SEMS and occurred in 5.8% to 25% of cases[19,20]. Having a stent of uniform caliber and covered with teflon or a similar material are 2 factors which may predispose to stent migration.

To address these problems, this prototype RCSEMS was designed with 2 key features. Firstly, a long removal string was attached to the distal end of RCSEMS. Removal of RCSEMS is possible by grasping this string with standard or "rat-tooth" forceps introduced *via* the working channel of the scope. Also, the RCSEMS has a waist diameter of 8 mm with 10 mm at both ends. These design features allow the radial force of the metallic stent to be directed maximally to the center hence inhibiting stent migration.

In conclusion, our initial experience in 2 cases treated with a prototype RCSEMS has shown no migration, easy insertability and removability with excellent stricture resolution at the end of the treatment and during medium-term follow-up. A pilot randomized, controlled trial is currently underway at our institution to verify the effectiveness and safety of this new device.

Abstract

Cholelithiasis and choledocholithiasis occur frequently in pregnancy and their management can be complicated. Traditional endoscopic retrograde cholangiopancreatography (ERCP) is the first line treatment for choledocholithiasis, but in addition to its baseline risks, fluoroscopy poses an additional radiation risk to the fetus. Endoscopic ultrasound (EUS) is an accurate modality for detecting common bile duct stones, but its role has not been defined in pregnancy. We describe an alternative management strategy to conventional ERCP in a pregnant patient with choledocholithiasis and cholangitis detected using EUS and choledochoscopy.

Key words: SpyScope; Endoscopic ultrasound; Choledocholithiasis; Management; Pregnancy

TO THE EDITOR

We read with great interest the experiences of Fishman *et al*[1] in managing choledocholithiasis with choledochoscopy. Endoscopic ultrasound (EUS) is an accurate modality for detecting common bile duct (CBD) stones, but its role has not been defined in pregnancy. We describe an alternative management strategy to conventional endoscopic retrograde cholangiopancreatography (ERCP) in a pregnant patient with choledocholithiasis and cholangitis detected using EUS and choledochoscopy.

A 26-year old pregnant female at 28-wk gestation presented with right upper quadrant pain, progressive jaundice, and low-grade fever. Her past medical history was significant for sickle cell disease, preeclampsia and choledocholithiasis. She underwent a previous ERCP for stone removal after her last pregnancy. Upon presentation to the hospital, her total bilirubin was 6.8 mg/dL, aspartate transaminase 139 U/L, alanine transaminase 113 U/L, alkaline phosphatase 128 U/L and white blood cells count was 16 500/mm^3. Transabdominal ultrasound revealed a 9-mm common bile duct with a possible filling defect. In order to avoid radiation exposure to fetus by fluoroscopy, EUS and choledochoscopy were used to examine the bile duct and achieve its complete clearance. The linear echoendoscope revealed multiple hyperechoic well-rounded stones throughout the common bile duct (Figure 1A). A prior sphincterotomy was performed, so deep cannulation of the bile duct using the SpyGlass choledochoscope (Boston Scientific) was easily achieved. The SpyScope was useful in determining the exact location of the stones. A guidewire was advanced through the SpyScope into the left intrahepatic system. A 10-mm extraction balloon was used to extract multiple yellow pigment stones from the CBD. The SpyScope was then reinserted and complete clearance of the CBD was confirmed (Figure 1B). A 10-Fr

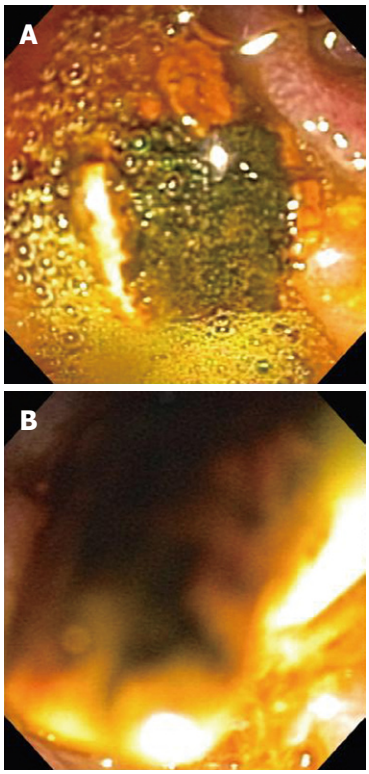

Figure 1 Multiple hyperechoic well rounded stones throughout the common bile duct (A), visualized and retrieved with Spyscope (B).

5-cm plastic biliary stent was placed to ensure drainage and prevent recurrent cholangitis during the remainder of her pregnancy. The linear echoendoscope was used to confirm adequate placement of the biliary stent. Subsequently, the patient had complete resolution of symptoms and improvement in her liver enzymes.

The incidence of gallstones during pregnancy is estimated to be 3%-12%[2]. Symptomatic gallstone disease is the second most common abdominal emergency in pregnant women and may require surgical intervention. In addition to the baseline risks of ERCP, fluoroscopy poses an additional radiation risk to the fetus. Various publications have been reported on using ERCP during pregnancy without fluoroscopy by using bile aspiration for confirmation of CBD cannulation, sphincterotomy and balloon extraction of stones[3,4]. All these approaches are not perfect with regard to ensuring complete CBD clearance. This case highlights how choledochoscopy and endoscopic ultrasound are safe alternatives to fluoroscopy for the evaluation of biliary disorders during pregnancy. If choledochoscopy is not available, an alternative approach is to use EUS-guided extraction balloon sweeps to achieve clearance of ductal stones.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in tahe field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case

report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Hepatocellular carcinoma (HCC) is the most common primary liver malignancy and represents an international public health concern as one of the most deadly cancers worldwide. The main etiology of HCC is chronic infection with hepatitis B and hepatitis C viruses. However, there are other important factors that contribute to the international burden of HCC. Among these are obesity, diabetes, non-alcoholic steatohepatitis and dietary exposures. Emerging evidence suggests that the etiology of many cases of HCC is in fact multifactorial, encompassing infectious etiologies, comorbid conditions and environmental exposures. Clarification of relevant non-viral causes of HCC will aid in preventative efforts to curb the rising incidence of this disease.

Key words: Hepatocellular carcinoma; Etiology; Non-alcoholic steatohepatitis; Obesity; Diabetes; Alcohol; Tobacco; Oral contraceptive

INTRODUCTION

Hepatocellular carcinoma (HCC) represents an international public health concern as one of the most common and deadly cancers worldwide. Globally, HCC accounts for 85%-90% of primary liver cancers[1] and its lethality is underscored by the fact that it is the third most frequent cause of cancer-related mortality[2]. In those patients who are not transplant candidates, HCC is particularly lethal, with a 5-year survival of less than 5%[3]. In the United States, the incidence of HCC appears to be increasing, with a more than twofold increase observed from 1976 to 2002 (Figure 1)[1,3,4]. A significant proportion of this increase is accounted for by the growing prevalence of hepatitis C virus (HCV) infection[5]. However, other potential causes of HCC are garnering close attention.

Increased body mass index and diabetes with subsequent development of non-alcoholic steatohepatitis (NASH) represent significant risk factors for HCC. This is especially concerning in light of the growing epidemic of obesity in adults and children over the past 25 years[1,5-8]. Other non-viral causes of HCC include iron overload syndromes, alcohol use, tobacco use, oral contraceptive use, aflatoxin exposure and betel quid chewing, a prevalent habit in the developing world. Emerging evidence suggests that the etiology of many cases of HCC is in fact multifactorial, including both viral infections and non-viral environmental and dietary exposures. This review focuses on the non-viral causes of HCC.

HEREDITARY HEMOCHROMATOSIS AND IRON OVERLOAD SYNDROMES

Hereditary hemochromatosis, a condition characterized by excess iron absorption, is caused by mutations in the

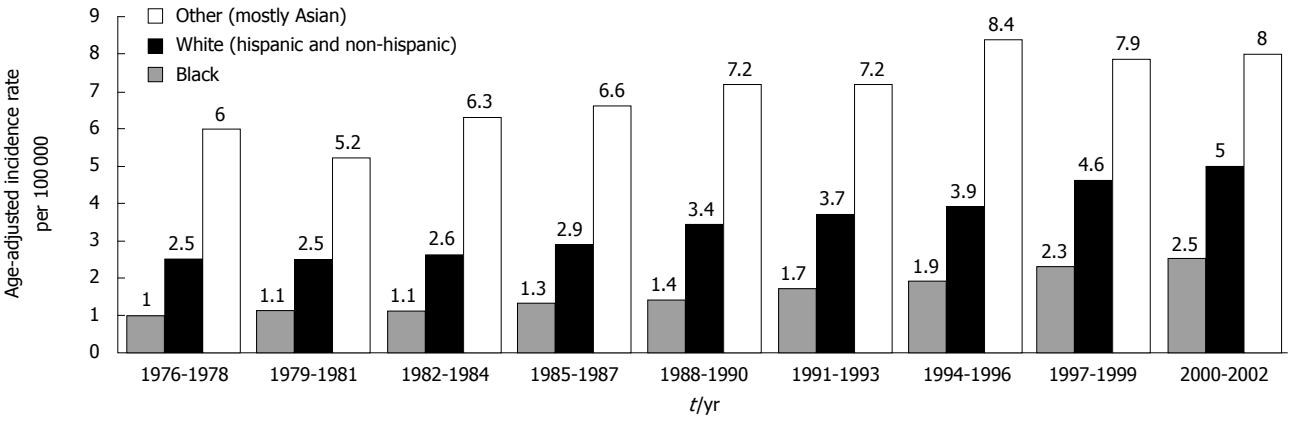

Figure 1 Average yearly, age-adjusted incidence rates for hepatocellular carcinoma men and women in the United States shown for 3-year intervals between 1976 and 2002. Whites included approximately 25% Hispanics, whereas other race was predominantly (88%) Asian. Hepatocellular carcinoma: epidemiology and molecular carcinogenesis. *Gastroenterology* 2007; 132: 2557-2576, Copyright (2007), with permission from Elsevier[1].

HFE gene and/or other mutations in the iron metabolism machinery. This condition represents one of the most common autosomal recessive genetic disorders, affecting as many as 1 in 200 people of Northern European descent[9-11]. The *HFE* gene is required for efficient *in vivo* iron metabolism and two mutations within the *HFE* gene product, C282Y and H63D, have been well described in patients with hereditary hemochromatosis[10]. The C282Y mutation, which results in a base pair substitution in which tyrosine is substituted for cysteine at amino acid 282, is found in the homozygous state in up to 83% of patients with hereditary hemochromatosis[10]. The H63D mutation, characterized by substitution of histidine with aspartic acid at codon 63, is present in a minority of cases of hereditary hemochromatosis either in a homozygous state or with one copy of the C282Y mutation, a state referred to as a compound heterozygote[10]. The clinical significance of this latter mutation within the *HFE* gene, however, continues to be controversial.

The altered iron metabolism seen in hereditary hemochromatosis leads to excess iron storage in the liver and the subsequent development of liver dysfunction. Although other organs systems are also susceptible to iron overload, the liver bears the majority of malignant disease, with those patients with hereditary hemochromatosis being 20 times more likely to develop liver cancer than all other cancers combined[12].

Several population-based and case-control studies have shown that the diagnosis of hereditary hemochromatosis confers a consistent and markedly elevated risk for the development of HCC[12-17]. A sentinel study from the US National Center for Health Statistics found that patients who were diagnosed with hereditary hemochromatosis and who died were 23-fold more likely to have liver cancer compared to those without a diagnosis of hemochromatosis [Proportionate Mortality Ratio (PMR) 22.5, 95% CI: 20.6-24.6)[13]. In addition, the relationship between hereditary hemochromatosis and HCC is modified by diabetes, sex and genetics. Subjects with liver

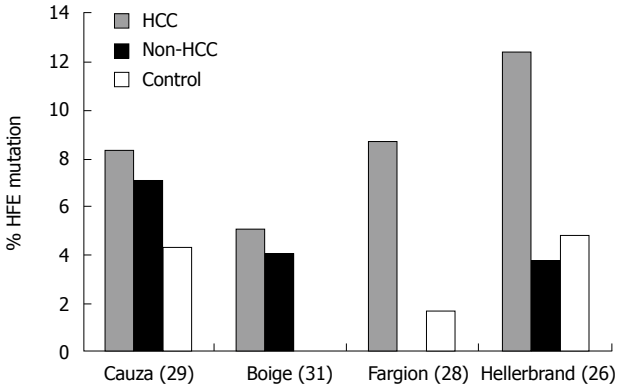

Figure 2 Prevalence of HFE mutations among patients with hepatocellular carcinoma, cirrhosis without hepatocellular carcinoma (non-hepatocellular carcinoma), and normal controls. Reprinted from Kowdley KV. Iron, hemochromatosis, and hepatocellular carcinoma. *Gastroenterology* 2004; 127: S79-S86, Copyright (2004), with permission from Elsevier [24]. HCC: Hepatocellular carcinoma.

cancer and concomitant diabetes mellitus were 82 times more likely to have a diagnosis of hemochromatosis[13]. Furthermore, a population-based study from Scandinavia found that men with hemochromatosis had a 29-fold increase in risk of liver cancer, whereas women with hemochromatosis had a sevenfold increase in risk[12]. Lastly, highlighting the genetic predisposition of disease and its consequences, an analysis of 5973 first degree relatives of patients with hemochromatosis found that these subjects had a nearly twofold increase in risk of HCC[12].

The presence of a single copy of the C282Y HFE gene mutation, although not diagnostic for hereditary hemochromatosis, has been studied to determine its prevalence and clinical significance in patients with HCC (Figure 2)[18-23]. Researchers comparing 81 patients with cirrhosis and HCC to 128 normal controls observed a significantly higher prevalence of the C282Y mutation in patients with HCC[18]. Another group observed that patients with HCC had a higher frequency of the C282Y mutation when compared to cirrhotic controls without HCC and healthy controls[19].

Additionally, they demonstrated that those subjects with the C282Y mutation had higher levels of serum ferritin, transferrin saturation, and hepatic iron deposition when compared to those without the C282Y mutation[19]. These studies suggest that increased iron load in HCC patients with a C282Y mutation exerts a cause and effect relationship in hepatocarcinogenesis[18,19]. This risk of HCC in patients with the C282Y mutation may not be equally conferred to all however. A recent prospective cohort study from France found that the C282Y mutation and iron overload were associated with a significantly increased risk of HCC among patients with alcoholic cirrhosis but not among those with HCV-related cirrhosis[23].

Contrary to the data presented above, two well-executed European studies did not find a significant difference in the prevalence of the C282Y mutation between patients with and without HCC[21,22]. Researchers from France observed comparable proportions of the C282Y heterozygous state in 133 cirrhotic patients with HCC and 100 without[21]. Likewise, in another cohort of 162 consecutive patients with HCC, the majority with cirrhosis, the frequency of the C282Y mutation did not differ from historical healthy controls or patients with HCV[22]. Concrete conclusions from these studies might be elusive, however, because of the small sample sizes, differences in the prevalence of the C282Y mutation in the respective populations, and referral bias to tertiary care centers[24].

More studies are therefore needed to determine correctly, in larger populations, the prevalence and effect of a single copy of the C282Y mutation. Additionally, on an individual basis, further study is needed to better characterize the comorbid, demographic and genetic factors that play a role in the risk of HCC in those with a single copy of the C282Y mutation.

It has also been proposed that the H63D mutation is not directly associated with hemochromatosis[10,25]. Certainly, none of the aforementioned studies observed a significant difference in the prevalence of the H63D mutation between patients with and without HCC[18-22]. Future studies are needed to assess further the relationship between this *HFE* gene mutation and the development of HCC.

Hereditary hemochromatosis is only one of the iron overload syndromes that leads to excessive iron deposition in the liver and other tissues. In fact, those patients with excess total body iron secondary to other etiologies have been shown to have a higher risk of HCC in the absence of genetic hemochromatosis[26-28]. Studies have suggested that conditions such as β thalassemia or iron overload in people of African descent might be associated with an increased risk of HCC[27,29,30]. One such study found that African iron loaded subjects had a 10-fold increase in the risk of developing HCC after adjusting for viral hepatitis, alcohol use and environmental exposures, such as aflatoxin[27]. Regardless of etiology, iron overload is not a benign condition and when recognized, surveillance for HCC should be undertaken.

NON-ALCOHOLIC FATTY LIVER DISEASE

Several case reports and subsequent observational studies have proposed that non-alcoholic fatty liver disease (NALFD), and more specifically, NASH, confers an elevated risk of developing HCC (Figure 3)[31]. NAFLD is a spectrum of clinical disease that ranges from benign or bland steatosis to NASH. The latter stage of this disease, through a process of chronic inflammation and subsequent hepatic fibrosis, can lead to cirrhosis[32]. The presence of cirrhosis itself is an independent risk factor for the development of HCC[33]. To characterize the natural history of NALFD, 420 patients identified in Olmstead County, MN, USA with the disorder were followed for an average of 7 years to determine overall mortality as well as liver related morbidity and mortality. In this population-based study, NAFLD was associated with a 34% increase in mortality and a significant increase in the risk of HCC, with two cases or 0.5% being diagnosed over the period of follow-up[34]. In subjects with NASH-related cirrhosis, however, the rate of HCC approached 10%[34]. These findings are well aligned with a series of studies from Japan. In one report, among 82 NASH patients treated from 1990 through 2001, six patients with HCC were identified over 11 years of follow-up[35]. All six patients developed HCC

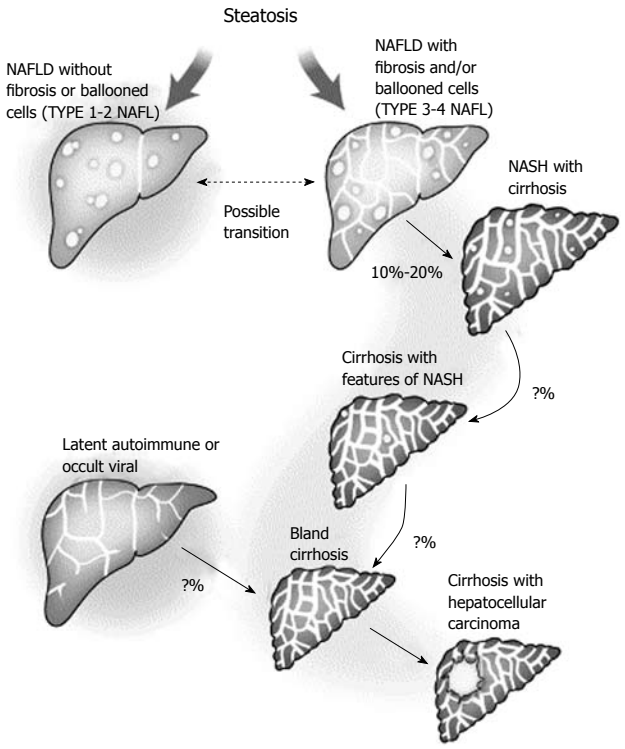

Figure 3 Progression of non-alcoholic fatty liver disease to cryptogenic cirrhosis. The explanation for the disappearance of steatosis remains uncertain but it is likely to be multifactorial and to involve changes in blood flow and exposure to fat-promoting hormones, as well as possible changes in the intracellular metabolism as a result of long-standing exposure to lipid peroxidation. Theoretically, this could represent a form of lipoatrophy that occurs within the fat-storing hepatocytes. Other forms of chronic liver disease may also present with a well-established bland cirrhosis. Efforts are needed to define better residual markers of past silent disease to improve our understanding of cryptogenic cirrhosis. Reprinted from Caldwell SH, Crespo DM. The spectrum expanded: cryptogenic cirrhosis and the natural history of non-alcoholic fatty liver disease. *J Hepatol* 2004; 40: 578-584, Copyright (2004), with permission from Elsevier[31]. NALFD: Non-alcoholic fatty liver disease; NASH: Non-alcoholic steatohepatitis.

[1]Patients with cirrhosis; [2]ORs for women were further adjusted for age at menarche, age at end of first pregnancy, and menopausal status; [3]Other factors adjusted for include disease at entry, weight loss in the last year, height-adjusted FEV1, triceps skinfold thickness, blood pressure-lowering medication, blood pressure, plasma cholesterol, glucose intolerance, and diabetes. Reprinted by permission from Macmillan Publishers Ltd: [Br J Cancer]. Larsson SC, Wolk A. Overweight, obesity and risk of liver cancer: a meta-analysis of cohort studies. *Br J Cancer* 2007; 97: 1005-1008, copyright (2007)[42].

in the setting of NASH-related cirrhosis[35]. In an update to this original observation, over a 17-year period, the authors found that among 382 patients with NASH, HCC was diagnosed in 34, 9% of the cohort, with 11 patients diagnosed during a 40-mo mean follow-up[36]. Comparing those NASH patients with and without HCC, multivariate logistic regression analysis identified older age (OR: 1.1, 95% CI: 1.03-1.2) and advanced hepatic fibrosis (OR: 4.2, 95% CI: 1.8-9.7) as independent predictors for the development of HCC[36]. In a prospective study of 118 patients with NASH and advanced liver fibrosis from the same cohort, the observed 5-year cumulative incidence of HCC was 7.6%, with HCC accounting for 46% of all fatalities[36]. In summary, these data highlight an association between NASH cirrhosis and an increase in the incidence of HCC over that of the general population. Therefore, regular HCC surveillance is imperative in patients with NASH cirrhosis.

The impact of NASH on the incidence of HCC may well be underestimated. In advanced fibrosis, an absence of steatosis may be appreciated, a finding which can obscure identification of the underlying etiology of liver injury in these patients. In this case, patients might be classified as having cryptogenic cirrhosis. In a United States study that examined 105 consecutive patients with HCC, after HCV, cryptogenic cirrhosis was the most common etiology of liver injury[37]. Among patients presenting with cryptogenic cirrhosis, 58% had a body mass index (BMI) $\geqslant$ 30, 47% had diabetes, and 50% had a prior histological diagnosis of NASH or clinical characteristics consistent with NAFLD. Furthermore, only 23% of subjects with cryptogenic cirrhosis were undergoing surveillance for HCC in comparison to 61% of subjects who had a history of HCV-related liver disease[37]. Clearly, these observations emphasize the importance of HCC surveillance in this group of patients and the failure thus far to appropriately screen for HCC in this disease process.

OBESITY

The prevalence of obesity has increased to epidemic proportions over the last three decades. Excess body mass is classified as overweight if the BMI is > 25 kg/m^2 and < 30 kg/m^2, or obese if the BMI is $\geqslant$ 30 kg/m^2. In addition to the increase in an array of disease processes observed with being overweight or obese, both classifications of excess body mass are associated with a higher risk of developing all cancers, including liver cancer[38]. In one population-based study from Sweden, 28 cases of HCC were diagnosed in 28129 patients from 1965 to 1993, thus conferring an almost threefold higher risk of HCC in obese patients[39]. A recent European case-control study observed a significantly increased risk of HCC among obese (OR: 3.5, 95% CI: 1.3-9.2) or diabetic (OR: 3.5, 95% CI: 1.6-7.7) patients without viral hepatitis. This risk of HCC was even greater if both obesity and diabetes were present comorbid conditions (OR: 11.8, 95% CI: 2.7-51.9)[40]. A Danish study further confirmed these results, finding a twofold increase in liver cancer incidence in obese subjects compared to non-obese subjects[41].

A meta-analysis of 11 cohort studies that evaluated the association between being overweight or obese and liver

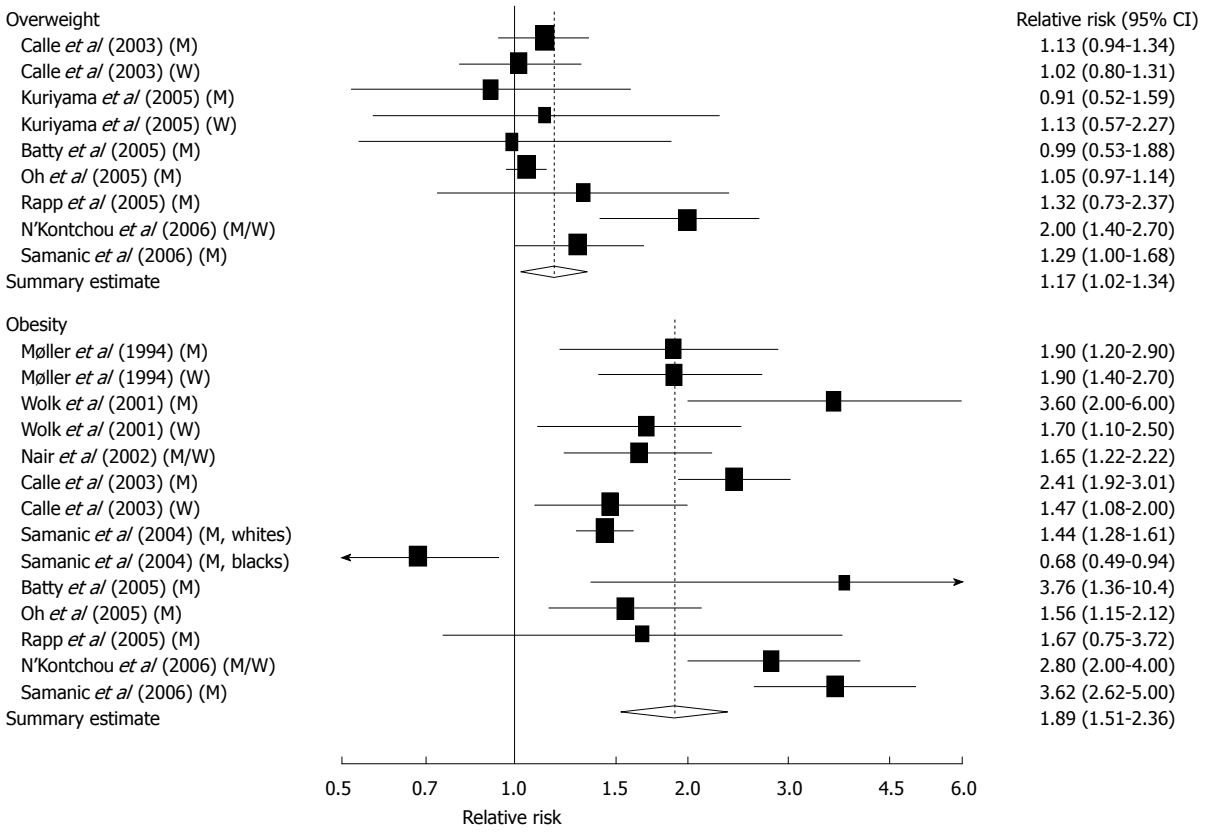

Figure 4 Relative risks of liver cancer associated with overweight and obesity. Relative risk estimates are for overweight and obese persons compared with normal weight persons. Tests for heterogeneity: overweight, Q = 16.83, P = 0.03, I^2 = 52.5%; obesity, Q = 88.03, P < 0.001, I^2 = 86.4%. M: Men; W: Women[42]. Overweight, obesity and risk of liver cancer: a meta-analysis of cohort studies. *Br J Cancer* 2007; 97: 1005-1008, copyright (2007)[42].

cancer was published in 2007, and clarified the risk of development of HCC (Table 1)[42]. Of the included studies, seven examined a total of 5037 overweight patients and 10 examined 6042 obese patients[42]. Patients who were overweight had a 17% increase in risk of developing HCC, whereas obese patients had an 89% increase in risk (Figure 4)[42]. Based on the prevalence of HCC, it was estimated that 28% of HCC cases in men and 27% in women were due to being overweight or obese[42].

In addition to an increased risk of developing HCC, overweight or obese patients appear to be at increased risk for HCC-related mortality. In a population-based study of cancer mortality and BMI, men with a BMI of 30-34.9 were found to have a twofold increase in the risk of death from HCC, with a 4.5-fold increase noted in men with BMI > 35[38].

Lastly, *via* the pathway of the metabolic syndrome with resultant NASH cirrhosis, obese patients have been found to be at an increased risk for HCC occurrence. Many lines of evidence point to the role of cirrhosis as a mediator in these patients. Firstly, patients presenting with cryptogenic cirrhosis were found to have a significantly higher prevalence of obesity than patients with cirrhosis from non-alcoholic hepatitis C or autoimmune liver disease, but a similar prevalence of obesity when compared to patients with documented NASH[43]. These data are supported by a case-control study in which 49 patients with cryptogenic cirrhosis were compared to 98 matched controls with an established cause of cirrhosis. In that study, obesity was significantly more prevalent in the cryptogenic cirrhosis patients[44]. Additionally, a retrospective analysis of 19 271 American patients who had undergone liver transplantation found that there were 653 cases of HCC, and those with a diagnosis of cryptogenic cirrhosis had an 11-fold increase in the risk of having HCC[45]. Therefore, being overweight and obesity, secondary to cryptogenic cirrhosis, or more likely undiagnosed NASH cirrhosis, can increase the risk of developing HCC. Clearly, these data suggest that screening is important for diagnosis of asymptomatic HCC and highlight the need for surveillance in this population.

DIABETES

Diabetes has been found to increase the risk of developing chronic liver disease and HCC[46]. Studies that have compared patients with cryptogenic cirrhosis to patients with a known etiology of their cirrhosis have shown a significantly higher prevalence of diabetes among the latter group[43,44]. Again, as noted with the overweight and obese, a similar prevalence of diabetes has been observed among patients with cryptogenic and NASH cirrhosis[43].

In addition to increasing the prevalence of chronic liver disease, diabetes has also been shown to be an independent risk factor for the development of HCC. In a recent systematic review of 13 case control studies, 11

supported an association between diabetes and the development of HCC[47]. Among the 13 case-control studies, subjects with diabetes were found to have a twofold increase in the risk of HCC; an association that was further strengthened by excluding studies with significant heterogeneity (Figure 5)[47]. This association was also appreciated amongst 12 cohort studies evaluated (Figure 6). The presence of diabetes remained an independent risk factor for HCC after adjustment for alcohol use or viral hepatitis in the studies that evaluated these factors[47]. However, as dictated by the limitations of the studies available in the literature, further well-defined studies are required to account for dietary factors and obesity.

DIET

Several studies have examined whether alterations in diet have an effect on the risk of HCC. A trial from Italy has examined a broad range of dietary habits among 185 patients with HCC and 412 patients without cancer[48,49]. Those with HCC were more likely to consume a large amount of calories, were five times more likely to be former drinkers, and were 30 times more likely to be infected with either HCV or hepatitis B virus (HBV). Among dietary compounds, consumption of iron and thiamine were associated with a significant threefold and twofold increase in risk of HCC, respectively. Conversely, β-carotene and linoleic acid consumption was associated with a reduced risk of HCC[48]. An association between intake of iron was also evaluated according to the presence or absence of viral hepatitis[48]. When compared to appropriate controls, consumption of iron among patients without viral hepatitis was associated with a significantly increased risk of HCC[48]. This increase in risk was not conferred to those with HCV or HBV. In a similar study, those subjects with consumption in the highest quartile for yogurt and milk, white meat and eggs had a significantly lower likelihood of developing HCC[50]. This effect was observed in patients with and without viral hepatitis[50].

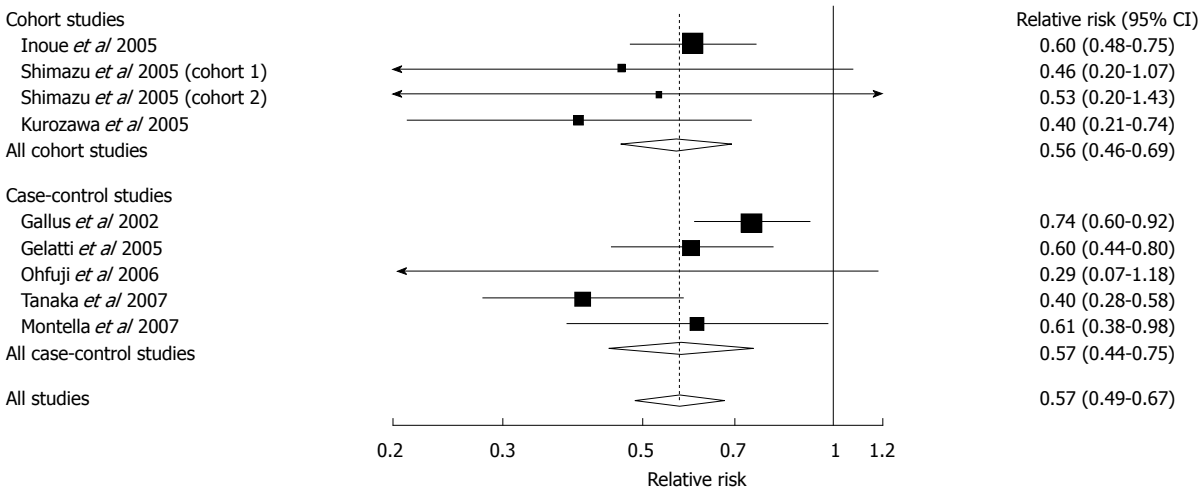

Figure 7 Relative risks of liver cancer associated with coffee consumption (per 2 cups/d increment). Squares represent study-specific relative risk estimates (size of the square reflects the study-specific statistical weight, that is, the inverse of the variance); horizontal lines represent 95% CIs; diamonds represent summary relative risk estimates with corresponding 95% CIs. Tests for heterogeneity: all studies, Q = 11.56, P = 0.17, I^2 = 30.8%; cohort studies, Q = 1.74, P = 0.63, I^2 = 0%; case-control studies, Q = 9.28, P = 0.05, I^2 = 36.9%. Reprinted from Larsson SC, Wolk A. Coffee consumption and risk of liver cancer: a meta-analysis. *Gastroenterology* 2007; 132: 1740-1745, Copyright (2007), with permission from Elsevier[66].

Other studies from Japan and Europe have found those who consume a large amount of green vegetables have a significantly lower likelihood of developing HCC[51-53]. One study has shown that eating green vegetables daily, as compared with consumption fewer times per week, had a protective effect against the development of HCC (OR: 0.75, 95% CI: 0.60-0.95)[51]. On the contrary, a Greek study has found no association between vegetable intake and reduction in the risk of developing HCC[54].

In summary, there is evidence to suggest that consumption of yogurt and milk as well as vitamin supplements offers a protective effect against HCC. The enthusiasm for these findings however should be tempered by the fact that the majority of these studies were retrospective in nature.

COFFEE

In addition to its reported association with reductions in bladder cancer and colorectal cancer, coffee consumption has also been extensively studied and appears to have a potentially favorable effect on the prevention of liver diseases, including HCC[55,56]. There are several hypotheses that could explain why consuming coffee attenuates the risk of developing HCC. One hypothesis argues that coffee intake lowers serum levels of γ-glutamyl transferase (GGT), which is associated with a lower incidence of HCC[56-59]. Coffee consumption has also been linked to a lower incidence of cirrhosis, which is a major risk factor for the development of HCC[56].

An analysis of two large prospective studies of > 70 000 participants in Japan has shown that those who drank one or more cups coffee daily had a significantly lower risk of developing HCC[60]. A case-control study of 2746 people has found that those who drank three or more cups of coffee were 40% less likely to develop HCC[56]. Similar results have also been found in an array of studies conducted in Europe and Japan[60-65].

Additionally, two meta-analyses that have examined the association between coffee drinking and the risk of developing HCC have recently been published. The first was inclusive of four cohort studies and five case-control studies[66]. In the pooled analysis, a 43% lower risk of developing HCC was found for those who drank more than two cups of coffee per day (RR: 0.57, 95% CI: 0.49-0.67) (Figure 7)[66]. The second meta-analysis examined four cohort studies from Japan and six from Japan and Southern Europe[67]. There were differing definitions of low and high coffee consumption, however, the results of the studies were consistent. In summary, those who drank any coffee compared to non-drinkers had a significantly lower risk of HCC (RR: 0.59, 95% CI: 0.49-0.72). The greater the coffee consumption, the greater the attenuation in HCC risk. Low coffee consumption was associated with a 30% reduction in risk and high consumption with a 55% reduction in HCC risk (Figure 8)[67].

Although these results are impressive and consistent, one must consider that the findings of an inverse relationship between coffee consumption and the risk of HCC might be influenced by bias. Coffee metabolism is impaired in cirrhotic livers as compared to the normal liver. This altered metabolism generates an increase in the untoward side effects of the beverage. Therefore, the presence of liver disease might lead affected patients to consume less coffee. This could result in a falsely negative association. Therefore, the potential bias of this association in the liver disease patient cannot be discounted.

ALCOHOL

The mechanism by which alcohol consumption increases the risk of HCC is primarily through the development of cirrhosis. It has been suggested that heavy alcohol consumption of > 80 g/d ethanol for at least 5 years increases the risk of HCC by nearly fivefold[68]. The risk appears to be proportional to the amount of alcohol consumed.

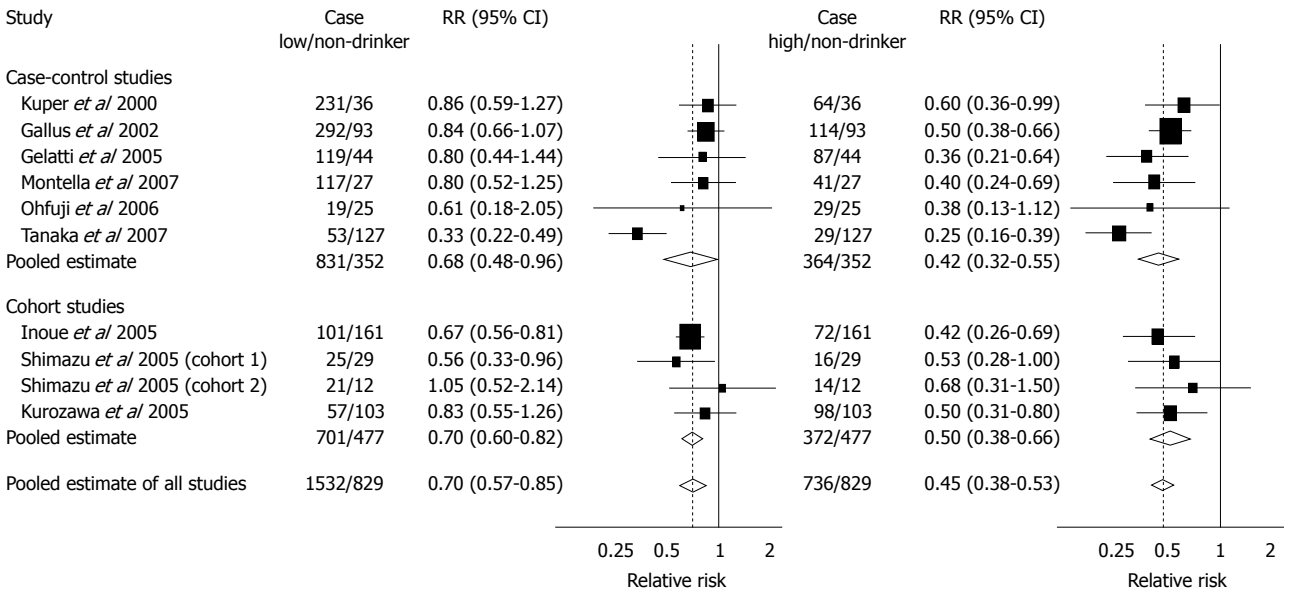

Figure 8 Summary RRs of hepatocellular carcinoma for low or moderate and high coffee drinkers *vs* non-drinkers from case-control and cohort studies. Low or moderate consumption was defined as < 3 cups per day for Gallus *et al*, Gelatti *et al*, Inoue *et al* and Montella *et al* and as < 1 cup per day for Ohfuji *et al*, Tanaka *et al*, Kurozawa *et al*, and Shimazu *et al*; High consumption was defined as ⩾ 3 cups per day for Gallus *et al*, Gelatti *et al*, Inoue *et al*, and Montella *et al* and as ⩾ 1 cup per day for Ohfuji *et al*, Tanaka *et al*, Kurozawa *et al*, and Shimazu *et al*. Bravi F, Bosetti C, Tavani A, Bagnardi V, Gallus S, Negri E, Franceschi S, La Vecchia C. Coffee drinking and hepatocellular carcinoma risk: a meta-analysis. *Hepatology* 2007; 46: 430-435[67]. Copyright 2007, John Wiley & Sons, Inc. Reproduced with permission of John Wiley & Sons, Inc.

As characterized by a meta-analysis, relative risks of 1.19 (95% CI: 1.12-1.27), 1.40 (95% CI: 1.25-1.56), and 1.81 (95% CI: 1.50-2.19) were associated with the consumption of 25, 50 and 100 g/d alcohol, respectively[69].

In addition to a daily dose response, persistent alcohol consumption appears to have a long-term effect on the risk of HCC occurrence. A prospective case-control study from Japan has observed that heavy alcohol drinkers, defined as > 600 L of alcohol during a lifetime, had a fivefold increase in the risk of HCC in comparison to non-drinkers or those who consumed < 600 L of alcohol (OR: 5.19, 95% CI: 2.53-10.64)[70]. However, the risk of HCC among those who consume low or moderate levels of alcohol remains unknown[1].

An association between genetic polymorphisms of the enzymes participating in the metabolic pathway of ethanol and the increased risk of HCC in heavy alcohol drinkers has been also proposed as a mechanism by which HCC develops. The frequency of aldehyde dehydrogenase 2 (*ALDH2*) genotype polymorphisms is significantly associated with increased risk of HCC in heavy alcohol drinkers (OR: 2.53, 95% CI: 1.63-58.60)[70]. A study from Italy has observed that, among subjects who consumed > 100 g/d of ethanol and were bearers of the gluthatione S-transferase M1 (GSTM1) null genotype had twice the risk of HCC compared with bearers of the GSTM1 non-null genotype (OR: 8.5, 95% CI: 3.9-18.6 *vs* OR: 4.5, 95% CI: 2.0-10.0)[71].

SMOKING

Several studies have evaluated the association between smoking and development of primary liver cancer. A prospective cohort study including 4050 men aged ⩾ 40 years who were followed-up for an average length of 9 years observed that those who smoked had a threefold increased risk of primary liver cancer when compared to never smokers (RR: 3.3, 95% CI: 1.2-9.5)[72]. Additionally, a study from Korea has found a 50% increase in the risk of primary liver cancer for current male smokers compared to never smokers[73]. In contrast however, a recent population-based case-control study from the United States did not observe a significantly increased risk of primary liver cancer among current male smokers[74]. Male ex-smokers, however, had a significant increase in risk of primary liver cancer, which suggests that there is perhaps a dose or duration response underlying this association[72-74]. Such responses were further explored in the Korean Cancer Prevention study that included 1 283 112 subjects[75]. Although the amount of smoking did not alter the risk of HCC, the duration of smoking significantly increased the risk of HCC for subjects who had smoked for > 20 years when compared to those who had smoked for < 10 years[75].

The association between tobacco and liver cancer and its reliance on host factors such as genetics, sex, and an underlying history of viral hepatitis has also been explored. With respect to the role of genetics, a small study from Japan has evaluated 78 patients with HCC and genetic polymorphisms of tobacco and alcohol-related metabolizing enzymes and 138 hospital controls without cancer. They have demonstrated that cigarette smokers did not have a significantly increased risk of HCC when compared with non-smokers[70]. To analyze the effect of sex, a prospective cohort study that included 83 885 patients followed up for 8 years observed a positive association between smoking and HCC in women who smoked > 10 cigarettes per day (RR: 4.2, 95% CI: 1.3-13.8)[76]. However, no significant increase in the risk of HCC was

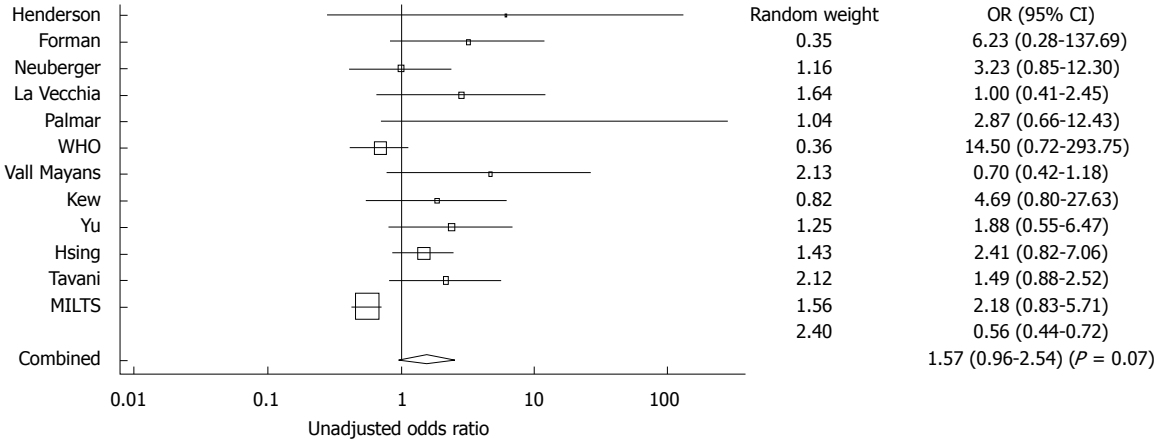

Figure 9 Forest plot showing adjusted OR and 95% CI for the association between oral contraceptive and hepatocellular carcinoma for the eight studies that included adjusted ORs. The diamond symbol indicates the weighted random pooled OR of all studies included in the analysis. Reprinted from Maheshwari S, Sarraj A, Kramer J, El-Serag HB. Oral contraception and the risk of hepatocellular carcinoma. *J Hepatol* 2007; 47: 506-513, Copyright (2007), with permission from Elsevier[95].

demonstrated among male smokers[76]. Additionally, to determine the effect of viral hepatitis on the association between HCC and tobacco, a prospective study of 12 008 men observed that smoking significantly increased the risk of HCC only in anti-HCV-positive patients but not in those who were anti-HCV-negative when compared to anti-HCV-negative nonsmoking individuals[77].

In addition to an increase in the risk of developing HCC, it is also suggested in the literature that smoking increases the risk of death in HCC. In the Korean Cancer Prevention cohort study, men who were current smokers had an increased risk of death from HCC[75]. Women who were current smokers did not have the same elevation in risk of HCC-related death as that observed in men[75]. These findings were further replicated in the Japan Collaborative Cohort (JACC) Study that analyzed 65 528 subjects aged 40-79 years[78]. In this cohort, an increased risk of death due to HCC was shown among current and ex-smokers[78]. Further analyses from the JACC cohort demonstrated that cigarette smoking significantly increased the risk of death from HCC in individuals positive for anti-HCV antibody[79].

ORAL CONTRACEPTIVES

Prior to the widespread use of oral contraceptives (OCs), benign liver tumors in young women were rarely observed. In the current case report literature, however, therapy with oral contraceptives appears to be associated with the development of benign liver tumors such as hepatic hemangioma, hepatocellular adenoma or focal nodular hyperplasia[80,81]. Although not well researched, it has been proposed that OCs might also be associated with malignant liver tumors including HCC[82,83]. Rarely, malignant transformation can occur within the context of hepatic adenomas. It is unclear, however, whether the use of OCs influences the likelihood of developing adenoma and that these benign tumors transform.

Within the literature, there have been 14 cases of hepatic adenoma with focal malignant transformation to HCC in women taking OCs[83-93]. The mean age of these patients at the time of diagnosis of malignant transformation was 36 years (range: 23-57 years) and the mean duration of OC use was 11 years (range: 1 mo-20 years)[83-93]. Although difficult to obtain from the literature, the frequency of HCC among hepatic adenomas appears to vary from 5% to 18%[89,92-94].

To evaluate further the risk of HCC in the setting of OC use, several observational studies have been conducted. A recent meta-analysis of 12 case-control studies, including 739 cases and 5223 controls, which evaluated the risk of HCC among women using OCs indicated that there was no increase in risk of HCC with short-term use; defined as < 5 years of exposure[95]. An analysis of all studies in the aforementioned meta-analysis yielded a pooled unadjusted OR of 1.57 (95% CI: 0.96-2.54)[95]. An adjusted analysis, which accounted for variables such as age, race and parity, did not yield significant findings (Figure 9)[95]. On the contrary, six studies have observed a significantly increased risk of HCC among women taking OCs for > 5 years; an increase in risk of 2-20-fold[95]. However, given the variable periods of duration used in each of the studies, a pooled estimate of risk could not be generated[95]. Based on these results, further studies are required to evaluate the association between OCs and the risk of HCC and how such risk is modified by duration of OC use. Additionally, it should be noted that an association between new-generation OCs with lower doses of hormones and the risk of HCC has not yet been explored.

BETEL QUID

The chewing of betel quid is woven into the cultural fabric of up to 20% of the world population. Betel quid consists of the nut of the *Areca catechu* palm (areca nut), betel leaf or fruit from *Piper betle* and red slaked paste[96]. These ingredients have been shown to have genotoxic, mutagenic and tumorigenic properties[97-102]. A case-con-

trol study from Taiwan has shown that betel quid chewing was an independent risk factor for liver cirrhosis (OR: 3.56, 95% CI: 1.41-8.96)[103].

Recently, two prospective case-control studies from Asia also have observed a significant association between betel quid chewing and the incidence of HCC. One such study included 263 pairs of age- and sex-matched patients with HCC and healthy controls and observed that betel quid chewing was an independent risk factor for HCC, with a threefold risk noted (OR: 3.49, 95% CI: 1.74-6.96). The aggregate risk increased with increasing duration and/or quantity of consumption[96]. These data were further supported by a study from Taiwan, including 420 age- and sex-matched patients with HCC and liver cirrhosis, liver cirrhosis only and healthy controls. In this study, a nearly sixfold and nearly twofold increased risk of HCC was observed in patients with HCC compared with healthy controls and patients with liver cirrhosis, respectively[104]. Additionally, they found an additive interaction between betel quid chewing and chronic HBV and/or HCV infection.

AFLATOXIN

Aflatoxin B1 (AFB1) is the major metabolite of the molds *Aspergillus fumigatus* and *Aspergillus parasiticus*. These molds grow on a variety of food products that are stored in warm and damp conditions or are cultivated in countries with hot and humid climates[1,105]. AFB1 induces a single nucleotide substitution in codon 249 in the *p53* tumor suppressor gene, which results in the change of the amino acid arginine to serine[106,107]. This mutation is present in up to 50% of patients with HCC who are indigenous to geographic regions with high exposure to AFB1[108-111]. On the other hand, this mutation is absent in patients with HCC from regions with low exposure to AFB1[112,113]. Moreover, it has been recently demonstrated that AFB1-albumin adducts in patients with HCC correlate significantly with the presence of plasma DNA hypermethylation and mutations in the *p16* and *p53* tumor suppressor genes[114].

Several studies have evaluated an association between the risk of HCC and exposure to AFB1. A prospective case-control study from China which included 18 244 middle-aged men showed that individuals with the presence of urinary aflatoxin biomarkers had a significantly increased risk of HCC after adjusting for HBV surface antigen seropositivity and cigarette smoking[115]. These data were further supported by a community-based cohort study from Taiwan which found that elevated AFB1 exposure measured by detectable AFB1-albumin adducts was an independent risk factor for HCC after adjustment for important confounders (OR: 5.5, 95% CI: 1.2-24.5)[116].

It should be stressed that areas with high exposure to AFB1 are also characterized by a high prevalence of HBV infection. AFB1 is independent of the risk conferred by HBV, however concomitant exposure to both HBV and AFB1 markedly increases the risk of HCC. When compared to those without HBV infection and absence of urinary AFB1 markers, the risk of HCC was 60 times higher in patients with HBV infection and a concomitant elevation of urinary AFB1 markers (RR: 59.4, 95% CI: 16.6-212.0)[115]. Patients with HBV infection and normal urinary AFB1 markers had sevenfold increase in risk of HCC when compared to appropriate controls[115].

CONCLUSION

Multiple non-viral factors have been implicated in the development of HCC. Hemochromatosis and iron overload syndromes have consistently been shown to dramatically increase the rate of HCC. Additionally, factors such as obesity and diabetes, which operate *via* NASH cirrhosis or perhaps independently, have also been demonstrated to increase the risk of HCC. This phenomenon has closely mirrored the epidemic of obesity over the last 15-25 years.

With respect to other exposures, although alcohol and tobacco clearly increase the risk of HCC development and mortality, other exposures such as coffee and high levels of vegetable consumption may be protective against this condition. Further studies are urgently needed to determine the pathogenesis that underlies the occurrence of HCC in the setting of these exposures, as well as the way in which such risk is modified by environmental and host characteristics such as genetics.

Clarification of relevant non-viral causes of HCC will help to focus clinicians on those risk factors that are modifiable. With more information, future surveillance efforts will be more appropriately targeted toward populations at greatest risk. This multilevel preventative approach will hopefully lead to a reduction in incidence of non-viral HCC, and a decrease in the patient morbidity and mortality as well as the societal economic burden associated with HCC.

Abstract

Primary biliary cirrhosis (PBC) is a chronic, progressive, cholestatic, organ-specific autoimmune disease of unknown etiology. It predominantly affects middle-aged women, and is characterized by autoimmune-mediated destruction of small- and medium-size intrahepatic bile ducts, portal inflammation and progressive scarring, which without proper treatment can ultimately lead to fibrosis and hepatic failure. Serum autoantibodies are crucial tools for differential diagnosis of PBC. While it is currently accepted that antimitochondrial antibodies are the most important serological markers of PBC, during the last five decades more than sixty autoantibodies have been explored in these patients, some of which had previously been thought to be specific for other autoimmune diseases.

Key words: Primary biliary cirrhosis; Autoimmune disease; Autoantibody; Anti-mitochondrial antibody; Anti-gp210 antibody; Anti-sp100 antibody; Anti-centromere antibodies

Peer reviewers: Christopher O'Brien, MD, Professor of Clinical Medicine, Chief of Clinical Hepatology, Center for Liver Diseases, Division of Liver and GI Transplantation, University of Miami School of Medicine, 1500 Northwest 12th Ave., Suite #1101, Miami, FL 33136, United States; Dr. Ulrich Beuers, Professor, Department of Gastroenterology and Hepatology, Academic Medical Center, University of Amsterdam, PO Box 22700, NL-1100 Amsterdam, The Netherlands; Atsushi Tanaka, MD, PhD, Associate Professor, Department of Medicine, Teikyo University School of Medicine, 2-11-1, Kaga, Itabashi-ku, Tokyo 173-8605, Japan

INTRODUCTION

Primary biliary cirrhosis (PBC) is a progressive autoimmune liver disease characterized by infiltration of lymphocytes in portal tracts, progressive destruction of intrahepatic small bile ducts and the presence of serum antimitochondrial antibodies (AMA)[1,2]. As is the case for the majority of autoimmune diseases, PBC affects predominantly women. Recent investigations have suggested that PBC, sometimes asymptomatic, is not a rare disease. During the last several years advanced biochemical assays, further delineation of specific liver histological findings, more effective serum autoantibody detection methods and improved diagnostic abilities have led to higher prevalence estimates worldwide[3-5]. Currently it is believed that PBC is likely to be triggered by a combination of environmental factors including infection in a genetically susceptible individual. This hypothesis is supported by the high concordance rate of PBC among first-degree relatives and in homozygous twins (approximately 60%)[6,7]. Specific immunologic damage to biliary epithelium and a mechanism of tissue destruction in PBC has been elucidated[8,9]. In addition, epitopes of T cells and B cells targeting mitochondrial autoantigens have been identified[10-12]. Furthermore, a number of autoantibodies previously thought to be spe-

cific markers for another autoimmune disease have been detected in patients with PBC.

Disease progression and clinical manifestations in PBC varies. The fact that a variety of autoantibodies have been detected in PBC suggests the disease has a complicated pathogenesis. In this review, the properties of these autoantibodies and their autoantigen characteristics, as well as their pathogenetic and clinical significance were discussed.

AMA

The presence of AMA is pathognomonic for PBC[13], and it is generally accepted that AMA can be detected in serum years before the advent of any clinical manifestation or biochemical abnormality[14-16]. AMA were first described in 1958[17] in sera from patients with chronic liver disorders and then detected by Walker *et al*[18] in 1965 using an immunofluorescence test. In the past 40 years an enormous number of experimental studies have focused on AMA, and numerous rewarding discoveries have been made. There are nine subtypes of AMA, four of which have been involved in PBC, including anti-M2, anti-M4, anti-M8 and anti-M9. It has been demonstrated that the autoantigens recognized by anti-M2 are located in the inner membranes of mitochondria, whereas those recognized by anti-M4, anti-M8 and anti-M9 are located in the outer mitochondrial membranes. Anti-M9 can be detected in both anti-M2-positive and -negative PBC patients, while anti-M4 is only positive in the presence of anti-M2. All four of these AMA subtypes are relatively specific for the diagnosis of PBC.

Anti-M2

M2 has been found to contain five antigenic determinants, with molecular weights of 70 kDa (a), 56 kDa (b), 51 kDa (c) 45 kDa (d) and 36 kDa (e), all of which were identified subsequently as members of the 2-oxoacid dehydrogenase complex of enzymes within the mitochondrial respiratory chain, including the E2 subunit of the pyruvate dehydrogenase complex (PDC-E2), the E2 subunit of the branched-chain 2-oxoacid dehydrogenase complex, the E2 subunit of the 2-oxoglutarate dehydrogenase complex, E1t alfa subunits of PDC and E3 binding protein (protein X)[19,20]. The exact molecular weight of the M2 band differs among laboratories according to mitochondria species being used and specifics of techniques for antigen preparation and detection. In patients with PBC, approximately 90%-95% of serum samples react against PDC-E2, making this the most important autoantigen in the disease. Anti-M2 is the most important subtype used in routine diagnostic tests for PBC. Its level in affected sera is high and it also exists in other body fluids such as saliva and bile[21-23]. As AMA is considered to be the hallmark of PBC, a positive test is potentially diagnostic, or at least indicative that the individual is at increased risk for future development of PBC[15].

Anti-M4

The anti-M4 antibody was originally detected in patients with chronic cholestatic liver disease (mixed form) associated with two different types of complement-fixing AMA[24]. M4 is a single antigen with molecular weight of 52 kDa. It can be detected by a complement fixation test but not immunoblotting. Unlike M2, the M4 antigen is trypsin-insensitive and its band at sucrose densities is 1.08 to 1.14. Anti-M4 is found predominantly in patients with histological features of chronic active hepatitis and PBC. Recent studies have identified the major proteins in the M4 fraction which is related to the PDC-E1 subunits and sulphite oxidase[25,26].

Anti-M8

The M8 antigen is also trypsin-sensitive with a band at sucrose densities of 1.16 to 1.24. Anti-M8 has been found only in coexistence with anti-M2, the presence of anti-M8 indicates progressive disease activity. On the other hand, not all anti-M2-positive patients have anti-M8. Like M4, the M8 antigen also locates in the outer mitochondrial membranes[27].

Anti-M9

Anti-M9 antibody was accidentally found when testing anti-M2-positive sera against trypsinized submitochondrial particles from rat liver shown to be devoid of anti-M2[28]. Anti-M9 antibody is detected predominantly in patients with asymptomatic and early PBC, and it also can be positive in anti-M2-negative PBC patients. Unlike anti-M4 and anti-M8, which seem to reflect disease activity, anti-M9 antibody occurs early in PBC. Patients with only anti-M9 have all the typical biochemical features found in classic anti-M2-positive patients, but seem to have slower disease progression and benign outcome, whereas patients having complement-fixing antibodies against anti-M2, anti-M4, and anti-M8 seem to have more active disease and worse outcome[29-31], though this finding wasn't supported by a blinded study on Dutch PBC patients conducted by Vleggaar *et al*[32].

ROLE OF AMA IN PBC PATHOGENESIS

Although AMA serve as highly sensitive markers for the diagnosis of PBC, autoantibodies against various mitochondrial enzymes can frequently be detected in patients with other diseases, such as primary Sjögren's syndrome (pSS), scleroderma, autoimmune hepatitis[33,34] and some infectious diseases like tuberculosis and viral hepatitis[35-38]. It is very interesting that the prevalence of AMA in first-degree relatives of PBC probands is as high as 13.1%, whereas in gender, age, race, and residence-matched controls the prevalence is only 1%, suggesting that environmental risks and genetic determinants are likely implicated in the etiology of PBC[7].

As no clinical correlation can be found, and animal models with serum AMA do not consistently have PBC-like liver lesions, the exact role played by AMA in the immunopathology and pathogenesis of PBC remains elusive. However, current data indicate that the destruction

of biliary cells is mediated by liver-infiltrating autoreactive T cells specific for the dominant PDC-E2 autoantigen[39]. The dominant epitopes of autoreactive T and B cells have been identified. The $CD4^+$ T cell epitope appears to localize to peptides 163-176, the $CD8^+$ T cell epitope appears to localize to peptides 159-167, while the B cell epitope appears to localize to peptides 167-186[39-43]. Furthermore, the most prominent immune features of autoreactive $CD4^+$ and $CD8^+$ T cells can be detected in peripheral blood from patients with PBC. The disease-related AMA-specific $CD8^+$ T cells are enriched up to about 10-fold and the $CD4^+$ T cells are enriched up to more than 100-fold in liver compared to peripheral blood samples[42,44]. Presently the data suggest that B and T cells in PBC patients respond simultaneously to the same autoantigen, and that both are involved in the pathogenesis of PBC.

Study of stored sera of well-characterized PBC patients followed for 7-28 years indicate that AMA levels are not associated with disease severity and progression. Most studies except the one conducted by Poupon *et al*[45] did not support that AMA levels could be affected by treatments during the observation period[45-47]. In fact, low levels of AMA persisted for up to 11 years following liver transplantation[47]. AMA are non-organ- and non-species-specific, and contain IgA, IgG and IgM subclasses. Data from PBC patients demonstrate that the presence of AMA IgA in sera or saliva might be associated with disease progression[23] and some studies suggested that greater concentrations of AMA IgA in biliary and mucosal secretions, constant transcytosis, would render the exposed cells more susceptible to apoptosis resulting in subsequent bile duct damage[48], while others proposed the hypothesis that AMA IgA can be transported to the vascular side of the bile duct cell where it can induce apoptosis by reacting with PDC-E2-like molecules located on the luminal surface cell membrane[49]. Many studies have demonstrated that the different AMA IgG subclasses have different clinical significance. PBC patients positive for IgG3 AMA had histologically more advanced disease and were more frequently cirrhotic than those who were negative. Furthermore, there was a positive correlation between AMA IgG3 titers and Mayo risk scores: this subclass is associated with poor prognosis, possibly reflecting the peculiar ability of this isotype to engage mediators of immunological damage[50].

Currently it is believed that a positive AMA titer is virtually pathognomonic of current PBC or risk for future development of the disorder, although the mechanisms leading to the generation of AMA have not been elucidated. Several possible mechanisms have been suggested regarding the generation of AMA, such as oxidative damage, molecular mimicry and changed biliary epithelial cell (BEC) apoptosis[51,52]. The fact that high levels of AMA can be detected in patients with acute liver failure supports the hypothesis that oxidative stress-induced liver damage may lead to induction of AMA[53]. But it is also surprisingly true that the AMA in these patients disappear rapidly, suggesting the pathogenesis of PBC is multifactorial. It has been demonstrated that molecular mimicry between bacterial or viral antigens and mitochondrial antigens can trigger the generation of AMA in PBC[54,55]. Modification of the inner lipoyl domain of E2 with halide or ethyl halide results in increased reactivity of AMA from PBC patients, suggesting that xenobiotics might make cellular components antigenic[56].

There is growing evidence showing that the onset of PBC may be the result of inefficient removal of apoptotic cells. It is of interest to note that a recent report proposed that PDC-E2 in patients with PBC is released without caspase cleavage from apoptotic BEC, supported by the fact that glutathionylation of the lysine lipoic acid moiety on the PDC-E2 is sometimes, though not commonly, decreased by serum AMA *via* Bcl-2[57]. Other studies show that apoptotic cells are phagocytosed by BECs, a function mediated by anti-CD16, and so consequently act as an exogenous source of autoantigens in cholangiocytes[9,58]. Defects in the elimination of apoptotic cells can lead to secondary necrosis accompanied by subsequent release of intracellular components, which might explain the generation of autoantibodies against intracellular antigens like AMA[59].

Further studies in the field of AMA in PBC have led to speculation about the existence of an AMA-negative PBC subgroup. It is not clear whether there is indeed such a subgroup, having distinct features, or if this is an artifact due to technical limitations of current AMA detection methods leading to false-negative results in some PBC patients[60]. Present data indicate that there is no discernable difference between AMA-positive and -negative PBC in terms of clinical manifestations, liver biochemistry and histopathology findings, disease course, as well as response to treatment[61-63]. As more sensitive and specific serologic tests are applied, many patients initially believed to be AMA-negative are subsequently found to be AMA-positive[64,65]. These findings cast doubt on the existence of a true AMA-negative PBC subgroup.

ANTINUCLEAR ANTIBODIES IN PBC

Antinuclear dot antibodies (SP100, PML, NDP52 and SP140)

PBC patients often have autoantibodies with nuclear dot (ND) stain patterns in the indirect immunofluorescence (IIF) assay. The major antigens associated with ND are as follows: sp100 proteins, which are transcription-activating proteins autoantigenic primarily in patients with PBC and occasionally in rheumatic disorders[66,67]; promyelocytic leukemia (PML) protein, a transformation and cell-growth suppressing protein aberrantly expressed in PML cells that was discovered in studies of the development of acute PML; NDP52, a protein of the myosin VI binding partners which was previously shown to contribute to innate immunity[68,69]; and sp140 proteins, which are identified as autoantigenic proteins in PBC recently. Sp100 and PML were discovered in the context of leukemic transformation and as autoantigens in PBC[70].

They are reported to be co-autoimmunogenic, often in patients with PBC[71]. The sp100 antigen was described by Szostecki *et al*[66] as a peptide of 480 amino acids with an aberrant electrophoretic mobility to 100 kDa, and a calculated molecular weight of 53 kDa. It was subsequently characterized by complementary DNA cloning, and the deduced amino acid sequence was found to contain sequence similarities with HIV-1 nef proteins[72]. The prevalence of anti-sp100 antibodies in PBC is about 25%, and it appears to be highly specific for a diagnosis of PBC, but only when other diseases can be excluded and the typical clinical context is present[73,74]. The presence of anti-sp100 antibodies serves as a serologic marker of PBC, which could be useful in clinics to confirm the diagnosis, especially in AMA-negative PBC patients[75,76]. Recent data indicate that as reports of AMA-negative PBC decrease due to development of more sensitive and specific serologic tests for serum AMA, anti-sp100 antibodies appear to be more common in AMA-positive PBC patients than in those who are AMA-negative[77,78]. Also, anti-sp100 antibodies are increasingly found to be present in many clinical conditions, such as systemic lupus erythematosus (SLE) and pSS. It is of interest to note that among female patients with urinary tract infections but no liver disease, 80% of the AMA-positive, but none of the AMA-negative patients were also positive for anti-sp100 antibodies. It is also well established that among PBC patients, about 74% of patients with urinary tract infections were positive for anti-sp100, whereas the positivity was only 4.8% in PBC patients without urinary tract infections[79]. Given the high specificity of anti-sp100 as an immunoserological hallmark of PBC, these findings support the hypothesis that some infections such as *Escherichia coli* are involved in the induction of PBC-specific autoimmunity.

PML protein was discovered in cells of patients with acute PML as a protein fused with the retinoic acid receptor-a (RAR)[80,81]. PML protein functions as a nuclear hormone receptor transcriptional coactivator[82]. Subsequently it was shown to form ND patterns when tested by immunofluorescence microscopy with serum anti-PML antibodies from PBC patients. Anti-PML antibodies often coexist with anti-sp100 antibodies in individuals with PBC[71], and are present in about 19% of PBC patients[83]. Current study indicates that anti-PML antibodies are highly specific for PBC even when autoantibodies against mitochondrial antigens are not found[84].

Anti-sp140 antibodies were recently identified for the first time in patients with PBC by Granito *et al*[85]. They are present in about 15% of PBC patients and are highly specific for PBC. Anti-sp140 antibodies coexist with anti-sp100 and anti-PML antibodies. No association was found between anti-sp140 and any particular clinical feature of PBC.

Antinuclear pore antibodies (gp210 and p62)

In addition to AMA, a number of nuclear antigens have been recognized as targets of antinuclear antibodies (ANA) in patients with PBC, including several components of the nuclear pore complex (NPC), such as the gp210 and p62 proteins. These antibodies have a nuclear periphery fluorescence pattern in the IIF assay, as first reported by Ruffatti *et al*[86] in 1985. Several reports revealed that the frequency of PBC-specific nuclear envelope antibodies ranged from 16% to 30%[76,87], and that the frequency increased greatly when fluorescent-labeled specific antiserum of the IgG subclass was applied[88,89]. In 1990 a study by Lassoued *et al*[90] showed that autoantibodies from patients with PBC having a punctate fluorescence pattern in IIF react with a protein of molecular mass approximately 200 kDa, which was identified as the NPC membrane protein gp210[91]. Gp210 is an integral glycoprotein of the nuclear pore consisting of three main domains: a large glycosylated luminal domain, a single hydrophobic transmembrane segment and a short cytoplasmic tail. Gp210 is recognized by antibodies in approximately 25% of patients with PBC[92]. The gp210 epitope recognized by most of the autoantibodies is a 15 amino acid stretch in the cytoplasmic, carboxyl-terminal domain of the protein. In the ANA category, these anti-gp210 antibodies are particularly significant since they are highly specific for PBC[93,94]. In addition, several reports link the presence of anti-gp210 antibodies in PBC patients with disease severity and poor prognosis. Since the presence of anti-gp210 antibodies correlates with an unfavorable disease course and more rapid progression, it is useful for monitoring the effect of ursodeoxycholic acid and for the early identification of patients at high risk for end-stage hepatic failure, and so may potentially become an important prognostic marker in PBC patients[95,96]. Findings to date clearly indicate that anti-gp210 antibodies having the best predictive value regarding progression to end-stage hepatic failure. The proposed mechanism for this predictive role is based on the following hypothesis that the breakdown of immunological tolerance to mitochondrial antigens such as PDC-E2 is not enough for the progression to hepatic failure, whereas the breakdown of immunological tolerance to nuclear antigens such as gp210, in which molecular mimicry is involved as well as increased and aberrant expression of gp210 in small bile ducts, may play a crucial role[97].

A few years after the discovery of anti-gp210 antibodies in PBC, reactivity of PBC sera with a 60 kDa component of NPC was reported. Anti-p62 antibodies, which also generate a perinuclear pattern in IIF, were first described in 1987[98-100]. They occur as frequently as the anti-gp210 glycoprotein autoantibodies[101], and with a specificity for PBC of up to 97%. Anti-p62 antibodies reacting with the 60 kDa component localize to the NPC. The frequency of anti-p62 antibodies in PBC is about 30%-55%. Their presence in PBC is not associated with AMA, but is associated with disease progression. Data from a multicenter study indicated that anti-p62 complex antibodies might be related to the progressive or advanced stage of PBC[99,102], that their prevalence is higher in symptomatic patients and that they are associated with more severe

Table 1 Autoantibodies in primary biliary cirrhosis that are closely related to other autoimmune diseases

No.	Autoantibody	Autoantigen properties	Prevalence in PBC (%)	Clinical associations	Ref.
ANA					
1	Anti-chromatin	Chromatin	8.9-25.0	Anti-chromatin antibodies are reported to be associated with disease activity in AIH, but their roles in PBC remains to be investigated	[99,127-129]
2	Anti-dsDNA	Double-stranded deoxyribonucleic acid	17.0-22.0	Anti-dsDNA antibodies are one of important criteria for the diagnosis of SLE. Co-existence of AMA and anti-dsDNA autoantibodies can be considered the serological profile of AIH/PBC overlap syndrome	[76,127,128,130,131]
3	Anti-ssDNA	Single-stranded deoxyribonucleic acid	59.0-71.0	Anti-ssDNA antibodies can be detected in many diseases	[132,133]
4	Anti-histone	Histone	43.6	Anti-histone antibodies are generally considered to be related to drug-induced lupus, though it can be detected in many autoimmune diseases including PBC	[132,134]
5	Anti-scl-70	Topoisomerase-1	3.0-24.0	Anti-scl-70 antibody serve as a specific maker for diffuse SSc and presents in 30%-60% of subjects with diffuse SSc	[127,132]
6	Anti-Sm	Proteins of 28/29, 16, 16.5, 18, and 12, 11, 6 kDa which participate in pre-messenger RNA processing into spliced mature mRNA	7.0-34.0	Anti-Sm autoantibodies are highly specific for SLE	[76,127,132,135]
7	Anti-SSA	Intracellular ribonucleoproteins of 60 and 52 kDa that are associated with small RNAs	5.0-30.0	Anti-Ro(SS-A) and anti-La(SS-B) antibodies are more frequently seen in SS and SLE. Their presence in PBC suggests that PBC often overlaps with SS	[76,127,132,135,136]
8	Anti-SSB	An intracellular ribonucleoprotein of 47 kDa that are associated with small RNAs	2.0-21.0		
9	Anti-RNP	Ribonucleoprotein	5.0	More frequently seen in SLE	[76,127]
10	Anti-Jo-1	Histidyl tRNA synthetase	26.0	Anti-Jo-1 antibodies are predominantly detected in patients with myositis	[135]
11	Anti-U1RNP	U1snRNPs that contain specific proteins of 70, 33 and 20 kDa	3.1-5.0	Anti-U1snRNP antibodies predominantly present in SLE, and can be detected in PBC patients. The clinical significance of anti-U1snRNP antibodies in PBC is unknown	[137,138]
Other liver diseases-associated autoantibodies					
12	Anti-SMA	A variety of target antigens including F-actin, G-actin, myosin, tropomyosin, troponin, desmin, vimentin, keratin, *etc.*	8.0-25.0	Anti-SMAs present mainly in AIH-Ⅰ, and can also be detected in chronic active hepatitis. The presences of anti-SMAs in PBC are potential indicators of AIH/PBC overlap syndrome	[131,139]
13	Anti-SLA	SLA and liver and pancreas antigen	2.0-3.9	Anti-SLAs are autoantibodies seen in AIH-Ⅲ.The presences of SLA autoantibodies in PBC indicate secondary autoimmune hepatitis	[9,140,141]
14	Anti-LKM	Liver kidney microsomal antigen	0.7	Anti-LKM antibodies occur preferentially in AIH-Ⅱ. Anti-LKM autoantibodies can be seen in 21.4% of HCV-infected PBC patients, which suggests a close association between LKM and HCV-infected PBC	[142]
15	Anti-ASGPR	Asialoglycoprotein receptor	22.0-23.0	Anti-ASGPR antibodies mainly present in AIH and PBC. The autoimmune responses against ASGPR have been implicated in the development of AIH and PBC	[143-146]
16	Anti-LCM	Liver cell membrane specific antigen	42.0	Anti-LCM antibodies are detected predominantly in patients with HBsAg-negative chronic active hepatitis, but are also found in other liver diseases such as PBC	[147-149]
17	Anti-LSP	Liver specific protein	48.5	Anti-LSP antibodies present in viral hepatitis and autoimmune liver disease, and are found to correlate with severity of periportal inflammation and piecemeal necrosis in PBC	[144,150]
18	Anti-calreticulin	Calreticulin	20.0	Anti-calreticulin antibodies present in autoimmune liver disorder and IBD. They are not specific for PBC	[151,152]
19	Anti-FH	Fumarate hydratase	19.4	Anti-FH antibodies are found to be present predominantly in AIH. It can also be detected in PBC and other liver disease. The prevalence and clinic significance of anti-FH in PBC need further study	[153]
20	Anti-PGAM-B	Phosphoglycerate mutase isozyme B	16.7	Anti-PGAM-B antibodies are found to be present in 70.0% of AIH and 16.7% of PBC. It is also present in about 10% of viral hepatitis and 3.7% of healthy control. The clinical significance of anti-FH needs further study	[154]

21	Anti-p97/VCP	P97/valosin-containing protein	12.5	Anti-p97/VCP antibodies predominantly present in PBC, and can be detected in about 9.7% of AIH. The presence of anti-p97/VCP antibodies in PBC suggests less progressive disease course and benign prognosis	[155-157]
22	Anti-GSTA1-1	Glutathione S-transferase	10.0	Anti-GST autoantibodies are detected in 16.0% of AIH and 10.0% of PBC. Patients of AIH with positive anti-GST have severe diseases and poor prognosis	[158]
23	Anti-ASL	Argininosuccinate lyase	23.0	Anti-argininosuccinate lyase is a newly identified autoantibody in liver disease and its clinical relevance remains unknown	[159]
24	Anti-calmodulin	Calmodulin	IgM 50.0 IgA 42.9	Anti-calmodulin autoantibodies neither associate with anti-SMA, ANA and AMA, nor with hyperglobulinemia. The clinic significant of anti-calmodulin is unclear	[160]
Gastroenteropathy-associated autoantibodies					
25	ASCA	Baker's yeast saccharomyces cerevisiae	24.2	ASCA serves as a serological marker of Crohn's disease, and has also been detected in other autoimmune disorders and in 5%-6.3% of blood donors. The prevalence of ASCA in AIH is 20%-30%, in AMA-negative PBC 44%. ASCA is common in PBC patients and correlates with higher level of circulating IgA. The prevalence of ASCA in PBC may be an indirect sign of enhanced mucosal immunity, but does not necessarily indicate concomitant inflammatory bowel disease	[161-163]
26	Anti-Galectin-3	Galectin-3, a member of -galactoside-binding lectins	30.0	Anti-Galectin-3 autoantibodies are primarily associated with Crohn's disease, and correlate negatively with disease activity. The significance of anti-Galectin-3 IgG autoantibodies in patients with PBC is unknown	[164]
27	Anti-tTG	Tissue transglutaminase	10.0-26.7	Anti-tTG autoantibody is mainly found in celiac disease. The prevalence of anti-tTG in PBC varies due to different types of substrate utilized in detection	[127,165,166]
28	AGA	Gliadin	16.0-21.0	Anti-gliadin antibodies are considered as the most reliable serological markers for celiac disease. They are also frequently seen in PBC, and IgA subclass of anti-gliadin antibodies are more pronounced in patients with Scheuer's stage Ⅲ-Ⅳ disease	[166,167]
Vasculitis-associated autoantibodies					
29	ANCA	Antigens including proteinase 3, myeloperoxidase, bactericidal/permeability-increasing protein, lactoferrin,human leukocyte elastase, cathepsin G, lysozyme, azurocidin, *etc.*	2-26	ANCAs are primarily associated with systemic vasculitides such as Wegener's granulomatosis, microscopic polyangiitis and Churg-Strauss syndrome	[76,131,168]
30	Anti-MPO	Myeloperoxidase	9.0	Predominantly in microscopic polyangiitis, necrotizing and crescentic glomerulonephritis, Churg-Strauss syndrome	[169]
31	Anti-PR3	Proteinase 3	3.0	Predominantly in Wegener's granulomatosis, and also detectable in microscopic polyangiitis, necrotizing and crescentic glomerulonephritis	[127]
32	Anti-LF	Lactoferrin	25.0-35.7	Are detected in several autoimmune disorders, such as Crohn's disease, SLE, systemic vasculitides. They are not specific markers for PBC	[170,171]
Thrombophilia-associated autoantibodies					
33	Anti-β2GP Ⅰ	β(2)-glycoprotein Ⅰ	IgG 2-15	Represent specific features of patients with antiphospholipid syndrome. Their presence in PBC often indicates severe disease and worse prognosis	[127,172,173]
34	Acl	Cardiolipin	IgG 27.3		
35	Anti-PS	Phosphatidylserine	IgM 75		
36	Anti-PT	Prothrombin	IgG 7		
37	Anti-PE	Phosphatydilethanolamine	IgG 5		
Diabetes mellitus-associated autoantibodies					
38	Anti-GAD	Glutamic acid decarboxylase	5.5	Anti-GAD occurs preferentially in the patients with type 1 diabetes. Clinical significance of Anti-GAD in PBC is unclear	[174]
39	Anti-SOX13	Transcriptional factor SOX13	18.0	SOX13 was initially identified in type 1 diabetes. The present of anti-SOX13 in PBC may merely indicate an immune response to products of damage to parenchymal tissue	[175]
Autoimmune thyroid diseases-associated autoantibodies					
40	Anti-TG	Thyroglobulin	54.5	Anti-TG, anti-TPO and anti-TR are markers of autoimmune thyroid diseases. Their significances in PBC are unknown	[176]
41	Anti-TPO	Thyroid peroxidase	45.5		
42	Anti-TR	TSH receptor	9.1		

Others autoantibodies					
43	Anti-CCP	Cyclic citrullinated peptide	2.7-4.0	Anti-CCP antibodies are highly specific for RA with sensitivity of 60%-70%. Presence of anti-CCP antibodies in PBC patients suggests RA overlap	[125,126,177]
44	Anti-ClpP	Microbial caseinolytic proteases P	30-47	ClpP is highly conserved among bacteria. Anti-ClpP in PBC suggests infection factors and molecular mimicry involved in the pathogenesis	[178,179]
45	Anti-β-subunit of bacterial RNA polymerase	β-subunit of bacterial RNA-polymerase	32.8	These autoantibodies in PBC, suggest bacterial triggers of PBC	[180]
46	Anti-EPO	Eosinophil peroxidase	52.5	PBC patients with positive anti-EPO antibodies have less peripheral eosinophils	[181]
47	Anti-p53	Nuclear protein of 53 kDa that regulates cell proliferation and apoptosis	8.0	Anti-p53 autoantibodies are commonly seen in malignancies and organ-specific autoimmune diseases such as type 1 diabetes, thyroid diseases, PBC and AIH	[182]
48	Anti-acetylcholine receptor	Nicotinic acetylcholine receptor	58.8-74.0	Anti-acetylcholine receptor antibodies are primarily associated with myasthenia gravis, though PBC patients with positive anti-acetylcholine receptor antibodies do not have clinical symptoms of myasthenia	[169,183,184]
49	Anti-CA Ⅱ	Carbonic anhydrase Ⅱ	18-31	Anti-CA Ⅱ antibody is likely a nonspecific marker of autoimmunity. It has been detected in a variety of autoimmune diseases, including Graves' disease, type 1 diabetes, SS, SLE, AIH and PBC. In cases of PBC, no significant correlation has been found between anti-CA Ⅱ antibody and AMA	[185-189]
50	Anti-α enolase	α-enolase	28.6	Anti-α-enolase antibodies present in a variety of inflammatory and autoimmune disorders, such as SLE, IBD, RA and AIH, and are not likely to be specific markers for any disease. They might be involved in destruction of biliary epithelium and are associated with hepatic failure	[190-195]
51	Anti-HSP	Heat shock proteins	45.7	Enhanced biliary expression of heat shock protein is found in PBC. Anti-HSPs are common in PBC, and are related to titers of AMA. They might cross-react with the main mitochondrial antigens in PBC	[196-199]
52	Anti-FKBP12	FK506 binding protein 12	44.4	The significance of anti-FKBP12 antibodies in PBC is unclear	[200]

SLA: Soluble liver antigen; PBC: Primary biliary cirrhosis; AMA: Antimitochondrial antibodies; SLE: Systemic lupus erythematosus; SSc: Systemic sclerosis; ANA: Antinuclear antibodies.

disease, defined as the presence of cirrhosis or its complications. In addition, it has been reported that anti-p62-positive patients have higher levels of serum bilirubin and more marked inflammatory infiltrates on liver biopsy[87].

Antinuclear envelope antibodies (Lamin and Lamin B receptor)

The nuclear envelope is a bilayered membranous structure that can be divided into five distinct components: the inner nuclear membrane, having a distinct set of integral membrane proteins; the outer nuclear membrane; a perinuclear space, which is continuous with the lumen of the endoplasmic reticulum; the pore domains, regions where the inner nuclear membrane and outer nuclear membrane come together and fuse; and an underlying nuclear lamina, containing the nuclear lamins[103]. A smooth membrane fluorescence pattern is characteristic of the presence of antibodies to nuclear lamins in IIF using sera from PBC patients. Three subtypes of anti-lamin antibodies have been described: anti-lamin A, B and C[102,104-106]. Anti-lamin antibodies do not seem to be disease-specific as they are found in patients with several different autoimmune disorders, such as SLE, chronic fatigue syndrome, and PBC[107-110]. Anti-lamin A, B and C antibodies are detected with frequencies of 6%-8% in sera from patients with PBC. The usual scenario is to find anti-lamin A and C together, and less frequently either anti-lamin B alone or all three in the same patient[111].

Lamin B receptor (LBR) is a protein integral to the inner nuclear membrane with a nucleoplasmic, amino-terminal domain of 208 amino acids, followed by a carboxyl-terminal domain with eight putative transmembrane segments. Anti-LBR antibodies from PBC patients recognize the nucleoplasmic, amino-terminal domain but not the carboxyl-terminal domain. Anti-LBR antibodies appear to be highly specific for PBC, but their clinical significance is unclear. The prevalence of anti-LBR antibodies in PBC is approximately 2%-6%[76,102,112,113].

Anti-centromere antibodies

Anti-centromere antibodies (ACA) are important diagnostic markers of systemic sclerosis (SSc), found in about 25% of these patients[114]. In patients with CREST syndrome or limited cutaneous SSc, the positivity rises to 50%-90%. ACA in SSc are usually associated with a good prognosis, though they are not specific for SSc. ACA can be detected in patients with other rheumatic diseases including pSS, SLE and PBC (about 30%)[115-120]. It is of interest to note that several subtypes of ACA have been identified, including anti-CENP-A, anti-CENP-B, anti-CENP-C and anti-CENP-O antibodies[121]. Research during the past several years has found that prevalence of the ACA subtypes

differs among various autoimmune diseases[122]. Recent studies have demonstrated that ACA positivity in patients with PBC is of significant predictive value for progression to portal hypertension[123,124].

OTHER AUTOANTIBODIES DETECTED IN PBC

Although extensive research has focused on AMA, it is of interest to note that, to date, more than sixty different autoantibodies have been found in PBC patients. Some target at nuclear or cytoplasmic molecules and cell membranes, while others react with lipid components. Some, like AMA, occur frequently and almost universally in PBC, while others, like anti-lamin and anti-LBR, are present in only a few patients. It should be noted that among these autoantibodies, some are not specific for any disease, and some are thought to be more closely related to other autoimmune diseases, such as anti-CCP which is relatively specific for rheumatoid arthritis[125,126]. Prevalence and properties of these autoantibodies in PBC are summarized in Table 1.

CONCLUSION

The presence of serum autoantibodies is characteristic of PBC, and is useful in the clinical diagnostic process in combination with histology and imaging studies. Numerous autoantibodies are found in sera from patients with PBC. This suggests that the development of PBC is a multi-factorial process. With growing numbers of clinical studies of autoimmune diseases and extensive application of more sensitive testing methods for antibodies, it has gradually been realized that the association between an individual autoantibody and autoimmune disease is not as specific as previously thought. AMA is very sensitive and anti-gp210 and anti-sp100 are highly specific for PBC. Other antibodies found in PBC, such as ACA, ASCA, ANCA and anti-sm, could also be found in other autoimmune diseases[131,161,162,168]. Although some autoantibodies are believed to be associated with the pathogenesis of PBC, these associations are likely to be extremely complicated and surely exert complex effects in many different ways. It is hard to understand these delicate associations based on our current knowledge of PBC, and further advanced studies are required to elucidate the pathogenesis of this autoimmune disease.

Abstract

Polypectomy of colonic polyps has been shown to reduce the risk of colon cancer development and is considered a fundamental skill for all endoscopists who perform colonoscopy. A variety of polypectomy techniques and devices are available, and their use can vary greatly based on local availability and preferences. In general, cold forceps and cold snare have been the polypectomy methods of choice for smaller polyps, and hot snare has been the method of choice for larger polyps. The use of hot forceps has mostly fallen out of favor. Polypectomy for difficult to remove polyps may require the use of special devices and advanced techniques and has continued to evolve. As a result, the vast majority of polyps today can be removed endoscopically. Since electrocautery is frequently used for polypectomy, endoscopists should be thoroughly familiar with the basic principles of electrosurgery as it pertains to polypectomy. Tattooing of a polypectomy site is an important adjunct to polypectomy and can greatly facilitate future surgery or endoscopic surveillance. The two most common post-polypectomy complications are bleeding and perforation. Their incidence can be decreased with the use of meticulous polypectomy techniques and the application of some prophylactic maneuvers. This review will examine the technique of polypectomy and its complications from the perspective of the practicing gastroenterologist.

Key words: Colonic polyp; Polypectomy; Colonoscopy; Polypectomy technique; Complications

INTRODUCTION

Polypectomy is a fundamental skill utilized by all endoscopists who perform colonoscopy. Mastery of polypectomy is difficult and requires both significant experience and study. It is clear that polypectomy is efficacious in reducing the risk of colon cancer development by interrupting the adenoma to carcinoma progression[1,2]. Endoscopic techniques used in colonoscopic polypectomy continue to evolve, and it is important for all endoscopists to be familiar with these concepts.

Decision making about how to perform polypectomy is often made during colonoscopy when a polyp is detected. A general rule is that all potential adenomas should be removed. The endoscopic appearance of a polyp is often not necessarily a good indicator of its histologic nature. While as many as 70% of diminutive polyps (less

than 5 mm) may be adenomas, the risk of any particular polyp containing malignancy increases with the size of the polyp[3-6]. The method chosen for polypectomy is often related to the appearance and size of the polyp. Polyps are usually described as being pedunculated, sessile or flat. The risk of a polyp 2 cm in size or larger being malignant is greater than 10%[7]. Some polyps blur the lines though, by not falling into these strict categories. Nevertheless, consideration of polyp characteristics is helpful in determining the best approach to polypectomy[8].

COLD FORCEPS POLYPECTOMY

The simplest method for polypectomy is cold forceps removal. A survey of common practices among gastroenterologists found that cold forceps polypectomy was the technique of choice for small polyps, particularly polyps 1 to 3 mm in size[9]. In slightly larger polyps, jumbo forceps could be considered. Cold forceps can easily grasp small polyps that otherwise might be too small to snare.

After passing the forceps through the channel, the forceps and the scope can be manipulated in order to grasp as much polyp tissue as possible. Turning the scope to bring the polyp to the five to seven o'clock position can be useful since that is the position at which the forceps exit the endoscope channel. After closing the forceps on the polyp, a gentle pull on the wire removes the bite of polyp from the colon mucosa. The area is examined to determine if further bites are necessary to complete polyp excision.

Advantages to cold forceps polypectomy include avoiding risk associated with electrocautery and an almost negligible risk of colonic perforation[10]. One challenge associated with cold forceps polypectomy is that after the initial bite, minor bleeding can obscure the polypectomy field increasing the risk of leaving residual polyp behind[11].

HOT FORCEPS POLYPECTOMY

Hot forceps polypectomy is another option for small polyps. Hot forceps polypectomy is similar to cold forceps except it uses electrocautery to try to destroy residual polyp tissue intentionally left behind[12]. In hot forceps polypectomy, only the tip of the polyp is grabbed in the forceps. The small polyp is pulled into the colon lumen to create a tent-like effect and electrocautery is applied to destroy the polyp base while preserving the polyp tissue inside the forceps as a histological specimen[13].

Over the years, the use of hot forceps has fallen out of favor. One randomized study by Ellis looked at 72 polyps 6 mm or less in size and found that hot forceps still left residual polyp tissue behind 22% of the time compared to only 5%-14% of the time with either cold or hot snare[14]. Another study by Peluso retrospectively looked at 62 hot forceps polypectomies for polyps 3-6 mm in size and found that 17% of the time residual polyp tissue remained on follow-up endoscopic exam 1 to 2 wk later[15]. Cold forceps and snare polypectomy have been described as having a 16% residual polyp rate which suggests that hot forceps are either no better or even worse than other accepted methods of polyp removal. Hot forceps may still be useful though for small polyps that have a tip easily grasped with forceps but a polyp base that is hard to reach yet could still be destroyed with application of electrocautery.

SNARE POLYPECTOMY

Snare polypectomy was found to be the preferred method for removal of polyps 1 cm or greater in size in a survey of common gastroenterology practices[9]. A snare is a self-contained metal ring that is opened over the polyp and then closed entrapping polyp tissue for resection by closing the ring. Before pulling the snare out of the scope, the polyp should be brought to the six o'clock position. Sometimes advancing the snare proximal to (beyond) the polyp is useful if the polyp is behind a fold or inclined to flop out of the opened snare. The snare can also be used to position a pedunculated polyp in such a position as is more amenable to capturing once the snare is opened. Once the polyp is captured in the snare, the snare plastic sheath should be advanced moving the polyp away from the scope tip if electrocautery is to be used to avoid electrical damage to the scope. When snaring a pedunculated polyp, the snare should be placed about half way up the stalk, so that after cutting, a stalk remnant is left which can be grabbed or clipped if hemorrhage occurs. The polyp is pulled away from its base into the lumen tenting the colon wall to avoid burning the adjacent deep colon layers[11].

A snare can be either hot or cold in that it can be supplemented with electrocautery or not. During hot snaring, the endoscopist's assistant should close the snare slowly and gently. If the snare is too tight prior to electrocautery application, it could result in inadvertent cold cutting the polyp, resulting in bleeding from the stalk or in the snare becoming entrapped into coagulated tissue in the stalk[16]. Once the snare is in position, a few seconds of electrocautery can be applied if opted for, and then the endoscopist instructs the assistant to cut through the polyp.

There are many different types of snares each with specific advantages which can be chosen depending on the situation. Oval and hexagonal snares are most commonly used. We suggest using a barbed snare for hard to grab tissue as can be the case in flat or sessile polyps or when the snare slipping off the polyp seems to be a problem. Crescent snares are often used in EMR. A rotatable snare is useful when initially the snare comes out of the scope in such a way that is not optimal for snaring the polyp and it is desirable to rotate the snare to an angle that is better for capturing the polyp. A mini-snare can be used for cold snaring smaller polyps or to remove a small amount of residual tissue after piecemeal polypectomy[17]. There is a combination snare-injection needle which allows for quick injection prior to opening the snare and avoids having to change out an injection needle wire for

the snare (i-Snare system, US endoscopy, Mentor, Ohio, USA)[18].

ELECTROCAUTERY

The purpose of electrocautery in polypectomy is to either provide extra power in cutting tissue or to prevent bleeding by coagulation of tissue. The basic principle in electrocautery is that if enough electrical current is delivered, heat will be generated to cause cellular bursting leading to tissue cutting. If somewhat less heat is generated then cell shrinkage leading to tissue coagulation occurs. Even pure cut current causes some coagulation, and pure coagulation current has some cutting property. Snares and hot forceps use monopolar electrocautery, which means that the electrical circuit runs through the patient body to a grounding pad placed on the patient. Cautery probes can also use bipolar electrocautery, which means that the electrical circuit runs between two electrodes both located on the tip of the probe. Energy deliverance is also proportional to the time it is applied, so the length of time the endoscopist keeps their foot on the pedal is very important[16]. The use of coagulation current has been associated with more delayed post-polypectomy hemorrhage, whereas the use of cutting and blended current have been associated with more immediate hemorrhage[19]. A review of electrocautery by Morris suggests using coagulation at a setting of 20 Watts for hot snaring. Since cut has also been associated with a higher risk of perforation, we suggest first using coagulation for standard colonoscopic snare polypectomy. Then after using coagulation, the endoscopist can consider using some cut function next if the polyp has a thick stock and coagulation alone is unable to cut through it or in the case that the snare becomes entrapped on the polyp stock. For hot forceps electrocautery coagulation at 10-20 Watts can be used[16]. Most modern electrosurgical units have preset polypectomy settings.

LARGE POLYPS

In the past, large polyps often required surgery for removal, but now many can be managed endoscopically[20]. Endoscopic Mucosal Resection (EMR) can be performed on sessile polyps 2 cm in size or larger. EMR involves submucosal injection (often of saline) creating a cushion for the polyp and then hot snaring the polyp either *en bloc* (all together) or piecemeal (multiple snarings). EMR can provide resection down to the muscularis propria[21-23]. There is no official distinction between saline assisted piece meal polypectomy and EMR but typically the term polypectomy is reserved for removal of flat lesions measuring less than 2 cm and the term EMR is used for larger lesions[4,24]. Endoscopic Submucosal Dissection aims to remove all dysplastic tissue en-block as one piece rather than the piecemeal technique that is used with saline assisted polypectomy and EMR[25]. Large polyps are often adenomatous, therefore complete resection is the goal even though it is often time-consuming. Iishi found that 55% of polyps resected in piecemeal fashion required further resection on a repeat colonoscopy, but complete resection was possible in 83% of polyps after up to three repeat colonoscopies[26]. Flat and sessile polyps can be challenging to snare as they are often level with the colon floor. The first piece of tissue snared can leave divots or ledges in the remaining polyp that can make it more easily grabbed in subsequent snares. If residual polyp tissue is left after piecemeal polypectomy, argon plasma coagulation (APC) can be used to tryw to destroy the residual tissue[27]. After any piecemeal polypectomy, the site should be re-examined in 2 to 6 mo to evaluate for any residual polyp tissue[7,8].

POLYP RETRIEVAL

Once polyp tissue is snared, actually retrieving it can be challenging. Many endoscopists periodically experience the frustration of successfully snaring a large adenoma-appearing polyp only for it to fall out of view or get lost in the colon somewhere[28]. However, even experienced endoscopists may fail to retrieve polyp tissue up to 16% of the time[8]. Possibly the most common way to retrieve a polyp once it is snared is to drive the scope up to the polyp in the six o'clock position and then to suction the polyp through the scope into a trap, using a back flush if needed. If the polyp is too big to be suctioned into the scope, the snare can be used to cut the large polyp into pieces small enough to fit through the suction channel. Polyp tissue can also be grabbed with forceps while the entire colonoscope is withdrawn. In these cases the forceps can be advanced out a few centimeters so that simultaneous examination of the remaining colon can be performed while the specimen is kept in view. A Roth net can be used to remove large polyps or several polyp fragments at once. Also, an overtube can be used for easy repeated colonoscopic intubation to the polypectomy site with repeated removal of polyp fragments[29,30].

RESIDUAL POLYP TISSUE

Leaving residual polyp tissue behind leaves behind cells that may continue to progress through the adenoma to carcinoma sequence, therefore the purpose of polypectomy is to break that sequence. Risk of residual polyp tissue is often the outcome measured in studies comparing different methods of polypectomy, such as snare *vs* forceps. In an observational study, Tappero *et al*[17] found that a snare never left behind residual polyp tissue but cold forceps often did. Zlatanic found that for treating residual tissue, piecemeal polypectomy left behind residual tissue 46% of the time, APC destruction still left residual tissue 50% of the time, and doing nothing left behind residual polyp obviously 100% of the time[24].

THE CHALLENGING POLYPECTOMY

Some polyps provide distinct challenges that call for utilizing other approaches than just standard polypectomy techniques. Endoscopists periodically find polyps that

are very difficult to remove. These can include polyps that are located behind colon folds, polyps that are very large, polyps that are just out of reach, and flat, carpeted, or thick polyps. For polyps hiding behind folds and large pedunculated polyps, Valentine *et al*[31] described a technique using a double channel therapeutic endoscope. A tripronged grasper is advanced *via* one of the channels to pull the polyp into better view and into the snare, while a snare for polypectomy is inserted through the other channel. A standard upper endoscope can also be considered for difficult to reach polyps as it has a tip with a tighter bending angle than a colonoscope[32]. A side viewing scope can be used for polyps that are behind folds or on a side of the colon wall unable to be reached by a standard colonoscope. Friedland[33] described either retroflexing the colonoscope or injecting a large amount of saline proximal to the lesion as options to try to reach polyps on the inside wall of tight turns. Even two different scopes manipulated by two endoscopists can be attempted with one scope grabbing the polyp and pulling it into a convenient location while the other scope performs polypectomy has been described[8]. Colon spasms can present a challenge by constantly moving the polyp in and out of view, and glucagon can be given intravenously to decrease these spasms[8]. Some polyps may not be amenable to endoscopic polypectomy and are better served with surgery. If a large polyp is in the cecum, extends into the ileocecal valve, or extends into the appendix, surgery may need to be considered. Also polyps that involve more than 30% of the colon circumference are often impossible to remove endoscopically[11].

Injection

An important related tool to consider for polypectomy is injection with either saline or epinephrine (1:10000) into the polyp base or stalk. The submucosa is the target location for fluid deposit, so the endoscopist should try not to penetrate the colon wall with the needle. Injected fluid can diffuse fast, so sometimes repeat injections are needed. Injection is suggested in the literature for larger polyps specifically. Most studies looking at resection of large or giant polyps include epinephrine injection in their polypectomy protocol. Injection can lift up flatter polyps rendering them more polypoid and more amenable to snare polypectomy and complete resection[34]. The injected fluid may also serve as a safety cushion by increasing the distance between the mucosa and the muscle layer and serosa, thereby at least theoretically decreasing risk of perforation[21,35]. If a polyp does not lift with an appropriate injection technique it may be caused by an underlying cancer extending to deeper colon layers. Pedunculated polyps with large stalks are more inclined to bleeding. Injecting these large stalks before snare polypectomy may provide prophylactic hemostasis and reduce the risk of a post-polypectomy bleed. Epinephrine is a potent vasoconstrictor, and both saline and epinephrine can exert a tamponade effect on blood vessels[36]. A study by Dobrowolski randomized 100 polyps to either epinephrine injection or no injection and found one post-polypectomy bleed in the injection group compared to 8 bleeds in the no injection group[37].

Endoloops

In addition to injection, another option for prevention of post-polypectomy bleed is an endoloop[38]. The endoloop is a detachable oval-shaped nylon snare. It is deployed in the same way as a standard snare but then tightened and released around the stalk or base of the polyp prior to polypectomy. A gastroenterology survey showed that 38% of endoscopists report using endoloops[9]. A trial done in Greece by Kouklakis randomized 64 patients with polyps greater than 2 cm in size to get either epinephrine injection or a combination of endoloop and endoclip placement. The combination endoloop and clip group did significantly better with only 3% post-polypectomy hemorrhages compared to the epinephrine group which had a 12% rate of post-polypectomy hemorrhage[39]. The Di Giorgio study found a lower rate of post-polypectomy bleed at 1.8% with a detachable snare compared to 3% for epinephrine injection and 8% for no prevention[40]. In 152 snare polypectomies, Paspatis *et al*[41] found that combination epinephrine injection with endoloop placement was associated with only a 1% rate of delayed bleeding whereas epinephrine used alone was associated with an 11% rate of delayed bleeding. However many problems with endoloops such as slipping off the polyp stalk, inadequate tightening, and persistence of bleeding despite endoloop placement were described in a retrospective study by Matsushita *et al*[42].

Tattooing

Large or polyps suspicious for invasive cancer should be considered for tattooing for easier future localization either by a surgeon during colectomy or by an endoscopist during future surveillance colonoscopy[43,44]. Endoclip placement and inter-operative colonoscopy are other ways to re-identify a lesion, however the endoclips can slip off prior to surgery, and inter-operative colonoscopy can be cumbersome and time-consuming. India ink is the preferred identification agent for tattooing polyps[45] because the ink is phagocytosed by macrophages giving the site an almost permanent easily detected marking. Other dyes like indigo carmine and methylene blue are too rapidly resorbed to be useful. Commercially available India ink is a sterile carbon based dye suspended in stabilizing particles and diluted in normal saline to a 1:100 concentration[46]. India ink is injected through an injection needle and targeted to the submucosal layer of the inter-haustral folds. Common practice is to place a tattoo on more than one side of the lesion in either a two or a four quadrant manner. Injecting at an oblique angle tangential to the colon wall can avoid penetration of the colon wall which can result in inflammation and a diffuse staining of the peritoneum thereby obscuring the surgeon's view during operation[44,47]. To ensure proper ink placement, a double injection technique has been described in which 1 mL of saline is first injected creating a submucosal bleb[48]. Once the

saline bleb is made, the needle is left in place, the saline syringe is changed to an India ink syringe and about 0.1 to 2 mL of tattoo ink is then injected into the bleb space[49,50]. After tattooing the polyp site, the endoscopist should also include in the report the distance of the site from the anal verge in centimeters to aid in future localization.

ENHANCED POLYP DETECTION AND CLASSIFICATION TECHNIQUES

Standard colonoscopy based on white light may have a polyp miss rate of anywhere from 1% to 26%[51]. Also distinguishing truly neoplastic lesions from normal or benign tissue endoscopically can be challenging. Potentially unnecessary biopsies require pathologic evaluation leading to increased costs, so one advantage of enhanced detection techniques includes avoiding this increased cost[52]. Some newer modes of enhanced polyp detection and classification have been developed over the last few years. High definition colonoscopy, chromoendoscopy, and narrow band imaging (NBI) are useful to enhance polyp detection. Confocal Laser Endoscopy, and spectroscopic colonoscopy are more for enhancing polyp classification.

High definition colonoscopy (complete system can cost $215 000 from Olympus America, Center Valley, PA, USA) provides an image containing more pixels and better picture quality than standard definition colonoscopy. One retrospective study by Buchner showed a significantly higher polyp and adenoma detection rate (4%-5% increase in yield) with high definition colonoscopy compared to standard definition colonoscopy for polyps less than 1 cm and in the left colon[53].

Another enhanced detection technique, chromoendoscopy, uses indigo carmine (25 g costs about $40) that is flushed over the colonic mucosa to demarcate polyp architecture, vascular pattern and pit detail. This can highlight subtle differences between normal colonic tissue and polyp tissue making polyp detection easier. NBI, a type of virtual chromoendoscopy, is another enhanced mode that uses special narrow band filters to enhance surface and vascular pattern appearance of potential polyps. NBI may be useful for distinguishing between hyperplastic and adenomatous polyps as well. One study from Japan looked at NBI in the evaluation of 617 colorectal lesions and reported a sensitivity of 90.9% and a specificity of 97.1% for differentiating non-neoplastic from hyperplastic lesions[54]. Round and stellate pit patterns represent benign lesions, and villiform, gyrus-like, and irregular patterns represent neoplastic lesions. Many standard colonoscopies now have NBI capability (which means no additional cost to patients when it is used) which is activated by pushing a button on the head of the scope[55,56].

A new spectroscopic probe (not commercially available yet) has been developed that detects the increased microvascular blood supply in normal tissue at the periphery of a polyp that may be unseen or behind a fold. This alerts the endoscopist "like a metal detector going off" to examine the nearby mucosa more carefully to find the polyp thereby increasing detection[57].

Confocal laser endoscopy (CLE) is an enhanced mode of polyp classification (Cellvizio, Paris, France). Once a potential polyp is endoscopically detected, the lesion is focused on for analysis to determine if it is benign or neoplastic. Thousands of optical fibers bundled together take 12 pictures per second and provide image resolution detailed to the micron level. Pit pattern, crypt architecture, and vascular patters are analyzed; and irregular vessels, presence of mucin and increased tissue density indicate a neoplastic lesion. CLE is either integrated into the scope or used as a separate probe passed through the accessory channel[58]. A study from Mayo Jacksonville found CLE to have a sensitivity of 76% and a specificity of 72% in differentiating non-neoplastic from neoplastic lesions. Interobserver agreement over what the images represented was found to be 78%[59].

HEMORRHAGE

Even though the benefit of polypectomy is significant in terms of reducing the risk of colon cancer development, polypectomy is not without some risk of complications. Most complications are related either to post-polypectomy hemorrhage or perforation. Hemorrhage is the most common and is usually divided into immediate (less than 12 h post-procedure) and delayed (after 12 h post-procedure but up to 30 d). There is a greater risk of immediate hemorrhage associated with cut or blended electrocautery and a greater risk of delayed hemorrhage with the use of coagulation current. These specific risks should be appreciated and weighed when choosing electrocautery type.

Dobrowolski *et al*[60] noted that the risk of post-polypectomy hemorrhage ranges from 0.3% to 6% but can be as high as 24% in large polyps. He found that hemorrhage was more likely in polyps larger than 17 mm, pedunculated polyps with stalks thicker than 5 mm, sessile polyps, and malignant polyps. Watabe found that hypertension also puts patients at risk for a delayed post-polypectomy hemorrhage[61].

Immediate hemorrhages are frequently noticed during colonoscopic examination as bleeding from the polypectomy site is directly visualized. In these cases, either epinephrine injection into the base of the polypectomy site or endoclip placement is often considered as first line hemostatic therapy. Endoloop placement can also be considered and applied either to a stalk or to a larger polypectomy base for hemostasis. If snaring a pedunculated polyp results in a visibly bleeding stalk, sometimes grasping the stalk with the snare and holding pressure for 5 min can stop the hemorrhage[36].

Endoclips can be placed onto a bleeding residual stalk or empirically placed just lateral to the polypectomy site to tamponade any supplying blood vessels[62]. Endoclips can also be placed prophylactically at the polypectomy site after removal of the polyp. A group in Spain looked retrospectively at 34 polypectomies using endo-

clips either before or after resection of polyps 15-40 mm in size with stalks 5-12 mm in thickness. They found that all episodes of bleeding could be controlled with the use of endoclips. They also found that the clips easily catch stalks around 5 mm in thickness but that two clips could be placed on stalks thicker than that[63].

Friedland *et al*[64] described performing polypectomy on polyps less than 1 cm in size in actively anticoagulated patients. He placed endoclips prophylactically at the polypectomy site and had no more incidence of post-polypectomy bleed than in non-anticoagulated patients.

Many forceps polypectomies result in some minor oozing from capillaries at the polypectomy site, and this is usually self-limited and resolves after continued visualization. Delayed hemorrhage can require hospitalization, blood transfusion, and repeat colonoscopy for definitive hemostasis.

PERFORATION

Perforation is a serious complication that can result from polypectomy and can often have major clinical ramifications for the patient after the procedure is over[65]. Factors contributing to perforation include mechanical stress from the scope, barotrauma, electrocautery, and the depth of the polyp resection itself. The risk of perforation with all colonoscopies has been estimated somewhere around 1 perforation per 1000 to 2000 colonoscopies[66-68]. Risk of perforation however increases in polypectomies involving longer electrocautery time, removal of larger polyps, location in the cecum, and large sessile polyps requiring piecemeal removal.

If a perforation is visualized during the procedure itself, the endoscopist can consider an attempt at closure with endoclips. The progress of Natural Orifice Translumenal Endoscopic Surgery research has highlighted the reality of closing a perforation endoscopically with endoclips[69]. However, emergency computed tomography imaging, antibiotic administration, bowel rest and surgical consultation still play an important role. Unfortunately, approximately 5% of perforations result in patient death[11].

Similar to perforation but less serious is post-polypectomy syndrome, another complication where there is a transmural burn not resulting in perforation. Post-polypectomy syndrome presents with leukocytosis, fever and abdominal pain in the absence of free air on imaging. Treatment of post-polypectomy syndrome is usually conservative involving antibiotics, fluids, and bowel rest[8].

CONCLUSION

In summary, colonoscopic polypectomy is a continuously evolving therapy that has been remarkable at reducing the risk of colorectal cancer. Gastroenterologists must be thoughtful and proficient in techniques such as snaring, injection, tattooing, and all other tools related to polypectomy for endoscopic success. Cold forceps seem to be preferred for small polyps and snares for larger. Coagulation current may be the electrocautery mode of choice for polypectomy, although it is associated with higher risk of delayed hemorrhage. Difficult to reach polyps continue to require various endoscopic tricks and an ability to improvise for successful resection. There are several options for prevention of bleeding in large polyps including injection, endoloops, and endoclips. Many complications can actually be managed endoscopically. On the research stage, there is still a shortage of studies about many specific aspects of polypectomy, and there is a significant need for more quality studies in the future.

Abstract

In the gut of patients with Crohn's disease and patients with ulcerative colitis, the major forms of inflammatory bowel diseases (IBD) in humans, the tissue-damaging immune response is mediated by an active cross-talk between immune and non-immune cells. Accumulating evidence indicates also that cytokines produced by these cells play a major role in initiating and shaping this pathologic process. One such cytokine seems to be interleukin (IL)-21, a member of the common γ-chain-receptor family. IL-21 is produced in excess in the inflamed intestine of patients with IBD mostly by activated CD4+ T helper cells co-expressing interferon-γ and follicular T helper cells. Moreover, both *in vitro* and *in vivo* studies indicate that excessive IL-21 production leads to the activation of multiple signaling pathways that expand and sustain the ongoing mucosal inflammation. In this article, we review the available data supporting the pathogenic role of IL-21 in IBD.

INTRODUCTION

The organized lymphoid tissue of the gastrointestinal tract contains large numbers of immune cells that are deputed both to protect from infectious diseases and to evoke immune tolerance[1,2]. Perturbations in this delicately balanced microenvironment can promote the collapse of tolerance, thus leading to chronic inflammation that alters the integrity and function of the gut[3]. This occurs for example in patients with Crohn's disease (CD) and patients with ulcerative colitis (UC), the major forms of inflammatory bowel diseases (IBD) in humans[4]. In both these conditions, the tissue damage is mediated by an excessive and poorly controlled immune-inflammatory reaction directed against components of the normal bacterial flora[5,6]. Evidence also indicates that an active and dynamic interplay between immune and non-immune cells plays a major role in initiating and shaping this pathologic process, and that cytokines are essential mediators of this cross-talk[7-9]. One such cytokine seems to be interleukin (IL)-21, a product of activated CD4+ T helper (Th) cells, follicular Th cells (TFH), and Natural killer (NK) T cells, which exerts regulatory effects on multiple cell types[10-13]. In this article, we review the available data supporting the pathogenic role of IL-21 in IBD.

IL-21 IS MADE BY TH1 CELLS AND FOLLICULAR TH CELLS IN THE HUMAN GUT

Initial studies conducted in our laboratory showed that IL-21 protein is over-produced in the inflamed gut of

patients with CD and patients with UC as compared to normal controls[14]. These data were confirmed by a recent study showing that IL-21 mRNA expression is increased in rectal mucosa from patients with active UC compared to UC patients in remission and healthy controls and that, in UC, IL-21 gene expression correlates with histological activity of the disease[15]. A genome-wide association study for IBD has identified risk variants in the chromosomal 4q27 region harbouring the *IL-2* and *IL-21* genes, suggesting that polymorphism(s) in this region might contribute to regulation of IL-21 production/function[16-18]. However, it is noteworthy that expression of IL-21 in the uninflamed mucosa of IBD patients does not differ from that seen in the normal colonic mucosa, and that peripheral blood T cells isolated from IBD patients and healthy controls express similar levels of IL-21[14]. Therefore, it is plausible that up-regulation of IL-21 in IBD is strictly linked to the ongoing mucosal inflammation.

In both CD and UC, IL-21 is made by CD4+ but not CD8+ T cells[14]. By flow-cytometry it was also shown that the majority of IL-21-producing CD4+ T-LPL co-express interferon (IFN)-γ, and to a lesser extent IL-17A, supporting the hypothesis that, in IBD, IL-21 is preferentially made by Th1 rather than Th17 cells[19]. At the present time, it remains unclear how IL-21-positive cells co-expressing IFN-γ differentiate in the human gut. Since Th1 cells are abundant in the human gut, and particularly in CD mucosa[20-22], it is conceivable that Th1 cells can acquire the ability to make IL-21 in response to specific stimuli. Indeed, we have recently shown that *in vitro* stimulation of intestinal lamina propria (LP) CD4+ T cells with IL-12, the major inducer of Th1 cell response, enhances the fraction of cells producing IL-21 or both IL-21 and IFN-γ[19].

IL-21 is also produced by TFH cells in the human gut, and the fraction of IL-21-producing TFH cells is significantly higher in CD than in UC and controls[19]. Interestingly, activation of mucosal T cells with IL-12 leads to enhanced production of IL-21 by TFH cells[19], thus confirming that IL-12-driven signals positively regulate IL-21 production in the gut.

IL-21 ENHANCES INFLAMMATORY PATHWAYS IN THE GUT

A large body of evidence supports the concept that excessive production of IL-21 in the gut has deleterious consequences for the host. IL-21 is highly produced in the gut of wild-type mice with dextran sulfate sodium (DSS)- and trinitrobenzene sulfonic acid-relapsing (TNBS)-induced colitis[23]. Notably, IL-21-deficient mice are largely protected against disease in both models[23]. Amelioration of both DSS- and TNBS-induced colitis in IL-21-knockout mice is associated with a marked decrease in Th17-related molecules, such as IL-17 and IL-17F. Administration of IL-21R/Fc, a fusion protein that binds to IL-21 and prevents it activating cell-surface receptors, in wild-type mice attenuates DSS-colitis, confirming the pro-inflammatory role of IL-21 in this model[23]. A similar scenario emerges from studies in human IBD[19]. Stimulation of intestinal mucosal T cells with IL-21 results in enhanced activation of transcription factors (i.e. Stat3, Stat4 and T-bet) and marked synthesis of IFN-γ and IL-21 itself[14]. Moreover, treatment of CD mucosal cells with IL-21R/Fc reduces Stat4 and T-bet and inhibits IFN-γ production. Neutralization of IL-21 in CD mucosal cell cultures leads also to a decreased expression of IL-17A[23]. Taken together these data indicate that IL-21 is able to expand Th1 and Th17 cell responses in the gut, even though further experimentation is needed to elucidate the basic mechanism by which IL-21 exerts these regulatory effects.

Initially described as an important regulator of the function of immune cells[24,25], IL-21 has been recently shown to also regulate the activity of non-immune cells. Gut myofibroblasts and epithelial cells express constitutively IL-21R and are able to respond to IL-21[26]. In particular, stimulation of colonic myofibroblasts with IL-21 enhances the synthesis of matrix metalloproteinases (MMPs)[26], a family of proteases that are supposed to participate in the tissue damage and remodelling occurring in IBD[27,28]. The IL-21-driven induction of MMPs can be potentiated by tumor necrosis factor α, and associates with no change in the production of tissue inhibitors of MMPs[26]. Regulation of MMPs by IL-21 does not however seem to occur at the transcriptional level, because stimulation of fibroblasts with IL-21 does not alter the MMP RNA expression[26]. Additionally, the intracellular level of MMP proteins is not increased by IL-21, and the IL-21-induced MMP synthesis is not affected by inhibitors of gene transcription and *de novo* protein synthesis[26]. Therefore, it is plausible that IL-21 preferentially increases the secretion of either pre-constituted or newly synthesized MMPs. The *in vivo* relevance of these findings relates to the demonstration that supernatants of CD mucosal cells induce myofibroblasts to secrete MMP and this is partially inhibitable by IL-21R/Fc[26].

IL-21 induces activation of mitogen activated protein kinases in colonic epithelial cells thereby promoting the secretion of macrophage inflammatory protein (MIP)-3α[29], a chemokine up-regulated on the inflamed gut epithelium of IBD patients and involved in the recruitment of T cells in the gut mucosa[30,31]. In line with these observations, blockade of endogenous IL-21 in cultures of IBD mucosal explants reduces MIP-3α synthesis by epithelial cells[29].

IL-21 INHIBITS REGULATORY T CELL DIFFERENTIATION AND MAKES CD4+ T CELLS RESISTANT TO TREGS-MEDIATED IMMUNE-SUPPRESSION

Regulatory T cells (Tregs) play an important role in maintaining homeostasis and preventing autoimmunity in various organs, including the gut[32,33]. Tregs specifically express the transcription factor forkhead winged helix transcription factor gene (Foxp3), which is also functionally required for their regulatory activity[32]. In addition to naturally occur-

ring Tregs that are produced by the thymus as a functionally distinct and mature population of T cells[33], Tregs can arise in the periphery upon conversion of CD4+CD25- T cells into Foxp3-positive-CD4+CD25+ cells in response to activating stimuli and transforming growth factor (TGF)-β1[34,35]. This phenomenon seems to occur in the normal gut, where TGF-β1 synergizes with other regulatory molecules (e.g. IL-10, retinoic acid) in mounting an effective counter-regulatory response[36,37]. However, if activation of naïve CD4+CD25- T cells occurs in the presence of TGF-β1 and inflammatory stimuli, they tend to differentiate into effector Th17 cells rather than into Tregs[38]. IL-21 seems to accomplish this function, given that it can cross-regulate Tregs induction and direct the development of Th17 cells[39]. Interestingly, colitis induced by the transfer of naïve T cells into severe combined immunodeficient mice is suppressed by TGF-β1-induced Tregs generated *in vitro* in the absence of IL-21 but not by T cells generated in the presence of TGF-β1 and IL-21[40]. By contrast, these latter T cells exacerbate colitis with increased expression of IL-17 and a reduced number of Foxp3-expressing cells in the gut mucosa[40]. Consistent with this is the demonstration that blockade of IL-21 associates with high numbers of Foxp3-positive Tregs and reduced tissue damage in the colon and small intestine of mice with acute graft *vs* host disease[41].

IL-21 is also able to counteract the regulatory effects of Tregs by providing human CD4+ T cells signals that raise their threshold for suppression by Tregs[42]. Collectively these observations delineate another mechanism by which IL-21 contributes to amplify the ongoing inflammation in IBD.

CONCLUSION

There is no doubt that IL-21 modulates the activity of several cell types that orchestrate the tissue damage in IBD, and that blockade of IL-21 signalling attenuates the ongoing mucosal inflammation in experimental models of IBD. Therefore, it is conceivable that the near future will witness the use of novel therapeutic strategies aimed at inhibiting IL-21 activity in IBD. However, some important issues related to the blockade of IL-21 function must be taken into consideration before moving into the clinic. For instance, we should not forget that IL-21 plays a decisive role in the control of B cell and plasma cell function, and that IL-21 signalling may attenuate the course of IgE-mediated diseases[24,25]. Moreover, blockade of IL-21 could potentially enhance the risk of malignancies and exacerbate chronic viral infections given the ability of IL-21 to trigger CD8+ T cell-dependent immune reactions against tumors and viruses[43-48]. At least in some circumstances, IL-21 stimulates IL-10 production, thereby promoting tolerogenic rather than inflammatory responses. If so, anti-IL-21 therapy could paradoxically enhance the risk of autoimmunity.

Abstract

AIM: To investigate the effects of the free radical scavenger bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl) decandioate (IAC) in the dextran sodium sulphate (DSS) experimental model of ulcerative colitis.

METHODS: Colitis was induced in Sprague Dawley male rats by administration of 5% DSS in drinking water. IAC (30 mg/kg, lipophilic or hydrophilic form) was administered daily (orally or ip) for 6 d until sacrifice. Colonic damage was assessed by means of indirect (Disease Activity Index score) and direct measures (macroscopic and microscopic scores) and myeloperoxidase (MPO) activity. Neutrophil infiltration within the tissue and glutathione S-transferase activity were also investigated.

RESULTS: DSS-induced colitis impaired body weight gain and markedly increased all inflammatory parameters. Six-day treatment with lipophilic IAC significantly reduced intestinal damage caused by inflammation, induced a down-regulation in MPO activity (0.72 ± 0.12 and 0.45 ± 0.12 with lipophilic IAC *po* and ip, respectively, *vs* 1.10 ± 0.27 in untreated DSS colitis animals) and minimized DSS-induced neutrophil infiltration, while hydrophilic IAC administered orally did not ameliorate DSS-induced damage.

CONCLUSION: These results support the hypothesis that reactive oxygen metabolites contribute to inflammation and that the radical scavenger IAC has therapeutic potential in inflammatory bowel disease.

INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease (CD) are chronic inflammatory diseases of the gut of unclear etiology: environmental and genetic factors regulating mucosal immune response, mucosal barrier function and response to intestinal microflora are all thought to contribute to the pathogenesis of these diseases, characterized by mucosal inflammatory infiltrates, intestinal barrier function alteration and erosive loss of mucosa and submucosa[1,2].

Because of extensive mucosal damage and massive infiltration of polymorphonuclear and mononuclear leukocytes[1,2], reactive oxygen and nitrogen radical species are produced and released, resulting in potential oxidation and peroxidation of a large number of molecules (e.g. proteins, lipids and DNA). Indeed, the intestinal mucosa of patients with inflammatory bowel disease (IBD) is characterized by radical species overproduction and imbalance of the most important antioxidants[3,4] leading to oxidative damage; self-sustaining cycles of oxidant production may amplify inflammation and mucosal injury in UC, where activated neutrophils and macrophages mainly contribute to active lesions[5,6]. The phagocytes present in the mucosa of IBD patients, indeed, can produce reactive oxygen metabolites such as superoxide and hydrogen peroxide, through both respiration burst and prostaglandin and leukotriene metabolism. Radical species released during inflammation increase mucosal permeability and contribute to the recruitment and activation of further neutrophils, thus initiating and/or propagating inflammation and tissue damage[6].

Antioxidant compounds and free radical scavengers improved colitis in several experimental models[7,8]. Recently, in a proof of concept study, we have shown that the radical scavenger bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate (IAC) protects the rat colon from DNBS-induced colitis, which mimics human CD[9]. DNBS is a contact sensitizing allergen which causes immunological activation; acute pathological features include focal necrosis and acute inflammation, followed by a chronic infiltration of mononuclear cells[10].

In this present study, we investigated the effects of IAC in a different model of colitis, i.e. one that is induced by dextran sodium sulphate (DSS), which differs from the DNBS model in terms of tissue inflammatory and immunological activation, as well as severity of the inflammatory process, and is thought to closely mimic human UC[10]. In the DSS model, as in UC, only the mucosa is affected by inflammation; early damage includes shortening and dropout of crypts, particularly over lymphoid aggregates, progressing to focal ulceration, mononuclear cell and neutrophil infiltration. Similar to UC, DSS provokes acute inflammation and macrophage activation, with consequent epithelial cell injury and activation of innate immune responses by luminal bacterial components and eventual activation of T cells[2,11,12].

We tested two different forms of IAC in DSS colitis, with either hydrophilic or lipophilic character. Due to its peculiar physico-chemical properties, IAC readily diffuses through the cellular membrane and can reach virtually any compartment where the production of free radicals occurs, possessing equal radical scavenging activity[13]. This represents an advantage, because it can directly react with free radicals.

MATERIALS AND METHODS

Animals

Male Sprague Dawley rats (180-200 g body weight; Harlan Italy, S. Pietro al Natisone, Udine, Italy) were used in this study. Animals were housed in a controlled environment and had free access to food and water throughout the study. Before starting any experimental procedure, in order to minimize stress, animals of all experimental groups were weighed and gently manipulated in the laboratory environment for 30 min every day for at least 1 wk. All experiments were carried out according to the guidelines set forth by EEC Directive 86/609 on the care and use of experimental animals. The protocol for induction of colitis was reviewed by the Institutional Committee on the care and use of experimental animals of the University of Bologna and was authorized by the Italian Ministry of Health. A persistently hunched posture and labored respiration, a markedly erect coat and a weight loss of more than 20% were considered as humane end-points at which to euthanize the animals.

Induction of colitis

Colitis was induced using a previously described method[14]. DSS (molecular weight, 40 kilodaltons; ICN Biomedicals Inc, Aurora, OH) was added to drinking water at a final concentration of 5% (wt/vol) for 5 d. Controls were all time-matched and consisted of rats receiving normal drinking water only. The DSS solution was replenished daily and mean DSS consumption was noted per cage at the end of 5-d treatment.

Experimental design

We studied groups of rats with and without colitis (n = 6-12 per group), which were treated with the radical scavenger IAC (Figure 1) synthesized in our laboratory[13], starting the day before the induction of colitis for 5 d. IAC (30 mg/kg), hydrophilic or lipophilic form, was administered once daily at the same time (orally or ip) as water solution or suspension. In our previous work, we observed that treatment with hydrophilic IAC *po* in DNBS-induced colitis induced only a minor protective effect, while when administered ip, it was unable to reduce inflammation, therefore we decided to only test the hydrophilic form *po* in this study[9].

The dose of 30 mg/kg was selected on the basis of previous studies, in which IAC showed the best antioxidant activity[15] and protective effect in DNBS-induced colitis[9]. At the end of this 7-d period, the animals were killed and their colons collected for further analysis.

Tissue collection

Before tissue samples were collected, the entire colon was

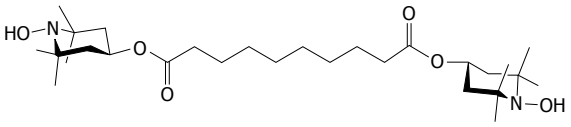

Figure 1 Bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate structure.

removed, the length starting from 1 cm above the anus to the top of the cecum and the weight of the colon still containing fecal contents were measured. Then the colon was opened longitudinally and washed with phosphate buffered saline (PBS) to remove luminal contents; at this time, the consistency of any stools found within the colon and the gross macroscopic appearance of the colon were noted. Whole-wall colonic samples were pinned flat on wax, fixed in cold neutral 4% formalin and then placed in 25% sucrose in PBS at 4℃ for cryoprotection and embedded in optimal cutting temperature tissue freezing medium. Seven-micron-thick sections of colon were cut, serially mounted on glass and processed for routine hematoxylin-eosin (HE) staining and naphthol AS-D chloroacetate esterase assay. Specimens of colonic tissue were also removed, snap frozen in liquid nitrogen and stored at -80℃ until subsequent assays.

Assessment of the severity of colitis

Disease activity index: Disease activity index (DAI) scores have historically well correlated with pathological findings in a DSS-induced model of IBD[16]. DAI is the combined score of weight loss, stool consistency and bleeding, as detailed in Table 1. All parameters were scored from day 0 to day 5 during DSS treatment.

Total macroscopic score: When rats were sacrificed, the colon was removed, opened longitudinally and washed with PBS to remove luminal contents and macroscopic damage was immediately assessed. The macroscopic parameters analyzed before tissue samples were collected were: colon length starting 1 cm above the anus to the top of the cecum, weight of the colon still containing fecal contents, stool consistency and gross macroscopic appearance of the colon. Decreases in filled colon weight are indicative of colonic hypermotility[17]. Indeed, colons from animals with severe colitis can be seen to be nearly devoid of fecal contents. Colon shrinkage is also commonly observed in DSS colitis and is indicative of colonic smooth muscle contraction[17,18]. Total macroscopic score was assigned according to a previously described scoring system[16]; details for each parameter are reported in Table 2.

Histology: Seven-micron-thick sections of colon were cut, serially mounted on glass and processed for routine HE staining. Colonic damage was scored based on a published scoring system that considers amount of inflammation (from 0, none, to 3, severe), extent of inflammation (from 0, none, to 3, transmural), crypt damage (from 0, none, to 4, entire crypt and epithelium lost) and tissue regeneration (from 4, no tissue repair, to 0, complete regeneration or normal tissue)[11].

Table 1 Disease activity index score parameters

Stool consistency	Bleeding	Weight loss	Maximum score
0 = formed	0 = normal color stool	0 = no weight loss	10
1 = mild-soft	1 = brown color stool	1 = 5%-10% weight loss	
2 = very soft	2 = reddish color stool	2 = 11%-15% weight loss	
3 = watery stool	3 = bloody stool	3 = 16%-20% weight loss	
		4 = > 20% weight loss	

Myeloperoxidase assay

Specimens of colonic tissue (50 mg) were assayed using a previously described method[19]. Myeloperoxidase (MPO) is a granule-associated enzyme present in neutrophils and other cells of myeloid origin, and widely used as a marker of intestinal inflammation. Colonic tissues were homogenized in ice-cold potassium phosphate buffer (pH 6.0) and centrifuged for 10 min at 6000 *g* at 4℃. The supernatants were then collected, added to a solution of *O*-dianisidine (Sigma-Aldrich, Milan, Italy) and hydrogen peroxide and assayed to assess MPO activity.

MPO was expressed in units per milligram of tissue, where 1 U corresponds to the activity required to degrade 1 μmol of hydrogen peroxide in 1 min at room temperature.

Glutathione S-transferase activity

Colonic samples (25 mg) were obtained using a previously described method[9]. The supernatant was collected and then assayed for glutathione S-transferase (GST) activity[20]. Assessment of protein content in colonic samples was performed using the Quick Start™ Bradford Protein Assay (BIO-RAD, Hercules, CA, USA); the protein-dye complex absorbance was read using a spectrophotometer at 595 nm. GST activity was expressed as μmol/mg of protein per min.

Naphthol AS-D chloroacetate esterase assay

In order to identify neutrophil infiltration within the tissue, we used a commercially available kit (naphthol AS-D chloroacetate esterase; 91C, Sigma-Aldrich, Milan, Italy). This enzyme is considered specific for cells of granulocytic lineage and its sites of activity show bright red granulation. Seven-micron-thick sections of colon were used for this assay. Briefly, tissue sections were fixed in citrate-acetone-formaldehyde solution and assayed according to the manufacturer's protocols. Specimens were mounted with mounting media (glycerol-PBS, 9:1), examined by light microscope (ECLIPSE 90i, Nikon Instruments, Calenzano, Italy) and representative photomicrographs were taken by DS-5M digital camera (Nikon Instruments, Calenzano, Italy).

Table 2 Total macroscopic score parameters

Stool consistency	Bleeding	Colon damage score	Colon weight score	Colon length score	Maximum score
0 = formed	0 = absent	0 = no inflammation	0 = < 5% weight loss	0 = < 5% shortening	14
1 = loose	1 = present	1 = hyperemia	1 = 5%-14% weight loss	1 = 5%-14% shortening	
2 = liquid		2 = slight erosion	2 = 15%-24% weight loss	2 = 15%-24% shortening	
		3 = extensive erosion/ulceration	3 = 25%-35% weight loss	3 = 25%-35% shortening	
			4 = > 35% weight loss	4 = > 35% shortening	

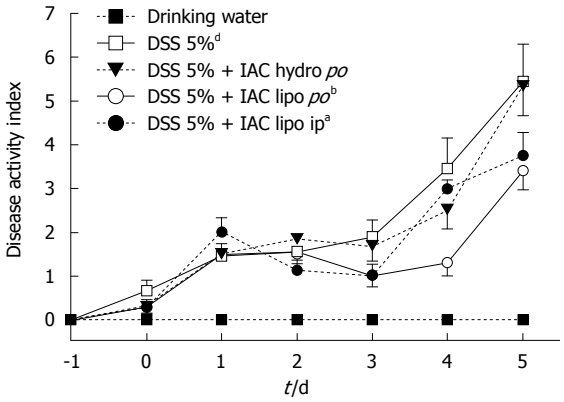

Figure 2 Effect of bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate 30 mg/kg on disease activity index in the different experimental groups. Data are expressed as mean ± SE; n = 5-12 rats per group. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* dextran sodium sulphate (DSS); $^{d}P < 0.001$ *vs* drinking water. Bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate (IAC) hydro: Hydrophilic form of IAC; IAC lipo: Lipophilic form of IAC.

Statistical analysis

Results are expressed as mean ± SE. Statistical analysis was performed using analysis of variance (one-way or two-way, as appropriate, with the Bonferroni's correction for multiple comparisons). A P value < 0.05 was considered significant. N refers to the number of animals used for each experiment (n = 8-16). Calculations were performed using GraphPad Prism™ (version 5.01, GraphPad Software Inc., San Diego, CA, USA).

RESULTS

Assessment of colitis

All rats with DSS colitis progressively lost weight and manifested bloody diarrhea. DAI was significantly increased together with all inflammatory parameters (Figures 2-6). On day 5 after DSS administration, the colonic mucosa of inflamed rats was edematous and erythematous with occasional areas of mucosal erosion. Compared to non-inflamed rats, the colon weight was decreased, the colon length was significantly shorter and a marked increase in total macroscopic damage score was noted (Figure 3, panel A). Colitis was characterized by mucosal ulceration, crypt dropout and a marked neutrophil infiltration extending throughout the mucosa and submucosal layers (Figure 5B) and by a 20-fold increase in microscopic damage score over the non-inflamed control animals (Figure 3, panel B); crypt abscesses and depletion of goblet cells were observed in some regions of colonic mucosa. A 3-fold increase in MPO activity was found (Figure 3, panel C) compared with healthy rats. Moreover, in DSS-treated animals, we detected neutrophil infiltration (red cells, Figure 6B) with respect to controls (Figure 6A), extending throughout the mucosa and submucosa. GST activity slightly decreased in inflamed animals as compared with healthy controls, although statistical significance was not achieved (1.40 ± 0.14 *vs* 1.27 ± 0.11).

Effect of IAC on DSS-induced colitis

Six-day treatment with lipophilic IAC (30 mg/kg, orally and ip) reduced intestinal inflammation and damage: indeed, treated rats had neither bloody diarrhea nor perianal injury and an improvement was observed in gross findings (clinical signs and symptoms of colitis) such as weight loss (Figure 2). Total macroscopic score was significantly improved by drug treatment (Figure 3, panel A). DSS-induced colon shrinkage and weight loss were significantly improved by IAC treatment (lipophilic) as compared to inflamed rats, and these features were similar to healthy controls (Figure 4). Moreover, lipophilic IAC (orally and ip) significantly decreased DSS-induced microscopic damage (Figure 3, panel B and Figure 5D), down-regulated MPO activity (Figure 3, panel C) and also minimized DSS-induced neutrophil infiltration within the colonic wall (Figure 6D).

In contrast, hydrophilic IAC 30 mg/kg orally was able to decrease only microscopic damage score, but substantially failed to protect the colon from DSS-induced damage (Figures 2-4, 5C and 6C).

GST activity was not significantly affected either by hydrophilic IAC *po* (1.27 ± 0.10 *vs* 1.27 ± 0.11 in DSS 5%) or lipophilic IAC *po* (1.28 ± 0.07 *vs* 1.27 ± 0.11 in DSS 5%) or ip (1.00 ± 0.07 *vs* 1.27 ± 0.11 in DSS 5%, P = 0.07).

DISCUSSION

This study shows that the lipophilic form of IAC at the dose of 30 mg/kg significantly ameliorates damage and inflammation in DSS-induced colitis, an experimental model of UC, and is far better than its hydrophilic form, since it positively affected all the parameters under scrutiny. This different activity on inflammation can be ascribed to the differing ability of the two distinct forms of IAC (hydrophilic *vs* lipophilic) to distribute in cell membranes and intra-/extra-cellular compartments; hydrophilic IAC may have a particular profile of absorption and distribution, leading to a lower concentration within areas of major damage.

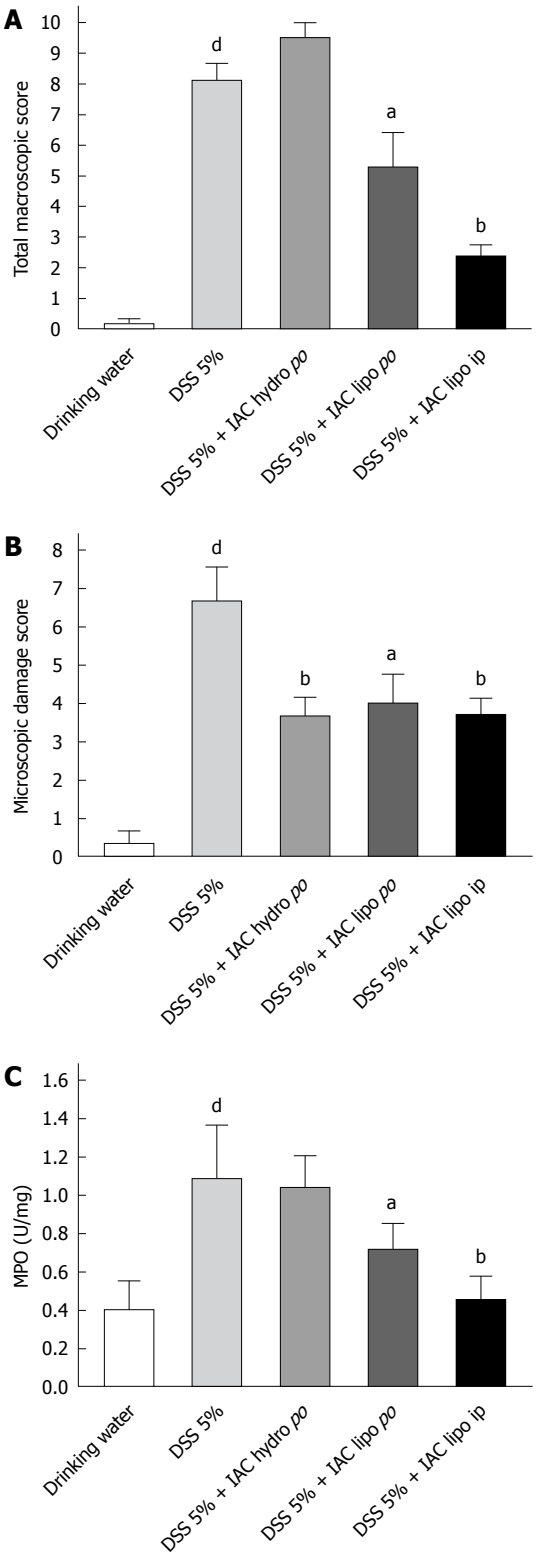

Figure 3 Effect of bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate 30 mg/kg (hydrophilic or lipophilic form) on total macroscopic (A) and microscopic damage score (B) and on myeloperoxidase activity (C) in the different experimental groups. Treatment with hydrophilic bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate (IAC) *po* decreased colonic microscopic damage but had no effect on macroscopic and myeloperoxidase (MPO) activity. Six-day treatment with lipophilic IAC *po* and ip significantly reduced intestinal damage induced by inflammation. Data are expressed as mean ± SE; n = 5-12 rats per group. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* dextran sodium sulphate (DSS); $^{d}P < 0.001$ *vs* drinking water. ICC hydro: Hydrophilic form of IAC; IAC lipo: Lipophilic form of IAC.

Different experimental models can be used for pathophysiological studies and, because of their similarity to human IBD (UC and CD), they represent useful tools to test the therapeutic potential of new drugs. These models allow the study of early events and interactions among different components of IBD and the identification of immunologic processes and genes determining susceptibility to inflammatory disorders. Although there is no unique model of IBD and the various experimental models differ in their pathophysiology, each of them can be useful to gain insight into the multi-factorial nature of IBD[10].

In DSS-induced colitis, as in UC, only the mucosa is affected by inflammation; early damage includes shortening and dropout of crypts in the left colon, particularly over lymphoid aggregates, progressing to focal ulceration, mononuclear cell and neutrophil infiltration.

Reactive oxygen, nitrogen and carbon species are produced and released during the acute phase of inflammation, resulting in epithelial damage with consequent activation of innate immune responses by luminal bacterial components and eventual activation of Th1 and later Th1/Th2 responses during chronic colitis[2,11].

In our study, 5-d treatment with 5% DSS induced weight loss and bloody diarrhea and caused a substantial degree of inflammation and tissue injury in the rat colon, which was edematous, erythematous and characterized by mucosal ulceration. Moreover, inflammation was associated with polymorphonuclear colonic infiltrate (histology, MPO activity and naphthol AS-D chloroacetate esterase assay). Indeed, within the bowel wall of IBD patients and of animals with experimental colitis, a massive infiltration of polymorphonuclear and mononuclear leukocytes, which may produce large amounts of free radicals, is commonly observed[1,9,21,22].

During DSS-induced colitis, we also studied GST activity. GST is a detoxification enzyme catalyzing the conjugation of reactive electrophiles with the thiol glutathione, providing cellular protection from highly reactive electrophiles[23]. A significant decrease in the GST activity was reported in patients with family history of colon cancer and polyps[24]; moreover, GST level changes have been observed both in IBD patients[25] and in some experimental models of colitis[23,26]. The only marginal (not statistically significant) decrease in GST activity observed by us on day 5 after DSS administration is actually in line with data obtained by Clapper *et al*[23], who showed cyclical changes in GST activity during acute DSS colitis, with a significant decrease in enzyme activity on days 2 and 7, while on day 5 they reported only marginally decreased GST activity, exactly as we did.

Treatment with lipophilic IAC (30 mg/kg, orally and ip) significantly ameliorated colonic damage and inflammation induced by DSS, decreased MPO activity and also minimized DSS-induced neutrophil infiltration within the colonic wall. These observations extend and corroborate our previous report that IAC is effective in DNBS-induced colitis[9], a quite different model where DNBS causes transmural immunological activation and inflam-

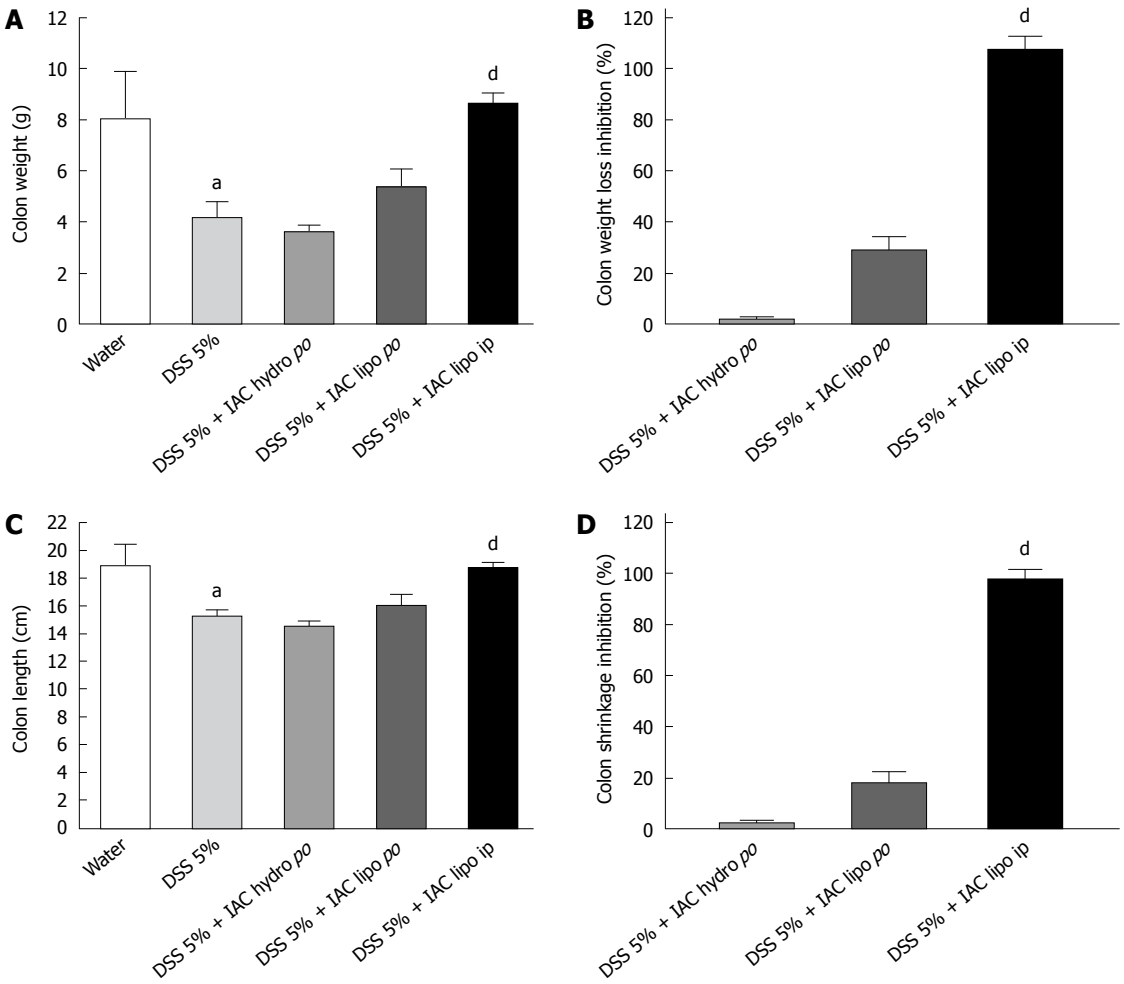

Figure 4 Effect of bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate 30 mg/kg (hydrophilic or lipophilic form) on dextran sodium sulphate-induced colon weight loss (absolute value, A, and % inhibition, B) and shrinkage (absolute values, C, and % inhibition, D) in the different experimental groups. Six-day treatment with lipophilic bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate (IAC) ip significantly inhibited colon weight loss and colon shrinkage induced by inflammation, while the hydrophilic form had no effect. Data are expressed as mean ± SE; n = 5-12 rats per group. $^{a}P < 0.05$ *vs* water; $^{d}P < 0.01$ *vs* dextran sodium sulphate (DSS). IAC hydro: Hydrophilic form of IAC; IAC lipo: Lipophilic form of IAC.

mation resembling CD. In our hands, lipophilic IAC was slightly more effective ip than orally, probably because it undergoes protonation at low gastric pH after oral administration and is more quickly excreted from the gut (the protonated form has higher polarity). For clinical use, it may be necessary to protect IAC from low gastric pH using a specific formulation.

Thus, lipophilic IAC is protective both in DNBS and DSS experimental models of inflammation and has a wide spectrum of activity; its lipophilic form (ip) significantly reduced DAI (30%), macroscopic and microscopic damage (70% and 45%, respectively) and decreased MPO activity (58%) in DSS-induced colitis. Likewise, in DNBS-induced colitis, treatment with lipophilic IAC can decrease macroscopic and microscopic damage (55% and 46%, respectively), reduce MPO and tumor necrosis factor-α tissue levels (80% and 30%, respectively) and lipidic peroxidation (40%).

Notably, in both the DSS and DNBS models[9], IAC is able to significantly decrease MPO activity and neutrophil infiltration within the bowel wall. In both experimental models, as in several human inflammatory diseases such as rheumatoid arthritis and IBD, infiltrating neutrophils are the major candidate for the production of reactive oxygen radicals[27]. Oxidative damage may represent a pathogenic factor in IBD because intestinal inflammation is accompanied by increased production of reactive oxygen and nitrogen species and an imbalanced antioxidant response[1,28,29]. Indeed, free radical production is a key mechanism for the appearance and the maintenance of colonic inflammation in experimental models of colitis[7,30,31].

Thus, we can hypothesize that IAC exerts its protective effects by reducing inflammatory neutrophil infiltrate and by scavenging reactive oxygen species produced by infiltrating cells which during inflammation contribute to the recruitment and activation of further neutrophils, and by counteracting this self-sustaining cycle of oxidant production, which propagates inflammation and tissue damage. This hypothesis of reduced oxidative damage by IAC is not contrary to its lack of activity on GST levels because, in our hands, GST levels were only marginally affected by DSS-induced inflammation. It has been shown that treatment with antioxidant compounds and radical scavengers exerts a protective effect in several models of

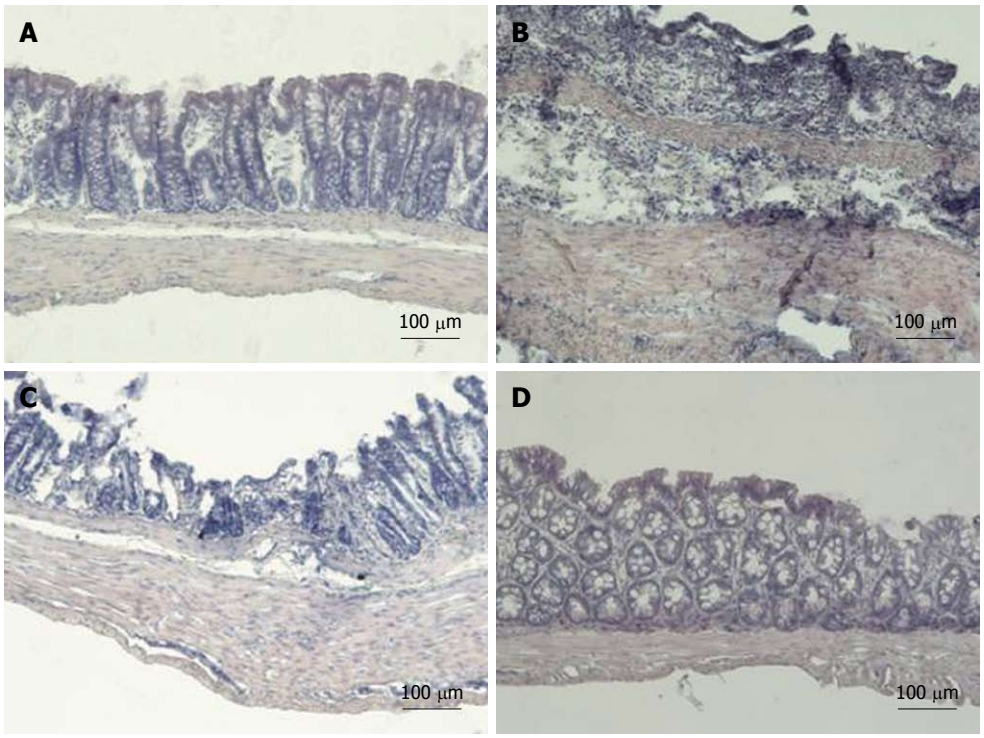

Figure 5 Representative examples of cross sections of distal colon. A: From a non-inflamed rat [drinking water + bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl) decandioate (IAC) vehicle orally]; B: From an inflamed rat [dextran sodium sulphate (DSS) 5% in drinking water + IAC vehicle orally]. Note the dramatic loss of mucosal architecture with crypt dropout and the granulocyte infiltrate extending throughout the mucosa and submucosa; C, D: Cross sections of distal colon from an inflamed rat treated with hydrophilic (C) and lipophilic (D) IAC 30 mg/kg orally (C) and intraperitoneally (D). Lipophilic (*po*, not shown here, and ip) IAC 30 mg/kg decreased the microscopic damage produced by DSS, facilitating mucosal healing, reducing inflammatory cells infiltration and muscle thickening (panel D). Hydrophilic IAC *po* failed to protect the colon from the damage induced by DSS (panel C).

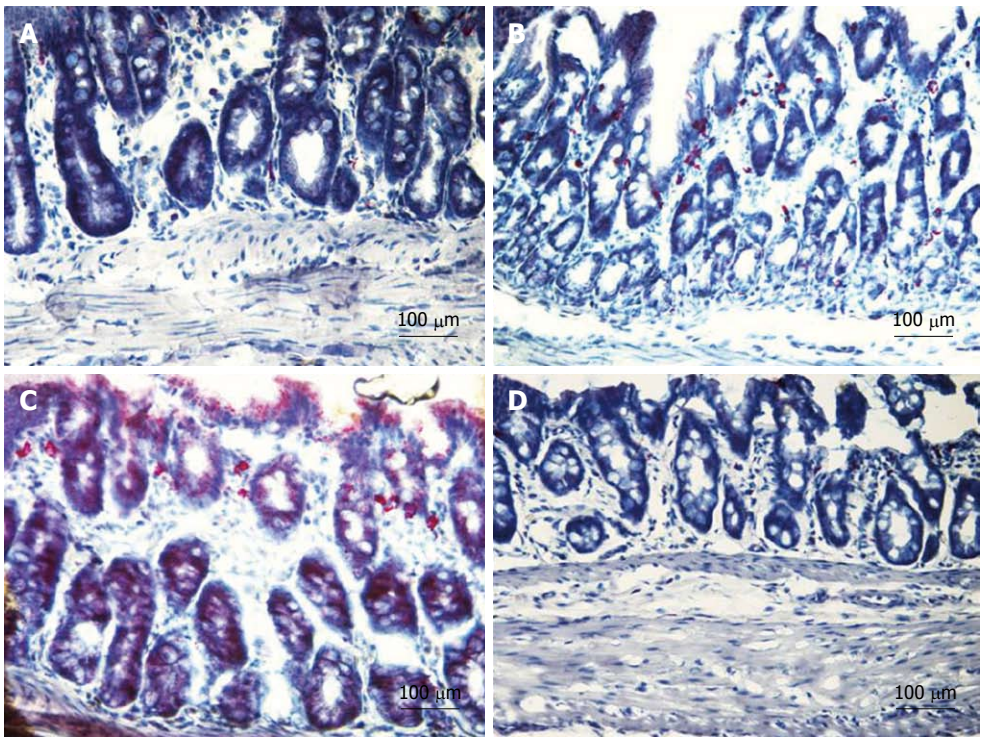

Figure 6 Naphthol AS-D chloroacetate esterase positivity (red) in cross section of distal colon. A: Tissue sections obtained from non-inflamed rats showed occasional red staining indicating a low presence of neutrophils within the bowel wall under physiological conditions; B: From a rat with colitis (5% dextran sodium sulphate in drinking water, panel B). Compared to non-inflamed rats, tissue from rats with colitis showed a massive neutrophil infiltration extending throughout the mucosa (note the scattered degranulation within the crypts and submucosa); C, D: Treatment with bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate (IAC) 30 mg/kg hydrophilic form *po* (C) was unable to suppress neutrophil infiltration especially in the mucosa. Treatment with lipophilic IAC both *po* (not shown) and ip (D) almost completely suppressed neutrophil infiltration within the colonic wall.

intestinal inflammation[9,32,33]: Cuzzocrea *et al*[7,34] demonstrated that treatment with antioxidants such as tempol and M40403, a superoxide dismutase mimetic, ameliorated TNBS/DNBS experimental colitis, probably by limiting leukocyte recruitment. However, cyclic nitroxides such as tempol are very persistent in water or organic solutions, but when used *in vivo* or in a biological sample are reduced to the parent hydroxylamine by several enzymatic processes mainly involving ascorbate or glutathione. IAC is more stable in physiological solutions and possesses a stronger antioxidant capability than that of the aforementioned cyclic nitroxides; it is easily distributed through cell membranes and intra-/extra-cellular compartments, thus it can directly react with oxidant molecules within the cell, where free radicals are produced[35]. In DNBS-induced colitis, IAC seems to display higher activity than tempol, at least in reducing MPO activity and neutrophil infiltration[7]. Recently, the lipophilic form of IAC was used in different experimental disease models all characterized by oxidative stress (e.g. nonobese mouse diabetes model[15] and a rat model of transient middle cerebral artery occlusion[36]), as well as *in vitro*[37], with positive results.

Notably, IAC is a low molecular weight radical scavenger which can rapidly react with most carbon-, nitrogen- and oxygen-centered radicals of biological interest, including peroxyl, superoxide, and peroxynitrite radicals[13]. Its antioxidant activity is a direct effect of the molecule itself; its activity is due to hydroxylic hydrogen transfer to peroxyl radicals, which generates the corresponding nitroxide, unable to propagate the autoxidation chain. Its peculiar physico-chemical properties affect its partition properties across cell membranes and both intra- and extra-cellular compartments: the free form is highly lipophilic (the calculated logP is 4.01) and easily crosses the cell membrane, allowing distribution to any compartment where the production of free radicals occurs, but it is also in equilibrium with the protonated form, which administered to a biological system is completely water-soluble and distributes in the extra-cellular compartments[13].

In conclusion, our data show that treatment with the lipophilic (but not the hydrophilic) form of the radical scavenger IAC, at the dose of 30 mg/kg, ameliorates DSS-induced colitis in rats. These results, taken together with our previous data showing a protective effect of lipophilic IAC in DNBS-induced colitis, provide further evidence of the involvement of reactive oxygen species in inflammation and support the concept that antioxidant therapy may have an important role in treatment of IBD.

COMMENTS

Background

Ulcerative colitis (UC) and Crohn's disease are chronic inflammatory bowel diseases (IBDs) of unclear etiology: environmental and genetic factors regulating mucosal immune response, mucosal barrier function and response to intestinal microflora are all thought to contribute to the pathogenesis of these diseases, characterized by mucosal inflammatory infiltrates, intestinal barrier function alteration and erosive loss of mucosa and submucosa. Indeed, the intestinal mucosa of patients with IBD is characterized by radical species overproduction and imbalance of the most important antioxidants leading to oxidative damage.

Research frontiers

Over the last two decades, the incidence and the prevalence of IBD seem to have increased; IBDs cause a large number of hospitalizations for the patients affected. Many drugs are used to treat IBD, given for a variety of reasons: to suppress inflammation in patients with active disease, to prevent flare-ups in those with inactive disease, to control symptoms such as pain or diarrhea or to replace or supplement essential nutrients which are poorly absorbed because of extensive disease or surgery. However, the etiology of IBD is still unknown and new therapeutic options are needed, as available drugs are still unsatisfactory to treat and heal IBD.

Innovations and breakthroughs

It is generally hypothesized that oxidative stress is a potential etiological and/or triggering factor for IBD, because the detrimental effects of reactive oxygen molecules have been well established in the inflammation process. Antioxidant compounds and free radical scavengers have been shown to improve colitis in several experimental models suggesting an important role of reactive oxygen species in intestinal inflammation. This study clearly shows the effect of an antioxidant molecule in an experimental model of colitis which resembles human UC, indicating a potential clinical application for this class of compounds in treating IBD.

Applications

The protective effect shown by antioxidant therapy in this experimental model of colitis indicates a potential clinical application for this class of compounds in treating IBD. However, several clinical studies have been largely disappointing, probably due to the inability of the antioxidant to reach sufficient concentrations at the inflammation site. Lipophilic bis(1-hydroxy-2,2,6,6-tetramethyl-4-piperidinyl)decandioate (IAC) is easily distributed through cell membranes and intra-/extra-cellular compartments and directly reacts with oxidant molecules within the cell, where free radicals are produced. For clinical use, it may be necessary to protect IAC from low gastric pH using a specific formulation in order to improve its bioavailability.

Peer review

The study is well done with adequate supporting documentation, controls and references. The difference in activity between the lipophilic and hydrophilic forms of IAC in suppressing dextran sodium sulphate-induced colitis is a novel and important finding.

Abstract

AIM: To investigate the effects of malnutrition and re-feeding on the P2X2 receptor, nitric oxide synthase (NOS), calretinin, calbindin and choline acetyltransferase (ChAT) in neurons of the rat ileum.

METHODS: We analyzed the co-localization, numbers and sizes of P2X2-expressing neurons in relation to NOS-immunoreactive (IR), calbindin-IR, ChAT-IR, and calretinin-IR neurons of the myenteric and submucosal plexus. The experimental groups consisted of: (1) rats maintained on normal feed throughout pregnancy until 42 d post-parturition (N); (2) rats deprived of protein throughout pregnancy and 42 d post-parturition (D); and (3) rats undernourished for 21 d post-parturition and then given a protein diet from days 22 to 42 (DR). The myenteric and submucosal plexuses were evaluated by double labeling by immunohistochemical methods for P2X2 receptor, NOS, ChAT, calbindin and calretinin.

RESULTS: We found similar P2X2 receptor immunoreactivity in the cytoplasm and surface membranes of myenteric and submucosal neurons from the N, D and DR groups. Double labeling of the myenteric plexus demonstrated that approximately 100% of NOS-IR, calbindin-IR, calretinin-IR and ChAT-IR neurons in all groups also expressed the P2X2 receptor. In the submucosal plexus, the calretinin-IR, ChAT-IR and calbindin-IR neurons were nearly all immunoreactive for the P2X2 receptor. In the myenteric plexus, there was a 19% increase in numbers per cm^2 for P2X2 receptor-IR neurons, 64% for NOS-IR, 84% for calretinin-IR and 26% for ChAT-IR neurons in the D group. The spatial density of calbindin-IR neurons, however, did not differ among the three groups. The submucosal neuronal density increased for calbindin-IR, calretinin-IR and ChAT-IR neurons. The average size of neurons in the myenteric plexus neurons in the D group was less than that in the controls and, in the re-fed rats; there was a 34% reduction in size only for the calretinin-IR neurons.

CONCLUSION: This work demonstrates that expression of the P2X2 receptor is present in inhibitory, intrinsic primary afferent, cholinergic secretomotor and vasomotor neurons. Undernutrition affected P2X2 receptor expression in the submucosal plexus, and neuronal and size. These changes were rescued in the re-fed rats.

INTRODUCTION

ATP is known to be a co-transmitter in the nervous system and a ligand of the P2X receptor family, which is made up of seven known receptor subunits (PX_{1-7})[1]. In the myenteric plexus, electrophysiological studies have found P2X receptors in 80%-90% of neurons[2]. P2X receptors play an important role in synaptic transmission within the neural pathways and mediate intestinal motility[3-5]. Immunohistochemical studies have documented the distribution of P2X receptors in the enteric nervous system of guinea pigs[6-11], rats[12-14] and mice[15,16]. There is only one earlier study in which the authors have reported expression of $P2X_2$ receptor in calretinin and calbindin neurons in the ileal myenteric plexus of rats[12].

The effects of undernutrition on enteric and other autonomic neurons have been investigated[17-25]. In the enteric nervous system, a 27% decrease in the number of enteric neurons in the jejunum of rats submitted to severe prenatal malnutrition has been reported[18], and a mean neuronal loss of 13% in the myenteric plexus of the proximal colon has been observed after malnutrition[20]. Experiments that have examined the effect of re-feeding on enteric neuronal number suggest that, when neurons are reduced in number by undernutrition, they do not recover[18]. However, other reports have described a 15% decrease in the sizes of myenteric neurons from the large intestine of pre- and postnatally protein-deprived animals, as well as recovery of normal size after re-feeding[21]. A 45% size reduction in enteric neurons of the small intestine has also been observed following undernutrition[22].

The present work analyzed the effects of pre- and postnatal protein undernutrition and postnatal re-feeding on neurons immunoreactive for the $P2X_2$ receptor, by specifically examining the expression of nitric oxide synthase (NOS), calretinin, calbindin and choline acetyltransferase (ChAT) in these neurons, as well as neuronal density and somatic size in the myenteric and submucosal plexuses in the rat ileum.

MATERIALS AND METHODS

Experimental animals

The study was conducted according to current legislation on animal experiments of the Biomedical Science Institute of the University of São Paulo. Young male and female Wistar rats (200-240 g body weight) were mated. After conception, which was assumed to have occurred when vaginal sperm plugs were found, the females were placed in individual cages. During pregnancy, the nourished mothers received an AIN-93G normal protein diet (protein, 20%; fat, 7%; carbohydrate, 20% and fiber, 5%), and the undernourished mothers received the AIN-93G diet with low protein (protein, 5%; fat, 7%; carbohydrate, 20% and fiber, 5%) (Rhoster Indústria e Comércio Ltda, São Paulo, Brazil). The rats were maintained under standard conditions at 21℃, with a 12-h light/dark cycle, and all groups were supplied with water *ad libitum*. After parturition, the dams and pups received the same diet that the dam had during pregnancy. Only the male animals in the litters were used for experimentation. Females remained in the litters but were not investigated. There were three experimental groups. The first group of rats was maintained on normal feed throughout pregnancy until examined at 42 d (P42) (N, n = 5). The second group was protein-deprived throughout pregnancy and postnatally for 42 d (P42) (D, n = 5). The third group of rats was the deprived plus re-feeding group (DR, n = 5), in which animals were undernourished until P21, and then received the AIN-93G normal protein diet from P22 to P42[21,22]. At P42, animals were weighed and euthanized in a CO_2 chamber and the anterior abdominal wall was opened. The small intestine was removed and washed in PBS. The surface area of the small intestine was measured using a planimeter.

Immunohistochemistry

Fresh segments of ileum were removed from each animal of the N, D and DR groups and placed in PBS (0.15 mol/L NaCl in 0.01 mol/L sodium phosphate buffer, pH 7.2) that contained nicardipine (10^{-6} mol/L; Sigma, St Louis, MO, USA) to inhibit tissue contraction. The dissected pieces were opened along the mesenteric border and cleaned of their contents using PBS. They were then pinned out tautly, mucosa-side down, onto a balsa-wood board and fixed overnight at 4℃ in paraformaldehyde in 0.2 mol/L sodium phosphate buffer (pH 7.3). The next day, the tissue was cleared of fixative with three 10-min washes in 100% DMSO, followed by three 10-min washes in PBS. All tissue was stored at 4℃ in PBS that contained sodium azide (0.1%). The fixed tissue was dissected and the mucosa, submucosa and circular layers were removed to obtain longitudinal muscle-myenteric plexus whole mounts. In the second type of preparation, the mucosa and muscularis externa were removed to reveal the intact submucous layer. Whole-mount preparations of the myenteric and submucosa of the ileum were preincubated in 10% normal horse serum in PBS that contained 1.5% Triton X-100 for 30 min at room temperature, to reduce non-specific binding and to permeabilize the tissue (Table 1). To localize $P2X_2$ receptor immunoreactivity, we used a rabbit antiserum raised against amino acid sequence 457-472 of the rat $P2X_2$ receptor, with a single Cys extension at the N-terminal (AB5244; Chemicon, Temecula, CA, USA). Incubation was for 48 h at 4℃ at a dilution of 1:120 in 10% normal horse serum in PBS that contained 1.5% Triton X-100. Double labeling was achieved using combina-

Table 1 Characteristics of primary and secondary antibodies

Donkey anti-mouse IgG Alexa 594		1:200	Molecular probes

NOS: Nitric oxide synthase; ChAT: Choline acetyltransferase.

tions of antisera (Table 1). Following incubation in primary antisera, tissue was given three 10-min washes in PBS and incubated in a mixture of secondary antibodies (Table 1). Further 10-min washes in PBS were made before tissue was mounted in glycerol buffered with 0.5 mol/L sodium carbonate buffer (pH 8.6).

Imaging

Preparations were examined on a Leica microscope equipped with the appropriate filters for Alexa 488 (450-490 nm excitation filter and 515-565 nm emission filter) and Alexa 594 (530-585 nm excitation filter and 615 nm emission filter). Images were recorded using an Image-Pro-Plus-coupled camera and Image-Pro Plus software (Media Cybernetics, Bethesda, MD, USA). Preparations were also analyzed using confocal microscopy on a Zeiss confocal scanning laser system installed on a Zeiss Axioplan 2 microscope (Carl Zeiss). The system had a krypton/argon laser for differential visualization of the fluorophores using a 488-nm excitation filter and a 522/535-nm emission filter for 488 and 568 nm excitation filters and a 605/632 nm emission filter for Alexa 594. The images were 512 × 512 pixels in size and the thickness of each optical section was 0.5 μm. Immunoreactive cells were scanned as a series of optical sections with a center spacing of 0.2 μm. Confocal images were collected using LSM 5 Image Zeiss processing software (Carl Zeiss MicroImaging, Germany). Images were further processed using Corel Photo Paint and Corel Draw software programs (Corel Corporation).

Quantitative analyses

The proportions of neurons in which antigen immunoreactivity was co-localized were determined by examining double-labeled neurons. Neurons were first located by the presence of a fluorophore that labeled one antigen, and then the filter was switched to determine whether the neuron was labeled for a second antigen, located with a second fluorophore of a different color. In this way, proportions of neurons labeled for pairs of antigens were determined. The cohort size was 100 neurons and data were collected from preparations obtained from at least four animals. The percentage of neurons immunoreactive to a second neurochemical was calculated and expressed as mean ± SE. The numbers of P2X$_2$-immunoreactive (IR), NOS-IR, calbindin-IR, calretinin-IR and ChAT-IR neurons and nerve cell perikarya were measured by examining the whole-mount preparations under a binocular microscope at a magnification of 100 ×. All neurons present in each 1 cm^2 were counted. The nerve cell perikarya profiles area, major axes, and minor axes of 50 nerve cell perikarya from each animal were obtained on a semiautomatic morphometry device, the Image-Pro Plus Program.

Table 2 Body weight and small-intestinal area of pre- and postnatal protein-deprived rats at 42 d postnatal

	N	D	DR
Body weight (g)	160 ± 10	40 ± 18[a]	100 ± 22
Area of small intestine (cm^2)	20.41 ± 3.7	13.3 ± 0.6[a]	16.5 ± 0.4

[a]$P < 0.05$ *vs* protein deprived, Tukey's test for multiple comparisons.

Statistical analysis

mean ± SE were calculated and compared by analysis of variance and Tukey test for multiple comparisons, as appropriate. The level of significance was set at $P < 0.05$.

RESULTS

The mean body weight of animals of the N group (160 ± 10 g) was approximately 400% greater than that of the D group (40 ± 18 g). The body weight of the DR group (100 ± 22 g) was restored to within 20% of normal at P42 ($P < 0.05$). The small intestine area of the D group was 34% less ($P < 0.05$) than that of the N group, and there was no statistical difference between the N and DR groups (Table 2).

The qualitative results demonstrated that P2X$_2$ receptor immunoreactivity was found in the myenteric and submucosal plexuses of the ileum of all groups. Positive labeling was seen in the cytoplasm and surface membranes of most nerve cells of the nourished, undernourished and refed groups (Figure 1). The labeling intensity of the P2X$_2$ receptor in the myenteric and submucosal ganglia of the N, D and DR groups was similar. Double-labeling studies were conducted to identify neurons that had P2X$_2$ immunoreactivity co-localized with NOS, calbindin, calretinin and ChAT in ileal myenteric neurons (Figure 1), and calbindin, calretinin and ChAT in the ileal submucosal plexus of the N, D and DR groups (Figure 2). In all groups, the cellular morphology of the myenteric plexus showed that NOS-IR neurons had a Dogiel Type I morphology, while calretinin-IR neurons exhibited Dogiel Type II morphology, and calbindin-IR neurons had both small and large Dogiel Type II neurons. In the submucosal plexus, calbindin-IR neurons had Dogiel Type II morphology. The intensity of ChAT immunoreactivity was reduced in some neurons of the myenteric and submucosal ganglia of undernourished rats.

Co-localization

The quantitative results revealed that, in the myenteric plexuses, the majority of NOS-IR, calbindin-IR, calretinin-

A-C: P2X2 receptor-IR (green) co-localized with nitric oxide synthase (NOS)-IR (red); D-F: P2X2 receptor-IR (green) co-localized with calbindin-IR (red); G-I: P2X2 receptors (green) co-localized with calretinin (red); J-L: P2X2 receptors (green) co-localized with choline acetyltransferase (ChAT) (red). Double-labeled neurons are indicated by arrows.

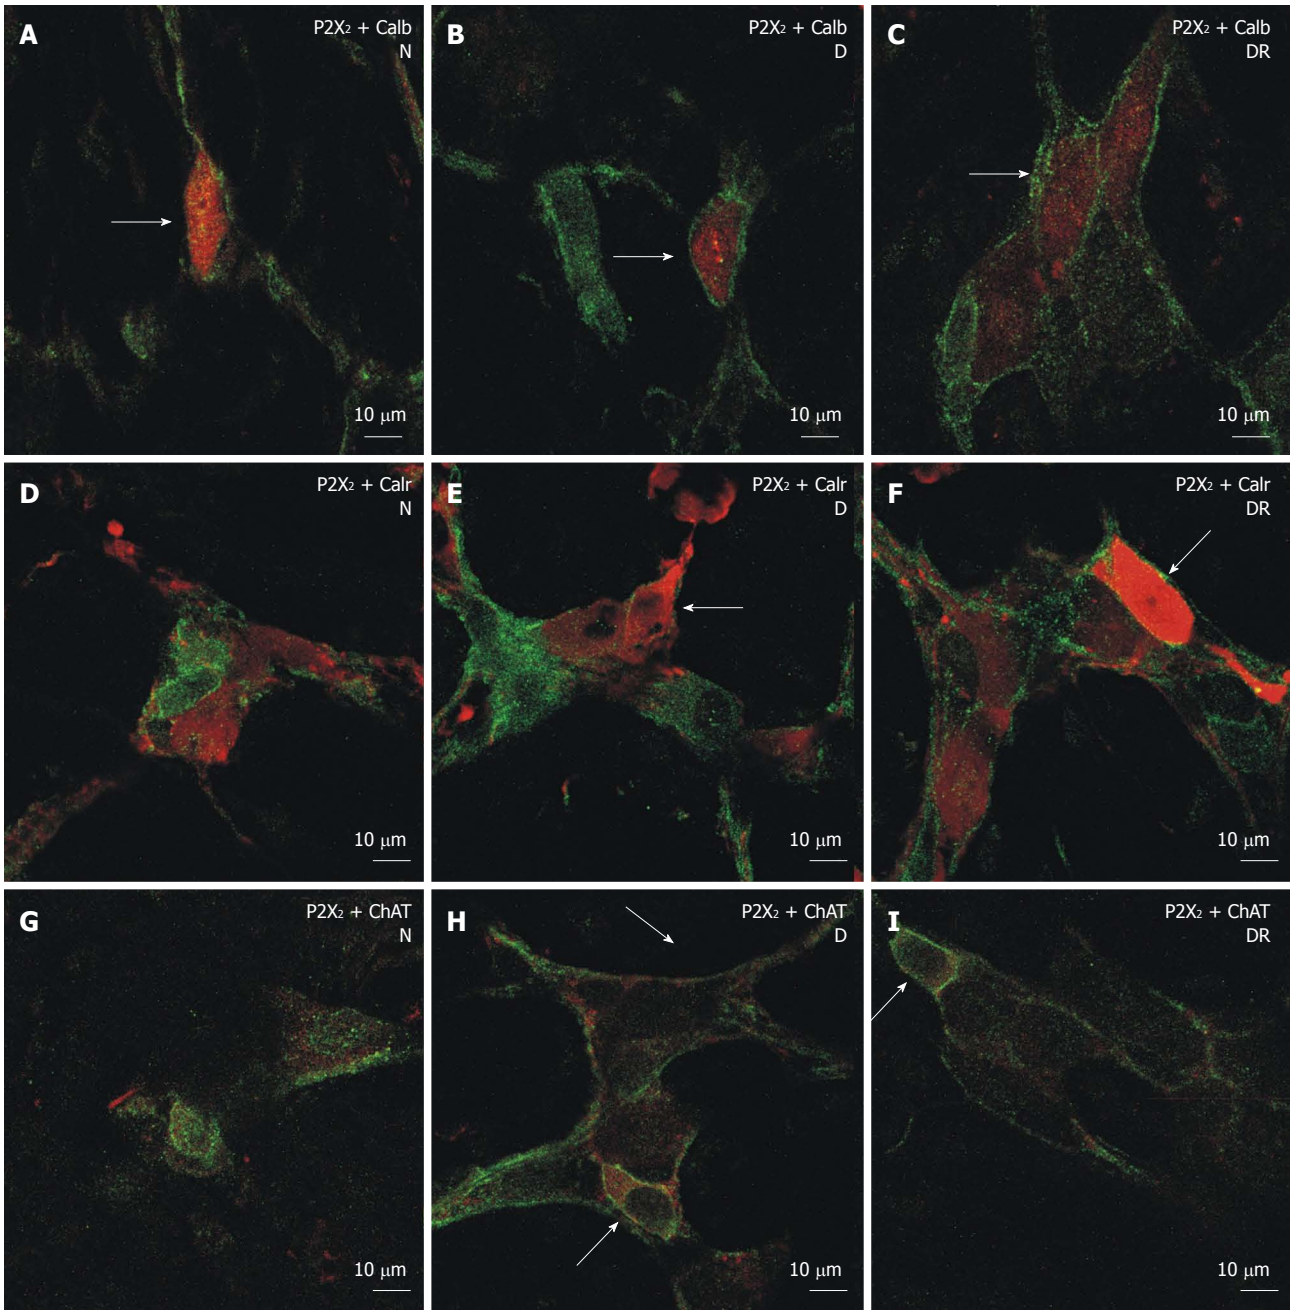

Figure 2 Co-localization of P2X2 receptor immunoreactivity with calbindin, calretinin and choline acetyltransferase immunoreactivity in the ileal submucosal plexus in N, D and DR groups. A-C: P2X2 receptor (green) co-localized with calbindin (Calb) (red); D-F: P2X2 receptor (green) co-localized with calretinin (Calr) (red); G-I: P2X2 receptor (green) co-localized with choline acetyltransferase (ChAT) (red). Double-labeled neurons are indicated by arrows.

IR and ChAT-IR neurons also were immunoreactive for the P2X2 receptor. In the submucosal plexus of the ileum, P2X2-IR neurons were also calbindin-IR, calretinin-IR, and ChAT-IR.

In the myenteric plexus, the majority of NOS-IR neurons were immunoreactive for the P2X2 receptor (N group was 99% ± 0.6% co-localized, D group was 100%, and DR group was 99% ± 0.4%). Also, the majority of calbindin-IR neurons were IR for the P2X2 receptor (N group was 98% ± 0.4%, D group was 100%, and DR group was 99% ± 1%). The majority of calretinin-IR neurons were also IR for the P2X2 receptor (group N was 100%, D group was 98% ± 0.6%, and DR group was 98% ± 1%). Most ChAT-IR neurons were also IR for the P2X2 receptor in the N, D and DR groups (96.2% ± 2%, 96.2% ± 2%, and 97% ± 3%, respectively).

In the submucosal plexus, co-localization between calbindin-IR and P2X2 receptor-IR neurons was complete in the N, D and DR groups. The co-localization between P2X2 receptor-IR and calbindin-IR was 16% ± 0.7% in the N group, 31% ± 2% in the D group, and 24% ± 3% in the DR group ($P < 0.002$). In all three groups, calretinin-IR and ChAT-IR neurons co-localized 100% with P2X2 receptor-IR neurons.

NOS: Nitric oxide synthase; ChAT: Choline acetyltransferase.

Neuronal density

In the myenteric plexus, the number of neurons per unit area was increased by 19% for P2X$_2$ receptor-IR neurons ($P < 0.01$), 64% for NOS-IR neurons ($P < 0.002$), 84% for calretinin-IR neurons ($P < 0.001$), and 26% for ChAT-IR neurons in group D ($P < 0.02$); calbindin-IR neuron density, however, did not differ among the three groups ($P > 0.05$, Figure 3). In the myenteric plexus, the total number of NOS-IR neurons, taking into account the change in intestinal surface area (Figure 4), calbindin-IR neurons and ChAT-IR neurons did not differ significantly between the three groups. There was, however, a 20% increase in the numbers of calretinin-IR neurons and decrease in P2X$_2$ receptor cells with undernutrition relative to controls ($P < 0.05$, Figure 4).

In the submucosal plexus, the density of P2X$_2$ receptor-IR, calbindin-IR and ChAT-IR neurons increased significantly in the undernourished group (67%, $P < 0.0003$; 189%, $P < 0.001$ and 42%, $P < 0.01$, Figure 5). Calretinin-IR neuron density did not differ among the three groups ($P > 0.05$, Figure 5). In the submucosal plexus, the total numbers of the calretinin-IR neurons decreased by 23% ($P < 0.05$), and this was accompanied by an 89% increase in the calculated numbers of calbindin-IR neurons. In this region, there was no change in the numbers of ChAT-IR neurons (Figure 6).

Nerve cell perikarya

Neuron size (nerve cell perikarya, the major and minor axes of the myenteric plexus neurons) of the calretinin-IR neurons were approximately 34% smaller in the protein-deprived rats ($P < 0.001$) than the control or re-fed rats. There was an increase of 35% in the nerve cell perikarya of calbindin-IR neurons and a 14% increase in the minor axes of the calbindin-IR neurons in the DR group, as well as a decrease of 15% in the major axes of the NOS-IR neurons (Table 3).

In the submucosal neurons, there were group differences ($P < 0.05$) with respect to the neuron size of calbindin-IR, calretinin-IR and ChAT-IR neurons. There was a 13% decrease in the major axes of calretinin-IR and ChAT-IR neurons ($P < 0.05$) and an 18% increase in the minor axes of calbindin-IR neurons ($P < 0.05$). Neu-

DISCUSSION

Various methods have been used to induce experimental undernutrition[26]. The protocols of undernutrition and re-feeding employed in this study were effective, because malnourished animals lost weight, which was then recovered by re-feeding. These findings agree with those of other studies that have used similar protocols[21,22].

The antigen markers for different functional classes of neurons have been determined for guinea pig and mouse small intestine, and to a lesser extent in other mammals[27-31]. The expression patterns have been partly described in the rat[32,33]. NOS is expressed in inhibitory motor neurons in all species in the small and large intestine, whereas all other neuron types, such as excitatory motor neurons, interneurons, and intrinsic primary afferent neurons (IPANs) are immunoreactive for ChAT in the mouse and rat myenteric plexus[30,33-37]. Dogiel Type II neurons, which are intrinsic primary afferent neurons in all species

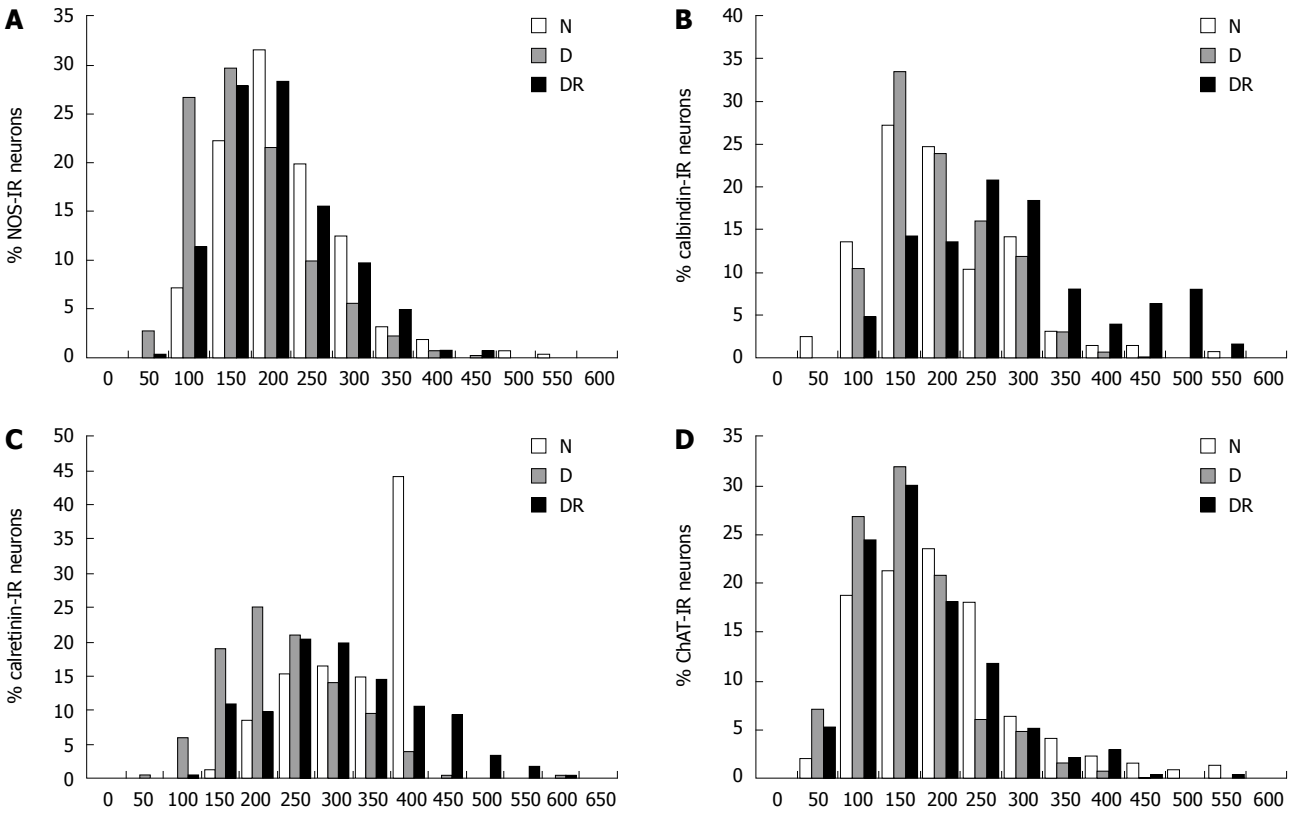

Figure 7 Histograms showing the distribution of areas (μm^2) of neurons immunoreactive for nitric oxide synthase (A), calbindin (B), calretinin (C) and choline acetyltransferase (D) in the ileal myenteric plexus of the N, D and DR groups. NOS: Nitric oxide synthase; ChAT: Choline acetyltransferase.

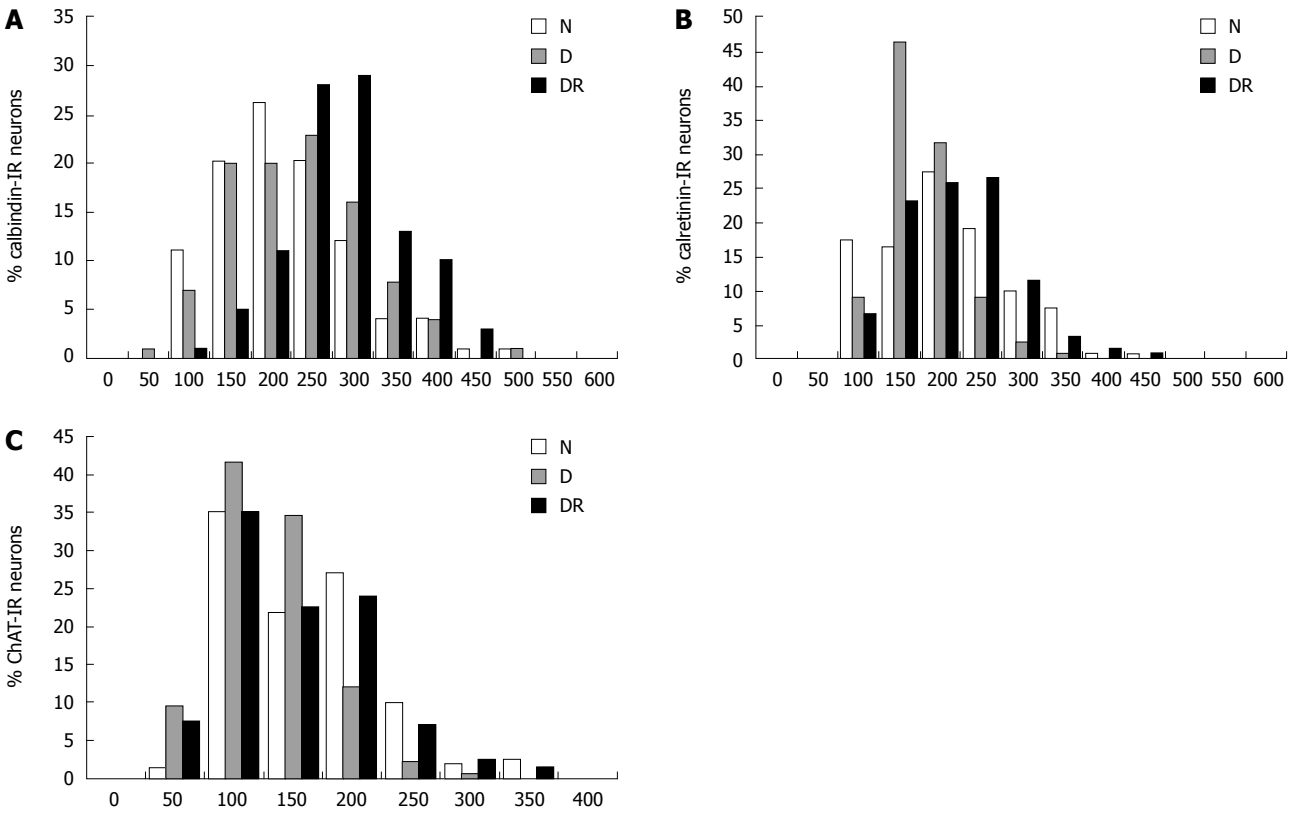

Figure 8 Histogram showing the distribution of areas (μm^2) of neurons immunoreactive for calbindin (A), calretinin (B) and choline acetyltransferase (C) in the ileal submucosal plexus of the N, D and DR groups. ChAT: Choline acetyltransferase.

studied, including rats[38], are immunoreactive for calretinin in the rat small intestine[33]. The subclasses of neurons in the submucosal ganglia of rat ileum have not been extensively studied but, by analogy with other small mammals, they are likely to include cholinergic and non-cholinergic secretomotor neurons and, possibly, IPANs[27,29,37]. In accordance with the data from rats and other small mammals, we chose the enzyme NOS to identify inhibitory motor neurons, ChAT to identify excitatory motor neurons and interneurons, calretinin to identify IPANs, and calbindin, which is a marker of many neurons in the rat small intestine. Within the three groups, the NOS-IR neurons had Dogiel Type I morphology and the calretinin-IR neurons in the myenteric and submucosal plexuses had Dogiel Type Ⅱ morphology while presenting various sizes. Calbindin-IR neurons exhibited four distinct morphologies: the Dogiel type Ⅱ neurons (large and small) and Dogiel type I neurons (small and elongated). These findings are consistent with the literature[37].

By qualitative analyses, there were no differences in neuron morphology between the N, D and DR groups. There was also no observed change in the labeling intensity of neurons immunoreactive for NOS, calretinin, and calbindin among the three groups. However, the intensity of ChAT immunoreactivity was reduced in some neurons of the undernourished group and increased in the re-fed group. These results are consistent with other studies in which a decrease in the intensity of ChAT immunoreactivity in the myenteric neurons of malnourished animals has been reported[22,39]. Other enzymes, such as NADH diaphorase, also show decreased immunoreactivity in malnourished and recovery in re-fed animals[21,22].

Previous studies have revealed the presence of $P2X_2$, $P2X_3$ and $P2X_7$ receptor-containing neurons in the enteric nervous system of guinea pigs[6-11], rats[12-14] and mice[15,16]. In the current work with the rat enteric nervous system, we found that $P2X_2$ receptors were present in both the cytoplasm and cytoplasmic membrane in neurons of the myenteric and submucosal plexuses.

The co-localization of different neuronal markers described in this work confirm the presence of $P2X_2$ receptors in NOS-IR, calretinin-IR, and calbindin-IR enteric neurons, as well as in ChAT-IR neurons of the myenteric and submucosal plexuses. ATP has been reported to depolarize 70%-90% of guinea-pig enteric neurons, which indicates that many enteric neurons have ionic P2X receptors[2,3]. In the myenteric plexus of rats, we found that the $P2X_2$ receptors exhibited complete co-localization with NOS-IR, calretinin-IR, calbindin-IR and ChAT-IR neurons in the three groups examined, without significant differences among them. This finding is consistent with the literature, which demonstrates the presence of the receptor in inhibitory neurons, as well as intrinsic excitatory and secretomotor/vasodilator primary afferent neurons in guinea pigs[7] and rats[12].

Our analyses of co-localization in the submucosal plexus showed that all calretinin-IR, ChAT and calbindin-IR neurons co-localized with $P2X_2$ receptor-IR neurons. However, there was a significant increase ($P < 0.05$) in the co-localization of $P2X_2$ neurons with calbindin-IR neurons in the undernourished group, which recovered in the re-fed DR group. This result agrees with Xiang and Burnstock's[12] findings, in which they reported expression of $P2X_2$ receptor in calretinin and calbindin neurons in the ileal myenteric plexus of rats. The co-localization that we described in the myenteric and submucosal plexuses suggested that malnutrition did not change neurochemical coding, for the markers that were used, in the enteric nervous system.

Changes in the density of myenteric neurons have been observed in various regions of the gastrointestinal tract in models of undernutrition[20-23,25,39] and recovery is observed in re-fed rats[21,22,25]. The increase in neuronal density in undernourished protocols is likely due to decreases in the surface area of the small or large intestine[20-22,39]. In our work on the myenteric plexus, neuron densities were increased for $P2X_2$ receptor-IR, NOS-IR, ChAT-IR and calretinin-IR neurons in the D group, and went back to control levels in the DR group. This increase in neuron density was due to a reduction of approximately 34% in small-intestinal area in the D group. There was recovery of the intestinal area in the DR group. In contrast, the density of calbindin-IR neurons in the myenteric plexus did not differ among the three groups ($P > 0.05$). Moreover, the increases in neuron density in the myenteric plexus in the D group were dependent upon the neuronal class examined. NOS-IR neuron density increased by 64%, calretinin-IR neurons by 84%, and ChAT-IR neurons by 26%; these data suggest that undernourishment affects the neuronal subtypes differently. There was no change in the calculation of the total number of NOS-IR, calbindin-IR or ChAT-IR neurons in the small intestine of the three groups. However, the calretinin-IR neuron numbers were increased (20%) in the undernourished group and $P2X_2$ receptor-IR neurons were decreased by around 25% in the D and DR groups.

The density of $P2X_2$-receptor-expressing neurons in the myenteric plexus in group N was about 51 000/cm^2 in our study. This value is higher than the combined sum of the two major neuronal subtype populations of the myenteric neurons: NOS (8000/cm^2) + ChAT (26 000/cm^2). This discrepancy could be due to $P2X_2$ receptor staining in another neuronal class, which was not immunoreactive for NOS, calbindin, calretinin or ChAT. Also, $P2X_2$ receptor labeling could have also stained enteric glial cells. The presence of P2X and P2Y receptors has been described in astrocytes and microglia of the central nervous system[40,41] and in enteric glial cells[9,42]. In the mammalian enteric nervous system, the proportion of glial cells to neurons is about three to one[43-45].

The tonic release of ATP into the extracellular space without a particular stimulus is a widespread physiological process. However, the release of ATP into the extracellular environment is also caused by pathophysiological events like inflammation, ischemia, injury as a consequence of cell damage or acute cell death, and metabolic

stress[46]. All physiological effects of ATP including fast purinergic transmission and co-transmission, the secretion of neuropeptides, and mechanosensory transduction might be amplified by overtly increased extracellular concentrations of ATP[46].

Studies from the literature have reported changes in the expression of purinergic receptors in different dietary conditions in the central nervous system. A diet deficient in zinc, for example, increases expression of $P2X_6$ receptors in the hippocampus of rats[47], which suggests that dietary zinc levels also affect protein expression and could act as a modulator of the receptor function. Increased $P2Y_1$ receptor mRNA expression in the hypothalamus after food restriction has been reported in rats[48], and the data indicate that expression of ADP/ATP-sensitive $P2Y_1$ receptors in the hypothalamus is dependent on feeding conditions. The enhanced expression of the $P2Y_1$ receptor during the early and late interval of restricted feeding suggests an increased demand for purinergic signaling to enhance the activity of hypothalamic neurons. Also, there is an indication of $P2Y_1$ and A_{2A} that purinergic receptor mRNA expression is altered during acute and chronic food deprivation[49]. Some authors have suggested that ATP/ADP, acting as extracellular signal molecules in the rat brain, is involved in the regulation of food intake, possibly depending on $P2Y_1$-receptor-mediated nitric oxide production[50].

During metabolic stress, such as hypoglycemia or brain ischemia, activation of different P2 receptors has been demonstrated *in vivo* and *in vitro*. The $P2X_2$ and $P2X_4$ receptors are upregulated after oxygen and glucose deprivation in organotypical slice cultures and in CA1 and CA3 pyramidal cells after *in vivo* ischemia in gerbils[51]. During *in vivo* and *in vitro* ischemia, the $P2X_7$ receptor density is upregulated in microglia and on astrocytes and neurons[52]. Prenatal protein malnutrition might increase circulating concentrations of ATP, and this increases $P2X_2$ expression in cells. Enhancement of $P2X_2$ receptors in the D group suggests an increased demand for purinergic signaling. These changes were all reversed in re-fed rats, which demonstrated the effectiveness of re-feeding upon enteric neuron recovery.

Changes in neuronal expression of $P2X_{1-7}$ purinoceptors are frequently seen not only as a result of maturation and neuronal differentiation, but also after various types of acute insults to the central nervous system such as ischemia, hypoxia, mechanical stress, axotomy, and inflammation. Purinergic mechanisms are involved in the etiology of many neurodegenerative conditions, especially due to the large extracellular release of ATP, adenosine, and other neurotransmitters[46,53] upon neural damage. Prolonged stimulation of ATP receptors results in changes in the location and density of P2 receptors in the cell membrane[46]. Increased $P2X_3$ receptor expression has been observed in inflammatory bowel disease of the large intestine, which suggests that changes in this receptor can cause pain and dysmotility of the bowel[54].

Nitrergic neurons (using nitric oxide synthesized by NOS) and cholinergic neurons (those that use the acetylcholine synthesized by ChAT) represent two major subpopulations of myenteric neurons[55], although these patterns vary between guinea pigs[56], mice[30,57] and rats[33,36].

Our work implies that differences between groups in the total neuronal density in the myenteric plexus are comprised principally of changes in the NOS-IR-and ChAT-IR neuronal populations. The total neuron density in the myenteric plexus was approximately 34 800/cm^2 in the nourished group. This neuronal density is greater in comparison with that in previous studies, which have reported values of 15 000 to 20 000/cm^2[58], 10 000/cm^2[59] and 18 000/cm^2[60]. These differences could be, in part, due to methodology as well as the different ages and strains of rats used.

Marese *et al*[61] have quantified neuronal numbers in the myenteric plexus of the duodenum using the Giemsa histological method and myosin V pan-neuronal immunohistochemical labeling. These studies have demonstrated that the number of neurons/cm^2 decreases with animal age between 21 and 428 d. Our experiments used 42-d-old rats of the same lineage (Wistar), and the estimate of neuron density in our work is within the 21-60 d range reported by Marese *et al*[61] (21 d: Giemsa 89 335 neurons/cm^2; myosin V: 59 364/cm^2; 60 d: Giemsa: 47 814/cm^2; myosin V: 30 291/cm^2).

In the present work, the proportions of NOS-IR and ChAT-IR neurons were 32% and 68%, respectively, in the myenteric plexus of the malnourished group. Consistent with previous studies[35,56], we found that these proportions were maintained in the D and DR groups.

Submucosal plexus

ChAT-IR neurons comprised the majority of submucosal plexus neurons in the three groups. These findings agree with prior studies, which have described most neurons of the submucosal plexus as ChAT-IR[33,56]. We demonstrated, for the first time, an increase in the density of $P2X_2$ receptor-IR, calbindin-IR, calretinin-IR and ChAT-IR neurons in the deprived animals, which returned to control levels in the re-fed animals in the submucosal plexus. This increase was due to a 34% reduction in the area of the small intestine in the deprived animals.

The total number of calbindin-IR submucosal neurons increased in the small intestine of undernourished animals, in contrast to a decrease in calretinin-IR neurons and no change in the number of ChAT-IR neurons. These data indicate that the lack of protein nutrition can also have an impact on the chemical coding of the submucosal plexus. Differences in these measures between the myenteric and submucosal plexuses might reflect a differential effect of malnutrition or undernutrition on these two regions, as well as a differential effect of undernourishment on each neuronal subtype. In addition, the increase of calbindin-expressing neurons in the submucosal plexus could be a compensatory mechanism in response to the decrease in these neurons in the myenteric plexus.

Neuronal sizes

Previous immunohistochemical studies have shown that

undernutrition affects the neuron size profile of the gastrointestinal tract[20,21,39]. Analyses using the Giemsa technique[20,62] and histochemistry[22] have found no significant differences in the neuronal sizes in the small intestine in nourished, undernourished and re-fed animals. The present work, using an immunohistochemistry technique, was unable to verify exactly which neuronal class showed changes in size. In the myenteric plexus, there were decreases in size of the calretinin-IR neurons in groups D and DR. There was also an increase in the size of calbindin-IR neurons in the DR group, compared to the N and D groups. There was no change ($P > 0.05$) in the size of ChAT-IR neurons among the three groups. The size of NOS-IR neurons also did not change, consistent with previous reports[58]. In the submucosal plexus, the sizes of calbindin-IR, calretinin-IR and ChAT-IR neurons were not affected by undernutrition. However, the major axes of the calbindin-IR and minor axes of the calretinin-IR and ChAT-IR neurons decreased in group D, with recovery in group DR. The differences between the submucosal and myenteric plexuses suggest again that undernutrition affects the two plexuses differently. The distribution areas of NOS-IR, calbindin-IR, calretinin-IR and ChAT-IR neurons in our study ranged from 100 to 500 μm^2, in agreement with previous reports[22].

The current study demonstrates that both undernourishment and re-feeding has a different impact on neuronal subtypes. Undernutrition also differently affects the myenteric and submucosal plexuses; changes in calbindin-IR neuronal density in the submucosal plexus were not reflected in the myenteric plexus, where only the profile of the calretinin-IR neurons was affected by dietary restriction. These changes were all reversed in re-fed rats, which demonstrated the effectiveness of re-feeding upon enteric neuron recovery.

ACKNOWLEDGMENTS

We would like to thank Professor Jackson Cioni Bittencourt and Assistant Professor Carol Fuzeti Elias for providing the Leica Microscope for the analyses.

COMMENTS

Background

The myenteric and submucous plexuses are affected in undernourished and re-fed rats.

Research frontiers

The chemical coding and $P2X_2$ receptor expression following malnourishment and re-feeding are unknown.

Innovations and breakthroughs

The present study showed the effects of undernourishment and re-feeding on the morphology of the $P2X_2$-immunoreactive (IR), nitric oxide synthase-IR, calbindin-IR, calretinin-IR and choline acetyltransferase-IR neurons of the myenteric and submucosal plexuses.

Applications

The present study suggests that re-feeding can restore almost all of the changes to inhibitory intrinsic primary afferent neurons and cholinergic neurons seen in undernourished animals.

Peer review

This is a study of the effects of deprivation and restoration of protein on neuronal development in the submucosal and myenteric plexuses. The results describe changes induced by protein deprivation that are largely reversible by re-feeding.

Abstract

AIM: To investigate and elucidate the molecular mechanism underlying varioliform gastritis for early detection, prevention and intervention of gastric cancer.

METHODS: A combination of two-dimensional gel electrophoresis and mass spectrometry was used to detect the differentially expressed proteins between varioliform gastritis and matched normal mucosa. The selected proteins were confirmed by Western blotting and reverse transcription polymerase chain reaction (RT-PCR) in additional samples and the function of some proteins in varioliform gastritis was analyzed by bio-method preliminarily.

RESULTS: We identified 21 differentially expressed proteins in varioliform gastritis, and compared them with matched normal mucosa. Eleven proteins were upregulated and ten downregulated in varioliform gastritis when compared with the same proteins in individual-matched normal gastric mucosa. These proteins are related to metabolism, oxidation, cytoskeleton, apoptosis, signal transduction and other aspects of cells. Two novel proteins, thioredoxin domain-containing protein 5 (TXNDC5) upregulated in varioliform gastritis, and neuropolypeptide h3 [phosphatidylethanolamine-binding protein 1 (PEBP1)] downregulated in varioliform gastritis, were further investigated. Their expressions were validated by Western blotting and RT-PCR in 12 cases of varioliform gastritis which was matched with normal mucosa. The expression level of PEBP1 in varioliform gastritis was significantly lower ($P < 0.05$) while that of TXNDC5 was significantly higher than that in matched normal gastric mucosa ($P < 0.05$).

CONCLUSION: There are some changes of protein expression in varioliform gastritis. Downregulation of PEBP1 and upregulation of TXNDC5 are involved in the development of varioliform gastritis.

INTRODUCTION

Varioliform gastritis is currently recognized as a special kind of chronic gastritis characterized by nodules, thickened fugal folds and erosions. These features appear to be

unusual and different from those seen in chronic gastritis. The diagnosis can be easily made by endoscopic examination. But the morbidity of varioliform gastritis has increased quickly recently in China. Very little is known about the etiopathogeny, clinical significance and evolution of this disease. The molecular biological researches on varioliform gastritis are very limited and no proteomics research on this disease has been found up to date. So the molecular mechanism of this disease is still unclear. The role of *Helicobacter pylori (H. pylori)* remains unknown. Although a close relationship between this gastritis and the bacteria was suggested to exist over the last few years, But no *H. pylori* infection was found in the gastric mucosa of some patients with varioliform gastritis. What is the reason?

Gastric cancer is the second most common malignancy in the world. Each year, about 798 000 people are diagnosed as having gastric cancer (9.9% of total cancer cases) and 628 000 people die from the disease (12.1% of cancer deaths)[1]. In eastern Asian countries including China, the morbidity and mortality of gastric cancer have ranked the first among all kinds of cancer and grown rapidly in the past two decades. Gastric carcinogenesis is not a well-known process, and the central paradigm for the initiation and development of gastric carcinoma is still not very clear.

In 1960, Munoz Monteavaro *et al*[2] reported varioliform gastritis with "*in situ*" carcinomatous transformation. It was reported a case of ampullary carcinoma accompanied with gastroenteropathy due to diffuse varioliform gastritis. Similarly, Cappell *et al*[3] reported adenomatous transformation in a patient with varioliform gastritis who had serial gastroscopies. This report also suggests a possible association between varioliform gastritis and gastric neoplasia. Several other groups have reported similar findings and performed a more comprehensive analysis of relationship between varioliform gastritis and gastric cancer[4-6].

The elevations could persist and appear as sessile polyps after the erosions heal and symptoms relieved after treatment. Adenomatous transformation was reported in some patients with varioliform gastritis. These reports suggested a possible association between varioliform gastritis and gastric neoplasia. Although this disease was concluded as a kind of precursor disease of gastric cancer at Sydney Conference, the mechanism of carcinogenesis from varioliform gastritis was unknown. Gastric cancer might be effectively controlled if this premalignant lesion-varioliform gastritis-is detected and treated before invasion occurs. Therefore, it is crucial to elucidate the molecular mechanism underlying varioliform gastritis. Some current mechanistic models focus almost on the localized lesion or *H. pylori* infection, with much less attention paid to pathologic changes occurring in the normal-appearing mucosa without *H. pylori* infection from which such lesions emerge.

The pattern of expressed proteins can reflect the information about the functional status and health of the tissue. Recently, the development of new methods for protein analysis has led to the emergence of a new field of clinical proteomics, in which these techniques are harnessed to identify functional molecular or biomarkers of cancer and other diseases[7], but there is hardly any study on the differential expressions of proteins in varioliform gastritis and normal-appearing mucosa.

In the present study, we used proteomic techniques to test the hypothesis that normal gastric mucosa from a patient with varioliform gastritis would exhibit different pattens of protein expression with the disordered mucosa from the same patient. By this approach, comparison of anatomically normal and disordered tissues against the same genetic background could be made.

MATERIALS AND METHODS

Sample collection

Samples were taken from 17 patients with varioliform gastritis in the Second Affiliated Hospital of General Hospital of PLA (Table 1). These patients were examined by ^{13}C urea breath test and the results were all negative. The results of autoantibody detection were also negative in these patients. The case of *H. pylori* infection and autoimmune disease was excluded. Normal gastric mucosa was defined as that 5cm adjacent to the elevations. All samples were obtained by biopsy in endoscopic examinations for these patients. Four pieces of elevatory tissues and normal mucosa were collected from each patient, respectively. One piece of the elevatory tissue underwent pathological diagnosis, and the others were saved for future studies. The patients were well informed in accordance with the disciplines of the Ethics Committee of Biomedicine, General Hospital of PLA, China.

All samples were snap-frozen in liquid nitrogen and stored in a deep freezer (-80℃) until used. Tissues (80-150 mg) were crushed in liquid nitrogen and lysed in 1 mL of 7 mol/L urea, 2 mol/L thiourea, 4% 3-[(3-cholamidopropyl) dimethylammonio] propanesulfonate (CHAPS), 65 mmol/L dithiothreitol (DTT), and 0.2% Bio-Lyte (pH 5-8, Bio-Rad, Hercules, CA) with sonication on ice. The lysates were centrifuged at 20 000 × *g* for 1 h at 4℃. Supernatants were removed and concentrations were determined by the Bio-Rad AC DC protein assay kit (Bio-Rad). The protein samples were stored at -80℃. Before 2-DE was performed, the protein samples were purified using the Readyprep 2-D cleanup kit (Bio-Rad) according to the manufacturer's instructions.

Clinical data of samples

Detailed clinical and pathological data from the health care information center were reviewed. None of the patients had received treatment prior to endoscopic examination. Of the 17 patients, 11 were men, and six were women; the mean age was 51 years (range, 34-72 years, Table 1). No patient suffered from varioliform gastritis with other concurrent gastric diseases. All tissues of varioliform gastritis had definite histologic diagnoses: acute and chronic mucosal inflammation (n = 12), acute and chronic mucosal inflammation with lymphocytic infiltration (n = 5). None of them had *H. pylori* infection or low-to-moderate dysplasia.

Table 1 Characteristics of varioliform gastritis patients in this study

Patient No.	Sex	Age (yr)	Lesion site	Histology
1	F	77	Gastric antrum	Acute and chronic mucosal inflammation, *H. pylori* (-)
2	F	54	Gastric antrum	Acute and chronic mucosal inflammation, *H. pylori* (-)
3	F	59	Gastric body and gastric antrum	Acute and chronic mucosal inflammation with Lymphocytic infiltration, *H. pylori* (-)
4	F	43	Gastric body and gastric antrum	Acute and chronic mucosal inflammation, *H. pylori* (-)
5	F	62	Gastric antrum	Acute and chronic mucosal inflammation, *H. pylori* (-)
6	F	68	Gastric body and gastric antrum	Acute and chronic mucosal inflammation, *H. pylori* (-)
7	M	44	Gastric antrum	Acute and chronic mucosal inflammation with Lymphocytic infiltration, *H. pylori* (-)
8	M	36	Gastric antrum	Acute and chronic mucosal inflammation, *H. pylori* (-)
9	M	76	Gastric antrum	Acute and chronic mucosal inflammation with Lymphocytic infiltration, *H. pylori* (-)
10	M	67	Gastric antrum	Acute and chronic mucosal inflammation, *H. pylori* (-)
11	M	55	Gastric antrum and pylorus	Acute and chronic mucosal inflammation, *H. pylori* (-)
12	M	45	Gastric antrum	Acute and chronic mucosal inflammation, *H. pylori* (-)
13	M	72	Gastric antrum	Acute and chronic mucosal inflammation with Lymphocytic infiltration, *H. pylori* (-)
14	M	57	Gastric antrum and pylorus	Acute and chronic mucosal inflammation, *H. pylori* (-)
15	M	61	Gastric antrum	Acute and chronic mucosal inflammation with Lymphocytic infiltration, *H. pylori* (-)
16	M	51	Gastric antrum	Acute and chronic mucosal inflammation, *H. pylori* (-)
17	M	78	Gastric antrum and pylorus	Acute and chronic mucosal inflammation, *H. pylori* (-)

H. pylori: *Helicobacter pylori*.

Two-dimensional gel electrophoresis

Individual paired samples of normal gastric mucosa and varioliform gastritis were analyzed by 2-DE as described by Xing previously[8]. Briefly, linear gradient 24-cm (pH 5-8) ready strip (Bio-Rad) was rehydrated overnight at 16℃ with 200 μg of protein samples in 500 μL of rehydration buffer (7 mol/L urea, 2 mol/L thiourea, 4% CHAPS, 65 mmol/L DTT, and 0.2% Bio-Lyte). Isoelectric focusing (IEF) was performed using PROTEAN IEF Cell (Bio-Rad). After IEF, the immobilized pH gradient strip was immediately equilibrated in equilibration buffer Ⅰ [6 mol/L urea, 2% sodium dodecyl sulfate (SDS)], 0.375 mol/L Tris-HCl pH 8.8, 20% glycerol, and 2% DTT) for 15 min and then in equilibration buffer Ⅱ (6 mol/L urea, 2% SDS, 0.375 mol/L Tris-HCl pH 8.8, 20% glycerol, and 2.5% iodoacetamide) for 15 min. SDS-polyacrylamide gel electrophoresis was carried out on 12% SDS-polyacrylamide gels (25 cm × 20.5 cm × 1.0 mm) using the PROTEAN Plus Dodeca Cell (Bio-Rad) at a constant voltage of 200 V at 20℃. After electrophoresis, the gels were stained using the Silver Stain Plus Kit (Bio-Rad). The above processes were performed in triplicate for each sample.

Gel imaging and analysis

The silver-stained 2-DE gels were scanned on a GS-800 Calibrated Imaging Densitometer (Bio-Rad) at a resolution of 300 dots per inch. Intensities of protein spots were analyzed with Amersham Biosciences-Imagemaster v5.0. The differential protein spots were defined as those having a 5-fold higher or lower level of differential expression in at least 9 cases compared with the normal mucosa.

Spot cutting and in-gel digestion

The 17 samples were used for spot cutting. Equal protein masses of each sample (normal gastric mucosa and varioliform gastritis tissue) were pooled, and 300 μg of the mixture was loaded for 2-DE. The differentially expressed protein spots were identified as described in the preceding text. These spots were excised from gels by Proteomeworks Spot Cutter (Bio-Rad), destained for 20 min in 30 mmol/L potassium ferricyanide/100 mmol/L sodium thiosulfate [1:1 (v/v)], and washed in Milli-Q water until the gels shrank and bleached. The gel pieces were incubated in 0.2 mol/L NH_4HCO_3 for 20 min and dried by lyophilization. Twenty microliters (20 μg/mL in concentration) trypsin (proteomics grade, Sigma, St. Louis, MO) was added into each gel piece, and incubated at 37℃ overnight. The peptides were extracted three times with 50% acetonitrile and 0.1% trifluoroacetic acid and dried in a vacuum centrifuge.

Mass spectrometry

The digests were analyzed using a Bruker Autoflex Ⅱ TOF/TOF mass spectrometer with delayed extraction in which α-cyano-4-hydroxycinnamic acid was exploited as the matrix. The total 2-μL solution was applied onto a target disk and allowed to air-dry. Mass-to-charge ratios were measured in a reflector/delayed extraction mode with an accelerating voltage of 20 kV, a grid voltage of 63%-65%, positive polarity, and a delay time of 200 nanoseconds. Laser shots at 300 per spectrum were used to acquire the spectra from 800 to 4000 Daltons. Trypsin autolysis products were used for internal mass calibration. Database searching was performed using Mascot software (http://www.matrixscience.com). The search parameters were the nrNCBI database, human, 10-150 kDa, trypsin (1 missed enzymatic cleavage), and 100-ppm mass tolerance. The best match was the one with the highest score, and a significant match was typically a score of more than 70 ($P < 0.05$).

Western blotting analysis

After the analysis of selected proteins, two differential proteins were confirmed by Western blotting analysis in additional samples for validating the 2-DE results. West-

ern blotting analysis was performed in 12 cases of varioliform gastritis with individual-matched normal mucosa. Tissue samples were lysed as described above and protein extracts (50 μg) were separated on a 12% SDS-polyacrylamide gel. Proteins were transferred to a poly-vinylidene difluoride membrane (Bio-Rad). After blocking, the membranes were incubated with a rabbit monoclonal antibody of phosphatidylethanolamine-binding protein 1 (PEBP1) (dilution of 1:2000; Epitomics, California, MA) and polyclonal goat anti-thioredoxin domain-containing protein 5 (TXNDC5) antibody (dilution of 1:1000; Cell Signaling Technology, Danvers, MA). Subsequently, the membranes were incubated in horseradish peroxidase-anti-rabbit and horseradish peroxidase-anti-goat IgG (Abcam, Cambridge, UK), respectively. The specific proteins were visualized with chemiluminescent reagent (Pierce Biotechnology, Rockford, IL). As a control for equal protein loading, blots were restained with anti-actin antibody (dilution of 1:4000; Santa Cruz Biotechnology, Santa Cruz, CA). The band intensity was analyzed by PDQuest software v7.1. The relative expression level was calculated as the intensity ratio of PEBP1 or TXNDC5 to that of actin. The association between categorical data was analyzed using the SPSS11.0 software package.

Reverse transcription polymerase chain reaction of TXNDC5 and PEBP1

The total RNAs of additional samples were extracted by homogenization in Trizol (Invitrogen) for validating the 2-DE results. cDNA synthesis was performed in 20 μL reaction system of reverse transcription including 5 μg RNA. Amplification of TXNDC5, PEBP1 and β2-MG acting as internal control was carried out in DNA thermal cycler (Perkin Elmer) using equal cDNA as template. PCR products were separated by 1.5% agarose gel electrophoresis, scanned and analyzed with VDS ImageMaster system (Pharmacia).

Preliminary functional analysis of TXNDC5 and PEBP1

To understand the function of TXNDC5 and PEBP1 in varioliform gastritis, they were imported into Pathway Studio (demo), and a visualized interaction map was generated with information from Ensembl database, the Pfam protein family database, Prosite database, GNF GeneAtlas database and PDB database. Each node represents either a protein entity or a control mechanism of the interaction. We intended to find the key pathway including TXNDC5, PEBP1 and other proteins in our proteomics research by analyzing the protein interaction networks.

Statistical analysis

SPSS11.0 statistical software was used for the statistical analysis.

The gray values of the protein candidates were analyzed by the nonparametric Wilcoxon test. The intensity ratio of PEBP1 or TXNDC5 to that of internal control in Western blotting or reverse transcription polymerase chain reaction (RT-PCR) analysis was analyzed by one-factor analysis of variance.

RESULTS

Differential protein expression of varioliform gastritis

The 2-DE protein patterns were studied in 17 patients with varioliform gastritis and individual-matched normal mucosa tissues. About 1800 proteins were detected in each gel. The proteins expressed in varioliform gastritis were compared with those in matched normal tissues. The differentially expressed candidates were the protein spots having a 5-fold higher or lower level of differential expression in at least 9 cases (Figure 1A and B). In this study, 21 significantly different candidate protein spots were found. They were also present in the 2-DE gel. Eleven proteins were upregulated and 10 downregulated in varioliform gastritis compared with the same proteins in individual-matched normal gastric mucosa. The quantities of all detected spots were analyzed by the nonparametric Wilcoxon test. These candidate spots were then analyzed by mass spectrometry (MS), and a total of 18 proteins (Figure 1C and Table 2) were identified. We failed to detect three protein spots. There might be several reasons, such as lower abundance, errors in the operation, lower reliability of the MS results, and characteristics of these proteins. More work will be done on the three protein spots in the future studies.

Validation of PEBP1 and TXNDC5 by Western blotting

The two novel candidate proteins, PEBP1 and TXNDC5, were studied further among the differentially expressed proteins. Their expression profiles in varioliform gastritis have not been reported previously. Western blotting analysis showed that TXNDC5 was upregulated significantly in varioliform gastritis but not in normal gastric mucosa (mean ± SD: 0.37 ± 0.05) (Figure 2B). Compared with that in normal mucosa (mean ± SD: 0.76 ± 0.12), PEBP1 was significantly downregulated in varioliform gastritis (mean ± SD: 0.18 ± 0.08) ($P < 0.05$, by Student's test or the Friedman test) (Figure 2A).

Validation of PEBP1 and TXNDC5 by RT-PCR

Using semiquantitative RT-PCR, 476 bp fragment of TXNDC5, 451 bp fragment of PEBP1 and 876 bp control fragment of β2-MG were amplified (Figure 3). The mean ratios of the absorbency of PEBP1 band normalized to the control band were 0.35 ± 0.09 and 1.23 ± 0.27 in 12 cases of varioliform gastritis and normal mucosa. *P* value was lower than 0.05 when Student's *t* test was used to compare the ratios of the two groups (Figure 3B). Those of TXNDC5 were 1.15 ± 0.07 and 0.23 ± 0.06 in 12 cases of varioliform gastritis and normal mucosa, respectively ($P < 0.05$) (Figure 3A). The results suggested that the difference of TXNDC5 and PEBP1 between varioliform gastritis and normal mucosa could be obvious at the mRNA level.

Preliminary functional analysis

TXNDC5 and PEBP1 were imported into Pathway Studio (demo) to build an interaction network. The connectivity of TXNDC5 and PEBP1 was 40 and 145, respectively. The average connectivity of proteins identified was about

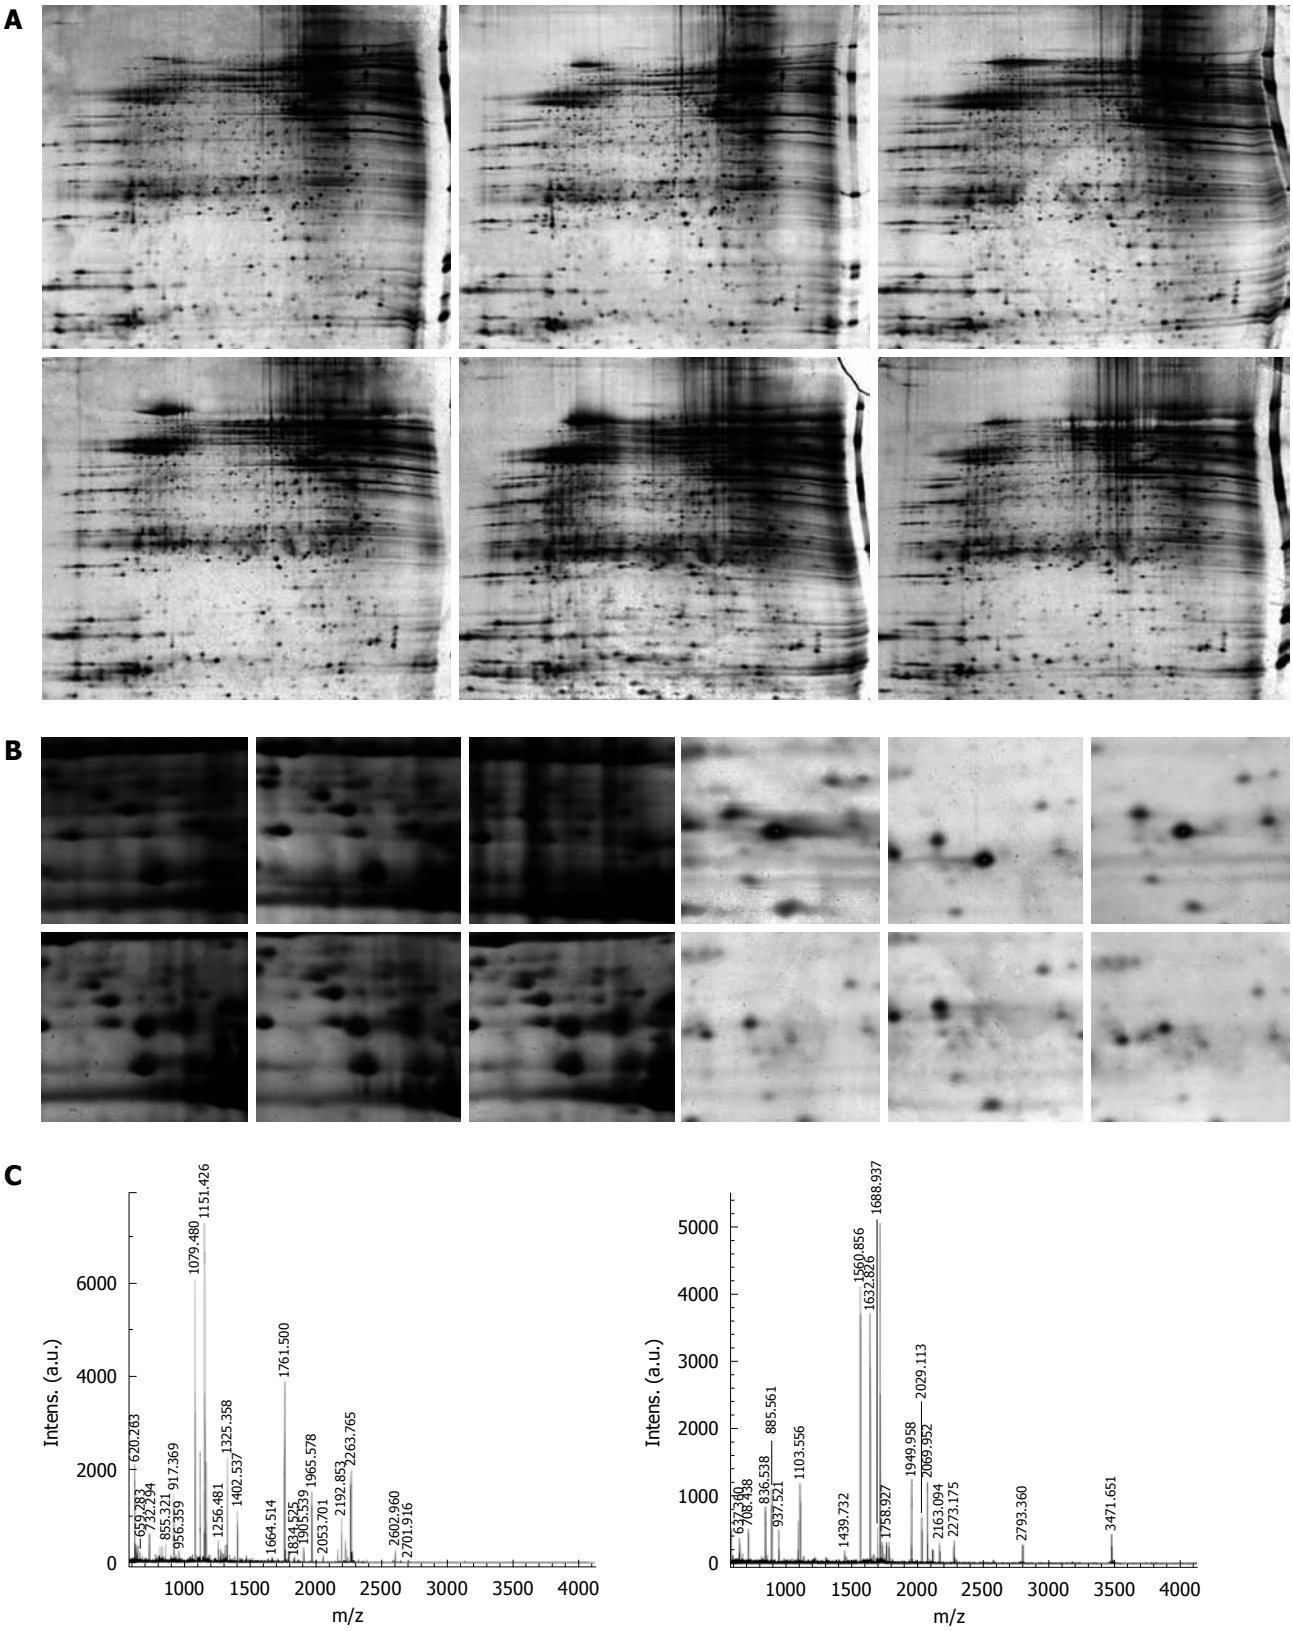

Figure 1 Detection and analysis of differentially expressed proteins in varioliform gastritis. A: Representative 2-DE images of matched varioliform gastritis and normal gastric mucosa tissue. The proteins expressed in varioliform gastritis were compared with those expressed in matched normal tissue. The protein spots that showed more than 5-fold differential expression in at least nine cases were taken as differentially expressed candidates. Of 21 differentially expressed protein spots, 18 were identified by mass spectrometry (MS) (protein nomenclature can be seen in Table 2); B: The magnified regions of the 2-DE gel of upregulated thioredoxin domain-containing protein 5 (TXNDC5) (left) and downregulated phosphatidylethanolamine-binding protein 1 (PEBP1) (right) in varioliform gastritis, compared with normal tissue; C: MS of in-gel trypsin digests of these proteins and analysis of the depicted peptide spectrum resulted in the identification of TXNDC5 (left) and PEBP1 (right).

Table 2 Differentially expressed proteins in varioliform gastritis

ID No.	Protein name	Gene name	Accession No.	Mass (Da)/pI	Cover rate (mean, %)	Mascot scores	Intensity of candidate protein spots[a] (positive rate)	General function/comments
	Up-regulated proteins							
1	Thioredoxin domain containing protein 5 precursor	*TXNDC5*	Q8NBS9	47629.2/5.3	25	228	36.5 ± 3.1, 2.7 ± 0.4 (100%, 44.4%)	Controlling the oxidative protein folding in endoplasmic reticulum
2	Proliferating cell nuclear antigen	*PCNA*	P12004	28762.4/4.7	37	184	18.6 ± 4.2, 3.3 ± 0.9 (94.4%, 70.5%)	Cell growth and maintenance
3	40S ribosomalprotein SA	*RPSA*	P08865	32702.4/4.79	46	104	64.3 ± 11.1, 11.5 ± 2.8 (100%, 88.3%)	Originally known as laminin receptor precursor and p40
4	Heat-shock protein β-1	*HSPB1*	P04792	22768.5/5.9	33		73.8 ± 13.4, 12.7 ± 3.4 (100%, 100%)	A HSP27 isoform (pI5.68)
5	Inorganic pyrophosphatase2	*PPA2*	Q9H2U2	35472/5.9	69	245	24.1 ± 2.7, 3.6 ± 1.2 (94.4%, 58.9%)	Overexpressed in some cancer tissues
6	S100 calcium-binding protein A10	*S100A10*	P60903	11195.5/6.8	62	148	43.0 ± 5.7, 5.9 ± 2.7 (88.9%, 41.2%)	It may function as a regulator of protein phosphorylation in the ANXA2 monomer
7	Nucleoside diphosphate kinase A	*NME1*	P15531	17137.7/5.8	49	193	59.4 ± 12.6, 13.2 ± 5.8 (82.4%, 70.6%)	It plays a major role in the synthesis of nucleoside triphosphates other than ATP
8	Proteasome activator complex subunit 1	*PSME1*	Q06323	38966.2/7.6	53	138	83.8 ± 17.4, 10.5 ± 4.7 (100%, 41.2%)	Implicated in immuno-proteasome assembly and required for efficient antigen processing
9	Ubiquitin thiolesterase L3	*UCHL3*	P15374	26337/4.7	42	174	62.4 ± 11.9, 13.7 ± 7.1 (88.9%, 29.4%)	Ubiquitin-protein hydrolase involved in the processing of both ubiquitin precursors and ubiquitinated proteins
10	S100 calcium-binding protein A6	*S100A6*	P06703	11732.8/5.6	71	234	21.6 ± 5.3, 3.7 ± 1.1 (82.4%, 23.5%)	Preferentially expressed when quiescent fibroblasts are stimulated to proliferate
	Down-regulated proteins							
11	Cell division cycle 2-like protein kinase 5	*CDC2L5*	Q14004	48212.2/8.3	37	168	1.7 ± 0.5, 14.2 ± 2.6 (17.6%, 52.9%)	May be a controller of the mitotic cell cycle involved
12	BTG3 protein	*BTG3*	Q14201	29117.3/9.1	64	265	5.8 ± 2.3, 47.4 ± 6.1 (29.4%, 82.4%)	Overexpression impairs serum-induced cell cycle progression from the G0/G1 to S phase
13	Neuropolypeptide h3	*PEBP1*	P30086	31270.6/5.7	58	220	2.9 ± 1.4, 58.6 ± 11.8 (17.6%, 100%)	Binds ATP, opioids and phosphatidylethanolamine
14	Heat-shock protein 17 kDa	*HSPB3*	Q12988	16966/5.7	39	105	16.8 ± 4.4, 89.5 ± 14.7 (100%, 100%)	Inhibitor of actin polymerization
15	Caspase-5 precursor	*CASP5*	P51878	47815/9.2	48	201	7.6 ± 2.6, 45.9 ± 11.7 (41.2%, 77.8%)	Mediator of apoptosis
16	Cytokeratin 20	*KRT20*	P35900	48487/4.9	52	131	2.9 ± 0.4, 17.5 ± 3.6 (29.4%, 52.9%)	It plays a significant role in maintaining keratin filament organization in intestinal epithelia. When phosphorylated, it plays a role in the secretion of mucin in the small intestine
17	Eukaryotic translation initiation factor 3 subunit 2	*EIF3I*	Q13347	23354/4.9	44	173	8.9 ± 2.3, 46.3 ± 17.2 (35.3%, 100%)	Binds to the 40S ribosome and promotes the binding of methonyl
18	Ribosomal protein S12	*RPS12*	P25398	14526.0/5.6	56	141	5.7 ± 1.4, 52.6 ± 10.3 (29.4%, 70.6%)	Belongs to the ribosomal protein S12e family

[a]$P < 0.05$ *vs* the normal gastric mucosa. *t* test was used for analyzing the difference of the intensity of candidate protein spots. PEBP1: Phosphatidylethanolamine-binding protein 1; TXNDC5: Thioredoxin domain-containing protein 5.

57. Our results showed that some members of mitogen-activated protein kinase (MAPK) family and some molecules involved in nuclear factor (NF)-κB and tumor necrosis factor were hot points with higher connectivity. From the mimical molecular network, we concluded that NF-κB, MAPK and interferon γ (IFN-γ) pathways were the cores of the whole network. The downstream-related cancer and other phenotypes were linked to the three pathways. The reaction of cell to IFN-γ could be the initiating agent of this molecular interaction network (Figure 4).

DISCUSSION

Because of limited knowledge on varioliform gastritis, the molecular events underlying this disease were still unknown, and the patients could be faced with more risk of gastric cancer. It was confirmed that the mucosal lesion of varioliform gastritis could develop into malignant tumor. Proteomic studies can help understand the early stages in the genesis of varioliform gastritis and has the potential to aid in the prevention and intervention for gastric can-

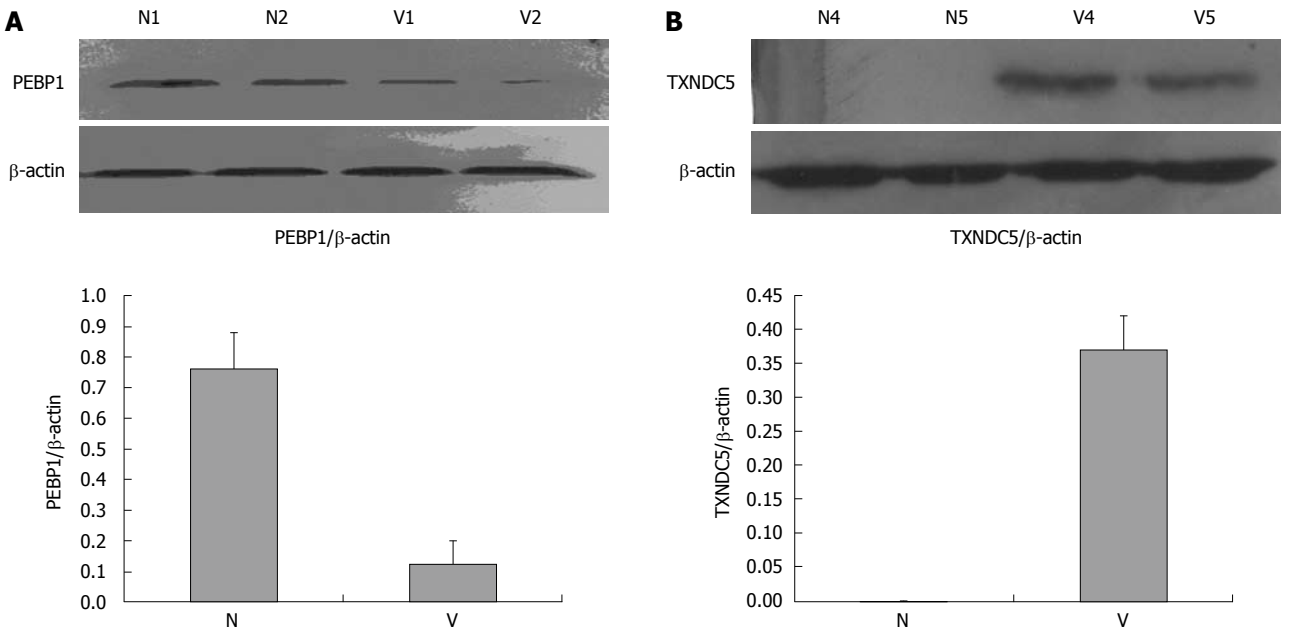

Figure 2 Western blotting analysis of phosphatidylethanolamine-binding protein 1 and thioredoxin domain-containing protein 5. A: Marked downregulation of phosphatidylethanolamine-binding protein 1 (PEBP1) in varioliform gastritis (V) tissue. Protein extracts (50 μg) were separated on a 12% sodium dodecyl sulfate-polyacrylamide gel. Proteins were transferred to a poly-vinylidene difluoride membrane. After blocking, the membranes were incubated with rabbit monoclonal antibody of PEBP1 (dilution of 1:2000) and subsequently incubated with HRP-anti-rabbit IgG. The specific proteins were visualized with chemiluminescent reagent. As a control for equal protein loading, blots were restained with anti-actin antibody. Immunosignals were quantified by densitometry scanning. The relative quantification was calculated as the ratio of PEBP1 expression to actin expression as shown in the followed chart; B: Upregulation of thioredoxin domain-containing protein 5 (TXNDC5) in varioliform gastritis in comparison with that in normal (N) mucosa. The same experimental process was performed, except that the membranes were incubated with polyclonal goat anti-TXNDC5 antibody (dilution of 1:1000).

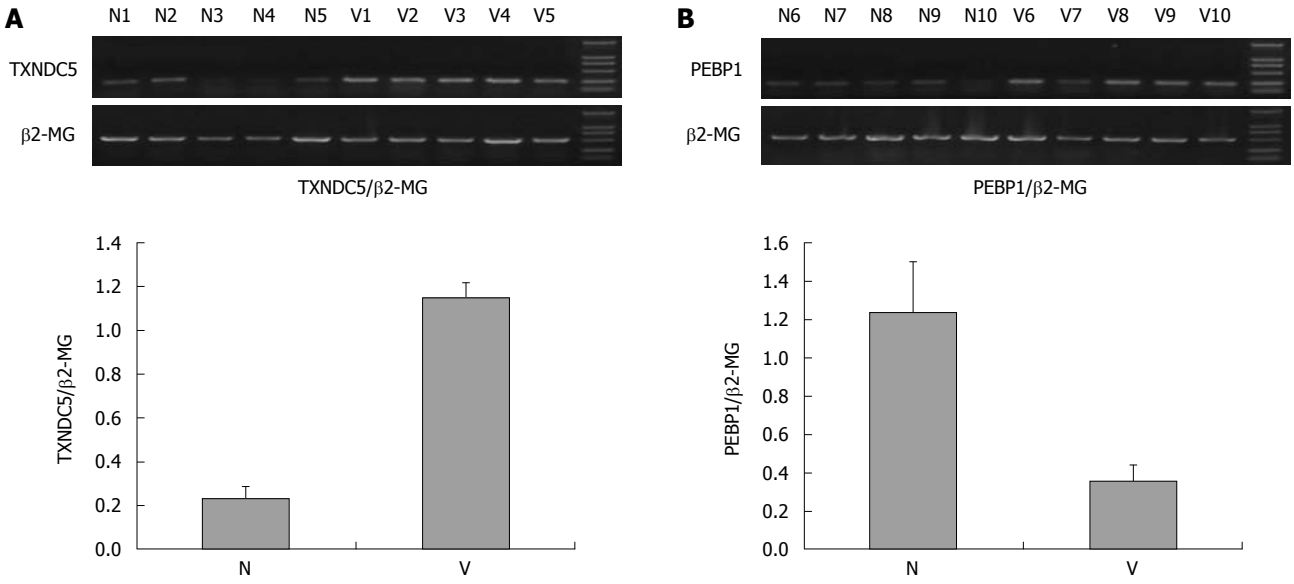

Figure 3 Reverse transcription polymerase chain reaction analysis of thioredoxin domain-containing protein 5 and phosphatidylethanolamine-binding protein 1. A: Marked upregulation of thioredoxin domain-containing protein 5 (TXNDC5) in varioliform gastritis (V). The total RNAs of additional samples tissues were extracted by homogenization in Trizol (Invitrogen), cDNA synthesis was performed in 20 μL reaction system of reverse transcription including 5 μg RNA. Amplification of TXNDC5, with β2-MG acting as internal control, was carried out in DNA thermal cycler. PCR products were separated by 1.5% agarose gel electrophoresis. The bands were quantified by densitometry scanning. The relative quantification was calculated as the ratio of TXNDC5 expression to β2-MG expression as shown in the followed chart; B: Downregulation of phosphatidylethanolamine-binding protein 1 (PEBP1) in varioliform gastritis in comparison with that in normal (N) mucosa. The same experimental process was performed. The relative quantification was calculated as the ratio of PEBP1 expression to β2-MG expression as shown in the followed chart.

cer. In this study, we used the common approach of 2-DE coupled with MS to study the differentially expressed proteins in individual-matched cases of normal mucosa and lesion of varioliform gastritis and confirmed the differential expression of PEBP1 and TXNDC5 by Western blotting or RT-PCR.

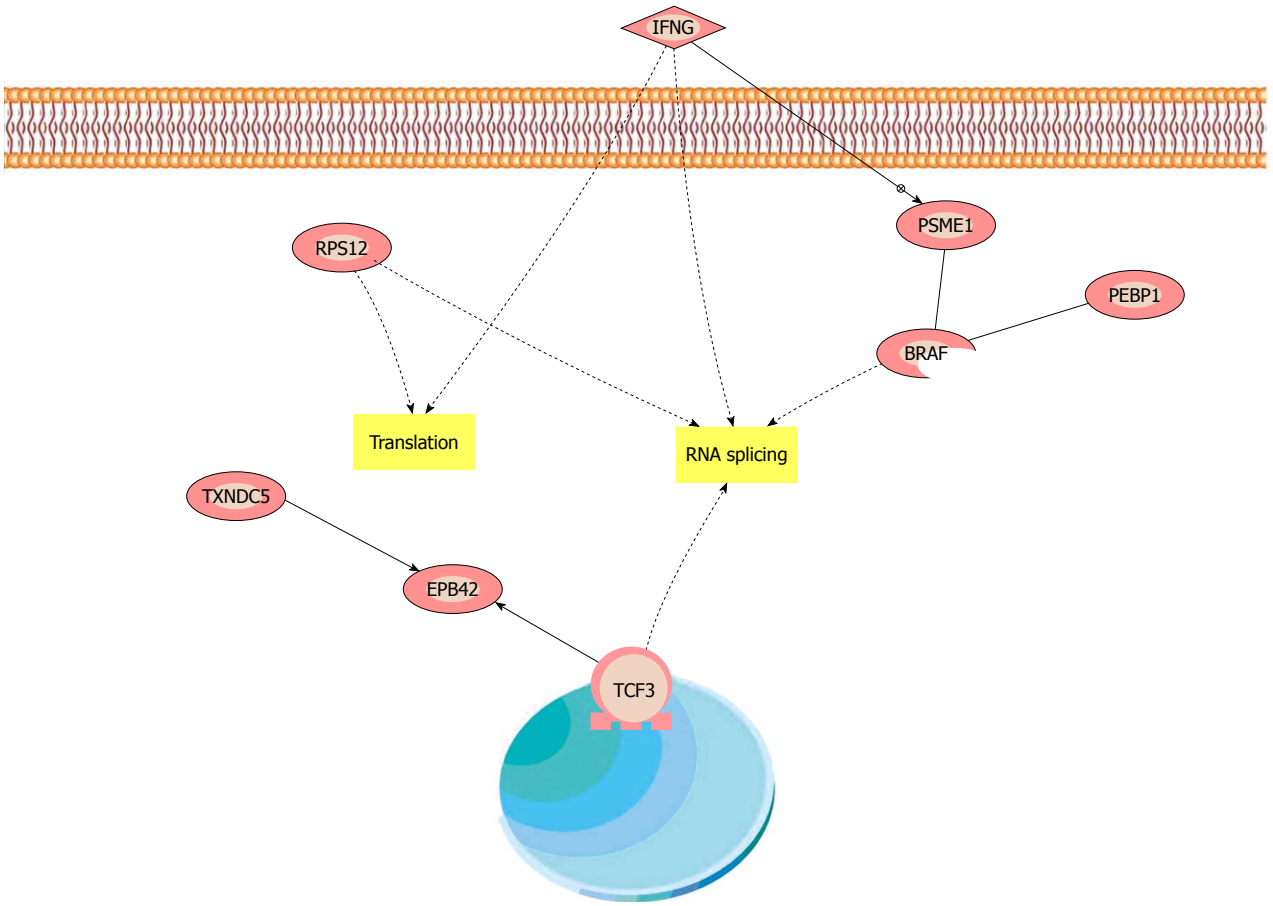

Figure 4 Compendious biological interaction networking of phosphatidylethanolamine-binding protein 1 and thioredoxin domain-containing protein 5 in varioliform gastritis. Phosphatidylethanolamine-binding protein 1 (PEBP1) and thioredoxin domain-containing protein 5 (TXNDC5) were imported into Pathway Studio (demo), and an interaction map was generated. Compendious molecular interaction pathway which linked PEBP1, TXNDC5 and interaction pathways and interferon γ (INFG). INFG could induce some complex molecular interaction in cells and impact on cell proliferation and apoptosis, and then could promote the formation of varioliform lesion.

A concept in cancer biology is that tumors arise and grow from some precancerous lesions as a result of the multiple changes of the genes or proteins which could influence the functions of cells *via* different molecular biological pathways. So it could be very important to find out these molecular changes and their functional pathways. The changes can be detected and analyzed in genomics and proteomics. A differential protein expression profile is a snapshot of the proteomics composition of a specific tissue at a specific time, which can be a key clue for further studies on the underlying mechanisms.

In this study, we identified 21 differentially expressed proteins in varioliform gastritis. However, none of these proteins (Table 2) had been reported in previous studies on this disease. We used a 5-fold cut-off according to the previous studies[9,10], and only found 21 differentially expressed proteins between varioliform gastritis and normal mucosa in the 2-DIGE study. We believe that some major molecular mechanisms underlying the disease should be implicated. There are also some methodological discrepancies in the process of our proteomic study, including the sample collection, the separation and identification of proteins and the analysis of results. Some low-abundance protein spots could not be displayed clearly, which should be further analyzed by a more advanced method.

PEBP1 expression was strong in normal mucosa, but significantly downregulated in varioliform gastritis. An alternative name of PEBP1 was Raf kinase inhibitory protein (RKIP) that belongs to the PEBP family. It is an inhibitor of the Raf/MEK/MAP kinase signaling cascade and is a suppressor of cancer metastasis[11]. Some researches[12,13] have confirmed that PEBP1 regulates activation of MAPK, NF-κB and G protein coupled receptors. As a modulator of key signaling pathways, PEBP1 affects various cellular processes, including cell differentiation, the cell cycle, apoptosis and cell migration. To date, emerging evidence[14-21] suggests that PEBP1 plays a crucial suppressing role in tumorigenesis and metastasis of prostate cancer, ovarian cancer, cervical cancer, colorectal cancer, liver cancer and breast cancer. It represents a novel effector of signal transduction pathways leading to apoptosis and a prognostic marker of the pathogenesis of human cancer cells and tumors. Chatterjee *et al*[22] have examined the expression patterns of PEBP1 and STAT3 in samples from 143 patients with gastric adenocarcinoma using tissue microarrays. Their results indicate the predictive and protective role of PEBP1 expression in gastric adenocarcinoma of the intestinal subtype. Downregulated expressions of PEBP1 could decrease patients' survival. Collectively, these studies suggest that the PEBP1 or RKIP gene, as a poten-

tial tumor suppressor gene, is involved in gastric cancer initiation and progression, and expression of PEBP1 could be downregulated at initiation of tumorigenesis. Our results confirmed that PEBP1 expression was downregulated in varioliform gastritis compared with that of normal mucosa. We, therefore, postulate that this downregulation of PEBP1 might denote a step of the potential canceration.

TXNDC5 was significantly upregulated in varioliform gastritis although its expression remained in normal mucosa. TXNDC5 was first detected by 2-DE analysis of the luminal environment of the endoplasmic reticula of hepatic tissues in 2003[23]. As a novel PDI-like protein, TXNDC5 was highly expressed in endothelial cells. This tissue-specific expression is unusual among members of the PDI family. Sullivan *et al*[24] have confirmed that TXNDC5 could protect endothelial cells from stress-induced apoptosis. In contrast to PDI, which is essential for the survival of endothelial cells in the resting as well as the stressed state, TXNDC5 protects endothelial cells only under conditions of stress. They have found that loss of TXNDC5 results in reduced secretion of adrenomedullin and endothelin-1 together with a reduction in membrane-bound CD105, while TXNDC5 is essential for folding of CD105. The results of Edman's and Freedman's researches[25,26] suggested that TXNDC5 could play important roles in antioxidative injury, antianoxia-induced apoptosis, and promotion of proliferation in cells. Some recent studies showed that upregulation of TXNDC5 was found in tumors of the cervix, uterus, stomach and lung[24]. Nissom *et al*[27] found that a variant of the TXNDC5 gene was upregulated in poorly differentiated hepatocellular carcinoma (HCC) but unchanged in well-differentiated HCC. According to these reports, we think that TXNDC5 gene could be a tumor-enhancing gene, but the detailed biological roles of TXNDC5 in varioliform gastritis and gastric cancer remain to be elucidated. The upregulation of TXNDC5 in varioliform gastritis suggests that this disease could be related to gastric cancer, with higher risk than what was thought before.

The NF-κB and MAPK signaling pathways regulate growth in many tumors or inflammation, suggesting the cooperative role of these two pathways in the regulation of cell proliferation and apoptosis. *H. pylori* is known to be the cause of most gastric diseases, including both peptic ulcer disease and gastric cancer. Fox *et al*[28] think that the induction by *H. pylori* of cytokines and chemokines and growth-related genes is mediated by the MAPK and NF-κB signaling pathways, and Shibata *et al*[29] and Lee *et al*[30] have confirmed this conclusion. Kacar *et al*[31] and Chen *et al*[32] found that MAPK signaling pathway could be a causative factor in the alterations of the gastric mucosa infected by *H. pylori* and MAPK activation seems to be a significant and persistent event in the *H. pylori*-induced neoplastic transformation. IFN-γ acts through distinct cell surface receptors and induces transcription of an overlapping sets of genes. MHC class I genes are inducible by this interferon. IFN-γ is the gastric mucosal immunological reaction produced by T helper cells when gastric mucosa is infected by *H. pylori*[33-35]. It could induce the changes of TXNDC5 or PEBP1 and impact on the NF-κB and MAPK signaling pathways in our molecular interaction network of varioliform gastritis. We supposed that varioliform gastritis should be the results of a series of molecular interactions induced by IFN-γ or other molecules as an immunological reaction against microorganism infection according to previous reports and our research. But most of the previous studies focused on *H. pylori*, and the researches on other pathogens were very limited. So there could be some other bacteria or viruses which could induce an analogous immunological reaction against *H. pylori* in the gastric mucosa of varioliform gastritis patients without *H. pylori* infection.

In summary, our study showed a differential protein expression profile of varioliform gastritis compared with that of matched normal mucosa. The candidate proteins may confirm the previous conclusion that varioliform gastritis is one of the major precursor diseases of gastric cancer. The risk of potential canceration could be higher than what was thought previously, so effective treatment strategies should be studied and adopted for this disease in the future.

COMMENTS

Background

Varioliform gastritis is a chronic gastritis with a potential of developing into gastric cancer. To date, the etiopathogeny of the disease is unclear. So it is crucial to elucidate the molecular mechanism underlying the disease for preventing gastric cancer.

Research frontiers

At present, the researches on varioliform gastritis focused mostly on endoscopic diagnosis and treatment or clinical feature. The reports on the molecular mechanism of the disease are very limited. As a new field of clinical proteomics is emerging, many new techniques have been developed to identify functional molecules or biomarkers of cancer and other diseases.

Innovations and breakthroughs

In this research, a differential protein expression profile of varioliform gastritis was indicated compared with that of matched normal mucosa. The important differential proteins and potential signal pathways have been provided for the future studies.

Applications

The results of this study provided some valuable clues for elucidating the molecular mechanism of varioliform gastritis and the relationship between the disease and gastric cancer. Some potential biomarkers were indicated for the early diagnosis of gastric cancer and therapeutic targets for this tumor.

Terminology

Varioliform gastritis: a special kind of chronic gastritis characterized by nodules, thickened fugal folds and erosions. Although it is a very common gastritis, its features appear to be unusual and different from those seen in chronic gastritis.

Peer review

The authors used proteomic techniques to identify differences in protein expression patterns in normal gastric mucosa *vs* mucosa characterized by varioliform gastritis. The study is well designed, represents a large amount of work, and will potentially be very helpful to further studies in the field of cancer research and treatment.

Abstract

AIM: To evaluate tracking of magnetically labeled mesenchymal stem cells (MSCs) after intraportal transplantation.

METHODS: Mononuclear cells were isolated from bone marrow aspirates of pigs by density gradient centrifugation, cultured and expanded, after which, they were incubated with super paramagnetic iron oxide (SPIO). Prussian blue staining was performed to highlight intracellular iron. To establish swine models of acute liver injury, 0.5 g/kg D-galactosamine was administrated to 10 pigs, six of which were injected *via* their portal veins with SPIO-labeled MSCs, while the remaining four were injected with unlabeled cells. Magnetic resonance imaging (MRI) was performed with a clinical 1.5T MR scanner immediately before transplantation and 6 h, 3 d, 7 d and 14 d after transplantation. Prussian blue staining was again performed with the tissue slices at the endpoint.

RESULTS: Prussian blue staining of SPIO-labeled MSCs had a labeling efficiency of almost 100%. Signal intensity loss in the liver by SPIO labeling on the FFE (T2*WI) sequence persisted until 14 d after transplantation. Histological analysis by Prussian blue staining confirmed homing of labeled MSCs in the liver after 14 d; primarily distributed in hepatic sinusoids and liver parenchyma.

CONCLUSION: MSCs were successfully labeled with SPIO *in vitro*. MRI can monitor magnetically labeled MSCs transplanted into the liver.

Key words: Magnetic resonance imaging; Mesenchymal stem cells; Super paramagnetic iron oxide; Stem cell transplantation

INTRODUCTION

In recent years, cell transplantation has had the advantages of lower cost, lower risk, and simpler manipulation of the procedure compared with orthotopic liver transplantation. A large body of evidence has suggested that mesenchymal stem cells (MSCs) could differentiate into liver-like cells with partial hepatic functions under appropriate environmental conditions *in vivo* and *in vitro*[1,2]. Given that autolo-

gous cell transplantation helps prevent immunological rejection, which is always a problem for orthotopic liver transplantation, MSCs can be regarded as seeding cells for transplantation in relation to liver diseases.

The major issue in liver cell transplantation is monitoring migration, distribution, and differentiation of the transplanted cells. Conventional tissue slicing is unable to distinguish between transplanted donor cells and the recipient cells, therefore, the tissue or organ has to be removed at certain time points and processed with special biochemical procedures to visualize the tagged cells. However, these tagging methods require *in vitro* preparation and examination of histological materials, which are unsuitable for noninvasive and repeated monitoring of *in vivo* transplanted cells under clinical conditions. Therefore, more recent research has focused on *in vivo* real-time tracking and detecting the fate of transplanted cells by using appropriate imaging technologies[3].

The present study had two purposes. First, we incubated swine autologous MSCs with super paramagnetic iron oxide (SPIO) *in vitro*, followed by stem cell transplantation performed *via* the portal vein in acutely injured liver models. Second, we investigated the characteristics of magnetically labeled swine MSCs by magnetic resonance imaging (MRI), as well as intrahepatic dynamic distribution.

MATERIALS AND METHODS

Animal care

Ten outbred white swine of either sex weighing 15-20 kg each were maintained under conventional conditions in the Laboratory Animal Center of the Affiliated Drum Tower Hospital of Nanjing University Medical School. All animal procedures were approved by the Animal Care Ethics Committee of Nanjing Drum Tower Hospital.

MSC isolation, culture and characterization

Porcine MSCs were isolated by bone marrow aspirates from the iliac crests of the animals as previously described, with slight modification[4]. Mononuclear cells were collected by gradient centrifugation over a Ficoll histopaque layer (20 min, 400 *g*, density 1.077 g/mL) (TBD, China) and seeded at a density of 1×10^6 cells/cm^2 in growth medium that contained low-glucose Dulbecco's modified Eagle's medium (DMEM-LG; GIBCO, USA) supplemented with 10% fetal bovine serum (FBS; GIBCO, USA), penicillin (100 IU/mL) and streptomycin (100 μg/mL). The non-adherent cells were removed after the first 24 h and changed every 3-4 d thereafter. When the cells reached 80% confluence, they were detached using 0.25% Trypsin-EDTA (GIBCO, USA) and re-plated at a density of 1×10^4 cells/cm^2 for expansion. Surface marker identification of the cultured MSCs was performed with a FACScan (Becton Dickinson, Franklin Lakes, NJ, USA) by fluorescein isothiocyanate (FITC)-labeled monoclonal antibody staining to CD45 (Antigenix America, Huntington Station, NY, USA) and phycoerythrin (PE)-conjugated antibodies against CD29 (VMRD, Pullman, WA, USA), CD44 and CD90 (Becton Dickinson). Isotypic antibodies served as the control.

MSCs were labeled with Feridex (Advanced Magnetics, Cambridge, MA, USA), as previously described[5]. Briefly, the polyamine poly-l-lysine (PLL) hydrobromide (Sigma, St Louis, MO, USA) was used as the transfection agent. A stock solution of PLL (1.5 mg/mL) was added to DMEM at a dilution of 1:1000 and mixed with Feridex (50 μg/mL) for 60 min at room temperature on a rotating shaker. MSCs of passage 5 were added to the culture medium that contained the Feridex-PLL complex, so that the final concentrations of Feridex and PLL were 25 μg/mL and 0.75 μg/mL, respectively. The cells were placed into six-well plates (Corning, NY, USA) overnight at 37℃ in a 95% air/5% CO_2 atmosphere.

Prussian blue staining

After being incubated overnight with the Feridex-PLL complex, the MSCs were washed three times to remove excessive contrast agent. For Prussian blue staining, which indicates the presence of iron, the coverslip samples were fixed with 4% paraformaldehyde for 30 min, washed, incubated for another 30 min with 2% potassium ferrocyanide in 6% hydrochloric acid, washed again, and counterstained with nuclear fast red.

Cell viability assay

Firstly, MSCs were inoculated in 96-well plates at 1×10^4 cells per well at 37℃ in a 95% air/5% CO_2 atmosphere. Twenty-four hours later, final concentrations of Feridex in the Feridex-PLL complex (25, 50, 100 and 200 μg/mL) were added to each well with 11 other duplicates and incubated overnight. The remaining cells, which were not labeled with the complex and served as control cells, were kept under identical conditions. The magnetically labeled and non-labeled cells were then maintained in fresh culture medium for 2 d and washed twice. Ten microliters of cholecystokinin octapeptide (CCK-8; Dojindo Laboratories, Kumamoto, Japan) was added per well for 4 h. The absorbance was then measured at a wavelength of 450 nm.

Swine model of acute liver injury

Under general anesthesia with mechanical ventilation *via* an endotracheal tube, animals were administered a dose of 0.5 g/kg of D-galactosamine (D-Gal; Sigma) dissolved in 5% glucose solution, *via* the external jugular vein. Venous blood samples were drawn 6, 12 and 24 h after the operation for biochemical analysis.

Intraportal transplantation of MSCs

Animals were randomly assigned to either control ($n = 4$) or experimental (liver injured) groups ($n = 6$). The abdomens of the liver-injured animals were opened to expose the portal vein, and approximately 1×10^7 labeled MSCs suspended in 2 mL DMEM were slowly injected into the portal vein. A 30-gauge needle was used for the procedure. The pinhole at the injection site was pressed for hemostasis. Thereafter, the laparotomy incision was enclosed

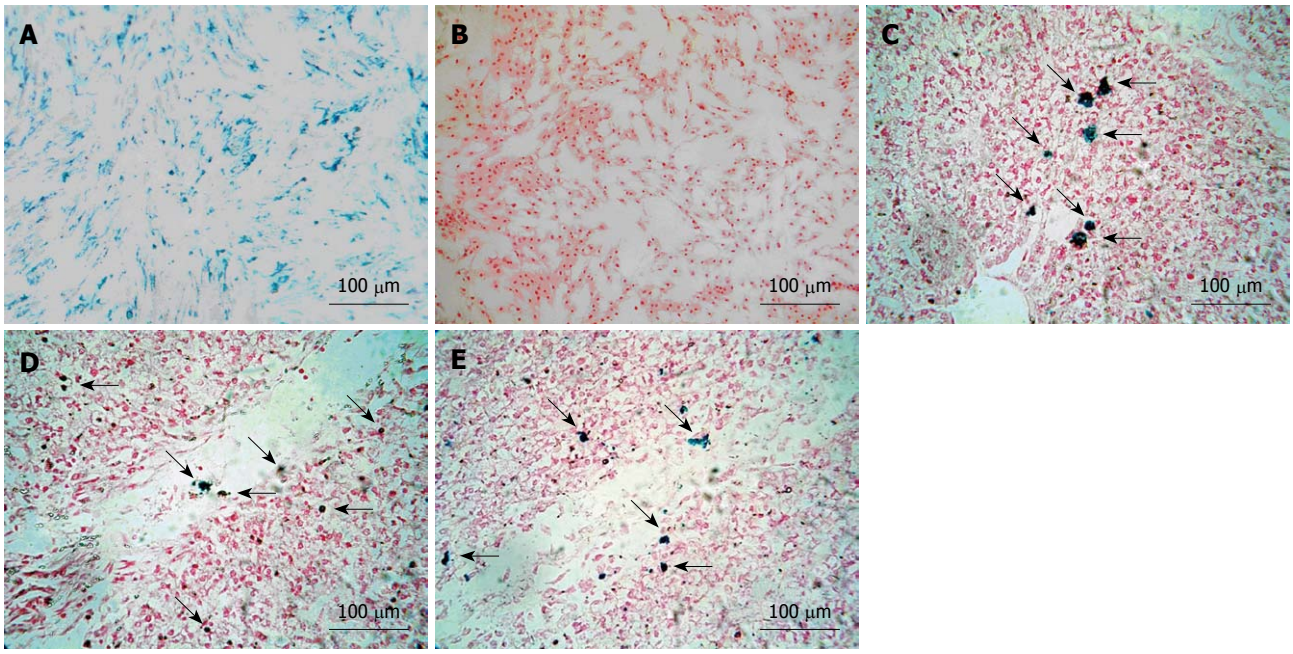

Figure 1 Characterization of labeled mesenchymal stem cells. A: Almost 100% of labeled mesenchymal stem cells (MSCs) were positive for Prussian blue staining (magnification 100 ×); B: No blue particles were observed in unlabeled group (magnification 100 ×); C-E: Prussian blue staining for liver tissue slicing displayed several blue-positive cells scattering in and around sinusoids on day 3 and 7, and the experimental group at the endpoint of the experiment (magnification 100 ×). Arrows indicate Prussian blue positive MSCs.

in layers. The control group underwent the identical procedure except that the injected cells were unlabeled.

MRI and data acquisition

Animals underwent MRI of the liver immediately before, and 3, 7 and 14 d after injection of cells. MRI was performed with a 1.5-T imaging device (Philips Medical Systems, Eindhoven, the Netherlands). The pig was anesthetized and placed supine on a plastic flat plate. The scanning sequence was as follows: (1) SE: T1WI, TR 120 s, TE 14 ms; (2) FSE: T2WI, TR 3000 ms, TE 96 ms; and (3) FFE: T2*WI, TR 485 ms, TE 14.0 ms, flip angle, 18°.

Histological assessment

Two weeks after cell transplantation, animals were sacrificed for histological examination. Liver tissues taken from both the control and experimental groups were fixed with 4% paraformaldehyde, embedded in paraffin, cut into 5-mm sections and stained with hematoxylin and eosin (HE) as well as Prussian blue for examination under a light microscope.

Statistical analysis

Data were shown as mean ± SE. The two-tailed unpaired Student's *t* test was used to evaluate the statistical significance of differences which was set with a *P* value less than 0.05.

RESULTS

MSC phenotype

Twenty-four hours after first seeding, MSCs could be seen in newly formed colonies. Observed under the microscope, the MSCs rapidly grew fibroblast-like cells with a single nucleus. After the first passage, they looked like spindles or asters with a slim body. At passage 5, however, most of the miscellaneous cells were eliminated, and the remaining uniform fibroblast-like cells were MSCs. The expression of different cell surface markers, including CD29, CD44, CD45 and CD90, of MSCs from passage 5 was determined by flow cytometry; the results of which showed that > 90% of MSCs of passage 5 were positive for CD29, CD44 and CD90, but negative for CD45 (data not shown).

Characterization of labeled MSCs

MSCs stained with Prussian blue showed results (blue particles) in all labeled cells. The labeling rate was approximately 100%, which was calculated under a light microscope *via* counting the numbers of positive cells in five random fields (Figure 1A). In contrast, no blue particles were observed in the unlabeled group (Figure 1B).

Proliferation of labeled MSCs

The growth curve of CCK-8 with Feridex-PLL labeled MSCs showed that the cellular proliferation of the 25 and 50 μg/mL subgroups were not significantly influenced by different concentration ($P > 0.05$). Figure 2 shows that MSCs labeled with higher concentrations of complex were somewhat inhibited in proliferation, which indicated that < 50 μg/mL Feridex-PLL would be suitable for MSC labeling in future transplantation.

Establishment of acute liver injury model

Acute liver injury was effectively induced in all animals. Serum alanine aminotransferase (ALT), aspartate amino-

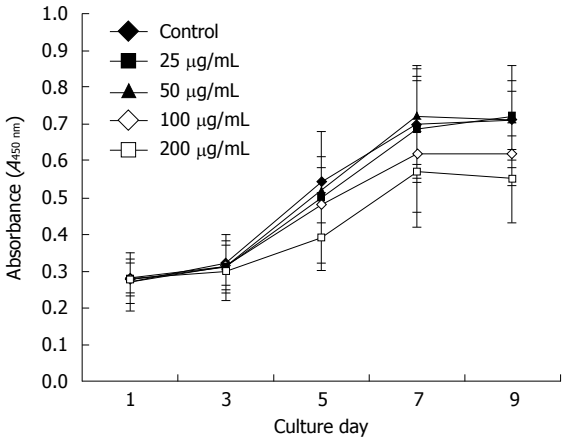

Figure 2 Growth curve of CCK-8 with Feridex-poly-l-lysine-labeled mesenchymal stem cells. Cellular proliferation of 25 and 50 μg/mL subgroups were not significantly influenced ($P > 0.05$). Mesenchymal stem cells (MSCs) labeled with higher concentrations of complex were somewhat inhibited, which indicated that < 50 μg/mL Feridex-poly-l-lysine would be suitable for MSC labeling.

transferase (AST) and bilirubin levels were all significantly and progressively elevated 6 h after D-Gal induction (Table 1, $P < 0.05$). The porcine model clinically presented listlessness, loss of appetite and xanthochromia. Liver tissue samples from the injured model group after 24 h injection of D-Gal demonstrated severe hepatic necrosis in 60%-70% of the lobule, sinusoidal congestion, vacuolization, trabecular fragmentation, and granulocytic infiltration (Figure 3). Twenty-four hours after administration of D-Gal, the animals were ready for transplantation (Table 1).

MR tracking of magnetically labeled MSCs

Signal intensity decreased 6 h after intrahepatic transplantation of labeled MSCs on the FFE sequence, but gradually approached close to normal on day 14 (Figure 4). For the control group, there was no visible difference at each time point after transplantation compared with before.

Histological demonstrations

The Prussian blue staining demonstrated several blue-positive cells scattered in and around the sinusoids in the experimental group on day 3 and 7 and the endpoint of experiment (Figure 1C-E), which indicated the presence of the magnetically labeled MSCs transplanted into the liver.

DISCUSSION

Bone marrow-derived MSCs are multipotent adult stem cells of mesodermal origin with the potential for self renewal. Because MSCs have the ability to differentiate into cells of multiple organs/systems such as hepatocytes, osteoblasts, chondrocytes, adipocytes and myocytes under appropriate stimuli[1,2,6-9], they have generated considerable interest for their potential use in regenerative medicine and tissue engineering. Given the ease of their isolation, extensive expansion rate and differentiation potential, as well as their immunosuppressive properties, MSCs may be suitable candidates for seed cells for hepatocyte transplantation, in addition to being potential carrier cells for gene therapy[10], which holds a promising future in the treatment of acute or chronic liver failure and metabolic liver diseases. Despite their important potential, however, the detailed processes involved in MSC implantation, migration, and differentiation in the liver remain to be elucidated.

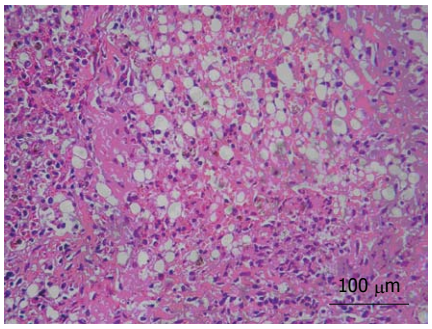

Figure 3 Histology of acutely injured liver tissue. Liver tissue samples from the injured model group after 24 h injection of D-galactosamine demonstrated severe hepatic necrosis of 60%-70% of the lobule, sinusoidal congestion, vacuolization, trabecular fragmentation, and granulocytic infiltration of the portal space and septa (magnification 100 ×).

Table 1 Biochemical parameters before and after the injection of D-galactosamine

	Pre-injection	6 h after injection	24 h after injection
ALT (U/L)	31.2 ± 2.6	87.5 ± 13.2	181.9 ± 12.8
AST (U/L)	28.9 ± 3.8	134.0 ± 7.8	564.8 ± 89.7
TBIL (μmol/L)	3.2 ± 0.45	26.7 ± 3.2	43.0 ± 2.9

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; TBIL: Total bilirubin.

Previous tissue slicing experiments have been unable to monitor the dynamic changes of transplanted cells in the living body. Accordingly, a noninvasive and living labeling technique is needed with respect to MSC intrahepatic transplantation. With the advent of molecular imaging technologies, *in vivo* real-time tracking and detecting the fate of transplanted stem cells may become a reality[3,11,12]. Cells for transplantation have been labeled with MR contrast agents since the beginning of the 1990s. In this regard, MRI appears most promising for dynamically monitoring *in vivo* cell migration after transplantation, due to its well known properties of relative long-term imaging, high spatial resolution, and sharp contrast[13]. Currently, SPIO MRI contrast agents have been most widely used for tracking transplanted cells in various organs because of their strong signal attenuation properties[14-18]. In particular, dextran-coated SPIO nanoparticles have been approved by the US Food and Drug Administration for use in hepatic reticuloendothelial cell imaging, and ultrasmall SPIOs are in phase Ⅲ clinical trials for use as blood pool agents or for use with lymphography[19-21]. However, such contrast agents cannot be used to label efficiently stem cells *in vitro* in their native unmodified form[22]. By conjugating antigen-specific internalizing monoclonal antibodies to the surface dextran coating, cells can be magnetically labeled

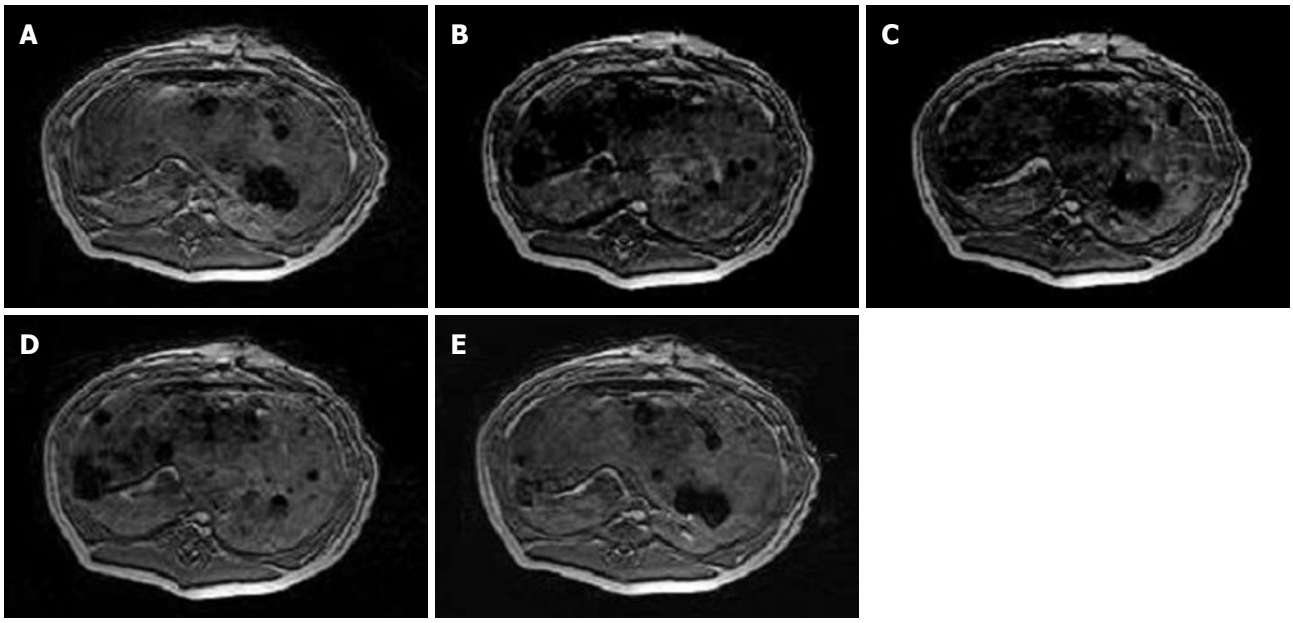

Figure 4 Magnetic resonance imaging of Feridex-poly-l-lysine labeled mesenchymal stem cells in the liver. A: No loss of signal in the liver before transplantation; B: Significant signal intensity loss was observed in labeled mesenchymal stem cells on FFE sequences 6 h after transplantation; C, D: Attenuation of signal loss appeared over time; E: T2*-weighted images gradually approached to the normal level at the endpoint of the study.

during their normal expansion in culture medium. In the present study, we used PLL as a transfection agent to magnetically label MSCs *in vitro* by the establishment of a Feridex-PLL complex through electrostatic interactions. This encourages cellular membrane endocytosis and transportation of Feridex into endosomes without requiring novel synthesis or covalent binding of proteins or antibodies to the dextran coating. Our results indicated that the labeling efficiency in our study approximated to 100% as expected. Subsequent analysis of the inhibitory effects of different concentrations of Feridex-PLL complex on MSCs revealed < 50 μg/mL Feridex was a relatively safe and effective dose for MSC labeling, which was suitable for transplantation study.

So far, most studies concerning MRI of grafted stem cells have been applied to animal brains, spines and hearts[17,23,24]. MRI techniques offer the possibility of tracking labeled cells *in vivo* noninvasively and repeatedly during extended study periods. The potential of MRI for future clinical interventions within the realm of regenerative cell therapy has been elegantly demonstrated in previous studies, and MRI fluoroscopy has been used to guide the delivery of MR-labeled adult stem cells into damaged organs. In our study, migration and retention of porcine MSCs after intraportal transplantation were demonstrated by using *in vivo* MRI. Significant signal intensity loss was observed in labeled MSCs on FFE sequences 6 h after transplantation. Thereafter, it gradually approached normal levels on day 14. The loss of signal could be attributed to either biodegradation of the contrast agent, the process of cellular division, or cellular migration to neighboring organs. To confirm the long-term results, Prussian blue staining was performed to demonstrate positive cells in liver tissue slices at the endpoint of the experiment. Furthermore, the dispersed distribution of labeled MSCs confirmed that the acute injured liver model may offer an ideal microenvironment for cell recruitment and implantation.

In summary, the present study incubated porcine MSCs with Feridex-PLL complex *in vitro*, and *in vivo* real-time tracking and detecting of magnetically labeled MSCs were manipulated by MRI in models of acute liver injury. Future research will focus on the optimized numbers of transplanted MSCs, distribution beyond injured liver, as well as safety and therapeutic effects concerning liver regeneration after MSC intraportal transplantation. In addition, our newly established co-culture system for hepatocytes and MSCs for cell transplantation and bioartificial liver devices should also be monitored[25].

COMMENTS

Background

In recent years, cell transplantation has had the advantages of lower cost, lower risk, and simpler manipulation of the procedure compared with orthotopic liver transplantation. Autologous cell transplantation helps prevent immunological rejection, which is always a problem for orthotopic liver transplantation. Moreover, a large body of evidence has suggested that mesenchymal stem cells (MSCs) differentiate into liver-like cells with partial hepatic functions under appropriate environmental conditions *in vivo* and *in vitro*. Therefore, MSCs could be regarded as seeding cells for transplantation in relation to liver diseases.

Research frontiers

One of the major issues in liver cell transplantation is monitoring migration, distribution, and differentiation of the transplanted cells. Present tagging methods require *in vitro* preparation and examination of histological materials, which are unsuitable for noninvasive and repeated monitoring of *in vivo* transplanted cells under clinical conditions. Therefore, more recent research

has focused on *in vivo* real-time tracking and detecting the fate of transplanted cells by using appropriate imaging technologies.

Innovations and breakthroughs

The authors sought to label MSCs *in vitro* with super paramagnetic iron oxide (SPIO) and to monitor the labeled cells with magnetic resonance imaging (MRI). Through this research, they found a new invasive and repeatable monitoring method.

Applications

This method of labeling and monitoring cells could be applied to research in cell transplantation. In future, it could be considered as an invasive and repeatable monitoring method for clinical cell transplantation.

Terminology

SPIO is an MRI contrast agent that shows a high signal during imaging.

Peer review

In this study, authors successfully showed the use of swine mesenchymal stem cells in an acute liver injury model. The study should be considered as a brief report as it is a nice piece of information.

Abstract

AIM: To investigate the interstitial cells of Cajal (ICC) number using a new rat model.

METHODS: Sprague-Dawley rats were assigned to two groups. The first group received gavage with *Campylobacter jejuni* (*C. jejuni*) 81-176. The second group was gavaged with placebo. Three months after clearance of *Campylobacter* from the stool, precise segments of duodenum, jejunum, and ileum were ligated in self-contained loops of bowel that were preserved in anaerobic bags. Deep muscular plexus ICC (DMP-ICC) were quantified by two blinded readers assessing the tissue in a random, coded order. The number of ICC per villus was compared among controls, *Campylobacter* recovered rats without small intestinal bacterial overgrowth (SIBO), and *Campylobacter* recovered rats with SIBO.

RESULTS: Three months after recovery, 27% of rats gavaged with *C. jejuni* had SIBO. The rats with SIBO had a lower number of DMP-ICC than controls in the jejunum and ileum. Additionally there appeared to be a density threshold of 0.12 DMP-ICC/villus that was associated with SIBO. If ileal density of DMP-ICC was < 0.12 ICC/villus, 54% of rats had SIBO compared to 9% among ileal sections with > 0.12 ($P < 0.05$). If the density of ICC was < 0.12 DMP-ICC/villus in more than one location of the bowel, 88% of these had SIBO compared to 6% in those who did not ($P < 0.001$).

CONCLUSION: In this post-infectious rat model, the development of SIBO appears to be associated with a reduction in DMP-ICC. Further study of this rat model might help understand the pathophysiology of post-infectious irritable bowel syndrome.

Key words: Post-infectious irritable bowel syndrome; Bacterial overgrowth; Interstitial cells of Cajal; Campylobacter

INTRODUCTION

A recent series of studies suggested a link between small

intestinal bacterial overgrowth (SIBO) and irritable bowel syndrome (IBS)[1,2]. The latest of these is a study that compared jejunal cultures between IBS patients and controls[3]. In that study, the number of coliform bacteria was higher in the small bowel of IBS compared to healthy controls.

Another potential bacterial pathogenesis in IBS is related to the development of IBS symptoms after acute gastroenteritis [post-infectious IBS (PI-IBS)]. In a recent meta-analysis, almost 10% of normal subjects developed IBS after an incident of bacterial gastroenteritis[4]. Initial research in this area focused on possible inflammatory events, as suggested by increased lymphocyte counts in the rectal mucosa[5-7]. Recent evidence has linked post-infectious events to the development of SIBO in a rat model of PI-IBS[8]. In this model, rats exposed to *Campylobacter jejuni* (*C. jejuni*) have persistent altered stool form that is linked to the development of SIBO in 27% of rats, based on quantitative polymerase chain reaction (PCR). This finding in rats suggests that, at least in the case of *C. jejuni*, a possible mechanism for PI-IBS could be the development of SIBO. How SIBO develops in this model is not known. In humans, it has been speculated that SIBO in IBS patients is related to a reduced number of fasting migrating motor complexes[9]. This has been a recognized cause of SIBO since 1977[10].

The important role of interstitial cells of Cajal (ICC) in gastrointestinal physiology has been elucidated over the past 10-20 years. ICC are required for normal intestinal motility. Their role as intestinal pacemakers has been established in a number of model systems[11-13]. Labeling ICC with anti-Kit antibodies provides an opportunity to evaluate ICC of gastrointestinal muscles in patients with various motility disorders. Reduced numbers or loss of ICC is associated with several motor dysfunctions, including achalasia, intestinal pseudoobstruction, infantile pyloric stenosis, diabetic gastroparesis, ulcerative colitis, and slow-transit constipation[14-19]. Loss of ICC also interferes with electrical pacemaker activity, slow-wave propagation, and gastrointestinal motor neurotransmission[12,13,20,21].

Given the significant role of ICC in modulating the neuromuscular activity of the gut, we sought to investigate whether the development of SIBO in the rat model infected with *C. jejuni* is associated with reduction in intestinal ICC.

MATERIALS AND METHODS

Development of post-infectious rats

After confirming no pre-existing presence of *C. jejuni* in their stools, 66 outbred Sprague-Dawley rats were randomized (in a 1:1 ratio) into two groups. One group was gavaged with a 1 mL solution containing *C. jejuni* 81-176 at 10^8 CFU/mL (C+ rats) in Brucella broth. The control rats were gavaged with an identical solution without *C. jejuni* (C- rats).

Following gavage, all the rats were housed at two per cage. However, the rats receiving *Campylobacter* (C+) were housed separately from the control (C-) rats to avoid the possibility of cross contamination of the *C. jejuni* infection between the two groups.

In the first 3 d after gavage, stool was collected from both groups to verify that intestinal colonization in C+ rats had occurred. It was also used to confirm the absence of infection in C- rats. Stool was later obtained in the C+ group on days seven and 14 after infection and then every 2 wk until two consecutive negative cultures for *C. jejuni* were confirmed.

After 90% of the C+ rats no longer had detectable *C. jejuni* in the stool, they were considered to be in the post-infectious time period. At this point, they were housed for three additional months. During this time, both groups were treated equally with respect to food, water, and environment. In the 3 d just prior to euthanasia (at 3 mo into the post-infectious period) stool was collected from each rat and graded blindly according to an *a priori* stool form grading score. This score was based on whether or not there was loose or normal stool in a blinded evaluation. Any loose stool was considered abnormal. The stool was also cultured to determine if there was any lingering case of *Campylobacter* (C+).

Campylobacter gavage

The *C. jejuni* 81-176 strain used in the gavage of the rats was obtained from freezer stocks, plated on selective media, and incubated for 36-48 h under microaerophilic conditions at 42℃ to create a bacterial lawn. This lawn was then harvested from these plates and suspended in Brucella broth. The concentration of bacteria was estimated spectrophotometrically and confirmed *via* serial dilution and plating on selective media. In the 30 min prior to *Campylobacter* gavage, rats were gavaged with a 1 mL solution of 5% sodium bicarbonate using a ball-tipped inoculating needle. This was done to neutralize gastric acid to increase the likelihood of intestinal colonization of the pathogen. Subsequently, a 1 mL suspension of *C. jejuni* in Brucella broth (5×10^8 CFU/mL) was administered by gavage.

Bowel sampling

Three months after clearance of *Campylobacter* from the stool, fresh stool was obtained from all rats. This was used to determine the presence or absence of prolonged *C. jejuni* colonization. Stool was also qualitatively evaluated for stool form as described above.

Rats were then euthanized. Immediately following euthanasia, a laparotomy was performed whereby precisely determined segments of the ileum, jejunum, and duodenum were obtained, as previously described[8]. The first 2 cm segment at each location was a ligated self-contained loop of bowel. Sutures were placed on either side to prevent exposure to air. Samples were kept at 4℃ in an anaerobic bag for transport. These self-contained loops were then used to extract bacterial contents for the determination of bacterial number using quantitative

PCR, as previously described[8]. The quantity of bacteria in these segments was compared between control rats and rats 3 mo after recovery from *Campylobacter*. SIBO was considered to be present when bacterial count in the *Campylobacter* treated rats exceeded two standard deviations above the mean count found in the control group.

In each rat, a 2 cm segment of small bowel immediately adjacent to the closed loop of small bowel was resected and sent for bacterial quantitation. This second piece of bowel was opened longitudinally along the mesenteric border and placed in a solution of 10% formalin (VWR, West Chester, PA). After paraffin and mounting, the tissue was stained.

Immunohistochemistry

Rats were then divided into three groups based on the presence or absence of *Campylobacter* and SIBO. The three groups were a random selection of eight control rats (C-), eight *Campylobacter*-infected rats that were found to have bacterial overgrowth (C+/SIBO+), and eight randomly selected rats that received *Campylobacter* gavage but did not develop bacterial overgrowth (C+/SIBO-). Sections from each paraffin block were stained immunohistochemically using Polyclonal Rabbit Anti-Human CD117, c-kit (Dako-Cytomation, Carpinteria, CA). The positive control used to test the quality of the stain was a c-kit positive gastrointestinal stromal tumor. ICC were quantified by two blinded readers assessing the tissue in a random, coded order. The number of ICC was evaluated in the region of the deep muscle plexus ICC (DMP-ICC) according to the number of villi. The number of DMP-ICC per villus was compared among controls, C+/SIBO-, and C+/SIBO+.

Statistical analysis

Statistical comparisons for the number of DMP-ICC per villus were made by one-way analysis of variance among three groups and differences from controls was further analyzed using the Wilcoxon Rank-Sum Test. To compare the density threshold of ICC per villus, a Fisher's exact test was used. A P value of <0.05 was considered significant.

RESULTS

Campylobacter infection

Out of 66 rats used in the study, none had stool culture demonstrating *C. jejuni* before gavage. Of these rats, 33 were gavaged with vehicle (C-) and 33 rats received approximately 5×10^8 CFU *C. jejuni* 81-176 (C+). Six rats died of trauma secondary to gavage (three in each group). Among the remaining 30 rats that received *C. jejuni*, all had stool cultures that confirmed intestinal colonization by *C. jejuni*, and all but one rat cleared this colonization by 14 d.

As previously reported[8], C- rats were then used to determine the normal range of flora in the duodenum, jejunum, and ileum. Using these control data, eight C+ rats (27%) were found to have SIBO and were designated C+/SIBO+.

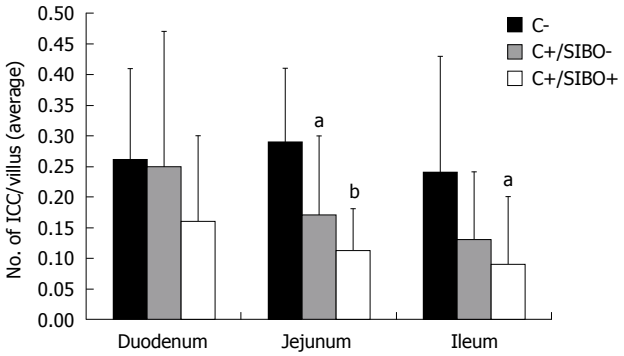

Figure 1 The number of interstitial cells of Cajal per villus in the duodenum, jejunum, and ileum. C-: Rats that received vehicle gavage; C+/SIBO-: Rats gavaged with *Campylobacter* but which did not develop small intestinal bacterial overgrowth (SIBO); C+/SIBO+: Rats gavaged with *Campylobacter* that later developed SIBO. $^aP < 0.05$, $^bP < 0.001$ *vs* control.

The number of DMP-ICC per villus

The number of DMP-ICC per villus was determined in C-, C+/SIBO-, and C+/SIBO+ rats. As shown in Figure 1, the rats with SIBO had the lowest number of DMP-ICC. This was more obvious in the jejunum and ileum than in the duodenum. Although there was a reduction of ICC in the C+/SIBO- group, this was not as great as was seen in the C+/SIBO+ group. Figure 2 shows representative examples of ileal biopsies in the C-, C+/SIBO-, and C+/SIBO+ groups, respectively. There was a reduced number of CD117 stained cells in the deep muscular plexus in the C+/SIBO+ group.

Density threshold of DMP-ICC

The number of DMP-ICC was then used to determine the level of ICC compared to SIBO. The data suggested that rats with < 0.12 ICC/villus were most likely to have SIBO. In fact, 54% of rats with a density < 0.12 ICC/villus in the ileum had SIBO compared to 9% in which DMP-ICC density was ⩾ 0.12/villus ($P < 0.05$). Using all levels of bowel, the density threshold was even more relevant. If the density of DMP-ICC/villus was < 0.12/villus in more than one of the three bowel segments, 88% had SIBO compared to 6% if the figure was ⩾ 0.12/villus ($P < 0.001$).

Differential effects of campylobacter on ICC

When the number of DMP-ICC was noted by segment of bowel according to whether rats received vehicle or *Campylobacter*, a significant difference was seen (Figure 3). There was a graded affect on DMP-ICC population, such that the greatest effect on reduction in DMP-ICC was in the distal small bowel. Reduction was also seen in the jejunum and ileum. This contrasted to the control group, whereby DMP-ICC density was uniform from proximal to distal small bowel.

DISCUSSION

In a previous study, we demonstrated that in a post-infectious rat model, altered bowel function persisted in

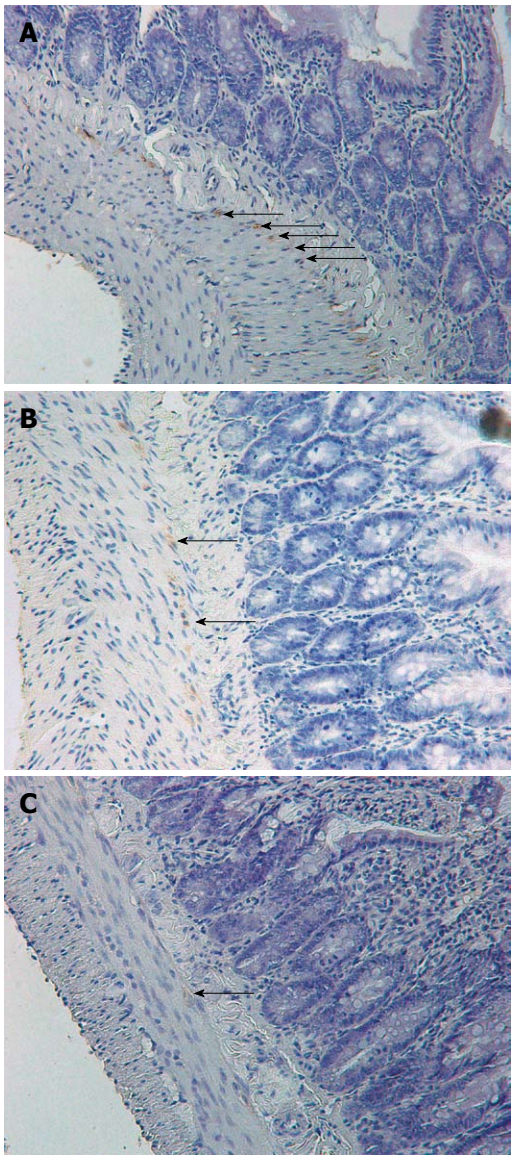

Figure 2 Interstitial cells of Cajal (arrows) in the ileum stained with CD117 (magnification 40 ×). A: Control rat; B: Rat exposed to *Campylobacter* that did not develop small intestinal bacterial overgrowth (SIBO), demonstrating persistent CD117 staining of interstitial cells of Cajal (ICC) cells; C: Rat exposed to *Campylobacter* that developed SIBO, demonstrating a reduction in CD117 staining of ICC cells. In this case, the staining is slight and the arrow indicates a "possible" stained cell.

a large number of rats even 3 mo beyond the clearance of the infection[8]. 27% of rats were found to have SIBO by quantitative PCR. SIBO correlated with those animals that had the most altered stool form. In this study, we attempted to further understand how SIBO could develop in this post-infectious rat model by studying the ICC. We found that long after *Campylobacter* infection had cleared, there was an apparent reduction in the number of DMP-ICC. This reduction appeared most evident in rats that developed SIBO after clearing *Campylobacter*. Furthermore, when the DMP-ICC density is less than 0.12/villus, SIBO is predicted to occur.

Six to seventeen percent of IBS patients believe their symptoms began after acute gastroenteritis[22], and the

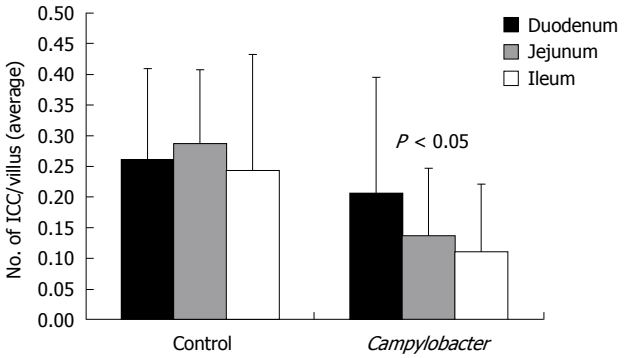

Figure 3 The effect of *Campylobacter* on interstitial cells of Cajal is greater in the distal small bowel (based on one-way analysis of variance).

incidence of PI-IBS following bacterial gastroenteritis is reported to be between 4%-31%[7,23-26]. In a 6-year follow up study, 57% of subjects thought to have developed PI-IBS still had altered bowel function consistent with IBS[27]. This growing body of literature on PI-IBS has led to two recent meta-analyses[4,28]. Both studies estimated that IBS has an incidence rate of about 10% after a case of acute gastroenteritis.

Two issues make PI-IBS very important in research on IBS pathophysiology. First, acute gastroenteritis is very common, and with a 10% rate of IBS development, this phenomenon might be very important in the development of IBS as a whole. Secondly, this is the first demonstration of a direct cause and effect relationship in the precipitation of IBS. How an acute gastrointestinal infectious process produces IBS in humans remains poorly understood, but some investigators have found residual inflammatory changes in the gut among patients with PI-IBS. These include increased numbers of lymphocytes, enteroendocrine cells, and mast cells in PI-IBS[5-7,26,29,30]. It is difficult to guarantee uniformity of population and pathogen in human studies of PI-IBS as they rely on studying a group of humans who emerge from an outbreak of infectious diarrhea. As a result, the study of inflammation and other factors in PI-IBS have been moving into animal models of PI-IBS.

One model that has been studied for some time is a *Trichinella spiralis* (*T. spiralis*)-infected mouse model. Beyond inflammatory changes, research in this model has looked at the long term effect on gastrointestinal motility. A major finding in this model was that, after resolution of the initial pathogen-related inflammatory response and elimination of the nematode from the gut, there was persistent intestinal neuromuscular dysfunction[31]. *T. spiralis*-induced mucosal inflammation led to prolonged effects on intestinal smooth muscle, and to colonic visceral hyperalgesia[32,33]. Although models such as this are vital to our understanding of PI-IBS, no model had been developed to investigate the more common human pathogens believed to cause the bulk of PI-IBS. These include *Campylobacter*, *Salmonella*, and *Shigella*, among others[34].

Two existing theories of bacterial events (post-infectious

and SIBO) now appear to be linked, based on a recent study suggesting that *C. jejuni* infection precipitates altered stool form and SIBO in a rat model[8]. How this occurs is currently unknown, although one study has demonstrated that acute *C. jejuni* infection alters intestinal myoelectric activity. In ileal segments of rabbits, alteration of action potential activity was seen in the small intestine infused intraluminally with *C. jejuni* and its cell-free filtrate[35]. In that study, the rabbits were monitored for only 24 h after exposure to *C. jejuni*. Unfortunately, no long term studies were done, and the cause of these effects was unknown.

An important cell in the control of gut motor function is the ICC. A growing list of animal models appears to support the notion that ICC are impaired in the presence of inflammation-induced changes in motor control. With acetic acid-induced inflammation, a reduction in resting membrane potential and the amplitude and duration of slow waves was related to the damage of the ICC in circular muscle cells in dogs[36]. In another study using the earlier described *T. spiralis*-model, damage to the structure of ICC networks within the region of the myenteric plexus was seen[32]. When jejunal inflammation was induced by *Nippostrongylus brasiliensis* in rats, changes in myenteric neurons, circular muscle cells, and ICC were observed[37].

In this study, we investigated whether the development of SIBO in the postinfectious rat model is related to the alteration of DMP-ICC populations, and whether this could in some way be linked to the development of IBS. In this study, *Campylobacter* gavaged rats were found to have a reduction of DMP-ICC density 3 mo after clearance of *Campylobacter*. More interesting was that the DMP-ICC density also corresponded to the development of SIBO. Rats with SIBO had the lowest DMP-ICC density. We could further evaluate a density threshold of DMP-ICC per villus which predicts SIBO. If the density of DMP-ICC/villus was not greater than 0.12 in more than one location among duodenum, jejunum, and ileum, 88% of the rats had SIBO. Although this finding does not examine the numerous contributions to gut motor function in addition to ICC, the possibility is raised that through some effects on ICC or neuromuscular mechanisms, acute gastroenteritis produces a long term effect that allows for the development of SIBO.

How *Campylobacter* affects DMP-ICC is unknown, but two possibilities include a toxin or a result of the initial acute inflammatory reaction. Although inflammation seems to be an obvious possibility, ICC's have a significant amount of "plasticity". Loss of ICC in pathological conditions does not always mean permanent injury. This "plasticity" of ICC was found in a murine model of partial bowel obstruction[38]. After the onset of the obstruction, hypertrophy of the smooth muscle layers and progressive loss of ICC orad to the site of obstruction were observed. Recovery of ICC and restoration of slow wave activity after removal of the obstruction were achieved within 30 d. In addition, injury to ICC due to inflammation is repaired in the course of time. Structural damage was observed in the network of ICC for 2 wk after *T. spiralis* infection. The structural changes were accompanied by aberrant pacemaker activity and abnormal slow waves. Sixty days after infection, motility and ICC recovered to normal values[32]. Unlike these two studies, we found a persistent decrease in the number of DMP-ICC 3 mo after clearance of infection. This was not due to any persistent *Campylobacter* colonization, as the pathogen was not detectable by culture in any location of the gastrointestinal tract. However, it is presumed that some event related to *Campylobacter* is responsible for this persistent reduction of DMP-ICC. This particular layer of ICC might be important. For example, in the W/W^{v} mouse, the DMP is intact and, despite loss of all other layers of ICC and loss of electrical slow wave, the migrating motor complex also remains intact[39]. Thus, DMP destruction might have an impact on mechanisms that protect against bacterial overgrowth.

An alternative explanation would be that SIBO is contributing to the reduction of ICC. Although not considered in this study, one means of determining this would be to provide antibiotic treatment to rats and count ICC after eradication of SIBO. The challenge with examining this concept is that it is difficult to identify SIBO in a live rat. This would make it difficult to know which animal should receive antibiotics.

It can be considered that ICC is just a marker of more global damage. In our study, smooth muscle was not evaluated. In a mouse model after acute nematode infection, altered neuromuscular function and long-lasting muscle contractility were noted[31,33]. The findings were considered as a model of PI-IBS. Further studies are needed to evaluate smooth muscle, toxin, and the effect of inflammation with *Campylobacter* infection.

In conclusion, rats with SIBO that developed 3 mo after *Campylobacter* gavage had a decreased number of ICC in the jejunum and ileum compared to control rats. Furthermore, the density threshold of ICC per villus appears to predict SIBO. These data suggest that a decrease in the number of ICC in the small intestine is implicated in the pathogenesis of PI-IBS. Elucidating which *Campylobacter*-related factor produces this decrease in the number of ICC may contribute greatly to our understanding of PI-IBS and lead to potential treatments for IBS.

COMMENTS

Background

There is a growing interest in understanding newly discovered bacterial mechanisms in the pathophysiology of functional bowel disease. These mechanisms might result innovative treatments for diseases such as irritable bowel syndrome (IBS).

Research frontiers

Two bacterial hypotheses have emerged in IBS. The first hypothesis is that IBS appears to develop in humans after an episode of acute gastroenteritis. The other bacterial hypothesis is that a proportion of patients who already have IBS appear to have small intestinal bacterial overgrowth (SIBO) and improve with antibiotic therapy.

Innovations and breakthroughs

Recently, a new animal model of post-infectious IBS has been developed on the basis of a common human pathogen, *Campylobacter jejuni* (*C. jejuni*). In

this model, IBS-like symptoms appear to develop in rats 3 mo after clearance of the initial infection. At this time, a proportion of these rats have bacterial overgrowth, based on quantitative polymerase chain reaction. These data now link acute gastroenteritis to the development of bacterial overgrowth and symptoms in an animal model.

Applications

This new animal model will facilitate the discovery of the cascade of events that lead to IBS and SIBO. One candidate in the cascade is likely to be an effect on the neuromuscular apparatus of the gut.

Terminology

Post-infectious IBS is the development of IBS after a self-limited infection of the intestine, such as acute gastroenteritis. Interstitial cells of Cajal (ICC) are nerve cells in the intestinal lining that are important for maintaining the function of the gut.

Peer review

In this manuscript, the authors investigate the potential role of a decreased number of ICC in causing SIBO after a *C. jejuni* infection in rats. The paper is well written and is pleasant to read. The experiments have been carefully designed and executed.

Abstract

AIM: To evaluate the prevalence of breast tumors in adult females with chronic hepatitis C virus (HCV) infection.

METHODS: Prospective, single-center study, based on female outpatients consulting in a liver unit, for 1 year. The study group included females with present and/or past history of chronic infection by HCV. Patients with spontaneous recovery were excluded. Chronic hepatitis had been proved by liver biopsy in the majority of cases and/or biological markers of inflammation and fibrosis. The control group included female patients with other well documented chronic liver diseases: chronic hepatitis B, alcoholic liver disease, autoimmune hepatitis, hemochromatosis, non alcoholic liver disease, chronic cholangitis. Participating patients were prospectively questioned during consultation about past breast history and follow-up by mammography.

RESULTS: Breast carcinoma was recorded in 17/294 patients with HCV infection (5.8%, 95% CI: 3.1-8.4) *vs* 5/107 control patients (4.7%, 95% CI: 0.67-8.67). Benign tumors of the breast (mastosis, nodules, cysts) were recorded in 75/294 patients with HCV infection (25.5%, 95% CI: 20.5-30.5) *vs* 21/107 (19.6%, 95% CI: 12.1-27.1) in the control group. No lesion was noted in 202 patients with HCV (68.7%, 95% CI: 63.4-74) *vs* 81 control patients (75.7%, 95% CI: 67.6-83.8). Despite a trend to an increased prevalence in the group with HCV infection, the difference was not significant compared to the control group (P = NS). In patients over 40 years, the results were, respectively, as follows: breast cancer associated with HCV: 17/266 patients (6.3%, 95% CI: 3.4-9.3) *vs* 5/95 patients (5.2%, 95% CI: 0.7-9.7) in the control group; benign breast tumors: 72/266 patients with HCV infection (27%, 95% CI: 21.7-32.4) *vs* 18/95 patients (18.9%, 95% CI: 11-26.8) in the control group; no breast lesion 177/266 (66.5%, 95% CI: 60.9-72.2) in patients with HCV infection *vs* 72/95 (75.7%, 95% CI: 67.1-84.4) in the control group. The differences were not significant (P = NS).

CONCLUSION: These results suggest that chronic HCV infection is not a strong promoter of breast carcinoma in adult females of any age.

Key words: Breast tumors; Breast cancer; Hepatitis C virus infection; Risk factor

INTRODUCTION

Several viruses have been involved in the occurrence of cancers[1]. For instance, human papilloma virus has been directly implicated in uterus cancer; poliomavirus in mesothelioma and brain tumors; Epstein-Barr virus in B-cell lymphoproliferative disease and nasopharyngeal carcinoma; herpes virus in Kaposi sarcoma[1]. Hepatitis C virus (HCV) is well-known to cause chronic hepatitis, cirrhosis and hepatocarcinoma[2-5]. The prevalence of HCV in France, as in other Western European countries, is around 1% and is estimated to be 1.6% in the United States[6-8]. The potential link between HCV infection and the risk of developing malignancy other than hepatocarcinoma has been recently raised in several studies[9-13]. There are several lines of evidence showing a role in the occurrence in non-Hodgkin lymphoma and lymphoproliferative diseases[9,10]. Recent studies argue for an increasing risk of intra-hepatic cholangiocarcinoma[11] and thyroid cancer[12]. The prevalence of HCV has been evaluated in elderly patients with tumors different from hepatocarcinoma and non-Hodgkin lymphoma (colorectal, prostate, breast, bladder, kidney)[13]. Among 236 patients, 87 (36%) were positive for HCV, a higher prevalence than in the patients of the control group (10%)[13]. A statistically significant difference was observed with kidney cancer, prostate cancer, and bladder cancer[13]. Finally, the link between hepatocarcinoma and another tumor has been assessed in a retrospective study including 37 patients[14]. Five patients (13.5%) had developed another primary cancer before or after hepatocarcinoma: kidney cancer, breast cancer, colorectal cancer, prostate cancer, or lymphoma. A common point between these 5 patients was HCV chronic infection. This suggested that HCV chronic infection may not only promote hepatocarcinoma, but also other solid tumors[14].

Therefore the aim of this study was to assess the frequency of breast tumors in adult females with chronic infection by HCV and whether this disease may be a promoting factor for the onset of benign or malignant breast tumors.

MATERIALS AND METHODS

This was a prospective, single-center study performed over 1 year in female patient aged ⩾ 20 years, consulting in the Liver Unit of Montpellier School of Medicine, France, for chronic liver diseases. The study group included patients with present or past chronic infection by HCV.

Patients

Inclusions criteria: Age ⩾ 20 years, the evidence of chronic infection by HCV based on the presence of serum anti-HCV antibodies, detection of serum HCV RNA by PCR tested on several occasions for a period longer than 1 year; chronic hepatitis C proved by liver biopsy (75% of patients) or non-invasive methods (25% of patients) including biological markers of inflammation and fibrosis of the liver such as Fibrotest-Actitest® and/or elastographic examination (Fibroscan®) as recently published[15-17]; agreement of the patient for participation in the study.

Exclusion criteria: A spontaneous recovery from HCV; co-infection by hepatitis B virus or human immunodeficiency virus; absence of capacity to understand or to answer the questions in the inquiry.

The control group included females seen sequentially and prospectively during the same period and affected by chronic liver disease over 1 year, with well defined characteristics based on clinical, radiological and histological features [chronic hepatitis B, chronic alcoholic liver disease, auto-immune hepatitis, hemochromatosis, non alcoholic fatty liver disease (NAFLD), chronic cholangitis, *etc.*].

Methods

The following information was collected during the consultation by using a questionnaire: past history of breast cancer or benign breast tumor; which type if any (adenoma, mastosis, cyst); performed examinations or treatment (mammography, biopsy, surgery); potential participation in a tumor detection program by mammography. Indeed, in our geographic area, there is a detection program for breast lesions with systematic mammography every 2 years for females over 40 years.

Statistical analysis

The data processing was performed using SAS software packages version 8.1. A general descriptive analysis was done for every parameter of the study. The distribution of qualitative variables (such as breast tumors) between groups was compared using χ^2 test. When the calculated frequency of the categorical data of the contingency table did not allow the use of the χ^2 test, Fisher's exact test was performed. A P level < 0.05 was considered as significant. Stratification was performed according to age brackets: 20 to 40 years, 41 to 60 years and more than 60 years. Unilateral and bilateral power was calculated *a posteriori*.

RESULTS

Four hundred and one patients fulfilled inclusion criteria and all agreed to participate in the study. The study group with HCV infection included 294 patients; the control group included 107 patients with the following chronic liver diseases: NAFLD, 32 cases; chronic hepatitis B, 10 cases; primary biliary cirrhosis, 17 cases; auto-immune chronic hepatitis, 13 cases; chronic alcoholic liver disease, 4 cases; chronic cholangitis, 9 cases; hemochromatosis, 4 cases; and other chronic liver diseases, 18 cases.

Patients' ages ranged from 21 to 84 years (median 58 years) in the HCV group and from 23 to 84 years (median 56 years) in the control group. The distribution by age was comparable in the two groups with a predominance of patients between 40 and 70 years: 20-40 years, n = 36 (8.9%) *vs* n =

Table 1 Characteristics of the 294 patients with chronic hepatitis C

	All patients
Median age (yr)	58 (21-84)
HCV Genotype	
HCV 1	63%
HCV 2	11%
HCV 3	19%
HCV 4-5	7%
Severity of liver disease[1]	
F0-F2	70%
F3	16%
F4	14%
HCV treatment	
Never treated	30%
Past or ongoing treatment	70%

[1]The extent of fibrosis has been expressed according to the METAVIR scale as previously described[15]. HCV: Hepatitis C virus.

15 (9.7%); 41-60 years, n = 132 (33%) *vs* n = 52 (45.9%); > 60 years, n = 126 (42.8%) *vs* n = 40 (37.4%). Other main characteristics of patients with chronic HCV infection, including genotype, severity of fibrosis and anti-viral treatment history, are shown in Table 1. They are similar to the features collected in the data bank of patients with HCV infection in our regional HCV network (3280 patients)[18]. In the control group, the percentage of chronic liver diseases reaching the stage of cirrhosis (stage F4 of METAVIR scale) was 13% (14/107 cases), which was similar to the HCV group (14%) (Table 1).

The programme of mammography for patient aged over 40 years was followed in 212/266 patients (79.7%) of the HCV group and in 74/99 patients (77.8%) of the control group. In younger patients, mammography had only been performed because of symptoms, in less than 15% of patients of both groups.

The prevalence of breast tumors is shown in Table 2. Among all patients, breast cancer was recorded in 5.8% (95% CI: 3.1-8.4) of HCV group patients *vs* 4.7% (95% CI: 0.67-8.67), a benign breast tumor in 25.5% (95% CI: 20.5-30.5) in the HCV group *vs* 19.6% (95% CI: 12.1-27.1) in the control group, no evidence of breast lesion in 68.7% (95% CI: 63.4-74) of patients in the HCV group *vs* 75.7% (95% CI: 67.6-83.8) in the control group. Despite a trend for a higher prevalence of malignant or benign tumors in the HCV group, there was no significant statistical difference with the control group (Table 2). Familial history of breast cancer was recorded only in 1 of the 17 patients in the HCV group and none in the 5 cases of the control group.

The same analysis was performed according age brackets as presented in Table 3. No breast cancer was recorded in females younger than 40 years in the two groups. The frequency was low for females between 41 and 60 years, with a mild predominance but no significant difference in the HCV group compared to the control group: 3.4% (95% CI: 0.5-6.4) *vs* 1.8% (95% CI: 0-5.3). Females older than 60 years exhibited the highest prevalence with 10.0% without any difference between the two groups. In all patients over 40 years, breast cancer in the HCV group was 17/266 patients (6.3%, 95% CI: 3.4-9.3) *vs* 5/95 (5.2%, 95% CI: 0.7-9.7) in the control group.

For benign breast tumors, frequency also varied according to age brackets: it was slightly lower in the HCV group *vs* the control group for females between 20 and 40 years. In contrast, it was slightly higher in the other two age brackets but the difference was not statistically significant.

The absence of breast tumors was slightly higher in females aged between 41 and 60 years, and older than 60 years in the control group *vs* the HCV group but the difference was not statistically significant.

DISCUSSION

In many parts of the world, breast cancer is the most frequent form of cancer in females[19-22]. Similarly in France, there are 49 000 new cases/year and 11 000 deaths for a population of 60 million inhabitants[23-25]. The incidence is 101 cases/100 000 females[25]. Overall, cancer occurs in one female out of 11. As with many other cancers, the risk increases with age (less than 10% of breast cancers are detected in patients younger than 40 years[21-24]. Then the incidence increases with age[21-24]. These observations justify a systematic detection in females from 50 years. The causes of breast cancer are poorly known. Nevertheless, some risk factors have been identified[25-28]: benign breast diseases, fertility (females without pregnancy or with first pregnancy later than 30 years old exhibit a higher risk), obesity particularly after menopause[25]. Familial and genetic factors may also increase the risk, in particular through a gene mutation (BRCA1-BRCA2)[28]. The role of oral contraceptives has been discussed[21-27]. The increase in risk has been mainly observed in oral contraceptive users with a family history of breast cancer[28].

The role of HCV in breast cancer has been recently raised[14] for the following reasons. Chronic HCV infection is clearly involved in the occurrence of hepatocarcinoma and lymphoma[3,4-10] and in several other solid tumors[11-13]. Some cases of breast cancer were observed in a recent study of patients with HCV[14] and several cases have been recorded during the regular follow-up of the large cohort of patients with chronic HCV infection seen in the Liver Unit of Montpellier School of Medicine (personal observation). This led to the present prospective study knowing that a program of systematic detection of breast tumors by mammography every 2 years in all females older than 40 years has been in place in our geographic area for nearly 20 years.

Global results of this study show a breast cancer frequency of 5.8% in adult females with chronic HCV infection. Intentionally, we included a group of young females, aged 20-40 years, to detect a potential signal in an age population known to not exhibit a particular risk. No malignant lesion was recorded. However, only a small proportion of these patients had undergone mammography. Therefore, the detection of a tumor was mainly based on

Table 2 Prevalence of breast tumors

	Patients with HCV infection (n = 294)		Patients with other chronic liver diseases (n = 107)		P value

HCV: Hepatitis C virus; NS: Not significant.

its clinical expression. This sub-group representing about 10% of the overall group has slightly lowered the global prevalence. Indeed, the prevalence of all patients aged more than 40 years is 6.3% and reaches its highest rate, 10%, in females aged more than 60 years. The prevalence may have been underestimated since the mammography program was not followed in 20% of patients. Results observed in the HCV group were similar to those found in the control group, including females with other types of chronic liver diseases and having the same breast tumor detection program. We observed a similar low frequency in younger patients and the same proportion of patients who did not follow the mammography program. Therefore, this did not influence the comparison between groups. Finally, a familial history of breast cancer was recorded in a single patient with breast cancer (in the HCV group). This factor does not appear to have influenced the result of our study. Overall, these data do not support the idea that HCV chronic infection is a factor which contributes markedly to breast cancer. This view is also reinforced by the fact that prevalence of breast cancer found in this study is within the range of those found in general French and occidental populations[19-24]. Nevertheless, the interpretation of the results needs to be balanced by some limitations, in particular the relatively low number of patients in the control group and the absence of a priori calculation of the number of patients required to show a significant difference between groups with high power. This is largely caused by the fact that the prevalence of breast cancer in patients with chronic liver diseases in general and in HCV infection in particular, was completely unknown when the study was started. Therefore, our study does not allow us to draw definite conclusions. Nevertheless, it may serve as basis to set a more powerful study with matched control groups.

In summary, results of this study allowed the evaluation of the prevalence of breast cancer in patients with HCV chronic infection and suggest that HCV is not a strong promoter of breast carcinoma in adult females of any age.

COMMENTS

Background

Chronic infection by hepatitis C virus (HCV) exhibits a high frequency worldwide and represents a major cause of chronic liver disease leading to cirrhosis and hepatocarcinoma. Its influence on the onset of malignant tumors is under investigation.

Research frontiers

Several recent studies suggest that HCV chronic infection can not only cause hepatocarcinoma and lymphoma but may also promote the onset of several other solid tumors involving biliary ducts, thyroid, prostate, kidney and bladder.

Innovations and breakthroughs

The prevalence of breast cancer in patients with chronic liver diseases in general and HCV chronic infection in particular, is unknown. The relationship between HCV infection and breast cancer has been recently suggested by anecdotal cases. This is the first study designed to evaluate the prevalence of breast malignant and benign tumors in female patients and to assess whether HCV chronic infection is a risk factor. The study has been performed prospectively, using other chronic liver diseases as the control group. The results show the same prevalence of breast tumors in both groups which suggests that HCV does not appear as a strong promoting factor.

Applications

This study has allowed us to estimate the prevalence of breast cancer in females with chronic HCV infection. The interpretation of the results is balanced

by the number of patients included in the study and statistical power. Nevertheless, this constitutes a step to design new studies with matched control groups including a much larger number of patients to evaluate a potential low impact of HCV in breast malignancy.

Peer review

The authors evaluated the association between HCV infection and breast cancer. The study included 294 patients with HCV infection. Control subjects were 107 women seen in the same liver clinic over a 1-year period. Overall, there was no difference in the frequency of breast cancer or benign breast lesions between HCV-infected patients and control subjects. The hypothesis is interesting, but the study has limitations as discussed.

Abstract

AIM: To assess the rate of spontaneous tube migration and to compare the effects of naso-gastric and naso-intestinal (NI) (beyond the ligament of Treitz) feeding in severe acute pancreatitis (SAP).

METHODS: After bedside intragastric insertion, tube position was assessed, and enteral nutrition (EN) started at day 4, irrespective of tube localization. Patients were monitored daily and clinical and laboratory parameters evaluated to compare the outcome of patients with nasogastric (NG) or NI tube.

RESULTS: Spontaneous tube migration to a NI site occurred in 10/25 (40%) prospectively enrolled SAP patients, while in 15 (60%) nutrition was started with a NG tube. Groups were similar for demographics and pancreatitis aetiology but computed tomography (CT) severity index was higher in NG tube patients than in NI (mean 6.2 *vs* 4.7, P = 0.04). The CT index seemed a risk factor for failed obtainment of spontaneous distal migration. EN trough NG or NI tube were similar in terms of tolerability, safety, clinical goals, complications and hospital stay.

CONCLUSION: Spontaneous distal tube migration is successful in 40% of SAP patients, with higher CT severity index predicting intragastric retention; in such cases EN by NG tubes seems to provide a pragmatic alternative opportunity with similar outcomes.

Key words: Acute pancreatitis; Enteral feeding; Tube migration; Nasogastric; Safety

INTRODUCTION

Acute pancreatitis (AP) is an acute inflammatory process which has different grades of severity and is characterized by high mortality rates in the case of infected pancreatic necrosis[1].

Severe AP (SAP) with pancreatic necrosis is therefore a hard challenge for clinicians, and its management is still debated. The aim of treatment is to prevent necrosis

infection and to manage the hypercatabolism secondary to extended pancreatic and extrapancreatic inflammation with an adequate nutritional, volumetric and hydroelectrolytic support. Nutritional support is presently considered a key issue in patient management. Enteral nutrition (EN) should be preferred to total parenteral nutrition (TPN) in patients with SAP[2,3], as also suggested by current guidelines[1,4-6]. EN is indeed associated with reduced mortality, lower septic complications, reduced surgical procedures and hospital stay[2,3], possibly owing to a trophic action on the intestinal wall and prevention/reduction of bacterial translocation.

However, in clinical practice EN is employed far less frequently than it should. A recent survey conducted by the Italian Society of Pancreatology has reported that only about 20% of SAP patients received EN, either as single nutritional support, or in combination with TPN[7]. This figure is slightly more encouraging in Holland where some 50% of patients with SAP received EN in an observational multicentre study[8].

The main obstacle to EN diffusion is that it is considered complicated, and to require specific skills. Indeed, to ensure full pancreatic rest, nutrition tubes should be placed in the jejunum[9,10]. Although spontaneous transpyloric migration of tubes after gastric positioning, and subsequent localization in the distal duodenum or jejunum, is possible, few studies have specifically addressed this issue in patients with AP. Endoscopic placement of a nasojejunal tube is a possible alternative, but it is troublesome, potentially risky, and variable success rates have been reported[11]. Other techniques and devices have been proposed to improve tube positioning beyond the ligament of Treitz[12-14], but results, although appealing, are preliminary and sometimes out of reach in daily clinical practice.

In the past few years, it has been proposed that EN through nasogastric (NG) tubes may be a simple, safe and equally valid alternative to nasojejunal tubes, with the potential advantage of earlier administration of nutrients[15-17]. However, NG feeding cannot be recommended at this time, and it is not clear if a subgroup of SAP patients may benefit more from this approach.

We speculated that a pragmatic possibility in real-world clinical practice would be to employ NG feeding whenever tube migration does not occur spontaneously.

The aims of this study were therefore to assess the rate of spontaneous distal migration of EN tubes in patients with predicted SAP, to identify possible factors associated with it, and to compare the safety and tolerability of EN with an elemental formula in patients who started nutrition with a "proximal", NG or a "distal", naso-intestinal (NI) tube, depending on the success of spontaneous tube migration.

MATERIALS AND METHODS

Patients

This is a pragmatic ("real world") study, prospectively evaluating patients with predicted SAP admitted to our Institution from January 2006 to November 2009. AP was defined by the presence of typical abdominal pain associated with serum amylase levels > 3 times normal value. Patients with predicted SAP, as defined by a Ranson's score of 3 or higher and/or by a CT severity index of 4 or higher (as reviewed in 1), were included.

Treatment protocol

SAP patients received appropriate fluid support, antibiotic prophylaxis with iv imipenem (500 mg every 8 h), antisecretory therapy with iv pantoprazole (40 mg once daily), and were offered EN. The EN protocol included positioning of a feeding tube (10 F Flexiflo tungsten-weighted polyurethane feeding tube**,** Abbott, Baltimore, USA). After lubrication with 20 mL of water, intubation was performed at the bedside in all cases and, once completed and verified by X-ray, the guide-wire was withdrawn and the tube fixed to the nose. Prokinetics (metoclopramide 10 mg) were administered twice a day for 3 d after intubation. Tip position was radiologically assessed after 24 (day 1) and 72 h (day 3). Position was considered "proximal" (NG) if the tube tip was in the stomach or in the duodenum, proximal to the ligament of Treitz, and "distal" (NI) if in the duodenum beyond the ligament of Treitz or in the jejunum. At day 4 EN was started irrespectively of tube position (either "NG" or "NI"). An elemental formula (Survimed®) was employed at increasing volumes, from 20 mL/h up to an energetic target of 2000 kcal per day (100 mL/h).

Measured outcomes

Patients were monitored daily by measurement of clinical and laboratory parameters, and pain through a quantitative score, based on the subjective evaluation and the need for analgesic drugs (0 = no pain, 1 = pain with no need of analgesics, 2 = pain responding to low dose analgesics, 3 = pain responding to high dose analgesics, 4 = pain not responding to high dose analgesics).

Pain recurrence, biochemical changes (amylase, lipase and C-reactive protein), side effects (such as nausea, vomiting or diarrhoea), success of EN in terms of caloric target and days necessary to reach it, as well as possible need to TPN switching, were recorded. Patients received further appropriate clinical and radiologic investigations when needed. Occurrence of pancreatic (infected necrosis) and/or extrapancreatic complications (renal and/or respiratory failure, bleeding) were also recorded, as well as the patients' clinical outcome (mortality, need for surgery) and length of hospital stay.

Statistical analysis

Categorical data (percentages) were compared by means of Fisher's exact test, and continuous data by means of *t*-test for independent samples. Possible associated risks were evaluated by logistic regression analysis.

RESULTS

Patients

During the study protocol, 116 patients with AP were admitted to our unit. Their demographics and clinical features are detailed in Table 1. Among them, there were 28 pa-

tients with predicted SAP (24.1%) who were offered EN as part of their treatment. Two patients refused tube positioning and received TPN, another patient spontaneously withdrew the tube on day 1 and refused further invasive treatments. Data concerning the remaining 25 patients were analysed.

Rate of spontaneous nutrition tube migration

Plain abdominal X-ray evaluation at day 3 demonstrated successful transpyloric tube migration and "NI" positioning in 10 (40%) patients. The tube did not migrate and remained "NG" in the other 15 patients (60%). As shown in Table 2, the two groups were similar in terms of sex, age and pancreatitis etiology. The predicted severity was not different according to Ranson's score, C-reactive protein or other biochemical values, but the CT severity index in the NG tube group was significantly higher than the NI group (mean 6.2 *vs* 4.7, $P = 0.04$). At a logistic regression analysis, we could not identify factors associated with the NG tube position, although CT severity index was the variable closest to significance (OR = 1.6 per unit, 95% CI: 0.95-2.9). Moreover, in all 4 patients (100%) with a CT severity index > 6, the tube did not migrate beyond the pylorus, compared to 11 of the 21 patients (52.3%) with an index ⩽ 6; however this difference was not statistically significant, probably due to the small number of patients.

Table 3 Tolerability and success of nutrition according to tube position *n* (%)

	Nasogastric (*n* = 15)	Nasointestinal (*n* = 10)	*P*
Tube malpositioning	0	0	-

TPN: Total parenteral nutrition.

Safety and tolerability of nutrition

There were no differences regarding complications of the feeding tube positioning, such as malpositioning, epistaxis or aspiration pneumonia between patients with a NG or a NI tube. Moreover, after EN start, there was no significant difference between the NG and the NI tube groups in terms of exacerbation of pain, biochemical changes (amylase, lipase and C-reactive protein), side effects or need to switch to TPN. A similar high percentage of patients reached the energetic target (2000 Kcal) in both groups without significant time difference (Table 3).

Clinical outcome

As detailed in Table 4, there was no significant difference in the clinical outcome between the two groups, although more complications occurred in the NG group.

DISCUSSION

In the present study spontaneous migration of the EN tube beyond the stomach occurred in 40% of predicted SAP patients, and a higher CT severity index was associated with the tube being retained in the stomach. However, EN was successfully delivered in some 90% of cases, even in those patients in which tube migration beyond the ligament of Treitz was unsuccessful. Similar results in terms of safety and tolerability were observed in patients with

Table 4 Clinical outcomes of patients according to tube position *n* (%)

	Nasogastric (*n* = 15)	Nasointestinal (*n* = 10)	*P*
Mortality	0	0	-
Need of surgery	0	0	-
Complications			
Infected pancreatic necrosis	3 (20)	1 (10)	1
Renal failure	1 (6.6)	0	1
Respiratory failure	2 (13.3)	0	0.1
Bleeding	1 (6.6)	0	1
Any of the above complications	4 (26.6)	1 (10)	0.6

an "NG" or an "NI" tube. Furthermore, both approaches were equally effective in providing the nutritional support needed, caloric goals were reached in similar time intervals and length of hospital stay was not different.

A first interesting result regards the rate of spontaneous tube migration after bedside positioning, without endoscopic or radiologic assistance. The feeding tube migrated to a NI position in 40% of cases, and patients with the NG tube had a significantly higher CT scan severity index. Bedside tube positioning caused only few mild complications without differences between the two groups, but no cases of aspiration pneumonia occurred. This finding is relevant, as although delivery of feeding into the small bowel should be associated with a lower risk of aspiration, there are few data supporting this view[18].

The rate of spontaneous distal tube migration with unguided probing is considered to be around 50% in patients admitted to intensive care units (ICU) for different diseases[19]. Few studies have reported these data specifically for patients with predicted SAP, with success rates of spontaneous migration ranging from 60% to 80%[20,21]. Our results are in agreement with a recent French study reporting an overall successful migration in 61% of patients with either mild or severe AP, with this rate being reduced to 48% in SAP patients having a CT severity index score $\geqslant 4$[21]. Similarly, in our experience, in all patients with extensive pancreatic necrosis (CT severity index > 6), the tube did not migrate beyond the pylorus, and the CT index seemed a risk factor associated with failed spontaneous migration. These data may be explained by an impaired transpyloric migration due to gastroparesis, or to mechanical obstacles caused by local oedematous reactions and/or fluid collections present in the most advanced SAP cases.

As far as tolerability and safety are concerned, we have not observed any significant difference between patients receiving EN either by NG or NI tube. The nutritional goal was reached in 93% of NG patients and 80% of NI. Our findings seem to be in agreement with those published by Eatock *et al*[15], who had randomized 49 SAP patients into two groups, administering EN through NG tube in 27 cases and through NI tube in the remaining 22. Patients had been monitored daily by severity index and pain score to evaluate changes in AP severity due to enteral feeding, and during hospital stay groups behaved similarly, no matter the kind of EN used. Another two randomized clinical trials[16,17] dealing with NG enteral feeding have supported the safety and efficacy of this nutritional route, and subsequent meta-analyses confirmed the lack of difference between the two approaches, although the paucity of available data was underlined as a factor limiting the evaluation[22,23].

Regarding clinical outcomes, we have not found any significant difference in terms of complications, mortality and length of hospital stay between the two groups, although most complications occurred in patients receiving NG feeding (Table 4). This small, not significant gap is probably due to a higher prevalence of extensive necrosis in the NG group, accordingly to the significant higher CT scores of these patients at entry. However, since our group of predicted SAP patients did not experience prolonged organ failure which is a key event in discriminating patients with more severe forms[24], and we observed absence of mortality in both groups, the findings obtained in our study may not apply to patients with SAP and prolonged multiple organ failure.

This is the first study of its kind observing the outcome of EN in SAP patients in a "real world" clinical setting, with the study protocol driven by the need to have more solid grounds in making clinical decisions about everyday medical care circumstances. Both the proximal and the distal enteral approaches result to be feasible, safe and effective in most patients.

The working hypothesis we wanted to test, and that seems to be confirmed by our results, was that when spontaneous tube migration fails EN can be safely administered through NG tube. This issue has a relevant impact on everyday clinical practice as the main limit to EN usage in AP is the technical difficulty in obtaining small bowel access, as reported by 72% of ICUs joining a national survey in Canada[25].

Of course, the present non-randomized study design cannot highlight the potential benefits of NG nutrition, such as the possibility of immediate start of EN after tube positioning, but only the potential harms caused by stimulation of pancreatic function. However our observation may support the need for further clinical research aimed at clarifying this issue. Furthermore, as the rate of spontaneous distal migration of the nutrition tube, and factors related with it, was one of the results the study was aimed at identifying, the design could not imply a randomization between NG and NI, nor a power calculation. As a consequence, it is possible that differences between groups have not been appreciated due to underpowered samples. In this view, the ongoing multicentre trial on gastric *vs* mid-jejunal feeding funded by the National Institutes of Health will probably provide further important information (http://clinicaltrials.gov Identifier: NCT00580749).

In conclusion, spontaneous distal tube migration in patients with predicted SAP is successful in 40% of patients, and CT severity index is higher in patients with failed distal migration of the nutrition tube. EN administered by NG or NI tubes seems to provide equal safety,

tolerability and efficacy, even if more results are necessary to validate the routinely use of NG tubes in SAP patients.

COMMENTS

Background

Severe acute pancreatitis (SAP) requires an adequate nutritional support. Enteral nutrition (EN) should be preferred to total parenteral nutrition in patients with SAP, as it is associated with reduced mortality and complications. However, in clinical practice EN is employed far less frequently than it should. The main obstacle to EN diffusion is that it is considered complicated, as to ensure full pancreatic rest, nutrition tubes should be placed in the jejunum, requiring often troublesome procedures. In the past few years, it has been proposed that EN through nasogastric (NG) tubes may be a simple, safe and equally valid alternative to nasojejunal tubes.

Research frontiers

The authors speculated that a pragmatic possibility in real-world clinical practice would be to employ NG feeding whenever tube migration to the jejunum of bedside inserted feeding tubes does not occur spontaneously. They therefore aimed at assessing the rate of spontaneous distal migration of EN tubes in patients with predicted SAP, to identify possible factors associated with it, and to compare the safety and tolerability of EN with an elemental formula in patients who started nutrition with a "proximal", NG or a "distal", naso-intestinal (NI) tube, depending on the success of spontaneous tube migration.

Innovations and breakthroughs

The authors found that spontaneous tube migration to a NI site occurred in 10/25 (40%) prospectively enrolled SAP patients, while in 15 (60%) nutrition was started with a NG tube. Groups were similar for demographics and pancreatitis aetiology but computed tomography (CT) severity index was higher in NG tube patients than in NI (mean 6.2 *vs* 4.7, $P = 0.04$). The CT index seemed a risk factor for failed obtainment of spontaneous distal migration. EN trough NG or NI tube were similar in terms of tolerability, safety, clinical goals, complications and hospital stay.

Applications

This is the first study of its kind observing the outcome of EN in SAP patients in a "real world" clinical setting, with the study protocol driven by the need to have more solid grounds in making clinical decisions about everyday medical care circumstances. Both the proximal and the distal enteral approaches resulted to be feasible, safe and effective in most patients. This issue has a relevant impact on everyday clinical practice as the main limit to EN usage in AP is the technical difficulty in obtaining small bowel access.

Peer review

NG tube insertion, a simpler approach, will probably replace total parenteral nutrition and nasojujunal feeding in the near future. Therefore, despite the small number of patients, this paper is suitable for publication after revision.

Abstract

AIM: To characterize clinicopathological and familial features of early-onset colorectal cancer (CRC) and compare features of tumors with and without microsatellite instability (MSI).

METHODS: Forty-five patients with CRC aged 45 or younger were included in the study. Clinical information, a three-generation family history, and tumor samples were obtained. MSI status was analyzed and mismatch repair genes were examined in the MSI families. Tumors were included in a tissue microarray and an immunohistochemical study was carried out with a panel of selected antibodies.

RESULTS: Early onset CRC is characterized by advanced stage at diagnosis, right colon location, low-grade of differentiation, mucin production, and presence of polyps. Hereditary forms represent at least 21% of cases. Eighty-one percent of patients who died during follow-up showed a lack of expression of cyclin E, which could be a marker of poor prognosis. β-catenin expression was normal in a high percentage of tumors.

CONCLUSION: Early-onset CRC has an important familial component, with a high proportion of tumors showing microsatellite stable. Cyclin E might be a poor prognosis factor.

Key words: Early onset colorectal cancer; Microsatellite instability; Lynch syndrome; Microsatellite stable colorectal cancer

INTRODUCTION

The prevalence of colorectal cancer (CRC) has been increasing during recent years. In 2004, it had the second highest incidence of all cancers and was the second most common cause of cancer-related death in the European Union[1]. Early onset CRC is infrequent, with an incidence of 2%-8% of all CRCs. In the United States, between 1992 and 2005, the incidence of CRC in young individuals (ages 20-49 years) increased at a rate of 1.5% per year in men and 1.6% per year in women[2].

Early onset of cancer is an indicator that a hereditary component is more likely. The most frequent hereditary form of CRC is Lynch syndrome. It is estimated to represent about 2%-5% of all CRCs, and is characterized by the development of CRC (and other types of cancer) at a mean age of 43 years[3-6]. Its molecular basis is a DNA mismatch repair (MMR) gene defect, which leads to changes in the length of repetitive DNA sequences, known as microsatellite instability (MSI).

The proportion of MSI tumors found in young patients varies between 19.7% and 41%, depending on the age of onset[7-9]. On the other hand, Lynch syndrome is estimated to cause about 1/3 of the CRC cases occurring at a young age[4,10,11]. There are some controversial aspects to the natural history and prognosis of early onset CRC, and some clinical and pathological differences compared to CRC in elderly patients[8]. Early onset CRCs are localized mostly in the right colon, are frequently poorly differentiated, show mucin production, and can develop synchronous and metachronous tumors[12]. These differences are more marked in cases with a family history suggestive of Lynch syndrome, or with molecular characteristics like MSI[8,12-14].

There is little information about microsatellite stable (MSS) forms of CRC in young adults, not only regarding their anatomoclinical features but also regarding their molecular characteristics. For example, there is an increased proportion of MSS tumors in young patients with rectal cancer[15]. Furthermore, several studies show that some alterations in molecular markers typical of MSS early onset CRCs also occur in sporadic cases of CRC, such as modified expression of APC, β-catenin and p53[9].

The aim of our study was to characterize early onset CRC by analyzing its clinical, pathological, familial, molecular, and immunohistochemical (IHC) features. We have determined the proportion of Lynch syndrome in our series, and have compared the characteristics of the MSS and MSI groups.

MATERIALS AND METHODS

Families, samples and data collection

A total of 45 individuals diagnosed with CRC at an age of 45 or younger were collected from two different Spanish institutions (Gregorio Marañón Hospital in Madrid, and Segovia General Hospital). All patients, or a first degree relative in case of death of the index case, provided written consent.

A full three-generation family medical history and colorectal paraffin-embedded tumors were obtained from each proband.

Personal and tumor clinicopathological information was obtained regarding age of onset, gender, location of the CRC (right/left colon or rectum), grade of cell differentiation (low, medium, or high), mucin production, modified Astler-Coller stage, the existence of polyps, and the presence of synchronous or metachronous CRCs. Mean follow-up was 60 mo.

To analyze the familial cancer history of each index case, we divided the neoplasms into two groups: Lynch syndrome-related tumors, and Lynch syndrome-unrelated tumors.

DNA extraction

A tissue specimen was obtained from the index case. Prior to DNA extraction, tumor and normal areas of the paraffin-embedded samples were selected *via* microscopic inspection. The proportion of tumor cells in the material used for DNA extraction exceeded 70% in all cases. DNA was extracted using proteinase K digestion, phenol-chloroform extraction, Phase Lock Gel™ Light (Eppendorf AG, Germany), and EtOH protocol precipitation.

MSI and MMR immunohistochemistry analyses

Microsatellite status was assessed using the BAT-26 mononucleotide marker, based on its high sensitivity[16-18]. However, in order to discard false negative results, all BAT-26 MSS cases fulfilling the Amsterdam I criteria[19], were analyzed using the Bethesda panel. BAT-26 was PCR amplified and fragments were evaluated using an ABI automated sequencer and GeneScan Software. For analysis of the Bethesda panel, we used the HNPCC Microsatellite Instability Test kit (Roche, Mannheim, Germany).

IHC staining for markers of the following processes was performed: MMR; apoptosis; cell adhesion; cell cycle; proliferation, and others. Markers and clones used are shown in Table 1. All samples were fixed onto a tissue microarray, on which the IHC analysis was carried out.

Scoring of tumor staining was done without any knowledge of the patients' family history or results of mutation analyses.

Detection of mutations and large deletions

Cases showing MSI and/or lack of expression of MMR proteins in tumors were screened for germline mutations in the DNA MMR genes *MLH1* and *MSH2*, by denaturing gradient-gel electrophoresis (DGGE) on a DCode System (BioRad), using primers and denaturing conditions previously reported, with slight modifications[20]. Some samples were analyzed by denaturing high-performance liquid chromatography (dHPLC) (http://insertion.stanford.edu/melt.html). When an anomalous band pattern was observed by DGGE or dHPLC, a new PCR product of the fragment was sequenced, using the BigDye Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems) and analyzed with a Genetic Analyzer ABI Prism 3130 (Applied Biosystems).

Statistical analysis

Continuous variables were expressed as the median values plus/minus SD, and categorical variables were expressed as number of cases and their percentage. Differences were considered significant when $P < 0.05$. For associations between clinicopathological, familial and molecular features, and MSI status, statistical analyses were performed using Pearson's χ^2 test for parametric variables, and Fisher's exact test for non-parametric variables. When those features were continuous variables, Student's *t*-test was used, as well as for some familial features, to compare the differences between both groups. The SPSS v.11.5 for Windows (SPSS, Inc., Chicago, IL) statistical package was used.

RESULTS

Clinicopathological features

We studied a total of 45 subjects diagnosed with CRC at an age of 45 years old or younger. Clinicopathological characteristics of all cases are shown in Table 2. A high proportion of tumors were located in the right side of the colon (45%). The proportion of poorly differentiated tumors was also notable (16%). The proportion of mucin-producing tumors (mucinous tumors and "signet ring" cell tumors) was 33% of all cases. More than 50% of all tumors were in an advanced stage when diagnosed, with lymph-node involvement and/or distant metastasis. Other remarkable features were incidence of polyps found during follow-up (33%) and three cases (7%) of synchronous and metachronous CRCs. Adenomatous polyps were the most frequently observed type of polyp (13/15).

Median overall survival was 60 mo, while Median Free-Disease Survival was 48 mo. Twenty-three point nine per cent of the patients showed recurrence during follow-up, and overall mortality was 38% (17 patients).

[1]Proportions were calculated for 42 tumors; [2]Statistical comparison between microsatellite stable (MSS) and microsatellite instability (MSI) groups was performed using Student´s *t* test. CRC: Colorectal cancer; NS: Not significant.

Familial features

Table 2 shows the familial cancer history data. One patient was a case with familial adenomatous polyposis (FAP); 27 (60%) were sporadic cases with Lynch syndrome (without Lynch syndrome-associated neoplasms in their families), while 20% showed familial aggregation, and eight fulfilled Amsterdam II criteria[6]. Apart from CRC, the other most frequent tumors were endometrial adenocarcinoma (six families) and gastric cancer (four families). Twelve families (27%) had other neoplasms not related to Lynch syndrome; the most frequent ones being breast cancer (four cases), larynx cancer (three cases), and leukemia (three cases).

[1]Not all tumors could be studied by immunohistochemical.

Molecular features

Forty-two of the 45 cases were studied for MSI. The three excluded cases were: the FAP case, with an *APC* gene germline mutation (c.916delCT), and two additional cases, due to lack of paraffin embedded tumor tissue. Thirteen tumors (31%) showed MSI and the remaining 29 were therefore defined as MSS.

Blood samples were taken from the MSI index cases for *MLH1* and *MSH2* mutation screening. *MSH6* was not studied because none of the tumors showed lack of Msh6 protein alone in IHC analysis. Eight of the 13 analyzed cases (62%) showed a pathogenic germline mutation in one of the MMR genes: three cases had a mutation in *MLH1*, and five cases had a mutation in *MSH2*. None of the MSS tumors showed lack of expression of MMR proteins in the IHC study.

IHC studies with the remaining antibodies were carried out on 28 cases (Table 3). A remarkable finding was the high proportion of tumors lacking expression of cyclin E, especially in those patients who died during follow-up (9/11). Similarly, all six stage D CRCs included in the IHC study also showed lack of cyclin E expression. The lack of cyclin E expression is either an indicator of poor prognosis or a marker of advanced stage disease. β-catenin and E-cadherin, two proteins in the Wnt pathway, which plays an important role in CRC carcinogenesis, were normal in a high proportion of studied tumors.

Comparison between MSI and MSS tumors

Clinicopathological features: The comparison of the clinicopathological characteristics of the two defined groups (MSS and MSI) is shown in Table 2. Statistically significant differences were observed in the age of onset, which was earlier in the MSI cases, and in the presence of "signet-ring cell" tumors, which were absent in the MSS group. No statistically significant differences were found in the other variables analyzed, probably due to the small sample size. However, it is important to underline that the MSI CRCs were more frequently located proximally (69%), were poorly differentiated with higher mucin production, and were associated with other CRCs. The frequency of polyps during follow-up was the same in MSS and MSI tumors (35% and 31%, respectively). Another remarkable feature was that more than a half of all cases were diagnosed at an advanced stage (with lymph node involvement and/or distant metastasis, stages C or D): 52% for MSS and 61% for MSI.

There might be a trend towards a better prognosis for the MSI group when compared with the MSS group, but without reaching statistical significance: 62 mo *vs* 48 mo for median overall survival, and 62 mo *vs* 29 mo in terms of median disease-free survival. Mortality was higher in the MSS group (41%) than in the MSI group (31%).

Familial features: Table 2 shows familial cancer information and results obtained from the comparison of the MSS and MSI families. MSI cases are more frequently associated to Lynch-related neoplasia. On the other hand, the proportion of sporadic cases is very high in MSS tumors (83%).

Molecular features: The comparison of the IHC study in MSI and MSS tumors is shown in Table 4. None of the MSS tumors demonstrated lack of expression of MMR proteins in the IHC study. There was, as mentioned above, a good correlation between MSI and the IHC study of the MMR proteins.

Normal expression of β-catenin reached the same proportion (86%) in both types of tumors, indicative of the integrity of the Wnt signalling pathway in early age-of-onset CRCs. The high rate of MSI tumors with lack of expression of CK20 and RAD50 was also remarkable.

DISCUSSION

Early onset of CRC in young adults used to be considered to be rare, but many recent reports suggest not only that early onset CRC reaches 8% of all CRCs, but also that it might be increasing[1,2]. Similarly, it is a common belief that early onset CRC is mainly related to hereditary forms, especially to Lynch syndrome. In our study, the presence of a familial background of CRC is confirmed in 38% of the cases, 18% fulfilling Amsterdam criteria type Ⅱ for Lynch syndrome. Hereditary forms of CRC were confirmed in nine patients of the present series. One was a FAP case with an APC germline mutation, and the other eight cases were Lynch syndrome. The rate of MSI in

our series is similar to that described in previous studies, ranging between 19.7% and 41%[7-9]. Twenty-nine cases showed MSS. This group showed a predominance of sporadic cases. Nevertheless, there were cases that showed a positive family history. Some of them might be associated to Familial CRC type X, namely cases with MSS tumors but fulfilling Amsterdam criteria for Lynch syndrome[21,22]. These findings, however, underline the important, but not unique role, of the known hereditary factors in this age group, prompting further searches for additional causative genes for inherited CRC.

The total sample of early age-of-onset CRCs is characterized by an important proportion of tumors that are localized in the right colon (44%), have a low-grade of differentiation (16%), produce mucin (33%), and have associated polyps (33%). Regarding pathological features, the strong trend towards low-grade differentiation and mucin production of tumors in this age group is described in the literature[7]. Other characteristics, such as synchronous and metachronous CRCs (7%) and the appearance of predominantly adenomatous polyps during the follow-up in a third of the cases, have rarely been studied previously[7,13].

Another finding is the advanced stage of the tumors at diagnosis, with more than half of the cases presenting with lymph node and/or distant metastasis in the pathological exam. This is the consequence of a delay in diagnosis, which is a characteristic of these early age-of-onset CRCs reported repeatedly in the literature[7,8,13].

The results obtained with the cyclin E antibody in the IHC study are quite remarkable. High levels of cyclin E, a G1/S phase transition controller, are found in many different tumors, including CRCs[23-25]. Cyclin E expression has only been evaluated in sporadic forms of CRC, with a variable value as a prognostic factor. Some publications suggest that lack of expression of cyclin E is associated with a faster growth of CRC, but others suggest the opposite[24,26,27]. Seventy per cent of our tumors showed lack of expression of this marker, especially the group of MSS CRCs, in which the proportion reached 86%, while the opposite occurred in the MSI group. The lack of expression of cyclin E might be associated with a poor prognosis, because expression was absent in most patients who died during follow-up (9/11), and all six stage D CRCs included in the IHC study also showed lack of expression of cyclin E. This was observed in both the MSS and the MSI groups, and in the latter group, the only case that showed lack of expression also died during follow-up. Although the sample size is small and the results must therefore be taken with caution, data related to cyclin E as a factor of poor prognosis must be validated in a larger series. In fact, it would be interesting to see if lack of expression of cyclin E corresponds with a subgroup of patients with apparently stable, near-diploid chromosomes and MSS (MACS); CRC in these patients shows an aggressive pattern and the MACS phenotype appears to be overrepresented in early-onset tumors[28,29].

Another important finding of the present study is related to the Wnt pathway. We found a high proportion of normal expression of β-catenin. This protein is an indicator of Wnt pathway dynamics[30], and the expression of β-catenin, mainly in the nucleus, is considered a good marker of the activity of the Wnt pathway[31,32]. The activation of this pathway often occurs in MSS tumors, but also in MSI tumors, independent of the age of onset[33]. Our findings, however, might indicate that the Wnt pathway is not involved in a substantial proportion of our early onset CRCs.

Early onset CRC is a heterogeneous group. To classify different subtypes with common etiology, the use of tools, such as MSI or IHC for MMR proteins, to identify an MMR system deficiency or an intact system (MSS) might be an appropriate and useful approach. All clinicopathological features analyzed in the global series tend to be more marked when the series is divided into MSI and MSS groups. MSI early onset CRCs showed characteristics similar to Lynch syndrome: earlier age of onset, predominant location in the right colon, and a high proportion of poorly differentiated tumors, in accordance with previous reports[8,13]. The same occurs with an elevated proportion of mucin-producing tumors (39%), and "signet-ring" cell tumors. MSS, on the contrary, are tumors that have an

older age of onset, are mainly located in the left colon, and have a low proportion of mucinous or "signet ring" cell tumors.

From the molecular point of view, our data must be confirmed in a larger series to reach more reliable conclusions. Nevertheless, some results should be emphasized. There is a good correlation between the lack of expression of MMR proteins and MSI. This is in agreement with published data, showing a positive prospective value of the IHC of 88%-100%[34,35]. Cyclin E is expressed in most of the MSI tumors, and the opposite occurs in the MSS, as published for sporadic CRC[27]. We found a normal expression of β-catenin in most MSI and MSS tumors. Our results contradict published findings for sporadic CRC, in which a high proportion of MSS tumors show an abnormal expression of β-catenin (90%), which decreases to 65% in MSI tumors[36,37]. There are few published studies focused on early onset CRC but in these the proportion of abnormal β-catenin expression is still significant (77.2% and 42.9% for MSS and MSI, respectively)[8]. Our results, however, should be confirmed by comparing them with control groups of CRCs, to exclude the possibility that technical differences or differences in interpretation of the staining patterns, might explain these contradictory findings.

Early onset CRC has an important proportion of hereditary forms of CRC. The apparent lack of involvement of the Wnt pathway is important, as is the possible value of cyclin E as a poor prognosis factor in early onset CRC. The advanced stage at diagnosis, as well as the still not fully understood group of MSS tumors, should promote a strong effort to diagnose these tumors at an earlier stage, providing a better understanding of MSS early onset CRC.

We thank the Pathology Department of Gregorio Marañón University Hospital and Segovia Hospital for providing us with the paraffin-embedded tissues, and Ron Hartong for his help with the English redaction of the article.

COMMENTS

Background

Initially early-onset colorectal cancer (CRC) was thought to be a group mainly composed by hereditary forms of CRC (Lynch syndrome), as early-onset is a characteristic of hereditary forms of cancer, and because of that, most of the publications focused on the hereditary component of this group of CRC.

Research frontiers

There is a larger group of hereditary forms of CRC, compared with that arising in the older population. However, there is an important proportion of tumors that apparently do not show characteristics of the already known hereditary forms of CRC, and which are not well studied.

Innovations and breakthroughs

This is the first time that a complete approach (clinicopathological, familial, molecular, and immunohistochemical) to the early-onset CRC has been performed. The authors have identified certain characteristics that seem to be more frequent in the early-onset CRC. The proportion of hereditary forms, though, represents a relatively small amount of the cases, and some interesting findings are presented that allow prognozing of these patients.

Applications

This is the first step towards a deeper understanding of early-onset CRC, an entity that is increasing in an especially sensitive group of population.

Peer review

The authors present an in depth analysis of young patients (< 45 years) presenting with CRC. Though the sample is small (n = 45) they perform a comparative analysis between those cases that are microsatellite stable and those that show microsatellite instability.

Abstract

AIM: To evaluate the overlap of autoimmune hepatitis in hepatitis C virus (HCV)-infected patients with intense interface hepatitis.

METHODS: Among 1759 patients with hepatitis C submitted to liver biopsy, 92 (5.2%) presented intense interface hepatitis. These patients were evaluated regarding the presence of antinuclear antibody (ANA), anti-smooth muscle antibody (SMA) and anti-liver/kidney microsomal antibody (LKM-1), levels of γ-globulin and histological findings related to autoimmune hepatitis (plasma cell infiltrate and presence of rosettes).

RESULTS: Among patients with hepatitis C and intense interface hepatitis there was a low prevalence of autoantibodies (ANA = 12%, SMA = 5%, LKM-1 = 0%) and the median γ-globulin level was within the normal range. Typical histological findings of autoimmune disease were observed in only two cases (2%). After applying the score for diagnosis of autoimmune hepatitis, only one patient was classified with a definitive diagnosis of autoimmune hepatitis. Since overlap with autoimmune hepatitis was not the explanation for the intense necroinflammatory activity in patients with chronic hepatitis C we sought to identify the variables associated with this finding. The presence of intense interface hepatitis was associated with more advanced age, both at the time of infection and at the time of the biopsy, and higher prevalence of blood transfusion and alcohol abuse.

CONCLUSION: Although possible, overlap with autoimmune hepatitis is a very rare association in HCV-infected patients with intense interface hepatitis, an unusual presentation which seems to be related to other host variables.

Key words: Hepatitis C; Liver biopsy; Antinuclear antibody; Autoimmune hepatitis; Interface hepatitis

Is autoimmune hepatitis a frequent finding among HCV patients with intense interface hepatitis? *World J Gastroenterol* 2010; 16(29): 3704-3708 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i29/3704.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i29.3704

INTRODUCTION

Hepatitis C is the main cause of liver-related morbidity and mortality and represents a worldwide public health problem[1]. An estimated 170 million individuals are infected with hepatitis C virus (HCV), corresponding to 3% of the world population[2].

Infection with HCV is characterized by a high chronicity rate (70% to 85%)[3-6], progression to cirrhosis in 20% to 30% of cases[1,6-8] and the development of hepatocarcinoma in 5% of patients[9]. In addition, this infection represents the most common indication for liver transplantation worldwide[10].

Histological analysis of patients chronically infected with HCV usually reveals some degree of fibrosis, generally associated with the presence of mild or moderate necroinflammatory activity[11]. However, a histological pattern demonstrating intense interface hepatitis has been reported[12,13]. In these cases a possible association with autoimmune hepatitis has been suggested, raising doubts regarding the correct diagnosis and the establishment of adequate treatment[14-16]. The objective of the present study was to evaluate the overlap with autoimmune hepatitis in HCV-infected patients with intense interface hepatitis.

MATERIALS AND METHODS

Patients

Patients chronically infected with HCV followed up at the Federal University of Sao Paulo between 1993 and 2006, who were submitted to a liver biopsy, were studied. The inclusion criteria were chronic infection with HCV (characterized by HCV-RNA positivity) and the presence of intense interface hepatitis upon histological analysis. Patients previously treated or who were HBsAg-positive were excluded.

A control group consisting of patients chronically infected with HCV, who presented absent, mild or moderate interface hepatitis, was included in order to evaluate if an eventual association of autoimmune hepatitis with hepatitis C was restricted to patients with intense necroinflammatory activity. In the absence of such association, a comparison with the control group was performed to evaluate other factors possibly related to intense interface hepatitis. This control group was randomly selected from the database of the Hepatitis Outpatient Clinic of the Federal University of Sao Paulo (1:1 ratio). The same exclusion criteria were adopted for the control group. For the comparative analysis, patients with associated diseases [human immunodeficiency virus (HIV), end-stage renal disease and kidney transplant] were excluded from both groups.

The study was approved by the local Ethical Committee.

Epidemiological characteristics

The patients were evaluated regarding gender, age, estimated duration of infection, age at the time of infection, abusive alcohol consumption (men > 40 g/d and women > 20 g/d), the presence of parenteral risk factors (intravenous drug use, hemodialysis or blood transfusion before 1992) and associated diseases (HIV, end-stage renal disease and kidney transplant). This information was recovered from charts where the data were systematically evaluated with a standardized questionnaire. The duration of infection was evaluated in patients with parenteral risk factors and was estimated from the first year of intravenous drug use or hemodialysis or from the year of first transfusion in patients who had received blood transfusions before 1992.

Laboratory tests

The liver enzymes alanine aminotransferase (ALT), aspartate aminotransferase (AST), γ-glutamyltransferase (GGT) and alkaline phosphatase were assayed by an automated kinetic method and were expressed as the following index: value obtained/upper limit of normal. γ-globulins were assayed by electrophoretic fractionation on agarose gel and densitometry. All biochemical tests were performed within a period of 3 mo from the date of the liver biopsy.

Antinuclear antibody (ANA), anti-smooth muscle antibody (SMA), anti-liver/kidney microsomal antibody (anti-LKM) and anti-mitochondrial antibody were determined by indirect immunofluorescence and the titer was considered significant when higher than 1/40.

The patients were tested for the presence of HBsAg and anti-HIV-1/2 using commercial kits (Abbott Laboratories, Chicago, IL, USA). Anti-HCV was determined with a third-generation enzyme immunoassay (Abbott Laboratories, Chicago, IL, USA). Qualitative HCV-RNA was detected by PCR using the Amplicor® Hepatitis C Virus Test, version 2.0 (Roche Molecular Systems, Branchburg, NJ, USA), with a detection limit of 50 IU/mL. HCV genotyping was performed by VERSANT HCV Genotype Assay - LiPA (Innogenetics N.V., Belgium).

Histological analysis

A liver biopsy was indicated in all patients, irrespective of ALT levels. Liver tissue fragments were obtained by percutaneous biopsy with a Tru-cut® needle. The liver biopsy slides were stained with hematoxylin-eosin, Masson's trichrome, Prussian blue (Perls' stain), and silver for reticular fibers (Gomori's stain), and were reviewed by a single pathologist who was unaware of the clinical data. Histological analysis included the determination of the grade of interface hepatitis and of the stage of fibrosis, which were assessed using a semiquantitative scoring system according to Ludwig[17]. Patients were classified as having intense interface hepatitis if they presented a score of periportal activity = 4, in a scale varying from 0 (no inflammation) to 4 (intense necroinflammatory activity).

In order to better characterize the presence of eventual histological components suggestive of autoimmune injury, the presence of plasma cell infiltrate and rosettes was also analyzed.

Scoring system for diagnosis of autoimmune hepatitis

All patients were evaluated regarding the reviewed interna-

Table 1 General characteristics of patients with intense interface hepatitis *n* (%)

	Intense interface hepatitis (*n* = 92)
Male gender	52 (57)
Age (mean ± SD, yr)	49.8 ± 10.5
Age at the time of infection (mean ± SD, yr)	29.5 ± 9.8
Parenteral risk factor	59 (64)
Duration of infection (mean ± SD, yr)	20.1 ± 8.7
History of blood transfusion	44 (48)
Intravenous drug use	13 (14)
Hemodialysis	2 (2)
Alcoholism	25 (27)
Human immunodeficiency virus-positive	5 (5)
Renal transplant	6 (7)
End-stage renal disease	2 (2)
Alanine aminotransferase (xULN)	4.1 (0.3-18.2)
Aspartate aminotransferase (xULN)	3.0 (0.9-10.4)
γ-glutamyltransferase (xULN)	4.1 (0.1-16.4)
Alkaline phosphatase (xULN)	0.9 (0.3-3.8)
γ-globulin (g/dL)	1.9 (0.73-5.74)
Antinuclear antibody	11 (12)[1]
Anti-smooth muscle antibody	5 (5)
Anti-liver/kidney microsomal antibody	0 (0)
Antimitochondrial antibody	1 (1)

Genotype non-1	24/77 (31)
Cirrhosis	53 (58)
Parenchymatous activity ⩾ 3	50 (54)
Intense plasma cell infiltrate	2 (2)
Rosettes	26 (28)

[1]All antinuclear antibody positive patients presented the speckled pattern; titers varied from 1/80 to 1/640. xULN: Times the upper limit of normal.

tional diagnostic criteria for autoimmune hepatitis according to the International Autoimmune Hepatitis Group[18].

Statistical analysis

The χ^2 test and Fisher's exact test were used for statistical analysis of categorical variables. Numerical variables were compared between the two groups using the Student *t*-test and Mann-Whitney test. A level of significance of 0.05 (α = 5%) was adopted.

RESULTS

Among the 1759 patients chronically infected with HCV submitted to a liver biopsy during the study period, 92 presented intense interface hepatitis, corresponding to 5.2% of the initial sample. The characteristics of these patients are shown in Table 1.

Among patients presenting intense interface hepatitis, there was a low prevalence of autoantibodies and the median γ-globulin level was within the normal range. Typical histological findings of autoimmune disease were observed in only two cases (2%). After applying the scoring system for diagnosis of autoimmune hepatitis only one patient was classified as having a definitive diagnosis.

Since overlap with autoimmune hepatitis was not the explanation for the intense necroinflammatory activity in patients with chronic hepatitis C, we sought to identify the variables associated with this finding. Therefore, we compared epidemiological, laboratory and histological characteristics between patients with intense interface hepatitis and a randomly selected control group consisting of chronic HCV-infected patients with absent, mild or moderate interface hepatitis. For comparison between groups, 13 patients with associated disease were excluded from the group with intense interface hepatitis: 6 patients with kidney transplant, 5 with HIV co-infection and 2 with end-stage renal disease.

Table 2 Comparative analysis of general characteristics between groups *n* (%)

	Group 1 (*n* = 79)	Group 2 (*n* = 79)	*P*
Male gender	44 (56)	49 (62)	0.42
Mean age (mean ± SD, yr)	50.8 ± 10.6	43.9 ± 11.5	< 0.001
Alcoholism	22 (28)	10 (13)	0.02
Blood transfusion	37 (47)	23 (29)	0.02
Intravenous drug use	10 (13)	9 (11)	0.81
Duration of infection (mean ± SD, yr)	22.2 ± 7.9	20.9 ± 7.5	0.49
Age at the time of infection (mean ± SD, yr)	28.6 ± 9.6	23.0 ± 11.2	0.02
ALT (xULN)	4.2 (0.3-18.2)	1.8 (0.9-11.3)	< 0.001
AST (xULN)	3.1 (0.9-10.4)	1.4 (0.8-5.8)	< 0.001
GGT (xULN)	3.8 (0.1-16.4)	1.1 (0.1-10.6)	< 0.001
Alkaline phosphatase (xULN)	0.8 (0.3-2.1)	1.0 (0.1-3.0)	0.32
γ-globulin (g/dL)	1.9 (0.7-4.0)	1.7 (0.9-3.7)	0.19
ANA positive	9 (11)	7 (9)	0.59
Genotype 1	43/65 (66)	54/79 (68)	0.78
Cirrhosis	50 (63)	20 (25)	< 0.001
Parenchymatous activity ⩾ 3	43 (55)	3 (4)	< 0.001

Group 1: Patients with intense interface hepatitis; Group 2: Patients with absent, mild or moderate interface hepatitis. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT: γ-glutamyltransferase; xULN: Times the upper limit of normal; ANA: Antinuclear antibody.

In the group of patients with intense interface hepatitis, the subjects were older and the proportions of blood transfusion and abusive alcohol consumption were higher. In addition, these patients presented higher levels of ALT (4.2 *vs* 1.8, $P < 0.001$), AST (3.1 *vs* 1.4, $P < 0.001$) and GGT (3.8 *vs* 1.1, $P < 0.001$). No difference in the proportion of patients with reactive ANA or serum γ-globulin levels was observed between groups (Table 2).

Regarding liver biopsy, the mean number of portal tracts observed was 11. Histological aspects are presented in Table 2. The proportion of patients with moderate to intense lobular necroinflammatory activity and cirrhosis was higher in the group with intense interface hepatitis ($P < 0.001$).

DISCUSSION

Previous studies have demonstrated that the presence of intense interface hepatitis in patients chronically infected with HCV is rare[19,20]. When this finding is present, other liver diseases, especially autoimmune hepatitis, should be carefully ruled out. In the present study, 1759 patients

chronically infected with HCV were initially evaluated and in 92 of them (5.2%) a liver biopsy revealed intense interface hepatitis, indicating that, although uncommon, this finding might be a histological pattern of hepatitis C.

The main objective of the present study was to evaluate the overlap with autoimmune hepatitis in HCV-infected patients with intense interface hepatitis. In this sample only two patients (2%) had serological and histological evidence of autoimmunity in the group with intense interface hepatitis and only one patient had a definitive diagnosis of autoimmune hepatitis based on the International Autoimmune Hepatitis Group scoring system[18]. Although a 12% prevalence of ANA was found among the intense interface hepatitis patients, there was no difference in the proportion of patients with positive ANA when they were compared to patients with less intense necroinflammatory activity. In addition, the prevalence of SMA and anti-LKM was very low in the group with intense interface hepatitis.

No histological lesions typical of autoimmune hepatitis were identified in all except two patients and the proportion of cases presenting a significant plasma cell infiltrate was very low in patients with intense interface hepatitis. The high proportion of patients with rosettes observed in the group with intense interface hepatitis was not considered as suggestive of autoimmune injury, since it reflects hepatic regeneration activity as a consequence of greater necroinflammatory activity and can be observed in other etiologies of liver disease[21,22]. These findings support the suggestion that overlap with autoimmune hepatitis is a very rare association in HCV-infected patients with intense interface hepatitis and raises the possibility that some mechanism related to the host-virus interaction might be responsible for the intense interface hepatitis observed.

Since overlap with autoimmune hepatitis was not found in association with intense necroinflammatory activity in patients with chronic hepatitis C we sought to identify other variables associated with this finding.

In comparison to the control group, the presence of intense interface hepatitis was associated with the following epidemiological characteristics: more advanced age both at the time of infection and at the time of the biopsy, and a higher prevalence of blood transfusion and alcohol abuse. With respect to age at the time of infection, a higher necroinflammatory hepatic activity was observed in patients with more advanced age at HCV infection[19,23]. However, the mechanisms related to this phenomenon are still unknown. One hypothesis is that the ability of the immune system to contain the pathological process triggered by the HCV infection declines with age. It is possible that the higher proportion of patients with a history of blood transfusion in the group with intense interface hepatitis, another association observed in this study, also reflects the association between more advanced age and intense interface hepatitis, since in this sample patients with a history of transfusion were older ($P = 0.025$).

Excessive alcohol consumption was another variable associated with intense interface hepatitis, suggesting that alcohol may modify the histological injury induced by HCV[23,24], rendering the disease more aggressive even in the absence of lesions characteristic of direct alcoholic hepatic disease. The mechanism whereby alcohol may aggravate the HCV-induced inflammatory process remains obscure.

Analysis of biochemical and histological characteristics demonstrated that patients with intense interface hepatitis present with more severe liver disease, including a high proportion of cirrhosis (63%). With respect to liver enzymes, significantly higher ALT, AST and GGT levels were observed, an expected finding since elevated aminotransferases[25] and GGT[26] levels have been shown to be associated with greater hepatic inflammatory activity.

Although an association between genotype 1 and more intense necroinflammatory activity has been demonstrated[27], no such association between HCV genotype and severity of liver disease was observed in the present study and in most of the studies reported in the literature[28-32].

Regarding histological findings, the histological variables associated with intense interface hepatitis were advanced fibrosis and more intense parenchymatous activity. Although the association between necroinflammatory activity and fibrosis is controversial, this finding supports the hypothesis that necroinflammatory activity influences the progression of hepatic fibrosis as demonstrated in other studies[33-36]. The parenchymatous activity was another variable independently associated with intense interface hepatitis. Although the interface hepatitis is the main histological lesion observed in chronic hepatitis C, whenever the necroinflammatory activity is intense, this process tends to involve all the compartments, and is not restricted to the portal tract.

In conclusion, the absence of elevated γ-globulin levels, the low prevalence of autoantibodies, the occurrence of typical histological findings of autoimmune disease in only two cases (2%), and a definitive diagnosis according to the autoimmune hepatitis score in only one case, suggest that overlap with autoimmune hepatitis is a very rare association in HCV-infected patients with intense interface hepatitis. The uncommon histological presentation of hepatitis C with intense interface hepatitis seems to be related mainly to other host variables.

COMMENTS

Background

Previous studies have demonstrated that intense interface hepatitis is an uncommon finding in chronic hepatitis C. When this finding is present, it raises doubt regarding a possible association with autoimmune hepatitis.

Research frontiers

The main objective of the present study was to evaluate the overlap with autoimmune hepatitis in hepatitis C virus (HCV)-infected patients with intense interface hepatitis.

Innovations and breakthroughs

This study demonstrated that overlap with autoimmune hepatitis is a very rare association in HCV-infected patients with intense interface hepatitis. This finding raises the possibility that some mechanism related to the host-virus interaction might be responsible for this histological pattern.

Applications

Considering that overlap with autoimmune hepatitis in HCV-infected patients with intense interface hepatitis is very uncommon, the best clinical approach for these patients should be antiviral therapy. These results reduce the dilemma of

whether immunosuppressive therapy is indicated for patients presenting with this histological finding.

Terminology

Interface hepatitis is a histological finding in liver biopsies observed in chronic hepatitis. It is also termed necroinflammatory periportal activity and was formerly known as piecemeal necrosis. Interface hepatitis is graded as mild, moderate or intense. In this study the authors aimed to evaluate HCV-infected patients with intense interface hepatitis.

Peer review

The paper is well written and represents timely research aimed at identifying a link between hepatitis C and autoimmune hepatitis.

Abstract

AIM: To analyze the outcome of patients who received concurrent capecitabine (Xeloda) and radiation (XRT) compared to the established concurrent 5-fluorouracil (5-FU) with radiation (5FU-RT) and fluoropyrimidine-based chemotherapy alone as adjuvant treatment in gastric cancers.

METHODS: All patients with gastric cancers who received adjuvant treatment at the National Cancer Centre Singapore between 1996 and 2006 were reviewed. Treatment outcomes of patients who received XRT were compared with those who had 5FU-RT or chemotherapy alone as adjuvant therapy for gastric cancers.

RESULTS: A total of 108 patients were reviewed. Median age at diagnosis was 60. The majority of the patients (64.8%) had advanced stage Ⅲ and Ⅳ disease (with no distant metastasis). All except 4 patients had D2 gastrectomy. Twenty one patients (19.4%) had positive surgical resection margins. Thirty three patients received XRT compared with 52 who had 5FU-RT and 23 who received chemotherapy alone. For the patients in the chemotherapy-only group, all had fluoropyrimidine-based therapy, with added cisplatin in 7 patients and epirubicin in 2 patients. Median recurrence-free survival was longer for the XRT group (52 mo) compared to the 5FU-RT (35 mo) and chemotherapy-only groups (25 mo) (P = 0.48). The patients in the XRT group achieved similar median overall survival (53 mo) as the 5FU-RT (54 mo) and the chemotherapy-only groups (44 mo) (P = 0.5).

CONCLUSION: Capecitabine with concurrent radiation was as effective as concurrent 5FU with radiation or fluoropyrimidine-based chemotherapy alone when used as adjuvant treatment in patients with gastric cancers.

Key words: Capecitabine; Radiation; Gastric cancer; Adjuvant chemotherapy

INTRODUCTION

Surgery is the curative treatment for gastric cancer. However, the outcome of large T3-T4 tumors and those with lymph node involvement remains poor after surgical resection alone with high risk of local and distant recurrence[1]. Many attempts had been made to improve the prognosis of resected gastric cancers. These include postoperative adjuvant chemotherapy with or without radiation and perioperative chemotherapy.

Adjuvant therapy in gastric cancer is a field of ongoing active research. The different modalities in the adjuvant setting include chemoradiation and chemotherapy alone. There is currently no randomized phase Ⅲ trial that directly compared these various modalities. Hence, the optimal adjuvant therapy in gastric cancer remains to be determined.

Capecitabine (Xeloda), an oral fluoropyrimidine, was shown to have equivalent efficacy to continuous-infusional 5-fluorouracil (5-FU) in several phase Ⅲ trials in metastatic gastric cancers. The REAL-2 study compared capecitabine or 5-FU in combination with cisplatin and oxaliplatin and showed no differences in response rates or survival between all the 4 combination regimens[2]. The ML 17032 trial comparing the combination of capecitabine with cisplatin to 5-FU with cisplatin showed that capecitabine and cisplatin had a better response rate (41% *vs* 29%) and overall survival (10.5 mo *vs* 9.3 mo)[3]. Because of the convenient oral administration of capecitabine, its use in the adjuvant setting is an attractive option to explore. In fact, capecitabine with concurrent radiation as an adjuvant or neoadjuvant treatment in resected gastric cancer and other gastrointestinal malignancies, particularly rectal cancer, has been explored in several studies[4-6]. These studies demonstrated that capecitabine with concurrent radiation was feasible with manageable toxicities. However, the regimen has never been compared with the more established concurrent 5-FU and radiation (5FU-RT) or adjuvant chemotherapy alone.

Hence, in this study, we aimed to analyze the outcome of patients who received adjuvant concurrent capecitabine and radiation (XRT) compared to those who received concurrent FU-RT or fluoropyrimidine-based chemotherapy alone in the adjuvant setting in gastric cancers.

MATERIALS AND METHODS

All patients diagnosed with gastric cancer who received adjuvant treatment at National Cancer Center Singapore from 1996 to 2007 were reviewed. Clinical information was collected retrospectively and included age, gender, performance status, *Helicobacter pylori* status, surgical outcome, tumor histology, carcinoembryonic antigen, baseline hematologic and biochemical parameters, recurrence and survival data.

The patients were divided into 3 groups based on the adjuvant treatment received. These included 5FU-RT, XRT and chemotherapy alone for analysis. The patients in the XRT group received 825 mg/m^2 capecitabine daily with concurrent radiation followed by capecitabine 2000 mg/m^2 every 3 wk for 6 cycles. Patients in the 5FU-RT group received chemoradiation which consisted of 5 cycles of 5-FU 400 mg/m^2 plus leucovorin (20 mg/m^2) given every 28 d with 2 cycles given concurrently with radiation. The total radiation dose in both the XRT and 5FU-RT groups was 45 Gy delivered over a period of 5 wk. The patients in the chemotherapy-only group received fluoropyrimidine-based chemotherapy.

The patients receiving XRT were compared with those who had 5FU-RT and fluoropyrimidine-based chemotherapy in terms of recurrence-free survival and overall survival. We also compared the patients who received radiation as part of their adjuvant therapy to those who received chemotherapy alone.

Comparison of the median age at baseline between treatment groups was done using the Mann-Whitney *U* test. Other baseline characteristics, such as gender, performance status, stage and grade, as shown in Table 1, were performed using Fisher's exact test.

Recurrence-free survival duration was calculated from the date of diagnosis to the date of recurrence or death (whichever occurred first) or last follow-up. Overall survival duration was calculated from the date of diagnosis to the date of death or last follow-up. The Kaplan-Meier method was used to estimate and plot the recurrence-free survival and overall survival curves for the 3 treatment groups. The log-rank test was used to test if the survival function for the treatment groups were statistically different at the 5% significance level.

For recurrence-free survival and overall survival, the Cox proportional hazards model was used to estimate the crude and age-adjusted hazard ratios between treatment groups using the XRT arm as the reference treatment. Age at diagnosis was included in multivariate Cox regression analyses to estimate the adjusted hazard ratios. Subgroup analysis of the recurrence-free survival and overall survival hazard ratios between the chemotherapy-only group and chemoradiotherapy (XRT or 5FU-RT) were performed using the Cox proportional hazard model for patients with a positive surgical margin, Stage 3 or 4, and positive nodes, respectively.

Statistical analysis

The Cox proportional hazards model and log-rank test were also used to estimate the hazard ratios to assess if any of the baseline characteristics were associated with recurrence-free survival and overall survival in each of the 3 treatment groups. Normality of the variables in the Cox model was assessed using a Q-Q plot and proportionality assumption of the Cox model was assessed using the Schoenfeld test.

Two-sided *P*-values of less than 5% were considered as statistically significant. The software used for the analyses was STATA version 9.1.

RESULTS

A total of 108 patients had received adjuvant therapy for gastric cancer at our institution in the specified period. Median follow-up duration was 23 mo.

[1]All *P*-values calculated using Fisher's exact test unless otherwise stated; [2]*P*-value calculated using the Mann-Whitney *U* test. XRT: Capecitabine + radiation; 5FU-RT: 5-fluorouracil + radiation; ECOG: Eastern Cooperative Oncology Group status; CEA: Carcinoembryonic antigen.

Thirty-three of these patients received XRT, 52 received 5FU-RT and 23 received fluoropyrimidine-based chemotherapy. Of the patients who received chemotherapy alone, 11 had capecitabine alone, 6 had ECF (epirubicin, cisplatin and 5-FU), 4 had XELOX (capecitabine and oxaliplatin) and 2 had 5-FU alone. Ninety-one percent of the patients in the XRT group, 89% in the 5FU-RT and 91% in the chemotherapy-only group completed the full course of adjuvant treatment.

The characteristics of these patients are shown in Table 1. Median age at diagnosis was 60 years. Sixty-five percent of the patients had advanced stage Ⅲ and Ⅳ (with no distant metastasis) disease. All except 4 patients had D2 gastrectomy (2 in the XRT group, 2 in the chemotherapy-only group). Twenty-one of these patients (19.4%) had positive surgical resection margins (14 in the 5FU-RT group, 4 in the XRT group and 3 in the chemotherapy-only group). The only significant difference in characteristics among the 3 groups of patients was median age, with the median age of the patients in the XRT group being greater than that of the other 2 groups.

Median recurrence-free survival was longer for the XRT group (52 mo) compared with the 5FU-RT (35 mo) and chemotherapy-only groups (25 mo). However, the recurrence-free survival curves between the 3 groups were not statistically significant ($P = 0.5$, Figure 1A, Table 2). Patients with positive surgical margins were found to have a significantly poorer recurrence-free survival in both the XRT and 5FU-RT groups but not in the chemotherapy-only group (Table 3).

The overall survival times of the patients in the 3 treatment groups were not statistically different ($P = 0.5$), with the median overall survival of the patients in the XRT group at 53 mo, the 5FU-RT group at 54 mo and the chemotherapy-only group at 44 mo (Figure 1B). Patients with positive surgical margins were found to have poorer survival across all the treatment groups (Table 3).

When comparing patients who received radiation as part of their adjuvant therapy to those who received chemotherapy alone, there was no statistical difference in recurrence-free survival and overall survival between these 2 groups of patients (Figure 1C and D). Subgroup analyses of patients with positive surgical margins, lymph node positive and T3 or T4 disease did not show a statistically difference in survival between patients who received radiation as part of their adjuvant therapy and those who did not (Table 4).

Treatment was generally well tolerated in the 3 treatment groups. In total only 6 patients (5%) had grade 3 or 4 toxicities, 4 in the 5FU-RT group, one in the XRT group and one in the chemotherapy-only group. Diarrhea was the most common grade 3 or 4 adverse effect. One

[1]Age-adjusted hazard ratio (HR). XRT: Capecitabine + radiation; 5FU-RT: 5-fluorouracil + radiation.

patient in the XRT group had acute myocardial infarction during the therapy period. There was one death from non-neutropenic sepsis during the adjuvant treatment in the 5FU-RT group.

DISCUSSION

Our study showed that XRT was as effective as 5FU-RT and fluoropyrimidine-based chemotherapy when given as adjuvant treatment for locally advanced gastric cancer. XRT had comparable recurrence-free and overall survival with the other 2 adjuvant regimens.

The Intergroup-0116 study has established the role of adjuvant chemoradiation for resected locally advanced gastric cancer in the United States. Compared to surgery alone, the addition of chemoradiation after resection leads to an increased local control (30 mo *vs* 19 mo, $P = 0.001$) and better median overall survival (36 mo *vs* 27 mo, $P = 0.005$)[7]. In our study, the median overall survival for patients receiving XRT or 5FU-RT was 53 and 54 mo, respectively. This outcome when compared to the Intergroup trial is encouraging as 66% of patients in our study population had T3 or T4 disease and 86% had lymph node-positive disease, similar to the study population in the Intergroup study (68% and 85%, respectively). This difference could be explained by the differences in surgical techniques. All except 2 of our patients underwent D2 gastrectomies compared to only 10% in the Intergroup study. This may suggest that the adjuvant treatment could be a measure to compensate for inadequate surgical treatment. Nevertheless, the extent of lymph node dissection remains an ongoing debate with trials from the Dutch Gastric Cancer Group[8] and Medical Research Council[9] showing a lack of survival benefit of D2 over D1 lymph node dissection. However, the role of adjuvant chemoradiation in D2-resected gastric cancer had been studied in a Korean prospective non-randomized trial involving 544 patients receiving postoperative 5FU-

5FU-RT: 5-fluorouracil + radiation; XRT: Capecitabine + radiation; HR: Hazard ratio.

radiation. This trial demonstrated significantly longer overall survival in the chemoradiation group compared to the surgery alone group (95.3 mo *vs* 62.6 mo, $P = 0.02$)[10]. Hence, there appears to be a role of adjuvant concurrent chemoradiation even in the setting of optimal surgical resection of gastric cancer.

Continuous infusion 5-FU was preferred over 5-FU bolus infusion in most of the gastrointestinal malignancies, especially colorectal cancer, and was also found to be more effective than the bolus 5-FU[11,12]. Continuous 5-FU infusion with radiation was used extensively in the neoadjuvant and adjuvant treatment of rectal cancer[13,14]. Oral capecitabine, in the metastatic and adjuvant setting, has been shown to be as effective as continuous 5-FU in gastrointestinal malignancies[2,12,15,16]. The ease of oral administration of capecitabine compared with the continuous infusion of 5-FU, which requires the placement of a central venous catheter, makes the use of capecitabine concurrent with radiotherapy an attractive option. Our results, albeit retrospective, showed an equivalent survival between XRT and 5FU-RT. Hence, XRT could be a reasonable alternative to 5FU-RT as adjuvant treatment in resected stomach cancer. Several phase Ⅰ / Ⅱ studies have already explored the addition of capecitabine with concurrent radiation[4,5] in adjuvant stomach cancer and shown it to be safe and tolerable.

Our analysis has shown that there was no survival difference between those who had radiation as part of their adjuvant therapy compared to those who did not. Even in patients with a positive surgical margin, the addition of radiation did not appear to significantly improve survival compared to adjuvant chemotherapy alone. The role of adjuvant chemotherapy had been studied in many phase Ⅲ Western trials but the results were inconsistent in showing a survival benefit of adjuvant chemotherapy over surgery alone[17-20]. Meta-analyses of these trials suggest a potential absolute increase in 5-year survival of 2% to 4% with adjuvant chemotherapy in resected gastric

cancer[21,22]. The Asian adjuvant trials had demonstrated more favorable results with a recent Japanese study on adjuvant S1 in resected stage Ⅱ or Ⅲ gastric cancer showing a significantly higher 3-year overall survival rate in the S1 group compared to the observation arm (80.1% *vs* 70.1%, $P = 0.003$)[23]. Hence, fluoropyrimidine-based chemotherapy may have a role in adjuvant treatment. However, there is currently no phase Ⅲ trial that compared adjuvant chemoradiation and chemotherapy alone. Our study has shown that there is no survival difference between adjuvant chemoradiation and chemotherapy, suggesting that adjuvant chemotherapy alone may be a reasonable option of adjuvant therapy in resected gastric cancer. A study involving capecitabine alone for adjuvant therapy in gastric cancer will be an interesting follow-up study.

In conclusion, XRT as an adjuvant therapy in resected gastric cancer can achieve similar outcomes to that of 5FU-RT or chemotherapy. The result from our hypothesis-generating study provides the basis for a further prospective study in evaluating the role of radiation with concurrent capecitabine as adjuvant therapy in resected gastric cancers.

COMMENTS

Background

Gastric cancer is a major cause of cancer deaths in the world. The outcome of large gastric tumors and those with lymph node involvement remains poor after surgical resection. The optimal adjuvant therapy after surgical resection remains to be determined.

Research frontiers

The most common strategies in the adjuvant treatment of gastric cancers include fluoropyrimidine-based chemotherapy with or without radiation. The introduction of capecitabine has largely replaced continuous-infusion 5-fluorouracil (5-FU) owing to its ease of administration. However, its efficacy is not proven in randomized phase Ⅲ trials involving gastric cancers. In this retrospective review study, the authors examined the role of capecitabine with radiation and compared its efficacy to the 5-FU with radiation regimen and fluoropyrimidine-based chemotherapy alone.

Innovations and breakthroughs

This study showed that capecitabine with concurrent radiation was as effective as 5-FU with radiation or fluoropyrimidine-based chemotherapy alone without radiation when given as adjuvant treatment for locally advanced gastric cancer.

Applications

This hypothesis-generating study will provide the platform for a larger randomized study to be conducted using capecitabine as one of the study regimens in adjuvant gastric cancer trials.

Terminology

Capecitabine and 5-FU are fluoropyrimidine-based chemotherapy commonly used in the treatment of gastrointestinal cancers.

Peer review

This is a retrospective clinical study that looked at the effects of chemoradiation therapy by using capecitabine in patients undergoing gastric surgery for gastric cancer. The results are well presented and the discussion is well organized. The conclusions are supported by the data and the tables contain appropriate information.

Abstract

AIM: To present a series of cases with life-threatening hemorrhage from ruptured hepatic artery pseudoaneurysm after pancreaticoduodenectomy (PD) treated with placement of stent-grafts.

METHODS: Massive hemorrhage from ruptured hepatic artery pseudoaneurysm after PD in 9 patients (6 men, 3 women) at the age of 23-75 years (mean 48 years), were treated with placement of percutaneous endovascular balloon-expandable coronary stent-grafts. All patients were not suitable for embolization because of a non-patent portal vein. One or more stent-grafts, ranging 3-6 mm in diameter and 16-55 mm in length, were placed to exclude ruptured pseudoaneurysm. Follow-up data, including clinical condition, liver function tests, and Doppler ultrasound examination, were recorded at the outpatient clinic.

RESULTS: Immediate technical success was achieved in all the 9 patients. All stent-grafts were deployed in the intended position for immediate cessation of bleeding and preservation of satisfactory hepatic arterial blood flow. No significant procedure-related complications occurred. Recurrent bleeding occurred in 2 patients at 16 and 24 h, respectively, after placement of stent-grafts and treated with surgical revision. One patient died of sepsis 12 d after the interventional procedure. The remaining 6 patients were survived when they were discharged. The mean follow-up time was 10.5 mo (range 4-16 mo). No patient had recurrent bleeding after discharge. Doppler ultrasound examination verified the patency of hepatic artery and stent-grafts during the follow-up.

CONCLUSION: Placement of stent-grafts is an effective and safe procedure for acute life-threatening hemorrhage from ruptured hepatic artery pseudoaneurysm.

Key words: Pancreaticoduodenectomy; Hemorrhage; Hepatic artery; Pseudoaneurysm; Stent-graft

INTRODUCTION

Delayed hepatic arterial hemorrhage after pancreaticodu-

odenectomy (PD) is not a common, but a potentially fatal complication[1-4]. Massive hepatic arterial bleeding occurs as a result of inflammatory vascular erosion related to pancreatic juice or bile leaking from an insufficient anastomosis and/or due to local infection. Treatment options include re-operation or endovascular catheter techniques such as coil embolization of the bleeding vessels. Surgical exploration and identification of the bleeding vessel may be difficult in acute situations and hazardous because of adhesions and surrounding postsurgical tissue friability[5,6]. Embolization of the bleeding artery has an immediate impact on patient survival but often excludes the distal circulation, which may be a risk factor for hepatic ischemia and even fatal hepatic necrosis, particularly in patients with portal vein stenosis or thrombosis[3,7-9].

Recently the use of stent-grafts to exclude aneurysms in splenic and other visceral arteries has been presented in single case reports[10-15]. We report our experience in 9 patients with delayed massive hemorrhage from ruptured hepatic artery pseudoaneurysm after PD, demonstrating the potential of interventional radiology in initial treatment of hemorrhage, instead of re-operation and coil embolization, using transluminal stent graft placement for emergency vessel repair retaining patency of hepatic artery.

MATERIALS AND METHODS

Patients

From March 2003 to December 2009, 9 patients (6 men, 3 women) at the age of 23-75 years (mean 48 years), referred to our department for delayed massive hemorrhage from ruptured hepatic artery pseudoaneurysm occurring 6 or more days after PD, were treated with percutaneous endovascular placement of balloon-expandable stent-grafts. All medical records, radiological reports, and images of the patients were retrospectively reviewed. Delayed massive hemorrhage occurring 5 or more days after PD in patients with stable hemodynamics was defined as a potentially life-threatening bleeding leading to hemorrhagic shock needing blood transfusions as previously described[2,3].

The indications for PD are listed in Table 1. Classic resection procedures were performed in all the 9 patients, including Whipple procedure (n = 6) and pylorus preserving pancreatoduodenectomy (n = 3). Pancreatic fistula (PF) after PD, diagnosed by routine assay of drainage fluid amylase levels, was present in 7 patients with local infection. PF was defined as drain output of any measurable volume of fluid on or after postoperative day 3 with amylase content 3 times greater than that of serum amylase activity[4]. Embolization of splenic artery was performed in 2 patients (Patients No. 1 and No. 2) due to bleeding from the splenic artery.

All the 9 patients presented with an unstable clinical condition with their heart rate higher than 90 beats per min, blood pressure lower than 80/40 mmHg, hemoglobin lower than 6.5 g/dL (reference range 13-18 g/dL), hematocrit lower than 40% (reference range 40%-54%), and blood transfusion greater than 5 U. Angiography revealed active hemorrhage from the hepatic artery pseudoaneurysm, including bleeding from the abdominal drain (n = 4), gastrointestinal tract (n = 2), or both (n = 3). Bleeding occurred in 7 patients (78%) before they were discharged and in 2 patients (Patients No. 5 and No. 7) after they were discharged following an uneventful postoperative course. The mean time between PD and onset of massive bleeding was 15.3 d (range 6-38 d).

All patients received an average blood transfusion of 10.6 U (9-12 U) before the interventional procedure. Of the 9 patients, 5 needed an average of 1520 mL (1200-1800 mL) fresh frozen plasma and 4 required intubation.

Emergency endoscopy performed in 3 patients showed mixed old and fresh blood in gastric lumen but no bleeding site. Computed tomography (CT) and ultrasonography were not performed because of the emergency situation.

Informed consent was obtained from the patients or their guardians before the interventional procedure.

Indication for stent graft placement

Instead of coil embolization, stent-graft was placed to exclude hepatic pseudoaneurysm because the patients had an obstructed portal vein prior to massive pseudoaneurysm bleeding, including thrombosis of the portal vein in 5 patients, tumor infiltration of the portal vein in 3 patients, and ligation of the portal vein during the surgical procedure in 1 patient. In patients with a non-patent portal vein, embolization of the common or proper hepatic artery was a high risk factor for hepatic ischemia and even fatal hepatic necrosis as previously described[9,16].

Endovascular techniques

After restoration of hemodynamic stability by aggressive resuscitation with intravenous fluids and administration of blood products, the patients underwent emergency abdominal angiography with standard Seldinger technique. All procedures were performed under local anesthesia (2% lidocaine). The patients were monitored by electrocardiogram and blood pressure measurements.

A pigtail catheter (4 Fr, Cordis, the Netherlands) was inserted into the abdominal aorta at level of the 12th thoracic vertebra, and an abdominal aortography was performed with digital subtraction angiography technique. The celiac trunk, hepatic artery, splenic artery, and superior mesenteric artery were selectively catheterized using a 4 Fr Cobra catheter (Cordis). Both arterial and portal venous phases were assessed, in order to detect the bleeding site and exclude the portal vein thrombosis.

Diameter of the affected artery at the located bleeding site was measured. A 0.35-inch guide-wire (Terumo Co., Tokyo, Japan) was passed into a distal branch of the right or left hepatic artery through the 4 Fr Cobra catheter under fluoroscopic guidance. The femoral 4 Fr introducer was replaced with an 8 Fr introducer with a 60 cm long vascular sheath (Arrow, Arrow International, USA).

A stent-graft (Jostent, Graftmaster, Coronary stent graft, Germany) was advanced into the distal extravasation site through the 8 Fr Arrow sheath over a 0.014 inch guide-wire (Table 2). The sheath was then pulled back to

Table 2 Outcome of the patients enrolled in this study after placement of stent grafts

Patient No.	Immediate technical success	Intensive care unit/ length of stay	Clinical outcome	Length of hospital stay (d)	Follow-up
1	Yes	Yes/19 d	Bleeding stopped, no further hemorrhage	48	4 mo exitus, AMI
2	Yes	Yes/7 d	Bleeding stopped, no further bleeding	28	16 mo, clinical and laboratory findings normal
3	Yes	Yes/10 d	Bleeding stopped, no further bleeding	38	10 mo exitus, underlying malignancy
4	Yes	Yes/15 d	Recurrent bleeding 16 h later, underwent surgical revision	32	2 d exitus, uncontrolled bleeding
5	Yes	No	Cessation of bleeding, no further hemorrhage	11	14 mo exitus, underlying malignancy
6	Yes	Yes/8 d	Bleeding stopped, no further hemorrhage	36	8 mo exitus, underlying malignancy
7	Yes	No	Bleeding stopped, no further hemorrhage	12	11 mo, clinical and laboratory findings normal
8	Yes	Yes/21 d	Recurrent bleeding 24 h later, underwent surgical revision	40	3 d exitus, multiorgan failure
9	Yes	Yes/24 d	Bleeding stopped, no further hemorrhage	43	12 d exitus, abdominal sepsis

AMI: Acute myocardial infarction.

the proximal extravasation site to allow initial exposure of the stent-graft. The stent-graft was then deployed by inflating the balloon to a pressure of 8 atmospheres. A 6/20-mm balloon catheter (Abbott Lab, IL) was then used to post-dilate the stent-graft. If placement of one stent-graft failed to completely exclude the pseudoaneurysm, a second or even a third stent-graft was placed in a coaxial overlapping manner. Control angiography was repeated to confirm the exclusion of pseudoaneurysm, no sign of contrast medium extravasation, and patency of the hepatic artery.

Post-procedural management

All individuals were given antibiotics to prevent infection with aerobic and non-aerobic bacteria but no anticoagulation or anti-platelet drugs immediately after the procedure due to the emergent hemorrhagic conditions.

Six patients were survived when they were discharged and aspirin (100 mg/d) was given lifelong after discharge. Follow-up data, including clinical condition and laboratory (liver function test) findings, were recorded at the outpatient clinic. Doppler ultrasound studies were performed every day for 1 wk after placement of stent-grafts, then every 2-3 d, followed by every month on an outpatient basis.

Outcome parameters

Technical success was defined as the successful deploy-

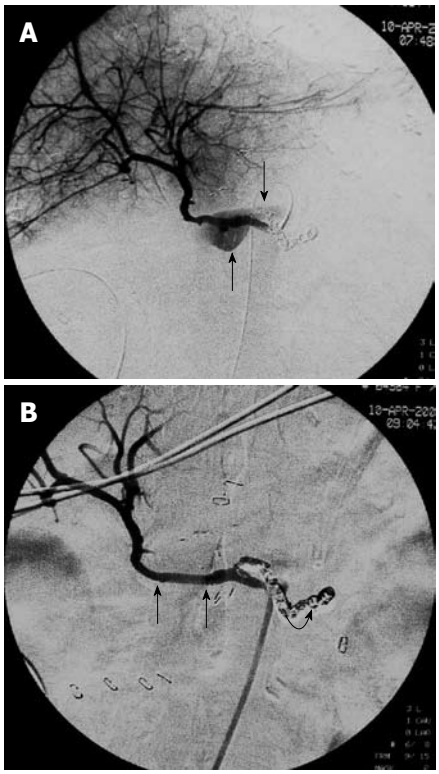

Figure 1 A 75-year-old female with pancreatic head malignancy underwent a pylorus-preserving pancreaticoduodenectomy (Case 1). A: Selective angiography of the common hepatic artery shows a large ruptured hepatic artery pseudoaneurysm with extravasation of contrast medium (arrows); B: Angiography after two stent-grafts placement demonstrates exclusion of the aneurysm and preserved hepatic artery blood flow through the stent-grafts (arrows). Note the splenic artery was embolized 4 d ago due to bleeding from the splenic artery (curved arrow).

ment of stent-graft within the intended artery, exclusion of pseudoaneurysm without evidence for contrast extravasation, cessation of immediate hemorrhage, and preservation of hepatic arterial flow. Clinical success was defined as the disappearance of signs or symptoms and improvement in laboratory findings. Re-bleeding from the same arterial focus after treatment was defined as clinical failure.

RESULTS

Immediate technical success

The selective angiography of celiac axis demonstrated active bleeding (extravasation of contrast agent) from the ruptured hepatic artery pseudoaneurysm in all patients (Figure 1A). A non-patent main portal vein was observed at the delayed phase in all patients.

Stent-graft placement was technically successful in all patients with the bleeding pseudoaneurysm completely excluded and stable hemodynamically achieved immediately (Figure 1B). The control angiography demonstrated patency of the hepatic artery in all individuals (Figure 2A and B). Each patient needed one or more stent-grafts to exclude his or her ruptured hepatic pseudoaneurysm. A total of 19 stent-grafts were implanted in 9 patients (Table 1).

The median time of interventional procedure, including diagnostic angiography, was 65 min (range 35-100 min).

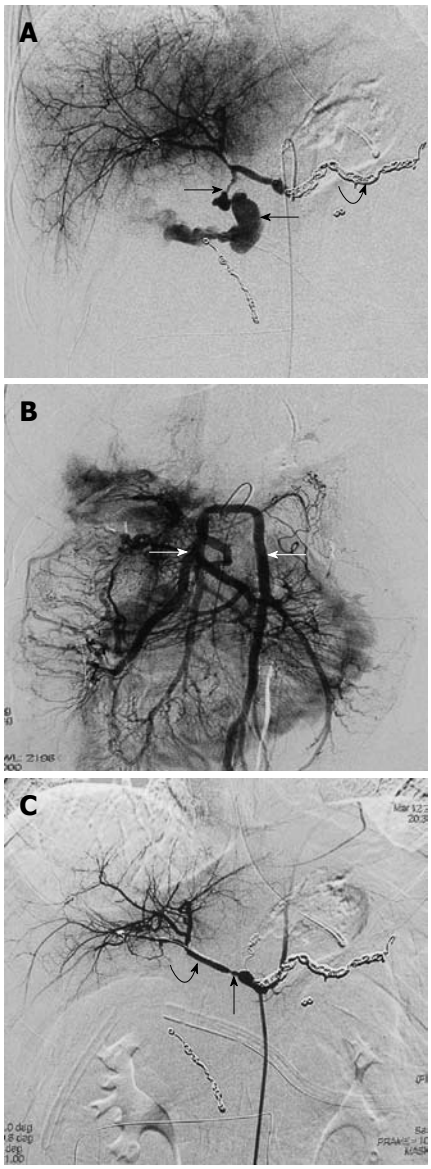

Figure 2 A 23-year-old female with pancreatic trauma underwent a pylorus-preserving pancreaticoduodenectomy (Case 2). A: Emergent selective angiography of the celiac trunk demonstrates massive extravasation of contrast medium into the abdominal cavity from the ruptured hepatic artery pseudoaneurysm (arrows). Note the splenic artery was embolized 6 d ago due to bleeding from the splenic artery (curved arrow); B: Digital substraction superior mesenteric artery angiogram with delayed phase demonstrates no visualization of the portal vein, and remarkable pooling of contrast medium at the branches of the SMV (arrows); C: Angiography after two pieces of stent-grafts placement shows exclusion of the bleeding hepatic pseudoaneurysm and good hepatic arterial blood flow through the stent-grafts (curved arrow). Note the spasm of the proximal hepatic artery (arrow).

No vascular adverse event occurred during the procedure. Control angiography showed vasospasm of the proximal and distal hepatic artery during and immediately after the procedure as expected because of the intra-arterial guide wire manipulation (Figure 2C), which did not affect the outcome of intervention. No major complication of the procedure was observed.

Clinical outcome

Seven patients were transferred to intensive care unit after

placement of stent-grafts with a mean stay time of 13.7 d (7-24 d). Four patients required intubation.

Hemodynamically stabilization was achieved in 7 of the 9 patients after the procedure without evidence of further bleeding (Table 2). Laboratory findings (liver function tests) were within the normal range 1, 3 and 7 d after the procedures and at the time when the patients were discharged.

Two patients (Patients No. 4 and No. 8) with clinical failure underwent surgical revision. In patient No. 4, the stent-graft was successfully placed, but his hemoglobin level dropped again 16 h after the procedure due to bleeding from the same artery probably due to the dislodgment of stent-grafts. This patient underwent surgical revision and died of uncontrolled bleeding 2 d after the procedure. In patient No. 8, recurrent bleeding occurred 24 h after the placement of stent-grafts due to bleeding from the same artery. He underwent surgical revision with haemostasis achieved. The patient died of multiorgan failure 3 d after the procedure.

Of the 7 patients with their bleeding completely controlled, one (Patient No. 9) died of intra-abdominal sepsis 12 d after the interventional procedure with no active bleeding until her death. Four patients were subjected to CT-guided interventional placement of additional drains close to the pancreaticojejunostomy due to considerable fluid collections. Two patients underwent re-operation for persistent abscess and PF.

Follow-up

Six patients were survived when they were discharged (Table 2). Their mean hospital stay time was 24.5 d (range 11-48 d). The mean follow-up time was 10.5 mo (range 4-16 mo). No further bleeding was seen during the follow-up. Clinical and laboratory follow-up findings were unremarkable. Doppler ultrasound examination verified the patency of hepatic artery and stent-grafts during the follow-up.

DISCUSSION

It was reported that approximately two thirds of delayed arterial hemorrhage cases after PD have an underlying collection or anastomotic leak, with pseudoaneurysm formation[1,2,4,5,9]. In our study, delayed hepatic arterial hemorrhage occurred in 7 of the 9 patients due to the local complication (PF).

Transcatheter arterial embolization (TAE) has been advocated as the first-line treatment modality for late-onset bleeding after PD[17-20], with a success rate of 83%-100% and a mortality of 0%-20%. In fact, the liver can tolerate embolization of the main hepatic artery without major consequences, since it has a dual blood supply from the portal and arterial circulations. Collateral arterial blood flow to the liver can also be expected. However, the number of collaterals is less than that of normal blood vessels after PD because of lymphadenectomy and skeletonization of the vasculature[3]. Embolization of the hepatic artery may result in liver failure and necrosis as well as intrahepatic abscesses[5,21,22].

In this study, all patients had an obstructed portal vein. Embolization of the hepatic artery itself, proximal and distal to the bleeding pseudoaneurysm, may influence the liver perfusion with an undesirable effect[9,16]. Thus, for preserving hepatic arterial blood flow, implantation of stent-grafts (covered stent) may be better than TAE[10-12].

In recent years, stent-grafts have been increasingly used in endovascular repair of thoracic and abdominal aneurysm, repair of traumatic subclavian artery and iatrogenic vascular injuries, and in exclusion of peripheral arterial aneurysms[23,24]. However, conventional peripheral vascular stent-grafts are 6-8 mm in diameter and 6 mm in length, making implantation difficult through the tortuous celiac arterial system. Moreover, stent-graft itself is less flexible and seldom used in the celiac system[25,26]. The Jostent, used in our patients for sealing perforation of coronary artery, is a covered stent, ranging 3.5-4.0 mm in diameter and 16-19 mm in length[27]. In the present study, placement of coronary stent-grafts was a useful procedure for the repair of ruptured hepatic artery pseudoaneurysm. However, angiography follow-up was not performed, but hepatic arterial flow was confirmed by Doppler ultrasound examination.

In this study, a high immediate technical success rate was archived using stent-grafts for bleeding hepatic artery pseudoaneurysm, which is consistent with the reported findings[10-15,22]. Bleeding was immediately controlled after placement of stent-grafts and all patients remained stable after the procedure. However, recurrent bleeding occurred in 2 patients, at 16 and 24 h, respectively, after the interventional procedure, possibly due to the dislodgment of stent-grafts.

Of the 7 patients with their bleeding successfully controlled, one died of intra-abdominal sepsis 12 d after the interventional procedure. Consequently, the patency of hepatic artery and stent-grafts without recurrent bleeding was achieved in 6 patients during a mean follow-up time of 10.5 mo (range 4-16 mo).

Placement of stent-grafts with preservation of organ arterial flow, if technically possible, may represent the best treatment option with the following advantages[10-15]. First, it permits immediate and effective control of hemorrhage, thus avoiding emergency surgery, and a second operation can be performed if hemodynamics is stable. Second, placement of stent-grafts is a minimally invasive technique with a low morbidity. Third, placement of stent-grafts preserves end-organ perfusion in the acute stage, thus reducing the risk of organ failure or infarction.

Placement of stent-grafts for hemorrhage from ruptured hepatic artery pseudoaneurysm has several limitations. First, although technical success has been achieved in most published case reports, stent-graft implantation in branches of the celiac trunk is not always possible[10,12,28]. Second, the procedure may lead to rupture of artery because of its eroded and fragile vascular wall, thus requiring emergency surgery. Third, placement of stent-grafts may

lead to in-stent-graft stenosis and occlusion[23,24,27]. It has been recommended that antiplatelet medication should be given after stent-graft deployment in order to prevent in-stent-graft stenosis.

In addition, placement of stent-grafts can control hemorrhage but cannot treat other potential complications[5,16]. To reduce the risk of recurrent hemorrhage, antibiotic therapy for peripancreatic infection and surgical revision of pancreatic or biliary anastomotic leakage may be necessary. Alternatively, pancreatic or biliary leakage can be treated by percutaneous drainage in some patients. In the present study, 6 patients recovered after placement of stent-grafts. Of the 6 patients, 4 underwent CT-guided placement of additional drains, and 2 underwent re-operation due to persistent abscess and PF.

This study has the following limitations: lack of a control group, randomization, and uniformity of evaluation and treatment. In fact, it is almost impossible to perform a prospective randomized study and no statistically significant conclusion could be drawn because of the limited number of patients.

In summary, placement of stent-grafts for acute life-threatening bleeding from hepatic artery pseudoaneurysm is a valuable alternative to embolization and surgical intervention. If technically possible, this technique should be considered the first-line treatment for bleeding from the common and proper hepatic artery, particularly in patients with a non-portal vein. Further data are required to evaluate its technical success rate, complications, and long-term outcome in a larger number of patients.

COMMENTS

Background

Delayed hepatic arterial hemorrhage after pancreaticoduodenectomy (PD) is not a common but a fatal complication, occurring in 7% of all patients. Its ideal management remains unclear and controversial.

Research frontiers

There are many diagnostic and therapeutic options for massive hepatic arterial hemorrhage after PD but no established guidelines are available. Traditional treatment modalities for massive bleeding include re-operation or endovascular catheter techniques such as coil embolization. Surgical exploration and identification of the bleeding vessel can be difficult in acute situations and hazardous because of adhesions and surrounding postsurgical tissue friability. Embolization of the bleeding artery has an immediate impact on patient survival but often excludes the distal circulation, which may have a risk of hepatic ischemia and even fatal hepatic necrosis, particularly in patients with portal vein stenosis or thrombosis. Placement of stent-grafts is a new procedure for control of bleeding without interruption of the distal circulation.

Innovations and breakthroughs

The authors reported the clinical outcome of 9 patients with life-threatening hemorrhage from a ruptured hepatic artery pseudoaneurysm after PD after treatment with a new interventional technique, namely placement of stent-grafts. This technique provides a good alternative option for the control of hemorrhage from ruptured hepatic artery pseudoaneurysm after PD, especially in those who cannot undergo embolization. Although the number of patients was small, the procedure demonstrated a lower mortality than conventional surgical intervention.

Applications

Instead of coil embolization, the authors used stent-graft placement to exclude ruptured hepatic pseudoaneurysm because the patients had an obstructed portal vein prior to massive bleeding. In patients with a non-patent portal vein, embolization of the common or proper hepatic artery may have a high risk of hepatic ischemia and even fatal hepatic necrosis. Placement of stent-grafts in bleeding hepatic artery can immediately and effectively stop the hemorrhage, thus avoiding emergency surgery, and a second operation can be performed if the hemodynamics is stable. Placement of stent-grafts is a minimally invasive technique with a low morbidity. Placement of stent-grafts preserves end-organ perfusion in the acute stage, thus reducing the risk of liver ischemia or failure.

Peer review

The authors describe a small number of patients with life-threatening hemorrhage from ruptured hepatic artery pseudoaneurysm after PD, who were treated with implantation of endovascular stent-grafts. The study is quite interesting and innovative. Placement of stent-grafts is a good procedure for the control of massive bleeding from hepatic artery, especially in those who cannot undergo embolization. Although the number of patients is small, the results can be considered satisfactory and encouraging.

Abstract

A 35-year-old mother was scheduled to be the living donor for liver transplantation to her second son, who suffered from biliary atresia complicated with biliary cirrhosis at the age of 2 years. The operative plan was to recover the left lateral segment of the mother's liver for living donor transplantation. With the use of cholangiography at the time of surgery, we found the right anterior segmental duct (RASD) emptying directly into the cystic duct, and the catheter passed into the RASD. After repairing the incision in the cystic duct, transplantation was successfully performed. Her postoperative course was uneventful. Biliary anatomical variations were frequently encountered, however, this variation has very rarely been reported. If the RASD was divided, the repair would be very difficult because the duct will not dilate sufficiently in an otherwise healthy donor. Meticulous preoperative evaluation of the living donor's biliary anatomy, especially using magnetic resonance cholangiography and careful intraoperative techniques, is important to prevent bile duct injury and avoid the risk to the healthy donor.

INTRODUCTION

Living donor liver transplantation (LDLT) is accepted around the world with the shortage of suitable deceased donors[1-4]. The safety of the living donor, an otherwise healthy individual, is important in the ethical considerations of performing LDLT[5]. Morbidity in living donors is not rare[3,6,7]. Preoperative imaging studies are needed not only to evaluate the donor's condition but also to exclude unsuitable candidates. The liver volume, condition of the liver parenchyma, and vascular anatomy are relatively easy to assess through imaging studies especially using multi-detector row computed tomography (MDCT). Variations in biliary anatomy are common,

and in order to avoid intraoperative biliary injury, precise preoperative imaging studies are needed. However, it is difficult to evaluate biliary anatomy because of the complicated nature of various imaging modalities. There is no consensus for preoperative imaging to evaluate the donor's biliary anatomy. Even today intraoperative cholangiography (IOC) has a very important role in the assessment of a donor's biliary anatomy.

We identified a rare biliary anatomic variant during LDLT. The donor had the right anterior segmental duct (RASD) emptying directly into the cystic duct. In this report, we present this rare but important anatomic variant and discuss preoperative biliary imaging and the procedure for IOC.

CASE REPORT

A 35-year-old mother was scheduled to be the living donor for liver transplantation to her second son, who suffered from biliary atresia complicated with biliary cirrhosis at the age of 2 years. There were no remarkable findings in her family or past medical history. On physical examination, she had a healed operative scar in the lower abdomen as a result of two caesarean section procedures. A preoperative medical evaluation was performed and her liver volume, condition of the liver parenchyma, and hepatic vascular anatomy made her a suitable living donor. Congenital absence of the right kidney and slight prolongation of the activated partial thromboplastin time were found, which were not considered as contraindications for donor surgery. At that time, preoperative imaging of the biliary system was not performed routinely in our institution. LDLT was then performed, using an upper midline incision to recover the left lateral segment. After intraoperative ultrasound examination, cholecystectomy was performed. Before the gallbladder was removed, IOC was attempted through the incision in the cystic duct based on the conventional practice. However, the catheter would not pass easily into the cystic duct. Instead, it passed through a small hole in the side wall of the cystic duct. Using cholangiography, we found that the RASD emptied directly into the cystic duct with the catheter inserted into the RASD (Figure 1A), and the right posterior segmental duct joined the left hepatic duct. The incision in the cystic duct was repaired carefully to prevent stenosis. After removing the left lateral segment, another intraoperative cholangiogram was performed through the stump of the left hepatic duct and no stenosis at the confluence of the RASD and cystic duct was seen (Figure 1B). Her postoperative course was uneventful.

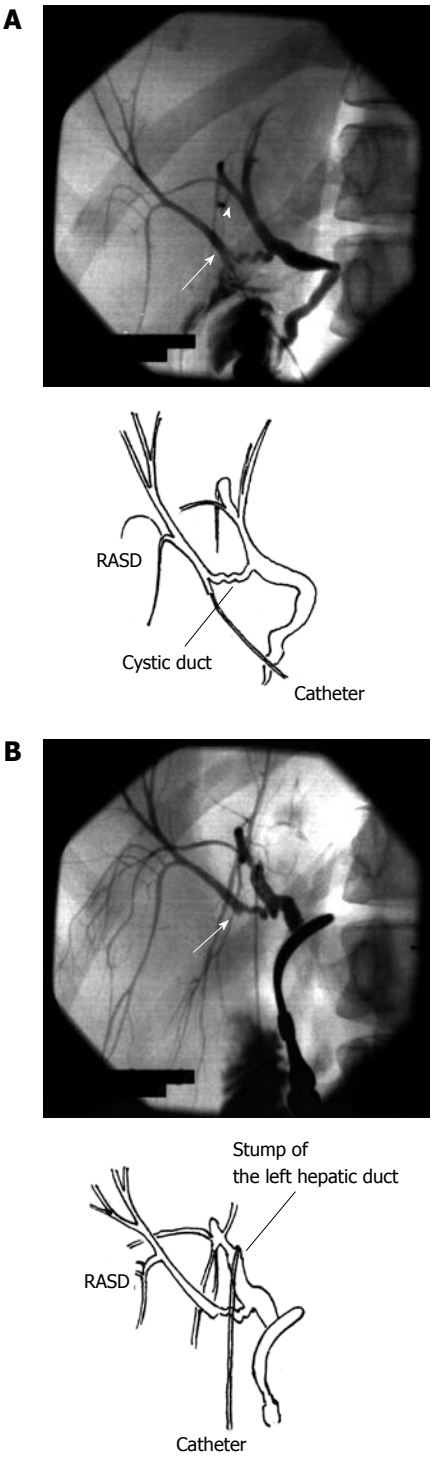

Figure 1 Intraoperative cholangiography. A: The right anterior segmental duct (RASD) emptying into the cystic duct is seen (arrow). The catheter is in the RASD. The right posterior segmental duct joining the left hepatic duct is also shown (arrowhead); B: After the left lateral segment was recovered, no stenosis was seen at the site of the repaired cystic duct (arrow). Cholangiography was performed through the stump of the left hepatic duct.

DISCUSSION

Biliary anatomical variants are frequently encountered[8], however, the variation reported in this case is very rare[9-12]. Champetier *et al*[13] stated that "The cystohepatic ducts drain the entirety of a hepatic territory of variable extent into the cystic duct or gallbladder", and they also emphasized the danger of these variants when performing a cholecystectomy.

The possibility of very rare biliary variations and the risks for the donor must be discussed in detail when ob-

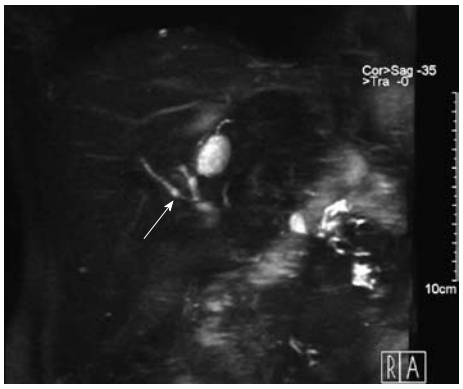

Figure 2 Magnetic resonance cholangiography was performed 3 mo postoperatively. The right anterior segmental duct and cystic duct are clearly seen (arrow).

taining informed consent. The living donor will be at risk, but continued efforts must be made to reduce the donor's morbidity as much as possible. In this case, we encountered a rare variant of biliary duct anatomy, but avoided injury to the RASD.

One of the ethical obligations of LDLT is to carefully protect the safety of the donor[5]. If the RASD was divided, the repair would be very difficult because the duct may not dilate sufficiently in an otherwise healthy donor. The donor might then suffer severe morbidities. To reduce the donor's risk, meticulous preoperative evaluation of the living donor's biliary anatomy is important. The transplant surgeons must be aware of biliary anatomic variants to prevent any intraoperative bile duct injury and minimize the risk to the donor. However, there is no single examination to demonstrate all biliary conditions expeditiously. Endoscopic retrograde cholangiography has some risks, such as the development of biliary injury, pancreatitis, and other conditions. MDCT is a breakthrough not only for demonstrating vascular anatomy but also to clearly depict the anatomy of the biliary system using biliary contrast material[14,15]. This modality also carries the risk of an allergic reaction. The possibility of a severe allergic reaction using vascular contrast material is only 0.04%[16]. On the other hand, biliary contrast materials have more risks of severe allergic reactions[17] and occur in up to 0.2% of patients according to the information from Japanese manufacturers. Dual enhanced MDCT is thought to be a very useful and accurate modality[14,15], but contains the relatively higher risk of an allergic reaction. Magnetic resonance cholangiography (MRC) is used in the preoperative examination of donors in some institutions[18,19]. However, MRC has relatively lower spatial resolution and a thin cystohepatic duct might not be accurately depicted. Postoperatively, the donor reported in this study was examined by MRC and the RASD was observed (Figure 2). The performance of this procedure was influenced by the intraoperative findings in this patient, but also led us to use MRC routinely in the preoperative evaluation of the donor's biliary anatomy to maximize the safety of the donors.

Careful intraoperative technique is also needed to improve the donor patient's safety, by assuring appropriate management of aberrant biliary branches. IOC is an essential modality to complete the donor transplantation procedure. In many cases, IOC is performed through an incision in the cystic duct; however, it may be hazardous to incise the cystic duct in a case as reported here. Therefore, we recommend using a modified IOC, incising the area of Hartmann's pouch. We believe that this method can reduce the possibility of injuring a very small but important biliary duct that might be not seen on preoperative imaging studies. It has been reported that IOC has some risks of allergic reactions[20], we believe that IOC itself is safe because little contrast material enters the systemic circulation. Using the knowledge gained from preoperative imaging and careful IOC, the safety of the donor is maximized.

In conclusion, to prevent injury of the bile ducts during the donor surgery of LDLT, preoperative delineation of the biliary anatomy is essential. Considering the donor's likelihood of suffering an allergic reaction, and the spatial resolution of various imaging modalities, we recommend MRC as the ideal preoperative biliary imaging study for the donors. IOC also plays an important role in the management of these donors. To perform IOC more carefully, we recommend that Hartmann's pouch should be incised first. By doing this we can help avoid transection of fine biliary branches that are not revealed during preoperative imaging, thus minimizing the likelihood of this avoidable complication.

Abstract

We report three rare cases of sclerosing angiomatoid nodular transformation (SANT) in the spleen. We compared the conventional and contrast-enhanced ultrasonographic appearance. The conventional sonographic examinations exhibited solitary lesions without common respects, while contrast-enhanced ultrasonography (CEUS) revealed nodular appearance mimicking its pathologic characteristics. It suggests that CEUS can provide morphologic information for diagnosing SANT.

Key words: Sclerosing angiomatoid nodular transformation; Contrast-enhanced ultrasonography; Ultrasound

INTRODUCTION

Sclerosing angiomatoid nodular transformation (SANT) is a rare benign lesion. Martel named it for its pathological characteristics[1]. Its particular morphologic appearance, immunophenotype, and benign clinical course indicate that it is a distinctive non-neoplastic vascular lesion in the spleen. We report the ultrasonographic images in three cases of SANT confirmed by splenectomy. Two of them also underwent contrast-enhanced ultrasonography (CEUS). We used a second-generation contrast agent, SonoVue (Bracco, Italy) at a dose of 1.2 mL[2].

CASE REPORT

Case 1

A 36-year-old man was found to have a splenic mass by a routine medical examination without any symptoms. Physical examination found nothing remarkable. No cervical or inguinal lymphadenopathy was found. The laboratory test results were as follows: hemoglobin 130 g/L, Ery 4.1 T/L, WBC 14.5 g/L, neutrophils 12.0 g/L and platelets 174 g/L, and all other data were within normal limits. Abdominal ultrasonography (US) was done using a 3.5C ultrasound transducer attached to a LOGIQ 5 Expert; it demonstrated a 4.2 cm × 3.7 cm well-demarcated, hypoechoic lesion in the spleen (Figure 1). The patient also underwent an MRI examination. On T1- and T2-weighted images, heterogeneous hypo-signal intensity with peripheral and septa enhancement, especially at the delayed phase, was displayed. The patient underwent splenectomy. In the surgery, the mass was found to have an integrated envelope and a heterogeneous cut surface. A few days after the surgery, his WBC and neutrophils became normal.

Case 2

A 37-year-old woman was referred to abdominal ultrasound examination because of pain in the left upper quadrant. Lesions were found both in her liver and spleen. Pro-

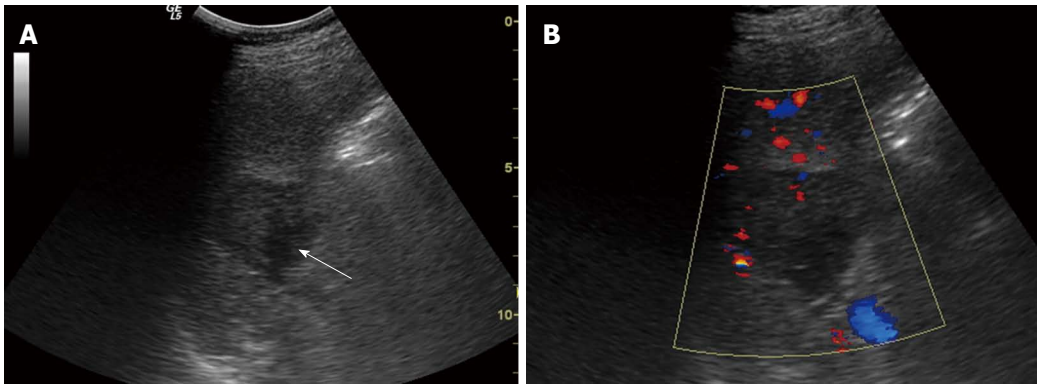

Figure 1 Conventional sonographic findings of sclerosing angiomatoid nodular transformation in a 36-year-old man. A: B mode ultrasonography demonstrates a hypoechoic lesion (arrow) in the spleen; B: Color Doppler flow imaging shows a low color-flow signal in the lesion.

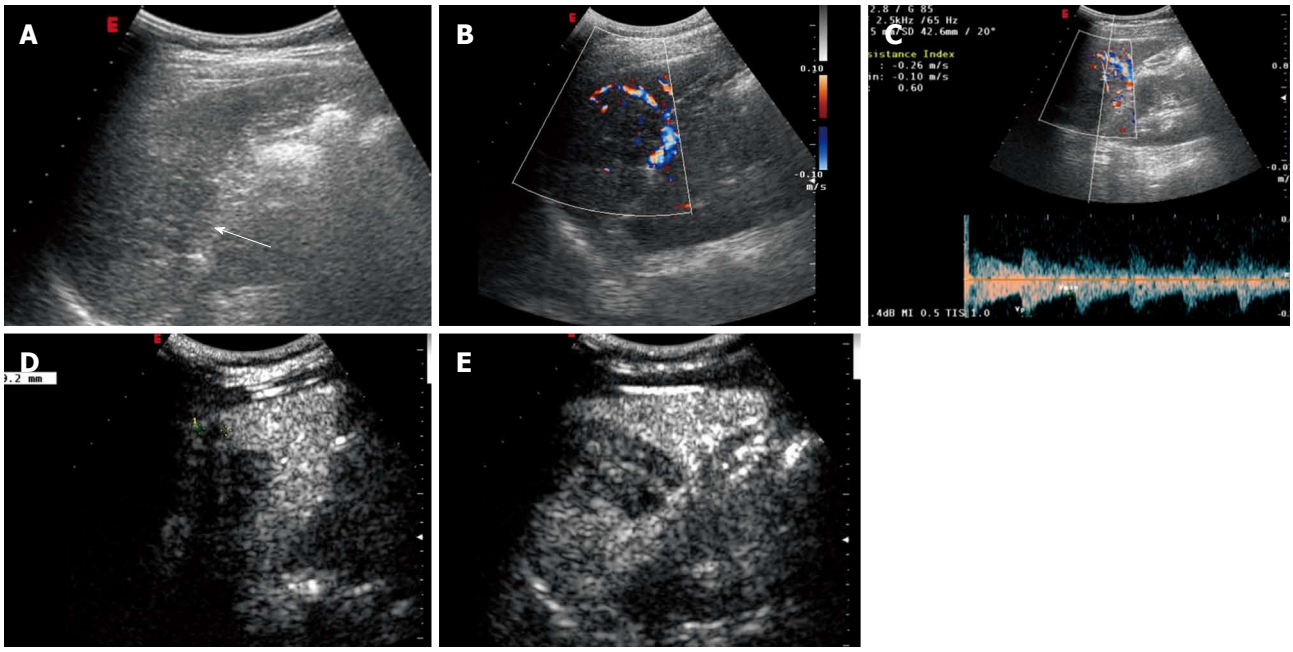

Figure 2 Conventional ultrasonography and contrast-enhanced ultrasonography findings of sclerosing angiomatoid nodular transformation in a 37-year-old woman with pain in the left upper quadrant. A-C: A heterogeneous hypoechoic lesion (arrow) in the spleen, with blood-flow signals in the peripheral area; D: There was a 0.9 cm homologous nodule attaching to the side of the lesion that became evident after being enhanced (2 min 48 s after injection); E: The lesion was enhanced homogeneously.

liferative disease of metastasis was taken into consideration during the differentiation process. Physical examination found nothing remarkable. No cervical or inguinal lymphadenopathy was observed. The laboratory tests yielded the following results: hemoglobin 120 g/L, Ery 3.88 T/L, WBC 4.6 g/L, neutrophils 3.2 g/L, platelets 214 g/L, CEA 1.16 ng/mL, AFP 2.4 ng/mL and CA19-9 6.79 U/mL. Other data were all within normal limits. Abdominal ultrasonography was done using a CA430E5-2 ultrasound transducer attached to a Technos ESAOTE DU 8; it demonstrated a 5.2 cm × 3.6 cm heterogeneous hypoechoic lesion in the spleen with an unclear margin. Color Doppler flow imaging (CDFI) showed blood-flow signals in the peripheral area of the lesion and resistance index (RI) was 0.66 (Figure 2A-C). The lesion was enhanced in the diffuse pattern from 11 s after injection, and appeared to be homogeneously hyperechoic in comparison with the splenic parenchyma in 21 s. It turned out to be isoechoic in 4 s and hypoechoic in 30 s after the injection (Figure 2E). The lesion showed a persistent enhancement up to about 7 min. Another 0.9 cm × 0.9 cm homologous nodule was found attaching to the lesion which became evident after being enhanced (Figure 2D). In order to reach a final diagnosis, the patient underwent surgical excision of the spleen and part of the liver. In the surgery, a splenic mass was firm with a clear margin. The pathological result is a SANT of the spleen and hemangiomas in the liver.

Case 3

A 39-year-old man was admitted to the hospital because of a left upper quadrant mass of unknown cause. Splenomegaly was suspected by physical examination. No cervi-

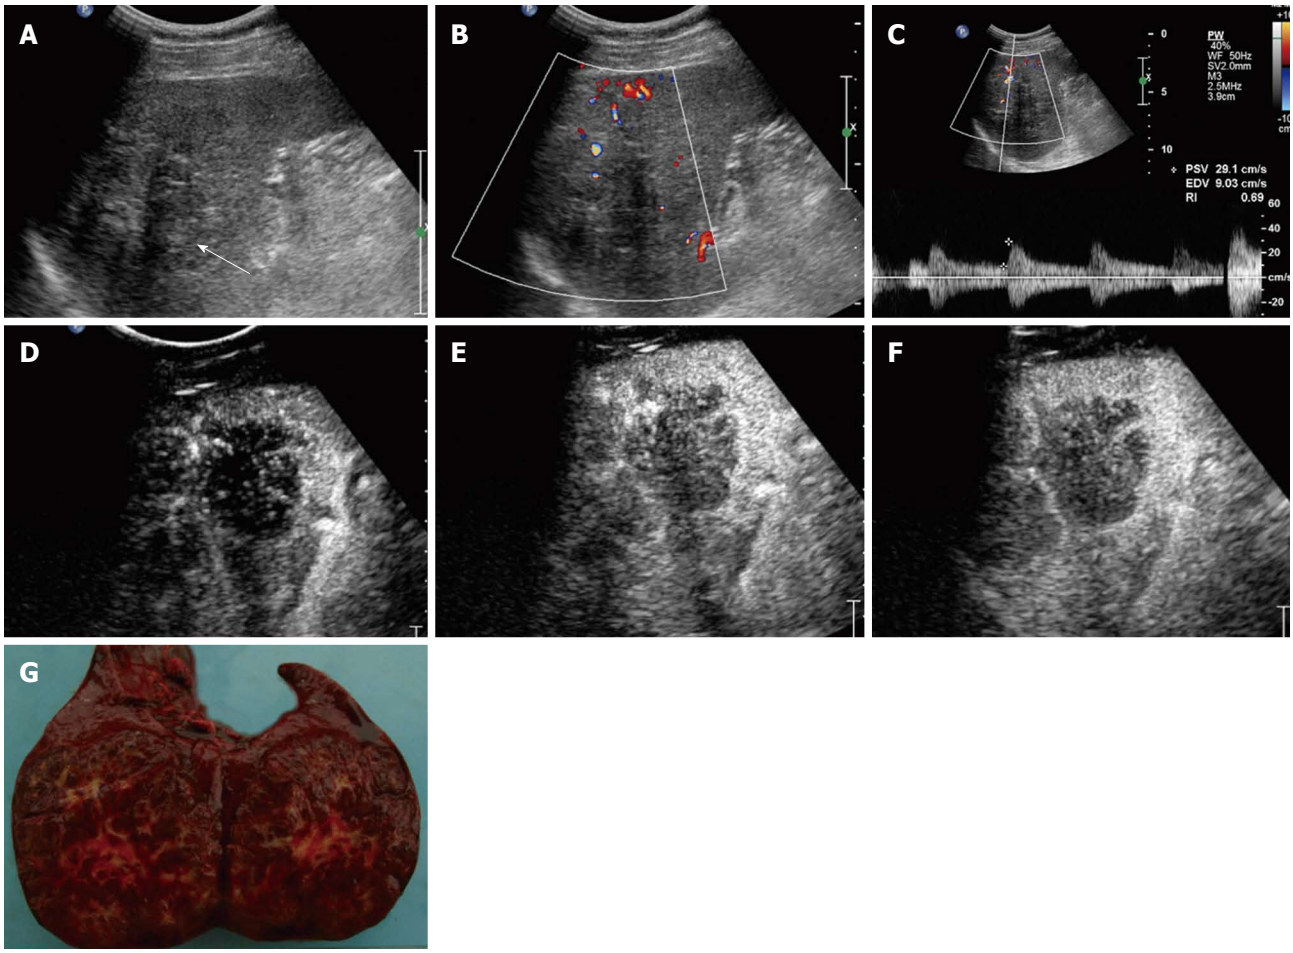

Figure 3 Conventional ultrasonography and contrast-enhanced ultrasonography findings of sclerosing angiomatoid nodular transformation in a 39-year-old man. A: A hypoechoic lesion (arrow) in the spleen; B and C: Color Doppler flow imaging shows branch-shaped and wire-like blood-flow signals inside and spot-shaped blood-flow signals in the periphery of the lesion; D: The lesion was enhanced in the branch-shaped diffuse pattern (15 s after injection); E: It presented heterogeneous lobular appearance when reaching its peak enhancement; F: Lots of septa inside the lesion; G: Surface of the lesion found during the operation.

cal or inguinal lymphadenopathy was found. The laboratory test results were: hemoglobin 123 g/L, Ery 4.23 T/L, WBC 6.7 g/L, neutrophils 4.6 g/L, platelets 167 g/L, CEA 0.56 ng/mL, AFP 2.4 ng/mL and CA19-9 3.6 U/mL. All other laboratory tests were within normal limits. Abdominal ultrasonography was done using a C5-2 ultrasound transducer attached to a Philips IU22; it demonstrated a 7.0 cm × 6.2 cm well-demarcated, hypoechoic lesion in the spleen. CDFI showed branch-shaped and wire-like blood-flow signals inside and spot-shaped blood-flow signals in the periphery of the lesion. RI was 0.50-0.66 (Figure 3A-C). The lesion was enhanced in the branch-shaped diffuse pattern from 12 s after injection (Figure 3D). It presented heterogeneous lobular appearance when reaching its peak enhancement in 23 s (Figure 3E). We also detected lots of septa inside the lesion (Figure 3F). It became hypoechoic in 37 s in comparison with the splenic parenchyma. The lesion showed a persistent enhancement up to about 3 min. Its enhancement intensity was less than that of the spleen during the whole enhancement process. Its structure and margin were clearer than those of conventional ultrasonographic images. The patient also received CT examination, which revealed a low-density mass with mildly septa enhancement. The final diagnosis of SANT was confirmed by operation (Figure 3G).

DISCUSSION

SANT is a rare mild vascular lesion in the spleen. The age of our patients ranged from 36 to 39 years. Two of them were asymptomatic (Case 1 and Case 3). The lesions were usually found incidentally. Few patients presented with abdominal discomfort or splenomegaly. Its etiology is still unclear. Concurrent diseases included chronic lymphocytic leukemia, lung squamous cell carcinoma, colonic carcinoma and some other diseases[1]. We cannot confirm whether hepatic hemangioma as shown in Case 2 is related to SANT. The lesion presented as a solitary mass measuring 3-17 cm in greatest diameter as reported before[1]. And usually it has a clear margin with a normal splenic parenchyma. The gross section shows splenic angiomatoid nodules as altered red pulp tissue is entrapped by a non-neoplastic stromal proliferative process[3]. SANT is composed of small blood vessels of three typically distinct immunophenotypes: cord capillaries (CD34+/CD8-/CD31+), sinusoids (CD34-/CD8+/

CD31+), and small veins (CD34-/CD8-/CD31+). It can be differentiated from other vascular tumors or tumor-like lesions, including hemangioma, littoral cell angioma (LCA), inflammatory pseudotumor (IPT) and follicular dendritic cell tumor (FDC), by immunohistochemical examinations.

Sonographic findings of our cases are described as follows: All the lesions were solitary and heterogeneous. Their greatest diameters were 3-7 cm. Two of them were hypoechoic and the other lesion was hyperechoic. Linear and slit-like hyperechoic septa was presented in one lesion (Case 3). The ratio of having a clear and unclear margin is 2:1. The color-Doppler showed arterial flow signals in all the lesions and their RIs were low. The contrast-enhanced images in the two lesions had something in common. The contrast media entered the lesions 1-2 s later than the splenic parenchyma. And they came out of the lesions earlier than that of the spleen. The lesions were both enhanced in diffuse pattern. One lesion (Case 3) presented a heterogeneous lobule with lots of septa inside at the peak enhancement. An extra 0.9 cm × 0.9 cm nodule attaching to the previously-found lesion was detected in Case 2 during the enhancement process.

Usually, we consider hyperechoic lesions in the spleen as benign ones on US images such as hemangioma. Malignant lesions are mostly hypoechoic and occur most frequently in lymphomas (80% of focal lesions)[4]. On conventional US images, the three lesions presented with different echogenicity. They were lack of consistency in their boundaries and shapes. An assessment of conventional US images does not provide any differential diagnostic clues. Additionally, color-Doppler technique is only capable of detecting some obvious color flow signals in big solid masses in the spleen. The images of conventional US examination are not characteristic.

We found few cases reporting the behavior of SANT with ultrasonography in the literature. Gutzeit reported a case of SANT[5], which had a hypoechoic halo, predominantly vascular on conventional US images and a "spoke wheel" pattern on CEUS images. In our cases, the heterogeneous lobule and lots of septa inside at the peak enhancement in Case 3 are similar to the "spoke wheel" pattern, but no vascular halo was present. The angiomatoid nodules are frequently delimited by concentric bands of collagen fibers, and there is always an inflamed fibrocellular to sclerotic stroma between the nodules at low magnification. Some exhibited fibrin deposition in the peripheral zone of the nodules. CEUS has shown to be useful in observing nodules whose contrast to the spleen parenchyma was enhanced after injection of SonoVue. Because of its multinodular angiomatoid appearance, SANT was described by Rosai[6] as the term "multinodular hemangioma". In conclusion, CEUS is a new imaging technique that provides direct visualization of vessel structure and morphologic characteristics of the lesions.

Pathologically, SANT has been thought to be a variant of IPT. SANT has fewer inflammatory cells and myofibroblasts than those in IPT. Martel *et al*[1] reported one case of fever and three cases of high erythrocyte sedimentation among 25 cases of SANT. One patient (Case 1) also had high WBC and neutro phils before the operation. Consequently, the US appearances of the lesions reported above are between those of IPT and hemangioma. It can explain the diversity of its echogenicity, morphology and boundary.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in tahe field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case

report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Format

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

The adenosine monophosphate-activated protein kinase (AMPK) and p70 ribosomal S6 kinase-1 pathway may serve as a key signaling flow that regulates energy metabolism; thus, this pathway becomes an attractive target for the treatment of liver diseases that result from metabolic derangements. In addition, AMPK emerges as a kinase that controls the redox-state and mitochondrial function, whose activity may be modulated by antioxidants. A close link exists between fuel metabolism and mitochondrial biogenesis. The relationship between fuel metabolism and cell survival strongly implies the existence of a shared signaling network, by which hepatocytes respond to challenges of external stimuli. The AMPK pathway may belong to this network. A series of drugs and therapeutic candidates enable hepatocytes to protect mitochondria from radical stress and increase cell viability, which may be associated with the activation of AMPK, liver kinase B1, and other molecules or components. Consequently, the components downstream of AMPK may contribute to stabilizing mitochondrial membrane potential for hepatocyte survival. In this review, we discuss the role of the AMPK pathway in hepatic energy metabolism and hepatocyte viability. This information may help identify ways to prevent and/or treat hepatic diseases caused by the metabolic syndrome. Moreover, clinical drugs and experimental therapeutic candidates that directly or indirectly modulate the AMPK pathway in distinct manners are discussed here with particular emphasis on their effects on fuel metabolism and mitochondrial function.

Key words: Adenosine monophosphate-activated protein kinase; Cell survival; Energy metabolism; Fatty liver; Insulin resistance; Glycogen synthase kinase 3β; p70 ribosomal S6 kinase-1

INTRODUCTION

Metabolic regulation of carbohydrate, lipid and protein, and synthesis of proteins and lipids are the principal functions of the liver, as well as xenobiotic detoxification. The

function and survival of organisms are dependent on the dynamic control of energy metabolism. The regulation of fuel metabolic processes can be mediated by hormones and other endogenous ligands in response to changes in energy status. Diverse signaling pathways contribute to the regulation of energy metabolism, which is associated with the activation of cell surface and nuclear receptors in hepatocytes. Thus, the modulation of specific pathways can provide therapeutic strategies for hepatic diseases that result from metabolic derangements[1].

In a variety of hepatic diseases, abnormal fat accumulation in the liver is often a prerequisite metabolic event for further pathogenesis[2]. Lipotoxicity can lead to the generation of oxidative stress and inflammation, ultimately causing apoptosis[3]. Programmed cell death is elicited by cell surface death receptors, the caspase cascade, deranged mitochondrial metabolism, and energy deficiency. Mitochondria, cytoplasmic organelles in eukaryotic cells, play a key role in energy utilization such as oxidative phosphorylation; dysfunction of mitochondria is closely related with apoptosis[4].

The relationship between fuel metabolism and cell survival strongly implies the existence of a shared signaling network, which is responsible for the regulation of both phenomena. Emerging evidence indicates that the adenosine monophosphate (AMP)-activated protein kinase (AMPK) and p70 ribosomal S6 kinase-1 (S6K1) pathway serves as a key pathway that regulates fuel energy metabolism. In addition, it has been suggested that AMPK controls the redox-state and mitochondrial function. In this review, we focus on the role of the AMPK pathway in hepatic fuel metabolism in conjunction with cell survival. Moreover, clinical drugs and experimental therapeutic candidates that activate the AMPK-S6K1 pathway in distinct manners are discussed here with particular reference to their roles in mitochondrial function and energy metabolism.

FUEL METABOLISM AND SIGNALING PATHWAYS IN THE LIVER

The liver plays a central role in fuel metabolism, and thus regulates dynamic catabolic and anabolic processes to maintain energy homeostasis of organisms. Breakdown products of carbohydrate and lipid (i.e. glucose and fatty acids) are common energy sources which are converted to adenosine-triphosphate (ATP) in mitochondria. In addition, mitochondria have many other metabolic functions, such as regulation of membrane potential, cellular metabolism, calcium signaling (including calcium-induced apoptosis), and apoptosis. During the process of catabolism, the mitochondrion serves as the main source of energy for the cell because it converts nutrients into energy *via* cellular respiration[5]. Most of the oxygen delivered to cells or organs is consumed by mitochondria for ATP generation. When the energy is excessive in the cell, mitochondrial energy production is inhibited so that glucose and free fatty acids can be stored as glycogen and fat through anabolic processes.

AMPK signaling pathways for fuel metabolism

AMPK: AMPK is a heterotrimer complex that consists of a catalytic subunit (α1/2) and two regulatory subunits (β1/2 and γ1/2/3), and functions as a serine/threonine protein kinase[6]; AMPK activation is mediated by phosphorylation of threonine-172 in the catalytic domain of the α subunit[7]. The activity of AMPK can be regulated by upstream kinases, which include liver kinase B1 (LKB1)[8], Ca^{2+}/calmodulin-dependent protein kinase kinase (CaMKK) β[9], and transforming growth factor β-activated kinase-1[10]. Both LKB1 and CaMKK increase the AMPK activity through direct phosphorylation of threonine-172 in the α subunit. In addition, LKB1 is constitutively active as a major upstream kinase. The upstream signaling molecules of LKB1 may include protein kinase C (PKC)-ζ[11], protein kinase A[12], and p90 kDa ribosomal S6 kinase[13]. The fact that the calcium/calmodulin complex regulates CaMKK suggests that AMPK may be involved in Ca^{2+} modulation in cells.

AMPK regulates energy homeostasis in various organs through response to hormones and nutrient signals. AMPK physiologically responds to the change in the AMP:ATP ratio, and thus serves as an intracellular sensor for energy homeostasis[7]. In addition to ATP production with switching off from anabolic processes in tissues, the activation of AMPK affects whole body fuel utilization and induces fatty acid oxidation and glucose uptake in skeletal muscle and heart, but inhibits lipogenesis and adipocyte differentiation[6-7]. In the liver, AMPK inhibits gluconeogenesis and synthesis of glycogen, fatty acid and cholesterol. Since AMPK plays a key role in metabolic regulation, it is recognized as an important target for metabolic disorders such as obesity, diabetes, and metabolic liver diseases.

S6K1: S6K1 is a mitogen-activated serine/threonine protein kinase that is associated with growth and cell cycle progression. In translational processes, S6K1 phosphorylates the S6 protein of the 40S ribosomal subunit. Phosphoinositide-3 kinase (PI3K)-the mammalian target of rapamycin (mTOR) regulates S6K1 as a distinct pathway from the Ras/mitogen-activated protein kinase cascade[14]. S6K1 signaling suppresses catabolic events such as lipolysis in adipose tissue and fatty acid oxidation in muscle, both of which stimulate ATP generation[15]. Since S6K1 is sensitive to nutrients including amino acids, nutrients negatively regulate insulin signaling by phosphorylating insulin receptor substrate-1 (IRS1) through S6K1 activation. Thus, S6K1 may also affect the regulation of nutrient and hormone signaling pathways under normal and pathological conditions (e.g. obesity, diabetes, and cancer). Moreover, S6K1 may play a role in the balance between survival and death in tissues including the liver. It is noteworthy that AMPK activation leads to inhibition of the mTOR/S6K1 pathway through tuberous sclerosis protein 2 (TSC2) phosphorylation[16]. The regulation of S6K1 by AMPK is now recognized as an important regulatory step, by which cells maintain energy metabolism.

AMPK as a target for metabolic diseases

Nonalcoholic fatty liver disease (NAFLD) is defined as a common liver disease ranging from steatosis to nonalcoholic steatohepatitis, and cirrhosis[2]. Moreover, NAFLD is considered as a main hepatic component of metabolic syndrome[17]. The characteristics of metabolic syndrome are obesity, insulin resistance, and cardiovascular disorders. In obese people mostly with insulin resistance, excessive fat is deposited in the liver and the raised hepatic lipid amount is closely associated with pathogenic processes of the syndrome[18,19].

Hepatic steatosis by liver X receptor-α-sterol regulatory element, binding protein-1c: A variety of conditions such as excess delivery of fatty acids, decreased oxidation of hepatic fatty acid and/or impaired synthesis or secretion of very low-density lipoprotein increase the sources of hepatic lipids, leading to fatty liver disease. The amount of accumulated fat is also increased by lipogenesis; emerging evidence supports the importance of *de novo* lipogenesis in abnormal hepatic fat accumulation in NAFLD patients[20,21]. Lipogenesis is transcriptionally regulated by the membrane-bound sterol regulatory element, binding protein-1c (SREBP-1c), which belongs to the basic helix-loop-helix-leucine zipper family. In the nucleus, SREBP-1c activates transcription of genes involved in lipogenesis, as supported by the finding that the overexpression of SREBP-1c in transgenic mice promotes the development of fatty liver. In animal models of insulin-resistant diabetes and obesity, the increased synthesis of fatty acids contributes to the development of hepatic steatosis.

Liver X receptor-α (LXRα), a transcriptional nuclear receptor, is a key regulator of lipogenic genes encoding for the enzymes that promote hepatic fat accumulation (e.g. fatty acid synthase, FAS; acetyl-CoA carboxylase, ACC; and stearoyl-CoA desaturase-1, SCD-1)[22,23]. Ligand activation of LXRα promotes induction of the lipogenic genes through SREBP-1c, causing increases in fatty acid synthesis and progression to steatosis, hypertriglyceridemia, and steatohepatitis[22]. Thus, SREBP-1c is an important target gene of LXRα. Since the LXRα-SREBP-1c pathway activates lipogenesis in the liver, it is an attractive target for the treatment of hepatic steatosis and hepatitis. In clinical situations, the expression of SREBP-1c and lipogenic genes including ACC and FAS is enhanced in NAFLD patients[24,25]. In addition, increases in LXRα target gene expression (e.g. ACC and FAS) were observed in the patients with fatty liver, which was accompanied by SREBP-1c activation, but not activation of carbohydrate responsive element-binding protein[26].

The AMPK-S6K1 pathway is involved in the regulation of LXRα-SREBP-1c and thus in LXRα-induced lipogenesis; chemical activation of AMPK in conjunction with its inhibition of S6K1 leads to the intervention of hepatic steatosis (Figure 1)[27]. As an example, AMPK activation by oltipraz treatment inhibits S6K1 activity, which inhibits the activity of LXRα[27] and prevents the ability of activated LXRα to bind the LXR binding site upstream

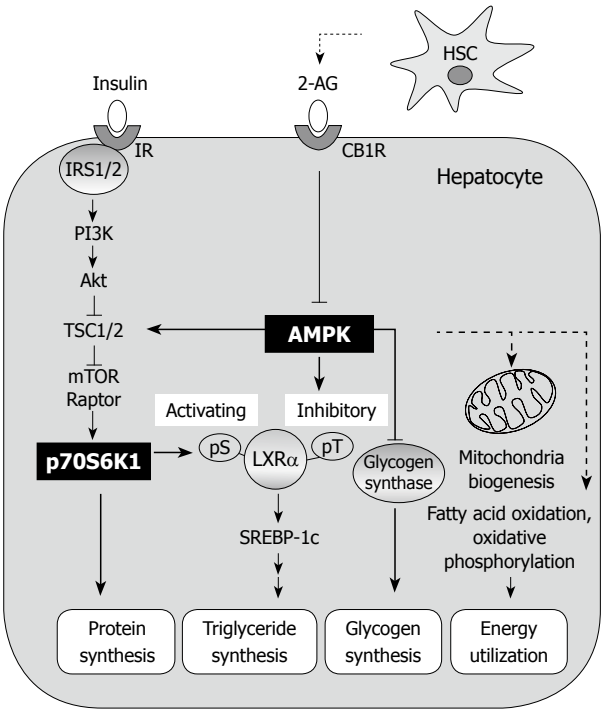

Figure 1 Adenosine monophosphate-activated protein kinase pathway in hepatic fuel metabolism. Adenosine monophosphate-activated protein kinase (AMPK), a metabolic energy sensor, negatively regulates protein synthesis through inhibition of the mammalian target of rapamycin (mTOR)-S6 kinase-1 (S6K1) pathway. The inhibitory effect of AMPK on liver X receptor-α (LXRα)-dependent triglyceride synthesis is opposed by the action of S6K1. AMPK also shuts down glycogen synthesis via inhibitory phosphorylation of glycogen synthase. AMPK as a fuel sensor induces glucose transport and fat oxidation in response to metabolic stress such as energy deprivation, and also increases mitochondrial biogenesis. AMPK counteracts energy depletion by stimulating energy production and limiting energy utilization. Endocannabinoids such as 2-arachidonoylglycerol derived from hepatic stellate cells decrease AMPK phosphorylation resulting in downregulation of lipogenic action. 2-AG: 2-arachidonoylglycerol; CB1R: Cannabinoid 1 receptor; HSC: Hepatic stellate cell; IR: Insulin receptor; Raptor: Regulatory-associated protein of mTOR; IRS1: Insulin receptor substrate-1; PI3K: Phosphoinositide-3 kinase; TSC1: Tuberous sclerosis complex 1; pS: Phospho-serine; pT: Phospho-threonine; SREBP-1c: Sterol regulatory element, binding protein-1c.

of the genes including SREBP-1c and CYP7A1. Therefore, the consequent repression of SREBP-1c expression contributes to decreased synthesis of fat in the liver[27].

Repeated alcohol consumption decreases the production of adiponectin secreted from adipocytes[28]. Adiponectin increases hepatic fatty acid oxidation through AMPK activation[29]. Therefore, it is tempting to speculate that AMPK activity is repressed as hepatic function deteriorates in alcoholic patients. Similarly, AMPK activity was decreased in animals which consumed alcohol for 4 wk[30]. As a compensatory response, alcohol consumption increased lipogenesis in the liver, which may also result from the reduced rate of fatty acid oxidation. Thus, pharmacological activation of AMPK may be of help in treating hepatic steatosis. Peroxisome proliferator-activated receptors (PPARs) play a role in sensing nutrient levels and regulating lipid and glucose metabolism[31]. Thiazolidinediones (TZDs) and fibrates that activate PPARγ and PPARα, respectively, are prescribed for patients with diabetes and/or

dyslipidemia. In those taking PPARγ agonists, insulin-mediated adipose tissue uptake and storage of free fatty acids are augmented with the inhibition of hepatic fatty acid synthesis, which may result in part from indirect activation of AMPK[32,33].

Hepatic insulin resistance: Insulin signaling is important in maintaining homeostasis of glucose, lipid, and protein metabolism, and thus induces anabolism in tissues. In addition, it has effects on normal growth and development. Insulin receptor and its associated protein IRS1 relay signal transmission to the PI3K-Akt pathway, which consequently increases mTOR-S6K activity. Activation of the mTOR-S6K1 pathway by insulin may lead to fat accumulation in adipose tissue, hypertrophy of skeletal muscle, growth of pancreatic β cells, and protein synthesis[15]. Therefore, the control of insulin signaling is tightly regulated by a negative feedback mechanism. In fact, the downstream components of the insulin receptor give inhibitory autoregulatory signals to upstream molecules along the insulin-signaling pathway or through unrelated pathways that cause insulin resistance. In particular, phosphorylation of IRS proteins on serine residues is a key step in the processes of physiological and pathological conditions. So, the kinases that phosphorylate IRS1/2 have been extensively studied.

Hepatic steatosis alone, or to a greater degree in combination with endotoxin challenge, makes the liver susceptible to oxidative damage and thus facilitates the pathologic process of hepatitis. The cytokines produced by accumulated fat with or without endotoxin cause insulin resistance. In particular, tumor necrosis factor α (TNFα) and interleukin-6 (IL-6) lead to insulin resistance through multiple mechanisms. These include c-Jun N-terminal kinase 1 (JNK1)-mediated serine phosphorylation of IRS-1, IκB kinase-dependent nuclear factor-κB activation, and suppressors of cytokine signaling-3 (SOCS-3) induction[34-36]. Since TNFα increases insulin resistance in peripheral organs, inhibition of TNFα activity and/or its decreased expression would be of help to overcome insulin resistance. However, IL-6 displays pleiotropic functions in a tissue-specific and time-dependent manner. IL-6 confers insulin resistance in hepatocytes through activation of SOCS protein through the Jak/Stat pathway to inhibit tyrosine phosphorylation of IRS1[36], while IL-6 increases insulin sensitivity by stimulating basal glucose transport in 3T3-L1 adipocytes[37], smooth muscle[38] and chondrocytes[39]. Acute treatment with IL-6 increases insulin sensitivity due to AMPK activation[40], while chronically elevated IL-6 leads to impaired insulin signaling and cellular insulin resistance *via* activating SOCS-3[36] and reducing the expression of the adiponectin, GLUT4, IRS1 mRNA, IRS-1 protein and its tyrosine phosphorylation[41,42].

Glucose is overproduced in the liver of patients with type 2 diabetes[43]. Because AMPK serves as an energy-saving mechanism, its activation decreases hepatic gluconeogenesis. The experimental results using gene knockouts, pharmacological means, or adenoviral activation of AMPK support the role of AMPK in the regulation of glucose production in the liver. Consistently, hepatic glucose production increased to show hyperglycemia and glucose intolerance in liver-specific AMPKα2 deficient mice. Hence, it is highly likely that the hepatic AMPKα2 isoform is critical for repressing hepatic glucose production and maintaining fasting blood glucose levels in the physiological range[44]. Consistently, AMPK activation by adenovirus expressing a constitutively active form of AMPKα2 as well as by 5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside (AICAR, a direct AMPK activator) or metformin reduced glucose output[45-47].

Activation of S6K1 exerts a negative feedback action on insulin signaling. As an example, TNFα secreted by non-parenchymal cells activates S6K1 in pathologic states. The important role of S6K1 on insulin resistance was proven by a study using S6K1-null mice[48,49]. A key role for mTOR-S6K1 regulation of insulin resistance was also supported by the finding that rapamycin blocked IRS1 phosphorylation[50,51], confirming the importance of S6K1 activity in inducing insulin resistance. Hence, insulin resistance induced by abnormal conditions such as hyperinsulinemia, obesity and excess nutrient availability is accompanied by an increase in S6K1 activity[48,52]. The result of a study using a knockout model proved the critical role of S6K1 and its physiological feedback importance to IRS1/2 and PI3K for insulin resistance. In an experimental model, the inhibitory effect of high-fat diet consumption on the insulin receptor-PI3K pathway is also mediated by S6K1. In our laboratory, it was found that the inhibitory modulation of S6K1 activity by beneficial candidates reversed insulin resistance and hyperglycemia[50]. In particular, oltipraz treatment inhibited S6K1 through AMPK activation. Consistently, a dominant negative mutant of AMPK abrogated S6K1 phosphorylation[50]. AMPK activation by other drugs like metformin and rosiglitazone also contribute to insulin sensitivity enhancement[47,53]. Similarly, other agents that inhibit insulin resistance also antagonize S6K1 activation downstream of AMPK[50]. So, these agents have the effects of improving insulin sensitivity through a mechanism involving AMPK-mediated S6K1 inhibition in hepatocytes[50].

JNK1 is activated by various stress signals such as cytokines or oxidative stress, and thus the activity of JNK1 increases under prediabetic or diabetic conditions. This important kinase is also implicated in the phosphorylation of IRS1/2[54-56], interfering with insulin action. The JNK pathway is stimulated by oxidative stress conditions, increased flux of free fatty acids and TNFα production, which contributes to developing insulin resistance. The importance of JNK activation is supported by the finding that a deficiency of JNK1 prevented insulin resistance in an experimental model[54]. Moreover, JNK mediates dysfunction of insulin secretion from β cells[57]. Hence, inhibition of JNK by chemical means may help improve insulin resistance and ameliorate hepatic energy metabolism[54,58]. For example, isoliquiritigenin from various natural herbs including licorice has a JNK-inhibitory effect. Thus, isoliquiritigenin is capable of repressing lipogenesis in the liver and protecting hepatocytes from oxidative

injury inflicted by fat accumulation through a novel JNK-dependent pathway that acts as an upstream component of LXRα (unpublished data).

CYTOPROTECTIVE EFFECT OF AMPK

An energy flux is a crucial factor for cell viability. To keep the energy supply constant, eukaryotic cells use AMPK as a mechanism to monitor ATP production and expenditure. As a consequence of its sensitivity to AMP levels, AMPK is activated by treatment with drugs including metformin and TZDs as well as by conditions of metabolic stress that repress ATP production (e.g. hypoxia or glucose deprivation). Thus, AMPK activation causes upregulation of ATP-producing catabolic pathways. However, AMPK inhibits ATP-consuming pathways including synthesis of fatty acids, cholesterol, glycogen, and proteins[59]. Although AMPK signaling is intricately tied to energy metabolism and homeostasis, it is also critical for various physiological processes including inflammation, and proliferation[60,61]. It is noteworthy that the AMPK-associated pathway may suppress apoptosis induced by glucocorticoids[62], hyperglycemia[63], hepatic ischemia-reperfusion[64] and oxidative stress[65-69]. AMPK activation has a beneficial effect on cell viability *via* protection of mitochondria from apoptosis: phosphorylation of glycogen synthase kinase 3β (GSK3β)[66], and phosphorylation of Bad, which leads to inhibition of cytochrome *c* release and attenuation of caspase-3 activity[70]. AMPK is also implicated in other pathophysiological responses in various cell types: a decrease in endoplasmic reticulum (ER) stress[71], DNA damage repair[72,73], autophagy[74,75], and the antioxidant defense system[65-69]. This review focuses on the role of AMPK in hepatocyte viability.

Regulation of autophagy and cell survival

Regulation of cellular balance between biosynthesis and turnover is crucial for the maintenance of metabolic homeostasis. Autophagy is an evolutionally conserved pathway for self-digesting of cytoplasmic components and organelles by lysosomal degradation[76]. Autophagy contributes to cell survival *via* removal of long-lived proteins and damaged organelles, thus this event plays a role in adaptive protection upon starved conditions[77]. In addition, a recent study showed that autophagy regulates lipid metabolism by inducing lipid utilization in hepatocytes, implicating a possible link with metabolic diseases[78]. The autophagic processes are regulated by several signal transduction mechanisms. Among them, AMPK activation induces autophagy in response to diverse stress conditions including energy depletion, ER stress, and hypoxia. The action of AMPK is mediated by the inhibition of mTOR-dependent signaling, which is a central inhibitory pathway of autophagy[79]. The AMPK-induced autophagy exerts a cytoprotective effect, which can be regulated by upstream kinases such as LKB1[74,75]. However, the role of S6K1 inhibition by AMPK in the modulation of autophagy is unclear. Despite these primarily defensive effects, autophagy mediates cell death under certain conditions[77], thus further study would help understand the role of AMPK in autophagy-associated cell viability.

Protection of mitochondria from external stress

Insulin resistance has been associated with a reduction in mitochondrial oxidative phosphorylation and ATP production, and thus downregulates the expression of genes encoding for oxidative metabolism[80-82]. Thus, mitochondrial dysfunction is frequently observed in the metabolic syndrome[82]. Under mitochondrial dysfunction caused by several endogenous or exogenous stimulants, it is difficult to maintain redox-homeostasis. In this situation, changes in mitochondrial membrane permeability (MMP) cause the release of proapoptotic mediators that can damage DNA and lead to apoptosis[83,84]. Oxidative stress inhibits endoplasmic reticulum calcium pumps, releasing calcium into the cytoplasm from endoplasmic reticulum. The cytoplasmic calcium is taken up by mitochondria, which makes the mitochondrial permeability transition pore (mPTP)[85,86]. In basal conditions, the mPTP is closed but opens in response to stress, allowing passage of small molecules. Opening of the mPTP causes MMP transition and cytochrome *c* release, inducing apoptosis. A number of studies have shown that chemical inhibitors of the mPTP have the ability to prevent the release of cytochrome *c* and protect cells from death[87]. Excess reactive oxygen species may enhance the opening of the mPTP, and cause mitochondrial depolarization and cytochrome *c* leakage[88,89]; the release of cytochrome *c* from mitochondria to cytoplasm activates procaspase-9 and Apaf-1, and stimulates apoptosome formation and caspase-3 activation so that it induces cell death[90].

AMPK-associated signaling mediates hepatocyte viability

AMPK: AMPK responds to external stress as a modulator of cell viability or death. In many cases, AMPK activation exerts a cytoprotective effect[62-64,66]. Chemical activation of AMPK protected cells from arachidonic acid-induced apoptosis and restored MMP. In this model, cell viability depended on mitochondrial function; treatment of the AMPK activator (e.g. oltipraz and resveratrol) protected cells from mitochondrial injury. Thus, the direct or indirect AMPK activators have the ability to protect cells from mitochondrial oxidative stress. This mitochondrial protective effect could be reversed by either compound C treatment or overexpression of the dominant negative mutant of AMPKα. In our laboratory, the AMPK-dependent antioxidant and cytoprotective effects had been tested with AICAR. Cellular H_2O_2 production increased by arachidonic acid treatment impairs mitochondrial function, and promotes apoptosis. Thus, arachidonic acid propagates apoptotic signals due to oxidative stress alone or in combination with an increase in mitochondrial Ca^{2+} uptake[91]. In this model, AICAR exhibited a cytoprotective effect against injury caused by arachidonic acid so that it abolished reactive oxygen species production in the cell. The data showing that

compound C treatment induced MMP transition indicate that AMPK is necessary for MMP regulation. AMPK increases its activity through TSC2 phosphorylation, which leads to translational suppression and cell size reduction under the situation of energy deprivation. Moreover, the phosphorylation of TSC2 protects cells from apoptosis induced by energy deprivation[16], suggesting that the downstream components of AMPK may be responsible for MMP regulation.

In a recent study, resveratrol, a polyphenolic component found in grapes and red wine, was shown to protect mitochondria from oxidative stress in an AMPK-dependent manner. AMPK activation by resveratrol depended on LKB1, but not CaMKK. Thus, LKB1 activation protects cells from apoptosis under the condition of energy stress[92]. The importance of LKB1 for AMPK-dependent cytoprotection is also supported by the result of the sauchinone study: sauchinone exerted a protective effect against MMP transition *via* LKB1 activation[69]. The upstream components that activate LKB1 include SIRT1[93], nitric oxide synthase[94], and protein kinase A[12]. In addition, we identified the formation of poly (ADP-ribose) (PAR) as the upstream event, by which resveratrol activates LKB1[66]. PAR polymerase (PARP) represents a nuclear enzyme that plays a role in DNA damage repair through PAR formation. In an energetic process, PAR causes rapid depletion of NAD^+, decreases ATP production, and thus leads to cell death[75]. In contrast, PARP prevents cell death through LKB1-AMPK-mediated autophagy activation[75], which may be associated with LKB1. Sometimes, AMPK activation may cause apoptosis; sustained AMPK activation (>10 h) triggered hepatocyte death through JNK and caspase-3 activation. In this process, p53, Bax and Fas ligand are upregulated or activated by activated JNK[95]. Hence, AMPK-dependent cell survival may rely on cell type, environmental conditions and on the duration of this kinase activation[95].

Mn-superoxide dismutase (Mn-SOD) as a mitochondrial enzyme converts the superoxide anion to hydrogen peroxide, and plays a role in cytoprotection[96]. Pro-oxidants like paraquat and dinitrophenol induce Mn-SOD in the liver[97,98]. Treatment with metformin or AICAR, an AMPK activator, increases the expression of MnSOD mRNA, suggesting that Mn-SOD induction may be coupled to the AMPK-associated pathway.

GSK3β: GSK3β is a constitutively activated serine/threonine kinase in normal state. This enzyme is well known as a regulator of glycogen metabolism, gene expression, and cell cycle progression[99]. GSK3β is inactivated by serine 9 phosphorylation[100], enabling cells to suppress mPTP opening[101] and prevent apoptosis of hepatocytes[66]. Hence, this kinase may contribute to cell viability against external stress (e.g. ischemia/reperfusion injury). It has also been recognized that inhibitory phosphorylation of GSK3β prevents phosphorylation of voltage-activated anion channel, and promotes binding of GSK3β with adenine nucleotide translocase. In our study, GSK3β inhibition protected mitochondria from mPTP opening and contributed to cell survival against severe oxidative stress[66], as also supported by other reports[102,103]. This contention is supported by the finding that treatment by a direct AMPK activator (i.e. AICAR) leads to GSK3β inhibition (Figure 2), as mediated with Raf1/ERK/p90 kDa ribosomal S6 kinase[104]. Some other cytoprotective compounds also act as AMPK activators, which include resveratrol and isoliquiritigenin, and cause GSK3β inhibition[66]. Thus, GSK3β phosphorylation may lie downstream of AMPK.

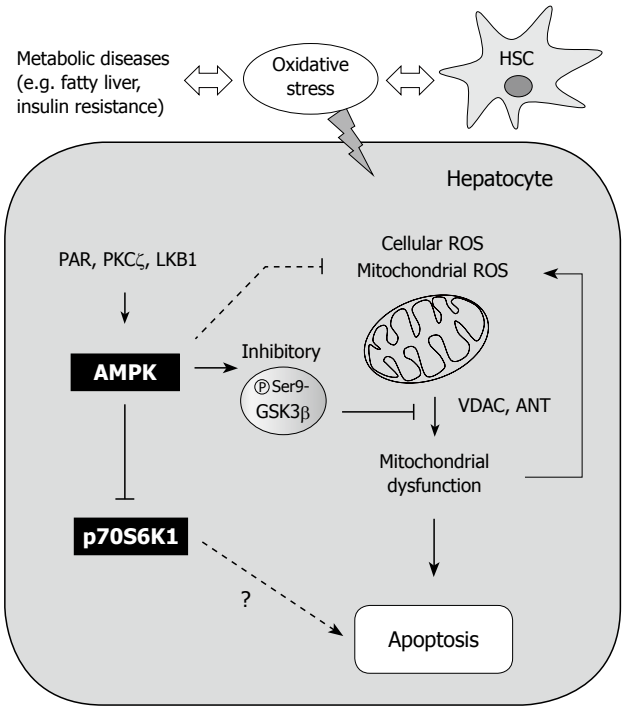

Figure 2 Adenosine monophosphate-activated protein kinase regulation of cell viability. Adenosine monophosphate-activated protein kinase (AMPK) protects cells from oxidative stress-induced H_2O_2 production and mitochondrial dysfunction, which results in part from the inhibitory phosphorylation of glycogen synthase kinase 3β (GSK3β). GSK3β inhibits mitochondrial function through voltage-activated anion channel (VDAC) phosphorylation. AMPK activation contributed to cell survival, whereas the regulatory role of S6 kinase-1 (S6K1) in apoptosis is still unclear. HSC: Hepatic stellate cell; PAR: Proliferator-activated receptor; PKC: Protein kinase C; LKB1: Liver kinase B1; ROS: Reactive oxygen species; ANT: Adenine nucleotide translocator.

PKC: In certain situations, necrosis may also be programmed through specific pathways. Hepatocytes undergo necrosis several hours after H_2O_2 treatment in association with PKC activation and/or AMPK inhibition, as evidenced by a decrease in cell death by PKC inhibitor treatment. Interestingly, PKC inhibition results in AMPK upregulation, suggesting that these two pathways are inversely coupled to each other[105]. Apparently, these pathways are linked to a cytoprotective effect, as shown by decreased H_2O_2-induced necrosis after treatment with PKC inhibitor or AMPK activator. Consistently, compound C treatment (an AMPK inhibitor) abrogated the ability of PKC inhibitor to protect cells, suggesting that PKC inhibitors have a cytoprotective effect through AMPK upregulation.

Table 1 Effects of candidate compounds on the adenosine monophosphate-activated protein kinase-S6 kinase-1 pathway and liver function

Chemicals	AMPK	S6K1	NAFLD	Hepatic insulin resistance	Cyto-protection in the liver	Effective conc.	Ref.

ND: Not done; UD: Unpublished data; ↑: Activation; -: No change; ↓: Inhibition; +: Beneficial effect against nonalcoholic fatty liver disease (NAFLD) or insulin resistance, or cytoprotection in the liver; AMPK: Adenosine monophosphate-activated protein kinase; S6K1: S6 kinase-1.

S6K1: In S6K1-/- hepatocytes, caspase-8 and Bid (a pro-apoptotic protein) were both down-regulated relative to control. A deficiency of S6K1 was not sensitive to the cascades of death receptor activation, as shown by no caspase-8 activation or FLIP$_L$ degradation in hepatocytes challenged by TNF-α or anti-Fas antibody treatment. The finding that Bid cleavage, cytochrome *c* release, caspase-3 activation, and DNA laddering were all attenuated by a deficiency of S6K1 raises the importance of S6K1 in the apoptotic process. Consistently, the lack of S6K1 did not diminish the BclxL/Bim ratio in cells deprived of serum, and thus prevented cytochrome *c* release and DNA fragmentation[106]. In an animal model, S6K1 deficiency enabled hepatocytes to survive against concanavalin A-induced apoptosis[106]. Inhibition of S6K1 may activate survival pathways through PI3K/Akt and ERK pathways. However, hepatocytes deficient in S6K1 underwent apoptosis on serum withdrawal when combined with PI3K or ERK inhibitor treatment[106]. In this sense, S6K1 inhibition along with Akt and ERK inhibitors, would enhance the efficacy of cancer chemotherapy for hepatocarcinoma[106]. In our oxidative stress model, rapamycin, an inhibitor of mTOR-S6K1 activity that causes dissociation of raptor from mTOR by binding FK506 binding protein 12, had no effect on apoptosis elicited by arachidonic acid + iron, suggesting that the inhibition of S6K1 alone may not be sufficient to promote cell viability. Overall, the inhibition of S6K1 may contribute to protecting hepatocytes from liver failure, and if so, it might result from improvement in insulin signaling.

AMPK REGULATION OF ENERGY METABOLISM AND CELL SURVIVAL

A series of beneficial compounds with the abilities of AMPK activation are listed in Table 1 and Figure 3, which may have liver-protective effects against external stimuli. Thus, the compounds that have modulating activities on metabolism may also have cytoprotective effects (Figure 4). In these actions, LKB1-dependent AMPK activation may be one of the key molecular pathways for cell survival. A number of studies have shown how AMPK responds to an increase in AMP as an energy sensing enzyme. In this way, it integrates diverse signal inputs, controls a number of metabolic enzymes in various cell types, and adapts cellular processes to the energy status. Since AMPK activation may not always be on the side of cell survival, the specific AMPK pathways responsible for cell viability still remain to be elucidated.

CLINICAL IMPLICATIONS

Metformin is a major drug used in the treatment of type 2 diabetes. AMPK activation by metformin suppresses hepatic glucose production and lowers blood glucose levels[47,112]. In addition, metformin has been shown to reverse fatty liver disease in humans[113,114]. TZDs belong to another important class of antidiabetic drugs that augment systemic insulin sensitivity. In diabetic patients, pioglitazone decreases hepatic fat content and increases splanchnic glucose uptake presumably through AMPK[115]. In addition, these medications may prevent simple hepatic steatosis from progressing to steatohepatitis. Although the molecular mechanism of AMPK activation by TZDs is unclear, AMPK activation is attributed to their ability to increase plasma adiponectin levels[53].

Hepatic ischemia-reperfusion injury, usually in association with liver transplantation and hepatic resection, is an important clinical issue. Ischemic preconditioning may

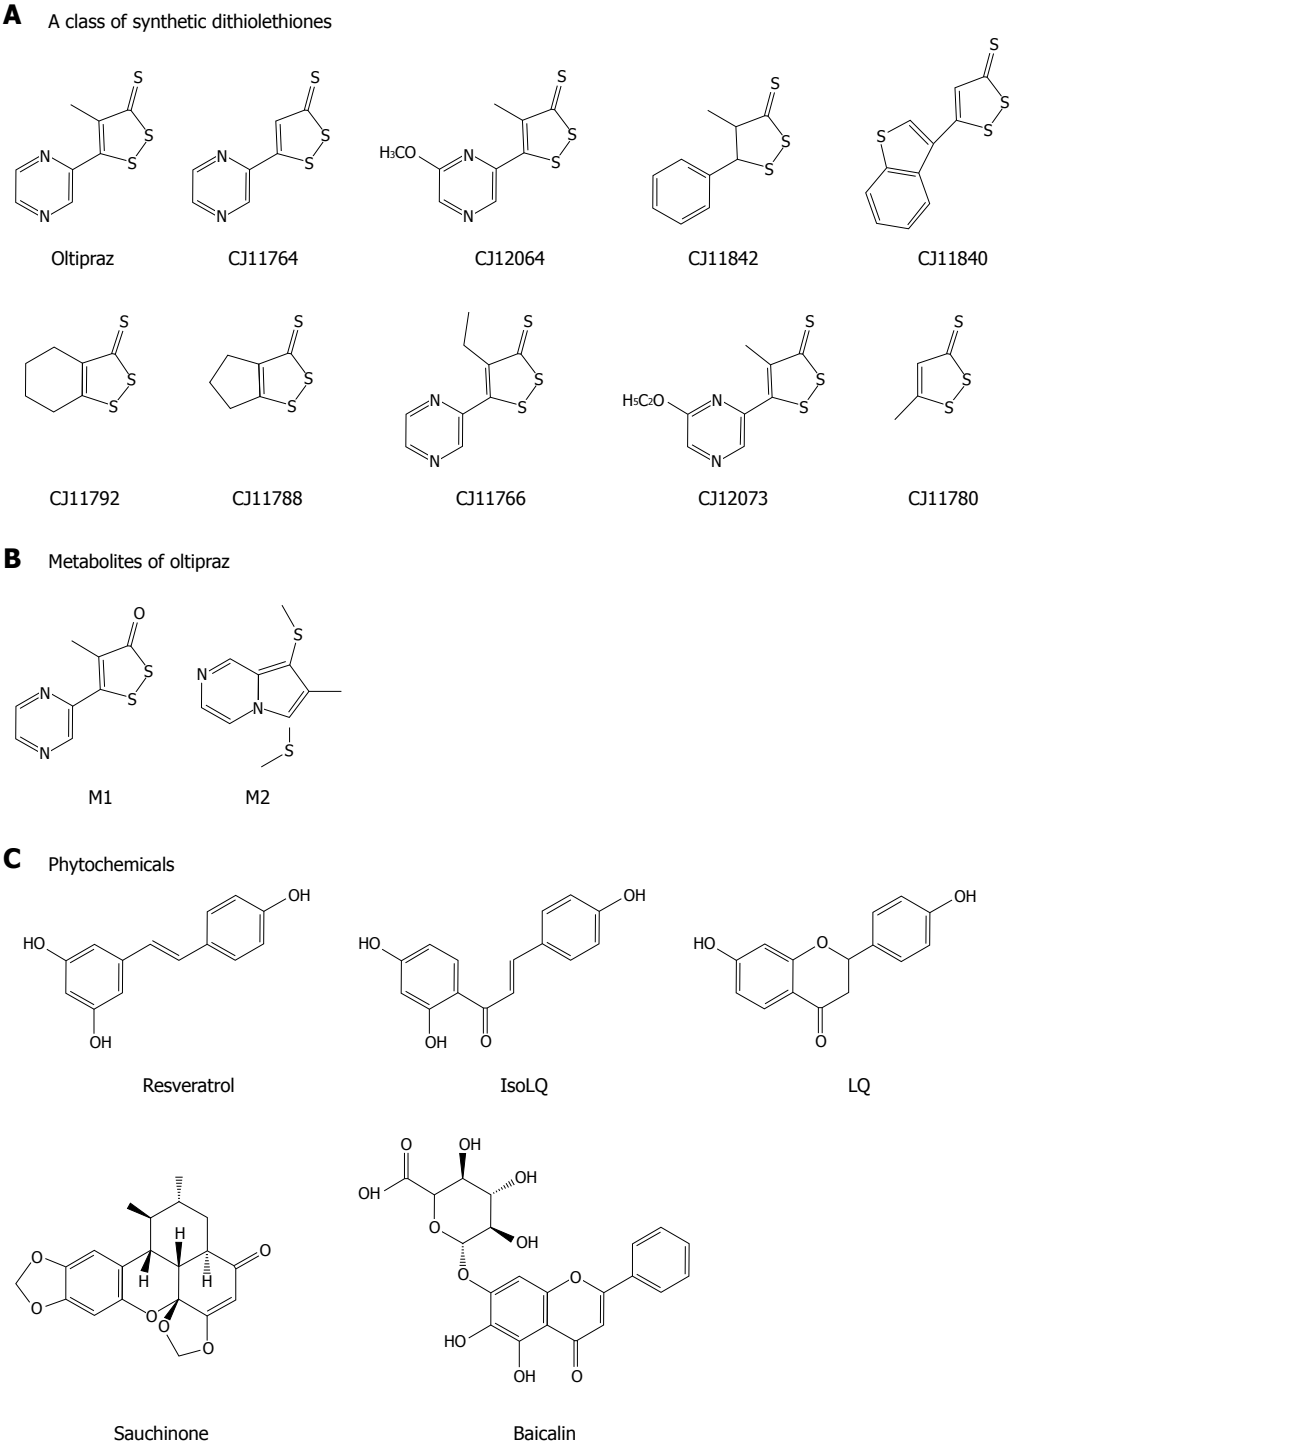

Figure 3 Chemical structures of adenosine monophosphate-activated protein kinase activators. be beneficial to patients with hepatic resections in which long periods of ischemia are necessary. Ischemic preconditioning prevents ATP degradation and intracellular accumulation of AMP induced by subsequent ischemia[116]. Increases in AMP levels during ischemia activate AMPK, while AMPK inhibition abolishes the effect of preconditioning, indicating that AMPK plays a role in this effect[64]. So, hepatic preconditioning may allow the liver to

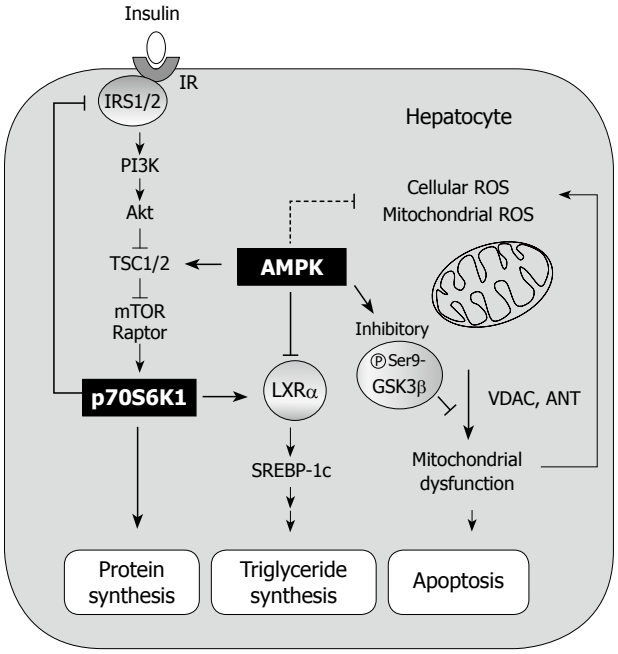

Figure 4 Dual regulation of fuel metabolism and cell viability by adenosine monophosphate-activated protein kinase. The adenosine monophosphate-activated protein kinase (AMPK)-S6 kinase-1 (S6K1) pathway regulates metabolic signaling flow. In addition, AMPK controls the redox-state and mitochondrial function, therefore its activation protects cells from apoptosis. AMPK is the key molecule to bridge the gap between fuel metabolism and hepatocyte viability. preserve energy metabolism during sustained ischemia[116]. Since AMPK activation by preconditioning may represent a new strategy to reduce the ischemia-reperfusion injury, modified preservation solutions containing AMPK activators may be of use, which should be evaluated in clinical settings.

CONCLUSION

As the mitochondrion plays a diverse role in essential cellular functions including energy production and homeostasis, redox cell signaling, and apoptosis, the chemical activators of AMPK protect hepatic mitochondria against toxic stress. The inhibition of S6K1 downstream of AMPK may also have a distinct role in liver biology. Thus, the AMPK pathway is associated with various pathological conditions, including metabolic syndrome and numerous apoptotic conditions. Because of the shared regulatory functions of AMPK in metabolism and cell viability, it becomes an advantageous target. In this review, we have proposed the concept that AMPK-associated signaling bridges the gap between fuel metabolism and hepatocyte viability, which may be of help in identifying valuable potential targets to prevent and/or treat derangement of metabolism and cell death in the liver.

Abstract

About 10%-15% of patients with gastroesophageal reflux disease develop Barrett's esophagus. This is considered a premalignant condition because it can progress from metaplasia to high-grade dysplasia, and eventually to adenocarcinoma. Recently, major advances have been made in the endoscopic treatment of Barrett's esophagus, therefore limiting the role of surgery in the treatment of this disease.

Key words: Gastroesophageal reflux disease; Barrett's esophagus; Esophageal adenocarcinoma; Laparoscopic fundoplication; Radiofrequency ablation; Esophageal endoscopic mucosal resection; Minimally invasive esophagectomy

Patti MG, Waxman I. Gastroesophageal reflux disease: From heartburn to cancer. *World J Gastroenterol* 2010; 16(30): 3743-3744 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i30/3743.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i30.3743

Gastroesophageal reflux disease affects an estimated 20% of the population in the United States. About 10%-15% of patients with gastroesophageal reflux disease develop Barrett's esophagus, which eventually can progress to adenocarcinoma, which is currently the fastest growing cancer in the United States. It is recognized that adenocarcinoma is in most cases the end stage of a sequence of events whereby the squamous esophageal epithelium is initially replaced by columnar epithelium without dysplasia. Subsequently, the metaplastic epithelium can progress to low- and high-grade dysplasia and eventually cancer[1-3].

This symposium addresses some key questions in the treatment of this disease process. The pathophysiology and diagnosis of the disease are reviewed, particularly in morbidly obese patients[4-10]. Based on the pathophysiology, the treatment of metaplasia is discussed. Special attention has been placed on new treatment modalities such as radiofrequency ablation and endoscopic mucosal resection, which have revolutionized the treatment of high-grade dysplasia and intramucosal carcinoma[11-16]. The remaining indications for esophagectomy in these cases are discussed[17]. Finally, we have reviewed what to do when invasive cancer is present, discussing the role of neoadjuvant therapy[18-20], the type of esophageal resection (transhiatal versus trans-thoracic)[21,22], and the current data available about minimally invasive esophagectomy[23,24]. The authors are both experts dedicated to the treatment of patients with esophageal disorders and have published extensively on these topics.

Abstract

This review focuses on the pathophysiology of gastroesophageal reflux disease (GERD) and its implications for treatment. The role of the natural anti-reflux mechanism (lower esophageal sphincter, esophageal peristalsis, diaphragm, and trans-diaphragmatic pressure gradient), mucosal damage, type of refluxate, presence and size of hiatal hernia, *Helicobacter pylori* infection, and Barrett's esophagus are reviewed. The conclusions drawn from this review are: (1) the pathophysiology of GERD is multifactorial; (2) because of the pathophysiology of the disease, surgical therapy for GERD is the most appropriate treatment; and (3) the genesis of esophageal adenocarcinoma is associated with GERD.

Key words: Gastroesophageal reflux disease; Pathophysiology; Acid reflux; Non-acid reflux; Esophageal manometry; Ambulatory pH; Barrett's esophagus; Esophageal adenocarcinoma

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a very prevalent disease. Population studies have repeatedly shown GERD-related symptoms in a significant proportion of adults. The Montreal consensus conference defined GERD as "a condition which develops when the reflux of gastric contents causes troublesome symptoms and/or complications"[1]. However, this definition did not include details of the pathophysiology of the disease and its implications for treatment. The Brazilian consensus conference considered GERD to be "a chronic disorder related to the retrograde flow of gastro-duodenal contents into the esophagus and/or adjacent organs, resulting in a spectrum of symptoms, with or without tissue damage"[2]. This definition recognizes the chronic character of the disease, and acknowledges that the refluxate can be gastric and duodenal in origin, with important implications for the treatment of this disease.

This review focuses on the pathophysiology of GERD and its implications for treatment.

GERD - ROLE OF NATURAL ANTI-REFLUX MECHANISMS

Although all normal individuals experience some sort of "physiological" gastroesophageal reflux, a highly efficient barrier exists between the stomach and the esophagus. From the esophageal side, esophageal clearance is pro-

moted by peristalsis and salivary production. A valve mechanism exists between the esophagus and the stomach, formed by the lower esophageal sphincter (LES), the diaphragm, the His angle, the Gubaroff valve and the phrenoesophageal membrane.

Peristalsis

Esophageal peristalsis is an important component of the antireflux mechanism because it is the main determinant of esophageal clearance of the refluxate. Defective peristalsis is associated with severe GERD, both in terms of symptoms and of mucosal damage[3]. As matter of fact, the composite reflux score (DeMeester score)[4] includes in its calculation two indirect measurements of esophageal clearance (number of reflux episodes longer than 5 min and length of the longest episode). In addition, the average esophageal clearance time can be calculated by dividing the total minutes the pH is below 4 by the number of reflux episodes. This association also explains the high prevalence and severity of GERD in systemic diseases that affects peristalsis, such as connective tissue disorders[5].

It is known that 40%-50% of patients with GERD have abnormal peristalsis[3]. This dysmotility is particularly severe in about 20% of patients because of very low amplitude of peristalsis and/or abnormal propagation of the peristaltic waves (ineffective esophageal motility)[6]. Esophageal clearance is slower than normal, therefore, the refluxate is in contact with the esophageal mucosa for a longer period of time and it is able to reach more often the upper esophagus and pharynx. Thus, these patients are prone to severe mucosal injury (including Barrett's esophagus) and frequent extra-esophageal symptoms such as cough[6,7].

It is still unclear whether esophageal dysmotility is a primary condition that leads to GERD, or it is a consequence of esophageal inflammation. Medical therapy does not ameliorate esophageal peristalsis[8,9]. However it has been shown that effective fundoplication improves the abnormal peristalsis in most patients[10].

LES

Physiologically, the LES is a 3-4-cm-long segment of tonically contracted smooth muscle at the distal end of the esophagus[11]. It is intuitive that the LES creates a high pressure zone between the esophagus and the stomach that prevents reflux. An effective LES must have an adequate total and intra-abdominal length, and an adequate resting pressure[12]. However, a normal LES pressure does not exclude GERD, because abnormal transient relaxation might occur. Periodic relaxation of the LES in normal individuals has been termed transient lower esophageal sphincter relaxation (TLESR), to distinguish it from relaxation triggered by swallowing. TLESR accounts for the physiological reflux found in normal subjects. When it becomes more frequent and prolonged, TLESR can contribute to reflux disease, and this phenomenon appears to explain the reflux seen in the 40% of patients with GERD whose resting LES pressure is normal. What determines TLESR is unknown, but postprandial gastric distention is probably involved[11,13]. It has been shown that a mechanically incompetent LES is progressively associated with worse mucosal damage[7].

At the present time, there are no medications used in clinical practice that act on the LES. Some studies are presently conducted using inhibitors of the GABA type B receptor, especially baclofen, but the effect of this medication is still not clear. These data underline that an incompetent LES represents a mechanical and permanent defect of the gastroesophageal barrier. Only fundoplication can correct the functional and mechanical profile of the LES, therefore resulting in control of any type of reflux from the stomach into the esophagus.

Diaphragm

The crus of the diaphragm provides an extrinsic component to the gastroesophageal barrier. This pinchcock action of the diaphragm is particularly important as a protection against reflux induced by sudden increases in intra-abdominal pressure[13]. This mechanism is obviously disrupted by the presence and size of a hiatal hernia.

Increase of thoraco-abdominal pressure gradient

Abnormal gastric emptying might contribute to GERD by increasing intra-gastric pressure. Patients with suspected abnormal gastric emptying should be tested with nuclear markers[14] or ultrasound[15]. If slow emptying is diagnosed, appropriate therapy should be considered. Medication such as metoclopramide and Nissen fundoplication improve gastric emptying[16].

There is also strong evidence of a possible link between obesity and GERD. Specifically, it has been shown that there is a dose-response relationship between increasing body mass index (BMI) and prevalence of GERD and its complications[17-19]. Some studies have reported that morbidly obese patients with GERD have a higher incidence of incompetent LES, transient LES relaxation and impaired esophageal motility than non-obese patients with GERD[8,20,21]. However, a detailed mathematical analysis has shown that the severity of GERD (based on the DeMeester score) is associated with BMI[22], which suggests that obesity plays an independent role in the pathophysiology GERD, mainly through increased abdominal pressure[18,23].

The association of different pulmonary diseases and GERD has recently gained renewed interest[24]. It has been shown that patients with end-stage lung disease have a high prevalence of GERD; up to 70%[25]. Although in these patients pan-esophageal motor dysfunction is frequently found[25], a more negative thoracic pressure with an increase in the gradient between intra-gastric and intra-thoracic pressure might also contribute.

GERD: ROLE OF MUCOSAL DAMAGE

Increasing severity of esophagitis is associated with increasing acid exposure[26]; however, erosive esophagitis is present in only 50% of GERD patients[7]. Some experts believe that the erosive and non-erosive forms of the

disease might actually account for different subsets of the disease; others believe that they represent two different and progressive stages of the disease.

It is still unclear if mucosal inflammation is a cause or a consequence of GERD. Evidence has shown that esophagitis is associated with esophageal body dysmotility[7]. However, it is still unclear if it is the cause or the effect of the altered peristalsis. We do know that medical therapy for GERD does not ameliorate esophageal peristalsis[8,9], whereas surgical therapy clearly results in improvement[10].

GERD: ROLE OF THE REFLUXATE

As previously mentioned, gastric and duodenal contents can reflux into the esophagus and adjacent organs. Gastric hydrochloric acid has long been recognized as harmful to the esophagus[27]. However, gastro-esophageal refluxate contains a variety of other noxious agents, including pepsin[26]. Currently, it is recognized that this component of the refluxate (commonly called bile reflux and identified by the Bilitec bile reflux monitor using bilirubin as a marker) is composed of bile salts and pancreatic enzymes[26], and is also injurious to the esophageal mucosa. It causes symptoms[28], and could be linked to the development of Barrett's esophagus[29] and esophageal adenocarcinoma[30].

Besides the constituents of the refluxate, symptom perception and mucosal damage also appear to be linked to the patterns of esophageal exposure and the volume of the refluxate. Individuals are more likely to perceive a reflux event if the refluxate has a high proximal extent and a large volume[26].

Acid suppression is the main treatment for GERD. It has evolved from topical alkaline antacids to very effective proton pump inhibitors (PPIs). Several studies have shown the efficacy of PPIs in almost neutralizing gastric acid. These medications make the refluxate less aggressive, which leads to symptom amelioration and healing of esophagitis[31]. However, they do not stop reflux or cure GERD, as different studies with intraluminal impedance technology have shown that PPI therapy alters the pH of the refluxate but does not change the occurrence and number of reflux episodes[32,33]. Currently, there is no specific medication that controls non-acid reflux. On the other hand, fundoplication blocks any type of gastric refluxate because it restores the competence of the gastroesophageal junction.

GERD: ROLE OF HIATAL HERNIA

Hiatal hernia and GERD were once considered synonyms and hiatal hernia was considered a *sine qua non* condition for GERD to occur[34,35]. Currently, it is well known that both conditions can exist independently. However, it is recognized that hiatal hernia disrupts most of the natural antireflux mechanisms, and is considered an independent factor for GERD[26]. The simple presence of an abdominal portion of the esophagus is considered an antireflux mechanism, because it is submitted to positive abdominal pressure and acts as a valve[34]. In addition, TLESR seems to occur more frequently when a hiatal hernia is present. Not surprisingly, the presence and size of a hiatal hernia are associated with a more incompetent LES (the pinchcock action of the diaphragm is absent), defective peristalsis, more severe mucosal damage, and increased acid exposure[36].

Hiatal hernia is associated with early recurrence and failure of medical therapy for GERD[34]. The reduction of a hiatal hernia with narrowing of the esophageal hiatus is a key element in fundoplication and its omission or failure is a cause of recurrence of GERD.

GERD: ROLE OF *HELICOBACTER PYLORI*

The association of GERD and *Helicobacter pylori* (*H. pylori*) is very controversial. While some argue that the infection might play a role in the prevention of GERD by altering the nature of the refluxate (gastritis leading to achlorhydria), others find no link between the infection and esophageal diseases[37,38].

Prevalence studies seem to suggest that *H. pylori* infection is inversely associated with reflux esophagitis in some populations[37]. Eradication studies also suggest that *H. pylori* infection is protective with respect to GERD[37].

If *H. pylori* protects against GERD, a logical assumption would be that it also protects against adenocarcinoma development. Furthermore, adenocarcinoma incidence is rising worldwide; however, the increasing pace is slow in underdeveloped countries, exactly where *H. pylori* incidence is higher. Indeed, the majority of epidemiological studies have found a protective association, and the results of three recently published meta-analyses have shown that *H. pylori* colonization of the stomach is associated with a nearly 50% reduction in cancer risk[39].

GERD AND BARRETT'S ESOPHAGUS

The history of Barrett's esophagus has been complicated by different opinions on the genesis of the disease[40]. Currently, it is unquestionable that Barrett's esophagus is an acquired disease caused by GERD, although risk factors and innate predisposition are still been scrutinized. Also, it is believed that most, if not all, esophageal adenocarcinoma arises in Barrett's mucosa[41].

With regard to GERD pathophysiology, Barrett's esophagus represents an end stage form of the disease. It encompasses pan-esophageal motor dysfunction that is characterized by abnormalities in esophageal peristalsis, defective LES, and bile reflux[42]. Most authors consider this form of GERD to be a surgical disease[43], based on the aforementioned points.

FROM PATHOPHYSIOLOGY TO TREATMENT

The simultaneous use of intra-esophageal impedance and pH measurement of acid and non-acid gastroesophageal

reflux has clearly shown that treatment with PPIs only changes the pH of the refluxate, without stopping reflux through a functionally or mechanically incompetent LES[44]. For instance, using this technology, Vela *et al*[44] have shown that during treatment with omeprazole, postprandial reflux still occurs but it becomes predominantly non-acid. In a study in normal subjects, Vela and colleagues also have shown that baclofen, a GABA B antagonist, is able to reduce both acid and non-acid reflux by decreasing TLESR, the primary mechanism for both acid and non-acid reflux[45]. This study signals an important shift toward treatment focused on the competence of the LES rather than the pH of the refluxate alone. This goal can also be achieved by fundoplication; an operation that can be done laparoscopically with a short hospital stay, minimal postoperative discomfort, fast recovery time and excellent results[46-49]. Long-term studies have shown that fundoplication controls symptoms in 93% of patients after 5 years and in 89% after 10 years[46]. The operation controls reflux because it improves esophageal motility, both in terms of LES competence and quality of esophageal peristalsis[10]. Control of reflux is not influenced by the pattern of reflux, and is equally effective when reflux is upright, supine or bipositional[47]. In addition, the operation is equally safe and effective in young or elderly patients[48]. Concern has been raised about the presence of postoperative dysphagia. In our experience, this occurs in about 8% of patients, irrespective of the type of fundoplication, and it resolves spontaneously in all but a few patients in a few months, without requiring re-intervention[49].

It is important to select the best treatment for the individual patient based on a review of symptoms, age, sex, esophageal function, and type of refluxate. We feel that laparoscopic fundoplication is indicated in the following circumstances: when heartburn and regurgitation are not affected by medical treatment; when it is thought that cough is induced by reflux (Mainie *et al*[50] have shown that patients with a positive symptom index resistant to PPIs with non-acid or acid reflux demonstrated by multichannel intraluminal impedance-pH monitoring can be treated successfully by laparoscopic Nissen fundoplication); poor patient compliance; cost of medical therapy if more than one pill/day of PPI is needed (most insurance companies in the United States pay for one pill/day only); and postmenopausal women with osteoporosis. It has been shown that PPIs and histamine-2 receptor antagonists can increase the risk of hip and femur fractures[51]. Therefore, medical treatment is not advisable for young and very symptomatic patients.

Finally, in a recently published meta-analysis of medical *vs* surgical management for GERD, Wileman *et al*[52] have shown that, in adults, laparoscopic fundoplication is more effective than medical management for the treatment of GERD in the short to medium term. Surgery, however, carries some risk and its application should be individualized and the decision to undergo fundoplication should be based on patient and surgeon preference.

CONCLUSION

The pathophysiology of GERD is clearly multifactorial. While medical therapy can only affect gastric acid production, fundoplication restores the function of the LES and improves esophageal peristalsis. In addition, fundoplication stops any type of refluxate because it restores the competence of the gastroesophageal junction. It seems that fundoplication alone does not cause regression of Barrett's esophagus and does not prevent the development of adenocarcinoma. It will be important to study in patients with Barrett's esophagus the long-term effect of surgery in association with new treatment modalities such as radiofrequency ablation (RFA) and endoscopic mucosal resection (EMR). The combination should be more effective than monotherapy, because RFA and EMR eliminate the metaplastic or dysplastic epithelium, while fundoplication stops reflux, which is the original cause of Barrett's esophagus.

Abstract

Gastroesophageal reflux disease (GERD) contributes substantially to morbidity and to costs in the United States health care system. The burden of this disease has resulted in attempts at improving diagnosis and characterizing patients. Numerous research and technical advances have enhanced our understanding of both the utility and limitations of a variety of diagnostic modalities. The purpose of this review is to highlight recent advances in GERD diagnostic testing and to discuss their implications for use in clinical practice. Topics addressed include esophageal pH monitoring, impedance testing, symptom association analyses, narrow-band imaging, and histopathology.

Key words: Gastroesophageal reflux disease; pH impedance; pH monitoring; Symptom association

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a common, chronic disease that affects up to 20% of the adult population in the United States[1]. It is the most frequent digestive system diagnosis in ambulatory care and at inpatient discharge[2]. GERD contributes in excess of $10 billion in annual direct health care costs, with the majority of cost attributed to proton pump inhibitors (PPIs)[2,3]. The substantial disease burden of GERD and recognition of PPI unresponsive patients has fostered numerous efforts to improve diagnostic and therapeutic monitoring modalities.

Research investigations have enhanced our understanding of both the utility and limitations of a variety of diagnostic modalities. Newer techniques for esophageal functional testing such as wireless pH capsule monitoring, duodenogastroesophageal (also referred to as alkaline or bile reflux) reflux detection, and esophageal impedance testing have been introduced over the past decade and are utilized in clinical practice. The American College of Gastroenterology, American Society for Gastrointestinal Endoscopy and American Gastroenterological Association have recently published updated reviews and guidelines on reflux management and monitoring[4-6]. This review highlights recent advances in GERD diagnostic testing and their utility in clinical practice. A literature search was conducted for English-language articles dealing with functional evaluation of the esophagus from 2008 to 2009. Databases included Medline and PubMed, with search

terms that included esophageal pH monitoring, GERD, and esophageal impedance.

ESOPHAGEAL pH MONITORING

Wireless capsule pH monitoring: Is it better than catheter systems?

A significant advance in pH recording has been the incorporation of an antimony electrode into a wireless capsule that transmits pH data to an external receiver *via* radiofrequency telemetry (433 MHz)[7,8]. Major advantages of the wireless system include patient tolerability and capability of performing extended recording periods of 2-4 d. Discomfort associated with conventional catheter electrodes can lead patients to minimize or avoid reflux-provoking stimuli such as meals and physical activity, thus decreasing the detection of abnormal acid exposure[9,10]. As a result of improved patient tolerability, the wireless pH system might provide a more accurate picture of an individual's acid exposure profile under more realistic conditions.

Several investigations have compared wireless to catheter-based pH monitoring. A recent study has evaluated simultaneous placement of the Bravo capsule and SlimLine catheter system in 55 patients referred with GERD symptoms and 53 healthy volunteers[11]. The Slimline system was removed after 24 h while the Bravo system recorded 48 h of data. The SlimLine catheter system recorded almost double the acid exposure time than the Bravo system in both patients and volunteers. A similar finding has been noted in previous studies[12,13]. There was correlation between pH values and a concordance of diagnostic yield of 82.1%. However, the authors argue that, due to a wide variation in repeated measurements and random variation, as measured by limits of agreement, the two methods are not interchangeable[11].

It is not clear from the study methods whether the increased acid detection by the SlimLine catheter system was due to a thermal calibration artifact intrinsic to the catheter pH recording system first reported in 2005[13]. This error has since been corrected. The SlimLine system also records a greater number of reflux events than does Bravo, which is related to a higher sampling frequency. This numerical difference has previously been shown to have a minimal effect on the overall acid exposure time[13,14]. Other potential explanations for the different measurements include lost data due to interrupted signal transmission by the wireless system, and movement of the pH sensor in the catheter system relative to the esophagogastric junction. The latter factor might be important given the axial shortening of the esophagus during swallowing, which could move the catheter electrode closer to or even transiently into the proximal stomach. The Bravo system was better tolerated and preferred by patients, although the investigators did report a failure rate of approximate 15% due to failure or premature detachment.

Prolonged monitoring: Is 4 d better than 1 d?

Extended pH monitoring using wireless technology might theoretically improve the detection of reflux and increase the sensitivity of testing. Several studies have demonstrated that increasing the recording period from 24 to 48 h increases the sensitivity of pH monitoring by 10%-26%[4,8]. Several studies have also consistently demonstrated higher acid exposure values on day 2 compared with day 1 with the wireless capsule. Although the differences are generally small, this might affect the interpretation in a subset of studies[11]. Most capsules are placed immediately after endoscopy, therefore, the observation raises concerns regarding the potential impact of conscious sedation on reflux detection in the time period immediately after endoscopy, when patients might be resting and avoiding typical activity.

Another advantage of a prolonged monitoring period is the ability to perform testing both on and off PPI therapy in a single study[15,16]. Controversy exists regarding whether pH monitoring is best done off or on PPI therapy, because there are advantages and disadvantages to each approach. Off-therapy testing evaluates the presence of abnormal acid exposure and maximizes symptom-reflux association owing to the greater number of symptom and reflux episodes. Off-therapy testing is used to document the presence of acid reflux in patients with non-erosive reflux disease, who are being considered for anti-reflux endoscopic or surgical therapy. Off-therapy testing is also employed for patients with a low index of suspicion for having reflux disease, such as those showing no symptomatic response to empiric trials of PPI therapy or those with atypical symptoms. In contrast, pH testing on PPI therapy can provide documentation of the effectiveness of PPI therapy.

The feasibility of pH monitoring for an extended duration was recently determined for 96 h (48 h off PPI therapy followed by 48 h on therapy) in 60 patients[16]. A single pH capsule was placed and calibrated to two separate receivers with the second receiver activated after 48 h upon initiation of PPI therapy. Reflux symptoms were also recorded. Complete 96-h data were available for 40 patients (67%) at completion of the study, with 20 patients having incomplete data transmission or early capsule detachment. A total of 14 patients had abnormal acid exposure in the first 48 h, and day 2 testing (off therapy) increased the detection of abnormal acid exposure by 10%. On PPI therapy, 39 out of 40 patients (97.5%) had complete normalization of acid exposure at day 4. In addition, three symptom association indices [symptom index (SI), symptom sensitivity index (SSI), and symptom association probability (SAP)] all decreased by day 4 on PPI therapy. Overall, the prolonged testing increased the detection of acid exposure and reflux events for symptom association measurements and allowed for evaluation of both acid exposure and symptom response to PPI therapy. Limitations of this approach included early capsule detachment in 15% and the need for two separate receivers. Updated models of the wireless pH capsule are expected to allow for prolonged 4-d recording with a single receiver.

pH sensor location: Is 5 cm the best site?

By convention, correct positioning of the catheter pH

electrodes is 5 cm above the proximal border of the lower esophageal sphincter (LES) and 6 cm above the squamocolumnar junction (SCJ) for the wireless pH capsule. These locations minimize potential noise from proximal stomach acid exposure, at the expense of decreased sensitivity. This is a particular concern for catheter- based systems in which esophageal shortening during deglutition results in relative movement of the pH sensor closer to the LES. Grigolon *et al*[17] recently have evaluated differences in subcardial pH measured at two different locations in GERD, as well as the role of hiatal hernia. Their study population consisted of 14 healthy volunteers and 11 and 10 GERD patients with and without a hiatal hernia, respectively. Wireless pH monitoring was performed using the Bravo capsule 2 cm below the SCJ, and all patients received a standardized lunch after placement of the capsule. The investigators confirmed that subcardial pH was highly acidic in the early stage after meals, but there was no difference between healthy subjects and GERD patients. The presence of a hiatal hernia did not affect the results. The findings build upon important observations made by this group regarding the role of the "acid pocket" in the pathogenesis of GERD. In clinical practice, substantial intrapatient variability and interpatient heterogeneity have limited the utility of intragastric pH monitoring.

Another study has evaluated 48-h pH recording, off PPI therapy, immediately above the SCJ compared to simultaneous results obtained at 6 cm above the SCJ in 62 patients with reflux symptoms and 55 controls[18]. GERD patients included those with erosive disease as well as non-erosive patients with typical reflux symptoms that are responsive to PPI therapy. Using a pre-defined specificity of 90%, monitoring immediately above the SCJ increased the sensitivity from 63% to 86% in all patients. The total percentage of time that pH was < 4 for the entire 48-h study was the parameter that best discriminated between GERD patients and controls. Patients with and without esophagitis had an increased sensitivity (78% to 97% and 47% to 73%, respectively) that indicated an increased discriminatory power for patients with more severe disease. These results were similar to another study in which pH measurements were obtained simultaneously 6 and 1 cm above the gastroesophageal junction (GEJ) in 40 GERD patients with and without erosive disease[19]. The investigators found improved diagnostic accuracy in patients with erosive disease but not non-erosive reflux disease (NERD). Although the results of these studies are encouraging for increasing the sensitivity of pH testing, especially in patients with more severe disease, more validation is needed before changing the conventional location of pH measurements.

pH-IMPEDANCE TESTING

Theoretical advantages

Intraluminal impedance monitoring detects changes in the resistance to electrical current across adjacent electrodes positioned in a serial manner along a catheter. Multiple electrodes positioned along the axial length of the impedance catheter determine the proximal extent of a reflux event. It is capable of differentiating antegrade from retrograde bolus transit, as well as liquid from gas reflux. A pH electrode incorporated into the recording assembly allows for simultaneous detection of acid content. Patient tolerability is similar to conventional pH monitoring as this is a catheter- based system. Likewise, recording has been limited to 24 h.

There is considerable debate on the current role of pH-impedance testing in clinical practice[20-22]. As PPI use for GERD has increased, patients presenting with typical or atypical reflux symptoms in spite of PPI therapy, and without erosive esophagitis, often pose a diagnostic and management challenge. The association of non-acid reflux events with symptoms has been demonstrated in several studies[23-26]. Impedance-pH monitoring is the most sensitive technique for the detection of reflux events. As a result of the ability to detect, localize and classify reflux events as acidic, weakly-acidic or alkaline, simultaneously, pH-impedance testing has been posited as the future standard for reflux detection and monitoring[27]. In addition, the more comprehensive reflux detection could guide more individualized therapy in patients based on their reflux profile as well as predict response to medical or surgical treatment[20,21].

Although theoretically superior to pH monitoring, the clinical utility of combined pH-impedance monitoring is still being investigated. Conventional pH testing has demonstrated high sensitivity and specificity in patients with GERD and erosive esophagitis. The chemical nature of non-acid reflux does not allow the presence of mucosal erosions to be used in the determination of sensitivity and specificity of impedance data. Therefore, studies that have examined the utility of impedance testing have relied upon symptom-reflux association methodology to support the clinical significance of non-acid reflux. As discussed below, substantial limitations for symptom-reflux association accuracy in the evaluation of acid reflux also apply to non-acid reflux. Furthermore, the reliance on symptom indices necessitates careful delineation of the specific symptom being evaluated. For instance, symptom association for regurgitation on PPI therapy is better detected by impedance testing than pH testing alone. However, the importance of non-acid reflux in generating symptoms of heartburn or chest pain is unclear. It has been demonstrated that the majority of persistent heartburn or chest pain events on PPI therapy are not related to either acid or non-acid reflux[26,28]. Extra-esophageal symptoms of globus, asthma and hoarseness might occur independent of individual reflux events and thus are inappropriate for reflux-symptom association analysis. GERD is often considered as a cause of chronic cough. Although studies have shown symptom correlation between cough and GERD, 50% of the cough episodes precede the individual reflux events, which demonstrates that cough-induced reflux occurs as often as reflux-induced cough[28].

Further difficulties in substantiating a role for pH-impedance monitoring arise from the absence of highly

effective, pharmacological therapies for non-acid reflux. Limited studies have used baclofen and baclofen analogs that inhibit transient LES relaxation. Surgical fundoplication is a more definitive means of arresting both acid and non-acid reflux, and ongoing studies are examining the use of pH-impedance results in predicting postoperative outcomes in refractory reflux patients. Additional limitations of impedance monitoring include low baseline impedance values generated by the mucosa of Barrett's esophagus and esophagitis, which make detection of liquid reflux problematic in such circumstances. Inaccuracies in the current versions of automated analysis software require careful and time consuming manual data correction[29].

Recent data

As a result of the ability to characterize acidity and determine number, duration, and location of reflux events, the majority of research using pH-impedance has focused on the challenges associated with diagnosing and treating NERD. A recent small study has evaluated 16 NERD patients with both pH-impedance and combined multiple pH monitoring in an effort to assess changes in reflux acidity and sensitivity to reflux events[30]. Compared to multiple site pH testing (at three locations), pH-impedance monitoring showed a small increase in sensitivity in detecting proximal reflux events. The authors reported that 30% of all distal acid reflux events became weakly acidic in the proximal esophagus, and a third of these events resulted in symptoms. Although the sample size was small, the results lend support to the concept of hypersensitivity in the proximal esophagus in a subset of NERD patients[31,32].

In a much larger study, Savarino *et al*[33] have evaluated the diagnostic utility of pH-impedance monitoring in 150 patients with NERD off PPI therapy. Among patients with normal distal esophageal acid exposure time, they found similar positive symptom associations for patients with acid reflux (15%) and non-acid reflux (12%). Twenty-six per cent of this group had a negative symptom association and were considered functional heartburn patients. The classification of patients with hypersensitive esophagus accorded by pH-impedance results (normal acid exposure time, positive symptom association) reduced the number of patients that would have been classified as having functional disease by 40%[33]. However, overall 87% of the 150 NERD patients had acid reflux identified as the etiology of their symptoms.

Impedance pH monitoring has also been used to compare reflux patterns between patients with erosive esophagitis and NERD[34,35]. In a small study of 26 patients, evenly split between NERD and erosive disease, pH-impedance monitoring did not reveal significant differences in mean reflux duration or the incidence of acid or non-acid reflux episodes. When stratified by type of reflux episode, patients with erosive disease did have slightly more liquid (mean 9 ± 2 *vs* 5 ± 1, $P = 0.07$) and acid (mean 9 ± 2 *vs* 4 ± 1, $P = 0.048$) reflux episodes in the supine position. Overall, pH-impedance could not discriminate between NERD and erosive esophagitis but this likely reflects the limited power of the sample size. In another study, Savarino *et al*[35] have compared a cohort of GERD patients with erosive and non-erosive disease with a control population and demonstrated increased acid exposure times, and frequencies of acid reflux events as well as proximal esophageal reflux extension, in both GERD subsets. Patients with erosive disease had a higher frequency and increased proximal migration of acid reflux events. Notably, the frequency of non-acid reflux events and their association with symptoms were similar in both erosive and non-erosive disease. Overall, the results of these studies lend further support to the argument for monitoring both acid and non-acid reflux episodes in further characterizing GERD and potentially directing management. However, the increased diagnostic yield of pH impedance over pH monitoring alone was limited and neither study has demonstrated that the increased detection results in improved patient therapeutic outcomes.

There has also been debate about whether pH-impedance monitoring should be performed on or off PPI therapy. This has recently been addressed in a small prospective study of patients with continued GERD symptoms on twice daily PPI therapy[36]. Using a randomized, crossover study design, combined 24-h pH-impedance monitoring was performed on (twice daily) and off PPI therapy for 7 d. Neither the number nor extent of reflux episodes was affected by PPI use. There were significantly more acidic reflux episodes off PPI therapy and more weakly acidic episodes on PPI therapy. However, there was lack of concordance between the SAP for both measurements, which was likely due to the small sample size of the study.

Ultimately, the benefit of using pH-impedance monitoring in routine clinical practice depends upon its ability to guide effective medical and surgical management. A prospective series of 12 patients in Switzerland evaluated using pH-impedance monitoring before and after anti-reflux surgery (mesh-augmented hiatoplasty)[37]. Although the sample size was small, the authors found that multichannel intraluminal pH-impedance monitoring significantly increased the number of reflux episodes detected before and after surgery compared to pH testing alone. There were also more patients identified as having a positive SI in the pH-impedance group. The study has found that pH-impedance monitoring provides increased data compared to pH testing alone, however, whether this information favorably affects management and long-term patient outcomes is yet to be determined. Future therapeutic trials using inhibitors of transient LES relaxation should provide valuable insights into the clinical significance of non-acid reflux.

SYMPTOM ASSOCIATION

Available methods

Three methods have been devised to use statistical calculations to correlate symptoms with acid reflux. Symptom correlation can be separately calculated for each symptom attributable to reflux, including heartburn, regurgitation

or chest pain. The application of symptom correlation to atypical reflux symptoms such as throat pain, hoarseness, cough and asthma is problematic given the lack of temporal association between such symptoms and individual reflux events. The first method developed was the SI[38], which involves dividing the number of symptoms associated with acid reflux events by the total number of symptoms, which yields a percentage. A second approach is the SSI[39], which divides the total number of reflux episodes associated with symptoms by the total number of reflux episodes. The third approach for symptom-reflux correlation is the SAP[40]. This involves constructing a contingency table with four fields: (1) positive symptom, positive reflux; (2) negative symptom, positive reflux; (3) positive symptom, negative reflux; and (4) negative symptom and negative reflux. Fisher's exact test is then applied to calculate the probability that the observed association between reflux and symptoms occurred by chance. An SAP value > 95% indicates that the probability that the observed association between reflux and the symptom occurred by chance is < 5%.

Both the SI and SSI do not take into account the total number of reflux and symptom events. Thus, in patients with very infrequent or frequent reflux episodes or symptoms, random, temporal associations between reflux and symptoms might produce an inaccurate result. Another important distinction between the methods is that the SAP determines the statistical validity of symptom-reflux associations, whereas the SI and SSI provide information on the strength of the association.

Does it work?

Past attempts to validate the utility of the symptom indices have shown conflicting results with some groups reporting correlation with PPI response[41,42], whereas others have shown high discordance rates of the indices and mediocre specificity and sensitivity[43]. As with any test used in clinical practice, reproducibility is paramount and this issue has been addressed recently in 21 patients with GERD symptoms[44]. The SI, SSI and SAP were determined in concert with 24-h pH-impedance monitoring. The SAP and SSI showed the highest reproducibility compared with the SI. The study was performed under "real world" conditions of ambulatory monitoring, which suggested that the symptom association indices, although far from ideal, can play a role in relating symptoms to reflux episodes. The limitations of symptom association and remaining cognizant of what the three methods do not measure should be considered before applying these in clinical practice. The symptom correlation tests should be viewed as complementary information that links symptoms with reflux events, which does not ensure response to either medical or surgical therapy.

OTHER MODALITIES AND ISSUES

Narrow-band imaging

Use of narrow-band imaging (NBI) to enhance the contrast between esophageal and gastric mucosa and improve visualization of the SCJ has been studied in GERD patients. NBI has been shown to increase reproducibility in grading esophagitis[45] and the ability to detect changes in the microvasculature at the SCJ[46]. More recently, a prospective study has evaluated the use of NBI to differentiate erosive esophagitis (EE) from NERD and controls[47]. A total of 107 patients underwent endoscopy with NBI. Compared to conventional endoscopy, NBI allowed for an increased detection of micro-erosions, vascularity, and mucosal islands ("pit patterns"). In terms of differentiating patients using these criteria, EE and NERD patients had a higher prevalence of micro-erosions and vascularity compared to controls. EE and NERD patients were only differentiated by an increased vascular surface in the absence of pit patterns (sensitivity 86.1%, specificity 83.3%). Although NBI with endoscopy is unlikely to serve as a standard for the diagnosis of GERD, it could serve as an adjunct in the classification of erosive and non-erosive disease.

Histopathology

The use of histological characteristics to help diagnose GERD, and specifically NERD, has garnered increased attention and has recently been reviewed[48]. Although there are limitations to many of the studies that have evaluated histology, dilation of the intracellular space (DIS) has emerged as a promising diagnostic marker of NERD[48,49]. There is also evidence that DIS can be affected by PPI treatment, potentially serving as a clinical endpoint in therapy. However, definitive histological parameters of DIS have yet to be defined for reflux disease. Histological parameters such as basal cell hyperplasia and papillae elongation have proven less sensitive or specific for GERD, but might ultimately play a role when used in combination with DIS[48,50]. Ultimately, histopathological characteristics will likely be used in concert with other modalities to diagnose and characterize GERD better.

Eosinophilic esophagitis as a confounder

Eosinophilic esophagitis (EoE) has been increasingly diagnosed in pediatric and adult populations over the past 15 years[51]. Patients can present with a variety of symptoms including dysphagia, food impaction, heartburn, and chest pain[52,53]. However, these symptoms are not specific for the diagnosis and it can be difficult to differentiate EoE from GERD. Presently, the diagnosis of EoE is defined by the combination of clinical symptoms and histological characteristics of mucosal eosinophilia (> 15 eosinophils/high-power field)[52]. Supportive features include the presence of mucosal rings, longitudinal furrows and exudates in the esophagus. Disorders such as hypereosinophilic syndrome, connective tissue disorders, GERD, drug hypersensitivity reactions or infectious esophagitis should either be excluded or deemed non-causal in the eosinophilia.

A recent retrospective case control study has evaluated clinical, endoscopic and histological characteristics that could differentiate GERD from EoE[54]. The combination of nine characteristics (age, dysphagia, food allergy,

esophageal rings, linear furrows, white plaques, no hiatal hernia, maximum eosinophil count, and eosinophil degranulation) differentiated GERD from EoE in their population[54]. However, as GERD is prevalent in approximate 20% of the United States population, it is inevitable that many patients will have coexisting disease[52,55]. Moreover, acid reflux itself might produce tissue eosinophilia or allow for allergen sensitization[56]. A significant proportion of suspected EoE patients respond both symptomatically and histologically to PPIs, which blurs the distinction between EoE and GERD even further[57,58].

CONCLUSION

As a result of complexities in phenotypic heterogeneity and pathophysiology, there is no single gold standard diagnostic modality for GERD. pH monitoring has the greatest accuracy in patients with typical heartburn and erosive esophagitis, but unfortunately, it suffers from significant limitations when applied to atypical manifestations in NERD patients. Advances in pH monitoring, most notably wireless pH capsule technology, have improved patient tolerability and allowed for prolonged recordings that allow for both detection of acid reflux and response to therapy. The sensitivity of pH monitoring might be enhanced by pH capsule positioning closer to the SCJ, but further validation is needed because of concerns for diminished diagnostic specificity. pH-impedance has clearly increased the understanding of acid and non-acid reflux pathophysiology. When combined with symptom indices, pH-impedance detection of weakly and non-acidic reflux has the potential to provide information that might guide management. Therapeutic trials that have demonstrated the predictive value of impedance data support this practice. Recent results using NBI and histopathology are of significance. Taken together, these methods lend themselves to a reductionist view of GERD, whereas patients are classified into better-defined sub-groups. This strategy could ultimately result in more effective, individualized management of GERD and improved outcomes.

Abstract

Increases in the prevalence of obesity and gastroesophageal reflux disease (GERD) have paralleled one another over the past decade, which suggests the possibility of a linkage between these two processes. In both instances, surgical therapy is recognized as the most effective treatment for severe, refractory disease. Current surgical therapies for severe obesity include (in descending frequency) Roux-en-Y gastric bypass, adjustable gastric banding, sleeve gastrectomy, and biliopancreatic diversion with duodenal switch, while fundoplication remains the mainstay for the treatment of severe GERD. In several large series, however, the outcomes and durability of fundoplication in the setting of severe obesity are not as good as those in patients who are not severely obese. As such, bariatric surgery has been suggested as a potential alternative treatment for these patients. This article reviews current concepts in the putative pathophysiological mechanisms by which obesity contributes to gastroesophageal reflux and their implications with regards to surgical therapy for GERD in the setting of severe obesity.

PARALLEL TRENDS IN GASTROESOPHAGEAL REFLUX DISEASE AND SEVERE OBESITY: CAUSALITY OR COINCIDENCE

Obesity has dramatically increased over the past few decades, with the prevalence of obesity among adults in the United States, defined as body mass index (BMI) $\geqslant$ 30 kg/m^2, increased from 13% in 1960-1962[1] to 32% in 2003-2004, with 3% of men and 7% of women classified as being severely obese (BMI $\geqslant$ 40 kg/m^2) in a recent estimate[2]. BMI itself is a strong predictor of overall mortality, with a progressive excess in mortality noted above the optimum BMI of 22.5-25 kg/m^2, due mainly to metabolic and vascular disease[3]. Indeed, the prevalence of the metabolic comorbidities that contribute to atherosclerosis appears to increase significantly with increasing BMI[4,5].

In parallel with this trend in obesity is the perception that the prevalence of gastroesophageal reflux disease (GERD) has increased as well, currently affecting between 8% and 26% of the population in the western world[6-8]. These data, however, are somewhat difficult to interpret,

as these longitudinal population-based studies rely primarily upon subjective GERD symptoms rather than physiological measures of GERD. Nonetheless, there has been a significant increase in the prevalence of serious sequelae related to GERD[9-11], including Barrett's esophagus and adenocarcinoma of the distal esophagus, which strongly suggests that the severity, if not the prevalence, of GERD is in fact increasing.

Furthermore, because the prevalence of GERD is markedly higher in overweight and obese individuals as compared to those with normal BMI[12,13], GERD itself is now recognized as obesity-related comorbidity. Indeed, the importance of the relationship between excess visceral adiposity and GERD is demonstrated by the greater correlation between GERD and waist circumference and waist-to-hip ratio (markers of central obesity) than that between GERD and BMI[14]. However, the prevalence of GERD, even in the setting of severe obesity, is < 50%[15], which suggests that severe obesity itself is not sufficient to cause GERD, and that in the majority of severely obese individuals, at least some of the physiological mechanisms that prevent GERD remain reasonably intact. As such, when managing GERD in a severely obese patient and considering surgical therapy, it is useful to review the proposed mechanisms by which obesity contributes to GERD pathophysiology.

ROLE OF SEVERE OBESITY IN GERD PATHOPHYSIOLOGY

Fundamental to the development of GERD is a failure of the anti-reflux barrier that comprises the lower esophageal sphincter (LES) and the crural portion of the hiatus. LES function is directly dependent on intrinsic LES pressure (LESP, normal, 10-24 mmHg), total LES length, intra-abdominal LES length, and the frequency and duration of transient LES relaxation (TLESR). Indirectly, LES function is affected by the pressure gradient between the intragastric and intraesophageal environment.

When compared to healthy asymptomatic control subjects, 43 consecutive severely obese patients were found to have a lower LESP (11.9 ± 5.3 mmHg *vs* 15.9 ± 2.7 mmHg), and 51% were noted to have abnormal acid exposure[16]. Similarly, in a large cohort of patients with foregut symptoms, the prevalence of a mechanically defective LES (based on hypotensive LES, total length, or abdominal length) increased as BMI increased, with 55% of obese patients demonstrating a defective LES[17]. While nearly 30% of the 1659 subjects in this study were noted to be obese, specific data regarding severely obese individuals were not described. In contrast, in another large cohort of patients with GERD, mean LESP was in fact significantly greater in subjects with severe obesity (17 ± 9.2 mmHg *vs* 14 ± 7.6 mmHg), and 62% of severely obese subjects with GERD had a normal (39%) or hypertensive (23%) LES compared to only 46% of individuals with BMI ⩽ 35 kg/m^2; 10% of whom were noted to have a hypertensive LES[18]. The authors of this study hypothesized that the mechanisms responsible for GERD might be different in the setting of severe obesity, and that the observed increased LESP could represent a compensatory mechanism against the increased pressure gradient between the stomach and esophagus, which ultimately remains inadequate to prevent GERD. This finding also has important implications with regards to surgical therapy, as conventional anti-reflux procedures (i.e. fundoplication) seek to correct the defective LES.

TLESR could be the most important reflux mechanism in the setting of a functioning LES, and it has been observed that fundoplication reduces the frequency of TLESR[19]. Based on high-resolution manometry and concurrent fluoroscopy in non-obese patients, the key events that lead to opening of the gastroesophageal junction during TLESR include LES relaxation, crural diaphragm inhibition, esophageal shortening, and a positive pressure gradient between the stomach and the gastroesophageal junction lumen[20]. Obese individuals without GERD were noted to have an increased frequency of TLESR (7.3 ± 2.0 events/2 h *vs* 2.1 ± 1.2 events/2 h) compared to normal weight individuals, whereas LESP and LES length were similar between the two groups[21]. Similar findings have been noted in the setting of severe obesity[22].

Several factors might contribute to the increased gastroesophageal gradient seen with obesity[23], including increased intra-abdominal pressure[24], increased intragastric pressure[25], increased negative inspiratory intrathoracic pressure[26], and a mechanical separation between the LES and the extrinsic compression provided by the diaphragmatic crura[23]. The latter is a key step in the development of hiatal hernia, which, based on endoscopic evidence, is more prevalent in obese individuals than normal weight individuals[27,28]. Indeed, the negative effects of the presence of hiatal hernia on LES function might in fact be greater than the effects of obesity *per se*[17].

SURGICAL TREATMENT OF GERD

There is substantial controversy regarding the long-term efficacy and durability of fundoplication in the setting of obesity, and fewer data still to inform clinicians as to its effectiveness in the setting of severe obesity. A major concern regarding the long-term durability of fundoplication in severe obesity is the presumed increased risk of hiatal hernia recurrence, projected from the well-recognized contribution of obesity to the risk of hernia recurrence following abdominal wall hernia repair[29,30]. In a study of 224 consecutive patients with 3 years follow-up who underwent laparoscopic Nissen or transthoracic Belsey Mark Ⅳ (BM-Ⅳ) fundoplication, overall symptomatic recurrence was 31.3% in obese patients (22.9% Nissen, 53.8% BM-Ⅳ), compared to 4.5% in normal-weight individuals[31]. In another cohort study, preoperative severe obesity was associated with a higher rate of fundoplication failure, defined as the need for reoperation, lack of satisfaction, or severe symptoms at follow-up[32]. This study was limited by the small number of severely obese patients (only seven out of 166) and loss of patients to follow-up.

In another study of patients who were undergoing gastric bypass after failed fundoplication, the majority of failures were found to be due to wrap disruption rather than intrathoracic wrap migration[33]; the latter being the most common anatomical failure in normal and overweight patients. In contrast, several studies have demonstrated short-term and medium-term outcomes in obese patients that are comparable to those in non-obese patients[34-37]. These data are somewhat limited in their applicability to severely obese individuals, however, due to their lack of physiological outcomes measures, small numbers of severely obese patients, and relatively short follow-up period.

BARIATRIC SURGERY AND GERD

Bariatric surgery has become a widely accepted form of treatment for severe obesity, and several studies have demonstrated a significant reduction in GERD symptoms and medication utilization, as well as weight and metabolic comorbidity, including diabetes, hypertension and dyslipidemia[38,39]. Indeed, given the frequent presence of these and other comorbidities in the setting of severe obesity, the importance of significant and sustained weight loss for the overall health of severely obese patients, and the conflicting data regarding the outcomes of fundoplication in severe obesity, bariatric surgery is increasingly being seen as a more appropriate surgical treatment for GERD in severe obesity, even though objective measures of GERD outcomes might be comparable between fundoplication and gastric bypass[40]. Earlier concerns regarding the comparative safety of bariatric surgery (gastric bypass in particular) and Nissen fundoplication have been addressed by the recent finding that the morbidity and mortality rates of the two procedures were very comparable when using the University Health System Consortium database to identify morbidly obese patients who underwent laparoscopic gastric bypass (n = 21 156) or laparoscopic Nissen fundoplication (n = 6108) at American academic medical centers between 2004 and 2007[41]. Instead, discussion today is centered around the differential effects of currently performed bariatric operations [Roux-en-Y gastric bypass (RYGB), adjustable gastric banding (LAGB), biliopancreatic diversion with duodenal switch (DS), and sleeve gastrectomy (SG)] on GERD, as well as other obesity-related comorbidity.

RYGB AND GERD

RYGB accounts for over half of the currently performed bariatric operation in the United States, and appears to have a very favorable impact on GERD[42-45]. Its recognized effectiveness has even led to its use in non-severely obese patients with GERD[46], particularly in the setting of failed fundoplication[33]. Its efficacy in treating GERD is thought to be related to the relatively low acid production of the small-volume (15-30 mL) gastric pouch[47], reduction of esophageal biliopancreatic refluxate by use of a roux limb measuring at least 100 cm in length[48,49], and weight loss. The physiological effects of the anatomic configuration of RYGB, and specifically, the configuration of the gastric pouch, might in fact be a more important contributor to reflux improvement than reducing alkaline bile reflux or weight loss. When comparing GERD remission as measured by symptom resolution and medication discontinuation, super-obese patients (BMI $\geqslant$ 50 kg/m^2) who underwent RYGB had a higher rate of GERD resolution than those who underwent DS, despite the greater weight loss seen in the latter group[15].

LAGB AND GERD

Since its FDA approval in 2001, LAGB has rapidly become a popular bariatric surgical option for patients and surgeons due to its relative technical simplicity, perceived advantageous safety profile, and lack of gastrointestinal tract division or reconstruction (and consequent malabsorption). The effects of LAGB on GERD are conflicting, however, with some studies demonstrating improvement in physiological GERD metrics[16], while others show improvement on GERD questionnaires and/or through the discontinuation of GERD medications[50,51]. In contrast, several studies have demonstrated measured exacerbation of esophageal acid exposure, GERD symptoms, and the development or worsening of esophageal dysmotility following LAGB[52-54]. The mechanism by which LAGB may improve GERD is not well characterized, but is thought to include weight loss, increase in LESP, and reconstitution of the angle of His. It has been hypothesized that the poorer GERD outcomes following LAGB might be attributable to an unrecognized hiatal hernia at the time of initial band placement, which has led some to suggest that the presence of hiatal hernia is a contraindication to LAGB[55], whereas others have suggested that aggressive identification and concomitant repair of hiatal hernia improves outcomes and reduces the need for reoperation due to band slippage or pouch dilation[56]. Given these conflicting data, most bariatric surgeons do not recommend LAGB to severely obese patients with significant GERD, particularly in the setting of hiatal hernia.

SG, DS AND GERD

SG is a restrictive procedure initially described as the first procedure of a two-staged duodenal switch operation in very-high-risk super-obese patients, and is rapidly gaining popularity as a stand-alone bariatric operation. As with LAGB, early data regarding the impact of SG on GERD are mixed[57], and very little long-term or comparative data regarding SG and GERD are available. While the resection of a substantial portion of the parietal cell mass, significant weight loss, and a possibly increased rate of gastric emptying might all contribute to improvement in GERD physiology, the relatively long and narrow anatomical configuration of the sleeve might increase resistance to esophageal emptying of physiological amounts of reflux, and the parietal cell mass remains significantly greater than that with RYGB. Furthermore, when bile reflux is

controlled as a factor (through biliopancreatic diversion in the setting of DS), symptomatic resolution of GERD is greater with RYGB[15]. As such, SG in the setting of significant GERD should be recommended with caution.

SEVERE OBESITY AND GERD: SURGICAL RECOMMENDATIONS

When surgical treatment of GERD is indicated in a severely obese patient, bariatric surgery rather than fundoplication should be strongly considered. Not only does bariatric surgery, and RYGB in particular, better address the mechanisms that lead to GERD in obese patients with the potential for greater durability, but it also addresses concomitant obesity-related comorbidity by achieving significant and sustained weight loss. Therefore, in this case, the surgeon has the opportunity to substantially improve the patient's quality of life, positively impact multiple chronic medical conditions, and possibly reduce the excess long-term mortality risk associated with severe obesity in an acceptably safe, minimally-invasive, and cost-effective manner. For many patients, this discussion might be the first in which bariatric surgery is introduced as a possible therapeutic option, and it is not uncommon for patients to express significant resistance to the idea. In other instances, patients might have been considering bariatric surgery but were hesitant to discuss the possibility with their primary care physician and are receptive to the opportunity to learn more about the procedures. Not uncommonly, this discussion might require several office visits with the surgeon, and it is important that, in addition to offering detailed information regarding the procedures, the severely obese patient with GERD undergoes multidisciplinary evaluation as do other potential bariatric surgery patients, given the need for life-long changes in eating and behavior, and the need for long-term medical follow-up and vitamin supplementation. In doing this, the surgeon can provide a therapy that goes significantly beyond treatment of GERD.

Abstract

Gastroesophageal reflux disease (GERD) affects an estimated 20% of the population in the United States. About 10%-15% of patients with GERD develop Barrett's esophagus, which can progress to adenocarcinoma, currently the most prevalent type of esophageal cancer. The esophagus is normally lined by squamous mucosa, therefore, it is clear that for adenocarcinoma to develop, there must be a sequence of events that result in transformation of the normal squamous mucosa into columnar epithelium. This sequence begins with gastroesophageal reflux, and with continued injury metaplastic columnar epithelium develops. This article reviews the pathophysiology of Barrett's esophagus and implications for its treatment. The effect of medical and surgical therapy of Barrett's esophagus is compared.

Key words: Gastroesophageal reflux disease; Barrett's esophagus; Lower esophageal sphincter; Esophageal motility; Proton pump inhibitors; Antireflux surgery

INTRODUCTION

Gastroesophageal reflux disease (GERD) affects an estimated 20% of the population, and with direct and indirect costs exceeding $10 billion annually, it is the costliest gastrointestinal disorder in the United States[1]. Much of this extraordinary sum goes to pay for increasingly more potent and widely prescribed medications to suppress gastric acid production. While these medications have been proven to relieve heartburn symptoms and heal esophagitis, they have not substantially altered the malignant complications of reflux disease. Adenocarcinoma of the esophagus, which occurs as a consequence of chronic gastroesophageal reflux, is increasing faster than any other cancer in the United States, and has surpassed squamous cell as the most prevalent type of esophageal cancer[2].

The esophagus is normally lined by squamous mucosa, therefore, it is clear that for adenocarcinoma to develop, there must be a sequence of events that results in transformation of the normal squamous mucosa into columnar epithelium. This sequence begins with gastroesophageal reflux, and with continued injury metaplastic columnar epithelium develops. Currently, in the Unites States, only an endoscopically visible segment of columnar mucosa that contains goblet cells on biopsy is considered to be premalignant, and patients with this condition are considered to have Barrett's esophagus. Barrett's esophagus is the precursor lesion for esophageal adenocarcinoma.

EPIDEMIOLOGY

The prevalence of Barrett's esophagus appears to be increasing in the Western world. It has been debated wheth-

er this represents a true rise in incidence or is secondary to a heightened awareness of the dangers of reflux disease among practitioners, and an increased use of upper endoscopy to evaluate patients with reflux symptoms[3]. The most convincing epidemiological evidence that the prevalence of Barrett's esophagus is actually increasing comes from a recent study in the Netherlands using their Integrated Primary Care Information database, which contains > 500 000 computerized patient records. In that study, there was a linear increase in the diagnosis of Barrett's esophagus that was even more pronounced if the increase was based on the number of upper endoscopies performed during the same time period (from 19.8/1000 upper endoscopies in 1997 to 40.4/1000 upper endoscopies in 2002)[4]. Epidemiological studies in England have also demonstrated an age-specific increase in the prevalence of Barrett's esophagus per 100 upper endoscopies during the years 1982-1996[5].

Thus, there is evidence that the prevalence of Barrett's esophagus is increasing, but it is clear that the true prevalence of Barrett's esophagus in the population is unknown, and likely much higher than would be expected based on clinical cases diagnosed by upper endoscopy. In one of the few autopsy studies that has evaluated the prevalence of Barrett's esophagus, Cameron *et al*[6] found 376 cases per 100 000 people in Olmsted County, MN, USA. This rate was five times higher than the clinical prevalence of Barrett's esophagus in this same area (82.6 per 100 000). Further support for the concern about a large sub-clinical population of individuals with Barrett's esophagus comes from a study done in veterans by Gerson *et al*[7]. They performed upper endoscopy in a group of patients who presented for routine sigmoidoscopy for colorectal cancer screening; none of whom had symptoms of reflux. Although there are obvious limitations to a study done primarily in older, white male military veterans, nonetheless, their finding that 25% of patients had Barrett's esophagus is concerning because, on the basis of symptoms, none of these patients would have been recommended to have upper endoscopy. These observations suggest that the majority of individuals with Barrett's esophagus go undiagnosed, either because they ignore minor reflux symptoms or, as the study in veterans suggests, they are truly asymptomatic.

PATHOPHYSIOLOGY

Overview

The development of Barrett's esophagus is likely a two-step process. The first step involves the transformation of normal esophageal squamous mucosa to a simple columnar epithelium called cardiac mucosa. This occurs in response to chronic injury produced by repetitive episodes of gastric juice refluxing onto the squamous mucosa. The change from squamous to cardiac mucosa likely occurs relatively quickly, within a few years, while the second step, the development of goblet cells indicative of intestinal metaplasia, proceeds slowly, probably over 5-10 years[8]. Once present, Barrett's esophagus can progress to low- and high-grade dysplasia, and ultimately to adenocarcinoma. This entire process is commonly described as the Barrett's metaplasia-dysplasia-carcinoma sequence.

Step one: Transition from squamous to columnar-lined esophagus

To understand what constitutes a columnar-lined esophagus an understanding of the anatomy and histology of the normal gastroesophageal junction is required. Unfortunately, the very definition of what is normal in this area remains controversial, with much debate centered on whether cardiac mucosa is normally present at the gastroesophageal junction. Although our understanding is gradually improving, Hayward's remark in 1961 that "the lower end of the esophagus is a region where the pathology, the physiology, and even the anatomy are not quite clear" remains appropriate even today[9]. In one of the first reports describing the normal gastroesophageal junction, Hayward indicated that a junctional or buffer zone of columnar mucosa is normally interposed between the acid-secreting oxyntic gastric mucosa and the acid-sensitive squamous esophageal mucosa[9]. Although an appealing concept, Hayward provided no data in support of his theory, and did not discuss the role of the lower esophageal sphincter which had been demonstrated to exist before his publication. According to Hayward, this junctional mucosa is normally found in a length of up to 2 cm at the gastroesophageal junction. He also noted the following about this junctional mucosa: (1) it was histologically distinct from normal gastric fundic and pyloric epithelium; (2) it did not secrete acid or pepsin but was resistant to both; (3) it was not congenital but acquired; (4) it was mobile and varied in length - creeping progressively higher into the esophagus with continued gastroesophageal reflux; and (5) it was potentially reversible with correction of reflux. Furthermore, he pointed out that it was located in the esophagus, and that it developed in association with gastroesophageal reflux[9].

Now, over 40 years later, there is still dispute about the histology of the normal gastroesophageal junction, but it is clear that normally there is none or at most 4 mm of cardiac mucosa in the distal esophagus at the gastroesophageal junction[10-13]. Longer lengths of cardiac mucosa are acquired secondary to chronic gastroesophageal reflux[14,15]. Supporting evidence for the concept that cardiac mucosa is acquired comes from both clinical and experimental studies. Experimental evidence comes from a 1970 study by Bremner *et al*[16] in which a series of dogs underwent stripping of the distal esophageal squamous mucosa, with or without creation of a cardioplasty to destroy the function of the lower esophageal sphincter. Squamous re-epithelialization occurred in those animals without gastroesophageal reflux, whereas in the animals with reflux after cardioplasty, the esophagus was re-epithelialized by a columnar epithelium that lacked parietal cells - the equivalent of cardiac mucosa in humans[16]. There is also clinical evidence in humans that columnar mucosa can replace normal esophageal squamous epithelium in the setting of gastroesophageal reflux. Following

an esophagectomy with gastric pull-up, reflux of gastric juice into the residual esophagus is common because there is no lower esophageal sphincter and a large hiatal hernia has been created. Postoperative endoscopy has revealed that many of these patients develop columnar epithelium that, on histology, is identical to cardiac mucosa proximal to the anastomosis in the residual esophagus, in what had pathologically been proven to be squamous mucosa at the time of the operation. Several series have revealed that this process is common, and occurs in ⩾ 50% of patients after esophagectomy with gastric pull-up, and that the length of columnar mucosa increases with longer follow-up[8,17-20]. Furthermore, the cardiac mucosa that develops in these patients proximal to the esophagogastric anastomosis has been shown to be biochemically similar to cardiac mucosa found in non-operated patients at the native gastroesophageal junction[17]. Additional support for the concept that cardiac mucosa is acquired comes from the fact that it is not found anywhere else in the gastrointestinal tract, and when present at the gastroesophageal junction, it is always inflamed and demonstrates reactive changes unrelated to either *Helicobacter pylori* infection or mucosal pathology elsewhere in the stomach[21]. This is atypical for a normal epithelium. Lastly, the presence of cardiac mucosa can be correlated with objective markers of GERD, including an incompetent lower esophageal sphincter, increased esophageal acid exposure on 24-h pH monitoring, a hiatal hernia, and erosive esophagitis[15].

The earliest manifestation of GERD might in fact be the presence of microscopic foci of cardiac mucosa at the gastroesophageal junction. This leads to the question of why the finding of a microscopic length of cardiac mucosa at the gastroesophageal junction is so common even in patients without the typical reflux symptoms of heartburn or regurgitation. This is likely to be related to the pathophysiology of early reflux disease. Evidence is accumulating that reflux disease begins with gastric distention after large and particularly fatty meals. Gastric distension leads to effacement of the lower esophageal sphincter and exposure of the squamous mucosa at the distal extent of the sphincter to gastric juice. The pathophysiology of the gastroesophageal junction has been best studied by Fletcher and McColl. They have noted that the gastric distension that occurs with eating can cause the lower esophageal sphincter to unfold by almost 2 cm in normal volunteers[22]. Moreover, they have identified an unbuffered acid pocket at the gastroesophageal junction following a meal; a phenomenon that they have attributed to gastric juice floating upon a lipid layer after ingestion of fatty food. By pulling back a pH catheter before and after a meal, they have been able to show that the pH step-up that corresponds to the functioning lower esophageal sphincter moved proximally with gastric distension, secondary to unfolding of the distal portion of the sphincter. By measuring acid exposure with a pH catheter positioned at the squamocolumnar junction, and another located 5.5 cm proximal to the squamocolumnar junction, Fletcher *et al*[23] have demonstrated significantly greater acid exposure at the squamocolumnar junction (median total percentage time pH < 4 of 11.7% *vs* 1.8% at 5.5 cm proximal to the squamocolumnar junction). This study has confirmed the presence of significant acid exposure at the most distal intrasphincteric segment of the esophagus in patients with otherwise normal acid exposure proximally at 5.5 cm above the squamocolumnar junction. These findings were subsequently extended when it was demonstrated that salivary nitrite is rapidly converted into nitric oxide when it comes in contact with gastric acid that contains physiological levels of ascorbic acid, and this reaction has been found to be maximal at the gastroesophageal junction[24]. The levels of nitric oxide generated at the gastroesophageal junction are potentially mutagenic, and might play a role in the pathophysiology of this region.

It is likely that continued injury to the distal esophagus and lower esophageal sphincter leads to progressive loss of the abdominal length of the sphincter. What started as transient sphincter unfolding with gastric distension gradually progresses to permanent sphincter destruction. With destruction of the sphincter, reflux disease is allowed to explode into the esophagus, and can lead to an increase in the length of cardiac mucosa, either as tongues or as a circumferential replacement of the distal esophageal squamous mucosa. This leads to progressive migration of the squamocolumnar junction proximally[25,26]. Confirmation of esophageal submucosal glands deep to areas lined by cardiac mucosa provides clear evidence that the development of cardiac mucosa is occurring in the esophagus in areas previously covered with squamous mucosa and not in the proximal stomach[26].

The precise details of the molecular mechanism by which squamous mucosa is transformed into cardiac mucosa remain unknown. However, there is likely to be a crucial interaction between normally sequestered esophageal stem cells and an intraluminal stimulus that drives this metaplastic process. Tobey *et al*[27] have demonstrated that exposure of esophageal squamous mucosa to gastric juice produces dilated intercellular spaces that allow molecules of up to 20 kDa to permeate down to the stem cells in the basal layer. Perhaps the sensation of heartburn occurs as a consequence of diffusion of hydrochloric acid through these intercellular spaces and stimulation of sensory afferent nerves[28]. These ultrastructural changes occur before gross or microscopic changes become apparent. Thus, one possibility is that factors present in the refluxed juice that gain access to the basal layer stem cells via these dilated intercellular spaces induce a phenotypic transformation such that cardiac columnar mucosal cells rather than squamous cells are produced.

Step two: Intestinalization of cardiac mucosa

Cardiac mucosa is thought to be an unstable epithelium, in part because of the severe inflammatory and reactive changes present on histology. It is hypothesized that cardiac mucosa progresses down one of two possible pathways, based on a combination of environmental and genetic factors. One pathway involves the expression of gastric genes and leads to the formation of parietal cells

within glands below the cardiac mucosa. Gastric differentiation leads to a mucosa called oxyntocardiac mucosa, and this is thought to represent a regressive or favorable change because oxyntocardiac mucosa is not premalignant, and appears to be protected from developing intestinal metaplasia. In the second pathway, expression of intestinal genes causes the formation of goblet cells within cardiac mucosa. In contrast to gastric differentiation, intestinal differentiation represents a progressive or unfavorable change because this mucosa is premalignant. Both oxyntocardiac mucosa and Barrett's esophagus have less inflammation than cardiac mucosa, which suggests that these mucosal types are more stable epithelia[29].

The development of goblet cells marks the transformation of cardiac mucosa into intestinal metaplasia. When an endoscopically visible length of this mucosa is present in the esophagus, the definition of Barrett's esophagus has been met. While gastroesophageal reflux is known to be the primary factor responsible for the development of Barrett's esophagus, the specific cellular events that lead to the transformation of cardiac mucosa into intestinalized cardiac mucosa are unknown. However, evidence is accumulating that intestinalization requires a specific condition or stimulus, and that Barrett's esophagus occurs in a stepwise process. The first step, from squamous to cardiac mucosa, is likely to occur in response to acid reflux. The second step, development of intestinal metaplasia, is likely to occur in response to a different type of luminal insult. Numerous studies have demonstrated that, although isolated acid reflux can cause esophagitis, Barrett's esophagus is associated with the presence of a mixture of acid and bile salts[30-32]. Furthermore, clinical experience dating back 30 years has suggested a role for refluxed bile in the development of intestinal metaplasia. In 1977, Hamilton and Yardley observed the development of columnar mucosa and intestinal metaplasia above the esophagogastric anastomosis in a group of patients after esophagectomy. They noted that "severe symptoms of gastroesophageal reflux and bile staining of the refluxed material were documented only in the group with Barrett's. In addition, pyloroplasty had been performed more commonly in this group."[33]. Recently, in two separate analyses of patients with reflux with and without Barrett's esophagus, we found that the factor most associated with the presence of Barrett's esophagus in both men and women with GERD was abnormal bilirubin reflux, as determined by Bilitec monitoring[34,35].

Fitzgerald *et al*[36] have reported several interesting observations on how the dynamics of mucosal exposure to luminal contents might affect columnar epithelial cell proliferation and differentiation. Using cultured human Barrett's esophagus biopsy specimens, they have demonstrated that continuous exposure to acidic media at pH 3.5 resulted in increased villin expression (a marker for epithelial cell differentiation) and reduced cell proliferation. Villin expression was not detected when the culture medium was made more acidic (pH < 2.5). In contrast, a dramatic increase in proliferation occurred when the Barrett's esophagus tissue was exposed to a short (1 h) pulse of acidic medium (pH 3.5) followed by a return to neutral pH. Clinically, this same group has noted that effective acid suppression results in a shift of the Barrett's epithelium away from proliferation and toward differentiation[37]. However, the cellular consequences of duodeno-gastroesophageal reflux in the setting of gastric alkalization with acid suppression medications were not addressed in that study.

It has been hypothesized that the mechanism by which acid and bile interact to cause Barrett's esophagus is related to the ionized state of bile salts[38]. It appears that in a weakly acidic environment certain bile acids are particularly toxic. At pH 3-6, these bile salts are soluble and non-ionized, and can enter mucosal cells, accumulate, and cause direct cellular injury[39]. When the luminal pH is higher than the pKa, these same bile acids are ionized and cannot cross the phospholipid membrane. Further, when the luminal pH is lower, as normally it is in the stomach, bile acids precipitate out of solution and are harmless[40]. Thus, it is only at this critical pH range of 3-5 that certain bile acids become non-ionized and able to cross the cell membrane. Once inside the cell, the pH is 7 and the bile acids become ionized and are trapped inside the cell where they have been shown to result in mitochondrial injury, cellular toxicity and mutagenesis[41-44]. Consequently, this mid-range gastric pH of 3-5 is a danger zone for patients with duodeno-gastroesophageal reflux.

It remains uncertain whether the transformation of cardiac mucosa to intestinalized cardiac mucosa represents a phenotypic change secondary to the induction of genes, or a mutational event within the columnar cells. Mendes de Almeida and colleagues have demonstrated biochemically that both cardiac mucosa and intestinal metaplasia express sucrase-isomaltase and crypt cell antigen - two small intestine marker proteins; however, in that study only three patients with cardiac mucosa were evaluated[45]. Das has developed a murine monoclonal antibody (DAS-1) that reacts specifically with normal colonic epithelial cells, and subsequently he has found that it also reacts with an unknown epitope in Barrett's mucosa[46]. Griffel *et al*[47] have reported that the DAS-1 antibody stained cardiac mucosa without intestinal metaplasia in seven patients, and that six of these patients later developed histological evidence of intestinalization on repeat biopsies. Likewise, we noted that the pattern of immunostaining with cytokeratins 7 and 20 was similar in cardiac mucosa and Barrett's esophagus[48]. These findings suggest that, biochemically, cardiac mucosa and intestinal metaplasia are similar, and that cardiac mucosa is the precursor of intestinalized columnar epithelium, or Barrett's esophagus.

Currently, the length of Barrett's esophagus is divided into short (< 3 cm) and long (≥ 3 cm) segments based on the endoscopically determined length of the columnar streak or column in the distal esophagus. Clinically, patients with long-segment Barrett's esophagus tend to have more severe reflux disease than those with short-segment disease. Patients with long-segment Barrett's esophagus have a higher prevalence of hiatal hernia, more commonly have a defective lower esophageal sphincter, and dem-

onstrate greater esophageal acid and bilirubin exposure on 24-h pH and Bilitec monitoring[30,49]. Despite the differences in length, there is evidence that short and long-segment Barrett's esophagus are biochemically similar[48,50]. This is supported by the clinical observation that the risk of malignancy is similar for both short and long segments of Barrett's esophagus[51].

The presence of goblet cells is the *sine qua non* of Barrett's esophagus. The likelihood of finding intestinalization correlates with the length of the columnar segment. Once 4 cm of cardiac mucosa are present in the distal esophagus, nearly all patients will be found to have intestinal metaplasia on biopsy[49,52]. However, the location of goblet cells in a columnar-lined segment is not uniform, and often the entire length of columnar esophagus does not demonstrate intestinal metaplasia. Goblet cell density is greatest near the squamocolumnar junction and becomes more variable distally[29]. In other words, if intestinal metaplasia is present within a columnar-lined segment of the esophagus, it will always be present proximally at the squamocolumnar junction. Goblet cells might extend throughout the entire length of the columnar segment. The length of Barrett's esophagus is determined by the endoscopic length of columnar mucosa and not by the length of mucosa showing intestinal metaplasia. In other words, a 6-cm segment of columnar mucosa with intestinal metaplasia only at the proximal 1 cm is still considered long-segment Barrett's esophagus, but the clinical behavior of this long-segment Barrett's might differ substantially from a 6-cm segment of columnar mucosa with intestinal metaplasia throughout the entire length. The current definition of Barrett's esophagus does not take this into account.

The time course to develop goblet cells is uncertain, but it appears to take a minimum of 5-10 years[38,53]. Studies involving esophagectomy patients have indicated that cardiac mucosa develops rapidly, often within 1-2 years. Intestinalization of the columnar segment in these patients occurs significantly later, typically after another 3-5 years[18-20,33,54]. These findings might reflect an accelerated course of events because these patients often have significantly greater reflux of acid and bile than the typical patient with GERD. However, this clinically relevant human model does demonstrate the two-step process of Barrett's esophagus, starting with columnarization followed by intestinalization in some patients.

The molecular mechanisms by which cardiac mucosa acquires goblet cells remain to be elucidated. However, there is increasing evidence that expression of the homeobox gene Cdx-2 plays a pivotal role. The expression of this gene increases with progression from squamous mucosa with esophagitis to cardiac mucosa, and is maximal in the setting of intestinal metaplasia[55-57]. Experimental work has suggested that Cdx-2 expression can be modulated by the pH of luminal material[58]. Furthermore, an individual's response to an inflammatory stimulus might also participate in the mucosal adaptation to reflux disease. Fitzgerald *et al*[59] have demonstrated that esophagitis and Barrett's esophagus have distinct cytokine profiles that reflect different inflammatory responses to reflux-induced injury. Moreover, even within a given Barrett's esophagus segment, the inflammatory response is more severe at the proximal end near the squamocolumnar junction, which could explain the greater tendency for intestinalization to occur at this location[60]. Furthermore, the specific cytokine polymorphism of a given individual might also influence the development of Barrett's esophagus. Preliminary work from Gough *et al*[61], for example, has demonstrated that specific polymorphisms of interleukin (IL)-1 receptor antagonist and IL-10 are more common in patients with Barrett's esophagus than those with esophagitis. Thus, a genetically determined inflammatory response to reflux might influence the pathway of disease in each individual patient.

DYSPLASIA AND MALIGNANT TRANSFORMATION

Barrett's esophagus is a premalignant mucosa, and has an increased proliferation rate, decreased apoptosis, and an increased fraction of diploid and aneuploid cells compared to normal epithelium[13,62]. The combination of increased proliferation and decreased apoptosis allows genetic abnormalities to develop and accumulate, and drives the development of dysplasia and malignant transformation in Barrett's esophagus[63]. Although non-dysplastic Barrett's esophagus is a simple columnar epithelium with homogenous nuclei arranged close to the basement membrane, dysplasia results in both cytological and architectural abnormalities, including loss of nuclear polarity, pleomorphic appearance, and the development of glandular distortion[64]. By convention, there are four broad categories used by pathologists to describe the dysplastic process: (1) no dysplasia; (2) indefinite for dysplasia; (3) low-grade dysplasia; and (4) high-grade dysplasia. This classification system has been adapted for use in Barrett's esophagus from that used in ulcerative colitis[65,66]. The most significant category, high-grade dysplasia, is characterized by carcinoma *in situ* with malignant cells that do not invade the lamina propria.

The grading of dysplasia has great clinical utility in stratifying risk of subsequent cancer in patients with Barrett's esophagus, and to date, it is the most important predictive marker for the development of invasive adenocarcinoma. However, the ability to grade dysplasia remains a subjective endeavor, particularly outside specialized centers with expert gastrointestinal pathologists[67]. Even among focused gastrointestinal pathologists there is discordance, particularly with regard to the presence of low-grade dysplasia[68]. This lack of precision inherent in histopathological grading has stimulated efforts to identify more objective molecular and biochemical indicators of an increased risk for progression in patients with Barrett's esophagus. It has been demonstrated that in medically treated patients with Barrett's esophagus and low-grade dysplasia, the risk of progression is increased in patients with aneuploidy[69]. It is hoped that other molecular mark-

ers that are better able to predict which patients with Barrett's esophagus are at increased risk for progression will be identified in the future.

NATURAL HISTORY OF BARRETT'S ESOPHAGUS

Although it is widely accepted that Barrett's esophagus is a premalignant condition, the degree of risk remains uncertain. A meta-analysis by Shaheen *et al*[70] of 25 articles published between 1984 and 1998 concluded that the incidence of adenocarcinoma in patients with Barrett's esophagus was approximately 0.5% per patient-year, with a range from 0.2% to 2.9%. However, these studies were done in patients being treated for reflux, including those that had antireflux surgery, and thus these estimates might not reflect the true natural history of Barrett's esophagus progression. Known risk factors for progression to dysplasia and cancer include hiatal hernia size, the length of Barrett's esophagus, patient age, and the presence of cellular and molecular abnormalities, including abnormal ploidy status and *p16* or *p53* gene abnormalities[69,71-74].

The natural history of dysplasia is not well characterized, but the risk of malignancy increases with the development of low- and high-grade dysplasia. The best data have come from Reid *et al*[69], and in a carefully followed group of patients. they reported that low-grade dysplasia progressed to cancer in 4% over 5 years, whereas high-grade dysplasia led to cancer in 61% at 5 years. It is also clear that progression is variable, with some patients progressing at a steady pace over several years, while others have stable non-dysplastic or low-grade dysplasia in Barrett's esophagus for many years, and then rapidly develop high-grade dysplasia and cancer. Theisen *et al*[75] conducted a review of patients who received follow-up through the entire sequence of Barrett's esophagus, low-grade dysplasia, high-grade dysplasia, and adenocarcinoma to better understand the chronology of these events. In a group of 28 patients that presented with adenocarcinoma, a median of 24 mo passed from the initial diagnosis of Barrett's esophagus. Progression from low-grade to high-grade dysplasia occurred over a median of 11 mo. Once high-grade dysplasia was diagnosed, the median time to diagnosis of cancer was 3 mo. Although this timeline was variable for each individual, in the cohort of patients that had progression of Barrett's esophagus to cancer, the process occurred within 3 years. However, because most Barrett's esophagus patients do not progress onto dysplasia and cancer, the cohort in this retrospective study might not be applicable to all patients. Furthermore, because few of these patients had been in long-term Barrett's esophagus surveillance programs, it is not possible to separate prevalent from incident cancers in this group, and the actual month and year that Barrett's esophagus developed in each patient is also unknown. Thus, information on progression of Barrett's esophagus is largely anecdotal.

IMPACT OF ANTIREFLUX THERAPY ON THE NATURAL HISTORY OF BARRETT'S ESOPHAGUS

Medical therapy of Barrett's esophagus

There are three goals for treating patients with Barrett's esophagus: (1) stop reflux; (2) promote or induce healing or regression of the metaplastic epithelium such that the high-risk mucosa (intestinal metaplasia) is eliminated; and (3) halt progression to dysplasia and cancer. Most patients with Barrett's esophagus are treated medically; however, adequate medical therapy is difficult because of the degree of impairment of the lower esophageal sphincter and the poor esophageal body motility that are frequently present. This is likely to be the reason why the least controlled symptom in patients with Barrett's esophagus receiving medical treatment is regurgitation[76]. Medical treatment options are limited to dietary and lifestyle modifications, promotility agents, and acid-suppression therapy. Sampliner and the Practice Parameters Committee of the American College of Gastroenterology have stated that "the goal of therapy of Barrett's esophagus should be the control of the symptoms of GERD", and that "symptom relief is an appropriate endpoint for the therapy of Barrett's esophagus"[77]. However, this viewpoint flies in the face of logic. Gastroesophageal reflux causes both Barrett's esophagus and esophageal cancer. Symptoms are not part of the pathophysiology of the disease. Rather, they are merely the variably expressed byproduct of reflux. Many patients with Barrett's esophagus have few or no reflux symptoms; probably as a consequence of an altered sensitivity of the metaplastic epithelium to refluxed acid. Consequently, the eradication of symptoms, if present, cannot be equated with elimination of reflux. Katzka and Castell[78] have demonstrated that standard-dose omeprazole (20 mg/d) failed to suppress acid sufficiently to keep gastric pH neutral for a full 24 h in patients with Barrett's esophagus. Furthermore, increasing the dose of the omeprazole until all symptoms were alleviated was an unreliable measure of effective therapy, since 80% of patients studied with 24-h pH still had abnormal distal esophageal acid exposure[78]. Sampliner likewise found that high-dose proton pump inhibitor administration (lansoprazole, 60 mg/d) failed to normalize the 24-h pH test in over a third of patients with Barrett's esophagus who were tested while on therapy[76]. Even if complete suppression of acid could be achieved 24 h/d, 7 d/wk, for 350 d/year, impedance studies have shown that the number of reflux events is unchanged. Acid reflux events are merely converted to non- or weak acid reflux events, because the physiological abnormalities that lead to reflux are unaddressed by medical acid suppression therapy[79,80]. The role of continued weak or non-acid reflux in the progression of Barrett's esophagus is undefined, but it may explain the paucity of evidence that acid suppression therapy alters the natural history of Barrett's esophagus.

The second and third goals of therapy in patients with Barrett's esophagus are to eliminate the high-risk mucosa,

i.e. intestinal metaplasia, and prevent progression to dysplasia and cancer. Medical therapy has not been shown to achieve either of these goals reliably. Several reports have concluded that medical therapy does not cause regression of intestinal metaplasia[81-83]. This might be different in patients with short-segment Barrett's esophagus. Weston *et al*[84] have described the loss of goblet cells from lengths of intestinal metaplasia < 2 cm in 32% of patients treated medically for 1-3 years. In contrast, only two of 29 patients (7%) with lengths of intestinal metaplasia ⩾ 3 cm had loss of goblet cells.

With respect to the efficacy of medical therapy in preventing progression of Barrett's esophagus to dysplasia and cancer, there is speculation that prolonged, and perhaps inadequate acid suppression might actually promote the development of Barrett's esophagus and its complications[32]. Lagergren *et al*[85] have recently reported that the risk of esophageal adenocarcinoma was increased nearly eightfold among persons in whom heartburn, regurgitation, or both occurred at least once weekly compared to persons without these symptoms. They noted that the risk of esophageal adenocarcinoma was three times higher among patients who used medication for symptoms of reflux compared to those who did not use any antireflux medication[85]. Others, including Ortiz *et al*[82] and Hameeteman *et al*[86] have also linked medical therapy for Barrett's esophagus with progression to dysplasia and adenocarcinoma. In the study by Hameeteman *et al*[86] from the Netherlands, 50 patients with a columnar-lined esophagus were treated medically and followed from 1.5 to 14 years (mean 5.2 years). Of these 50 patients, initially only 34 had intestinal metaplasia on biopsy of the columnar mucosa. At completion of the study, 37 patients had intestinal metaplasia, which indicated that three patients developed Barrett's esophagus during the 5-year study period. In addition, at the start of the study, six patients had low-grade dysplasia and one had high-grade dysplasia. By the end of the 5-year study, 10 patients had low-grade dysplasia, three had high-grade dysplasia, and five had adenocarcinoma[86]. Similarly, Sharma *et al*[87] followed 32 medically treated patients with short segment Barrett's esophagus (mean length: 1.5 cm) for a mean of 36.9 mo, and found a 5.7% annual incidence of progression to dysplasia. During the 98 patient-years of follow-up in their series, two patients developed high-grade dysplasia, and one of these patients progressed to cancer. Recall that the expected rate of cancer is 1 per 100 patient-years of follow-up. All patients in the study by Sharma and colleagues were treated with omeprazole, ranitidine, and/or promotility agents. They commented that most patients developed dysplasia while on acid suppression medication, and they concluded that medical treatment does not prevent the development of dysplasia. A recent retrospective observational study in patients with Barrett's esophagus suggested that proton pump inhibitor use was associated with a reduced incidence of high-grade dysplasia or adenocarcinoma compared to patients not taking such medication, but there was no difference in the incidence of dysplasia between groups[88].

Antireflux surgery for Barrett's esophagus

In contrast to the ongoing weak or non-acid reflux that occurs with acid suppression therapy, antireflux surgery restores lower esophageal sphincter function and abolishes reflux of gastric contents into the esophagus. Consequently, an antireflux operation ends the repetitive injury to both the metaplastic and normal esophageal mucosa. Randomized clinical studies have confirmed superior control of reflux following antireflux surgery compared to medical therapy, and antireflux surgery has been proven safe, effective, and durable[82,89]. In addition, many patients are candidates for a minimally invasive laparoscopic approach associated with a short hospital stay and rapid recovery. We therefore favor the performance of an antireflux procedure in patients with Barrett's esophagus.

There have been conflicting reports about whether intestinal metaplasia regresses following antireflux surgery. Brand, in 1980, described complete regression in four of 10 patients with Barrett's esophagus who underwent fundoplication[90]. Subsequently, most reports have demonstrated that while some regression of the length of Barrett's esophagus is common, complete regression occurs only rarely, particularly with long-segment disease. In contrast, intestinal metaplasia of the cardia and short segments of Barrett's esophagus much more commonly regress to no intestinal metaplasia after fundoplication[91-93]. Furthermore, during prospective follow-up of patients with a columnar-lined esophagus without intestinal metaplasia treated either medically or with antireflux surgery, Oberg *et al*[94] showed that significantly fewer patients developed intestinal metaplasia after antireflux surgery.

Perhaps of greater importance is the issue of progression of Barrett's esophagus to dysplasia or cancer after surgical treatment of reflux disease. Compared to medical therapy, antireflux surgery is associated with a reduced incidence of dysplasia and adenocarcinoma. McCallum *et al*[95] have prospectively followed 181 patients with Barrett's esophagus. Twenty-nine had antireflux surgery while the remaining 152 patients were treated medically. After a mean follow-up of 62 mo in the surgical group and 49 mo in the medical group, there was a significant difference in the incidence of dysplasia and adenocarcinoma. Dysplasia was found in 3.4% of the surgical group compared with 19.7% in the medically treated group. No patient in the surgically treated group developed adenocarcinoma of the esophagus compared with two medically treated patients. They concluded that compared with medical therapy, an antireflux operation in patients with Barrett's esophagus was significantly associated with the prevention of dysplasia and cancer. Similarly, Katz *et al*[96] have followed 102 patients with Barrett's esophagus for a mean of 4.8 years. By 3 years, approximately 8% of the medically treated patients had developed dysplasia. In contrast, patients treated by antireflux surgery had a significantly reduced risk of developing dysplasia ($P = 0.03$)[96]. In the only randomized controlled trial that has compared medical therapy with antireflux surgery for Barrett's esophagus, Parrilla *et al*[97] showed that patients with functioning fundoplication had a significantly reduced incidence of developing dysplasia

compared to patients on medical therapy. Evidence at the molecular level has shown that antireflux surgery reduces the expression of genes potentially involved in the progression of Barrett's esophagus to cancer down to the level of control subjects without reflux[98,99]. These studies provide an insight into how antireflux surgery might be protective against progression of Barrett's esophagus to cancer.

Opposing these studies are two Swedish database studies that have suggested that antireflux surgery does not protect against progression to cancer. However, the serious flaw in both these studies is that the prevalence of Barrett's esophagus was not known in either population, and it is quite likely that far more patients in the antireflux surgery group had Barrett's esophagus than the comparison groups[100,101]. The presence of Barrett's esophagus is the leading known risk factor for subsequent development of esophageal adenocarcinoma, therefore, both studies only add to the controversy rather than provide any reliable answer to this important issue. Another factor that complicates any analysis of progression of Barrett's esophagus after antireflux surgery is that the cellular and genetic alterations that lead to the development of dysplasia and adenocarcinoma might have already occurred before the antireflux procedure. It has been estimated to take up to 6 years for adenocarcinoma to develop within Barrett's esophagus with low-grade dysplasia, and thus some cancers, particularly those that present during the first few postoperative years, probably do not represent progression of disease after surgery. McDonald *et al*[102] have made this point in a study from the Mayo Clinic. They found invasive adenocarcinoma in two patients and carcinoma *in situ* in one patient during surveillance after antireflux surgery, but they noted that no patient developed carcinoma after 39 mo, despite a median follow-up of 6.5 years, and a maximum follow-up of 18.2 years.

CONCLUSION

There is increasing evidence that at the normal gastroesophageal junction, esophageal squamous mucosa abuts oxyntic fundic mucosa of the stomach. With exposure to gastric juice, the squamous mucosa is injured, and over time becomes replaced by columnar cardiac mucosa. Deterioration of the lower esophageal sphincter allows reflux to extend up into the esophagus, and the squamocolumnar junction migrates proximally. Although it is likely that acidic gastric juice drives the transformation of squamous mucosa to cardiac mucosa, there is substantial evidence that other components of gastric juice, particularly bilirubin, are essential for subsequent intestinalization of the cardiac mucosa.

Barrett's esophagus is a premalignant mucosa, and the risk of malignant transformation is approximately 0.5% per patient-year. The finding of dysplasia is currently the most commonly used indicator of increased malignant risk, but it has high inter-observer variability. It is expected that ultimately molecular markers will prove more helpful than histology in Barrett's esophagus, and there are ongoing efforts to determine biomarkers that will better delineate an individual's risk for progression to cancer. Surveillance endoscopy in patients with Barrett's esophagus has proven efficacy, but is time-consuming and haphazardly applied. Currently, screening endoscopy is not recommended for Barrett's esophagus, but given the dramatic increase in the incidence of esophageal adenocarcinoma, new technologies that permit widespread and cost-effective screening are needed. Patients with Barrett's esophagus are commonly treated with acid-suppressive medication, but there are few data that this therapy alters the natural history of the disease, and thus current medical guidelines are to treat for symptomatic relief rather than for documented pH control. Antireflux surgery abolishes reflux and has been shown to normalize gene expression in patients with Barrett's esophagus, but controversy persists regarding the impact of an antireflux procedure on the risk of Barrett's esophagus progression.

Abstract

Barrett's esophagus (BE) is a change in the esophageal mucosa as a result of long-standing gastroesophageal reflux disease. The importance of BE is that it is the main risk factor for the development of esophageal adenocarcinoma, whose incidence is currently growing faster than any other cancer in the Western world. The aim of this review was to compare the common treatment modalities of BE, with the focus on proton pump inhibitors and operative fundoplication. We performed a literature search on medical and surgical treatment of BE to determine eligible studies for this review. Studies on medical and surgical treatment of BE are discussed with regard to treatment effect on progression and regression of disease. Although there is some evidence for control of reflux with either medical or surgical therapy, there is no definitive evidence that either treatment modality decreases the risk of progression to dysplasia or cancer. Even though there is a trend toward antireflux surgery being superior, there are no definitive studies to prove this.

Key words: Barrett's esophagus; Intestinal metaplasia; Proton pump inhibitors; Nissen fundoplication; Esophageal adenocarcinoma; Gastroesophageal reflux

Peer reviewer: Marco Giuseppe Patti, MD, Professor of Surgery, Director, Center for Esophageal Diseases, University of Chicago Pritzker School of Medicine, 5841 S. Maryland Avenue, MC 5095, Room G 201, Chicago, IL 60637, United States

INTRODUCTION

Barrett's esophagus (BE) is defined as a change of any length in the distal esophageal epithelium, which can be recognized as columnar-type mucosa at endoscopy and confirmed as intestinal metaplasia (IM) by biopsy of the tubular esophagus[1]. BE is a complication of gastroesophageal reflux disease (GERD) through damage of the esophageal mucosa from refluxed contents[2,3]. It is thought to be present in around 10% of patients with GERD[3,4], although the exact incidence is unknown. As a result of the substantial increase of esophageal adenocarcinoma (AC) in patients with BE, it is considered the major risk factor for this form of cancer. In fact, over the past decade there has been acceleration in the incidence of AC in the Western world, presumably from a rise in GERD, its treatment, or other environmental factors. In the United States, it is estimated that 1.5-2 million people have BE[5].

It has been estimated that the risk for developing esophageal AC when IM is present is approximately 0.5% per year[6]. Although the factors that affect progression are not completely known, it is tempting to assume that the risk is increased by continued exposure of the IM to gastric contents[7].

Screening for BE in patients with chronic heartburn is not widely considered to be cost-effective, but surveillance in patients with BE is generally advised[8]. This, however, puts a heavy burden on resources for endoscopists. To prevent the development of esophageal cancer and to try and reduce the need for surveillance, the available treatment modalities for BE have been evaluated. The goal for treating patients with BE is generally directed at controlling associated symptoms of GERD, because quelling symptoms is a much more immediate endpoint for adjusting or changing therapy. Nevertheless, in this review, we discuss the possible treatment options for BE, with a focus on their effect on the Barrett's mucosa itself. The two most common treatments of GERD and associated BE are medical (proton pump inhibitors, PPIs) and surgery (fundoplication). Recently, more attention has been paid to other possible (medical) treatment options of BE that are not specifically aimed at reducing reflux. We briefly cover these treatment options as well.

LITERATURE SEARCH

A PubMed search was performed to identify publications using the following MeSH terms: "Barrett esophagus" and "proton pump inhibitors" or "surgical procedures, operative". Publications had to be published in the English language in peer-reviewed journals. Only studies published from 2000 onward with endoscopic biopsy results after treatment were deemed eligible. If publications were from the same research group, the most recent or most applicable study was chosen.

The abstracts of the results were read to determine eligibility for this review. If deemed eligible, full-text versions of the studies were acquired. From these full-text articles, references were checked to find publications that were missed using the search with MeSH terms[9-12]. Twenty studies were found to be eligible for this review. Five were on medical treatment (PPIs), 11 were on surgical treatment and four compared the two treatments.

DEFINITIONS

Progression of BE in this review is defined as a change in histological findings on biopsy from either IM to any form of dysplasia or an increase in grade of dysplasia. Development of AC is also considered progression of disease. Regression is defined as change from high-grade dysplasia (HGD) to low-grade dysplasia (LGD) or no dysplasia, change from LGD to metaplasia or loss of metaplasia, and change from IM to complete loss of metaplasia. Shortening of the segment or development of squamous cell islands, although considered by some as regression, usually is not accurately measured and reported, and is therefore, not considered regression in our report. Short-segment BE (SSBE) is defined as a length $\leqslant$ 3 cm seen at endoscopy and confirmed by biopsy. Long-segment BE (LSBE) is defined as > 3 cm.

LIMITING PROGRESSION

Ultimately, the goal of treatment for BE is to prevent cancer. Both medical and surgical treatment studies therefore have traditionally been focused on showing results of preventing progression of disease. We first discuss the results for PPI treatment, then those of operative treatment using fundoplication, and finally, studies that have compared these two treatment modalities.

Medical treatment

Three recent studies have investigated the effect of PPI treatment on the risk of progression of BE to dysplasia or AC[9,13,14]. The results of studies of PPI treatment with regard to progression and regression of disease are shown in Table 1. The results of these studies suggest a protective effect of PPIs in limiting the progression of BE.

In the study by Hillman *et al*[13], (350 patients with BE over a 20-year period), patients were stratified according to delay in starting PPI therapy after the diagnosis of BE was established. Patients who delayed PPI therapy for $\geqslant$ 2 years after being diagnosed with BE had 5.6 times higher risk of developing LGD than patients who used PPI within the first year after diagnosis. Furthermore, patients with BE had up to a 20 times higher risk of developing HGD or AC when PPI therapy was delayed for 2 years after diagnosis of BE. Although this suggests a substantial protective effect, the absolute risk of developing HGD or AC was low (n = 11; 3%) at a median follow-up of 4.7 years.

The small rate of progression of BE makes it very difficult to show a difference between treatments. In another study, the risk of developing LGD within 5 years of the diagnosis of BE was around 2.5%, and the risk of HGD/AC was around 2% while taking PPI therapy. Cooper *et al*[9] have shown this in a study of 188 patients with IM who were treated with a PPI. However, when following patients for > 5 years, Nguyen *et al*[14] recently have found a much higher risk of developing AC. They have studied 344 patients diagnosed with BE without dysplasia, with a mean follow-up of 7.6 years. They found that the chance of developing HGD or AC was 7.4%. Moreover, this risk was even higher when not taking PPIs (14.2%). Taken together, the results of these non- controlled studies suggest that PPIs have a protective effect, but they do not eliminate the risk of developing AC.

Surgical treatment

Surgical treatment of BE most often involves fundoplication for GERD. Where PPIs are only able to decrease acid content in the stomach (and thus change the pH of the refluxate), surgery has the ability to prevent any type of reflux. Therefore, many have argued that surgery is a more effective therapy for BE. All 11 publications on surgical treatment for BE that met our screening criteria included results on prevention of progression, as well as regression of metaplasia or dysplasia[15-25]. In this section, we discuss only the results of the effect of fundoplication on the rate

of progression. The results of studies on surgical treatment for limiting progression and causing regression are summarized in Table 1.

In the reported case series, the number of patients is relatively low since a minority of patients is referred for surgery. As a result, because progression can take a long time and is still a relatively rare event (especially on medical therapy), large studies with several hundred patients would be needed to show a clinically significant benefit. Still, it is interesting to look at several trends, and as can be seen in Table 1, almost uniformly there is a low incidence of progression to dysplasia and even a lower incidence to AC.

Hofstetter *et al*[15] have published the study with the longest follow-up. They showed results for a series of 97 patients, with complete endoscopic follow-up in 79, at a median of 5 years. No patients developed HGD or AC, but four had progression of metaplasia to LGD (5%). Bowers *et al*[16], have reported a similar series with a mean follow-up of 4.6 years. Their 104 patients underwent open or laparoscopic fundoplication. Of these, 64 patients had endoscopic follow-up with biopsy. None of the patients developed HGD or AC. Only one patient had progression to LGD (1.5%).

Control of reflux

The hypothesis that surgery is superior to medical therapy comes from the assumption that surgery provides better control of GERD than do PPIs, and this should translate into lower progression rates. Indeed, there is some circumstantial evidence for this. Lagergren *et al*[26] and Csendes *et al*[27] have suggested that, when esophageal AC occurs after antireflux surgery, it is usually in the face of persistent or recurrent reflux. This observation, that control of reflux is essential in preventing progression of disease, is backed up by the fact that, in most studies, the patients with progression after surgical treatment seem to have recurrent reflux. In a series of 58 patients by O'Riordan *et al*[20] who underwent open or laparoscopic Rossetti-Nissen fundoplication, four were found to have progression of disease after a follow-up of 45 mo. All four patients were found to have abnormal postoperative acid scores[20]. In another study, Biertho *et al*[24] have published the results of 70 patients with BE who had endoscopic follow-up for 4.2 years after laparoscopic fundoplication. Three patients had progression of disease, but none developed HGD or AC. All three patients with progression had recurrence of GERD symptoms. We published our results of 106 patients with BE who underwent laparoscopic fundoplication[18]. Endoscopic follow-up with biopsies was performed in 90 patients with a median follow-up of 30 mo. One patient was found to have developed AC at 10 mo after the operation (and thus likely had at least dysplasia at the time of operation). One patient developed HGD and one LGD. The patient with HGD had LGD preoperatively and for 3 years thereafter, and then developed recurrent GERD symptoms with an abnormal 24-h pH. One year later this patient was found to have developed HGD despite being on medical therapy. Still, despite the fact that surgery is not perfect, the rate of progression to HGD or AC seems around 1.5%, which is lower than that typically seen in medical treatment.

One of the difficulties in evaluating the results of these treatments is the overall low incidence of patients with BE progressing to AC. Although decreasing the total burden of BE might actually decrease the risk of cancer, it is difficult to track. The results of the studies suggest that surveillance after medical treatment is necessary. After surgical treatment, there is also still progression of

Table 2 Medical therapy *vs* surgery for Barrett's esophagus *n* (%)

disease (particularly in patients with LSBE), although the risk seems to become very small when this treatment is successful. Patients are generally reluctant to have surveillance, as shown by the low number of patients who actually have endoscopy after fundoplication. Another difficulty in interpreting the results is the follow-up of these studies that ranges from 0.9 to 7.6 years. With a disease that, in general, progresses only slowly, studies with follow-up of 10-20 years are needed. In contrast, studies on surgical treatment with the longest follow-up have still shown very low incidence of progression. The study on medical treatment with the longest follow-up did show a higher chance of progression of disease[14], although that study was possibly confounded by selection bias.

Medical vs surgical treatment

There have been very few studies comparing medical and surgical therapy; in fact, in our review, we only found two studies on progression of disease worthy of comment. The results of these are summarized in Table 2.

In one, Gatenby *et al*[6] published the results of their review of a cohort of 738 patients with BE enrolled in a national registry. They compared patients with anti-reflux surgery (n = 41) to those treated medically with PPIs (n = 551), H2 receptor antagonists (H2RAs) (n = 42), H2RA followed by PPI (n = 95), or no treatment (n = 9). Their outcome parameters were progression of disease to LGD, HGD or AC. They could not control for many other selection factors, which might have confounded the results, such as severity of disease. After a follow-up of 5 years after medical therapy and 6 years after surgical therapy, there was however a trend toward antireflux surgery being more protective. No patients in the antireflux group developed HGD or AC as compared to 4.3% in the all-medical therapies group (P = 0.13). There were not enough patients in the surgical arm to determine if this was a significant difference.

Parrilla *et al*[28] have published the only randomized study comparing medical treatment (n = 43) and antireflux surgery (n = 58). In that study, 101 patients with BE were treated between 1982 and 2000. Medical treatment consisted of H2RA treatment initially and then omeprazole from 1992 onward. Surgery was performed through laparotomy with Nissen fundoplication in 56 patients and a Collis-Nissen procedure in the other two because of short esophagus.

All patients had annual clinical, endoscopic and histological follow-up, and patients who had an operation also had a pH study and manometry at 1 year postoperatively and every 5 years thereafter, or if they presented with recurrent GERD symptoms. Mean follow-up was 6 years for the medical therapy group and 7 years for the surgical group. Progression of BE to any dysplasia was found in eight patients (19%) in the medical treatment group and in three in the surgical group (5%). Although the P value was not specified in their paper, according to our calculations using Fisher exact test, there was a protective effect of fundoplication (P = 0.05). Two patients in each group progressed to AC, which was confirmed after esophageal resection. Although differences in progression rates between the two groups were not significant according to the authors, when a sub-analysis was performed including only patients in the surgical arm with normal pH, the progression rate dropped to 2%, which was a significantly lower chance of progression of disease than in the medical group (P < 0.05).

CAUSING REGRESSION

IM without dysplasia is a benign condition, therefore, inducing regression is not considered as important as limiting progression. Nevertheless, if IM is no longer present, then it theoretically can no longer progress to cancer, thus it has been reported as a surrogate for measuring the response of various therapies. Disappearance of IM seems to be a slightly more common occurrence after effective treatment of GERD and therefore is a more easily studied endpoint.

Medical treatment

The only two studies that we found that have published results of regression of BE following medical treatment are by Heath *et al*[10] and Horwhat *et al*[11]. The results of these studies are shown in Table 1, together with the studies on progression of disease.

The purpose of the study by Heath *et al*[10] was to investigate the effect of long-term celecoxib in patients with BE with dysplasia. The mechanism for chemoprevention of celecoxib is thought to be through inhibition of cyclooxygenase (COX)[30]. They randomized 100 patients with low or high-grade Barrett's dysplasia to treatment with either celecoxib (n = 49) or placebo (n = 51). Although this study did not focus on PPI therapy, > 90% of these patients were concomitantly on a PPI. After 48 wk of treatment, endoscopic biopsy results showed a regression of dysplasia in 41.9% of patients on celecoxib and 41%

on placebo (P = 0.89), either from LGD to no dysplasia or from HGD to LGD (although differentiation between those events in this study was not possible). In contrast, 14% (n = 6) and 15.4% (n = 6) respectively had an increase in highest grade of pathology, with three patients in each group developing AC. These mixed results might say more about the variability in interobserver reliability of dysplasia, as has been reported[31]. However, the results do suggest that patients with dysplasia can regress with medical therapy alone.

Horwhat *et al*[11] looked at LSBE and SSBE. They contacted 101 patients after a mean follow-up of 46 mo. Most patients received PPI therapy but seven underwent fundoplication. Of the 38 patients with LSBE, 23 underwent endoscopy. Six patients developed dysplasia (26%) and two cancer (9%). No patient with LSBE had regression of disease. Of the 63 patients in the SSBE group, 44 underwent endoscopy. Three patients were found to have progression of disease (7%) *vs* 13 with regression (30%). They found an almost linear relationship between BE segment length and normalization of the epithelium, that is, the chance of progression of disease is significantly higher in LSBE compared with SSBE. Unfortunately, it is unclear in this study whether the patients with regression or progression had medical or surgical treatment.

Surgical treatment

The results of regression of BE with surgical treatment are shown in Table 1, together with the results of progression. The literature suggests that regression of BE occurs with some regularity after fundoplication, even regression to completely normal squamous epithelium. Hofstetter *et al*[15] have reported that 16 of their 79 patients (20%) had regression of disease in some fashion. Of the 16 patients with LGD, seven had regression (44%), and of the 63 patients with IM, nine had complete loss of metaplasia (14%).

It is important to consider that LGD is sometimes over-reported because of inflammation from ongoing GERD, and surgery could make it easier for the pathologist to interpret the biopsies. Nevertheless, other studies have suggested regression in a substantial number of BE patients. Desai *et al*[19] have found a loss of metaplasia in seven of 50 patients (14%) postoperatively. Two out of the three patients with LGD had regression to non-dysplastic BE. In the study by Bowers *et al*[16], it has been found that 31 of 66 patients had loss of IM (47%) after antireflux surgery. Patients with regression had shorter lengths of BE preoperatively and longer follow-up after the operation.

That patients with SSBE have a higher incidence of regression than those with LSBE seems logical, and it has been consistently seen in studies where long and short-segment BE has been distinguished. In the study by O'Riordan *et al*[20], eight of 57 patients (14%) were found to have complete regression. Six of these patients had SSBE preoperatively. They have also found regression from LGD to non-dysplastic BE in six of eight patients. Biertho *et al*[24] have reported that complete regression was found in 23 of their 70 patients (33%). All patients with regression had SSBE preoperatively. Regression from LGD to non-dysplastic BE occurred in two of three patients.

Our experience mirrors that of other authors who have found that complete regression occurs only in patients with SSBE. Of the 54 patients with SSBE before surgery, 30 (54%) had no evidence of IM at last follow-up. In contrast, none of the 38 patients with LSBE before surgery had complete regression[18]. These observations suggest that the chance of accomplishing regression is especially high in patients with earlier disease. Therefore, earlier referral for surgery might increase the chance of cure from BE even further.

Medical vs surgical treatment

Only one small study comparing medical and surgical treatment directly has been published that focuses on regression of BE. The results are summarized in Table 2.

Rossi *et al*[29] prospectively studied 19 patients with high-dose PPI and 16 patients with fundoplication. All patients had LGD. After 18 mo follow-up, a high percentage of patients were found to have regressed to IM after medical (63%) as well as surgical treatment (100%). Although the rate was higher in the surgical group, the small numbers make it difficult to use the study to draw any definitive conclusions. Parrilla *et al*[28] also have reported data on regression of disease in their randomized study, although they do not comment on this, with 2/43 (4.6%) having regression from LGD to IM with medical therapy, and 5/58 (8.6%) after surgical therapy ($P > 0.05$).

When comparing both treatment modalities, antireflux surgery seems to be more successful in prevention of progression and in promoting regression than medical treatment with PPI. The number of patients studied and the quality of the studies however were low, therefore, a firm conclusion cannot be drawn. Complications from the operation are also not taken into account and these studies generally come from surgical centers of excellence. On the other hand, the patients that underwent an operation are more likely to have had more severe disease than the patients that are treated medically.

OTHER MEDICAL TREATMENT

Almost all patients with BE, because of their associated GERD, are treated with PPIs (unless they have surgery), therefore, it makes sense to evaluate the effect of acid reduction on the natural history of BE. However, there have been other medical therapies investigated for the purpose of addressing IM primarily. For example, Vaughan *et al*[32] have shown a potential role for nonsteroidal anti-inflammatory drugs (NSAIDs). The effect of NSAIDs is thought to be through their anti-inflammatory effect through inhibition of COX-2 production[33]. Ogunwobi *et al*[34] have made a theoretical argument for statins, stating that they might affect proliferation and apoptosis in esophageal cancer cells. The protective effect of these medications is further supported by a

recent study by Nguyen *et al*[35]. In this retrospective observational study using pharmacy data, they have shown a reduced risk of developing AC in patients with BE and filled NSAID prescriptions. They have also studied statins as chemopreventive medications, however, they are concerned about confounding with statin therapy because patients had short periods of use, therefore, conclusions cannot be drawn about these medications.

Other publications contradict the role of NSAIDs in preventing progression. One is the study by Heath *et al*[10] that was discussed earlier, which did not find a difference when comparing patients on or off celecoxib. Gatenby *et al*[36] have published results of a national registry in the United Kingdom of BE, where they did not find a difference in development of dysplasia or AC between patients on or off aspirin. To evaluate further the effect of aspirin treatment of BE on progression to cancer, a large randomized trial (AsPECT) is ongoing, which is comparing patients on PPI therapy with and without aspirin[37].

Many other medications, such as ursodeoxycholic acid, hormone replacement therapy and n-3 fatty acids have been studied[38-41], but all have too little information to recommend their use currently. Dietary interventions through antioxidants, fiber and vitamins have been studied for their effect on risk of cancer in general and for prevention of esophageal AC. However, mixed results have been reported[42].

Very few clinical studies have been carried out on treatment modalities other than antireflux surgery using fundoplication, or medical treatment using PPIs. Therefore more (large) studies are necessary before any firm conclusions can be drawn on the chemopreventive qualities of agents such as aspirin, selective COX inhibitors or diet modifications.

CONCLUSION

Consensus on the best treatment for BE remains elusive, because there has not been a large definitive study to date that has compared PPIs and fundoplication (nor is there likely to be one). There is, however, a trend toward lower risk of progression with anti-reflux surgery compared with anti-acid medication, especially when anti-reflux surgery is successful. In addition, there seems to be a greater chance of regression of disease with anti-reflux treatment, but the importance of this regression is unclear. Theoretically, surgery controls gastroesophageal reflux better than PPIs do (which mostly reduces the acid component), therefore, it is appealing for some to consider this a real difference, and therefore, recommend surgery for patients with BE, even though it is not definitively proven. As a result, treatment of BE has to be given based on the patient's preference and control of GERD symptoms. Just like GERD without IM, those with IM should consider fundoplication if symptomatic, despite appropriate medical therapy. The effect of fundoplication on the natural history of the epithelium should be a secondary concern. Whichever treatment is pursued, surveillance remains important, because the risk of cancer is not eliminated despite the decrease in risk through both PPIs and surgery.

Abstract

The annual incidence of adenocarcinoma arising from Barrett's esophagus (BE) is approximately 0.5%. Through a process of gradual transformation from low-grade dysplasia to high-grade dysplasia (HGD), adenocarcinoma can develop in the setting of BE. The clinical importance of appropriate identification and treatment of BE in its various stages, from intestinal metaplasia to intramucosal carcinoma (IMC) hinges on the dramatically different prognostic status between early neoplasia and more advanced stages. Once a patient has symptoms of adenocarcinoma, there is usually locally advanced disease with an approximate 5-year survival rate of about 20%. Esophagectomy has been the gold standard treatment for BE with HGD, due to the suspected risk of harboring occult invasive carcinoma, which was traditionally estimated to be as high as 40%. In recent years, the paradigm of BE early neoplasia management has recently evolved, and endoscopic therapies (endoscopic mucosal resection, radiofrequency ablation, and cryotherapy) have entered the clinical forefront as acceptable non-surgical alternatives for HGD and IMC. The goal of endoscopic therapy for HGD or IMC is to ablate all BE epithelium (both dysplastic and non-dysplastic) due to risk of synchronous/metachronous lesion development in the remaining BE segment.

Key words: Barrett's esophagus; High-grade dysplasia; Intramucosal carcinoma; Esophagectomy; Endoscopic mucosal resection; Radiofrequency ablation; Cryotherapy

INTRODUCTION

The annual incidence of adenocarcinoma arising from Barrett's esophagus (BE) is approximately 0.5%[1-3]. Through a process of gradual transformation from low-grade dysplasia (LGD) to high-grade dysplasia (HGD), adenocarcinoma can develop in the setting of BE[4]. The clinical importance of appropriate identification and treatment of BE in its various stages, from intestinal metaplasia (IM) to intramucosal carcinoma (IMC) hinges on the dramatically different prognostic status between early neoplasia and more advanced stages. Once a patient has symptoms from adenocarcinoma, there is usually locally advanced disease with an approximate 5-year survival rate of about 20%[5,6].

Esophagectomy has been the gold standard treatment for BE with HGD, due to the suspected risk of harboring occult invasive carcinoma, which has been

estimated to be as high as 40%[7,8]. Our previous analysis of the published literature demonstrated that the true prevalence of submucosal invasive carcinoma in the setting of HGD was actually 12%, which was much lower than the pooled reported historical rate of 40%[9]. Esophagectomy has also been routinely performed for BE with IMC, despite a low incidence of lymph node metastasis of < 1% that is associated with non-invasive T1a disease[10]. Additionally, esophagectomy is associated with significant morbidity and mortality even in high-volume centers[11,12].

With these issues in mind, the paradigm of BE early neoplasia management has recently evolved, and endoscopic therapies have entered the clinical forefront as acceptable non-surgical alternatives for HGD and IMC. The goal of endoscopic therapy for HGD or IMC is to ablate all BE epithelium (both dysplastic and non-dysplastic) due to risk of synchronous/metachronous lesion development in the remaining BE segment[10]. Endoscopic therapies can be further subdivided into tissue-acquiring and non-tissue-acquiring modalities. Tissue acquisition can be achieved through endoscopic mucosal resection (EMR), while photodynamic therapy (PDT), radiofrequency ablation (RFA), and cryotherapy all ablate tissue without the benefit of histological specimen retrieval. A brief technical review and pertinent available efficacy/safety data are summarized for these various modalities in treating stages of early BE neoplasia that ranges from IM to IMC. Modalities such as argon plasma coagulation, multipolar electrocoagulation, and laser therapies are not be discussed as current mainstay therapies due to high BE relapse rates, infrequent usage, or significant risk of buried gland development[13].

EMR

EMR can be performed through a variety of techniques: free-hand, lift-and-cut, cap-assisted, or band-assisted. Injection of saline with a sclerotherapy needle is performed to create a submucosal fluid cushion, and a snare is used to entrap directly the mucosal tissue in the free-hand method. In the lift-and-cut approach, a dual channel endoscope is used to introduce simultaneously a grasping forceps and snare for resection. The cap technique uses a clear distal attachment with an inner rim around which a crescent-shaped snare is carefully fitted. The target area is injected for submucosal lift, then suction is applied through the cap, and tissue is entrapped by the snare for subsequent mucosal excision. Band-assisted techniques are modifications of the variceal band ligation device that allows for injection and then deployment of bands for mucosal pseudopolyp creation. A snare is then introduced and the mucosa is resected either above or below the band[14].

Focal EMR can be performed for endoscopically visible lesions that are suspicious for malignancy. However, several previously published studies on focal resection have demonstrated a high rate of synchronous and recurrent lesion development, which ranged from 14% to 47%, and increased with longer observation times[15-22]. As a result of this limitation of focal EMR, complete Barrett's eradication EMR (CBE-EMR) has been advocated and performed in select centers, with the intent to remove all BE epithelium curatively, to reduce the potential risk of synchronous or metachronous lesion development. Complete responses have ranged from 76% to 100%. The complication profile of EMR includes stricture formation, with an incidence rate that approaches 50%, bleeding and perforation. Of note, most esophageal stenoses and bleeding are amenable to endoscopic treatment[23-26].

When evaluating the effect of EMR on final histopathological staging, our center long-term results with CBE-EMR have revealed that initial EMR upstaged seven of 49 (14%) and down-staged 15 of 49 (31%) final pathology results when compared to pre-EMR biopsy results. Among the upstaged group, four patients had advanced pathology that was found after index EMR (either submucosal carcinoma or IMC with lymphatic channel invasion). All four of these patients had visible lesions upon endoscopy[26]. This is the crucial point that distinguishes EMR from all other non-tissue-acquiring modalities that would have inadvertently attempted ablation of advanced pathology in the setting of presumed BE HGD treatment.

PDT

The goal of PDT is destruction of tissue through a light-sensitizing reaction sequence. A photosensitizer is first administered which accumulates in esophageal malignant and pre-malignant tissue before light activation therapy. Porfimer sodium is the most common photosensitizer, and this is delivered intravenously 72 h before the procedure. Alternatively, oral 5-aminolevulinic acid (ALA) and intravenous m-tetrahydroxyphenyl chlorine (mTHPC) can be used. Activation of the photosensitizing agent occurs upon exposure to either bare cylinder or balloon-based diffusing light fibers that are placed alongside the target tissue via an endoscopic approach. The resulting molecular excitation reacts with oxygen to create radical oxygen species that cause eventual cell apoptosis[27].

A multicenter trial by Overholt *et al*[28] randomized BE HGD patients to receive twice daily oral omeprazole (20 mg) with or without porfimer sodium PDT administration. The study found that, at 5 years, PDT was significantly more effective than proton pump inhibition (PPI) alone, in elimination of HGD (77% *vs* 39%, $P < 0.0001$). Prevention of cancer progression was a secondary outcome that also showed a significant difference, with the PDT/PPI group demonstrating half the likelihood of developing cancer and longer time to cancer progression.

Overholt *et al*[29] have conducted another porfimer PDT study of 103 patients with LGD, HGD, or IMC with a mean follow-up of 50.65 mo (SD 20.57) (range: 2-122 mo). Intention to treat success rates were 92.9%,

77.5%, and 44.4% for the respective LGD, HGD, and IMC groups. Three patients (4.6%) developed sub-squamous adenocarcinoma. Strictures occurred in 18% with one session of PDT, 50% with two treatments, and 30% in the overall group.

ALA PDT has shown 97% and 100% complete response rates for treatment of BE with HGD and IMC, respectively, in a median follow-up period of 37 mo (interquartile range: 23-55 mo). Disease-free survival of HGD patients was 89%, and 68% in patients with IMC. The calculated 5-year survival was 97% for HGD and 80% for IMC, but no deaths were related to Barrett's neoplasia[30].

In a pilot study of PDT using mTHPC for seven patients with HGD and 12 patients with IMC, Lovat and colleagues found that treatment results were variable based on red versus green light usage. Successful ablation was achieved in four out of six mucosal carcinoma and three out of four HGD patients who received red light. However green light exposure failed to achieve successful disease eradication or long-term remission[31]. Significant complications such as death occurred after premature biopsy performance after treatment. This limited sample size study demonstrated that although mTHPC can destroy BE epithelium, the optimal light and drug dosimetry are still unknown[31].

To date, no randomized, controlled prospective trials have been conducted to compare PDT and surgery for BE neoplasia management. However, a retrospective data analysis of HGD patients who received PDT (n = 129) or esophagectomy (n = 70) has revealed no statistically significant differences in mortality or long-term survival based on choice of treatment modality[32].

The major side effects of PDT include photosensitivity that requires patients to avoid post-procedure skin sunlight exposure, non-cardiac chest pain, and symptomatic stricture formation. Risk factors for post-PDT stricture development include history of prior esophageal stricture, performance of EMR before PDT, and more than one PDT treatment in a single session[33]. Another concern about PDT is development of sub-squamous BE glands that could harbor neoplastic potential. The clinical significance of this finding is still not fully understood. However, reports of adenocarcinoma arising from sub-squamous BE glands after PDT therapy have been described[29,34]. For these reasons, PDT usage has gone out of favor in recent years, with the availability of other endoscopic ablative options.

RFA

Using a either a balloon-based catheter or a focal device, RFA of BE tissue can be achieved in either a circumferential or localized fashion. After initial insertion of a sizing balloon into the esophagus, the optimal size of the circumferential balloon is selected based on various pressure measurements in different locations. The ablation process is a series of two separate applications of direct thermal energy with the electrodes embedded in either the circumferential or focal device. Scraping of treated tissue is performed between the first and second ablation to ensure adequate and uniform thermal contact. The most common complications associated with RFA include non-cardiac chest pain, non-transmural lacerations, and stricture formation (lower stricture rate when compared to EMR).

After thermal dose-escalation animal testing and pre-esophagectomy human experiments[35,36], the first larger clinical evaluation of RFA was performed on BE patients without dysplasia in the Ablation of Intestinal Metaplasia (AIM) study from 2003 to 2005. This multicenter trial demonstrated a 70% complete remission of BE in the circumferential-balloon-treated group at 1 year follow-up, without evidence of subsequent stricture formation or buried BE among 4306 biopsy fragments evaluated[37]. A subsequent AIM Ⅱ study reported 98% complete remission of IM after stepwise circumferential therapy with additional focal ablative therapy of remaining BE[38].

RFA was also studied in 142 patients with BE HGD. At 1 year follow-up, complete remission of HGD was achieved in 90.2%, complete remission of dysplasia in 80.4%, and complete remission of IM in 54.3% of patients[39]. In a recent landmark multicenter, sham-controlled trial, 127 patients with dysplastic BE were randomly assigned to receive either RFA or a sham procedure. The measured primary outcomes at 1 year included complete eradication of dysplasia and intestinal metaplasia. Based on an intention-to-treat analysis, in patients with LGD, complete eradication of dysplasia occurred in 90.5% in the ablation group, compared to only 22.7% in the control group ($P < 0.001$). In the HGD sub-group, complete eradication occurred in 81% of ablated patients as compared with 19% of the control group ($P < 0.001$). Overall, 77.4% of ablation patients demonstrated complete eradication of IM, as compared to 2.3% in the control group ($P < 0.001$). There was less disease progression in patients in the ablation group (3.6% *vs* 16.3%, $P = 0.03$) and fewer cancers developed (1.2% *vs* 9.3%, $P = 0.045$). There were more reports of chest pain after ablation than after sham procedures, and a 6% esophageal stricture rate was reported in the treated group[40]. This stricture rate is markedly lower than that commonly reported for EMR, which confers a significant advantage for RFA in treatment of BE with flat HGD.

In patients who demonstrate visible lesions in the setting of HGD, a combination of EMR and RFA has recently been studied. Pouw and colleagues have reported on performance of EMR for visible lesions with subsequent ablation of the remaining segment[41]. Complete histological eradication of all dysplasia and IM was achieved in 43 patients (98%). Post-ablation complications included mucosal laceration at prior EMR sites (n = 3) and transient dysphagia (n = 4). No dysplasia recurred after a 21-mo follow-up period[41]. A more recent multicenter European trial involved EMR of visible lesions, followed by serial RFA. Focal escape endoscopic resection was utilized in cases of BE persistence despite RFA. The study

included 24 patients, and achieved neoplasia and IM eradication in 95% and 88% of patients, respectively. These rates improved to 100% and 96%, respectively, following escape EMR in two patients. No neoplasia recurred within a median 22-mo follow-up period[42]. Neo-squamous epithelium rigorous EMR and biopsy evaluation in a group of 22 post-RFA patients with baseline BE with IMC or HGD showed no evidence of persistent genetic abnormalities or buried BE glands[43]. To date, as far as we are aware, no published studies exist on outcomes of sole RFA therapy of BE with IMC.

CRYOTHERAPY

Cryotherapy is the latest modality to arrive on the endoscopic horizon of ablative options. This technology utilizes sprayed liquid nitrogen freeze-thaw cycles that result in tissue destruction by intracellular disruption and tissue ischemia, with relative preservation of the extracellular matrix to promote less fibrosis formation[44,45]. The procedure requires placement of an orogastric decompression tube to allow for adequate excess nitrogen gas expulsion to prevent inadvertent gastrointestinal viscus perforation. Repeat treatment sessions can be conducted every 4-6 wk as needed to ensure complete remission of the target area.

In a prospective open-label trial, Dumot *et al*[46] enrolled patients with BE and HGD or IMC who were not deemed surgical candidates or who refused esophagectomy. EMR was used for pathological staging of nodular areas before cryoablation and focal residual areas during the follow-up period. Patients with prior ablation therapy were not excluded. Twenty-seven of 30 patients had pathological downgrading post-treatment. After a median follow-up of 1 year, elimination of cancer or downgrading of HGD was achieved in 80% of IMC and 68% of HGD patients. A perforation occurred in a patient with Marfan syndrome, with the prototype system. Of six patients who showed a complete response, three had recurrence of dysplasia or cancer in the gastric cardia.

The efficacy and safety of liquid nitrogen cryotherapy has been demonstrated in a four-center study of 23 patients (17 with HGD, four with IMC, and three with early-stage adenocarcinoma). Complete response to HGD was found in 94% with HGD, and 100% with IMC and cancer. Complete response to IM was noted in 53% with HGD, 75% with IMC, and 67% with cancer. No symptoms were reported in 48% of 323 procedures. Esophageal strictures developed in three patients, but all were successfully treated by dilation. Other complications included chest pain, dysphagia, sore throat, and the gastric perforation noted in the Marfan patient as above[47].

CONCLUSION

BE early neoplasia treatment has undergone transition from radical esophagectomy to endoscopic organ-preserving options. The key to successful endoscopic management hinges on appropriate selection of candidate patients and detection of visible lesions through careful white light, high-definition endoscopy and ancillary imaging techniques such as narrow-band imaging and/or endomicroscopy. All visible lesions must be removed by EMR for definitive histopathological staging and to ensure adequacy of resection margins. Total eradication of the entire BE segment must occur to protect against synchronous/metachronous lesion development.

As a result of the higher risk of stricture development associated with EMR, our center currently employs a hybrid approach to treatment of BE early neoplasia that is based on segment length. For BE segments that measure $\leqslant$ 5 cm and harbor HGD or IMC, a CBE-EMR approach is used. For patients with BE segments > 5 cm, all focal lesions are resected, and the remaining flat BE is ablated using RFA to decrease the rate of stricture formation.

The critical research issues that still remain unanswered for endoscopic BE management center on: long-term survival and remission rates of both treated neoplasia and IM; development and significance of buried BE glands; quality of life and cost assessments for the various modalities compared to surgical cohorts; the role of these therapies for LGD or non-dysplastic BE; and the clinical impact of post-endoscopic therapy surveillance.

Abstract

High-grade dysplasia (HGD) and intramucosal carcinoma (IMC) in the setting of Barrett's esophagus have traditionally been treated with esophagectomy. However, with the advent of endoscopic mucosal resection and endoscopic ablative therapies, endoscopic therapy at centers with expertise is now an established treatment of Barrett's-esophagus-related neoplasia, including HGD and IMC. Esophagectomy is today reserved for more selected cases with submucosal invasion, evidence for lymph node metastasis, or unsuccessful endoscopic therapy.

Key words: Barrett's esophagus; High-grade dysplasia; Intramucosal carcinoma; Endoscopic mucosal resection; Esophagectomy

INTRODUCTION

High-grade dysplasia (HGD) and intramucosal carcinoma (IMC) in the setting of Barrett's esophagus (BE) have traditionally been treated with esophagectomy. However, with the advent of endoscopic mucosal resection and endoscopic ablative therapies, endoscopic therapy at centers with expertise is now an established treatment of Barrett's-esophagus-related neoplasia, including HGD and IMC. Esophagectomy is today reserved for more selected cases with submucosal invasion, evidence for lymph node metastasis, or unsuccessful endoscopic therapy. This review highlights the updated role of and approaches for esophagectomy in the management of HGD and IMC in BE and discusses risk factors associated with submucosal invasion, lymph node metastasis, or unsuccessful endoscopic therapy.

TRADITIONAL APPROACH: ESOPHAGECTOMY AS THE STANDARD OF CARE FOR HGD

HGD in the setting of BE has been identified as a key risk factor in the progression to esophageal adenocarcinoma (EA). Patients with HGD are at a higher risk for progressing to EA than are patients with BE with no or low-grade dysplasia (LGD). This has given rise to performing prophylactic esophagectomy for the treatment of HGD to prevent EA. In addition to the risk of progression to EA, the surgical literature has reported a high risk of coexisting adenocarcinoma in patients with HGD that is

not diagnosed by endoscopic biopsy. The esophagectomy literature has reported varying prevalence of occult EA in patients with BE and HGD, ranging from 0% to 73%, and frequently approximates to a rate of around 40%[1-7]. Thus, the role of esophagectomy for the treatment of HGD is underlined by both prevention of cancer and cure of occult cancer.

Concerns have previously been raised as to whether esophagectomy is appropriate for most patients with HGD and IMC. Newer data have suggested that the incidence of invasive cancer is probably much lower than the 40% rate previously estimated[8]. This suggests that esophagectomy for HGD is unnecessary in more than 80% of patients in whom it is performed. At the same time, newer endoscopic techniques for evaluating and managing HGD and IMC have been developed and clinically tested. Currently, the approach to HGD and IMC is more complex and provides much more individualized care of patients than previously was available.

ENDOSCOPIC EVALUATION OF BARRETT'S-ESOPHAGUS-RELATED NEOPLASIA

The management of BE has been greatly influenced by the advent of endoscopic mucosal resection (EMR) and endoscopic ultrasound (EUS). Prior to the advent of endoscopic ablative techniques, whether intramucosal cancer was different from invasive cancer was a moot point, given that esophagectomy was indicated in either case. However, with endoscopic therapy now available for IMC, the distinction must be acknowledged. When evaluating treatment options it is crucial to understand the difference between the presence of intramucosal cancer limited to the mucosal lining, which only has a minimal nodal metastasis risk[9-11] and might be locally treatable, and the presence of cancer with invasion into the submucosa, which carries a higher nodal metastasis risk and requires surgery and/or systemic therapy[9,12-16].

Understanding pathological definitions is instrumental in managing a patient with Barrett's-related neoplasia. Dysplasia is neoplastic cytological and architectural atypia without evidence of invasion past the basement membrane. The diagnosis of LGD or HGD is based on the severity of cytological criteria that suggest neoplastic transformation of the columnar epithelium[17]. HGD and carcinoma *in situ* are regarded as equivalent. IMC is tumor that is limited to the lamina propria and is considered T1a by the American Joint Committee on Cancer staging. Submucosal carcinoma (SMC) is a tumor that invades past the muscularis mucosa into the submucosa, but not into the muscularis propria. Vessel invasion might be either venous or lymphatic channel invasion.

In a systematic review of the surgical literature that has reported the rates of cancer in patients who were undergoing esophagectomy for prophylactic treatment of HGD, the pooled average was 39.9% in the 441 patients who underwent esophagectomy for HGD among 23 studies[5]. These rates were largely based on retrospective studies with varying aims, sizes, definitions, and methodology. This average rate is consistent with previous pooled studies by Edwards *et al*[1], Ferguson *et al*[6], and Pellegrini *et al*[7] who have reported rates of 41%, 43% and 47%, respectively. However, the majority of these patients had IMC, whereas the rate of submucosal invasive cancer was decreased to 12.7% when applying both standardized criteria and strict definitions.

Prospective studies with rigorous endoscopic criteria in the EMR literature have reported lower rates of occult submucosal invasive disease. Among patients presenting with HGD and IMC who were undergoing complete BE EMR, the rate of occult submucosal invasive cancer was 4%[18]. Pech *et al*[19] have reported their long-term experience with EMR and other ablative procedures for Barrett's-esophagus-related neoplasia. They achieved a complete response in 96.6% and the 5-year survival rate was 84%. In their experience, esophagectomy was required in only 3.7% of patients initially presenting with HGD or IMC[19].

The management of HGD and IMC has now shifted from esophagectomy to endoscopic therapy to achieve total Barrett's eradication[18,20,21]. The concept of total Barrett's eradication highlights the importance of not only treating the known neoplasia, but also eradicating all of the at-risk Barrett's epithelium, to treat any synchronous lesions and hopefully prevent any metachronous lesions. Although expertise might vary from site to site and patient characteristics need to be taken into account, there is now acceptance of endoscopic therapy for HGD and IMC, and esophagectomy is no longer the standard of care[22].

Endoscopic modalities include tissue-acquiring therapies that include focal EMR, complete Barrett's EMR, and endoscopic submucosal dissection. Tissue-acquiring modalities are important to stage a visible lesion in the setting of HGD or for the treatment of IMC. HGD might also be treated with ablative therapies, such as photodynamic therapy, which has the longest experience of the ablative therapies[23], radiofrequency ablation, which has demonstrated initial success[24], and cryotherapy, which is a newer modality[25]. Chennat and Waxman have described these endoscopic therapies in further detail in their article in this issue.

HIGH-RISK CHARACTERISTICS OF BARRETT'S NEOPLASIA

Endoscopic therapy has advantages in that it is organ-preserving and does not have the same morbidity and mortality as surgery. However, not all cases are successful or appropriate for endoscopic therapy. Indications for esophagectomy include lymph node metastasis and failure of endoscopic therapy. Risk factors for submucosal invasion, lymph node metastasis, and failure of endoscopic treatment need to be incorporated into the management strategy of a patient with HGD and IMC. These risk factors are evident in endoscopic appearance, pathological characteristics, and results of endoscopic treatment (Table 1).

Table 1 High-risk characteristics associated with submucosal invasion, lymph node metastasis, or unsuccessful endoscopic therapy

Endoscopic characteristics
Long-segment Barrett's esophagus
Visible lesions with high risk endoscopic characteristics
Polypoid mass
Excavated lesions or ulcers
Evidence of lymph node involvement by EUS + FNA
Pathological characteristics
Multifocal HGD
Evidence of submucosal invasion
Deeper two thirds of the submucosa carries high risk of lymph node metastasis
Moderately or poorly differentiated tumor
Evidence of lymphatic channel invasion
Evidence of vascular invasion
Evidence of neural invasion
Treatment characteristics
Failure of ablation of remainder for Barrett's epithelium
Piecemeal endoscopic resection (as opposed to *en bloc* resection)
Longer time to achieve eradication

EUS: Endoscopic ultrasound; FNA: Fine needle aspiration; HGD: High-grade dysplasia.

Endoscopic characteristics

Long-segment BE has been identified as a risk factor for cancer[26] and for recurrence of neoplasia with endoscopic therapy[19]. Furthermore, visible lesions in the setting of HGD are more at risk for harboring occult cancer than flat dysplasia[5,27,28].

Careful white light examination is essential for targeting biopsies and resection of visible lesions because visible lesions in the setting of dysplasia have a high risk of occult cancer. Furthermore, the type of lesion is correlated with risk of submucosal invasion. Standardization of endoscopic appearance of visible lesions is now developing, and more attention is being given to non-protruding lesions. The updated Paris classification is based on the Japanese classification of gastric lesions. In the esophagus, superficial lesions based on endoscopic appearance include the following classifications: protruding pedunculated (type 0- Ⅰ p), protruding sessile (0- Ⅰ s), slightly elevated (0- Ⅱ a), completely flat (0- Ⅱ b), slightly depressed (0- Ⅱ c), excavated (0-Ⅲ), or a mixed pattern[29]. Type 0-Ⅲ is suspicious for submucosal invasion. Type 0- Ⅰ and type 0- Ⅱ c lesions are also associated with increased risk of submucosal penetration[30]. Thus, protruding or depressed lesions are at higher risk than those slightly raised or flat areas. EMR provides an opportunity to stage the depth of a lesion in areas of question.

Endoscopic ultrasound in BE demonstrates a thickened mucosal lining. It is not optimal for differentiation between a T1a tumor (IMC) and a T1b (SMC) tumor, and EMR is better suited for depth staging at this range[31]. However, given the risk of lymph node metastasis in patients with IMC, EUS with fine needle aspiration (FNA) might identify patients not eligible for endoscopic therapy[32]. EUS with or without FNA is a reasonable procedure in all patients with IMC and patients with visible lesions, who have a higher risk of occult cancer. Any patient found with lymph node involvement should be referred for esophagectomy. The utility of EUS in flat HGD might be questioned[33].

Pathological characteristics

The diagnosis of HGD, IMC, and invasive cancer represents a biological and histological continuum. Although pathological assessment is the gold standard, interpretation is subject to a great deal of variability among pathologists. There is high inter-interpreter variability in diagnosing HGD as reported in the literature[34-38]. Due to limited sample size and depth, as well as potential crush artifacts, pathologists might not reliably be able to distinguish between HGD, IMC and SMC on a single biopsy specimen. One of the advantages of EMR specimens is that pathologists are better able to stage lesions because they provide large and intact pathological specimens.

In evaluations of specimens from EMR for Barrett's neoplasia, moderately or poorly differentiated cancers are more likely to invade the submucosa[30,39]. HGD obtained from multiple levels throughout a BE segment has a higher risk of being associated with occult cancer[28]. Furthermore, in a risk analysis performed on patients with either HGD or IMC, multifocal neoplasia has been cited as a risk factor for recurrence after endoscopic therapy[19]. Risk factors for lymph node metastasis in EA are vascular invasion, lymphatic channel permutation, neural invasion, and grade of the tumor[40,41]. In EA, submucosal invasion of the most superficial third does not carry the same lymph node metastasis risk as the deeper two thirds[40]. Manner *et al*[42] have reported favorable outcomes with endoscopic resection of low-risk SMC in their long-term experience of endoscopic resection. However, larger trials are needed before adopting endoscopic therapy as standard practice for these superficial submucosal invading tumors.

Treatment characteristics

Endoscopic resection specimens not only provide a histological specimen that is important for accurate pathological diagnosis, but also provide a means for assessing treatment adequacy. Lateral margins might indicate that further endoscopic treatment is necessary, whereas positive deep margins indicate that surgery is appropriate. The following are associated with a higher risk of recurrence: length of time to complete eradication of neoplasia with multiple endoscopic treatment sessions; piecemeal resection; and no ablative therapy to target the remainder of the at-risk Barrett's epithelium[19].

Although there is ongoing interest and early investigations for genetic or molecular markers to predict endoscopic response[43], none of these markers has been validated for clinical use.

ADVANTAGES OF ESOPHAGECTOMY

The strategy of performing esophagectomy for HGD or IMC not only cures the index condition, but also addresses occult cancer and prevents cancer death[44]. Although endoscopic treatment is an appropriate and cost-effec-

tive[45] approach for the treatment of many patients with HGD and IMC, patients who are appropriate surgical candidates can benefit from esophagectomy. The surgical specimen enables accurate staging of disease to diagnose areas of occult cancer, and confirms treatment adequacy with negative margins and lymph nodes. Conventional approaches are transhiatal esophagectomy and transthoracic esophagectomy. Minimally invasive esophagectomy (MIE) techniques are growing in popularity because of their perceived benefits of reduced pain, lower incidence of postoperative complications, and faster recovery. These MIE techniques include video-assisted thoracoscopy surgery with laparotomy or laparoscopy, laparoscopy with a right thoracotomy, or laparoscopic transhiatal resections. These procedures have been studied in mostly retrospective studies and conclusions are limited in terms of direct comparisons to open surgery due to lack of prospective randomized trials[46,47].

The issue of the morbidity and mortality of esophagectomy is the major concern for either open esophagectomy or MIE. Adverse outcomes include pulmonary complications, hemorrhage, anastomotic leakage, infections, and recurrent nerve palsy. Although one study based on a national Veteran's Affairs database has reported morbidity of almost 50% and mortality of 10%[48], the expertise and volume of the center, the experience of the surgeon, the patient risk factors, and the indications for esophagectomy should be taken into account[49-51]. In institutions with expertise and high volumes, the mortality rate is 2%-3%[52]. It is also important to note that esophagectomy specifically for HGD has a different risk profile than that of esophagectomy for cancer. Comorbid diseases, debilitation from cancer and/or neoadjuvant therapy, and issues with locally advanced disease are not as predominant in patients with HGD. A pooled mortality rate of 1% was calculated among six studies that involved esophagectomy for HGD[49]. Quality of life indicators for patients who underwent esophagectomy for HGD and IMC are equivalent to those of the general population[53].

INDICATIONS FOR ESOPHAGECTOMY FOR BARRETT'S HGD OR IMC

Strong indications for esophagectomy include lymph node metastasis and failure of endoscopic therapy. Invasion of tumor into the submucosa is still considered a strong indication for esophagectomy, although invasion into the superficial third of the submucosa does not carry the same lymph node metastasis risk as the deeper two thirds, and potentially could be treated endoscopically[29,42]. Factors to consider in the management strategy for HGD and IMC include characteristics that are associated with lymph node metastasis, submucosal invasion, and failure of endoscopic therapy, as listed in Table 1, and may serve as milder indications for esophagectomy. Excavated lesions (Paris classification 0-Ⅲ) are not typically considered to be amenable to endoscopic therapy due to high suspicion of submucosal invasion, whereas protruding lesions (0-Ⅰ) and depressed lesions (0-Ⅱc) are a concern for submucosal invasion and should be approached with caution endoscopically (Table 2). These circumstances allow for endoscopic resection to serve as a diagnostic tool to stage the lesion accurately to determine if the lesion is amenable to endoscopic therapy. Multifocal high grade is a milder indication for esophagectomy than previously considered, due to the evolving options of ablative therapy. These risk factors, as listed in Table 1, need to be weighed with patient characteristics, patient preferences, available surgical expertise, available endoscopic expertise, and surgical approach options to decide if esophagectomy or endoscopic therapy is appropriate for each case.

Table 2 Relative risk of submucosal invasion associated with endoscopic appearance of lesions

Endoscopic appearance	Paris classification	Relative risk of submucosal invasion
Polypoid	0-Ⅰp	Higher
Sessile	0-Ⅰs	Higher
Slightly raised	0-Ⅰa	Low
Flat	0-Ⅰb	Low
Slightly depressed	0-Ⅰc	Higher
Excavated	0-Ⅲ	Very high

WHICH OPERATION FOR BARRETT'S HGD OR IMC?

Selection of the appropriate approach to esophagectomy for HGD or IMC is based on a number of factors (Table 3). Prior surgery in the chest or abdomen might require an open rather than a minimally invasive approach, and prior esophageal surgery such as fundoplication might limit consideration of a vagal-sparing approach. Comorbidity such as severe pulmonary disease, or advanced age might encourage some surgeons to pursue an approach associated with less postoperative pulmonary morbidity, such as transhiatal esophagectomy[54]. Whether minimally invasive approaches offer a lower risk of postoperative pulmonary morbidity compared to open transthoracic approaches has not yet been adequately determined[47,55-57].

The appropriate extent of operation for HGD or IMC is somewhat complex and controversial, and is related to the length of esophagus that must be resected, the extent of soft tissue resection around the esophagus, and the regions for lymph node dissection. It is appropriate to examine the surgical specimen at the time of resection, and usually to perform a frozen section analysis of the proximal margin, to ensure that all the Barrett's mucosa has been removed. Limiting the resection to encompass just the Barrett's segment is probably not a good long-term strategy, because most reconstructive techniques using a gastric tube create a model of frequent reflux, thus exposing patients to the possibility of developing Barrett's mucosa in the remaining esophagus[58]. Indeed, this phenomenon has been well documented in the esophageal remnant after standard subtotal esophagectomy, and theoretically, the risk would be increased if more esophagus were left in place[58-64]. Some cases of adenocarci-

noma arising in such metaplastic epithelium have been described[65,66]. Therefore, a near total esophagectomy is recommended for patients who are undergoing esophagectomy for HGD or IMC.

The lateral extent of soft tissue resection for HGD or IMC is a more controversial problem, with the possible range extending from a vagal-sparing esophagectomy, in which no additional soft tissues are removed, to an extended *en bloc* esophagectomy, which sometimes includes the azygos vein, thoracic duct, contralateral pleura, a rim of diaphragm, and in some cases, even the posterior pericardium. With the increasing accuracy of EUS in assessing the depth of penetration of the primary tumor, anything more than removing a standard amount of soft tissue representing the lateral margins is not likely to provide the patient with benefits regarding local recurrence, but might add to postoperative morbidity. Whether a vagal-sparing operation offers the same freedom from local recurrence has not been sufficiently studied to date[67].

The appropriate extent of nodal dissection for HGD or IMC is also controversial. In order to stage esophageal cancer accurately it has been suggested that a minimum of 10 lymph nodes be resected for early-stage cancers[68]. The use of more extensive nodal dissections, especially three-field lymphadenectomy, are controversial for regionally advanced cancers and are likely inappropriate for HGD and IMC, although this question has not been formally studied.

The best surgical option for HGD or IMC is the one that produces the least morbidity, balanced against the best long-term survival. As present, any standard resection technique including open transthoracic, minimally invasive, and transhiatal approaches provide similar long-term outcomes, and transhiatal esophagectomy might have an advantage in reducing postoperative morbidity. The more extensive resections (open transthoracic, and minimally invasive) are likely to improve staging accuracy, particularly with regards to nodal status. Long-term functional status is similar regardless of the surgical approach. The use of vagal-sparing techniques, especially for HGD, has potentially interesting advantages with regard to quality of life, but has not been adequately evaluated in terms of staging accuracy and long-term outcomes. In the end, it is the surgeon's training and experience, in combination with the individual patient's needs that determines the most appropriate approach to esophagectomy for HGD or IMC.

CONCLUSION

Barrett's HGD or IMC can be primarily treated endoscopically with endoscopic resection and endoscopic ablation with the goal of total Barrett's eradication. Evidence of submucosal invasion, lymph node metastasis or failure of endoscopic therapy or their risk factors, which can be ascertained by endoscopic appearance, pathological characteristics, and treatment course, need to be incorporated into the decision-making process for endoscopic versus surgical treatment. Longer-term studies with additional risk analysis need to be carried out to be able to predict reliably which patients are amendable to endoscopic therapy and who may benefit from esophagectomy.

Abstract

The management of esophageal cancer has been evolving over the past 30 years. In the United States, multimodality treatment combining chemotherapy and radiotherapy (RT) prior to surgical resection has come to be accepted by many as the standard of care, although debate about its overall effect on survival still exists, and rightfully so. Despite recent improvements in detection and treatment, the overall survival of patients with esophageal cancer remains lower than most solid tumors, which highlights why further advances are so desperately needed. The aim of this article is to provide a complete review of the history of esophageal cancer treatment with the addition of chemotherapy, RT, and more recently, targeted agents to the surgical management of resectable disease.

Key words: Esophageal cancer; Multimodality therapy; Neoadjuvant therapy; Chemotherapy; Radiotherapy; Targeted agents; Disease management

INTRODUCTION

Esophageal cancer is the most rapidly increasing tumor type in the Western world[1,2]. Globally, esophageal cancer is the eighth most common malignancy and sixth most fatal, with approximately 460 000 new diagnoses and > 380 000 deaths annually[3]. The lifetime risk, as well as histology of esophageal cancer varies worldwide from 1 in 200 in the United States, with more than half of new cases being adenocarcinoma (AC) to more than 10 times that risk in Iran, Northern China, India, and Southern Africa, where the histology is > 90% squamous cell carcinoma (SCC), and mirrors the growing epidemic of tobacco abuse[3-5].

Although there are multiple, rare esophageal cancer histologies (e.g. gastrointestinal stromal tumors, leiomyosarcoma, and liposarcoma), AC and SCC are the two principle variants and account for > 98% of esophageal cancer diagnoses[6]. Historically, AC and SCC have been treated as a single disease entity with many older clinical trials not differentiating between the two histologies, even in study populations[7]. Over the years, however, a great deal of evidence has been compiled to support the notion that AC and SCC represent two separate diseases based on their differing etiology, epidemiology, prognosis, and response to treatment[8-11].

AC is highly associated with obesity and gastroesophageal reflux disease (GERD). Obesity increases the risk of developing GERD by approximately twofold due to elevated intra-abdominal pressure and a resultant laxity in the lower esophageal sphincter[12]. GERD leads to chronic

irritation of the distal esophagus and can eventually cause metaplasia by the replacement of normal, squamous epithelium by columnar epithelium and the formation of what is referred to as Barrett's esophagus. The new, secretory columnar cells are thought to be better-suited to withstand the erosive contents that spill over from the gastroesophageal junction (GEJ), but unfortunately, this change also increases the risk for dysplasia by sevenfold, with Barrett's esophagus evolving to AC at a rate of approximately 1% per year[13,14].

SCC, on the other hand, is almost always linked to tobacco and alcohol abuse. Current smokers have a ninefold increased risk of developing SCC of the esophagus, while heavy drinkers of alcohol have an increased OR of 5[15]. Combined, however, the synergistic effects of tobacco and alcohol abuse lead to a 20-fold increased risk of developing esophageal cancer[16], although more extreme abusers of the two have been reported to have an increased OR as high as 50 and even 107 in studies from Italy and South America, respectively[17,18].

Epidemiologically, there has been a dramatic shift in the two histologies[5]. In the United States between 1974 and 1994, there has been a staggering 350% increase in the number of patients with esophageal AC, which now represents 60% of all new esophageal cancer diagnoses. Prior to 1974, SCC constituted 90% of esophageal cancer in the United States, which was likely secondary to increased rates of tobacco abuse[5,19]. The median age of diagnosis for SCC is approximately one decade prior to that of AC, yet surprisingly, patients with SCC have been documented in more recent studies to fair worse[7-9,20,21]. This difference is likely to be secondary to the increased comorbidity of patients with SCC but, even more importantly, the location of the primary tumor. Compared to age and lung function, the adjusted OR for postoperative death for a tumor located in the upper third of the esophagus is 4[7,22]. SCC is usually a proximal lesion, with 75% of these cancers found to have contact with the tracheobronchial tree, while 94% of ACs are below the tracheal bifurcation[7].

With regard to location, it should be noted that the pathology, treatment and prognosis of SCC of the cervical esophagus are more closely related to that of SCC of the head and neck[23]. As such, this review instead focuses on the multimodality treatment of localized and locoregional cancer involving the thoracic esophagus and GEJ. The definition of what constitutes the GEJ is debatable in itself. Siewert and Stein have described the most accepted classification scheme for AC at the GEJ: type Ⅰ, AC arising from an area of intestinal metaplasia of the esophagus, which can infiltrate the GEJ from above; type Ⅱ, AC arising from the cardia of the stomach; type Ⅲ, subcardial gastric carcinoma that infiltrates the GEJ from below[24]. With the exception of overexpression of *COX-2* with type I GEJ AC, no known significant gene expression profile changes have been noted that differentiate the three sub-types consistently[25]. Type I GEJ tumors tend to have lymphatic drainage toward lower mediastinal and upper gastric lymph nodes, whereas type Ⅱ and Ⅲ GEJ tumors are more likely to drain to celiac axis nodes. As such, type Ⅰ GEJ tumors are generally treated as distal esophageal cancer, whereas type Ⅱ and Ⅲ GEJ tumors are viewed by many as gastric carcinomas[24,25].

TREATMENT

Surgery alone

Debate regarding the current standard of care for the management of esophageal cancer is ongoing[26-28]. Surgical resection alone has been the mainstay of treatment for decades[29], although its necessity has been called into question more recently for patients with SCC[30,31]. Although surgery is considered to offer the best chance of prolonged survival, alone it will only cure 15%-20% of patients with localized disease[32-35], and unfortunately, 50%-60% of patients with esophageal cancer have tumors that are considered inoperable, secondary to either tumor extension or medical comorbidity[29]. Contemporary outcome data for treatment with surgery alone report a median survival of 16 mo with a 1-, 2- and 3-year survival rate of 60%, 37% and 26%, respectively[32]. Local disease-failure rates with surgery alone are quite high at 58%, with two-thirds of those failures from lack of complete (R0) resection and one-third recurring locally despite an R0 resection[36]. Surgical approaches and techniques - transthoracic *vs* transhiatal resection with limited *vs* extended-field lymphadenectomy - are highly debated[34,35], and are beyond the scope of this review. What is clear, however, is that postoperative morbidity and mortality are decreased while overall survival (OS) is significantly improved in high-volume, expert academic centers[37,38]. Currently, National Comprehensive Cancer Network guidelines suggest surgery as a single-modality treatment option only for non-cervical T1 lesions without lymph node involvement[39].

Radiotherapy

Radiotherapy alone has been the historical treatment of choice for patients with esophageal cancer who are not surgical candidates. Radiotherapy delivered at 60-66 Gy over 6-6.5 wk has been associated with a 5-year OS ranging from 5% to 20% depending on tumor extent[40-42]. In a review by Earlam and colleagues, 49 earlier series that involved 8489 patients with SCC treated with radiotherapy alone have been reported to yield a 1-, 2- and 5-year survival rate of 18%, 8% and 6%, respectively[43]. Adding radiotherapy to the surgical management of esophageal cancer has the advantage of increasing local control of disease. In the adjuvant setting, radiotherapy can treat microscopic disease left behind after an incomplete surgery. In the neoadjuvant setting, radiotherapy can theoretically decrease the size of a lesion prior to surgery and potentially make that lesion more resectable. The obvious trade-off of increased local control with radiotherapy is poor wound healing in both settings and an increasingly difficult resection of previously irradiated tissue in the neoadjuvant setting.

As it stands, there have been five separate phase Ⅲ trials that have compared adjuvant radiotherapy with sur-

gery alone[36,44-47] (Table 1), and another five phase Ⅲ trials that have compared neoadjuvant radiotherapy to surgery alone[48-52] (Table 2). Although local control of disease was improved in each of the adjuvant radiation arms, there were increased complications secondary to adhesions, scarring and fistulas, and none reported an OS advantage in their entire study population as a whole. Among these trials, however, Xiao and colleagues randomized 495 patients with SCC to surgery followed by adjuvant radiotherapy or to surgery alone. Although the 5-year OS was not statistically different for all-comers (41% *vs* 32%, $P = 0.45$), a 5-year OS advantage was noted in a subgroup analysis of patients with stage Ⅲ disease (35% *vs* 13%, $P < 0.003$), which favored the arm that received adjuvant radiotherapy[47].

Of the five phase Ⅲ trials that have evaluated neoadjuvant radiotherapy in esophageal cancer, none has demonstrated an increase in resectability or OS in those treated with preoperative radiotherapy alone[48-52]. Although Nygaard and colleagues have reported a 3-year OS benefit, this was only after pooling patients who had received neoadjuvant radiotherapy with those who had also received neoadjuvant chemoradiotherapy, as there was no significant difference in survival found otherwise[51]. A meta-analysis of trials that have used neoadjuvant radiotherapy with a median follow-up of 9 years, and including data from 1147 patients who almost exclusively had SCC, has revealed a trend toward improved 5-year OS (OR: 0.89, 95% CI: 0.78-1.01, $P = 0.062$), but ultimately has failed to show a statistically significant survival advantage[53].

Chemotherapy

The theoretical advantages of adding chemotherapy to the treatment of esophageal cancer are for potential tumor down-staging prior to surgery, as well as targeting micrometastatic disease, and thus decreasing the risk of distant spread. Adjuvant chemotherapy with cisplatin-based regimens compared to surgery alone has been examined in three separate phase Ⅲ trials[54-56] (Table 3), with none of them reporting a statistically significant difference in OS, although Ando and colleagues have reported a 5-year disease-free survival (DFS) advantage (55% *vs* 45%, $P = 0.037$)[56]. In the neoadjuvant setting, there have been multiple randomized trials that have compared varying chemotherapeutic regimens to surgery alone[32,51,57-63] (Table 4). Clinical complete responses based on direct visualization and an assortment of imaging modalities have ranged from 19% to 58%, but the rate of pathological complete response (pCR) at the time of surgery was a disappointing 2.5%-13%. This is an unsurprising trend considering the relative ineffectiveness of chemotherapy alone in the treatment of esophageal cancer[32,51,57-63].

The UK Medical Research Council (MRC) trial included 802 patients of all histologies, and randomized patients

to two cycles of neoadjuvant cisplatin 80 mg/m^2 and infusional fluorouracil 1000 mg/m^2 per d for 4 d *vs* surgery alone. A rather striking distinction of this trial compared to others was that clinicians could give their patients neoadjuvant radiotherapy (25-32.5 Gy) irrespective of randomization, and 9% of patients on each arm received radiotherapy. R0 resections were reported in 60% of assessable patients that were treated with neoadjuvant chemotherapy *vs* 54% of patients treated with surgery alone ($P < 0.0001$). OS was also improved in the neoadjuvant group (HR: 0.79, 95% CI: 0.67-0.93, $P = 0.004$), with a median OS of 16.8 mo *vs* 13.3 mo, respectively[61]. Another large trial by Kelsen *et al*[32] has evaluated neoadjuvant chemotherapy in the Intergroup (INT) 0113 study with 440 patients, however, reported no difference in OS was reported. Two large meta-analyses also have failed to demonstrate a survival advantage with neoadjuvant chemotherapy[64,65], although another meta-analysis by Gebski *et al*[66] has reported a statistically significant OS benefit with neoadjuvant chemotherapy (HR: 0.90, 95% CI: 0.81-1.00, $P = 0.05$), which corresponds to a 2-year absolute survival benefit of 7%. Caveats to this meta-analysis are that no statistically significant benefit was seen for patients with SCC treated with neoadjuvant chemotherapy (HR: 0.88, 95% CI: 0.75-1.03, $P = 0.12$) and that, although there was a benefit seen with AC (HR: 0.78, 95% CI: 0.64-0.95, $P = 0.014$), these results were based solely on the single trial whose data were available for review - the MRC trial[61,66].

At least four separate trials have compared cisplatin-based perioperative regimens (neoadjuvant and adjuvant chemotherapy) to surgery alone in esophageal cancer[32,67-69] (Table 5). Those that focused solely on esophageal cancer did not reveal survival benefits[32,67], whereas the two that included patients with AC of the stomach and GEJ did show such a benefit[68,69]. The largest of these, published by Cunningham and colleagues, randomized 503 patients with AC to three preoperative and three postoperative courses of epirubicin 50 mg/m^2 and cisplatin 60 mg/m^2 with infusional fluorouracil 200 mg/m^2 per day for 21 d *vs* surgery alone. Although the majority of patients had gastric AC, approximately 26% of the patients enrolled had AC of the GEJ or distal esophagus. Despite the fact that 58% of patients were unable to tolerate all six cycles of chemotherapy, the perioperative chemotherapy group had a statistically significant higher likelihood of OS compared to those treated with surgery alone (HR: 0.75, 95% CI: 0.60-0.93, $P = 0.009$), with an improved median OS (24 mo *vs* 20 mo) and 5-year OS (36% *vs* 23%). Although postoperative complications were not increased (46% *vs* 45%), there was also no difference in the rate of R0 resection (69% *vs* 66%) or pCR (both 0%). Importantly, there was no evidence of heterogeneity of treatment effect based on the location of the primary tumor[68].

Chemoradiotherapy

Chemotherapy in conjunction with radiotherapy was

initially evaluated as a definitive treatment for patients deemed unable to proceed with surgery[70]. In combination, chemotherapy not only compliments but augments the effect of radiotherapy in a process known as radiation sensitization, secondary to synergistic DNA damage, cell cycle synchronization, and inhibition of repair and resistance pathways[71,72]. In addition to increasing the efficacy of radiotherapy and thus controlling local tumor growth, as mentioned earlier, chemotherapy theoretically also offers the ability to eradicate micrometastatic disease and decrease the risk of distant recurrence[73].

The seminal Radiation Therapy Oncology Group (RTOG) 85-01 trial has compared radiotherapy (50.4 Gy over 5 wk) with concurrent cisplatin 75 mg/m^2 and infusional fluorouracil 1000 mg/m^2 per day for 4 d to radiotherapy alone (64 Gy over 6.4 wk). The chemotherapy arm consisted of four cycles delivered every 4 wk during radiotherapy (cycles 1 and 2) and every 3 wk for the remainder (cycles 3 and 4). The study included 134 patients with 90% having SCC and all with T1-3 N0-1 M0 disease. The trial was closed early once an interim analysis revealed that there was a statistically significant survival advantage that favored concurrent chemoradiotherapy that later amounted to a 5-year OS of 27% *vs* 0%. There was no statistically significant difference in OS based on histology[70].

Although those who received concurrent chemoradiotherapy had a decreased risk of persistent disease or local recurrence compared to those who received radiotherapy alone in the RTOG 85-01 trial, the incidence of locoregional failure was still 47%[70], and the INT 0123 trial was launched in an effort to improve upon this, with the theory that higher doses of radiotherapy would be beneficial. A total of 236 patients with T1-3 N0-1 M0 disease were enrolled (85% with SCC) and randomized to high-dose radiotherapy (64.8 Gy) *vs* low-dose radiotherapy (50.4 Gy), with both arms receiving four cycles of concurrent chemotherapy (cisplatin 75 mg/m^2 and infusional fluorouracil 1000 mg/m^2 per day for 4 d every 4 wk). The INT 0123 trial was also stopped early after an interim analysis failed to reveal a significant difference in median OS (13 mo *vs* 18.1 mo), 2-year survival (31% *vs* 40%), or locoregional persistence/recurrence of disease (56% *vs* 52%) between the high-dose and low-dose radiotherapy arms, respectively[74]. With such unacceptably high locoregional failure rates with definitive chemoradiotherapy, in addition to the dismal prognosis of patients treated with surgical resection alone[32-35], numerous trials were begun to evaluate multimodality treatments that combine chemotherapy, radiotherapy, and surgical resection.

To date, at least nine randomized phase Ⅲ clinical trials have compared neoadjuvant chemoradiotherapy with surgery alone[33,51,75-82] (Table 6). These trials incorporated multiple chemotherapy regimens, doses of radiotherapy used (20-50.4 Gy), and timing of radiotherapy with regard to chemotherapy (sequential *vs* concurrent), in addition to differing by surgical procedures performed and histological types of esophageal cancer enrolled (AC, SCC, or both). Only two of these trials have revealed a significant survival benefit that favored multimodality treatment, and neither was without its imperfections[77,81]. Walsh and colleagues randomized 113 patients with AC to two courses of neoadjuvant cisplatin 75 mg/m^2 and fluorouracil 15 mg/kg per day for 5 d with concurrent radiotherapy (40 Gy over 3 wk) or to surgery alone. The median OS was 16 mo *vs* 11 mo (P = 0.01) with a 3-year OS of 32% *vs* 6% (P = 0.01), which favored the multimodality treatment arm[77]. This single-institution-based trial, however, has been heavily criticized for an OS of patients with localized esophageal cancer treated with surgery alone (6%) that was far inferior to historical controls[32].

The second study, the Cancer and Leukemia Group B 9781 trial, was closed early with only 56 of an expected 500 patients enrolled, secondary to poor accrual that was reportedly due to the unwillingness of many patients and physicians to enroll in the control surgery-alone arm. Patients were randomly assigned to two cycles of cisplatin 100 mg/m^2 and fluorouracil 1000 mg/m^2 per day for 4 d with concurrent radiotherapy (50.4 Gy over 5.5 wk) prior to surgery, or to surgery alone. An impressive 5-year OS of 39% *vs* 16% was reported with a median OS of 4.48 years *vs* 1.79 years (P = 0.002), respectively. Although the obvious clinical significance of these findings is hard to dispute, a trial with more robust participation would have gone a long way to alleviate any uncertainties regarding the best treatment strategy for resectable esophageal cancer[81].

[1]Neoadjuvant chemoradiotherapy; [2]Adjuvant chemoradiotherapy; [3]3-year OS; [4]20% of patients enrolled had AC of the gastroesophageal junction (GEJ). MS: Median survival; SCC: Squamous cell carcinoma; AC: Adenocarcinoma; B: Bleomycin; C: Cisplatin; F: Fluorouracil; V: Vindesine; NS: Not significant; OS: Overall survival.

With such inconclusive and often contradictory results in trials that have evaluated neoadjuvant multimodality treatment based on disparate study populations, a myriad of regimen protocols, and more importantly, small numbers of patients, numerous meta-analyses have subsequently been performed in an effort to synthesize these data into larger pools and discover if a survival benefit exists[66,83-87]. One of the first, published by Urshel and Vasan, included nine randomized controlled trials with 1116 patients and reported a 3-year survival benefit that favored neoadjuvant chemoradiotherapy (OR: 0.66, 95% CI: 0.47-0.92, $P = 0.016$), which was most pronounced when the chemotherapy and radiotherapy were given concurrently (OR: 0.45, 95% CI: 0.26-0.79, $P = 0.005$) instead of sequentially (OR: 0.82, 95% CI: 0.54-1.25, $P = 0.36$). Although patients who received neoadjuvant chemoradiotherapy were less likely to proceed to surgery (OR: 2.50, 95% CI: 1.05-5.96, $P = 0.038$), they were still more likely to have an R0 resection (OR: 0.53, 95% CI: 0.33-0.84, $P = 0.007$) with 21% having a pCR. Although there was a decreased risk of local-regional recurrence for those who received multimodality treatment compared to those who received surgery alone (OR: 0.38, 95% CI: 0.23-0.63, $P = 0.0002$), there was no difference in risk for distant recurrence. There was a statistically insignificant but nonetheless concerning trend toward increased treatment mortality (OR: 1.63, 95% CI: 0.99-2.68, $P = 0.053$)[84]. The most recent meta-analysis published by Gebski and colleagues has evaluated 1209 patients in 10 trials, and likewise found a statistically significant benefit with neoadjuvant chemoradiotherapy compared to surgery alone, with a 19% decreased risk of death (HR: 0.81, 95% CI: 0.70-0.93, $P = 0.002$) for both AC and SCC, which corresponded to a 13% absolute difference in survival at 2 years[66].

As noted earlier, Gebski *et al*[66] also have evaluated neoadjuvant chemotherapy compared to surgery alone in a meta-analysis. These separate meta-analyses have been published at the same time in conjunction with each other. Although the two neoadjuvant chemotherapy and chemoradiotherapy data pools are not directly comparable, the absolute survival benefit of chemotherapy appears to be less than that of chemoradiotherapy (7% *vs* 13% at 2 years). This point was further supported although not confirmed by Stahl *et al*[88] who randomized 126 patients with AC of the GEJ (55% were type I GEJ tumors) to 16 wk neoadjuvant chemotherapy using cisplatin and leucovorin-modulated fluorouracil, or 12 wk of the same regimen followed by 3 wk of cisplatin and etoposide with concurrent radiotherapy (30 Gy) prior to surgical resection. Those treated with multimodality neaodjuvant chemoradiotherapy did not have a significant increase in R0 resection (72% *vs* 70%), but did have an increased probability of achieving a pCR (15.6% *vs* 2%, $P = 0.03$) and having tumor-free lymph nodes at the time of resection (64% *vs* 38%, $P = 0.01$) compared to those treated with neoadjuvant chemotherapy. There was a trend toward improved 3-year OS (47% *vs* 28%, $P = 0.07$), which favored neoadjuvant chemoradiotherapy, but with just a third of the expected 354 patients enrolled in the trial prior to its closure due to poor accrual, there was no statistically significant difference noted.

Anecdotally, patients with esophageal cancer often lack the strength to complete adjuvant chemoradiotherapy, although there are data to support its use and tolerability in patients with tumors of the GEJ[82]. The U.S. INT 0116 trial enrolled 556 patients with resected AC of the stomach and GEJ; approximately 20% of those participating had GEJ tumors. Patients were randomized to either sur-

gery alone or surgery followed by four cycles of adjuvant leucovorin-modulated fluorouracil, with the second cycle concurrent with radiotherapy (45 Gy). The median OS was 27 mo *vs* 36 mo (HR: 1.35, 95% CI: 1.09-1.66, P = 0.005), which favored the adjuvant chemoradiotherapy arm. Although 17% of patients were unable to finish the protocol because of treatment-related toxicity, an impressive 64% of patients were able to finish the protocol completely. There was no difference in survival based on the location of the primary tumor[82].

Targeted therapy

Despite improvements seen with the multimodality treatment of esophageal cancer, cure rates remain disappointingly low[66]. As such, targeted agents that have been found to benefit patients with head and neck, breast, lung, colon, and pancreatic cancers have generated intense interest in esophageal cancer[89-91]. Multiple pathways have been evaluated at the molecular level with potential targets in esophageal cancer including cyclin-dependent kinases, nuclear factor κB, matrix metallopreoteinases, and the inhibition of *COX-2*. The most promising targets at present, however, appear to be the epidermal growth factor receptor (EGFR) and vascular endothelial growth factor (VEGF)[89].

There are at least four types of EGFR: EGFR (human EGFR-1, HER-1), HER-2, HER-3, and HER-4. EGFR signaling plays a crucial role in modulating cell proliferation, invasion, metastasis, and resistance to cell death[89]. Overexpression of EGFR proteins has been reported in 30%-70% of AC and SCC of the esophagus, with such overexpression correlating with more aggressive disease and worse outcome[92-94]. Multiple clinical trials have been launched in an effort to target EGFR in esophageal cancer, with the most common drug used being the IgG1 monoclonal antibody cetuximab[95-99]. A trial by Gold *et al*[95] using cetuximab as a second-line monotherapy in the metastatic setting was discouraging, although regimens using cetuximab in combination with FOLFIRI[96], cisplatin and docetaxel[97], and cisplatin and fluorouracil[98] have revealed that the drug shows promise in the treatment of esophageal cancer. A phase Ⅱ trial by Safran *et al*[99] has evaluated 57 patients with esophageal cancer that were treated with weekly carboplatin, paclitaxel and cetuximab with concurrent radiotherapy (50.4 Gy). Seventy percent of patients achieved a complete clinical response and, of the 49 patients who went on to surgery, 27% had a pCR. The RTOG 0436 trial - a phase Ⅲ trial that is evaluating carboplatin, paclitaxel, and concurrent radiotherapy with or without cetuximab - is currently ongoing.

Another EGFR that is more famously associated with breast cancer, HER-2, is also overexpressed in 19%-43% of patients with esophageal cancer, and can be targeted by trastuzumab - a humanized IgG1 monoclonal antibody against the same receptor[100]. The phase Ⅲ ToGA trial randomized 594 patients with locally advanced, recurrent, or metastatic gastroesophageal cancer with HER-2 overexpression to treatment with cisplatin and fluorouracil or capecitabine, with or without trastuzumab. The median OS was significantly improved and favored the arm that received trastuzumab (13.5 mo *vs* 11.1 mo, HR: 0.74, 95% CI: 0.60-0.91, P = 0.0048)[101]. How these results will affect future multimodality neoadjuvant treatment is unknown, especially considering the potential for cardiotoxicity in a patient population that is already at risk. Although there were no differences in symptomatic congestive heart failure between the two arms, the patients who received trastuzumab were more likely to experience asymptomatic decreases in their left ventricular ejection fraction (4.6% *vs* 1.1%)[101].

VEGF is a regulator of angiogenesis and is yet another potential target. Similar to EGFR, VEGF is also overexpressed in 30%-60% of esophageal cancer patients and is likewise associated with poor outcome[102]. There is even evidence to suggest that the level of VEGF expression increases during treatment with chemotherapy and radiotherapy, which makes it a particularly attractive target for multimodality neoadjuvant treatment[103,104]. Promising phase Ⅱ data with surgically unresectable AC of the GEJ combining bevacizumab - a humanized monoclonal antibody against VEGF - with cisplatin and irinotecan[105], as well as docetaxel, cisplatin and fluorouracil[106] are available, while trials that are incorporating neoadjuvant chemoradiotherapy with the addition of bevacizumab are currently ongoing[91]. As with trastuzumab, it is unknown how the potential toxicities inherent to bevacizumab - hypertension, thromboembolism, poor wound healing, bowel perforation, worsening arterial disease, and an increased risk of bleeding - will affect the treatment of esophageal cancer patients who often present with multiple comorbidities[107].

CONCLUSION

The optimal treatment strategy for resectable esophageal cancer is still a controversial topic. Multimodality neoadjuvant chemotherapy with concurrent radiotherapy has been accepted by many - although not all - as the standard of care, because such a regimen increases rates of pCR, R0 resection, and local tumor control, which all correlate with improved OS[33,66,77,78,81,84-86]. If one accepts the most recent meta-analysis, an absolute OS benefit exists but is likely to be just 13% at 2 years[66]. With such a small benefit, it is no wonder that the multiple underpowered clinical trials that have compared neoadjuvant chemoradiotherapy with surgery alone have found it difficult to demonstrate a survival difference.

Although such a survival benefit might seem small, it should be noted that it is in line with accepted treatment algorithms of other lethal malignancies, such as the addition of adjuvant chemotherapy in completely resected non-small cell lung cancer[108]. The need to treat approximately eight patients with a difficult-to-tolerate regimen to cure just one additional person is hardly ideal, yet these odds are not inconsequential when discussing them face-to-face with a patient who is at least felt to be sufficiently medically fit enough to withstand an esophagectomy.

Although neoadjuvant and perioperative chemother-

apy have also been found to be effective approaches for treating esophageal cancer, there is a reasonable amount of evidence to support the notion that such treatments are inferior to neoadjuvant chemoradiotherapy[66,88], while the data supporting adjuvant chemoradiotherapy can only be applied to patients with GEJ tumors at the present time[82]. How targeted therapy will affect our approach to resectable esophageal cancer is currently unknown as many of the trials to determine this are ongoing[91,99]. By participating in clinical trials and enrolling as many appropriate patients as we possibly can, these questions will hopefully be answered in a more timely and conclusive manner than previously seen in the history of esophageal cancer treatment.
