Esophageal cancer continues to represent a formidable challenge for both patients and clinicians. Relative 5-year survival rates for patients have improved over the past three decades, probably linked to a combination of improved surgical outcomes, progress in systemic chemotherapy and radiotherapy, and the increasing acceptance of multimodality treatment. Surgical treatment remains a fundamental component of the treatment of localized esophageal adenocarcinoma. Multiple approaches have been described for esophagectomy, which can be thematically grouped under two major categories: either transthoracic or transhiatal. The main controversy rests on whether a more extended resection through thoracotomy provides superior oncological outcomes as opposed to resection with relatively limited morbidity and mortality through a transhiatal approach. After numerous trials have addressed these issues, neither approach has consistently proven to be superior to the other one, and both can provide excellent short-term results in the hands of experienced surgeons. Moreover, the available literature suggests that experience of the surgeon and hospital in the surgical management of esophageal cancer is an important factor for operative morbidity and mortality rates, which could supersede the type of approach selected. Oncological outcomes appear to be similar after both procedures.

Key words: Esophageal cancer; Transhiatal esophageal resection; Transthoracic esophageal resection

INTRODUCTION

Esophageal cancer is the eighth most common cancer worldwide, with a wide variation in its frequency between high- and low-incidence regions. There are two main histopathological subtypes: squamous cell carcinoma (SCC) and adenocarcinoma. SCC is the most common subtype in several endemic regions of the world[1], with a high correlation to smoking and alcohol abuse, as well as chronic inflammation[2]. On the other hand, adenocarcinoma is commonly associated with Barrett's metaplasia, gastroesophageal reflux disease (GERD), and obesity[3]. It has become the most common subtype in the western hemisphere, and frequently involves the gastroesophageal junction (GEJ) and proximal stomach. SCC and adenocarcinoma of the esophagus are distinct entities and should be considered as such when defining optimal therapy. As

a result of its increasing incidence[4] and relationship with GERD, the following review focuses on adenocarcinoma of the esophagus.

Despite improvements in systemic chemotherapy and radiotherapy, and the increasing acceptance of multimodality treatment that have resulted in enhanced survival rates over the past three successive decades[5], surgical resection continues to be the mainstay of care for treatment of localized esophageal adenocarcinoma. Multiple approaches have been described for esophagectomy, and they can be thematically categorized under two major headings: transthoracic or transhiatal. The transthoracic procedure is performed more commonly by means of combined laparotomy and right thoracotomy (Ivor Lewis procedure). Other options include left thoracotomy with or without cervical incision, a single left thoracoabdominal incision, or a three-incision resection with a cervical anastomosis (McKeown procedure). The transhiatal approach is performed through midline laparotomy and left cervical incision. There has been considerable controversy about which procedure provides the best short- and long-term outcomes. The discussion centers around whether more extended resection through thoracotomy provides superior oncological outcomes than resection with relatively limited morbidity and mortality through a transhiatal approach. Decisions regarding surgical technique are frequently based on personal bias, surgeons' experience and comfort with a procedure. The issue of the extent of surgical resection is addressed first, with a brief description of each approach. The relevance of surgeon/hospital volume and its relationship with adequate outcomes after esophagectomy, and the role of surgery in the context of multimodality treatment are discussed separately.

TRANSTHORACIC ESOPHAGECTOMY

Transthoracic esophagectomy is most commonly performed *via* laparotomy followed by right thoracotomy and intrathoracic anastomosis (Ivor Lewis procedure). It was originally described in 1946 in two stages[6], and historically, it is the standard procedure against which all other techniques are measured. Left thoracotomy or thoracoabdominal incision provides adequate exposure to the distal esophagus, but presents greater difficulty to access the upper and middle thirds and to perform an anastomosis high in the chest.

Ivor Lewis esophagectomy starts through a midline incision in the abdomen. The left lobe of the liver is mobilized and retracted laterally, and the stomach is fully mobilized and freed from its vascular attachments, including an upper abdominal lymphadenectomy, while preserving the right gastroepiploic and right gastric vessels on whose pedicle the reconstructive conduit is based. The duodenum is mobilized completely *via* a Kocher maneuver and a pyloric drainage procedure is performed, to diminish gastric stasis and minimize aspiration[7,8]. The right diaphragmatic crus is divided with electrocautery to allow access to the mediastinum and to avoid constricting the transposed stomach. Placement of a feeding jejunostomy is commonly performed before abdominal closure and repositioning for the thoracic component of the procedure. Muscle-sparing right lateral thoracotomy is then performed through the fifth intercostal space. The mediastinal pleura that overlies the esophagus is incised, the azygos vein is divided, the intrathoracic esophagus is mobilized, and *en bloc* resection of the surrounding periesophageal tissue is performed, including mediastinal lymph node dissection.

After division of the proximal esophagus in the chest to ensure an adequate margin, the GEJ and stomach are transposed into the thoracic cavity. A gastric conduit is now created, with a linear stapler parallel to the greater curve, and the fundus is removed with a portion of the lesser curvature. The specimen is removed, and an esophagogastric anastomosis is performed. The McKeown procedure is an alternative three-incision approach, in which right thoracotomy is the initial stage of the procedure, followed by repositioning of the patient in the supine position for abdominal and left cervical incision, to achieve a cervical esophagogastric anastomosis.

The theoretical advantage of the transthoracic approach is a more thorough oncological operation as a result of direct visualization and exposure of the thoracic esophagus, which allows a wider radial margin around the tumor and more extensive lymph node dissection. However, the combined effects of an abdominal and thoracic incision might compromise cardiorespiratory function, especially in patients with coexisting lung or heart disease. The other disadvantage is that an intrathoracic anastomotic leak can lead to catastrophic consequences including mediastinitis, sepsis, and death. The three-incision modification of the procedure effectively eliminates the potential for complications associated with an intrathoracic esophagogastric anastomosis.

The perioperative mortality of transthoracic esophagectomy in experienced centers ranges from 9% to as low as 1.4%[9-15]. Five-year survival in approximately 25% of patients who undergo transthoracic esophageal resection has been reported. These reports include heterogeneous populations of patients with esophageal cancer that underwent a variety of surgical approaches, the use of adjuvant treatment in some but not all patients, and combined histologies (SCC and adenocarcinoma).

TRANSHIATAL ESOPHAGECTOMY

Transhiatal esophagectomy was first performed by Turner in 1933 for esophageal carcinoma[16]. During subsequent decades, it was not routinely performed since the transthoracic approach was preferred after general anesthesia became available. In 1978, Orringer described his initial series of blunt transhiatal esophagectomy, which kindled new interest in this procedure[17]. It has gained favor among surgeons concurrent with the rising incidence of adenocarcinoma of the distal esophagus, which is readily approachable through the diaphragmatic hiatus.

The abdominal portion of the procedure duplicates that of the previously described transthoracic approach

and includes mobilization of the stomach, pyloromyotomy and placement of a feeding jejunostomy. Again, cautery division of the right crus allows access to the mediastinum and dissection under direct vision of the distal and middle third of the esophagus. A left cervical incision along the anterior border of the sternocleidomastoid muscle provides exposure to the cervical esophagus. Circumferential dissection of the cervical esophagus is carried down to below the thoracic inlet, and blunt dissection is continued into the superior mediastinum to mobilize the upper thoracic esophagus, with care to avoid injury to the recurrent laryngeal nerve in the tracheoesophageal groove. The remainder of the dissection at the level of and superior to the carina is completed by blunt dissection through the esophageal hiatus. The cervical esophagus is then divided, the stomach and attached intrathoracic esophagus are delivered through the abdominal wound, and a gastric conduit is fashioned using a linear stapling device in the same manner as described above. The gastric tube is delivered through the posterior mediastinum to the cervical wound, where a cervical esophagogastric anastomosis is performed. The stomach is considered by most surgeons as the ideal replacement for the resected esophagus, although a segment of colon or a free flap of small bowel can be used as alternative conduits[18,19].

The postulated advantages of the transhiatal approach to esophagectomy are avoidance of a thoracotomy incision, which thereby minimizes pain and subsequent postoperative pulmonary complications; elimination of potentially life threatening mediastinitis as a result of an intrathoracic anastomotic leak; and a shorter duration of operation, which potentially results in decreased morbidity and mortality[17]. Leak of a cervical esophagogastric anastomosis can be handled in the vast majority of patients with opening of the cervical wound, followed by local wound care. Compared to transthoracic esophagectomy, transhiatal esophagectomy is associated with poor visualization of upper and middle thoracic esophageal tumors (potentially compromising the oncological integrity of the operation), increased anastomotic leak rate with subsequent stricture formation, and a higher risk of recurrent laryngeal nerve injury[20,21].

The reported postoperative mortality after transhiatal esophagectomy in individual series tends to be slightly lower than that of the transthoracic approach, between 1% and 7.5%[22-26], and 5-year survival rate is approximately 25%, which is not substantially different from that accomplished after the transthoracic approach. Orringer *et al*[26] have reported the most extensive experience with transhiatal esophagectomy. Their latest report involved 2007 patients, of which 1525 had a diagnosis of cancer. Seventy-two percent had adenocarcinoma, and 38% received neoadjuvant chemoradiation, with a 5-year survival rate of 29%. Among this series, their most recent group of 944 patients had a hospital mortality of 1%. The anastomotic leak rate was 9% in this same group, and recurrent laryngeal nerve injury occurred in 2% of cases. These results reflect those reported from other surgical series of transhiatal esophagectomy.

Table 1 Meta-analysis comparing transthoracic and transhiatal esophagectomy

STUDIES COMPARING TRANSTHORACIC *VS* TRANSHIATAL ESOPHAGECTOMY

The question of one approach being superior to the other continues to generate considerable controversy among surgeons. No definitive advantage in oncological outcome or postoperative morbidity and mortality can be concluded from the non-comparative case series mentioned above.

Two large meta-analyses have addressed these issues by utilizing collective reviews of numerous individual studies that have compared transhiatal esophagectomy to transthoracic esophagectomy[20,21]. Most of the studies included in these meta-analyses were retrospective in nature and were not consistent with respect to the surgical technique utilized and which therapy in addition to surgery was delivered. Nevertheless, the results of both were very similar.

The meta-analysis by Rindani *et al*[20] included almost 5500 patients from 44 series published between 1986 and 1996 (Table 1). The statistical analysis was descriptive rather than comparative due to the diverse nature of the series, and there was only one prospective randomized trial included, with a small sample and short follow-up. Postoperative respiratory and cardiovascular complications were almost identical between the two groups. The transhiatal group had a higher incidence of anastomotic leaks and recurrent laryngeal nerve injuries. Thirty-day mortality was 6.3% after transhiatal and 9.5% after transthoracic resection, but survival at 5 years was equivalent between the two procedures.

The second meta-analysis, by Hulscher *et al*[21], involved

over 7527 patients derived from 50 studies from 1990 to 1999 (Table 1). Six were prospective comparative studies, three of which were randomized, all with a relatively small sample size. None of these three studies could demonstrate a significant difference in morbidity, mortality, or long-term survival[27-29]. When all 50 studies were analyzed, no significant differences were demonstrated in the overall morbidity rate. Blood loss was higher after transthoracic esophagectomy, and it had a higher risk of pulmonary complications, chylous leakage (2.4% *vs* 1.4%) and wound infection (7.7% *vs* 4.3%). Similar to the previous meta-analysis, transhiatal esophagectomy had a higher incidence of anastomotic leakage and recurrent laryngeal nerve injury. Length of stay in the intensive care unit (ICU) and hospital were longer in the transthoracic group, and in-hospital mortality was significantly higher as well. Again, there was no difference in 5-year survival rates.

There have been a total of four randomized trials that have compared both techniques (Table 2). Three of them, included in the previous meta-analyses described above, could not provide definitive conclusions and each was hampered by an extremely small sample size, with non-significant differences reported between the two arms[27-29].

The fourth randomized trial, published in 2002 by Hulscher *et al*[30], has provided level I evidence regarding this controversial issue. Two hundred and twenty patients were assigned to either transhiatal or transthoracic esophagectomy with cervical anastomosis. The transthoracic esophagectomy procedure included *en bloc* resection of the thoracic duct, azygos vein, ipsilateral pleura, and all peri-esophageal tissue in the mediastinum, including a formal lymphadenectomy. Transhiatal esophagectomy had a shorter operative duration than transthoracic esophagectomy (3.5 h *vs* 6 h), with lower blood loss (1 L *vs* 1.9 L). Perioperative morbidity rate was also lower in the transhiatal group (pulmonary complications, 57% *vs* 27%; chylous leakage, 10% *vs* 2%). Duration of mechanical ventilation, ICU stay and hospital stay were all shorter in the transhiatal group. However, there was no significant difference in hospital mortality (transthoracic: 4%; transhiatal: 2%). Although initially a trend toward a survival benefit with transthoracic approach was seen, after longer follow-up, no difference in 5-year overall survival was found (transthoracic: 36%; transhiatal 34%). Notably, the transthoracic approach was of benefit in some subgroups; patients with 1-8 positive lymph nodes had better disease-free survival rate (64% *vs* 23%), and patients with tumors arising from the distal esophagus (rather than gastric cardia) tended towards a survival benefit (51% *vs* 37%, not statistically significant)[31]. However, this phase Ⅲ study was not adequately powered to address these subgroup analyses.

A large population-based study has been published recently, which has evaluated the results of both approaches through the Surveillance, Epidemiology and End Results (SEER) - Medicare linked database from 1992 to 2002[32]. A lower operative mortality was found after transhiatal esophagectomy (6.7% *vs* 13.1%). Although observed 5-year survival was higher after transhiatal esophagectomy, after adjusting for stage, patient and provider factors, no significant 5-year survival difference was found.

These data suggest that perioperative and oncological outcomes are not substantially influenced by the surgical approach to esophagectomy, and that either procedure is associated with acceptable results in the hands of expe-

rienced surgeons. Ideally, surgeons and hospitals treating patients with esophageal carcinoma should have expertise in both techniques. Some patients might even benefit from an individualized approach. For an older or higher-risk surgical patient, for whom perioperative recovery is an even greater concern than usual, a transhiatal approach could confer an advantage. In a fit patient with evidence of a limited number of involved lymph nodes, there is some evidence (although not level I evidence) that suggests a benefit in survival with the transthoracic approach. Still, available literature suggests that experience of the surgeon and hospital is likely to be a more important factor than is the type of approach selected.

SURGEON/HOSPITAL VOLUME AND ESOPHAGECTOMY

There is increasing evidence that confirms that patients who undergo complex oncological resections, such as esophagectomy, at high-volume hospitals by experienced surgeons have significantly lower rates of perioperative morbidity and mortality[33-35]. This association has been shown for several surgical procedures in studies that have used health-services-linked databases. However, the association between volume and outcome for esophagectomy is one of the strongest among all complex cancer operations[33-35]. Furthermore, a recent analysis of the SEER - Medicare linked data base[36] suggests that long-term survival, and therefore oncological outcome, is also volume dependent. The probability of surviving 5 years following esophagectomy in high-volume hospitals was 34%, whereas 5-year survival probability in low-volume hospitals was only 17%. This 17% absolute difference in 5-year survival following esophagectomy between high-volume and low-volume hospitals was the highest amongst all cancer resections surveyed. Volume-dependent discrepancy in 5-year survival could not be attributed to differences in the delivery of adjuvant therapy. Therefore, not only are short term procedure-related outcomes associated with surgical experience but long-term oncological outcomes might also be affected by surgeon and center volume/experience with esophageal resection. The basis for this improved survival has not been defined and requires further investigation.

ROLE OF SURGERY IN THE MULTIMODALITY THERAPY ERA

Relative 5-year survival rates for patients with esophageal cancer have improved over the past three successive decades[5,37]. The reasons for this trend are surely multifactorial and could include the widespread acceptance and use of a multimodality treatment approach, improved surgical outcomes, and progress made in systemic chemotherapy and radiotherapy.

Based on the current level I evidence, it can be reasonably argued that the addition of surgery to an effective regimen of chemoradiotherapy in patients with SCC of the esophagus might not improve outcome. Two randomized trials have addressed the role of chemoradiotherapy alone *vs* chemoradiotherapy followed by surgery in patients with SCC. The German Esophageal Cancer Study Group[38] has demonstrated better 2-year local, progression-free survival in the surgical group (64.3% *vs* 40.7%), although with increased treatment-related mortality (12.8% *vs* 3.5%), and equivalent overall survival between the two treatment groups. The FFCD 9102 trial[39], in which 90% of the patients had a diagnosis of SCC, found a higher frequency of locoregional relapse in the chemoradiotherapy alone group, but with a lower 3 mo mortality rate. As in the German study, survival rates were similar in both groups.

In contrast to SCC, the controversy regarding patients with esophageal adenocarcinoma has been centered on the added value of preoperative combined modality therapy, and not the necessity of surgical resection. Despite the fact that numerous phase Ⅲ trials[14,40-43] have compared preoperative chemoradiotherapy followed by surgery to surgery alone, it is not clear that preoperative chemoradiotherapy can be declared as a standard of care.

One randomized trial from Ireland[41] has shown a benefit in patients with adenocarcinoma, but definitive conclusions are hampered by the small sample size, unusually poor results with surgery alone, and short follow-up. More recently, the Cancer and Leukemia Group B initiated a trial that was closed prematurely due to poor accrual[43]. The most common histological tumor subtype in this study was adenocarcinoma. Reported median survival (4.48 years *vs* 1.79 years) and 5-year survival (39% *vs* 15%) favored trimodality therapy. Its major limitation was the incredibly small patient sample size due to poor accrual, although the findings had statistical significance.

Although the survival benefits have not been consistent, the majority of patients are down-staged with preoperative chemoradiotherapy, and for those patients who have a substantial response (complete pathological or major partial response defined by residual microscopic disease in the resected specimen) to preoperative chemoradiotherapy, there is a survival advantage. Surgery appears to be a crucial component of combined modality therapy to eliminate residual disease following chemoradiotherapy that leads to improved locoregional control and improved long-term survival. However, failure at a distant site is common and is the most frequent cause of death.

Even though the evidence for the benefit of preoperative chemoradiotherapy in the treatment of patients with esophageal cancer is not compelling, the combined modality approach has gained acceptance in most centers in the United States, and is by far the most frequent therapeutic option offered to patients with cancer of the esophagus. A meta-analysis has reported that preoperative chemoradiotherapy improved 3-year survival by 13% over surgery alone with similar improvement identified in patients with either SCC or adenocarcinoma histology[44]. Although the role of surgery has been questioned, especially for SCC, it can be reasonably concluded that esophageal resection remains an important, if not the most impor-

tant, therapeutic component of a combined modality approach to esophageal cancer. However further refinement of our treatment of patients with esophageal cancer is warranted. Patients who achieve a complete pathological response to combined chemoradiotherapy probably will obtain no advantage from undergoing esophagectomy, considering the substantial morbidity and mortality associated with the procedure. Unfortunately, current diagnostic methods are not reliable to identify this group of patients preoperatively. In contrast, it is reasonable to expect that patients with residual disease, either apparent or occult, following preoperative combined modality treatment will benefit from eradicating that residual disease with resection to give them the best opportunity for a long-term disease-free state. Surgeons interested in this lethal disease should direct their efforts to more accurate identification of those patients that will likely benefit from different single or combination treatment modalities, and tailor their therapeutic interventions accordingly.

Abstract

Esophageal resection is associated with a high morbidity and mortality rate. Minimally invasive esophagectomy (MIE) might theoretically decrease this rate. We reviewed the current literature on MIE, with a focus on the available techniques, outcomes and comparison with open surgery. This review shows that the available literature on MIE is still crowded with heterogeneous studies with different techniques. There are no controlled and randomized trials, and the few retrospective comparative cohort studies are limited by small numbers of patients and biased by historical controls of open surgery. Based on the available literature, there is no evidence that MIE brings clear benefits compared to conventional esophagectomy. Increasing experience and the report of larger series might change this scenario.

Key words: Esophageal resection; Transhiatal esophagectomy; Transthoracic esophagectomy; Esophageal cancer; Minimally invasive esophagectomy; Laparoscopy; Thoracoscopy

INTRODUCTION

Esophageal cancer is a devastating disease. It was estimated in 2002 that 462 117 individuals developed the disease and 385 892 died worldwide[1], which corresponds to a mortality rate of 83.5%. Surgery has been considered an essential part of the treatment of patients with esophageal adenocarcinoma. However, surgery has been traditionally associated with a high morbidity and mortality rate. A lot of progress has been made since Earlam and Cunha-Melo in 1980 reviewed the literature and reported 29% mortality for esophagectomy[2]. Recent series have shown much improved rates, but they are still far from ideal. For these reasons, minimally invasive esophagectomy (MIE) brought high hopes to this field.

This final paper from a seminar on heartburn and adenocarcinoma focuses on the minimally invasive approach to esophagectomy; a treatment that is suitable for Barrett's esophagus and high-grade dysplasia and for esophageal adenocarcinoma.

TECHNIQUE

The techniques for esophagectomy can be simplistically described as those that include thoracotomy (transthoracic) and those without thoracotomy (transhiatal). The same classification can be used for MIE. According to the preferred approach, thoracotomy can be replaced by thoracoscopy and/or laparotomy can be replaced by laparoscopy. Thus, the following different combinations can be found in the literature: (1) transhiatal esophagectomy -

laparoscopy and cervicotomy[3,4]; (2) transthoracic esophagectomy (three-field) - laparoscopy, thoracoscopy and cervicotomy[5,6]; (3) transthoracic esophagectomy (three-field) - laparotomy, thoracoscopy and cervicotomy[6]; (4) transthoracic esophagectomy (three-field) - laparoscopy, thoracotomy and cervicotomy[7]; (5) transthoracic esophagectomy (Ivor Lewis) - laparoscopy and thoracoscopy[5]; (6) transthoracic esophagectomy (Ivor Lewis) - laparotomy and thoracoscopy[8]; and (7) transthoracic esophagectomy (Ivor Lewis) - laparoscopy and thoracotomy[9].

Laparoscopy

The laparoscopic approach to esophagectomy has the purpose of: (1) dissection of the abdominal esophagus and esophageal hiatus; (2) abdominal lymphadenectomy; (3) preparation of the stomach to replace the esophagus; (4) pyloroplasty or pyloromyotomy; and (5) placement of a feeding jejunostomy.

Dissection of the abdominal esophagus and esophageal hiatus follows the same principles of laparoscopic antireflux surgery. In summary, five abdominal ports are usually used. The abdominal esophagus and esophageal hiatus are dissected. The gastro-hepatic ligament is open, which preserves the right gastric artery. The greater curvature of the stomach is mobilized, which preserves the right gastroepiploic artery. The left gastric artery and coronary vein are isolated and divided with an endo-GIA stapler. A gastric conduit is constructed by dividing the stomach, starting on the lesser curvature and finishing at the angle of His. Pyloroplasty or pyloromyotomy is usually performed. The tip of the gastric conduit is sutured to the esophageal specimen that is retrieved through the neck or through the thorax if the anastomosis is performed in the chest[5,9,10]. Alternatively, the gastric conduit might be created through a mini-laparotomy[11]. The colon is rarely used for esophageal replacement during MIE.

Extended abdominal lymphadenectomy might be added to the procedure based on the philosophy adopted for the treatment of esophageal cancer by the surgeon. It is safe and feasible with a laparoscopic approach, after the lessons learned with laparoscopic treatment of gastric cancer[12].

Thoracoscopy

The thoracoscopic approach to esophagectomy has the purpose of: (1) dissection of the thoracic esophagus; (2) thoracic lymphadenectomy; and (3) esophageal anastomosis.

Dissection of the esophagus is performed using four ports in the right chest. Carbon dioxide insufflation is not considered necessary by most surgeons. The deflated lung is retracted anteriorly and the mediastinal pleura overlying the esophagus is divided. The azygos vein is then divided using an endo-GIA stapler with a vascular cartridge. A Penrose drain is placed around the esophagus to facilitate retraction. The esophagus is circumferentially mobilized from the esophageal hiatus up to the thoracic inlet. An esophageal anastomosis might be performed above the level of the azygos vein with the aid of a linear stapler. Otherwise, once the thoracoscopic dissection is completed, the operation can continue with cervicotomy, and the continuity of the digestive tract is restored with transposition of the stomach to the neck[5,9,10].

Similarly to the laparoscopic approach, extended mediastinal lymphadenectomy might be performed.

TECHNICAL VARIATIONS

Hand-assisted esophagectomy

Some surgeons perform transhiatal MIE using a laparoscopic approach to the abdomen but include a subxiphoid midline incision for manual mobilization of the mediastinal esophagus through a hand-port[5].

Prone position

Some surgeons have proposed a prone position for thoracoscopy instead of a left lateral decubitus approach[13,14]. This approach is used in order to improve ergonomics, operative time and pulmonary complications. The patient is placed in the prone position and the esophagus is approached through the right chest. The right lung is kept ventilated but it is collapsed due to the action of gravity and an 8-mmHg CO_2 pneumothorax[13,14].

Palanivelu *et al*[13] have reported an incidence of 2% for pleural and pulmonary complications in 130 patients. Fabian *et al*[15] have shown no differences in blood loss, number of lymph nodes dissected, and complications in two small cohorts of patients operated in left lateral decubitus *vs* prone position. However, operation time was significant shorter. Although good results have been reported, this technique is not widely accepted.

Robotic surgery

Robotic surgery claims to have the advantages of: (1) eliminating the counter-intuitive motion of standard laparoscopy; (2) aligning the eyes and hands over the area of interest with improved ergonomics; (3) increasing freedom of instrument movement by allowing wrist and finger movements that standard laparoscopic instruments do not have; (4) minimizing instrument tremor; and (5) 3D stereoscopic vision with dual camera technology[16]. Different types of esophageal operations have been performed with the aid of a robotic platform. Cases of robotic esophagectomy have been shown to be safe and feasible, either through thoracoscopy[17] or laparoscopy[4].

Early results have shown a conversion rate ranging from 0% to 15%[4,18]. Operating time is still high for transthoracic robotic esophagectomy, at an average of 7.5 h, which leads to a high incidence of pulmonary complications that decreases with experience[18]. Long-term outcomes are still elusive.

Vagal-sparing esophagectomy

Vagal-sparing esophagectomy is an attractive alternative to conventional procedures to avoid postoperative complications associated with vagotomy. Vagal-sparing

MIE has been described and popularized by the Portland Group[19]. The technique follows the same principles as open surgery: the vagal nerves are mobilized off the distal esophagus and stomach to the level of the pylorus; two nasogastric tubes are passed distally through the cervical esophagus and into the gastric remnant; the gastric remnant is divided and the nasogastric tubes are incorporated into the staple line; and finally, the esophagus is inverted, stripped out and removed through the cervicotomy[19].

OUTCOMES

Intraoperative complications are still frequent and they are the main cause for conversion to open surgery. During laparoscopy, bleeding is the main complication, either at the splenic hilum or parenchyma (often requiring splenectomy) or during division of gastric vessels at the time of the preparation of the gastric conduit[5]. Liver injury has also been reported[6,20]. During thoracoscopy, bleeding is reported as well[6]; however, the presence of pleural adhesions is the main cause for conversion[5,6]. Overall, the conversion rate ranges from 3% to 18%[5,6] with an average of 5%-7% depending on the technique[21,22].

Postoperative complications average 40%-50%, but can reach 80%[6,21,22]. Pleural and pulmonary complications still account for a significant proportion of morbidity; an average of 22%[22]. Nguyen *et al*[5] have reported, in a large series of 104 patients, that postoperative major morbidity occurred in 12.5%, especially anastomotic complications, staple line leaks and pulmonary complications. Minor complications occurred in an additional 15% of cases[5].

Review papers show a median length of intensive care unit stay of 2-5 d, and a median length of hospital stay of 9-18 d after MIE[21,22]. Mortality rate ranges between 0% and 4%[5,6,20-22].

COMPARISON WITH OPEN SURGERY

As far as we are aware, no randomized controlled trials have compared MIE and open esophagectomy to date. Available data suggests that MIE is similar but not superior to conventional esophagectomy.

Morbidity and mortality

MIE was expected to reduce the morbidity and mortality rate of esophageal resection when compared to conventional surgery. However, a recent meta-analysis[23] has shown similar results for major morbidity, pulmonary complications and mortality when MIE and open surgery are compared either to transhiatal or transthoracic esophagectomy. Nguyen *et al*[5] also have shown similar pulmonary complications when MIE and open cohorts were compared. Perry *et al*[24] have compared the outcomes of open and laparoscopic transhiatal esophagectomy in two sets of patients from different periods of time. They have found that lower intraoperative blood loss and overall length of hospital stay favor MIE. Complication rates were no different.

Cost

As far as we are aware, no studies have compared cost for MIE and open surgery. It is intuitive, however, that direct operative costs are higher for MIE, especially with the use of endoscopic staplers. Moreover, the clinical benefits of MIE are not yet proven to be greatly superior to open surgery in order to decrease indirect costs.

Oncological radicality

Advantages of minimally invasive techniques include a magnified view of the operative field. This advantage theoretically enhances the ability to perform more radical lymphadenectomy. In contrast, surgeons might be less confident to work close to important vascular structures without a tactile feeling and the possibility to use their hands to control bleeding. Reported experiences with different types of cancer, such as colon[25] and stomach[26], have shown a comparable number of lymph nodes retrieved when open or minimally invasive surgery are compared. MIE shows similar results. Decker *et al*[22] have shown a mean 10-27 lymph nodes were dissected in MIE, depending on the technique adopted, and these numbers are comparable to open surgery and considered adequate[27].

Survival is expectedly similar to open surgery with an average of 40% at 5 years[22].

Learning curve

It has been shown that esophagectomy outcomes are highly linked to the experience and volume of the centers performing the operation[28]. The same seems to be true for MIE[22]. To the best of our knowledge, no studies have defined the number of procedures necessary for these techniques to become safe and effective. Advanced laparoscopic skills and experience with major foregut surgery (open and laparoscopic) are clearly necessary.

CONCLUSION

Minimally invasive surgery has the advantages of better cosmetic results, reduced operative stress, postoperative immobility, and pain. These advantages are obtained by minimizing the incisions to obtain access to natural cavities, i.e. decreasing the external surgical stress. Minimally invasive surgery does not change, however, the internal part of the operation and the surgical stress determined by it. The minimally invasive approach has gained rapid acceptance and has become the gold-standard operation where external stress is higher than internal stress, such as for cholecystectomy and hiatal hernia repair[29,30]. In operations in which internal surgical stress is intensive, such as a Whipple procedure, the minimally invasive approach is questionable[31]. This is also true for MIE. This review shows that, even with a minimally invasive approach, patients are not discharged earlier and the clinical consequences of intense internal aggression, such as systemic inflammatory response syndrome[32], are still noticed after MIE. For these reasons and for the

technical skills necessary to perform a MIE, it is not a disseminated and widely used approach for esophageal resection. Boone *et al*[33] have surveyed 269 surgeons, members of the International Society for Diseases of the Esophagus, the European Society of Esophagology Group, and the World Organization for Specialized Studies on Diseases of the Esophagus. They have found that MIE was the operation of choice for only 14% of the responders, while 60% of them never used the MIE approach. Similar results have been presented by Enestvedt *et al*[34]. Not surprisingly, they also have shown that MIE is performed more frequently by high-volume surgeons compared to those from low-volume centers.

The available literature on MIE is still crowded with heterogeneous studies with different techniques. As far as we are aware, there have been no controlled comparative trials, and the few retrospective comparative cohort studies have been limited by small numbers of patients and biased by historical controls of open surgery[22]. Moreover, few studies have included > 100 patients. Based on the available literature, there is no current evidence that MIE brings clear benefits compared to conventional esophagectomy. Growing experience and studies with larger numbers of patients could change this situation.

Abstract

AIM: To investigate the mechanisms of liver growth and atrophy after portal vein ligation (PVL) and its effects on tumor growth.

METHODS: Mice were subjected to PVL, partial hepatectomy, or sham surgery. The morphological alterations, activation of transcription factors, and expression of cytokines and growth factors involved in liver regeneration were evaluated. In a separate set of experiments, murine colorectal carcinoma cells were injected *via* the portal vein and the effect of each operation on liver tumor growth was studied.

RESULTS: Liver regeneration after PVL and partial hepatectomy were very similar. In ligated lobes, various cytokines, transcription factors and regulatory factors were significantly upregulated compared to non-ligated lobes after PVL. Atrophy in ligated lobes was a result of early necrosis followed by later apoptosis. Tumor growth was significantly accelerated in ligated compared to non-ligated lobes.

CONCLUSION: Tumor growth was accelerated in ligated liver lobes and appeared to be a result of increased growth factor expression.

Key words: Portal vein ligation; Tumor growth; Growth factor; Atrophy; Apoptosis

Portal vein ligation accelerates tumor growth in ligated, but not contralateral lobes. *World J Gastroenterol* 2010; 16(30): 3816-3826 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i30/3816.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i30.3816

INTRODUCTION

Liver resection is the standard treatment for patients with primary or secondary liver malignancies, and offers the only chance of long-term survival[1,2]. With advances in surgical techniques, perioperative management, and anatomical knowledge of the liver, major hepatectomy usually does not carry a high operative mortality in patients with normal hepatic function, or in those with large tumors, unless accompanied by technical failure. However, the morbidity and mortality after extensive hepatectomy, or major hepatectomy in patients with obstructive jaundice, hepatic dysfunction, or tumors increase due to postop-

erative liver failure caused by excessive loss of functional residual liver mass[3,4]. It has been reported that there is a strong correlation between the expected remnant liver volume and postoperative liver failure in patients who undergo liver resection[5]. Surgical resection of liver tumors requires a sufficient surgical margin that can lead to substantial loss of residual mass. However, it is essential to secure sufficient functional liver mass to prevent postoperative liver failure.

In 1920, Rous and Larimore showed that selective portal occlusion can produce atrophy of the occluded lobe and compensatory hypertrophy of the contralateral lobe in rabbits[6]. In the clinical setting, Makuuchi *et al*[7] first proposed portal vein embolization as a preoperative treatment to avoid postoperative liver failure due to insufficient remnant liver mass. Portal vein embolization is now widely accepted as a useful procedure to extend eligibility of patients with liver cancer for liver resection. However, one study has shown that some patients can become ineligible for scheduled surgery due to tumor progression after portal vein embolization[8], whereas another study has indicated that portal vein embolization neither prevents nor accelerates tumor growth[9]. Thus, the effect of portal vein embolization on tumor growth prior to resection is not well understood.

In the present study, we used a murine model of portal vein ligation (PVL) to determine the effects of ligation on the mechanisms of liver growth and regeneration. In addition, we evaluated how these mechanisms influence the growth of colorectal carcinoma tumors in ligated and contralateral lobes after PVL.

MATERIALS AND METHODS

Animal model

Male C57BL/6J and BALB/c mice (Jackson Laboratory, Bar Harbor, ME, USA) weighing 20-26 g were used in all experiments. This project was approved by the University of Cincinnati Animal Care and Use Committee and was in compliance with the National Institutes of Health guidelines. The C57BL/6J mice were randomly separated into a PVL group, partial hepatectomy group, and sham operation group. All mice were anesthetized with sodium pentobarbital (60 mg/kg, ip) and a midline laparotomy was performed. For PVL, the branch of the portal vein that fed the left and median hepatic lobes, which corresponded to 70% of the whole liver, was dissected under an operative microscope and ligated with an 8-0 PROLENE suture (Ethicon, Inc., Somerville, NJ, USA). Partial hepatectomy was performed according to the method of Higgins and Anderson[10], with slight modification. 7-0 PRONOVA sutures (Ethicon) were secured around the base of the left and median hepatic lobes, and the lobes were resected. Mice were sacrificed at the indicated time points after operation, and blood and liver samples were taken for analysis. The liver lobes to body weight ratio was determined.

Blood and tissue analysis

Blood was obtained by cardiac puncture for analysis of serum alanine aminotransferase (ALT) as an index of hepatocellular injury. Measurements of serum ALT were made using a diagnosis kit by bioassay (Wiener Laboratories, Rosario, Argentina). Liver tissues were fixed in 10% neutral-buffered formalin, processed, and embedded in paraffin for light microscopy. Sections were stained with hematoxylin and eosin (HE) for histological examination. Liver content of tumor necrosis factor-α (TNF-α), interleukin (IL)-6, IL-1β, hepatocyte growth factor (HGF), epidermal growth factor (EGF), transforming growth factor β1 (TGFβ1) was assessed by enzyme-linked immunosorbent assay (R&D Systems, Minneapolis, MN, USA). Liver samples were weighed and immediately placed in 10 volumes (wt/vol) of a protease inhibitor cocktail that contained 10 nmol/L EDTA, 2mmol/L phenylmethylsulfonyl fluoride (PMSF), 0.1 mg/mL soybean trypsin inhibitor, 1.0 mg/mL bovine serum albumin, and 0.002% sodium azide in isotonic PBS, pH 7.0. Tissues were disrupted with a tissue homogenizer, and lysates were incubated at 4℃ for 2 h. Samples were clarified by two rounds of centrifugation at 12 500 *g* for 10 min at 4℃.

Liver neutrophil accumulation

Liver myeloperoxidase (MPO) content was assessed by methods described elsewhere[11]. Liver tissue (100 mg) was homogenized in 2 mL buffer A (3.4 mmol/L KH_2HPO_4, 16 mmol/L Na_2HPO_4, pH 7.4). After being centrifuged for 20 min at 10 000 *g*, the pellet was resuspended in 10 volumes of buffer B (43.2 mmol/L KH_2HPO_4, 6.5 mmol/L Na_2HPO_4, 10 mmol/L EDTA, 0.5% hexadecyltrimethylammonium, pH 6.0) and sonicated for 10 s. After being heated for 2 h at 60℃, the supernatant was reacted with 3,3',3,5'-tetramethylbenzidine, and the optical density was read at 655 nm.

Proliferating cell nuclear antigen staining

Immunohistochemical staining for proliferating cell nuclear antigen (PCNA) was performed on paraffin-embedded liver tissue with anti-PCNA antibody using DakoCytomation ARK kit (Dako, Copenhagen, Denmark). A three-step peroxidase method was performed according to the manufacturer's instructions. PC-10 monoclonal antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA) was used at a dilution of 1:50, for 15 min at room temperature. The sections were counterstained with hematoxylin. Evaluation of PC-10 immunostaining was performed based on the percentage of positive nuclei of 400-600 hepatocytes from the 4-6 highest positive fields at high power (400 ×), and was expressed as PCNA labeling index.

Western blotting

Liver samples were homogenized in lysis buffer (10 mmol/L HEPES, pH 7.9, 150 mmol/L NaCl, 1 mmol/L EDTA, 0.6% NP-40, 0.5 mmol/L PMSF, 1 μg/mL leupeptin, 1 μg/mL aprotinin, 10 μg/mL soybean trypsin inhibitor, and 1 μg/mL pepstatin). Samples were then sonicated and incubated for 30 min on ice. Cellular debris was removed by centrifugation at 10 000 r/min. Protein concentrations

of each sample were determined. Samples that contained equal amounts of protein in equal volumes of sample buffer were separated in a denaturing 10% polyacrylamide gel and transferred to a 0.1-μm pore nitrocellulose membrane. Nonspecific binding sites were blocked with Tris-buffered saline (TBS; 40 mmol/L Tris, pH 7.6, 300 mmol/L NaCl) that contained 5% non-fat dry milk for 1 h at room temperature. Membranes were then incubated with antibodies to cyclin D1 (Santa Cruz Biotechnology), signal transducer and activator of transcription 3 (STAT3) (Cell Signaling Technology, Boston, MA, USA), and phosphorylated STAT3 (Cell Signaling Technology) in TBS with 0.1% Tween 20. Membranes were washed and incubated with secondary antibodies conjugated to horseradish peroxidase. Immunoreactive proteins were detected by enhanced chemiluminescence.

Electrophoretic mobility shift assay

Nuclear extracts of liver tissue were prepared by the method of Deryckere and Gannon[12], and analyzed by electrophoretic mobility shift assay. Double-stranded consensus oligonucleotides to nuclear factor (NF)-κB and activator protein (AP)-1 (Promega, Madison, WI, USA) were end-labeled with γ[^{32}P]-ATP (3000 Ci/mmol at 10 mCi/mL; Perkin Elmer, Waltham, MA, USA). Binding reactions (total volume 15 μL) that contained equal amounts of nuclear protein extract (20 μg) and 35 fmol (approximate 50 000 cpm, Cherenkov counting) of oligonucleotide were incubated at room temperature for 30 min. Binding reaction products were separated on a 4% polyacrylamide gel and analyzed by autoradiography.

Liver tumor model

The CT26 cell line is from an undifferentiated colon adenocarcinoma induced by N-nitroso-N-methylurethane injection in BALB/c mice. The CT26.WT cell line was obtained from American Type Culture Collection (ATCC; Rockville, MD, USA). CT26.WT cells were maintained in RPMI-1640 medium (ATCC) supplemented with 10% fetal bovine serum (FBS) and penicillin-streptomycin. Cells were incubated at 37℃ in a humidified atmosphere that contained 5% CO_2 in air. The cells were harvested from subconfluent cultures by 0.05% trypsinization and washed twice in PBS on the day of implantation. For the portal vein injection model, a midline incision was made and the portal vein was exposed by removing the intestine. A suspension of 2×10^5 CT26.WT cells was injected into the portal vein using a 31 G needle. After injection, a small piece of Gelfoam (Pharmacia Co., Kalamazoo, MI, USA) was pressed over the injection site for 2-3 min to obtain hemostasis. One week after tumor cell implantation, mice were subjected to portal vein ligation or sham surgery. One week after the operation, all mice were sacrificed and blood and liver samples were collected. The tumor growth was evaluated on HE slides and tumor area was determined by morphometry. Morphometric analysis was performed by image analysis software in five representative fields at low power (10 ×).

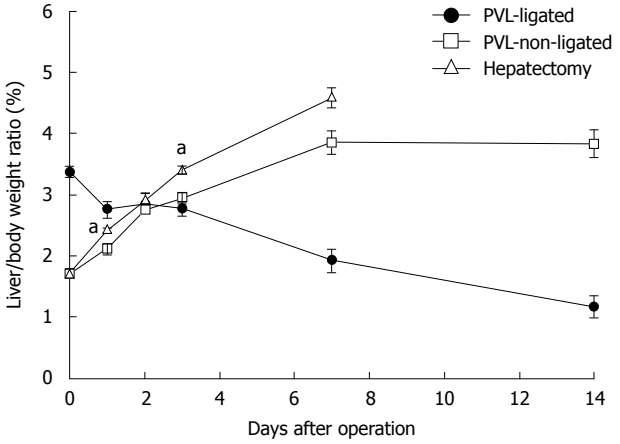

Figure 1 Changes in liver lobe to body weight ratio after portal vein ligation or partial hepatectomy. To evaluate liver regeneration after portal vein ligation (PVL) or partial hepatectomy, liver lobe to body weight ratio was determined. Data are mean ± SE with n = 4-6 per group. $^aP < 0.05$ *vs* PVL-non-ligated.

Statistical analysis

All data are expressed as mean ± SE. Data were analyzed with one-way analysis of variance with subsequent Student-Newman-Keuls test. Differences were considered significant when $P < 0.05$.

RESULTS

Liver growth and regeneration after PVL vs partial hepatectomy

To evaluate liver growth and regeneration after PVL or partial hepatectomy, we measured liver/body weight ratios. After partial hepatectomy, liver regenerated at the expected rate and returned to normal liver mass within 7 d (Figure 1). After PVL, non-ligated lobes grew at a rate similar to liver after partial hepatectomy, but reached a plateau of mass below that after partial hepatectomy (Figure 1). The ligated lobes atrophied at a constant rate and after 14 d, the mass of the ligated lobes was approximately one third of the starting mass (Figure 1).

In accordance with the changes in liver growth and regeneration, similar patterns were found when we examined hepatocyte proliferation by staining for PCNA. PCNA-positive hepatocytes increased in a similar fashion after partial hepatectomy and in non-ligated lobes after PVL (Figure 2). However, there were subtle differences noted. While the number of PCNA-positive hepatocytes was maximal in both partial hepatectomy and non-ligated lobes after PVL at 2 d after surgery, there were significantly more PCNA-positive hepatocytes in the partial hepatectomy group (Figure 2). Furthermore, the number of PCNA-positive hepatocytes dropped dramatically by day 3 after partial hepatectomy, whereas after PVL, the number of PCNA-positive hepatocytes in non-ligated lobes had a more gradual decrease and was significantly higher compared to that after partial hepatectomy (Figure 2). Despite these minor differences, our data confirm previous studies that the mechanisms of liver growth and regeneration are

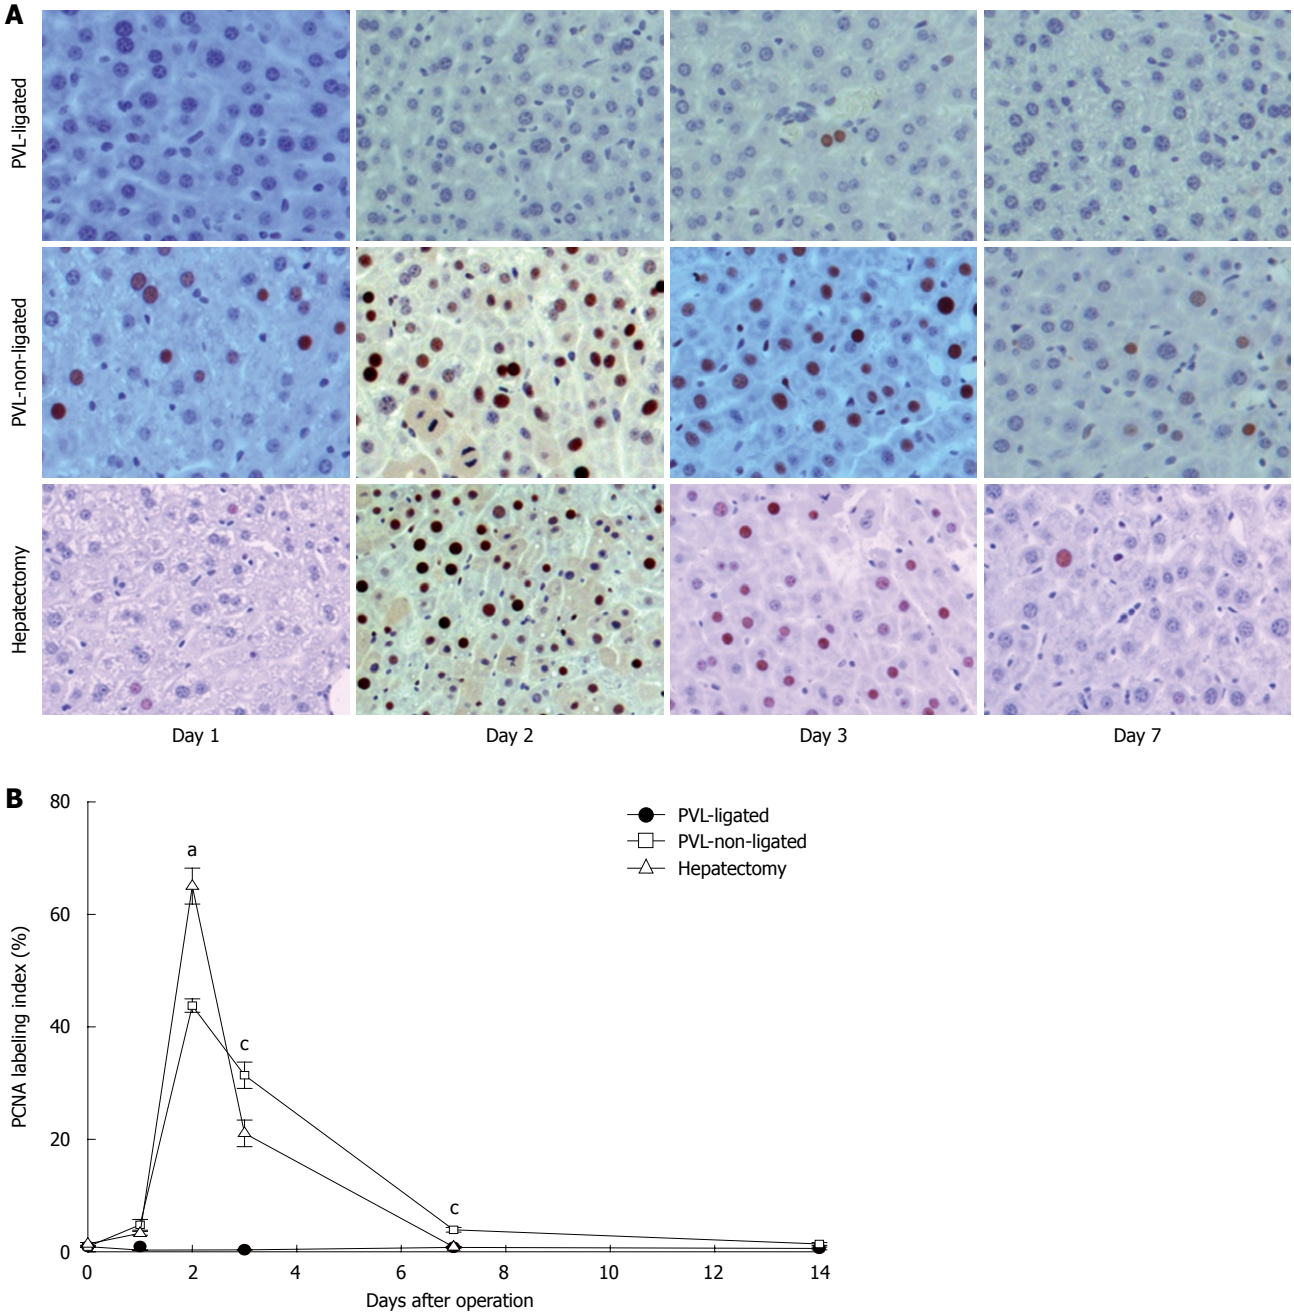

Figure 2 Hepatocyte proliferation after portal vein ligation. A: Hepatocyte proliferation was determined by immunohistochemical staining for proliferating cell nuclear antigen (PCNA). Original magnification was 200 ×; B: Quantitative analysis of PCNA labeling. PCNA labeling index was expressed as percentage of positive nuclei of 400-600 hepatocytes from the 4-6 highest positive fields at high power (400 ×). Data are mean ± SE with n = 4-6 per group. $^{a}P < 0.05$ *vs* PVL-non-ligated; $^{c}P < 0.05$ *vs* partial hepatectomy.

similar between that occurring in non-ligated lobes after PVL and that occurring after partial hepatectomy[13].

We next examined the mode of cell death after PVL. Serum levels of ALT were assessed as a measure of hepatocyte necrosis and TUNEL staining was performed to determine the amount of hepatocyte apoptosis. Serum levels of ALT peaked 1 d after PVL, but remained elevated for 14 d (Figure 3A). Corresponding with the ALT data, ligated lobes showed areas of necrosis within 1 d after PVL (Figure 3B, upper panels). These regions persisted for up to 7 d after PVL and were undetectable by day 14. In contrast, significant hepatocyte apoptosis was detected in ligated lobes, beginning at 7 d after PVL and persisting until 14 d after PVL (Figure 3B, lower panels). In non-ligated lobes, no evidence of hepatocyte necrosis or apoptosis was observed (data not shown).

Lobar differences in cytokine and growth factor expression after PVL

A variety of cytokines and growth factors are known to modulate liver growth and regeneration. To evaluate whether expression of relevant cytokines and growth factors is related to the growth of non-ligated lobes and/or the atrophy of ligated lobes, we measured the protein

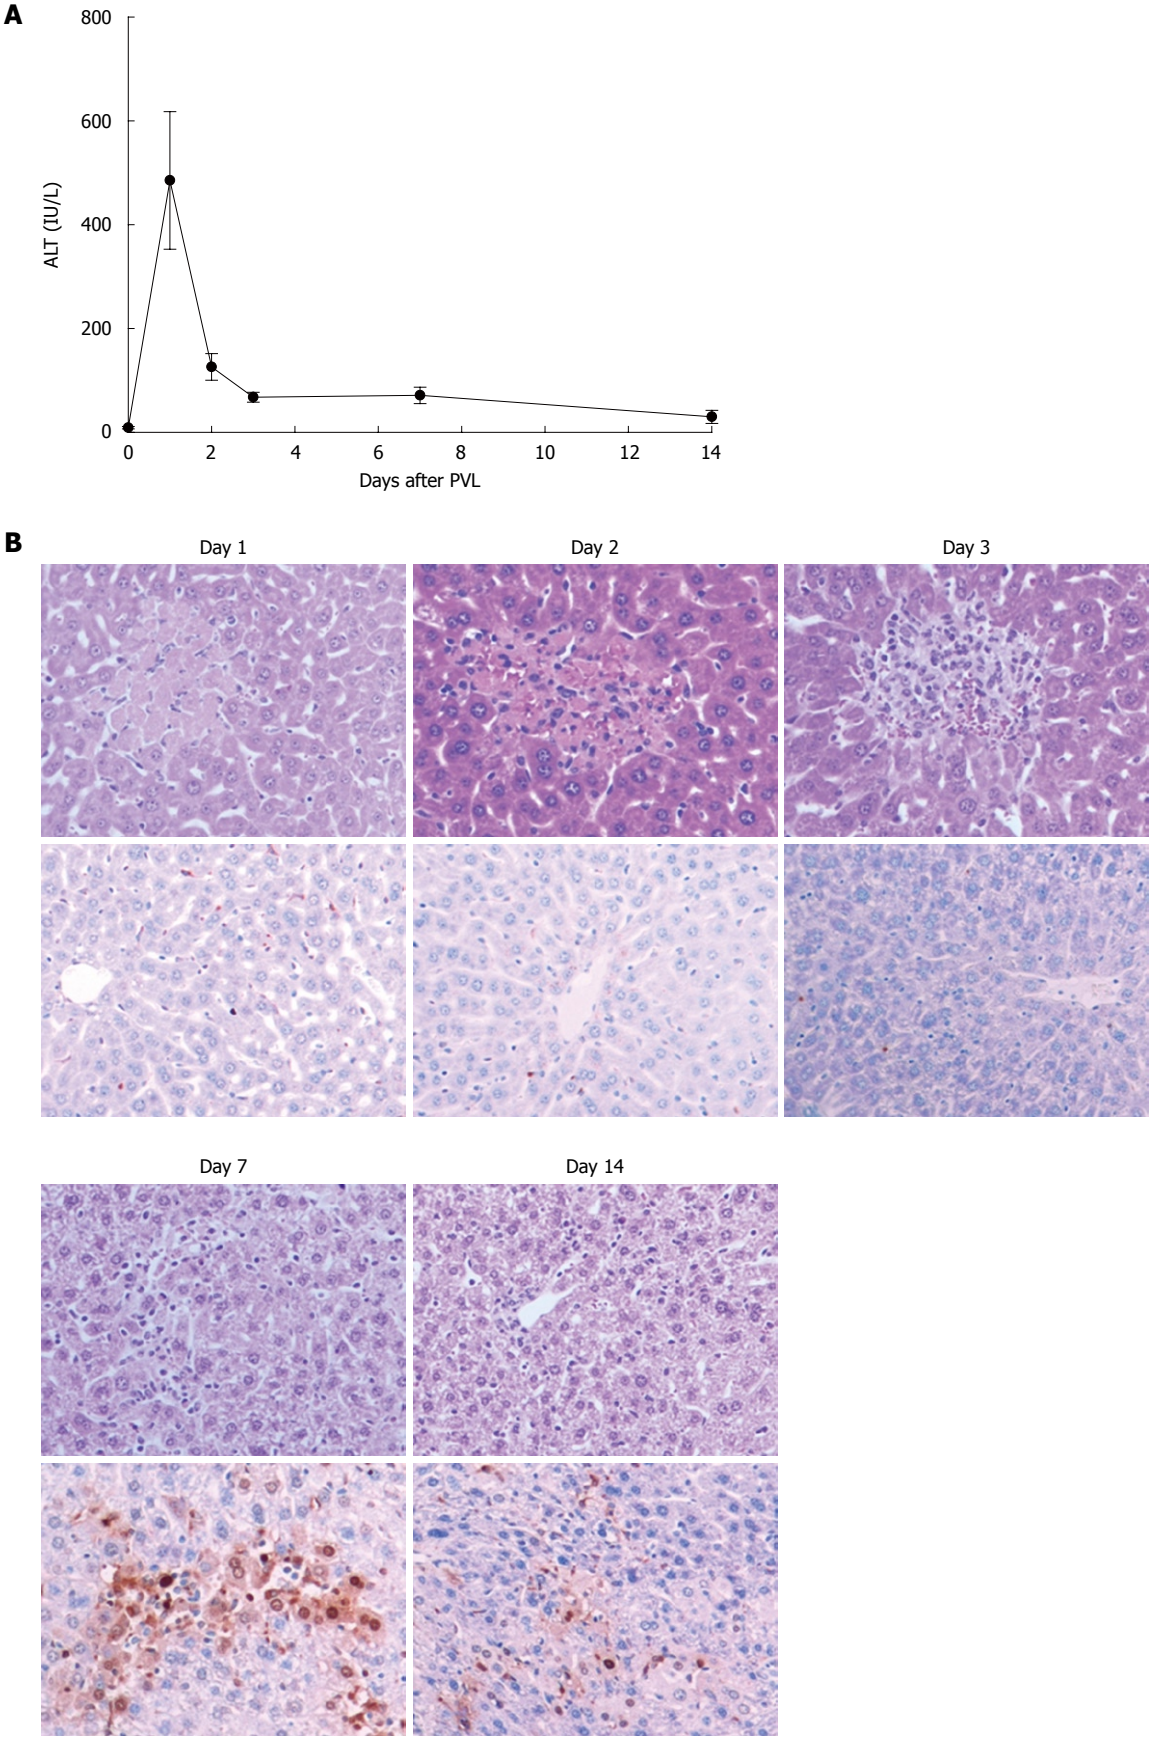

Figure 3 Effects of portal vein ligation on liver necrosis and apoptosis. A: Liver injury was measured by serum levels of alanine aminotransferase (ALT). Data are mean ± SE with n = 4-6 per group; B: Representative pictures of HE staining (upper) and TUNEL staining (bottom). TUNEL staining was performed to determine the amount of hepatocyte apoptosis. Original magnification was 200 ×. PVL: Portal vein ligation.

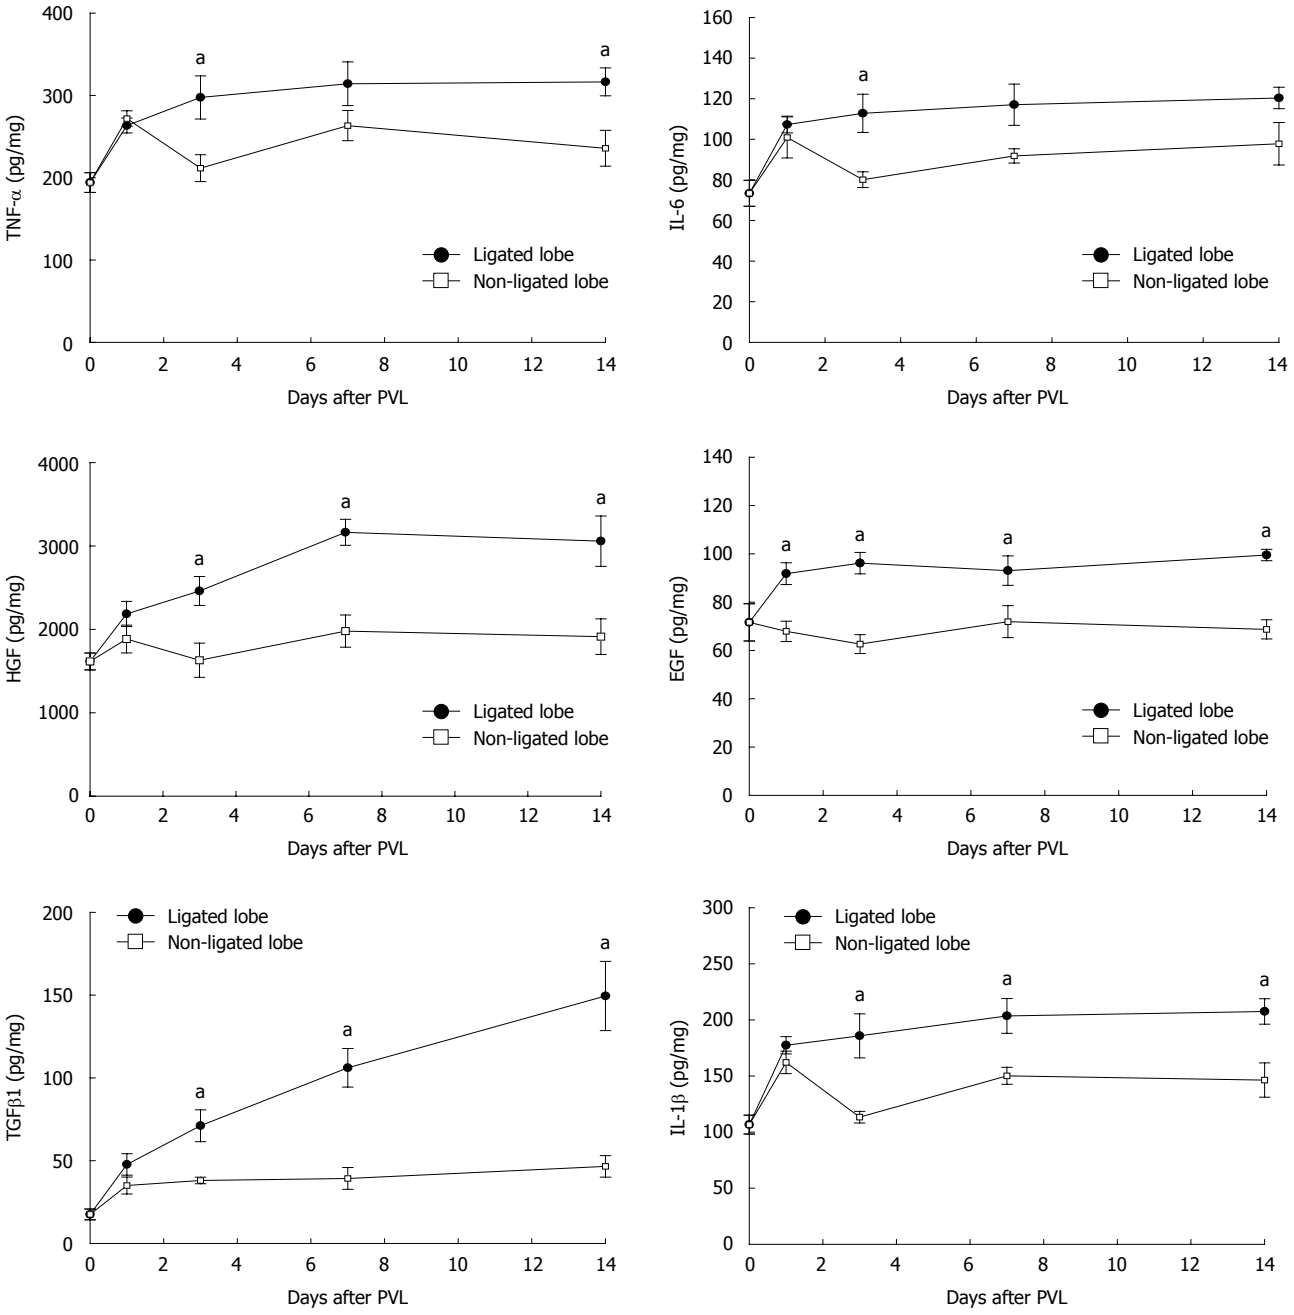

Figure 4 Effect of portal vein ligation on liver cytokines, growth factors, and chemokines. To evaluate whether expression of relevant cytokines and growth factors are related to the growth of non-ligated lobes and/or the atrophy of ligated lobes, liver levels of tumor necrosis factor-α (TNF-α), interleukin (IL)-6, hepatocyte growth factor (HGF), epidermal growth factor (EGF), transforming growth factor β1 (TGFβ1), and IL-1β were analyzed by enzyme-linked immunosorbent assay (ELISA). Liver lysates were processed for ELISA. Data are mean ± SE with n = 4-15 per group. $^{a}P < 0.05$ *vs* portal vein ligation (PVL)-non-ligated.

levels of HGF, EGF, TNF-α, IL-6, TGFβ1, and IL-1β in liver tissues. HGF and EGF are direct mitogens for hepatocytes and are crucial inducers of liver regeneration[14-16]. Expression of HGF and EGF were increased in both ligated and non-ligated lobes after PVL (Figure 4). However, expression of these mediators was much higher in ligated lobes compared to non-ligated lobes. TNF-α and IL-6 have been implicated as important contributors to liver growth and regeneration[14-16]. Expression of TNF-α and IL-6 increased similarly at 1 d after PVL in ligated and non-ligated lobes (Figure 4). By day 3, expression of TNF-α and IL-6 was significantly higher in ligated lobes compared to non-ligated lobes. TGFβ1 and IL-1β are known as suppressors of cell proliferation and might be involved in termination of liver regeneration[15,17]. We found that expression of TGFβ1 and IL-1β was increased 1 d after PVL in both ligated and non-ligated lobes (Figure 4). However, by day 3, expression of TGFβ1 had reached a plateau and IL-1β decreased in non-ligated lobes, whereas their expression had increased further in ligated lobes.

Divergent signaling mechanisms in ligated and non-ligated lobes after PVL

NF-κB, AP-1 and STAT3 are known to be important mediators of liver growth and regeneration[18,19], therefore,

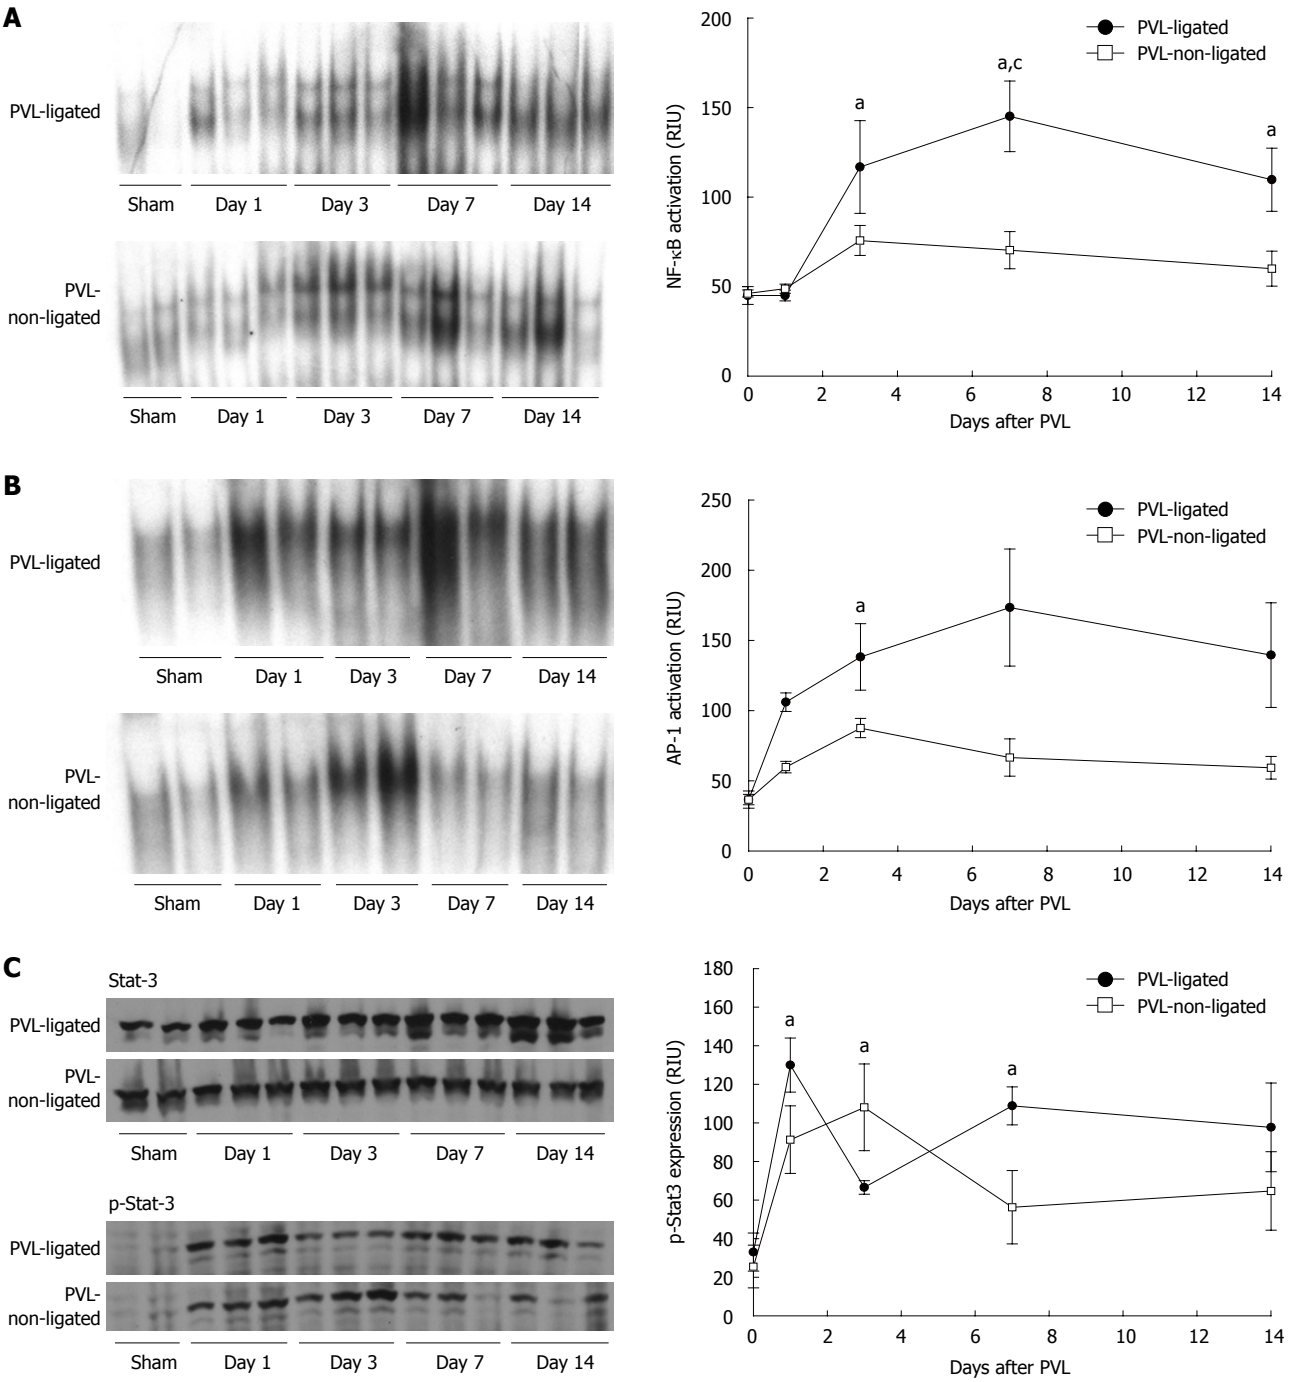

Figure 5 Transcription factor activation after portal vein ligation. Nuclear factor (NF)-κB (A), activator protein (AP)-1 (B) and signal transducer and activator of transcription 3 (STAT3) (C) were examined in liver extracts. For NF-κB and AP-1, liver nuclear extracts were analyzed by electrophoretic mobility shift assay. For STAT3, liver lysates were assessed by Western blotting. Results were quantitated by image analysis of autoradiograms and chemiluminescence films. Data are mean ± SE with $n = 4$ per group. A: $^{a}P < 0.05$ *vs* sham-operated group; $^{c}P < 0.05$ *vs* portal vein ligation (PVL)-non-ligated group; B: $^{a}P < 0.05$ *vs* PVL-non-ligated group; C: $^{a}P < 0.05$ *vs* sham-operated group.

we assessed the activation of these transcription factors in ligated and non-ligated lobes after PVL. NF-κB activation increased in both ligated and non-ligated lobes by day 3 after PVL; however, it was much greater in ligated lobes (Figure 5A). In non-ligated lobes, NF-κB activation remained elevated, albeit modestly, throughout the 14-d experimental period (Figure 5A). In contrast, activation of NF-κB in ligated lobes increased further, and remained significantly higher than in non-ligated lobes (Figure 5A). Supershift assays of NF-κB from each lobe indicated that the composition was composed primarily of p50/p65 heterodimers (data not shown).

In contrast to NF-κB, which did not become activated until 3 d after surgery, AP-1 activation occurred rapidly after PVL in both ligated and non-ligated lobes (Figure 5B). In non-ligated lobes, activation of AP-1 was increased modestly throughout the 14-d experiment. Similar to NF-κB, activation of AP-1 was much greater in the ligated

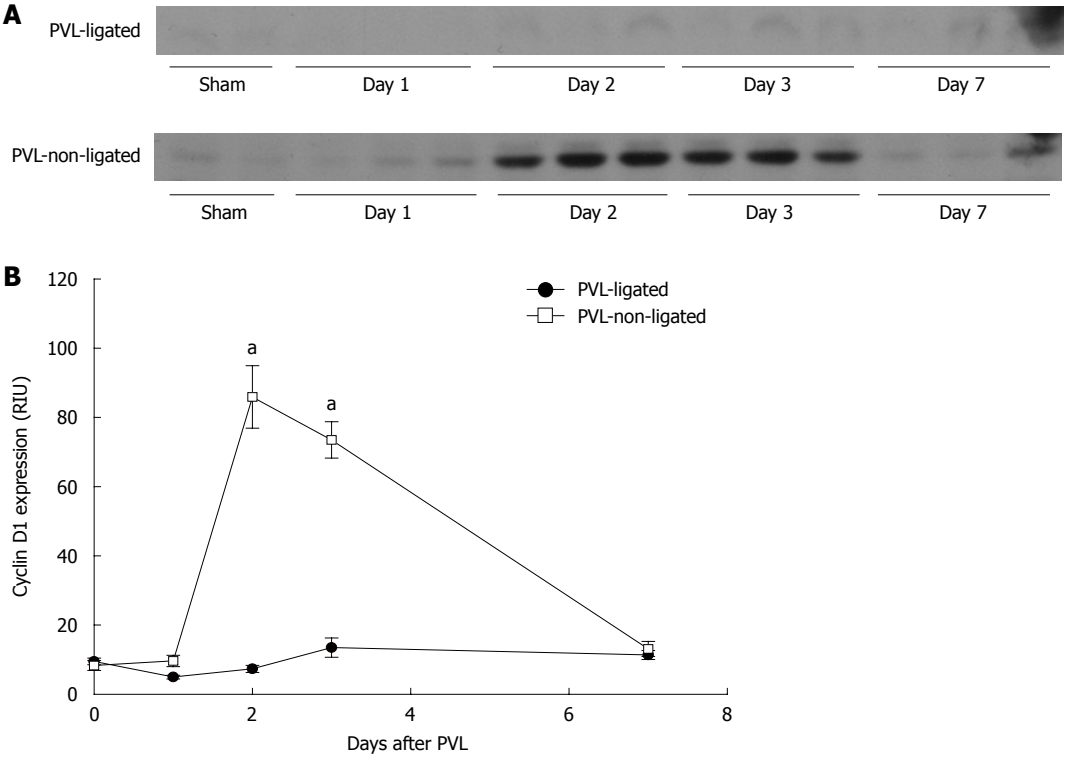

Figure 6 Liver cyclin D1 expression after portal vein ligation. A: Liver lysates were assessed for cyclin D1 protein expression by Western blotting; B: Chemiluminescence films were quantitated by image analysis. Data are mean ± SE with $n = 4$ per group. $^{a}P < 0.05$ *vs* portal vein ligation (PVL)-ligated group.

lobes compared to non-ligated lobes at every time point (Figure 5B). Supershift assays determined that the composition of AP-1 was similar in each lobe, primarily c-Fos, JunB, and JunD (data not shown).

STAT3 activation, as determined by STAT3 phosphorylation, was rapidly increased in both ligated and non-ligated lobes after PVL (Figure 5C). Interestingly, STAT3 activation decreased in ligated lobes at day 3 and then increased at days 7 and 14. In contrast, STAT3 activation in non-ligated lobes peaked at day 3 and then decreased at days 7 and 14.

Cyclin D1 is known to play a crucial role in the control of hepatocyte proliferation from G1- to S-phase[16,20,21]. Expression of cyclin D1 in non-ligated lobes was significantly increased after PVL, whereas there was no induction of cyclin D1 expression in ligated lobes (Figure 6).

PVL accelerates tumor growth in ligated, but not in non-ligated lobes

To investigate how the different milieus in ligated *vs* non-ligated lobes might alter the growth of liver tumors, mice were injected *via* the portal vein with murine colorectal carcinoma cells 7 d prior to PVL or sham surgery. We used murine colorectal carcinoma cells, CT26.WT, to reproduce the nature of colorectal liver metastases by injecting the cells into the portal vein. In sham-operated mice, there were similar amounts of small tumors in lobes that corresponded to ligated and non-ligated lobes (Figure 7A and B). In mice undergoing PVL, ligated lobes had large tumor nodules that were clearly visible on gross examination as well as histologically (Figure 7A and B). Quantitation of tumor area in liver sections demonstrated a four-fold increase in relative tumor size in ligated lobes *vs* non-ligated lobes (Figure 7C).

DISCUSSION

In the current study, we evaluated the effects of PVL on expression of cytokines and growth factors and signaling pathways that are known to contribute to liver growth and regeneration. Although the trigger for growth of contralateral lobes after PVL has not been fully elucidated, hemodynamic changes after PVL have been proposed as an initial event that contributes to this process[22]. Following PVL, arterial blood flow to the ligated lobe roughly doubles, while arterial blood flow to the non-ligated lobes is roughly 60% of normal[22]. Portal flow to the non-ligated lobes, however, more than doubles[22] and this increase in supply helps trigger growth mechanisms in the non-ligated lobes[23]. Hemodynamic changes are more drastic after partial hepatectomy because both arterial and portal flows to the remnant liver are increased. The difference in hemodynamic changes between PVL and partial hepatectomy could affect the degree and/or timing of expression of some proteins involved in regeneration[13,24] and cause a slight delay of regeneration in the non-ligated lobes. However, the gross regenerative responses are similar, as shown by our data.

Some studies have shown that the early growth/regenerative response, including activation of NF-κB, STAT3, IL-6, c-fos, c-myc, and c-jun, are similarly induced in both ligated and non-ligated lobes[18]. Other studies have shown

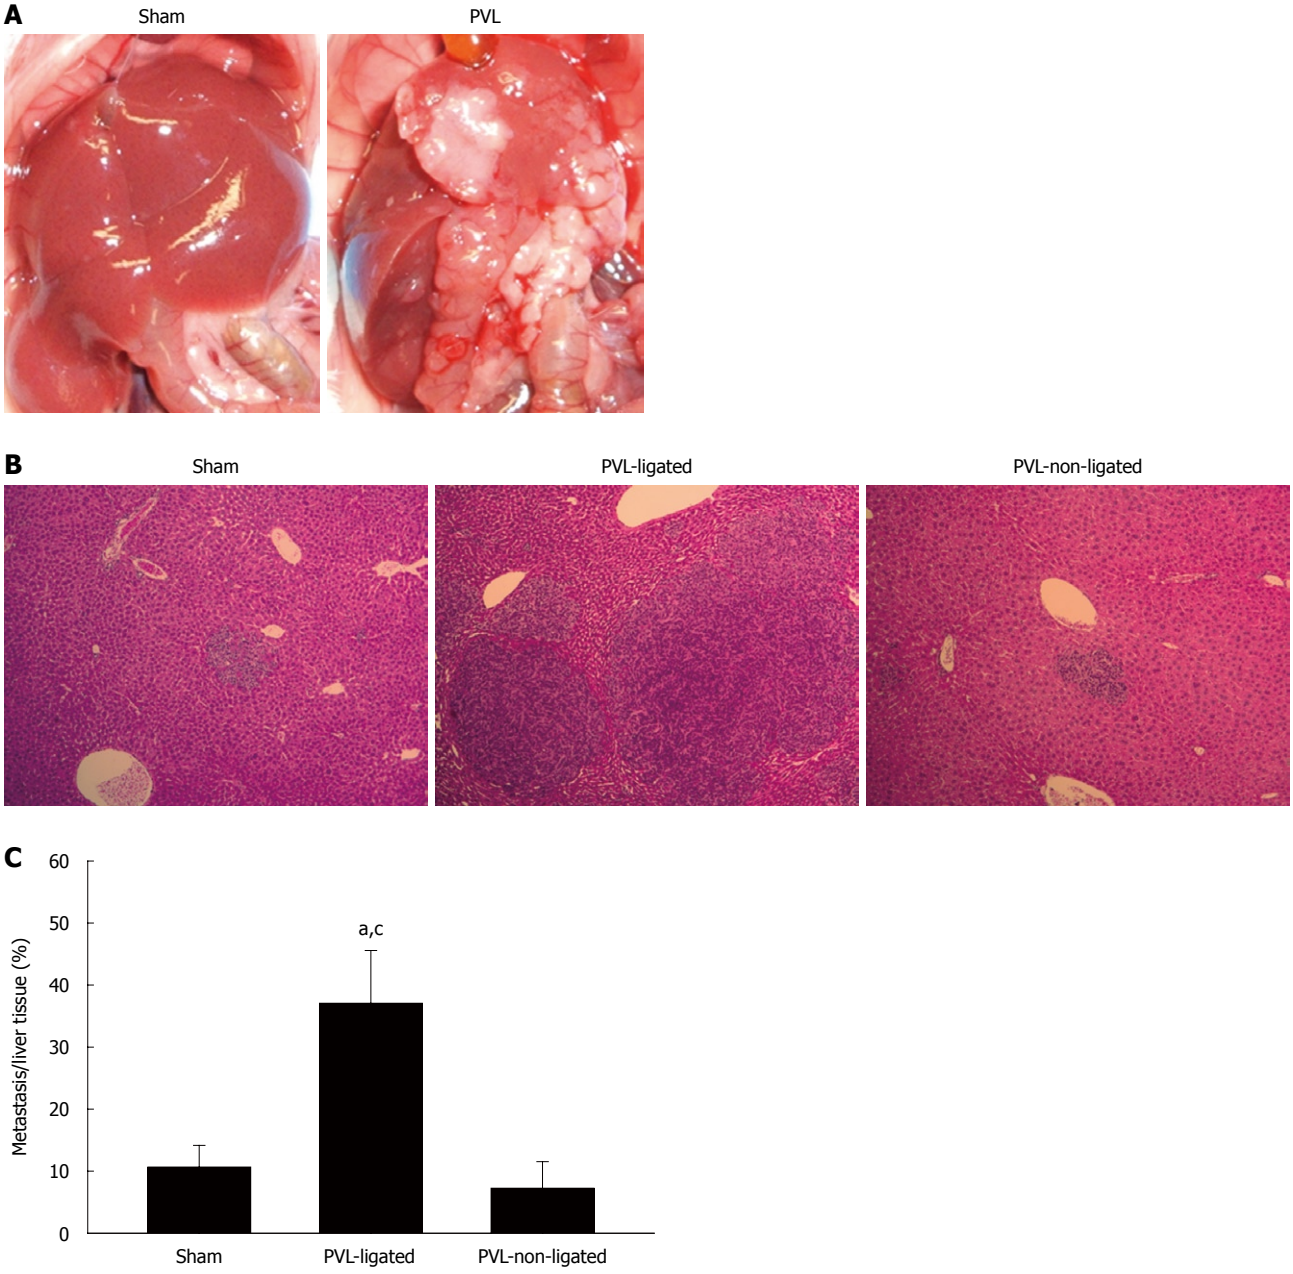

Figure 7 Effect of portal vein ligation on tumor growth. A: CT26.WT cells were injected into portal the vein. Mice were sacrificed at 14 d after injection following sham operation or portal vein ligation (PVL) performed on day 7 after injection; B: Representative pictures of liver histology after PVL. Small metastatic foci were observed in sham-operated and non-ligated lobes. Large metastatic foci were observed in ligated lobes. Original magnification was 10 ×; C: The ratio of metastases to normal liver was measured by morphometry. Data are mean ± SE with $n = 4$ per group. $^{a}P < 0.05$ *vs* sham-operated group; $^{c}P < 0.05$ *vs* PVL-non-ligated group.

differences in growth factor mRNA expression between ligated and non-ligated lobes[25]. Our data demonstrate that these growth and regenerative mechanisms are greatly increased in both ligated and non-ligated lobes, but are significantly greater in the ligated compared to non-ligated lobes. Cyclin D1 is the sole exception, being induced only in the non-ligated lobes. Cyclin D1 is known to play a crucial role in the control of hepatocyte proliferation from G1- to S-phase[20,21], and appears to be the determinant of proliferation or atrophy in non-ligated and ligated lobes, respectively.

The milieu in the ligated lobe, with greatly increased expression of cytokines and growth factors and increased activation of NF-κB and AP-1, is rather chaotic and not indicative of either a "survival" or "death" mode. TNF-α can function to promote hepatocyte proliferation or death, depending on the co-stimuli present[26-28]. NF-κB activation in hepatocytes is pro-survival and anti-apoptotic[29,30], whereas activation of AP-1 promotes hepatocellular injury and apoptosis[31]. The fate of the ligated lobe might be less dependent upon the changes in these factors, and more on the lack of nutrient and oxygen delivery. As is clear, the end result is atrophy of the ligated lobe through necrotic and apoptotic mechanisms. Despite this atrophy and the pro-hepatocyte death milieu, colorectal carcinoma metastases grew much faster in the ligated lobes compared to the non-ligated lobes after PVL. These findings are consistent with other studies

that have shown increased tumor growth in the ligated lobes after PVL[32,33]. However, our study offers more insight into the potential mechanisms that contribute to the increased tumor growth, as our data provide important information about the expression of growth factors and signaling pathways. HGF and EGF have a stimulatory effect on tumor cells[34,35], and therefore, the increased HGF and EGF observed in the ligated lobe after PVL could explain the accelerated tumor growth. TGFβ1 was also increased in the ligated lobe. Although TGFβ1 is generally known as a negative regulator in liver regeneration[15], some recent studies have reported a tumor promoter role for TGFβ1 in hepatocellular carcinoma and liver metastasis[36-38]. It has been shown that TGFβ1 is highly proliferative in CT26 cells, the colorectal carcinoma cell line used in our studies[39]. Furthermore, TGFβ1 is known to contribute to hepatocyte apoptosis, and colorectal carcinoma cells secrete significant amounts of TGFβ1, which might contribute to tumor growth[39,40]. Therefore, it is plausible that increased TGFβ1 expression in the ligated lobes significantly contributed to the accelerated growth of colorectal carcinoma tumors after PVL.

In summary, the present study demonstrated the signaling pathways that were activated in ligated and non-ligated lobes after PVL. Both lobes had increased expression of pro-proliferative cytokines and growth factors, as well as activation of pro-regenerative transcription factors, which help to define the molecular events that contribute to growth of contralateral lobes. Ligated liver lobes had significant increases in proliferative cytokines, growth factors and transcription factors compared to non-ligated lobes. While this response might constitute a survival mode for the hepatic parenchyma, it appears to provide an environment that facilitates tumor growth. PVL is a proven modality for increasing the functional liver remnant and extending the indications for surgery for metastatic liver disease. Future studies are needed to assess the effects of adjuvant or neoadjuvant chemotherapy on the hepatic expression of growth factors and tumor growth rate in this model.

COMMENTS

Background

Liver resection is the standard treatment for patients with primary or secondary liver malignancies, and offers the only chance of long-term survival. Although, the outcome of hepatic resection is improving, postoperative liver failure that results from insufficient functional liver volume after surgery could be lethal. Portal vein embolization is now widely accepted as a useful procedure to increase remnant liver volume and extend eligibility of patients with liver cancer for liver resection.

Research frontiers

Portal vein embolization is well known to induce hypertrophy of contralateral lobes. However, the manner in which portal vein embolization alters growth of the contralateral lobes and atrophy of the embolized lobe(s) is incompletely understood. Moreover, the effect of portal vein embolization on tumor growth is controversial.

Innovations and breakthroughs

In the current study, the authors demonstrated that various cytokines, transcription factors and regulatory factors were significantly upregulated in ligated lobes compared to non-ligated lobes after portal vein ligation. Tumor growth was accelerated in the ligated compared to non-ligated lobes and appeared to be a result of increased growth factor expression.

Applications

The results provide strong evidence of accelerated tumor growth in ligated lobes. This should be taken into account for the treatment strategy when patients undergo portal vein embolization.

Peer review

The experiments were well designed and well conducted. The topic relates to the advantages and/or disadvantages of the surgical procedure of portal vein embolization prior to major liver resections for hepatocellular carcinoma or other liver cancers.

Abstract

AIM: To investigate the number of intestinal immunoglobulin A (IgA+) plasma cells and expression of intestinal IgA in mice with acute liver necrosis.

METHODS: A model of acute liver necrosis was established by intraperitoneal injection of galactosamine (GalN) and lipopolysaccharide (LPS). Sixty mice were randomly divided into one of 4 equal groups: normal control, acute liver necrosis, LPS, or GalN. Hematoxylin and eosin staining, immunohistochemistry, and an enzyme-linked immunosorbent assay were employed to assess liver and intestinal injury, count intestinal IgA+ plasma cells, and measure the expression level of IgA and interferon γ (IFN-γ) in the small intestinal mucosa of mice.

RESULTS: Injured intestinal mucosa was observed in the acute liver necrosis group but not in the normal, LPS or GalN groups. Compared with the normal group, intestinal IgA+ plasma cells were slightly decreased in the LPS and GalN groups [429 ± 20 per high power field (HPF), 406 ± 18/HPF, respectively], whereas they were markedly decreased in the acute liver necrosis group (282 ± 17/HPF *vs* 495 ± 26/HPF in normal group, $P < 0.05$). The expression of intestinal IgA was also slightly decreased in LPS and GalN groups, but was markedly reduced in the acute liver necrosis group as determined by enzyme-linked immunosorbent assay ($P < 0.05$). In contrast, the level of IFN-γ was slightly increased in LPS, GalN and acute liver necrosis groups, but with no statistical significance ($P > 0.05$).

CONCLUSION: Intestinal IgA+ plasma cells and IgA expression levels indicating that mucosal immune barrier dysfunction, does exist in acute liver necrosis.

Key words: Acute liver necrosis; Intestinal mucosa; Immunity; Immunoglobulin A

INTRODUCTION

Patients with acute liver necrosis are at high risk for enterogenic infections. Enterogenic infections are an important cause of death in patients with acute liver

necrosis associated with intestinal barrier injury, including immunological barrier injury[1,2]. Immunoglobulin A (IgA) is an important component of the intestinal immunological barrier and is the most abundant immunoglobulin at mucosal surfaces where it plays crucial roles in mucosal protection[3]. The protective barrier of the gastrointestinal system is impaired in IgA deficiencies, and IgA-deficient individuals have a tendency to develop gastrointestinal infections[4]. Previous studies have shown decreased levels of secretory IgA and decreased numbers of IgA+ plasma cells in the intestinal tract during stress and thermal injury suggesting that the humoral immune function was dramatically inhibited in these situations[5,6]. Intestinal IgA was also decreased in endotoxemia and intra-abdominal sepsis models[7,8].

Previous studies have primarily focused on mechanical barrier interruption in acute liver necrosis models[9]. So far, no studies have shown a role for the intestinal immunological barrier in acute liver necrosis. It has been reported that an increase in levels of interferon γ (IFN-γ), a TH1 cytokine, was related to tissue injury[10] and led to a decreased expression of IgA[11].

This study set out to determine whether the number of intestinal IgA+ plasma cells and the expression of IgA were modified in mice with acute liver necrosis, in an attempt to establish whether dysfunction of the intestinal immunological barrier occurs during acute liver necrosis. In addition, IFN-γ levels in the intestinal mucosa were also evaluated.

MATERIALS AND METHODS

Animals

Sixty male BALB/c mice 6-8 wk of age (provided by the Laboratory Animal Center of the China Medical University) were housed under constant room temperature and humidity, and subjected to a 12 h light/dark cycle. Experiments were conducted in accordance with the Guiding Principles for the Care and Use of Laboratory Animals. Mice were equally and randomly divided into one of 4 groups: normal control, acute liver necrosis, lipopolysaccharide (LPS), or galactosamine (GalN). GalN (800 mg/kg body weight, Sigma, USA) and LPS (10 μg/kg body weight, Sigma, USA) were injected intraperitoneally to induce acute liver necrosis as previously described[12,13]. Serum, liver and proximal small intestinal tissues samples were obtained 9 h after GalN/LPS injection.

Blood biochemistry assay

Serum alanine transaminase (ALT) levels were determined using an automatic analyzer (Hitachi 7250; Hitachi, Japan).

Histological testing

The liver and proximal small intestinal tissue were separately stored in formalin, and embedded by paraffin. The liver and intestinal sections were cut at a thickness of 5 μm and stained with hematoxylin and eosin (HE) to explore the histopathological changes in the liver and intestinal mucosa.

Immunohistochemistry for intestinal IgA+ plasma cells

Intestinal IgA+ plasma cells were investigated by immunohistochemistry (IHC). Sections of proximal small intestine were deparaffined, and antigen retrieval was performed by pressure cooker boiling for 2 min in 10 mmol/L citrate buffer (pH 6.0). IHC analysis was performed using goat anti-mouse IgA (Zymed, USA, diluted 1:50) for 12 h at 4℃, and the secondary antibody (rabbit anti-goat IgG) was applied for 2 h at 37℃. Fresh peroxidase reaction mixture containing equal amounts of 0.02% hydrogen peroxide in H_2O and 0.1% diaminobenzidine in H_2O were prepared. Sections were mounted on Uvinert mountant (BDH, UK). Five fields of small intestinal mucosa lamina propria were examined in each section at high magnification (200 ×), and the number of IgA+ cells were counted (i.e. lymphocytes that stained a brownish-yellow color). The average number of IgA+ was calculated.

Enzyme-linked immunosorbent assay for IgA expression

The levels of intestinal IgA were examined by enzyme-linked immunosorbent assay (ELISA). Intestinal tissue (50 mol/Lg) immersed in 1 mL (10 volumes, w/v) of phosphate-buffered saline (PBS) was incubated at room temperature for 15 min. Samples were vortexed, left to settle for 15 min, revortexed until all material was suspended, then centrifuged at 12000 r/min for 10 min. The supernatant was collected and tested on an ELISA kit for IgA (Bethyl Laboratories, Montgomery, TX, USA). Briefly, 96-well microtiter plates were coated with goat anti-mouse IgA affinity purified antibody and incubated for 60 min, then washed with PBS, and each well was incubated with 1% bovine serum albumin in PBS to block any nonspecific binding. After washing with PBS containing 0.1% Tween-20, 100 μL test samples and 100 mol/L standards were added into each well and incubated for 60 min followed by incubation with peroxidase-labeled goat anti-mouse specific IgA antibody for 30 min. Then 0.1 mol/L acetate buffer containing 1 mg/mL ortho-phenylenediamine was prepared and 3 μL of the prepared solution in 10 mL of H_2O_2 was added to each well. The reactions were stopped by adding 25 μL of 2 mol/L sulfuric acid. The absorbance of each solution was determined at a wavelength of 450 nm.

Detection of IFN-γ in the intestinal mucosa

The small intestinal mucosa homogenate was prepared as described previously[8]. The levels of IFN-γ in the homogenate were measured by sandwich ELISA (Quantikine ELISA Kits, R&D Systems, Minneapolis, MN, USA) according to the manufacturer's instructions.

Statistical analysis

Software SPSS 11.0 was used for statistical analysis. Each value was expressed as the mean ± SE, and compared by using one-way ANOVA, followed by the Tukey test. $P < 0.05$ was considered statistically significant.

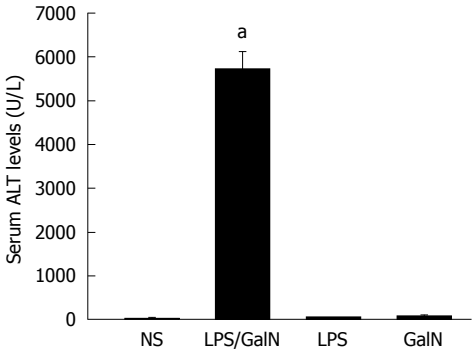

Figure 1 Serum alanine transaminase levels. Each value was expressed as mean ± SE. [a]$P < 0.05$ *vs* normal saline (NS). ALT: Alanine transaminase; GalN: Galactosamine; LPS: Lipopolysaccharide.

RESULTS

Mortality rate of mice and serum ALT levels

In the acute liver necrosis group, the mortality rate was 53.3% (8/15), compared to 0% in the other control groups. The serum ALT levels in LPS, GalN and normal groups were almost at the same level (44.3 ± 12.1, 74.2 ± 14.3, and 24.8 ± 14.7 U/L, respectively), but increased significantly in the acute liver necrosis group (5730.1 ± 383.5 U/L *vs* 24.8 ± 14.7 U/L, $P < 0.05$) (Figure 1).

Assessment of liver and proximal small intestinal injury with HE staining

In the normal group, the liver clearly showed normal structure of both the hepatic lobuli and hepatic cords. In contrast, the livers from the acute necrosis group had severe hemorrhage, hepatic necrosis, acidophilic degeneration in some residual hepatocytes, disappearance of hepatic cords, and deranged structure of hepatic lobules. Acidophilic degeneration and swelling were observed in the LPS group and edematous and spotty necrosis, as well as a few hepatic cells with acidophilic changes were found in the GalN group (Figure 2).

In normal, LPS and GalN groups, the intestinal mucosa was complete and the intestinal cells appeared ordered. In contrast, the intestinal mucosa of mice with acute liver necrosis were loosened and some of epithelial cells were edematous and necrotic (Figure 3).

IHC for IgA+ plasma cells

As shown in Figure 4, the number of IgA+ plasma cells within the lamina propria (as determined by IHC) were 495 ± 26/high power field (HPF), 282 ± 17/HPF, 429 ± 20/HPF and 406 ± 18/HPF in the normal, acute liver necrosis, LPS and GalN groups, respectively. The LPS group and GalN group had slightly lower numbers of IgA+ plasma cells than the normal group; however, the acute liver necrosis group had significantly lower numbers of IgA+ plasma cells compared to the other groups ($P < 0.05$, Figure 5A).

ELISA measurement of IgA

There was a slight decrease in the expression of IgA in LPS and GalN groups whereas no difference was noted in IgA expression in the small intestine compared with normal control. IgA expression in the small intestines from mice in the acute liver necrosis group was markedly reduced compared with the normal group ($P < 0.05$, Figure 5B).

IFN-γ in small intestinal mucosa

There were a slight increase in IFN-γ levels in LPS, GalN and acute liver necrosis groups, but no significant difference was noted compared with the normal group ($P > 0.05$, Figure 5C).

DISCUSSION

Acute liver necrosis is associated with a high mortality rate[14]. Infection is a common serious complication of acute liver necrosis and is a major cause of death[15]. A myriad of researchers have noted that secondary infections primarily originate from intestinal bacterial translocation. While the intestinal barrier has to be permeable for nutrients and macromolecules which are indispensable for growth and development, at the same time it also has to provide an effective barrier against harmful macromolecules and microorganisms to ensure local homeostasis[16]. The intestinal barrier consists of a mechanical barrier, immunological barrier, microorganism barrier, and a chemical barrier. The immunological barrier is considered the first line of antigen-specific immune defense against pathogenic microorganisms[17,18]. Recent reports indicated that immunosuppression, involving the local intestinal immunological barrier, is a major cause of intestinal bacterial translocation[19].

In agreement with previous reports[20,21], we found that injection of GalN/LPS induced increases in serum ALT and the development of severe hepatocyte necrosis. As the mortality of mice with acute liver necrosis was 53.3%, these findings indicate that the model employed to study IgA and IFN-γ was successful. In addition to the observed liver injury, loosened intestinal mucosa and some edematous and necrotic intestinal epithelial cells were also noted in the mice with acute liver necrosis. These features were not found in any of the other groups. These histological findings of intestinal mucosal injury in acute liver necrosis were consistent with other studies[14].

IgA is the most abundant immunoglobulin present on all mucosal surfaces, where it plays crucial roles in mucosal protection[3]. IgA is produced and released as a J chain-linked dimer by resident IgA+ plasma cells in mucosal tissues, including the extensive lamina propria of the intestine[22]. For decades, it has already been known that IgA plays a protective role in mucosal immunity. IgA exerts its protective effects *via* 3 primary mechanisms. First, IgA serves as an immunologic barrier which inhibits binding of organisms to mucosal surfaces. Next, the normal movement of IgA from the basilar to apical region of epithelial cells suggests that it may be effective in neutralizing intracellular pathogens. Finally, pathogens bound to IgA are taken up by macrophages *via* phagocytosis[23]. An additional property of IgA is its inability to trigger the release

of inflammatory mediators through receptors specific to its Fc domain[24-26].

IgA-deficient individuals have a tendency to develop infections and disorders of the gastrointestinal tract[27-29]. Zinneman *et al*[30] reported that the protective barrier of the gastrointestinal system was impaired in IgA deficiency

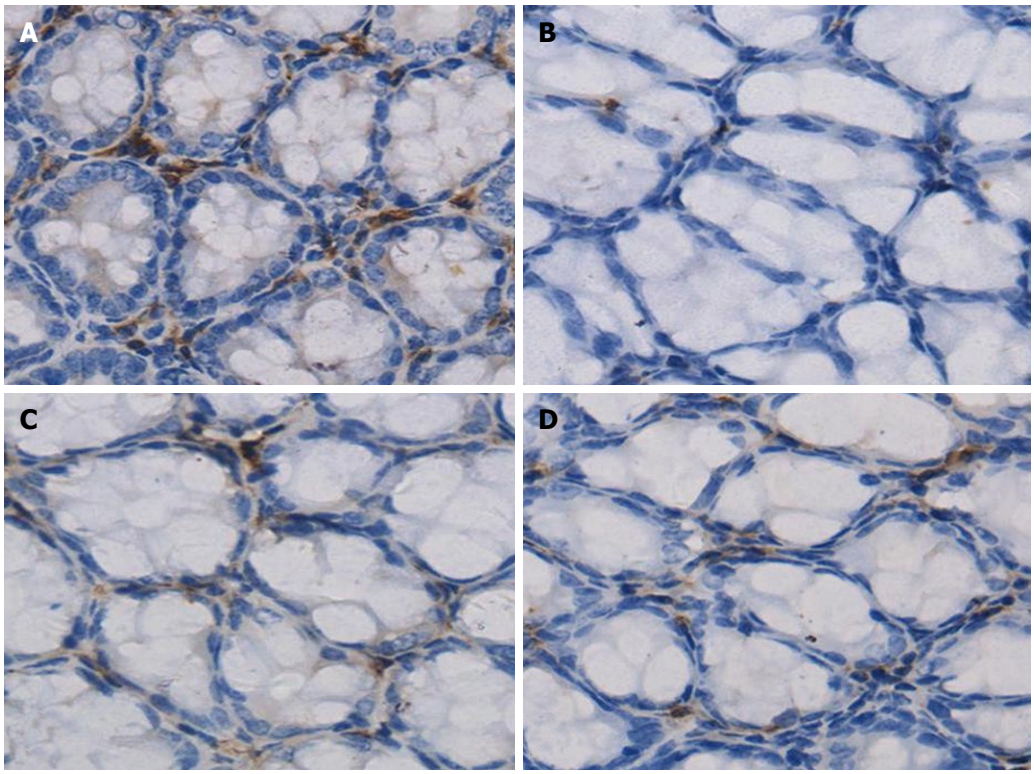

Figure 4 Immunoglobulin A+ cells determined by immunohistochemistry (400 ×). Immunohistochemistry demonstrated that Immunoglobulin A in the plasma cells within the lamina propria were stained brown. A: Normal group; B: Acute liver necrosis group; C: Lipopolysaccharide group; D: Galactosamine group.

and that protozoa such as *Giardia lamblia* can adhere to the epithelium, proliferate, and cause infection.

In the experiment presented herein, the number of IgA+ plasma cells and the IgA levels in intestinal mucosa in LPS and GalN groups showed a slight decrease but no significant difference was noted compared to the normal group. The number of IgA+ plasma cells and the IgA levels in the intestinal mucosa in the acute liver necrosis group were the lowest among all 4 study groups. The IgA+ plasma cells and the IgA levels were significantly different between the acute liver necrosis group and normal controls (Figures 5A and B). The decrease in the number of IgA+ cells and the IgA levels in the GalN/LPS group were significantly greater than the sum of the decrease in the LPS and GalN groups. It was thought that the decreased IgA+ plasma cells and decreased IgA levels in the intestinal mucosa were not the result of GalN or LPS injection, but rather of acute liver necrosis. These findings suggest that intestinal immunological barrier injury, which is a component of intestinal barrier injury, does occur in acute liver necrosis.

The mechanism of reduction in IgA+ plasma cells in acute liver necrosis is complicated and likely multifactorial. First, an increased rate of apoptosis in the subpopulation in Peyer's patches secondary to acute liver necrosis could negatively impact IgA+ plasma cell numbers[9,31]. Second, multiple organ damage, particularly the bone marrow, spleen, and mesenteric lymph nodes, in concert with mucosal edema and injury caused by acute liver necrosis, could affect the production and proliferation of IgA+ plasma cells. Third, the structural damage to the intestinal mucosa could interfere with recirculation of plasma cell precursors[32]. An accurate mechanism of IgA+ plasma cell reduction in acute liver necrosis clearly requires further study.

In this study, it was also found that the decreased IgA expression in acute liver necrosis coincided with a decline in IgA+ plasma cells. One explanation for this could be that the decrease in the number and function of IgA+ plasma cells leading to a simultaneous reduction in IgA secretion. At present, the specific pathogenesis and progression of acute liver necrosis remains unclear.

Inflammatory mediators are thought to be involved in the development and progression of acute liver necrosis. Previous studies reported that serum levels of a number of inflammatory factors, such as IFN-γ, are elevated in patients with severe liver injury[14,33]. In addition, IFN-γ is known to downregulate IgA expression[34].

In this study, IFN-γ levels in the small intestinal mucosa were slightly increased in LPS, GalN and acute liver necrosis groups, but no significant difference in IFN-γ expression was identified between the acute liver necrosis and normal control group. IFN-γ expression does not seem to explain the decrease in IgA secretion from the intestinal mucosa. Other factors involved in the reduction in IgA expression in acute liver necrosis warrant further attention.

In conclusion, this study found that mice with acute liver necrosis had a reduced number of intestinal IgA+ plasma cells and IgA expression levels indicating that mucosal immune barrier dysfunction does exist in acute

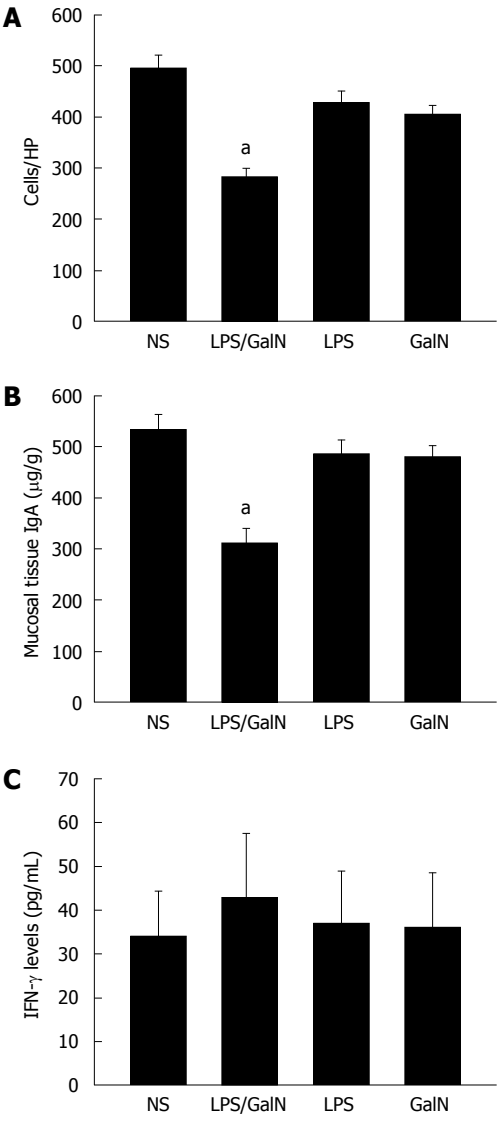

Figure 5 Immunoglobulin A+ plasma cells (A), the Immunoglobulin A expression levels (B) and interferon-γ expression (C) in intestinal mucosal tissue. $^{a}P < 0.05$ *vs* normal saline (NS). HP: High power field; GalN: Galactosamine; LPS: Lipopolysaccharide.

liver necrosis. IFN-γ expression does not seem to explain the decrease in IgA secretion from the intestinal mucosa. Further research regarding the mechanism(s) of intestinal immune barrier injury and ways to prevent this type of injury in acute liver necrosis is warranted.

We are grateful to Professor Ya-Luo Dong and Professor Dong-Yan Liu for their technical guidance and help.

COMMENTS

Background

Enterogenic infection is an important cause of death in patients with acute liver necrosis. Intestinal immunological barrier injury plays a vital role in the pathophysiology of enterogenic infection. Immunoglobulin A (IgA) is an important component of the intestinal immunological barrier and is the most abundant immunoglobulin present on mucosal surfaces, where it plays crucial roles in mucosal protection.

Research frontiers

IgA is considered a first line antigen-specific immune defense against pathogenic microorganisms and plays an important role in intestinal mucosal immunity. This study found significant changes in the number of IgA+ plasma cells and IgA expression levels during acute liver necrosis.

Innovations and breakthroughs

Previous studies have mainly focused on mechanical barrier interruption in acute liver necrosis models. So far, no studies have shown the indispensable nature of the intestinal immunological barrier in acute liver necrosis. In this study, the number of IgA+ plasma cells and IgA expression in mice with acute liver necrosis were determined to investigate whether dysfunction of the immunological barrier occurred during acute liver necrosis.

Applications

IgA is an important component of mucosal immune system and is significantly reduced during acute liver necrosis. Thus, a protective or an immunoregulative treatment of intestinal immune function could be beneficial in patients with acute liver necrosis.

Peer review

The manuscript by Fu *et al* describes studies examining in mice the change of intestinal IgA+ plasma cells and the expression of intestinal IgA in acute liver necrosis. Although the underlying mechanisms that contribute to the decreased expression of intestinal IgA was not thoroughly investigated, the study addresses an issue of topical interest, providing important data.

Abstract

AIM: To investigate the significance of ileocolonoscopy with histology in the evaluation of post-transplantation persistent diarrhea (PD).

METHODS: We retrospectively reviewed all records of renal transplant patients with PD, over a 3-year period. All patients were referred for ileocolonoscopy with biopsy, following a negative initial diagnostic work up. Clinical and epidemiological data were compared between cases with infectious or drug-induced diarrhea.

RESULTS: We identified 30 episodes of PD in 23 renal transplant patients (1-3 cases per patient). There were 16 male patients and the mean age at the time of PD was 51.4 years. The average time from transplantation to a PD episode was 62.3 ± 53.2 mo (range 1-199 mo). Ileocolonoscopy detected mucosal abnormalities in 19 cases, whereas the intestinal mucosa appeared normal in 11 cases. Histological examination achieved a specific diagnosis in 19/30 cases (63.3%). In nine out of 11 cases (82%) with normal endoscopic appearance of the mucosa, histological examination of blinded biopsies provided a specific diagnosis. The etiology of PD was infectious in 11 cases (36.6%), drug-related in 10 (33.3%), of other causes in three (10%), and of unknown origin in six cases (20%). Infectious diarrhea occurred in significantly longer intervals from transplantation compared to drug-related PD (85.5 ± 47.6 mo *vs* 40.5 ± 44.8 mo, $P < 0.05$). Accordingly, PD due to drug-toxicity was rarely seen after the first year post-transplantation. Clinical improvement followed therapeutic intervention in 90% of cases. Modification of immunosuppressive regimen was avoided in 57% of patients.

CONCLUSION: Early ileocolonoscopy with biopsies from both affected and normal mucosa is an important adjunctive tool for the etiological diagnosis of PD in renal transplant patients.

INTRODUCTION

Diarrhea occurs frequently following renal transplantation, with reported incidences as high as 64% in large clinical trials[1-3]. Although several cases are benign and easily manageable, post-transplantation diarrhea can persist for a long period and compromise the health status of the patients. In particular, it leads to water and electrolyte disturbances, interferes with the absorption of immunosuppressive drugs, often requires hospital admission, and thus negatively affects the quality of life of the patients[4]. An association between post-transplantation diarrhea and decreased graft and patient survival has also been reported[5].

The diagnostic algorithm of post-transplantation diarrhea should take into consideration the specific characteristics of this population, particularly the presence of significant immunosuppression[6,7]. Infectious agents are often implicated; however, manifestation of enteric infections can vary considerably in this population[8,9]. Atypical presentations and severe forms of common infections frequently occur, whereas opportunistic infections with unusual microorganisms are also encountered. On the other hand, immunosuppressive regimens can cause intense and persistent diarrhea (PD)[10]. The most prominent example is toxicity of mycophenolate mofetil (MMF), which can cause enterocolitis in a substantial proportion of patients[11-14], requiring modification of the immunosuppressive regimen. However, reducing the dose of immunosuppression might lead to graft loss[15].

In the present study we have analyzed all cases of PD in renal transplant patients in our Hospital between July 2006 and June 2009. Our aim was to investigate the utility of early ileocolonoscopy, with biopsies taken both from identified lesions and blindly from normal looking mucosa, in establishing a definitive diagnosis for the diarrheal episode.

MATERIALS AND METHODS

Patient population and definitions of PD

We retrospectively reviewed the records of all renal transplant patients who presented with PD and had ileocolonoscopy as part of their diagnostic work-up in our hospital between July 2006 and June 2009.

All patients were followed at the Renal Transplantation Unit of our Hospital. Demographic, epidemiological, and clinical characteristics of the patients at the time of each diarrheal episode were retrieved from the medical files. We defined PD as an episode of diarrhea with the following characteristics: (1) change in the bowel habits with more than three movements per day and decreased stool consistency lasting longer than 2 wk; (2) an etiological diagnosis was not established after initial testing, including detailed history and clinical examination, extensive hematological, and biochemical tests, as well as stool cultures for enteric pathogens, examination for ova and parasites, and examination for *Clostridium difficile* toxins-A and B; (3) failure of diarrhea to resolve following simple dietetic modifications and non-immunosuppressive medication adjustment; and (4) further testing including ileocolonoscopy was considered necessary by the attending nephrologist, because diarrhea interfered with health status and quality of life of the patient. All patients with PD were tested with polymerase chain reaction (PCR) for cytomegalovirus (CMV) in blood; however, colonoscopy was always performed to detect endoscopic and/or histologically evident CMV-colitis.

Over the 3-year study period there was an agreed standard practice between the Renal Transplantation Unit and G.I. Endoscopy Unit of the 1st Department of Internal Medicine, to which renal transplant patients with PD are referred for ileocolonoscopy. Polyethylene glycol was used for bowel preparation. Sodium phosphate-based regimens were avoided due to their reported nephrotoxicity. Colonoscopy was performed with sedation (midazolam) and analgesia (pethidine), as required. During endoscopy, multiple biopsies were taken from all areas with mucosal abnormalities as well as blind biopsies from normal looking mucosa of the terminal ileum and throughout the colon (4-6 biopsies from right and left colon, respectively). Upper gastrointestinal (GI) tract endoscopy was performed selectively according to the clinical judgment of the treating physicians.

We defined the following categories of PD in relation with the underlying cause: (1) infectious, when a microorganism with an established role as a diarrhea-causing agent was detected by microbiological, histological, or molecular methods; (2) drug-induced, when infectious agents were excluded and histological findings consistent with pharmaceutical injury (most often MMF-related) were detected in the biopsy specimens. Histological findings highly suggestive of MMF-colitis, included: (a) mucosal abnormalities characterized by atrophy, crypt architectural distortion, flattened crypt epithelium, increased cell apoptosis and regenerative epithelial changes; and (b) edema, moderate inflammatory infiltrations with increased number of eosinophils, crypt abscesses and cryptitis, and, in the more severe cases, focal erosions or ulceration[13]. In addition, a clear beneficial effect of modification of the immunosuppressive regimen (MMF-dose reduction or switching to Myfortic or azathioprine) on the severity of PD was required to confirm a drug (MMF)-associated etiology of diarrhea; (3) Other, when a definitive cause (not associated with immunosuppressive medications or infectious agents) was established by clinical, laboratory, and histological findings; and (4) unknown, when no causative factor was identified. This group included cases with nonspecific changes either in endoscopy and/or at histology.

Statistical analysis

The SPSS software was used for the analysis. Continuous variables were analyzed by the independent *t*-test or

Mann-Whitney test (if they did not meet the criteria for parametric comparison). Categorical variables were studied by corrected χ^2 test. For all comparisons a probability level (*P*) of 0.05 was considered significant.

RESULTS

Demographic data

Over the study period, 30 ileocolonoscopies were performed for 30 separate episodes of PD in 23 renal transplant patients (Table 1). One patient had three episodes, five had two, and seventeen patients had one episode of PD. In all but one patient, the cause of PD differed between separate episodes. There was a clear predominance of males (2.3:1 male/female ratio), independently of the etiology of diarrhea (Table 1). The cause of renal failure and transplantation was polycystic kidney disease in four patients, kidney stone disease in three, whereas Henoch-Schönlein purpura, IgA nephropathy, recurrent kidney infections, renal hypoplasia, medullary cystic disease, and polyarteritis nodosa accounted for one case each. The etiology was unknown in 10 patients.

The immunosuppressive regimens that were administered at the time of each case of PD are shown in Table 1. All patients with more than one episode of PD were receiving the same immunosuppressive medications in all episodes, with the exception of one patient who was switched from MMF/tacrolimus (1st episode) to everolimus/tacrolimus (2nd and 3rd episodes) and a second patient in whom MMF/tacrolimus was changed to mycophenolate sodium/tacrolimus.

[1]Ileocolonoscopy; [2]Including biopsies from normal-looking mucosa; [3]In this case biopsy was not taken because of typical pseudomembranous colitis in endoscopy; [4]Including cases with non-specific colitis in endoscopy or histology.

Endoscopic and histological studies

Twenty endoscopies were performed in inpatients and ten in outpatients. The cecum was reached in 26/30 colonoscopies (86.7%), with terminal ileum intubation in the vast majority of cases (22/26 with cecum intubation, 85%). We did not observe any serious complications related either to the preparation for colonoscopy, the use of sedatives/analgesics, or the procedure itself.

The diagnostic yield of ileocolonoscopy and histological examination of endoscopically obtained intestinal specimens are shown in Table 2. Biopsies were taken in all but one patient, in whom diagnosis of pseudomembranous colitis was established by typical history of prior antibiotic administration and endoscopic findings. Ileocolonoscopy revealed mucosal abnormalities in 2/3 of the patients. The most frequently encountered findings were

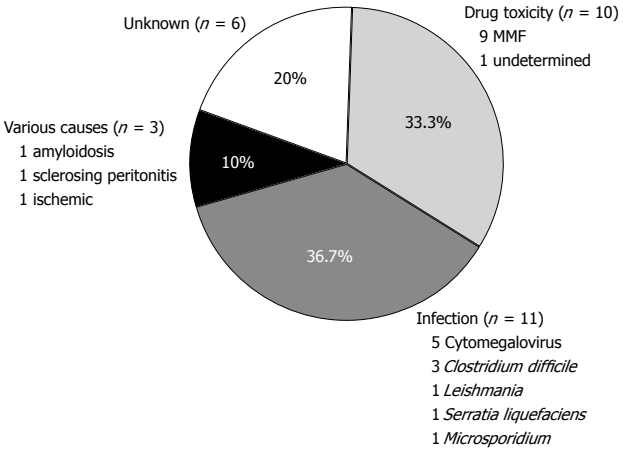

Figure 1 Causes of persistent diarrhea in renal transplant patients. MMF: Mycophenolate mofetil.

edema (loss of submucosal vascular pattern) and erythema of the mucosa, which were observed in 11 cases. More severe lesions included colonic ulceration (three cases), stenosis (two cases), submucosal hemorrhage (one case), and formation of pseudomembranes (two cases). We did not observe any endoscopic findings that were exclusively associated with infectious or drug-induced diarrhea (with the exception of pseudomembranous colitis).

Histological examination of biopsies obtained during endoscopy provided a definitive diagnosis in 19/30 cases (63.3%). More importantly, histology allowed for a specific diagnosis in nine out of 11 cases with normal endoscopic examinations (Table 2). Overall, an infectious cause was identified in 11 cases (Figure 1). The most prevalent infection was due to CMV, accounting for 16.6% of all cases. Interestingly, in 3/11 infectious cases (27%) there were no mucosal abnormalities seen on endoscopy. In three cases, diagnosis was established histologically in biopsy specimens taken from areas of normal looking mucosa (Table 2). These included two cases of CMV infection and one case infected with microsporidium. A case of leishmaniasis was diagnosed histologically by the recognition of the dot-like organisms within mucosal macrophages (Figure 2C). These were also revealed by Giemsa stain while PAS stain was negative.

In our study, we identified 10 episodes of PD (33.3%) that were related to toxicity of immunosuppressive drugs (Figure 1). All patients with drug-related diarrhea were receiving mycophenolate (eight MMF and two mycophenolate sodium) in combination with tacrolimus (eight cases), everolimus (one case), or sirolimus (one case). In the majority of drug-induced PD (6/10, 60%) the colonic mucosa looked normal on colonoscopy. Nevertheless, histological evaluation of blindly collected biopsies revealed mucosal changes consistent with MMF-colitis in all cases; thus establishing the diagnosis of drug-induced injury. These findings included mucosal abnormalities such as edema, atrophy, crypt architectural distortion, regenerative epithelial changes, and increased cell apoptosis with intraluminal apoptotic bodies (Figure 2A and B).

In our study there were three cases where a definitive diagnosis unrelated to infection or drug-toxicity was established. In the first patient, intestinal amyloidosis was diagnosed by histological examination and appropriate staining of a biopsy specimen obtained from the rectum. The second case involved a patient with sclerosing peritonitis. The pathophysiology of diarrhea was associated with external compression of the intestine by the sclerotic tissue and the accompanying motility and structural abnormalities, as diarrhea was completely abrogated following effective surgical decompression. Finally, in the third case, diarrhea was considered of ischemic origin as no other etiology was found and histology was compatible with ischemic intestinal injury. Taken together, these results show that endoscopy with histological examination of both affected and normal mucosa achieves a definitive diagnosis in the vast majority of PD in renal transplant patients.

Comparison between infectious and drug-induced PD

As our initial analysis showed that the majority of cases with PD were of infectious or pharmaceutical etiology, we then compared these two distinct groups for several characteristics. We observed no association between the type of diarrhea and the gender or age of the patient, or the type of donor (cadaveric *vs* living) (Table 1). In contrast, the time from transplantation to the PD episode differed significantly according to the etiological factor. In particular, this interval was considerably shorter in drug-related (40.5 ± 44.8 mo), as compared to infectious diarrhea (85.5 ± 47.6 mo, $P < 0.05$). There was a statistically significant difference between infectious and drug-induced PD ($P < 0.05$) in regards to their temporal distribution (Figure 3). In particular, while all but one case of infectious PD (91%) occurred later than 4 years post-transplantation, drug toxicity was usually seen at earlier time points. Accordingly, infection accounted for 14% of early episodes, whereas pharmaceutical toxicity accounted for 57%. In contrast, late episodes were caused primarily by infections (56%) and rarely by drugs (16.6%). In all, these results indicate that the time post-transplantation should be taken into consideration when searching for the etiology of PD in renal transplant patients, as different causes underlie early *vs* late episodes.

Outcome of PD

All but one case of infectious diarrhea required admission to the hospital, (91% admission rate) (Table 1). In contrast, fewer patients with drug-induced PD were admitted (60% admission rate). There was a trend towards longer hospital stay for patients with infectious diarrhea (mean hospital stay: 17.4 ± 11.6 d *vs* 8.5 ± 8.5 d for the drug-induced group, $P = 0.076$) (Table 1).

The overall outcome of PD was good, with cessation or improvement of diarrhea in 90% of cases (Table 1). There were two deaths in the infectious group, both unrelated to diarrhea. One patient with pseudomembranous colitis had a complicated clinical course due to disseminat-

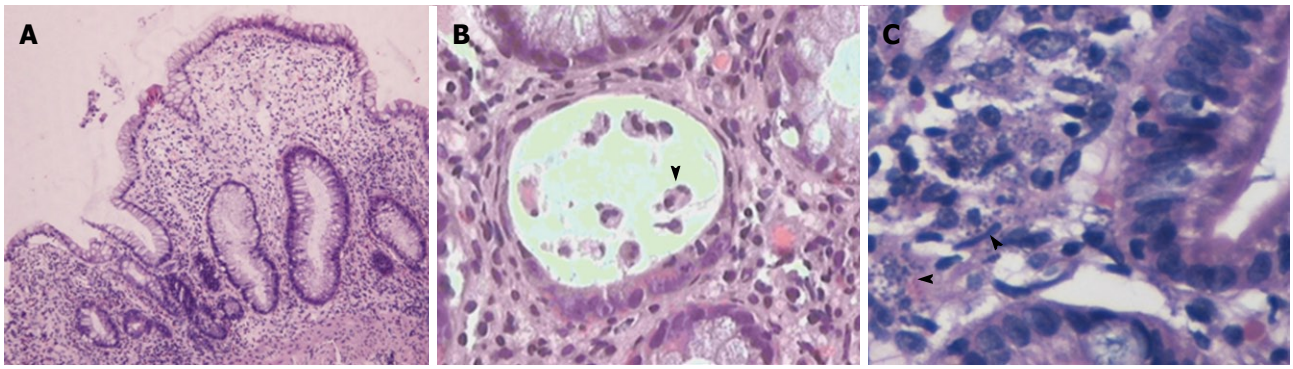

Figure 2 Histological photomicrographs from drug-induced and infectious cases of persistent diarrhea. A: Mycophenolate mofetil (MMF)-colitis, (HE stain, 200 × original magnification); B: MMF-colitis, with apoptotic bodies within the bowel lumen (arrowhead, HE stain, 400 × original magnification); C: Intestinal leishmaniasis with characteristic dot-like microorganisms within macrophages in the lamina propria (arrowheads, HE stain, 400 × original magnification).

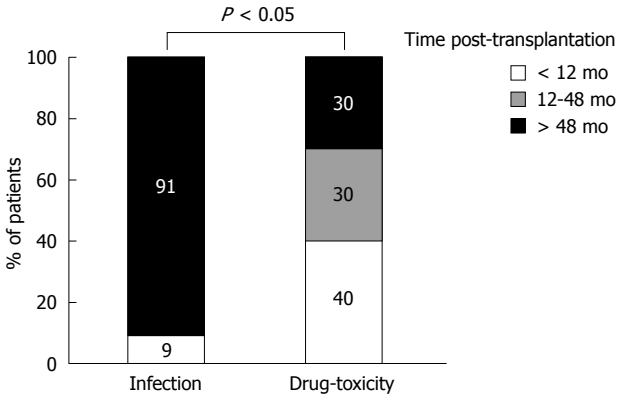

Figure 3 Distribution of infectious and drug-induced cases of persistent diarrhea in renal transplant patients according to the time post-transplantation.

ed fungal infection and was transferred to ICU where he eventually died. The other patient suffered from visceral leishmaniasis that had a fatal outcome.

Modification of immunosuppressive regimen was introduced in 12 cases. In five there was a switch from MMF to enteric-coated mycophenolate sodium, whereas in two the dose of mycophenolate was decreased with favorable outcomes in all cases. In four occasions mycophenolate had to be replaced by azathioprine. Finally, in one patient with drug-induced PD, diarrhea proved to be self-limited and required no change of immunosuppression. In our study, there was one case of graft loss in a patient with severe immunosuppression-related complications who had to stop all drugs with eventual loss of the graft.

DISCUSSION

In the present study we demonstrated that early ileocolonoscopy combined with histology of bowel mucosa, even without macroscopic abnormalities, is a critical component of the diagnostic evaluation of PD in renal transplant patients. We have shown that this approach provides a definitive diagnosis in the majority of cases, allowing prompt and specific treatment of the underlying cause, avoiding unnecessary modifications of the immunosuppressive regimen, and leading to favorable patient and graft outcome. Our data also indicate that PD is more likely due to drug-associated toxicity during the first post-transplantation year, while infectious diarrhea may occur throughout the post-transplantation period and is usually the cause of diarrhea after 4-year post-transplantation.

The majority of published studies on post-transplantation diarrhea did not take into account the severity or the duration of the episode[1-3,5]. In our study we focused on diarrhea that was judged as persistent, both in terms of long duration as well as of interference with the wellbeing of patients. We believe that these are the most clinically relevant cases and require extensive evaluation for the underlying causative agent. Our findings clearly show that there should be a low threshold for early ileocolonoscopy with histological examination in these patients. Such an approach is supported by the high percentage (80%) of definitive diagnoses that was accomplished in our study.

In a recent publication, a diagnostic algorithm for post-transplantation diarrhea was proposed, which introduced colonoscopy late in the course of evaluation and, more significantly, after modifications in immunosuppressive drugs were applied[16]. In fact, reduction of MMF is among the first measures taken in patients with post-transplant diarrhea[17]. This leads to cessation of diarrhea in a considerable proportion of cases, therefore avoiding the need for invasive tests such as colonoscopy. On the other hand, reducing the dose of immunosuppression often results in graft dysfunction[15,18,19]. In fact, in our study, the single episode of graft loss was associated with immunosuppression cessation due to severe toxicity, including drug-induced-diarrhea. Our results support the use of early endoscopy with histology in prolonged or refractory cases of diarrhea, as we were able to document non-drug-related causes in 46% of cases, thus avoiding unnecessary modifications of immunosuppressive regimens.

Early colonoscopy was suggested in a recent study on post-transplantation diarrhea, when there is strong clinical suspicion for CMV-colitis[20], including cases with positive PCR for CMV in the blood. Our findings support the use of colonoscopy with histology in this population, as it helps in establishing the localization of CMV in the intes-

tine and provides causality for chronic diarrhea. In fact, in our series, one of five cases with CMV-colitis had negative CMV-PCR in the blood, and a second one had very low number of CMV-DNA copies. Moreover, in some cases with positive CMV-PCR in the blood, colonoscopy and histology indicated absence of CMV-colitis, despite the presence of diarrhea, which was attributed to other causes.

To our knowledge there is only one published study that reported on the role of colonoscopy in renal transplant patients with diarrhea. Contrary to our study, Korkmaz *et al*[21] showed a 55% failure to establish a diagnosis with colonoscopy and/or histology. The higher rates observed in our study might be attributed to several factors. First, the severity of diarrhea in the Korkmaz study is not reported; it might, therefore, be the case that some colonoscopies were performed in milder cases with no obvious causative agent. Second, the accumulated experience on the histological lesions of MMF-colitis allowed us to use better-defined criteria for drug-induced toxicity; it is possible that such cases are included in the large number of non-specific colitis cases in the study by Korkmaz *et al*[21]. Finally, we took blinded biopsies in every patient, which was not the case in the aforementioned study. In another recent study only apparent lesions were biopsied during colonoscopy[22]. Our data clearly showed that histology of normal-appearing mucosa revealed pathognomonic findings in a considerable percentage of renal transplant patients with PD. In our study, this approach yielded a diagnosis in 27% of infection-related and in 60% of drug-induced cases of diarrhea.

Infectious agents and drugs accounted for the majority of PD cases in our cohort. This is in line with previous studies[23,24]. We detected a significant difference between the two groups (infectious *vs* drug-induced) regarding the time they occurred post-transplantation. In particular, the majority of drug-induced cases took place in the first years following transplantation. This distinction has also been observed in other studies[16]. This may be explained by the fact that intolerance to immunosuppressive regimen is expected to occur within relatively short time after their initiation[25]. In contrast, in our study, intestinal infection was diagnosed later than 4 years post-transplantation, almost exclusively. A temporal distribution of various infections post-transplantation has been reported[26]. These data, as well as our present findings, indicate that the search for PD etiology should be tailored to the individual patient, taking into consideration the time post-transplantation. In the case of an episode that takes place long after transplantation, intensive search for infectious agents is primarily required.

We were not able to establish a diagnosis in 6/30 cases (20%), including four that were classified as non-specific colitis. Follow-up revealed that diarrhea ceased or was greatly improved, indicating that self-limited infections and/or unspecified pharmacotoxicity underlay these cases. In fact, in one case *Candida albicans* was isolated from the stools, whereas in two others CMV-viremia was detected. However, since a direct proof of causality was not established, we classified these cases as non-specific colitis and not infectious. Only in two cases of unknown etiology was modification of immunosuppressive regimen considered necessary.

In conclusion, our results indicate that ileocolonoscopy has an important impact in the management of renal transplant patients with PD and should be an adjunctive tool for the causative diagnosis of PD. Endoscopy should be considered only after initial measures have failed to induce clinical improvement. These measures may include adjustment of the immunosuppressive regimen, particularly when diarrhea manifests during the initial post-transplantation months as the prevalence of drug-related causes is increased during that period. In any case, biopsies should always be taken from the lower GI tract as histology achieves a definitive diagnosis in the majority of cases, even when the intestinal mucosa appears macroscopically normal. This approach may offer the opportunity for specific treatment and lead to improved outcomes following renal transplantation.

COMMENTS

Background

Diarrhea is among the most common complications in patients who receive renal transplants and has been associated with poor outcomes in terms of quality of life as well as graft and patient survival. Infectious agents often cause diarrhea due to the universal administration of immunosuppressive regimens in this population. Immunosuppressants can themselves cause significant gastrointestinal toxicity, the most prominent example being mycophenolate mofetil-enterocolitis.

Research frontiers

Previous studies have reported diagnostic algorithms for the evaluation of post-transplantation diarrhea. Endoscopic and histological studies of the lower gastrointestinal tract have been incorporated only at the late steps of diagnostic protocols, usually when extensive clinical and laboratory work-up has been negative and modifications in the immunosuppressive scheme have been ineffective to induce diarrhea cessation.

Innovations and breakthroughs

In the present study, the authors investigated the usefulness of a standard approach for the evaluation of persistent diarrhea (PD) in renal transplant patients, which utilized an early ileocolonoscopy, i.e. as soon as limited laboratory testing came back negative. Moreover, biopsies were routinely taken both from all identified lesions but also blindly from normal looking mucosa. The present study demonstrated a high efficacy of this diagnostic scheme in establishing a definitive diagnosis for the diarrheal episode.

Applications

The application of early ileocolonoscopy with standard tissue sampling may facilitate etiologic diagnosis and targeted treatment of PD in renal transplant patients; thus avoiding unnecessary changes in the immunosuppressive regimen. This approach may be of particular importance in the late post-transplantation period, when non-drug related causes of diarrhea are increased.

Terminology

PD: an episode of diarrhea lasting longer than 2 wk and interfering with the health status and quality of life of the renal transplant patient, for which an etiological diagnosis is not established after initial clinical examination, baseline hematological and biochemical tests, as well as stool tests for infectious causes and which did not respond to simple dietetic modifications and non-immunosuppressive medication adjustments.

Peer review

The authors investigated the role of colonoscopy on persistent post-transplantation diarrhea. The results indicated that colonoscopy is a valuable diagnostic tool for evaluating transplant recipients with PD. The paper is well written and data clearly presented. The work contributes to the understanding and guides management of this important complication despite the small number of patients and selection bias.

Abstract

AIM: To investigate the association of colorectal adenomas with both *Helicobacter pylori* (*H. pylori*) infection and metabolic syndrome.

METHODS: Using a cross-sectional hospital-based study, we analyzed physical examination data from 9311 healthy subjects with overnight physical examinations performed between January 2004 and December 2006. Examined data included gender, age, life style, anthropometric measurements, blood pressure, biochemical and hematological studies, *H. pylori* infection detected by esophagogastroduodenoscopy and biopsy urease tests, and colorectal adenomas detected with a complete total colonoscopy.

RESULTS: The prevalence values for *H. pylori* infection, metabolic syndrome, and colorectal adenoma were 39.2%, 18.7%, and 20.7%, respectively. Colorectal adenoma risk factors included male gender [odd ratio (OR): 2.005, 95% confidence interval (CI): 1.740-2.310, $P < 0.001$], advanced age (OR: 1.046, 95% CI: 1.040-1.052, $P < 0.001$), smoking (OR: 1.377, 95% CI: 1.146-1.654, $P = 0.001$), increased body fat (OR: 1.016, 95% CI: 1.007-1.026, $P = 0.001$), higher white blood cell count (OR: 1.038, 95% CI: 1.005-1.073, $P = 0.025$), *H. pylori* infection (OR: 1.366, 95% CI: 1.230-1.517, $P < 0.001$), and metabolic syndrome (OR: 1.408, 95% CI: 1.231-1.610, $P < 0.001$). In addition, concomitant *H. pylori* infection with metabolic syndrome further increased the probability of colorectal adenomas.

CONCLUSION: Our study revealed *H. pylori* infection with concomitant metabolic syndrome might further increase the risk of colorectal adenomas.

Key words: Biopsy urease test; Colorectal adenoma; Colorectal cancer; *Helicobacter pylori*; Metabolic syndrome

INTRODUCTION

Colorectal cancer is an extremely common malignancy and one of the leading causes of cancer mortality worldwide. Colorectal adenoma is the premalignant lesion in colorectal cancer and develops into colorectal carcinoma

through the adenoma-to-carcinoma sequence[1]. The direct etiology of colorectal neoplasms is still unknown. However, previous epidemiological studies have identified family history, dietary factors, smoking, sedentary lifestyles, and alcohol consumption as potential contributors to colorectal neoplasm development[2]. Identification of the etiology of colorectal neoplasms might assist in the development of strategies targeted toward its prevention.

Helicobacter pylori (*H. pylori*) is a human pathogen that infects the gastric mucosa and causes inflammatory process that culminate in chronic gastritis, peptic ulceration, gastric lymphoma of mucosa-associated lymphoid tissue, and adenocarcinoma[3]. *H. pylori* is a gram-negative microaerophilic bacillus, and has been classified by the International Agency for Research on Cancer as a class I human carcinogen since 1994[4]. The role of *H. pylori* in colorectal carcinogenesis has been epidemiologically examined in recent decades; however, the association has remained inconclusive. Several studies have identified an association between *H. pylori* infection and colorectal neoplasms[5-9], while others have identified a negative association between the two[10-12]. Methodological issues might account for some of the inconsistent results, including the IgG serum antibody test and incomplete colonoscopic examinations for diagnosis.

Metabolic syndrome is a clinical cluster of metabolic abnormalities. It is also referred to as insulin resistance syndrome, and is diagnosed by criteria corresponding to the modified National Cholesterol Education Program (NCEP) criteria[13]. Diagnosis is fulfilled by the presence of any three of the following conditions: higher waist circumference ($\geq$ 90 cm in men and $\geq$ 80 cm in women), elevated triglycerides ($\geq$ 150 mg/dL), lower high density lipoprotein cholesterol ($<$ 40 mg/dL in men and $<$ 50 mg/dL in women), elevated blood pressure (systolic blood pressure $\geq$ 130 mmHg or diastolic blood pressure $\geq$ 85 mmHg), and elevated fasting glucose ($\geq$ 100 mg/dL). This syndrome might be a risk factor for type 2 diabetes and cardiovascular disease[14,15]. In recent years, metabolic syndrome has also been associated with an increased risk of colorectal adenoma. However, there is very limited medical literature examining the relationship between colorectal adenoma and metabolic syndrome[16-18]. Additional information on the correlation between metabolic syndrome and colorectal neoplasms could result in the recommendation for screening of colorectal neoplasms in the patient with metabolic syndrome.

Using a cross-sectional hospital-based study, we investigated the association of colorectal adenoma with both *H. pylori* infection and metabolic syndrome. Further, the probability of colorectal adenoma in patients with both *H. pylori* infection and metabolic syndrome was evaluated.

MATERIALS AND METHODS

A total of 11 787 asymptomatic subjects were admitted to the general physical examination department of the Buddhist Dalin Tzu-Chi General Hospital for general check-ups (two-day health examination) between January 2004 and December 2006. Excluding 2476 subjects aged below 40 years, a final total of 9311 study participants (3906 males and 5405 females) were enrolled in the study. The demographic data included age, gender, medical past history, and lifestyle. Clinical data included blood pressure, fasting plasma sugar, plasma lipids levels (total cholesterol, high density lipoprotein cholesterol, low density lipoprotein cholesterol, and triglycerides), and hematological variables. Anthropometric measurements including height (meters), weight (kilograms), and body fat (percent; Body Composition Analyzer TBF-410, Tanita, Japan) were also examined.

Metabolic syndrome was diagnosed with the modified NCEP criteria. *H. pylori* infection was detected by the biopsy urease test (CLO test, Pronto Dry, Gastrex, Poland) using standard video esophagogastroduodenoscopy (EGD) with gastrofibroscopes (GIFXP-240, GIFQ260, Olympus Optical, Tokyo Japan). A specimen for biopsy urease testing of each subject was taken from the gastric antrum using biopsy forceps and assessed within 60 min. The agar color of the biopsy urease testing turned from yellow to red when the biopsy specimen was infected with *H. pylori*, which contained intracytoplasmic urease. Colorectal adenomas were identified by complete total colonoscopy using standard video colonoscopes (CF 240I, Olympus Optical, Tokyo, Japan) by single- and double-handed methods under intravenous 1% Propofol (Fresenius Kabi, Austria). This study was performed under the approval of our hospital Institutional Review Board.

Statistical analysis

Data for continuous variables were expressed as mean ± SD. The *t* test was applied for continuous variables when the data fitted a Gaussian distribution. If the continuous data did not fit the Gaussian distribution, the Wilcoxon rank sum test was applied. Categorical variables were tested with the χ^2 test. Stepwise logistic regression analysis was conducted for significant variable selection. Basic model-fitting techniques for regression analysis were applied to assure the quality of analysis results, including variable selection, goodness-of-fit assessment, and regression diagnostics. Statistical significance was established for two-sided *P* values $<$ 0.05. All statistical analyses were performed with the SAS® software, version 9.1.3 (SAS Institute Inc., Cary, NC, USA) and R 2.6.2 (R Development Core Team, R Foundation for Statistical Computing, 2008, Vienna, Austria).

RESULTS

The median ages of the study participants were 54 years in males and 52 years in females. All subjects went through complete EGD examination, and 2.8% of participants had incomplete colonoscopy examination. The raw prevalence rates of *H. pylori* infection, metabolic syndrome, and colorectal adenoma were 39.2%, 18.7% and 20.7%,

Table 1 Baseline characteristics of the study subjects

Variable	Male	Female	*P*
n	3906	5405	
Age (yr)	54 (48, 61)	52 (47, 59)	< 0.001
Smoke, *n* (%)	884 (22.6)	49 (0.9)	< 0.001
Alcohol, *n* (%)	876 (22.4)	119 (2.2)	< 0.001
Body weight (kg)	67.6 (61.8, 74.2)	56.0 (51.3, 61.7)	< 0.001
Body fat (%)	22.7 (19.4, 26.1)	30.6 (26.8, 34.9)	< 0.001

WBC: White blood cell; *H. pylori*: *Helicobacter pylori*; MS: Metabolic syndrome; OR: Odd ratio; CI: Confidence interval.

respectively. A total of 1923 adenomas, including 1691 tubular adenoma, 208 tubulovillous adenomas, and 24 serrated adenomas, were detected. Males were significantly older ($P < 0.001$), were more likely to smoke ($P < 0.001$), drink alcohol ($P < 0.001$), have heavier body weight ($P < 0.001$), lesser body fat ($P < 0.001$), and higher systolic and diastolic blood pressure values ($P < 0.001$). Males additionally had a higher proportion of hypertension ($P < 0.001$), diabetes ($P < 0.001$), higher fasting blood glucose levels ($P < 0.001$), higher white blood cell (WBC) counts ($P < 0.001$), lower lymphocyte percentages ($P < 0.001$), and a higher prevalence of colorectal adenoma ($P < 0.001$). There were no significant differences in total plasma cholesterol levels ($P = 0.448$), metabolic syndrome frequency ($P = 0.154$), and *H. pylori* infection frequency ($P = 0.096$) between males and females (Table 1).

Multivariate logistic regression analysis revealed that male gender (OR: 2.005; 95% confidence interval (CI), 1.740-2.310, $P < 0.001$), advanced age (OR: 1.046, 95% CI: 1.040-1.052, $P < 0.001$), smoking (OR: 1.377, 95% CI: 1.146-1.654, $P = 0.001$), increased body fat (OR: 1.016, 95% CI: 1.007-1.026, $P = 0.001$), higher white blood cell (WBC) count (OR: 1.038, 95% CI: 1.005-1.073, $P = 0.025$), *H. pylori* infection (OR: 1.366, 95% CI: 1.230-1.517, $P < 0.001$), and metabolic syndrome (OR: 1.408, 95% CI: 1.231-1.610, $P < 0.001$) were associated risk factors for colorectal adenoma. Alcohol consumption (OR: 0.990, 95% CI: 0.826-1.187, $P = 0.915$) was not a risk factor for colorectal adenoma (Table 2). Under analysis with a conditional effect plot, colorectal adenoma risk was positively associated with WBC count among paired groups of positive and negative *H. pylori*-infected patients and paired groups of positive and negative metabolic syndrome patients (Figure 1).

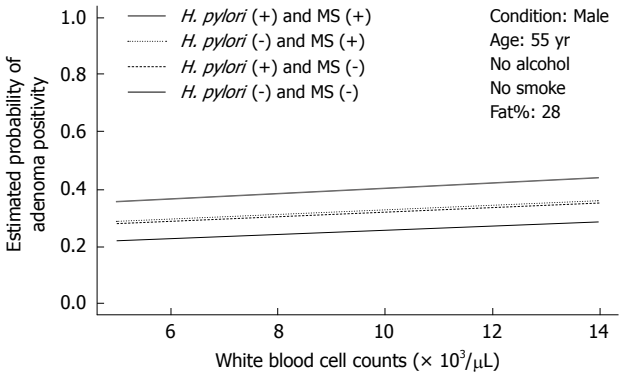

Figure 1 Conditional effect plot of *Helicobacter pylori* infection status and metabolic syndrome on the probability of adenoma positivity. The conditions were designed as non-smoking males at 55 years old and 28% body fat with the pair of both *Helicobacter pylori* (*H. pylori*) positivity and metabolic syndrome (MS) positivity *vs* another three pairs.

DISCUSSION

The results of our study supported the association of *H. pylori* infection with colorectal adenomas and were consistent with previous reports that metabolic syndrome might increase colorectal adenoma risk. It also showed that individuals with concomitant metabolic syndrome and *H. pylori* infection might have a further increased risk of colorectal adenomas.

The inconclusive results of previous studies concerning the relationship between *H. pylori* infection and colorectal neoplasm might have been due to sample bias, small sample size, inadequate consideration of potential confounding variables, and a varying frequency of cag A+ strains in the study populations[19,20]. In addition, incomplete colonoscopic studies and evaluation of *H. pylori* infection with the IgG serum test (which cannot represent real-time *H. pylori* infection) might also have contributed to the inconsistent results. The advantages of our study include large sample size, detection of *H. pylori* infection with the EGD and biopsy CLO test, and complete colonoscopy to the distal terminal ileum after good bowel preparation in 97.2% of the cases. Furthermore, patient lifestyle habits including smoking and alcohol consumption, gender, and age were also evaluated in this study. These factors might minimize potential variables during the data analysis.

However, there were also some limitations in our study. Patients in the study were selected from a population who sought routine physical examinations at our institute, and their psychosocial behaviors and lifestyle habits might differ from those in the general population, resulting in a confounding bias that could be ignored in the data analysis. Although *H. pylori* infection can be more accurately detected by biopsy CLO test than by the serum IgG method logically, in rare instances antral biopsies with CLO tests might not be representative of all gastric states of *H. pylori* infection. In addition, past historical data of diagnosis and treatment of *H. pylori* infection were not included in the analysis, although the enrolled cases were clinically asymptomatic. Additionally, blood insulin, gastrin levels, and proinflammatory cytokines were not measured. The study design also did not allow the identification of the pathologic mechanisms underlying the association of colorectal adenoma with metabolic syndrome and *H. pylori* infection.

The pathogenic mechanisms by which *H. pylori* exerts its malignant potential in the induction of colorectal neoplasms are not completely understood. A few studies have revealed that fecal shedding of viable *H. pylori* and its antigen occurs under certain circumstances[21,22], suggesting that *H. pylori* moves through the intestinal tract in direct contact with colonic mucosa, and could therefore locally activate colonic carcinogenesis. *H. pylori* was recently detected within colorectal carcinoma tissues[23]. The role of *H. pylori*-specific affinity for colorectal neoplasms requires further investigation. The presence of *H. pylori* might alter normal gastrointestinal flora as a consequence of progressive chronic gastritis with glandular atrophy and decreased acid production. This could further influence colorectal carcinogenesis. Persistent *H. pylori* exposure induces hypergastrinemia, which is a putative trophic factor for the large bowel mucosa. Cell proliferation and gastrin-induced genomic instability can increase the risk of DNA replication error and play a role in the development of colorectal neoplasms[24]. *H. pylori* infection might also result in direct damage to the colorectal mucosa or indirect damage to the epithelium through inflammatory responses. Contact between a repairing epithelium and endogenous or dietary carcinogens within the gut might transform the colorectal mucosa[25]. The CagA protein is the product of the cytotoxin-associated gene and is produced by cagA+ strains of *H. pylori*. It might locally activate colonic carcinogenesis through the induction of cytokine expression, including cytokines such as interleukin (IL)-8, which is associated with colorectal cancer[26]. In summary, *H. pylori* might result in local and distant interactions with colorectal mucosa and contribute to the pathogenesis of malignant transformation. However, further mechanistic studies are required.

Metabolic syndrome and its association with colorectal adenomas have been the subjects of recent study, and the pathogenic mechanisms for this potential association are still unclear. Insulin (a core contributor to metabolic syndrome) has been demonstrated to promote colorectal carcinogenesis in animal studies for more than 10 years[27,28]. It is postulated that insulin might exert proliferative effects on colonic tumor cells directly or indirectly *via* the insulin-like growth factor pathway[29]. Furthermore, increased production of proinflammatory cytokines and decreased production of anti-inflammatory adiponectin in adipocytes might be related to adenoma growth[30]. In addition, hypertriglyceridemia (a component of metabolic syndrome) might be involved in colorectal neoplasm pathogenesis. Triglycerides act as potent energy sources for cancer cell growth[31], and elevated serum triglyceride levels have been associated with increased synthesis of bile acids, which could promote large bowel carcinogenesis, as demonstrated in experimental studies[32]. Metabolic syndrome is associated with chronic inflammation, which might explain its possible association with colorectal adenoma. Adipose tissue and circulating levels of inflammatory cytokines [including tumor necrosis factor (TNF)-α and IL-6] are increased in obese and diabetic patients, and can induce several metabolic derangements characteristic of metabolic syndrome[33,34]. IL-6-induced C-reactive protein (CRP) could predict colon cancer occurrence; meanwhile, an elevated CRP level is a consistent feature of metabolic syndrome[35]. The findings indicate that chronic inflammation might be associated with colorectal carcinogenesis. In short, these evidence-base data suggest that metabolic syndrome might be a risk factor for colorectal neoplasm development.

In this study, concomitant with *H. pylori* infection and metabolic syndrome might further increase the risk of developing colorectal adenoma. The concomitant effect of metabolic syndrome and *H. pylori* might occur secondary to common inflammatory pathways of colorectal pathological mechanisms associated with metabolic syndrome and *H. pylori* infection. The inflammation-related factors of metabolic syndrome include IL-6, TNF-α, fibrinogen, and cyclooxygenase-2. The inflammation-related factors of *H. pylori* including IL-8, TNF-α, and the Cag A, Vac A, and babA2 proteins might display similar inflammatory effects attributable to the common inflammatory pathway. White blood cell counts are a risk factor of colorectal adenoma in the multivariate logistic regression analysis and might support this hypothesis of the involvement of the common inflammatory pathway. However, further investigations on the pathogenesis of this concomitant effect are necessary. Clinically, our results suggested that both *H. pylori* infection and metabolic syndrome should both be evaluated for the prevention of colorectal adenomas and carcinomas.

Studies have revealed that moderate alcohol consumption is related to increased insulin-sensitivity[36], while smoking exerted the opposite effect[37]. Other studies have suggested that both alcohol use and cigarette smoking were associated with increased risk of colorectal adenoma[38,39]. Cigarette smoking was related to colorectal adenomas in this study, although alcohol consumption was not. To clarify the association between alcohol consumption and colorectal adenoma, further studies are necessary.

In conclusion, this cross-sectional hospital-based study revealed a direct association of colorectal adenoma with *H. pylori* infection and metabolic syndrome. Furthermore, *H. pylori* infection concomitant with metabolic syndrome

might further increase the risk of colorectal adenoma. These results suggest that both *H. pylori* infection and metabolic syndrome should be considered important entities with regards to the prevention of colorectal adenoma and carcinoma. This is particularly important when a patient clinically presents with concomitant *H. pylori* infection and metabolic syndrome. The combined effects of metabolic syndrome and *H. pylori* infection should be further clarified.

COMMENTS

Background

Colorectal cancer is one of the leading causes of cancer mortality worldwide. Colorectal adenoma is the premalignant lesion in colorectal cancer. Identification of the etiology of colorectal neoplasms might assist in the development of strategies targeted toward its prevention. Previous epidemiological studies have identified family history, dietary factors, smoking, sedentary lifestyles, and alcohol consumption as potential contributors to colorectal neoplasm development. Recently, reports revealed that *Helicobacter pylori* (*H. pylori*) infection is associated with colorectal neoplasm, and a few reports disclosed that metabolic syndrome was also associated with an increased risk of colorectal adenoma. Based on these findings, the probability of colorectal adenoma in patients with both *H. pylori* infection and metabolic syndrome was further evaluated.

Research frontiers

Colorectal cancer is an extremely common malignancy, however, the direct etiology of colorectal neoplasm is still unknown. Epidemiologically, identification of the etiology of colorectal neoplasm might assist in development of strategies targeted toward its prevention. During latest decade, *H. pylori* infection and metabolic syndrome, respectively, were identified to be associated with colorectal neoplasms and hypotheses were provided to explain the mechanisms of their relationships. However, until now, there was no study focusing on whether concomitant *H. pylori* infection with metabolic syndrome in a patient will increase his or her risk of colorectal adenoma.

Innovations and breakthroughs

This study supported the association of colorectal adenoma individually with *H. pylori* infection and metabolic syndrome. Furthermore, *H. pylori* infection concomitant with metabolic syndrome might further increase the risk of colorectal adenoma.

Applications

These results suggest that both *H. pylori* infection and metabolic syndrome should be considered important entities with regards to the prevention of colorectal adenoma and carcinoma. This is particularly important when a patient clinically presents with concomitant *H. pylori* infection and metabolic syndrome; the increased risk of developing colorectal adenomas should be more seriously considered for preventive purpose.

Peer review

This paper reports an important study that assesses the rate of metabolic syndrome, *H. pylori*, and colonic adenomas in a large population of asymptomatic individuals. The significances of these findings are discussed in relation to previous studies, and hypothesis to explain the findings are reviewed. Strengths of the study include the size of the sample, high completion rate of colonoscopy, and the use of well-established diagnostic criteria for metabolic syndrome in this population. Limitations are acknowledged by the authors and include the single centre nature of the study, select patient population, and possible false negative results of HP testing.

Abstract

AIM: To study the germline mutation of *hPMS2* gene in 26 unrelated Chinese hereditary nonpolyposis colorectal cancer (HNPCC) probands and to fulfill the screening strategy for HNPCC in Chinese.

METHODS: Genomic DNA was extracted from the peripheral blood. To avoid the interference of pseudogene in detection of the remaining 11 exons (exon 1-5, 9, 11-15), long-range polymerase chain reaction (PCR) was conducted to amplify the complete coding region of *hPMS2* gene firstly. Then 1/8 of the PCR products were used as template to amplify the individual exon respectively and DNA sequencing was done. Direct DNA sequencing of the conventional PCR products of exon 6, 7, 8 and 10 of *hPMS2* gene was performed. The same analysis was made in 130 healthy persons without family histories of HNPCC to further investigate the pathological effects of the detected missense mutation.

RESULTS: One HNPCC proband fulfilled Bethesda guidelines and was found to carry the germline mutation of *hPMS2* gene, which has not been reported in Chinese HNPCC families. It was a missense mutation at c.1532C>T of exon 11. It was detected in three controls as well with an occurrence rate of 2.3% (3/130). Since it could not be found in the PMS2-single nucleotide polymorphism (SNP) database, this missense mutation is a new SNP unreported up to date. Meanwhile, 260 reported SNPs of *hPMS2* gene were detected in the 26 HNPCC probands. The 2nd and 5th exons were probably the hot SNP regions of *hPMS2* gene in Chinese HNPCC families involving 53.1% of all reported SNP.

CONCLUSION: The germline mutation of *hPMS2* gene may be rare in Chinese HNPCC families. The 2nd and 5th exons are hot SNP regions of *hPMS2* gene.

INTRODUCTION

Hereditary nonpolyposis colorectal cancer (HNPCC), or Lynch syndrome, is an autosomal dominantly inherited disease with cancer-susceptibility. Perhaps it is the most common cause of hereditary colorectal cancer, accounting for 5%-10% of the total colorectal cancers worldwide[1-3]. People inheriting this predisposition are at a particularly high risk of developing colorectal cancer with an early age of onset[3,4]. The affected patients always carry germline mutations in DNA mismatch repair (MMR) genes, mostly in *hMLH1, hMSH2*, and *hMSH6*[5,6]. Less commonly, mutations in other MMR genes are present. We analyzed the abnormalities of *hMSH2/hMLH1/hMSH6* genes in a series of Chinese HNPCC families fulfilling different clinical criteria. We studied germline mutation, large genomic variations of the entire coding regions of the three genes and methylation of *hMLH1* promoter in 58 Chinese HNPCC probands, in which 24 fulfilled Amsterdam criteria (AC)[7], 15 fulfilled Japanese criteria (JC)[8] and 19 met Bethesda guidelines (BG)[7]. The total detected gene abnormality rate was only 53.4% (31/58), including 29 cases of germline mutation and 2 cases of methylation of *hMLH1* promoter[9-14]. So the aberrant MMR genes other than *hMSH2/hMLH1/hMSH6* are suspected to be involved in Chinese HNPCC.

In order to accomplish our serial studies of Chinese HNPCC, we detected *hPMS2* germline mutation in 26 Chinese HNPCC families by long-range polymerase chain reaction (LR-PCR)-based sequencing in this study, and evaluated this manner in the molecular genetics screening of Chinese HNPCC.

MATERIALS AND METHODS

Materials

Twenty-six unrelated HNPCC probands registered from January 1998 to October 2005 at the Department of Abdominal Surgery in Shanghai Cancer Center were retrieved. Five of them fulfilled AC, 10 fulfilled JC and the remaining 11 fulfilled BG. Germline abnormalities of *MSH2/MLH1/MSH6* were excluded in all the 26 probands by PCR-based sequencing. Ten milliliter peripheral blood was collected from each proband for genomic DNA preparation. The peripheral blood samples of 130 healthy volunteers without any family history of hereditary disease or development of colon cancer in early age were obtained for control. The informed consents were signed by all the probands and volunteers before blood drawing. This study was approved by the Medical Ethical Committee of Shanghai Cancer Center, Fudan University. The whole procedures of the study were in accordance with the international rules and regulations.

DNA extraction

Genomic DNA was extracted from the peripheral blood using the QIAGEN (Hilden, Germany) DNA extraction kit and following the manufacturer's instructions. Concentrations of the genomic DNA were determined by an ultraviolet spectrophotometer (Beckman, DU640 type).

PCR amplification and DNA sequencing

LR-PCR (exon 1-5, 9, and 11-15): Since exon 1-5, 9, and 11-15 of *hPMS2* genes were severely hampered by the presence of multiple pseudogenes with highly similar sequences. LR-PCR was conducted to preferentially amplify *hPMS2* gene and avoid the interference of the pseudogenes.

Four overlapping sets of primers were designed to amplify the complete coding region of *hPMS2* gene by LR-PCR[15,16] (Table 1). The LR-PCR amplification profile is also shown in Table 1. Then 1/8 of the four LR-PCR products were used as template to amplify the 11 exons (exon 1-5, 9, 11-12 and 13-15) individually. The primer sequences are listed in Table 2.

PCR (exon 6, 7, 8 and 10): Conventional PCR was performed to detect the four exons (exon 6, 7, 8 and 10) which were seldom influenced by pseudogenes. Four sets of primers and PCR amplification profile are listed in Table 2.

DNA sequencing: The conventional PCR products were subjected to 2% agarose gel electrophoresis, while for LR-PCR products, 1% agarose was used with 9Kb as marker. After observation of clear and expected size bands, the products were purified and used as a template for sequencing reactions with BigDye terminator cycle sequencing kit (Applied Biosystems, Foster City, CA, USA). The sequencing primers were M13F or M13R. Automated fluorescence analysis was performed on a 3700 DNA sequence system (ABI, USA).

Bioinformatics analysis

Each result of sequencing was analyzed by DNAStar 5.08 bioanalysis software. The type of mutations and potential

significance were determined by comparing the corresponding amino acids and proteins in the following databases (http://www.ncbi.nlm.nih.gov/; http://www.ensemble.org/homosapies; and http://www.insight-group.org).

RESULTS

Germline mutation of hPMS2 gene in HNPCC probands

Among the 26 unrelated HNPCC probands, only one (H13) was found to carry the germline mutation of *hPMS2* gene. She was a 30-year-old female BG patient. The mutation was a missense mutation at codon 511 (ACG>ATG, Thr>Met) (Figure 1). To further investigate the pathological effects of the missense mutation, we analyzed the related exon 11 in 130 controls by PCR-based sequencing. The results showed that the mutation of codon 511, consistent with the HNPCC case at c.1532C>T of exon 11 of *hPSM2* gene, was also found in three healthy controls. The occurrence rate was approximately 2.3% (3/130). It could not be found in the PMS2-SNP database (http://www.nfdht.nl; http://www.insight-group.org; and http://www.ensembl.org). Thus, the mutation at c.1532C>T of *hPSM2* gene which we detected in the HNPCC patient is an unreported new single nucleotide polymorphism (SNP).

SNP detection and analysis of hPMS2 gene

By DNA sequencing, 27 loci on the exons of *hPMS2* gene including 260 reported SNP (http://www.ensembl.org/homo_sapies) were detected in the 26 HNPCC probands. Among them, 30% (78/260) were located in the 2nd exon, 23.1% (60/260) in the 5th exon, 13.8% (36/260) in the 15th exon, 10% (26/260) in the 7th exon, and 9.2% (24/260) in the 11th exon. However, none variant was detected in the remaining exons of the 1st, 3rd, 6th, 8th, 9th and 10th. The 2nd and 5th exons were probably the hot SNP regions of *hPMS2* gene because 53.1% of the reported SNP were located in them. Distribution of the SNP of *hPMS2* gene is shown in Table 3.

DISCUSSION

HNPCC, also called Lynch syndrome, is one of the most common autosomal dominantly inherited cancer syndromes with a high risk of colorectal cancer as well as other tumors occurring in endometrium, stomach, ovary, urinary tract, pancreas, small intestine, brain and skin. People with HNPCC take about 80% risk to develop colorectal cancer in their lifetime. It accounts for 2%-15% of all colorectal cancers. Compared to sporadic colorectal cancer, HNPCC possesses its own characteristics in clinical presentations, treatment, genetic features and management of kindred[17,18]. Many countries have established the clinical diagnostic criteria for HNPCC, such as AC, JC and BG. Defects in MMR genes, mainly in *hMLH1, hMSH2* and *hMSH6* were considered to be closely related to the genetic mechanism of HNPCC. The defection would

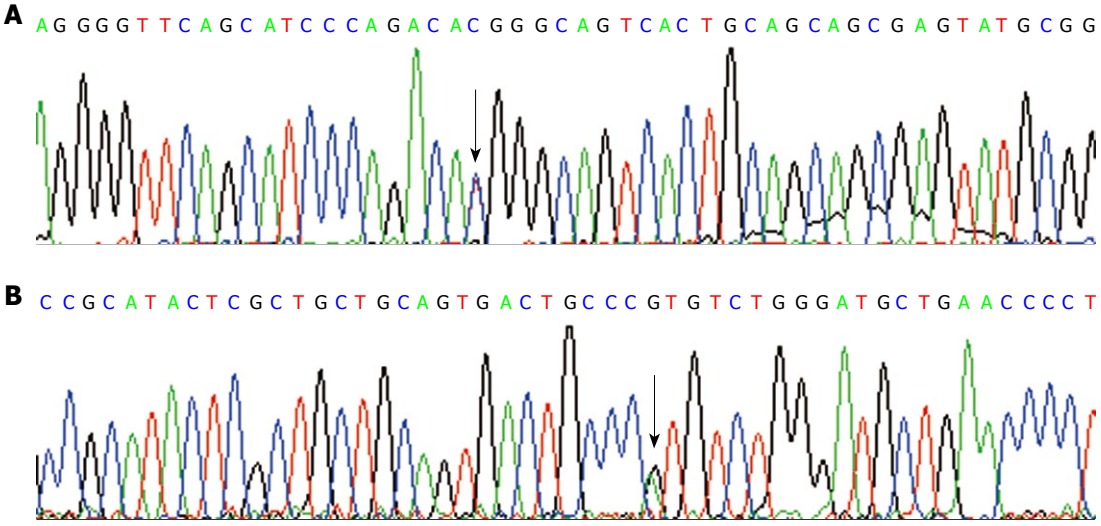

Figure 1 Missense germline mutation of exon 11 of *hPMS2* gene in the proband of H13 hereditary nonpolyposis colorectal cancer kindreds. A: The forward sequence; B: The reverse sequence. Arrow indicates the mutation site, the single basyl substitution was transversed from C to T (C>T) at the codon 511, the codon from ACG to ATG, causing the amiod acid changes from Thr>Met, the change was identified as a new single nucleotide polymorphism.

SNP: Single nucleotide polymorphism.

consequently lead to the dysfunction of MMR system, ultimately resulting in the development of neoplasm. So, detection of MMR gene mutation is the only gold criteria to make a diagnosis of HNPCC.

Within the family of MMR genes, germline mutations in the coding region of *hMSH2* and *hMLH1* could be detected in up to 45%-64% of all HNPCC families, while *hMSH6* about 10%. Previously we analyzed germline mutations and large genomic variations of the entire coding regions of *hMSH2*/*hMLH1*/*hMSH6* genes and the methylation of *hMLH1* promoter in 58 Chinese HNPCC probands, resulting in 29 germline mutations and 2 exhaustive inherited methylations of *hMLH1* promoter (excluding 3 part-methylations of *hMLH1* promoter). The total gene abnormality rate was only 53.4% (31/58). We suspected that the other MMR gene mutations might be associated with the remaining probands without *hMSH2*, *hMLH1* or *hMSH6* gene abnormalities.

The *hPMS2* gene is a member of a set of human mismatch repair genes, located on chromosome 7. It encodes the protein that plays an essential role in repairing DNA by forming an active protein complex with the MLH1 protein which interacts with MSH2 bound to mismatched bases. In 1994, Nicolaides *et al*[19] firstly found the germline mutation of *hPMS2* gene in a HNPCC patient. Since then, more and more data have proved that *hPMS2* germline mutation is involved in the development of HNPCC. In some reports, it could be detected in as high as 62% of HNPCC probands[20]. The *hPMS2* gene was suggested as the first candidate gene for testing germline mutations in HNPCC families in which *hMSH2*, *hMLH1*and *hMSH6* aberrant was excluded. However, genetic testing for germline mutation of *hPMS2* gene was technically challenging because they were severely hampered by a large family of highly homologous pseudogenes located on the same chromosome as the true *hPMS2*, such as *PMS2CL*. They shared similar sequences to *hPMS2* but had no functions. Data from literature indicated that the exon 6 to 8 and exon 10 of *hPMS2* could be easily screened by direct sequencing of genomic DNA without interference of pseudogenes. But detection of exon 1-5, 9 and exon 11-15 was complicated due to the interference of *PMS2*CL. LR-PCR was recommended as a useful method to preferentially identify *hPMS2* but not the pseudogenes. In this study, we used LR-PCR to investigate the germline mutation of *hPMS2* gene in those

HNPCC probands who did not carry *hMLH1/hMSH2/hMSH6* germline mutations investigated by the previous studies. Four overlapping sets of primers were designed to amplify the complete coding region of *hPMS2* gene by LR-PCR firstly. Then, exon-specific amplifications from the LR-PCR products were performed to obtain a clear sequence with no evidence of pseudogene contamination. We only found one missense mutation in 26 probands, which has not been reported in Chinese HNPCC families. This mutation could also be detected in the 130 control persons with an occurrence rate of about 2.3%. Since it could not be found in the PMS2-SNP database (http://www.nfdht.nl; http://www.insight-group.org; and http://www.ensembl.org), the mutation at c.1532C>T of *hPMS2* gene in our HNPCC case was an unreported new single nucleotide polymorphism (SNP). Our results showed that the germline mutation of *hPMS2* gene was probably a rare event in Chinese HNPCC, even in those probands without *hMLH1/hMSH2/hMSH6* mutations. It was consistent with the results of some other studies[21]. Interestingly, another mutation was found in the same nucleotide, c1532_1533 delCGinsAC, causing the amiod changes from Thr to Asn (http://www.insight-group.org). So, the exon 11 may be a hot SNP or mutation region of *hPMS2* gene.

The frequency of germline mutation in *hPMS2* gene was reported to be up to 62% if patients whose tumor tissues lacked protein expression of *hPMS2* or had MSI-H features, were selected[22]. Among the HNPCC families with monoallelic mutation in *hPMS2*, 65.5% were complied with BG. Recently, Niessen *et al*[23] identified 4 patients with pathogenic mutation of *hPMS2* among 97 patients with suspected Lynch syndrome who carried no germline mutation in *hMLH1*, *hMSH2* or *hMSH6*. All these 4 patients fulfilled BG and their corresponding tumor cells showed MSI-H and loss of expression of *hPMS2*. Clendenning *et al*[24] reported that a kind of frame-shift mutation of *hPMS2* occurred in 12 ostensibly unrelated Lynch syndrome patients with 20% being the deleterious mutation. However, those families with pathogenic mutation did not have significantly high incidence of Lynch syndrome associated malignant tumors, indicating that the germline mutation of *hPMS2* and occurrence of HNPCC were not concurrent sometimes. The patient with *hPMS2* gene mutation in our group also met the requirements of BG. By reviewing the family history of our mutation positive patient, we found that in her first-degree relatives, three suffered from colorectal cancer but diagnosed at age over 60 years, not in accordance with the typical feature of HNPCC. Although we are not so certain about this, the non-classical presentation of her family history, to some extent, represents the phenomenon of separation of HNPCC occurrence and *hPMS2* gene mutation.

At the same time, we detected the reported SNP in these 26 probands and found some interesting results. Most of the SNP (21/27) were in the exons and 12 were non-synonymous coding SNP(cSNP). Since these non-synonymous cSNP can induce the change of amino acid and the relationship between cSNP and pathogenesis of HNPCC still remains unclear, whether they are involved in the development of HNPCC and HNPCC related tumors needs to be further investigated.

In conclusion, the germline mutation of *hPMS2* gene is rare in the probands of Chinese HNPCC families. Since the testing of *hPMS2* gene mutation is costly and complicated, it may be not reasonable to be included in the screening strategy of Chinese HNPCC. However, the frequency of SNP of *hPMS2* gene is high and further studies are needed to identify its relationship with HNPCC.

ACKNOWLEDGMENTS

The authors are grateful to the patients who took part in this study and to the Cancer Hospital for providing blood and tumor specimens. The authors also appreciate the help from Professor Sun MH, Wang CF, Cai Q and Yan SY for the detection of germline mutations in *hMSH2*, *hMLH1* and *hMSH6* genes of the probands of the Chinese HNPCC cases, and Professor Mo SJ for supplying the Chinese HNPCC cases.

COMMENTS

Background

Germline mutations in mismatched repair genes can lead to hereditary nonpolyposis colorectal cancer (HNPCC). Previously, the authors had analyzed the abnormalities of *hMSH2*/*hMLH1*/*hMSH6* genes in a serious of Chinese HNPCC families and the total abnormality rate was only 53.4% (31/58). So the aberrant MMR genes such as *hPMS2* were suspected to be involved in Chinese HNPCC.

Research frontiers

HNPCC or Lynch syndrome, is an autosomal dominantly inherited disease with cancer-susceptibility. The testing of *hPMS2* gene mutation is costly and complicated, it may be not reasonable to be included in the screening strategy of Chinese HNPCC. However, the frequency of single nucleotide polymorphism (SNP) of *hPMS2* gene is high and further studies are needed to identify its relationship with HNPCC.

Innovations and breakthroughs

One HNPCC proband was found to carry the germline mutation of *hPMS2* gene. It was a new unreported coding SNP, which could also be detected in the control with an occurrence rate of 2.3% (3/130).

Applications

Germline mutations in genes can be used to diagnose early HNPCC and enrich the databases about HNPCC and SNP.

Terminology

HNPCC is an abbreviation of hereditary nonpolyposis colorectal cancer. Germline mutations are the mutations in genomic DNA.

Peer review

This is an interesting article which deals with a remarkably rare germline mutation, namely PMS2, which is important in the etiology of Lynch syndrome (HNPCC). Their science appears to be sound.

Abstract

Poorly differentiated endocrine carcinoma (PDEC) of the pancreas is a rare and aggressive tumor. First-line treatment is commonly a combination of etoposide and cisplatin, but there is no consensus regarding further treatment recommendations. In this report, we describe a case of pancreatic PDEC treated with gemcitabine as third-line chemotherapy. A 62-year-old man with pancreatic PDEC was administered etoposide plus cisplatin as first-line treatment; he then received irinotecan for tumor relapse. However, because irinotecan induced ileus in this patient, we chose gemcitabine as third-line chemotherapy. After two cycles of gemcitabine (1000 mg/m^2 on days 1, 8 and 15 every 4 wk), a partial tumor response was noted by computed tomography (approximately 68% reduction in tumor size). Our patient survived for 15 mo after diagnosis. This is a rare case of unresectable pancreatic PDEC, which showed a partial response to gemcitabine after the failure of two other regimens. Gemcitabine could be an effective treatment option for pancreatic PDEC that is resistant to other treatments.

Key words: Poorly differentiated endocrine carcinoma; Pancreatic endocrine tumor; Gemcitabine; Chemotherapy

INTRODUCTION

Pancreatic endocrine tumors (PETs) are rare neoplasms with an annual incidence of less than 1 per 100 000 people[1-6]. These tumors account for less than 1%-2% of all pancreatic neoplasms[1,7]. Poorly differentiated endocrine

carcinoma (PDEC) of the pancreas is characterized by aggressive tumor biology and poor prognosis. The biological behavior of PDEC is similar to that of small-cell lung cancer (SCLC), and metastatic pancreatic PDECs are often treated with the chemotherapy regimens that are used to treat SCLC. The combination of etoposide and cisplatin has been widely used to treat pancreatic PDEC because no promising chemotherapy regimens have been reported for this disease. Effective second- or later-line chemotherapy is still uncertain. Gemcitabine is an active agent against untreated and recurrent SCLC. In this report, we describe a case of pancreatic PDEC treated with gemcitabine as third-line chemotherapy.

CASE REPORT

A 62-year-old man with Crohn's disease had previously received treatment at a different hospital. In July 2007, his serum carcinoembryonic antigen (CEA) level was found to be elevated. A contrast-enhanced computed tomography (CT) scan of the patient's abdomen showed a tumor in the head of the pancreas and enlarged para-aortic lymph nodes. In September 2007, he underwent exploratory laparotomy, during which peritoneal dissemination was observed, and hence, a biopsy of the para-aortic lymph nodes was conducted. Based on the histological findings, small cell carcinoma of the pancreas was diagnosed.

Because the tumor was unresectable at the time of diagnosis, the patient was treated with a combination of etoposide and cisplatin as first-line chemotherapy in October 2007. The chemotherapeutic response was deemed to be partial, until multiple bone metastases to the skull, vertebrae, and pelvis were detected using CT after five cycles of chemotherapy. The patient was next administered irinotecan monotherapy as second-line chemotherapy, which started in March 2008. Irinotecan was stopped after one cycle because ileus occurred. He was referred to our hospital for further treatment in July 2008.

The patient had no family history of cancer, and the results of a physical examination were unremarkable. The laboratory findings were hemoglobin 11.5 g/dL (normal 14.0-17.0 g/dL), γ-glutamyl transpeptidase 113 IU/L (normal, 10-47 IU/L), glucose 136 mg/dL (normal, 69-104 mg/dL), CEA 12.8 ng/mL (normal, < 4.0 ng/mL), carbohydrate antigen 19-9 14 U/mL (normal, < 37 U/mL), neuron-specific enolase (NSE) 36.2 ng/mL (normal, < 10.0 ng/mL), and pro-gastrin-releasing peptide (pro-GRP) 338 pg/mL (normal, < 46 pg/mL). A contrast-enhanced CT scan of his abdomen revealed a low-density mass, 7.5 cm in diameter, in the head of the pancreas, as well as enlarged para-aortic lymph nodes at the time of admission. The pancreatic tumor did not show contrast enhancement (Figure 1A). A CT scan of his chest did not show any primary or metastatic pulmonary tumors. We reviewed an excised biopsy specimen of a para-aortic lymph node obtained at the previous hospital. Histological examination of the specimen showed small to intermediate-sized cells with a high nuclear-cytoplasmic ratio and frequent mitosis, and partial necrosis. Immunohistochemical staining revealed that these cells were strongly positive for NSE, CD56, and keratin; weakly positive for chromogranin A; and negative for vimentin, leukocyte common antigen, S-100, and CD99 (Figure 2). On the basis of the pathological findings, the para-aortic lymphadenopathy was determined to be caused by metastasis of PDEC. Therefore, pancreatic PDEC with para-aortic lymph nodes and bone metastases was diagnosed.

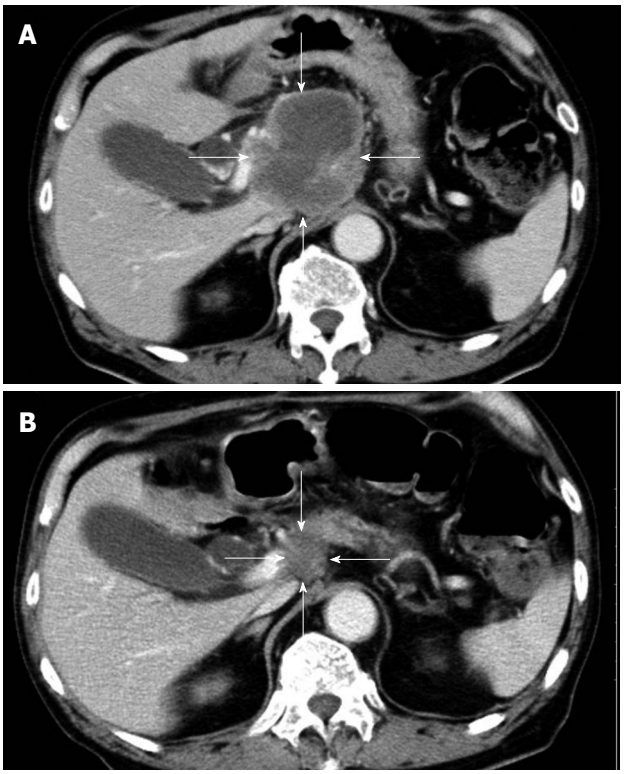

Figure 1 Contrast-enhanced computed tomography scan of the abdomen. A: There was a low-density mass, 7.5 cm in diameter, in the head of the pancreas at the time of admission. The pancreatic tumor (arrows) did not show contrast enhancement; B: A follow-up computed tomography scan showed that the pancreatic mass had reduced to 2.0 cm in diameter. The tumor (arrows) had markedly regressed 4 mo after starting chemotherapy with gemcitabine.

We chose gemcitabine as third-line chemotherapy. Starting in July 2008, the patient received 1000 mg/m^2 gemcitabine on days l, 8 and 15 every 4 wk.

After two cycles of gemcitabine, a CT scan of his abdomen showed regression of the pancreatic tumor (from 7.5 cm to 2.4 cm in diameter), and his serum NSE and pro-GRP levels had decreased to within the normal range. The chemotherapeutic response was deemed to be a partial response. After four cycles of gemcitabine, an abdominal CT scan showed a pancreatic mass that was 2.0 cm in diameter (Figure 1B). In November 2008, after day 15 of the fifth cycle, the patient requested that the therapy be stopped because of general fatigue. He died of multiple organ failure in December 2008.

DISCUSSION

Pancreatic PDEC is a rare neoplasm. Recently, Bettini *et al*[8]

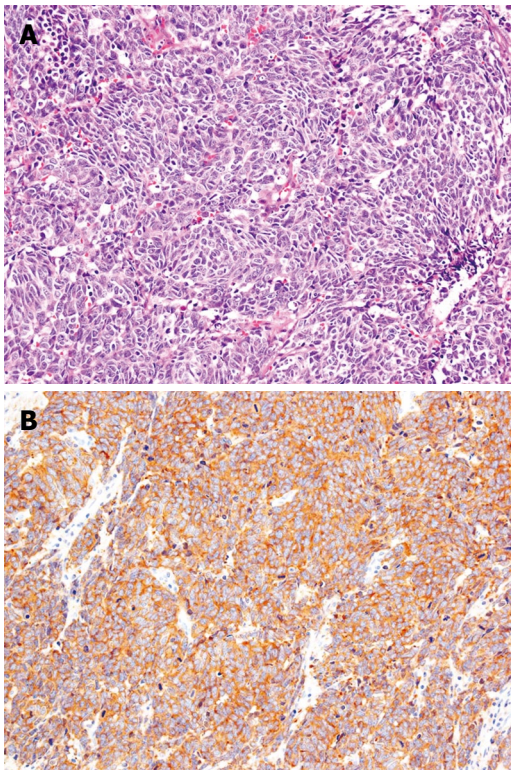

Figure 2 Histopathological findings. A: The excised para-aortic lymph node showed small to intermediate-sized cells with a high nuclear-cytoplasmic ratio. (HE stain, original magnification, × 200); B: Immunostaining for neuron-specific enolase was positive in the cytoplasm of many tumor cells (original magnification, × 200).

have reported that PDEC was diagnosed in 17 (9.4%) of 180 patients with non-functioning pancreatic endocrine tumors. PDEC is characterized by aggressive tumor biology and poor prognosis. Bettini *et al*[8] also have reported that all patients with PDEC died within 3.5 years after diagnosis (median, 11.8 mo), and that only 23.5% of the tumors were resectable at the time of diagnosis. Our patient survived for 15 mo after diagnosis. His survival time was longer than the median survival time that was reported by Bettini *et al*[8].

The standard treatment for advanced pancreatic PDEC has not yet been established. The initial approach to treatment of pancreatic PDEC is to attempt curative resection. However, liver and lymph node metastases are present in 32.5% and 59.5% of patients at the time of diagnosis[9]. Therefore, curative surgical resection cannot be achieved in most patients, and effective medical treatment to control metastatic lesions is urgently required. Systemic chemotherapy is proposed for patients with inoperable pancreatic PDEC, and adequate organ function and performance status; however, a standard chemotherapeutic regimen has not been established. In our patient, the tumor was inoperable owing to the presence of peritoneal dissemination and para-aortic lymph node metastases, and hence, systemic chemotherapy was administered to the patient.

The biological behavior of PDEC is similar to that of SCLC, and metastatic pancreatic PDECs are often treated with the same chemotherapy regimens that are used to treat SCLCs. Combination chemotherapy with etoposide and cisplatin, one of the standard regimens for SCLC, is commonly used to treat pancreatic PDEC.

Moertel *et al*[10] have reported that etoposide plus cisplatin produced good therapeutic results in patients with anaplastic neuroendocrine carcinoma (which has been defined as PDEC according to the recent WHO classification[11]), with an overall regression rate of 67% and a median regression duration of 8 mo [10]. Other investigators have reported similar results, with a median duration of response of 7-9 mo in patients with poorly differentiated endocrine tumors[12,13].

Since the report of Moertel *et al*[10], the combination of etoposide and cisplatin has been considered to be the reference treatment for PDEC; however, confirmatory studies have not been performed because of the rarity of PDEC. If this first-line chemotherapy fails to treat pancreatic PDEC, there is no consensus regarding further treatment recommendations. Irinotecan plus cisplatin is one of the standard regimens for extensive-stage SCLC[14]. In our case, the patient had been administered irinotecan monotherapy as second-line treatment before he was referred to our hospital. However, this therapy had been discontinued because ileus occurred after one cycle.

Several newer anticancer drugs, including paclitaxel[15], topotecan[16] and gemcitabine[17], have shown little activity as single agents against neuroendocrine tumors (NETs). Gemcitabine is a nucleoside analog with structural similarities to cytarabine and is widely used in the treatment of advanced pancreatic adenocarcinoma[18]. In a phase Ⅱ trial of gemcitabine for the treatment of metastatic NETs, Kulke *et al*[17] have reported that, although the treatment was well tolerated, no radiological responses were observed, 65% of the patients (n = 18) experienced disease stabilization, and that the median overall survival was less than 1 year. However, their study included various histological subtypes of NETs, and only two of the 18 patients had poorly differentiated NETs. Thus, the efficacy of gemcitabine for poorly differentiated NET of the pancreas remains unclear.

Gemcitabine is an active agent against untreated and recurrent SCLC[19-21]. The response rate to gemcitabine was reported to be 27% in patients with previously untreated SCLC[19]. In patients with previously refractory or recurrent SCLC treated with at least one chemotherapeutic regimen, gemcitabine resulted in response rates of 6%-17%[20,21].

We believe that gemcitabine is a reasonable treatment option for pancreatic PDEC, and we chose gemcitabine as third-line chemotherapy. After two cycles of gemcitabine, the pancreatic tumor showed marked regression, which resulted in a partial response. Gemcitabine has shown good efficacy as third-line chemotherapy for refractory pancreatic PDEC. The prognosis of pancreatic PDEC is extremely poor because of its highly aggressive behavior, and hence, effective second- and later-line treatments are important for improving prognosis. In light of this, gem-

citabine could be an effective treatment option for pancreatic PDEC that is resistant to other treatment.

Abstract

The use of contrast-enhanced intraoperative ultrasound for hepatocellular carcinoma has been already proposed as a novel technique to stage the disease during surgical resection. In the herein presented "letter to the editor", the authors underline some important points, which have been raised following the paper by Wu *et al*.

Key words: Hepatocellular carcinoma; Liver surgery; Contrast-enhanced intraoperative ultrasound; Cirrhosis

TO THE EDITOR

The recent paper by Wu *et al*[1] entitled "Application of contrast-enhanced intraoperative ultrasonography in the decision-making about hepatocellular carcinoma operation" published in the January issue of *World Journal of Gastroenterology* reports some experiences of the authors in contrast-enhanced intraoperative ultrasound (CEIOUS) for hepatocellular carcinoma (HCC). This paper raises a couple of questions that, we believe, need to be asked about.

First and foremost, the authors did not mention any of the previously performed and published studies on the same topic on the application of CEIOUS for HCC[2-7]. Such studies not only represent the first pioneer investigations on CEIOUS, but up to now they are the cornerstones of this new intraoperative imaging modality, which needs to be confirmed or confuted by further studies performed by other groups. In this sense, Wu *et al*[1] have lost this opportunity.

Second, it is unclear to the readers how the authors defined a lesion as malignant based on the CEIOUS findings. This is a pivotal point. Yet, CEIOUS for HCC requires a kind of classification to interpret its findings in order to make the correct diagnosis. In particular in case of cirrhotic liver, where the finding of multiple subcentimetric nodules is common, the typical arterial phase might not be very clear because some of those nodules are high-grade dysplastic nodules or early HCC with no anticipated standard contrast enhancement. Indeed, we proposed a classification that, we believe, could help in this sense, even if it probably requires some refinements[8].

Third, the reported value of specificity for CEIOUS is very high compared with that for intraoperative ultra-

sound (IOUS) and contrast-enhanced magnetic resonance imaging (CEMRI). The impression is that the authors calculated the specificity by adding the value of CEMRI and IOUS. When CEIOUS was performed on the same population of patients who had CEMRI and IOUS, its results in terms of sensitivity and specificity might be biased by the previous radiological findings. Only a true blind performance of different diagnostic methods might allow a true comparison in terms of diagnostic accuracy.

Finally, we thank that Wu *et al*[1], because our group, developed and supported the study of CEIOUS performed many years ago, both for HCC[2,4-6] and for colorectal liver metastases[9]. Thus, any new study on the same topic further sustains its use.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in tahe field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case

report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Natural orifice transluminal endoscopic surgery (NOTES) is a surgical technique that has received considerable interest in recent years. Although minimal access surgery has increasingly replaced traditional open abdominal surgical approaches for a wide spectrum of indications, in pancreatic diseases its widespread use is limited to few indications because of the challenging and demanding nature of major pancreatic operations. Nonetheless, there have been attempts in animal models as well as in the clinical setting to perform diagnostic and resectional NOTES for pancreatic diseases. Here, we review and comment upon the available data regarding currently analyzed and performed pancreatic NOTES procedures. Potential indications for NOTES include peritoneoscopy, cyst drainage, and necrosectomy, palliative procedures such as gastroenterostomy, as well as resections such as distal pancreatectomy or enucleation. These procedures have already been shown to be technically feasible in several studies in animal models and a few clinical trials. In conclusion, NOTES is a rapidly developing concept/technique that could potentially become an integral part of the armamentarium dealing with surgical approaches to pancreatic diseases.

Key words: Natural orifice transluminal endoscopic surgery; Pancreatic disease; Chronic pancreatitis; Pancreatic resection; Pancreatic drainage

INTRODUCTION

Flexible endoscopy has traditionally been limited to the intestinal lumen. However, in recent years various attempts to also provide endoscopic access to the peritoneal cavity for diagnostic and therapeutic procedures have been made. Two novel developments in gastrointestinal endoscopy and surgery have facilitated these attempts: (1) the establishment of endoscopic retrograde cholangiopancreatography in the 1970s and endoscopic ultrasound in the 1980s offered gastrointestinal endoscopists not only purely diagnostic but also therapeutic options; and (2) simultaneously, minimal access surgery increasingly replaced traditional open abdominal surgical approaches for a wide spectrum of indications. These developments led to a new and innovative, interdisciplinary way of accessing the

peritoneal cavity through the natural orifices of the body by means of transluminal endoscopic approaches to the abdominal cavity: natural orifice transluminal endoscopic surgery (NOTES). These new techniques avoid the need for abdominal incisions and may offer potential benefits, such as being less invasive and possibly more cost-effective than the traditional open or laparoscopic surgery for certain indications. In addition, NOTES may offer specific advantages for selected patient populations. For example, this technique seems especially relevant to those patients with high surgical risk, e.g. the morbidly obese patient or patients with multiple prior abdominal interventions or surgical wound infections. Since the method was first described by Kalloo *et al*[1] in 2004, surgeons and gastroenterologists have worked on transluminal access and intraabdominal surgical procedures[2].

In America and Europe, collaborative organizations of surgeons and gastroenterologists, the Natural Orifice Surgery Consortium for Assessment and Research™ (NOSCAR™)[3] and the EURO-NOTES Foundation (www.euro-notes.org), have been established to encourage and document the further development of NOTES. However, before establishing this new method and bringing it into general clinical practice, it must be confirmed to be safe and to provide real advantages for patients, thus avoiding the mistakes that were made when laparoscopic surgery was introduced a few decades ago. Therefore, the American Society for Gastrointestinal Endoscopy (ASGE) and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) Working Group met in 2006 to define in a white paper the hurdles and challenges (e.g. safe methods for closure of the gastric incision, avoidance of infections, *etc*.) to be addressed in the coming years[4].

The first experimental laparoscopy was reported in 1901 by the German surgeon Georg Kelling[5], who insufflated gas into the abdomen of dogs, but it was only 84 years later in 1985 that Erich Mühe performed the first laparoscopic cholecystectomy. Since this was rejected by the German Surgical Society, it took another two years until the French gynecologist, Philippe Mouret, reported a laparoscopic cholecystectomy with only four trocars, and that event finally triggered the interest in modern minimal access invasive surgery[6]. However, in the years that followed, many barriers to laparoscopic surgery had to be overcome. Critical elements of a new surgical technique include the development of appropriate instrumentation, requiring collaboration of medical professionals, engineers and the industry. Learning from the introduction of laparoscopic surgery, NOTES should only be implemented if all important aspects including feasibility and safety have been sufficiently evaluated, and indications have been clearly defined[7].

Training performed in a clean and safe environment, with performance analysis generating learning curves, improves patients' safety and outcomes and maximizes the benefits of implementation of new procedures such as NOTES[8]. Besides animal laboratory training, newly developed training phantoms for NOTES have been described[9].

Despite these important issues, NOTES techniques have developed rapidly over the past few years, mainly due to a close collaboration between surgeons and gastroenterologists and extensive experimental animal research. Multiple trials regarding the different access sites to the peritoneal cavity and endoscopic interventions in the abdomen have been described. The basic experience with this new procedure has been largely with animal studies; human case reports are rare, but the number is increasing steadily.

Using NOTES, surgeries like cholecystectomy[10,11], gastrojejunostomy[10,12], antireflux surgery[13], appendectomy[14], and splenectomy[15], as well as several gynecologic procedures including tubal ligation[16], oophorectomy[17] and partial hysterectomy[17], have been performed successfully in animal models *via* different approaches such as transgastric/transcolonic/transvaginal using current commercial endoscopes. Retroperitoneal interventions such as nephrectomy have also recently being described[18].

PURE OR HYBRID NOTES

According to the NOSCAR committee, pure NOTES is defined as flexible endoscopic procedures performed by crossing the respective lumen[5,19]. Natural orifices to the abdominal cavity that are actually used are the transgastric route (*via* the mouth), the transvaginal route, the transsigmoidal access *via* the anus, and the transurethral path. The use of single port surgery for percutaneous access is viewed controversially, and considered only if flexible endoscopes are used. The use of rigid instruments and even transanal endoscopic micro-surgery (TEM) are not considered as pure NOTES procedures.

Some difficulties result from these access sites as follows; firstly: penetrating the transluminal barrier with the endoscope, secondly: avoidance of contamination of the abdominal cavity, and thirdly: the closure of the entrance point. Once having passed the transluminal barrier further challenges arise. Intraoperative manipulations are possible but often limited by the unidirectional force exertion, the lack of haptic and tactile sensations and the limited triangulation with just one instrument. Medical scientists, engineers and industrial companies are working on various solutions, such as double channel endoscopes and bending instruments. Finally, the closure of the transluminal entrance has to be assured. This seems to be easier with the transvaginal and transurethral routes (which are also less prone to contamination) than with transgastric or transsigmoidal access. Nevertheless, all routes have their specific difficulties. Potential advantages of this new technique are the lack of incisional problems, e.g. pain, hernia, wound infections, as well as less adhesions and better cosmetic results.

Hybrid NOTES procedures include endoscopic surgery with the aid of laparoscopic vision or instruments for operation or access closure. The hybrid technique is actually the most commonly used form. Pure NOTES interventions are rare, and thus hybrid NOTES may serve as a temporary approach to further develop pure NOTES techniques. Parallel to the NOTES working group, the

New European Surgical Academy (NESA) founded the interdisciplinary working group for Natural Orifice Surgery (NOS) to develop surgical procedures using the natural body openings, e.g. by using a new surgical instrument, the Transdouglas Endoscopic Device (TED), a flexible multichannel instrument enabling single-entry "scarless" operations[20]. Whether pure NOTES, hybrid procedures or NOS, all these techniques are expected to move forward towards a less invasive surgical discipline.

The role of NOTES in pancreatic diseases has been analyzed in a relatively small number of experimental and clinical studies[21]. NOTES procedures might play a potential role in the diagnosis and therapy of pancreatic diseases, specifically in those areas where endoscopic and/or laparoscopic approaches have already been established, and are - at least in some centers - part of the clinical routine.

CURRENT SURGICAL PROCEDURES FOR PANCREATIC DISEASES

Open pancreatic surgery

There are various surgical procedures available for different pancreatic diseases. Resections include pancreatic head resections (classical, pylorus-preserving and duodenum-preserving partial pancreatoduodenectomies), segmental resections, distal resections, total pancreatectomies, enucleations and others. In addition, palliative procedures such as biliodigestive anastomosis and gastric bypass procedures are frequently carried out, as well as special procedures such as necrosectomy or pancreatic pseudocyst drainage (cysto-gastrostomy or cysto-jejunostomy). Open pancreatic surgery is still the gold standard but is now being challenged by endoscopic or laparoscopic approaches for a number of indications as discussed below.

Diagnostic approach for pancreatic tumors

Diagnostic laparoscopy has a limited role in potentially resectable tumors to evaluate local resectability, and to exclude distant metastases. In addition, in patients with locally non-resectable tumors who are scheduled for neoadjuvant therapy, laparoscopy is generally recommended to confirm diagnosis and to rule out occult metastasis[22,23].

Endoscopic treatment of pancreatic diseases

Endoscopic retrograde cholangiopancreatography (ERCP) offers a number of options in the diagnosis and management of pancreatic and biliary duct obstruction. However, ERCP as a diagnostic measure has been replaced to a large extent by modern imaging, e.g. MRI/MRCP. In addition, biliary or pancreatic duct drainage has a limited role in pancreatic and biliary diseases, being mostly restricted to the palliative setting. The development of endoscopic ultrasonography (EUS) offers further diagnostic accuracy for some pancreatic diseases, e.g. small tumors, neuroendocrine or cystic lesions/tumors. Nonetheless, there have been several novel therapeutic applications requiring an endoscopic approach. To cite an example, endoscopic ultrasound-guided celiac plexus block or pancreatogastrostomy and pancreatobulbostomy with stent insertion into the pancreatic duct for pain relief in patients with chronic pancreatitis[24,25]. Even procedures targeting pancreatic tumors with radiofrequency ablation[26], photodynamic therapy[27], and brachytherapy[28] using an endoscopic approach have been recently described in pilot studies. However, while there is a clear trend towards development of novel endoscopic procedures in the therapy of pancreatic diseases, evidence-based data are mostly lacking, and if present, point towards a more surgical approach, at least for some indications[29].

Laparoscopic pancreatic surgery

Drainage and necrosectomy: Internal drainage of pancreatic pseudocysts can be accomplished by traditional open or minimal access laparoscopic or endoscopic approaches. Minimal access surgery to drain pseudocysts can be performed with comparable morbidity and has become the standard of care in many cases; endoscopic approaches have similar success rates[30,31]. Open surgical necrosectomy for the treatment of infected pancreatic necrosis has relatively high morbidity and mortality rates; therefore minimal access laparoscopic as well as endoscopic or radiologic approaches are more commonly being used nowadays[32].

Bypass operations: Open (versus laparoscopic) gastrojejunostomy has been the standard palliative treatment in patients with unresectable pancreatic cancer with gastric outlet obstruction. It has a good functional outcome and relieves symptoms in many patients (if the patients were not treated by prior endoscopic stent therapy). Laparoscopic gastrojejunostomy has nowadays been proven as an effective palliation with rapid recovery in these advanced cases. Even transumbilical single-incision laparoscopic anastomoses have been reported as feasible and safe[33].

In cases of biliary obstruction (and in the case when endoscopic stent placement is not the treatment of choice), open biliodigestive anastomosis (hepaticojejunostomy) *vs* double bypass surgery (biliodigestive anastomosis and gastric bypass) has been a topic of discussion. However, laparoscopic hepaticojejunostomy is a relatively complex surgical procedure and only few reports are available for adult patients[34,35].

Laparoscopic pancreatic resections

Distal pancreatectomy: Laparoscopic distal pancreatectomies with or without preservation of the spleen have been performed and described since 1996[36]. The available data confirm that laparoscopic distal pancreatectomies are safe operations with similar or shorter operative times, blood loss, complication rates, and length of hospital stay for benign or noninvasive lesions of the pancreas in experienced hands[37,38]. As long as the resection margins are negative and the lymph node clearance is within accepted standards, this can also be performed for malignant lesions. Even though laparoscopic distal pancreatectomies are safe and feasible, most centers still carry out this resection as an open procedure[36].

Enucleation of pancreatic lesions: Laparoscopic enucleation of smaller lesions, especially with regard to neuroendocrine tumors, has also been described to be a feasible and safe approach[39]. It is associated with reduced postoperative hospital stay and comparable rates of pancreatic fistula in comparison to open surgery, although controlled trials and larger series are lacking to support these early observations.

Pancreaticoduodenectomy: Despite their early description by Gagner *et al*[40] in 1994, partial pancreaticoduodenectomies are considered extremely technically demanding for the laparoscopic approach. Recently published analyses describe laparoscopic partial pancreaticoduodenectomy as feasible, safe, and effective. Performed by highly skilled surgeons, even malignant lesions can be resected with negative margins and adequate lymph node dissection[41]. On this background, it remains to be seen whether laparoscopic pancreaticoduodenectomy can become the new surgical standard in the years to come[42].

NATURAL ORIFICE TRANSLUMINAL ENDOSCOPIC SURGICAL INTERVENTIONS IN PANCREATIC DISEASES

Diagnostic

Transgastric diagnostic endoscopic peritoneoscopy has been proven to be safe and feasible[43]. The first human clinical trial was performed on a group of ten patients with pancreatic masses. In four of these cases, peritoneal or liver biopsies were taken. Clinically significant contamination of the peritoneal cavity from the transgastric route was not observed[44]. In a recent study, 20 patients underwent laparoscopy and afterwards transgastric endoscopic peritoneoscopy, with comparable results for both procedures in 19 of 20 patients[45]. Safe and reliable gastric closure is now perhaps the only limitation to routine clinical implementation of this approach.

Therapeutic-non resection

Drainage and necrosectomy: In recent decades many interventional attempts to improve symptoms of chronic pancreatitis have been performed, such as decompression of the pancreas by stenting or stone extraction, as well as evacuation and drainage of pseudocysts. Endoscopic cystogastrostomy and cystoduodenostomy are important steps towards pure NOTES interventions[46]. In the reported case of a seven-year-old child, a hybrid NOTES cystogastrostomy was performed successfully through an existing gastrocutaneous fistula[47].

Therapy of necrotizing pancreatitis has changed in recent decades. Open approaches have increasingly been replaced by minimal access necrosectomies[48]. Minimal access approaches are often performed *via* an endoscopic transgastric access and therefore these procedures build the bridge to NOTES[49]. Indeed, transgastric/transduodenal necrosectomy has been carried out successfully in a number of studies with good long-term maintenance of the initial success and this approach has arguably been termed a currently practiced NOTES procedure[50].

Bypass operations: There have been no reports regarding pure NOTES operations for gastric and/or biliary bypasses. Hybrid NOTES for Roux-en-Y gastric bypass has been shown to be technically feasible in human cadavers[51].

EUS-guided therapeutic strategies in the therapy of pancreatic lesions: The EUS-guided injection of different substances seems to be a potential therapeutic option for cystic and also malignant pancreatic lesions. For example, the injection of ethanol into the pancreas in a swine model has been described and resulted in a localized concentration-dependent tissue necrosis without complications, which might arguably be used in the therapy of cystic lesions of the pancreas[52]. EUS-guided photodynamic therapy (PDT) with photosensitizing agents, as well as radio frequency ablation, has been shown to be safe and effective in ablation of pancreatic tissue, achieving local pancreatic tissue destruction[26,53]. EUS-guided injection of paclitaxel provided high and sustained localized concentrations in the porcine pancreas, leading to the assumption that this technique might be a potential minimal access therapeutic option for unresectable pancreatic tumors[54].

Therapeutic-resection

Distal pancreatic resections: Ryou *et al*[55] demonstrated in 2007 the technical feasibility of hybrid NOTES distal pancreatectomy in five pigs, and Matthes *et al*[56] demonstrated the feasibility of a pure NOTES distal pancreatectomy also in 2007. Allemann *et al*[57] reported on the initial experience in five pigs using a transvaginal retroperitoneal NOTES approach for distal pancreatectomy without any intraoperative complications. In a first randomized controlled trial of NOTES *vs* laparoscopic distal pancreatectomy in a porcine model, Willingham *et al*[58] demonstrated that there were no clinical or survival differences between NOTES and laparoscopy, although the laparoscopic operations were significantly faster (Table 1).

Enucleation of pancreatic lesions and partial pancreaticoduodenectomy: Only one actual study has been carried out concerning the feasibility of pancreatic tumor enucleation *via* a transgastric route in a porcine model[59]. No animal or human NOTES partial pancreaticoduodenectomies have currently been reported in the literature.

CONCLUSION

Transgastric/transduodenal drainage of pancreatic pseudocysts as well as necrosectomies are performed regularly in humans and have been shown to be safe and feasible, with a potential clinical benefit. Transgastric diagnostic peritoneoscopy for the staging of pancreatic cancer is also safe and feasible, and has been experimentally performed in humans. Pancreatic left resections, tumor enucleations and EUS-guided application of radiofrequency ablation,

NOTES: Natural orifice transluminal endoscopic surgery.

photodynamic therapy or application of chemotherapeutics seems to be feasible in porcine models. The oncological outcome of these interventions remains unclear. Biliary and/or gastric bypass operations, as well as partial pancreaticoduodenectomies, have rarely or never been performed using NOTES either in animal models or in humans.

In summary, NOTES may play an increasing role in the drainage of pancreatic pseudocysts and in necrosectomy, in the staging of pancreatic masses and also in the palliative treatment of unresectable pancreatic tumors. Other minimal access pancreatic procedures may be a long-term aim in ongoing development. It is obvious that technical issues, including instrumentation, visualization, intra-abdominal manipulation and gastric closure need further refinement.

Abstract

Studies concerning the eradication of *Helicobacter pylori* have resulted in a proliferation of meta-analyses. To date, there are 303 meta-analyses cited in PubMed, 113 dealing with the therapy of the infection. A chronological analysis of the results of meta-analyses performed between 1998 and 2010 shows that first-line standard triple therapies achieved eradication rates on an intention-to-treat basis of around 80%; prolonging treatment to 14, but not 10 d should improve the results. The proton pump inhibitors have a similar efficiency, and giving a double dose is more efficient than the standard doses of these drugs. Triple and quadruple therapies proved to be equivalent. Based on meta-analytical data, the decrease in efficiency over time cannot be substantiated: eradication rates < 80% followed from the introduction of triple therapies. As alternatives, ranitidine bismuth citrate-, levofloxacin- or furazolidone-based therapies were shown to obtain the same eradication rates as standard triple regimens. Sequential therapies and quadruple non-bismuth-based therapies were superior to standard triple therapies but their use is limited to certain countries. In the author's opinion, and from a meta-analytical viewpoint, standard triple therapies cannot yet be considered obsolete. Furthermore, non-inferiority trials are proposed for the future, including assessment of local contemporary antimicrobial resistance profiles and the CagA and CYP2C19 status of the enrolled patients.

Key words: Antibiotics; Eradication; *Helicobacter pylori*; Meta-analysis

BACKGROUND: META-ANALYSES IN THE EVALUATION OF *HELICOBACTER PYLORI* ERADICATION

The discovery of *Helicobacter pylori* (*H. pylori*) led to a tremendous scientific output with 28 441 papers published between 1983 and May 2010 (http://www.pubmed.com, accessed on 27 May, 2010). Randomised controlled trials (RCT) have emerged as the main method for assessing the efficiency of *H. pylori* eradication. The guidelines are based on the most recent results of RCTs[1-6]. It became clear that RCTs could not cover all aspects of anti-*H. pylori* treatments and thus, studies on eradicating the bacterium prompted many meta-analyses, developing

into a fashionable genre in scientific literature. In contrast with human studies, meta-analyses do not require ethical/institutional approval, they are much cheaper, while they only need a detailed literature survey - which is much easier in the age of the internet than before - and a professional statistical background. Meta-analysis itself is an evolving field of medical statistics: starting from simple summary statistics it applies increasingly sophisticated procedures. Its methodology is described in textbooks[7] and is available in software packages. Gastroenterology journals were keen to publish meta-analyses, which created an abundance of analyses, superfluous information, and even errors and confusion.

In spite of the high worldwide prevalence of *H. pylori*-related conditions, the eradication of the infection has not been the subject of megatrials with tens of thousands of cases, as has been the case with hypertension, hyperlipidemias or diabetes[8-10]. To date, there are 303 meta-analyses which have been published worldwide on the topic of *H. pylori*, 113 dealing with its eradication: these can be classified by subject as shown in Table 1. In this editorial, the current position of the standard triple therapies will be discussed from a meta-analytical perspective[11-34].

Table 1 Topics of meta-analyses of *Helicobacter pylori* eradication between 1992-2010

Topics of meta-analysis	No. of studies
First-line triple therapies	25
PPI-based therapies	22
Ranitidine bismuth citrate-based therapies	3
Bismuth-based quadruple therapies	2
Non-bismuth-based quadruple therapies	1
Histamine H_2 receptor blockers + two different antibiotics	5
Rescue (second- and third-line) therapies	3
Sequential therapies	4
Alternative therapies	4
Eradication in functional dyspepsia	20
Eradication in peptic ulcer	10
Effect of CagA status on eradication	1
Gastric cancer prevention	5
Eradication in children	2
Eradication in prevention of NSAID-ulcers	1
Eradication in extradigestive diseases	5
Effect of probiotics on eradication results	5
Eradication and antimicrobial resistance	4
Effect of CYP polymorphism on eradication	2
Adverse effects of eradication	4
Multiple topics	11
Total	113

PPI: Proton pump inhibitors; NSAID: Nonsteroidal anti-inflammatory drugs; CYP: Cytochrome P450 isoenzyme.

ARE FIRST-LINE STANDARD TRIPLE THERAPIES OBSOLETE?

According to the Maastricht I consensus[1], in naive *H. pylori*-infected patients, a 7-d triple therapy consisting of any of the available proton pump inhibitors (PPI) b.i.d. + amoxicillin 1000 mg b.i.d. and clarithromycin 500 b.i.d. or metronidazole 400 or 500 mg q.i.d. is recommended. In the United States, the same regimens are given for 10-14 d[2]. The recommendations date from 1996 and 1998, and remained unchanged in subsequent guidelines[3,4]. The Second Asia-Pacific[5] and the revised Japanese consensus[6] both recommended 7-d regimens including PPI + amoxicillin 1000 mg + clarithromycin 500 mg or metronidazole 400 mg b.i.d., or PPI + clarithromycin 500 mg + metronidazole 400 mg b.i.d.

Meta-analyses of the first-line standard triple therapies demonstrated eradication rates of around 80% on an intention-to-treat (ITT) and over 85% on a per protocol (PP) basis[11-17], with the different PPIs achieving similar results[18,21-23,27]. The duration of treatment did[16] or did not[29] influence the rates of eradication. High-dose PPIs were more efficient than standard doses[18,30] (Table 2).

Before the consensus era, successful eradication was considered to be the curing of the infection in more than 80% of cases on an ITT basis. This level was proposed by Graham et al in 1989 and later even higher rates (85%-90%) were considered realistic[35,36]. This rate was later accepted by the guidelines and consensus conferences. Some experts observed that the efficiency of standard triple therapies over the range of 7-10-14 d has decreased in recent years (i.e. < 80%)[34-37] and proposed that they should possibly be abandoned as being no longer effective. In a recent overview of the topic, the results of large trials document this decrease[35]. These studies, however, seem to be grouped rather arbitrarily, not as systematic reviews and no meta-analytic workup was performed. In fact, as shown in Table 2, many meta-analyses are based on studies performed between 1993 and 2000 and show that the eradication rates of first-line standard therapies are around 80%. Looking at the 95% CI, it is obvious that in a variable proportion of the studies, the rate is well under 80%, thus the decrease in efficiency of PPI-based triple therapies is not a new phenomenon: it existed from the introduction of these regimens[11-18]. An analysis of European congress abstracts published between 1997 and 2004 revealed no decrease in the efficiency over time of first-line therapies[28]. Most of the data came from a Spanish centre, using standardized data extraction, with study quality assessment and upgraded statistical methodology, resulting in high-quality meta-analyses[14-16,18-24].

REASONS FOR ERADICATION FAILURES

The main, but not the only, culprit for the lower eradication rates is antimicrobial resistance. Meta-analyses showed that macrolide resistance reduced the success rate of standard triple therapies by 20%-55%, and nitroimidazole resistance by 25%-50%[38-41]. Antimicrobial resistance, however, is always a local, and yet a uniform county/country/continental or even global phenomenon; therefore, determining of the local resistance rates must occur at the same time as the eradication trials - however, this rarely happens. Geographically, regions with low rates of eradication are not always the same as those with high antimicrobial resistance rates. Unfortunately, antimicrobial resistance

Table 2 First-line standard triple therapies for *Helicobacter pylori* eradication: chronological order and results of meta-analyses

determinations are largely neglected even in developed countries. It seems that the 27 years from the discovery of *H. pylori* were not enough for the medical community to understand that chronic gastritis and peptic ulcers are infectious diseases and doctors must think as infectionists in their therapeutic judgements. A recent study from California stated that the "epidemic" of antimicrobial-resistant infections was related to insufficient funding, surveillance, control, prevention, research and development and misguided regulation of antibiotic use, including in agriculture and especially for food animals[42]. In fact, none of the guidelines cited[1-6] or experts/opinion leaders[43] contraindicate explicitly the use of clarithromycin or metronidazole; they only outline the levels of antimicrobial resistance in which these compounds should be avoided.

Polymorphism of the CYP2C19 isoenzyme has been shown to result in significant differences of eradication rates between homozygous and heterozygous extensive metabolizers and poor metabolizers of omeprazole and lansoprazole, but not of rabeprazole; however, almost all the data are from Japan and China[29,31].

CagA positive status seems to affect eradication rates favorably, at least in Europe and North America[26]. Tailoring treatment after the determination of both CYP2C19 and CagA status yielded a 96% eradication rate *vs* 70% with standard triple therapy in Japan, without an increase in the final cost of successful eradication[44].

Eradication rates show significant geographical variations: a Canadian systematic review and meta-analysis revealed that although PPI-based triple regimens are recommended worldwide as first-line treatment, there are regional differences in success rates between Asia, Africa, North and South America and Europe that are not completely explained by antimicrobial resistance rates and local prevalence of the infection[45,46]. In our meta-analysis of European congress abstracts, we also found continental variations, without an east-west or north-south gradient[28]. Genetic differences of *H. pylori* strains infecting these populations might influence eradication rates but this has not yet been investigated.

ALTERNATIVE THERAPIES

Several alternatives to standard triple therapies have been proposed. Ranitidine-bismuth citrate (RBC) emerged in 1991 as a highly efficient drug in association with amoxicillin and clarithromycin; 3 meta-analyses showed that RBC-based triple therapies achieve similar rates of eradication to PPI-based regimens, and when given with nitroimidazoles are superior to PPI-based combinations[15,17,24]. The lack of worldwide availability and a fall in the product's promotion have led, however, to a limited use of this valuable compound. Levofloxacin given to 1926 cases in 11 studies as part of first-line triple therapy was superior to standard regimens (odds ratio 1.56, CI: 1.25-1.94)[31] and it was also found to be efficient and safe according to a Chinese meta-analysis[47]. Moxifloxacin, given in 4 studies to 772 patients, achieved 84.1% eradication as compared to the 73.6% of the standard therapy (relative risk: 1.13, CI: 1.01-1.27)[48], but resistance values forecast that the quinolones will suffer the same fate as macrolides. Furazolidone is cheap and useful in first-line treatment: when given with PPI + one antibiotic, it achieved eradication in 81.4% of cases, better than standard regimens (71.7%, odds ratio: 2.34, CI: 0.76-3.92), but this nitrofuran derivative has limited availability[49]. Three meta-analyses showed that 10-d sequential therapy is superior to standard regimens, but almost all studies are Italian: these data must be confirmed in other countries/populations before considering it a first-line therapy[50-52]. The non-bismuth concomitant quadruple therapies are also better than the standard regimens, and less complex than sequential therapy[33,36]. All of the regimens have their pros and cons: we still lack an ideal first-line therapy.

PROPOSAL FOR THE FUTURE

From a meta-analytical point of view, the decrease in the efficiency of standard triple therapies over time cannot be substantiated: sets of studies obtaining an eradication rate of less than 80% have existed from the beginning. Further studies are needed before abandoning them as being no longer effective. While there is no new antibiotic on the horizon that works against *H. pylori*, instead of the multistep approach of small pilot studies to identify effective new therapies, I would like to propose adequately powered non-inferiority trials with a pre-defined margin (10%, 15% or perhaps 20%) in which standard triple therapies are compared with the available alternatives, taking the antimicrobial resistance profile, CagA and CYP2C19

status into consideration. The design and methodology of non-inferiority trials are available[53]. If the inferiority of standard triple therapies is confirmed in this way, they can be abandoned and deleted from the guidelines. Until then, in this author's opinion, standard triple therapies should be given in most countries/regions as first-line therapies, according to the local guidelines. Furthermore, as leading authorities have stated, there is still much to be learned about the association of *H. pylori* with human disease and optimal therapy of these conditions[43].

ACKNOWLEDGMENTS

The secretarial help of Mrs. Jolán Józan (Semmelweis University, Department of Physiology, Budapest) and correction of the English manuscript by Mr. Douglas Arnott (EDMF Translation Services, Etyek, Hungary) are gratefully acknowledged.

Abstract

Colorectal cancer is the second most common cause of cancer-related death in many industrialized countries and is characterized by a heterogenic pool of cells with distinct differentiation patterns. Recently, the concept that cancer might arise from a rare population of cells with stem cell-like properties has received support with regard to several solid tumors, including colorectal cancer. According to the cancer stem cell hypothesis, cancer can be considered a disease in which mutations either convert normal stem cells into aberrant counterparts or cause a more differentiated cell to revert toward a stem cell-like behaviour; either way these cells are thought to be responsible for tumor generation and propagation. The statement that only a subset of cells drives tumor formation has major implications for the development of new targeted therapeutic strategies aimed at eradicating the tumor stem cell population. This review will focus on the biology of normal and malignant colonic stem cells, which might contribute to our understanding of the mechanisms responsible for tumor development and resistance to therapy.

COLONIC EPITHELIAL STEM CELLS

The adult colonic epithelium has a well-defined architecture organized into crypts, dynamic structures which are constantly self-renewing[1]. Each crypt unit is maintained by adult multipotent stem cells (SCs), located at the bottom of the structure itself, that are able to simultaneously self-renew and generate a population of transiently amplifying cells which in turn generate more mature cells. Three differentiated cell types mediate the function of colonic epithelium: the colonocytes, also termed absorptive enterocytes, the mucus-secreting goblet cells and the enteroendocrine cells.

Adult SCs are defined by several key functional properties including: self-renewal, potential for multilineage differentiation and tissue regeneration. Two different models have been proposed to localize the intestinal SCs; the "+4 position" model and the "stem cell zone" model[2]. According to the former, the intestinal SCs are located at +4 position relative to the bottom of the small intestine crypt, just above the non-cycling Paneth cells. These cells are actively cycling and, through asymmetric division, give rise to their differentiated progeny. The more recent "stem cell zone" model states that small undifferentiated cycling

cells, termed crypt base columnar (CBC) cells, are the true intestinal SCs. These cells are interspersed between the Paneth cells in the small intestine or located at the very bottom of the crypt in the colon.

Despite the fact that colonic crypts have long been known to harbor a functional stem cell compartment, the identification, isolation and characterization of colonic crypt SCs has been hampered by the absence of reliable molecular markers. Over the last 30 years, many studies have been performed to indirectly localize intestinal SCs within the colonic crypts by using techniques such as long-term retention of DNA label[3] or histone-GFP marking[4], both based on the "immortal strand hypothesis" proposed by Cairns[5]. According to this theory, SCs might selectively retain their old DNA strands, while donating the newly synthesized DNA strands to their progeny. However, this hypothesis is currently a subject of controversy due to the demonstrated absence of asymmetric genetic material segregation in hematopoietic stem cells[6]. Recently, several molecules have been proposed as markers of SCs in the intestine including the RNA-binding protein musashi-1 (Msi-1)[7] and Hes-1, a transcriptional repressor transactivated by Msi-1[8]. Hes-1 and Msi-1 were shown to be co-expressed by the putative SCs at the crypt base, but immunoreactivity was also observed in a broader population of cells.

Other putative biomarkers have been evaluated for distinguishing the SC population within the colon, such as members of the integrin superfamily of transmembrane glycoproteins including α2 and β1 subunits[9]. Additionally, Eph-B receptors have been described as important regulators of migration and proliferation in the intestinal epithelium[10]. However, the inhibition of Eph-B2/Eph-B3 signaling has been shown to reduce the number of proliferating cells without altering the stem cell number, suggesting that Eph-B receptors are unlikely to be independent biomarkers of colonic SCs.

Another possible intestinal stem cell marker recently identified is the polycomb protein Bmi-1, known to be involved in the maintenance of hematopoietic and neural stem cells[11]. In the small intestine, this factor is expressed in cells with stem cell features located near the crypt bottom[12].

The colonic epithelium is replaced every five days[13]. This high rate of tissue renewal depends on a complex interplay between processes involving cell proliferation, differentiation, migration, adhesion and cell death that are finely coordinated by a relatively small number of highly evolutionarily conserved signaling pathways including BMP, Sonic hedgehog, Notch and Wnt, the latter playing a critical role in the regulation of epithelial SCs in the intestinal tract.

Wnt signaling is required for self-renewal of gut SCs; it is involved in intestinal embryogenesis and adult intestinal epithelial cell proliferation[14,15]. The unique role played by the Wnt pathway in the physiology of the intestine led to the identification of the Wnt target gene *Lgr5* as a biomarker of intestinal SCs in mouse small intestine and colon. The *Lgr5* gene encodes a leucine-rich repeat containing G-protein coupled receptor, also known as Gpr49. Lgr5 expression is restricted to cycling CBC cells and it has been demonstrated that Lgr5-expressing cells differentiate into the expected functional lineages of the colonic epithelium[16].

Interestingly, the ability of single $Lgr5^+$ SCs to establish long-term culture and to generate crypt-villus organoid, without requiring a mesenchymal niche, has been also described[17].

Transcriptome analysis of $Lgr5^+$ epithelial cells isolated from the bottom of the small intestinal crypts led to the identification of a gene signature for these $Lgr5^+$ SCs[18]. Not surprisingly, many genes on the list were Wnt target genes whose expression was confirmed to be restricted to cells at the base of the crypts, as revealed by in situ hybridization. By this technique olfactomedin-4 (OLFM4) was also identified as a highly-specific and robust marker for $Lgr5^+$ SCs, even though its expression was not under the control of Wnt. The *OLFM-4* gene encodes a secreted molecule with unknown function, originally cloned from human myeloblasts[19], which is enriched in human colon crypts[20]. Due to the very low expression levels of Lgr5, OLFM-4 has been recently proposed as a more faithful SC marker highly expressed in CBC cells in human small intestine and colon[21].

COLORECTAL CANCER STEM CELL IDENTIFICATION

Tumors are composed of a heterogeneous mixture of cancer cells at various levels of differentiation, very similar to the structure of an organ. Recently, the "cancer stem cell" model of tumorigenesis has proposed that within the tumor mass there is a predetermined cell population with a "stem cell" phenotype, able to perpetuate the cancer, while the rest of the tumor cells are incapable of self-renewal. Even though it has long been assumed that mutations within adult colonic stem cells may induce neoplastic transformation, the proof of existence of colorectal cancer stem cells (CRC-SCs) has been hindered in the past years by difficulties in identifying a specific biomarker for this rare cell population. Only recently, new evidence has been provided that supports the existence of CRC-SCs, confirming that the tumorigenic cell population of CRC can be isolated on the basis of the expression of specific cell surface biomarkers. The standard analysis to ascertain the existence of a subpopulation of cancer stem cells (CSCs) is the demonstration that these cells can transfer the tumor in immunocompromised mice and replicate the phenotypic heterogeneity of the parental tumor. Several recent studies have evaluated the functionality of specific CRC-SC biomarkers by using a combination of flow cytometry to identify a "putative" SC population and xenograft models involving immunodeficient mice to determine their tumor initiating potential[22]. In the first two studies, CD133, also known as Prominin-1, was employed to identify the tumorigenic cell population within CRC[23,24].

O'Brien *et al*[23] isolated CD133$^+$ cells from seven primary colon cancers and ten extracolonic (metastatic) sites. When transplanted into the renal capsule of NOD/SCID mice, CD133$^+$ cells readily developed tumors displaying morphologic features equivalent to those of the parental cancer. Tumor phenotype was further maintained upon serial transplantation[23]. Similarly, in the second study, a population of CD133$^+$ cells, accounting for approximately 2.5% of tumor cells, was isolated from colon cancer specimens and perpetuated *in vitro* as floating colonies or "tumor spheres". These tumor spheres, expressing the epithelial adhesion molecule BerEp4, but not differentiation markers such as cytokeratin 20 (CK20), were enriched in a tumorigenic population and could be maintained for serial *in vitro* passages[24]. Both studies demonstrated the expression of CD133 also in normal colon tissue, although at a lower frequency, reinforcing the hypothesis that CD133$^+$ CRC-initiating cells in cancer samples might result from oncogenic transformation of normal colonic SCs. Subsequently, Dalerba *et al*[25] proposed CD44 and the epithelial surface antigen (EpCAM) as CRC-SC-specific markers, with further enrichment by CD166. Purified CD44$^+$/EpCAM^{HIGH} cells injected into NOD/SCID mice resulted in high frequency generation of tumor xenograft. In contrast, CD44$^-$/EpCAM^{LOW} cells lack tumor-initiating activity[25]. Further subfractionation of the CD44$^+$/EpCAM^{HIGH} cell population by using the mesenchymal stem cell marker CD166 increased the success of tumor xenograft. Finally, in a more recent study, aldehyde dehydrogenase 1 (ALDH) has been proposed as a promising new marker for normal and malignant human colonic SCs[26]. As few as 25 ALDH1$^+$ cancer cells, isolated by flow cytometry, were able to generate tumor xenografts. Notably, a subsequent isolation of cancer cells using a second marker (CD44 or CD133 serially) produced a modest further enrichment of tumor-initiating ability.

Significant controversies exist over the functional role of these CRC-SC markers. Major questions have been raised regarding CD133. Indeed, Shmelkov *et al*[27], using a transgenic mouse model in which the CD133 promoter drove *LacZ* reporter expression, demonstrated that CD133 was expressed by both mature and undifferentiated colonic epithelial cells, suggesting that CD133 is not restricted to the SC compartment[27]. Moreover, using confocal microscopy the authors reported that in primary colon cancer samples from humans and mice, CD133 was expressed in all epithelial, EpCAM$^+$ cells in the malignant tissue and that CD133 expression was excluded from the non-epithelial cell components of the tumor. Thus, they proposed that the inability of CD133$^-$ to generate tumors could be simply due to their non-epithelial nature. Furthermore, the same authors demonstrated that both CD133$^+$/EpCAM$^+$ and CD133$^-$/EpCAM$^+$ cell populations, isolated from liver metastasis of colon cancer, were able to generate tumors upon serial transplantation into NOD/SCID mice. Taken together these data appear to be in contrast with those previously published. However, the different techniques employed do not allow a direct comparison between the studies. Indeed, it is possible that primary and metastatic tumors may have a different expression pattern for CD133. Moreover, when Shmelkov *et al*[27] analysed primary tumors they did not perform the same functional assessment of tumor-initiating activity as was done in previous reports.

Regardless of the ongoing debate as to CD133 as a CRC-SC marker and the lack of evidence for a functional role in tumorigenesis of this marker, clinical data support the significance of this molecule in CRC, particularly as an independent negative prognostic marker[28]. Furthermore, the combined evaluation of CD133 and nuclear β-catenin can identify high risk cases of low stage CRC[29]. A comparison of expression of the three markers CD133, CD44 and CD166 that have been associated with CRC-SCs revealed that the expression of CD133 correlates with that of CD166, whereas both do not correlate with CD44, confirming that CD133 is, alone, the best marker to predict poor patient survival[30]. In a more recent report, Artells *et al*[31] observed longer relapse-free interval and increased overall survival in patients with lower levels of CD133.

To address the clinical relevance of CD133 for CRC metastasis in patients, Horst *et al*[32] analyzed CD133 expression in a matched case-control collection of 54 pairs of CRC with and without synchronous liver metastasis. They demonstrated that there is a strong correlation between high CD133 expression and synchronous liver metastasis. However, the authors did not observe any effect, when knocking down CD133, on colon cancer cell line proliferation, migration, invasion and colony formation. Thus, they conclude that CD133 is a marker with high prognostic impact for CRC, even though it seems to have no relevant functional role as a determinant of tumor progression.

Taken together these data confirm the need to identify biomarkers for CRC-SCs in order to improve our understanding of the mechanisms underlying tumor growth and progression. In this regard, Barker *et al*[33] have shown that deletion of APC in Lgr5$^+$ expressing cells leads to their transformation within days, suggesting that Lgr5 may mark not only normal intestinal stem cells, but also a limited population of CSCs. Simultaneously, using knock-in *LacZ* reporter mice within the Prominin-1 (*Prom1*) locus, Zhu *et al*[34] have shown that Prom1$^+$ cells, located at the base of the crypts in the small intestine, co-express Lgr5, generate the entire intestinal epithelium and are susceptible to neoplastic transformation.

From a clinical point of view, a recent study showed that Lgr5 was markedly over-expressed in the majority of advanced CRCs compared with normal mucosal tissue[35]. As expected, in situ hybridization analysis confirmed the expression of Lgr5 in CBC cells in both small intestine and colon. This Lgr5 expression, which was variable among CRC cases, correlated significantly with lymphatic and vascular invasion, lymph node metastasis and tumor stage, suggesting the involvement of this marker in tumor progression.

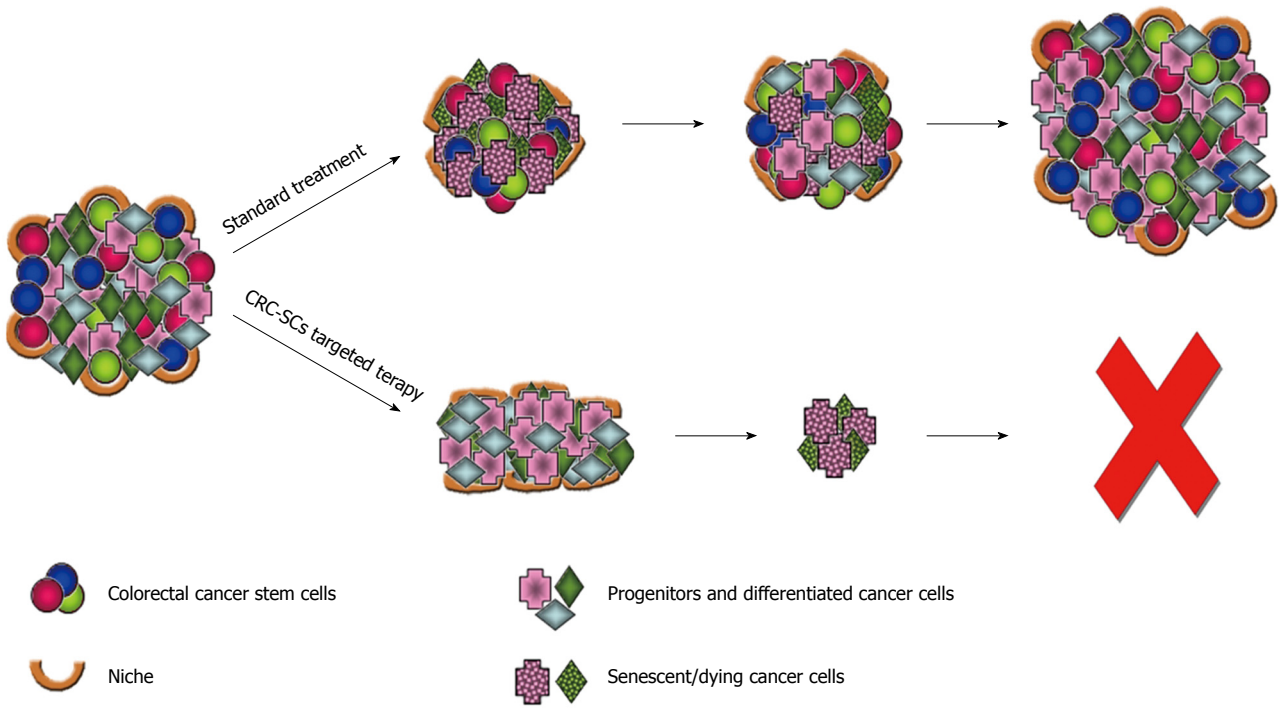

Figure 1 Therapeutic implication of cancer stem cells. The failure of current standard therapies in tumor eradication can be explained by assuming that colorectal cancer stem cells (CRC-SCs) are able to survive treatments leading to an only transitory clinical remission. Therapeutic strategies that specifically target the CRC-SC pool, by eliminating the self-renewing component of the tumor mass, could be more effective in eradicating the tumor and reducing the risk of relapse and metastasis.

A similar correlation has been described for the "stemness" gene *Bmi1* by Du *et al*[36]. Real-time analysis of 98 samples of CRC showed that high expression of Bmi-1 is directly correlated with poor patient survival.

IMPLICATION OF CRC-SC MODEL FOR THERAPY

The CSC model has important implications for cancer therapy. Many current cancer therapies target the most rapidly dividing cells, which represent the majority of the tumor cell population. This can result in a remarkable but frequently transitory clinical remission. Failure of conventional treatment options to eliminate the CSC compartment might result in tumor relapse and, more importantly, in the proliferation of therapy-resistant and more aggressive tumor cells, which ultimately reduce patient survival (Figure 1). Several features of CSCs may make them hard to eliminate. CSCs are relatively quiescent and this allows them to escape from chemotherapeutic regimens that typically target actively cycling cells. Moreover, as shown for their normal counterpart, CSCs have been proposed to exhibit high level expression of multidrug transporter family genes, likely resulting in more efficient efflux of chemotherapeutic drugs and innate multidrug resistance[37]. In addition, signaling pathways that regulate self-renewal of normal colonic SC population, such as Wnt, Hedgehog or Notch, are dysregulated in CRC leading to tumor development. The development of an efficient therapeutic approach would therefore require the identification of distinctive molecular pathways active in CSCs and the identification of agents that can either block CSC proliferation or induce CSC differentiation, thus enhancing sensitivity to chemotherapeutic drugs.

Together with resistance to chemotherapy, CSCs are frequently resistant to standard radiotherapy regimens. In this respect, it has been recently demonstrated that resistance to radiation of $CD133^+$ glioblastoma SCs can result from elevated expression of DNA damage response genes[38]. Radiotherapy for glioblastoma is associated with an increase in the proportion of the $CD133^+$ fraction. Similarly, Dylla *et al*[39] showed that CRC-SCs are enriched in residual tumors following chemotherapy and remain capable of rapidly regenerating tumor from which they were derived. The authors have further demonstrated that resistance is mediated, at least in part, by ALDH1 enzyme activity.

Together with intrinsic factors, the microenvironment, or niche, may influence the ability of CSCs to proliferate, migrate or invade. The niche is an anchoring site for CSCs, and adhesion molecules or microenvironmental soluble molecules, including growth factors and cytokines, can significantly contribute to the refractoriness to therapy.

Todaro *et al*[40] have recently demonstrated that the up-regulation of interleukin-4 (IL-4) in $CD133^+$ CRC-SCs is an important mechanism that protects these tumorigenic cells from apoptosis. $CD133^+$ CRC-SCs produce IL-4 as an autocrine growth factor promoting tumor resistance to chemotherapeutic agents such as 5-fluorouracil and oxaliplatin. Growth inhibition by these agents was significantly increased when cells were first treated with antibodies

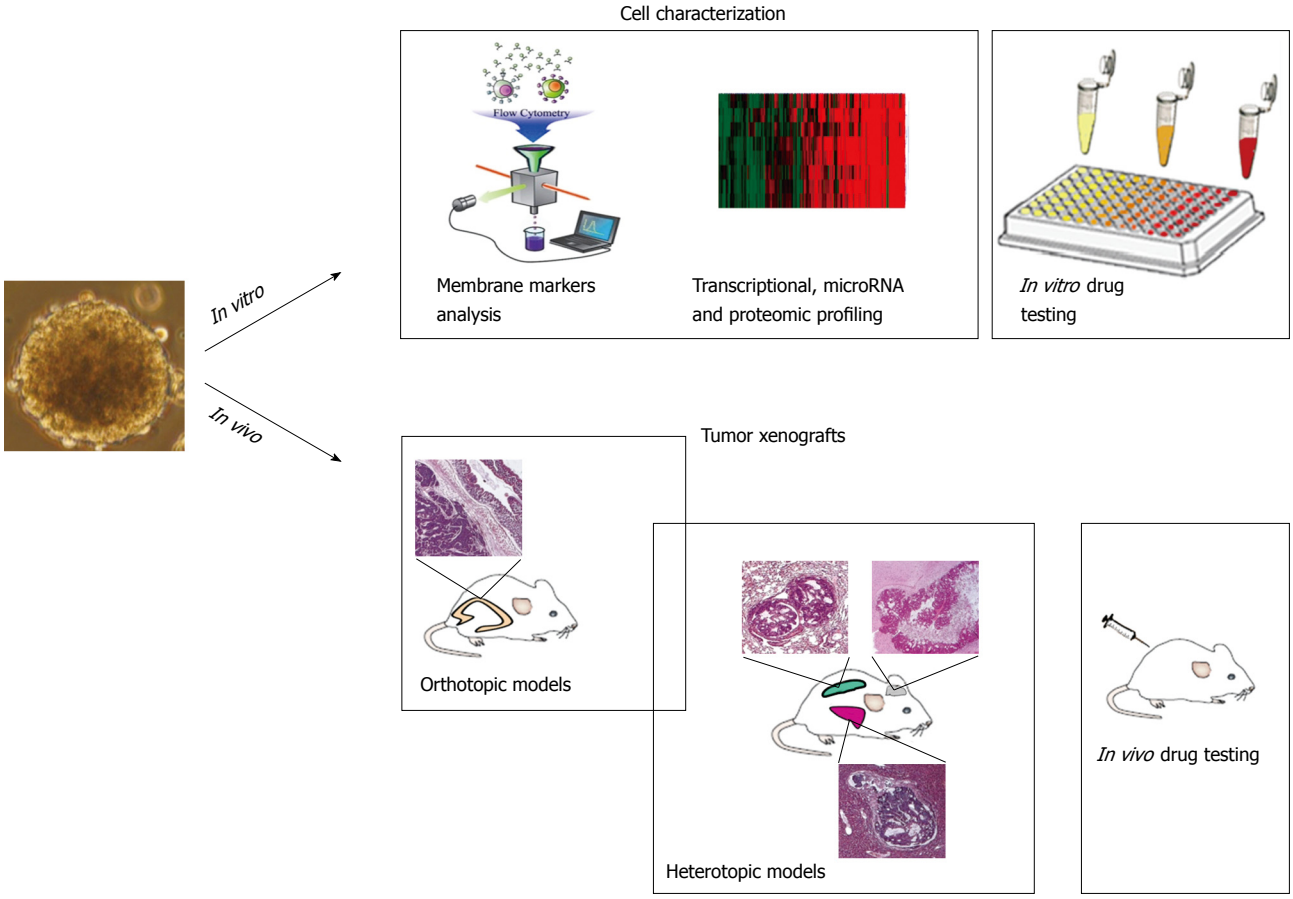

Figure 2 Colorectal cancer stem cells as a tool for drug discovery. *In vitro*, colorectal cancer stem cells (CRC-SCs), isolated from the tumor specimen, are propagated as "tumor spheres". Membrane marker analysis together with transcriptional, microRNA and proteomic profiling lead to the identification of molecular targets that are expressed by this cell population. These findings can be used to evaluate the cytotoxic ability of new compounds. *In vivo*, CRC-SCs can be orthotopically and heterotopically injected into immunocompromised mice generating tumors that mimic the cytoarchitecture of the parental tumors. The use of such mouse models of CRC allows for drug testing analyses in order to eradicate the primary tumor and avoid the formation of incurable metastases.

blocking the IL-4 signal. This phenomenon was confirmed in xenografts in which the administration of anti-IL-4 antibodies significantly reduced tumor growth after chemotherapy.

When human chemotherapy-resistant CRC cell lines (HT29/5FU-R and HT29/OxR) were developed following exposure of HT29 to increasing doses of 5-fluorouracil and oxaliplatin, there was a marked enrichment of $CD133^+$ and $CD44^+$ double positive cells. Phosphorylated and total insulin-like growth factor receptor (IGF-IR) levels were also increased in the resistant cell lines and their derived-tumors showed significantly greater growth inhibition in response to an IGF-IR mAb than parental cells, demonstrating that IGF-IR activation provided for enhanced sensitivity of CRC-SCs[41]. Other potential targets include specific targeting of symmetric stem cell division. To study new approaches to develop drugs that target CSCs, Boman *et al*[42] used computer modelling. They demonstrated that exponential increase in both SC and non-SC populations in CRC development involves an enhanced symmetric SC division. This finding suggests that any systemic therapy designed to effectively treat CRC and other cancers must act to control or eliminate symmetrical CSC division in tumors, while minimally affecting normal SCs[42].

Another important aspect to be considered with regard to the designing of novel and more effective therapies against CRC is that CRC-SCs represent an excellent tool for the preclinical evaluation of new anticancer therapies both *in vitro* and *in vivo*, where they generate xenografts that phenocopy the human tumor of origin (Figure 2). Currently available mouse models of CRC are based on chemically-induced tumors, genetically engineered animals and tumor implants in immunocompromised mice, and none of them faithfully replicates all the aspects of human tumor development. Reliable mouse models of human CRC are essential to understand the mechanisms underlying tumor development and pathogenesis. In this respect CSCs represent an innovative and powerful tool in cancer research by conjugating the advantages of *in vitro* amplification, high grafting efficiency and, more importantly, the ability to closely reproduce the original tumors in terms of histology and drug sensitivity.

Thus, a systematic approach to identify and challenge the CSC survival machinery appears to be mandatory in order to develop novel and more efficient stem cell-based therapies. Genome-wide analyses of cancer have revealed the existence of a great genetic variation among individual tumors, which makes extremely complex the use of an ex-

clusively genomic approach to cancer biology. At the same time, it is increasingly clear that tumors share common features in terms of protein pathway level, suggesting that a pathway-orientated perspective would represent the most effective approach to drug discovery and therapy. In a recent study, Fang *et al*[43] generated $CD133^+$ tumor sphere cultures from several colon cancer specimens and performed mass-spectrometry-based quantitative proteomics in order to identify cell surface proteins enriched on culture tumor cells. These cells retain the expression of cell surface markers such as CD133, CD166, CD44 and EpCAM as well as other stem cell-associated proteins including nestin, Bmi1 and Msi-1, thus confirming the value of this *in vitro* model for biological analysis of CSC populations as well as for drug screening experiments. Therefore, integrated strategies based on high-throughput proteomic, drug screening and gene expression-based approaches will allow in the near future the identification and targeting of survival signaling pathways in CSCs.

CONCLUSION

Increasing evidence shows that CSCs may play a critical role in tumor development and progression. CSC resistance to conventional therapies may explain why it is difficult to completely eradicate cancer and why recurrence is often inevitable. Thus, the identification and molecular characterization of CSCs is critical to develop therapeutic strategies that specifically target this rare population of cells and that are likely to be effective in eradicating tumors and in reducing the risk of relapse and metastasis.

Abstract

Although the prevalence of chronic hepatitis B virus (HBV) infection has declined in renal transplant recipients (RTRs), it remains a relevant clinical problem with high morbidity and mortality in long-term follow up. A thorough evaluation, including liver biopsy as well as assessment of HBV replication in serum (i.e. hepatitis B e antigen and/or HBV DNA) is required before transplantation. Interferon should not be used in this setting because of low efficacy and precipitation on acute allograft rejection. The advent of effective antiviral therapies offers the opportunity to prevent the progression of liver disease after renal transplantation. However, as far as we are aware, no studies have compared prophylactic and preemptive strategies. To date, the majority of RTRs with HBV-related liver disease have had a high virological and biochemical response to lamivudine use. However, lamivudine resistance is frequent with a prolonged course of therapy. Considering long-term treatment, antiviral agents with a high genetic barrier to resistance and lack of nephrotoxicity are suggested. The optimal strategy in RTRs with HBV infection remains to be established in the near future.

Key words: Hepatitis B; Renal transplantation; Lamivudine resistance

INTRODUCTION

Since the first successful renal transplantation in 1954, there has been an exponential growth in publications dealing with the care of renal transplant recipients (RTRs). Hepatitis B virus (HBV) infection is an established cause of morbidity and mortality in RTRs[1-4]. Although numerous studies have reported the impact of HBV status on patients and graft outcome in RTRs, the role in pathogenesis of liver damage is still unclear. In recent decades, as improvement in renal transplantation has been the result of better immunosuppression, organ preservation, and patient selection[5,6]. In addition, substantial improvement in the understanding of HBV virology and the natural course of infection, combined with highly sensitive HBV DNA assays and the advent of effective antiviral drugs with different mechanisms of action, has led to better therapeutic strategies for chronic HBV infection. It is of

increasing interest to determine the long-term outcome of HBV in RTRs. Hence, the aim of this study is to review the available literature concerning the natural course and clinical manifestations of HBV-related liver disease in RTRs. Furthermore, treatment of RTRs with HBV infection is discussed.

PREVALENCE RATES OF HBV INFECTION IN RTRs

The prevalence rates of hepatitis B surface antigen (HBsAg) seropositive status among RTRs varies among countries (Table 1), and it has been decreasing over time[3,7,8]. Mathurine and colleagues have reported that the prevalence of HBsAg decreased significantly (24.2% before 1982 *vs* 9.1% after 1982, $P < 0.001$)[3]. Recently, Santos *et al*[7] also have shown a marked decline in the prevalence of HBV infections over the last 15 years (6.2% in 1994 *vs* 2.3% in 2006). In our previous study[9], the prevalence of HBV infection in RTRs was 9.2% (51/554), which is lower than that reported previously in Taiwan in 1994 (20.9%, 14/67)[10]. The decreasing prevalence of HBV infection in this population can be attributed to the use of HBV vaccination, the use of erythropoietin for anemia and the consequent decreased need for blood transfusions during the pre-transplantation period.

TRANSMISSION OF HBV INFECTION BY RENAL TRANSPLANTATION: DONOR EVALUATION

The possibility of HBV transmission by organ transplantation can be predicted from the serological status of both donor and recipient. It is generally accepted that transplanting an HBsAg-positive allograft into an HBsAg-negative recipient carries a significant risk of *de novo* infection[11,12]. A recent meta-analysis has shown that recipients who are seropositive for HBsAg show an increased risk for mortality and graft failure compared with seronegative recipients[2]. This has resulted in a policy at many organ procurement organizations to restrict the use of kidneys from HBsAg-positive deceased donors. However, the rapid increase in patients with end-stage renal disease has exacerbated the shortage of donor organs. The ban on using kidneys from HBsAg-positive donors has been challenged under certain circumstances. A study from Thailand[13] has reported that 14 anti-HBsAg-positive patients received kidneys from HBsAg-positive donors and 27 HBsAg-positive patients received kidneys from HBsAg-negative donors. Hepatitis B hyperimmune globulin (HBIG) and lamivudine were not used at any time. The 10-year survival of these patients was not significantly different (92.8% *vs* 62.5%, $P = 0.14$). In a study from Turkey, Berber *et al*[14] have reported seven kidney transplants from HBsAg-positive donors. All of the recipients were HBsAg-negative and hepatitis B surface antibody (HBsAb)-positive. Prophylactic lamivudine treatment after transplantation was given. None of the patients who received a kidney from an HBsAg-positive donor developed clinical HBV infection in a mean 42-mo follow-up period. Jiang *et al*[15] have reported a prospective non-randomized controlled study: 373 HBsAg-positive RTRs received a kidney from HBsAg-positive ($n = 65$) or HBsAg-negative ($n = 308$) donors. Using a standardized immunosuppressive and antiviral regimen (400 U HBIG once and twice for recipients with HBsAg-negative or HBsAg-positive grafts, respectively; 400 U HBIG weekly for 3 mo and lamivudine 100 mg daily for 6 mo for recipients with HBV DNA-positive grafts), there was no significant difference in liver injury and patient survival. Therefore, it is suggested that kidney allografts from HBsAg-positive donors can be used safely in HBsAb-positive recipients with preexisting naturally acquired or vaccination-induced immunity to HBV. HBV viral status should be monitored, and HBIG and/or lamivudine should be prescribed, depending on donor HBV DNA status.

Table 1 Frequency of hepatitis B surface antigen-positivity in renal transplant recipients

Authors	HBsAg rate, % (*n*)	Reference year	Country of origin
Hu *et al*[10]	20.9 (14/67)	1994	Taiwan (China)
Mathurin *et al*[3]1	15.3 (128/834)	1999	France
Lee *et al*[4]	12.9 (62/477)	2001	Taiwan (China)
Chan *et al*[30]	13.2 (67/509)	2002	Hong Kong (China)
Morales *et al*[8]2	2.2 (76/3365)	2004	Spain
Aroldi *et al*[20]	14.2 (77/541)	2005	Italy
Santos *et al*[7]3	3 (37/1224)	2009	Portugal
Tsai *et al*[9]	9.2 (51/554)	2009	Taiwan (China)

[1]Prevalence of hepatitis B surface antigen (HBsAg) was 24.2% before 1982 and 9.1% after 1982 ($P < 0.001$); [2]Prevalence of HBsAg was 3.0% in 1990 and 2.0% in 1998; [3]Prevalence of HBsAg was 6.2% in 1994, 4.1% in 1998, 3.2% in 2002, and 2.3% in 2006.

NATURAL HISTORY OF HBV DISEASE IN RTRs

Defining the natural history of HBV infection among RTRs is difficult because of the unique characteristics of this population and chronic HBV infection has a long natural course, and it might need 10-20 years to see the key complications, most notably cirrhosis and hepatocellular carcinoma (HCC). The natural history of hepatitis B in the immunocompetent population has been described by Liaw *et al*[16]. Chronic HBV infection is a dynamic state of interactions between HBV, hepatocytes and the immune system of the patient. Therefore, the natural course of chronic HBV infection can be divided into four phases: immune tolerant, immune clearance, residual inactive, and reactive immune clearance phases. The reactive phase can be viewed as a variant of the immune clearance phase. However, in the population of RTRs, therapeutic immunosuppression post-transplantation might affect the host immune responses against HBV. In addition, most centers are reluctant to perform liver biopsies before and after renal transplantation due to concern about platelet

dysfunction. Furthermore, antiviral therapy is now widely available, which might change the course of hepatitis and stop disease progression. All these factors limit the clinician's understanding of the progression of liver disease in RTRs.

Fornairon *et al*[17] have reported a large cohort study of 151 HBsAg-positive RTRs. The spontaneous annual clearance rates of HBsAg, hepatitis e antigen (HBeAg), and HBV DNA were 0.1%, 3% and 3%, respectively, which are lower than in the general population. A high rate of persistent viral replication and reactivation, as defined by HBeAg reappearance, was observed in 30% after renal transplantation, which was significantly higher than in the general population. Degos *et al*[18] have demonstrated reactivation of HBV replication in 11 of 12 (92%) initially HBV-DNA-negative, HBsAg-positive RTRs after 3-12 mo and an increase in HBV DNA in 6 of 11 (55%) initially HBV-DNA-positive patients. In our study of 51 HBsAg-positive RTRs during a mean follow-up of 58 mo, 34 patients (67%) had higher HBV DNA levels at the end of follow-up than at baseline, which was associated with cirrhosis development[9].

Liver biopsy is a gold standard for the diagnosis of hepatic disease. A variety of studies has shown more severe courses in RTRs infected with HBV compared with non-infected patients. In 1985, Parfrey *et al*[19] performed a prospective study of 20 HBsAg-positive RTRs who underwent serial liver biopsy. There was a marked tendency to progression, and 82% of patients who had virus only, reactive hepatitis, or chronic persistent hepatitis on initial biopsy, subsequently developed chronic active hepatitis or cirrhosis on final biopsy. Fornairon *et al*[17] have reported the largest single-center evaluation of follow-up liver biopsies in HBsAg-positive RTRs: 310 biopsies in 131 RTRs, with two or more biopsies in 101 patients. At the time of renal transplantation, normal liver histology was found in 39%, chronic persistent hepatitis in 25%, chronic active hepatitis in 25%, and miscellaneous findings in 11% of patients. After a mean interval of 66 mo, histological deterioration was observed in 85.3% of these 101 patients who underwent serial liver biopsies, with occurrence of cirrhosis in 28% and chronic active hepatitis in 42%. Only 6% showed normal liver biopsy in the second biopsy. These results were in accordance with the findings in other smaller series. Aroldi *et al*[20] have reported 34 HBsAg-positive RTRs who underwent serial liver biopsy: 24 (71%) showed progression of liver fibrosis in which 15 patients evolved to cirrhosis, and six of them died of liver failure.

The reactivation of HBV infection in RTRs can also occur in HBsAg-negative but HBsAb- and hepatitis B core antibody (HBcAb)-positive patients. However, it is difficult to distinguish these from *de novo* infection. There have also been a few reports in the literature about the reactivation of HBV infection in RTRs with previously resolved HBV infection[21-23]. Blanpain *et al*[21] have reported two RTRs with cured HBV infection at the time of transplantation, as defined by the absence of HBsAg and the presence of HBsAb and HBcAb in the serum, who presented with HBV reactivation at 7 mo and 3 years after transplantation, respectively. Degos *et al*[18] have detected HBV DNA in seven of 35 RTRs (20%) following transplantation, who either had no serological evidence of HBsAg or HBV DNA before transplantation; a finding that suggests that immunosuppression can amplify even minimal residual HBV DNA. Based on this evidence, transplant physicians should be aware of the risk of HBV reactivation in patients with cured HBV infection before transplantation.

OUTCOME OF RTRs WITH HBV INFECTION: MORTALITY AFTER TRANSPLANTATION

Mortality is a reliable end-point in the natural course of HBV after renal transplantation. However, the impact of HBsAg on survival in RTRs has been controversial, especially in early studies. Some initial studies that have focused on 5-year survival rates generally have failed to show a difference between HBsAg-positive and -negative RTRs[24-27]. However, more recent studies with a large sample size and longer follow-up have suggested a detrimental effect of HBsAg on patient and graft survival[3,4,28,29]. Lee *et al*[4] have reported that the 10-year survival rate was much higher in the HBsAg-negative group (82.8%) than in the HBsAg-positive group (51.4%) ($P < 0.005$). Multivariate analysis has revealed that HBV infection is an independent risk factor for patient mortality. The major cause of death was liver failure in the HBsAg-positive group: 62.5% (10/16) *vs* 23.3% (7/30) in the HBsAg-negative group. Mathurin and colleagues also have reported that 10-year survival was significantly higher in non-infected (80% ± 3%) than in HBsAg-positive recipients (55% ± 6%). Multivariate analysis has shown that, in patients transplanted before 1982 (year of HBV vaccination), HBsAg was an independent factor for poor survival ($P < 0.0001$)[3]. In a case-control study by Mathurin, survival was significantly lower at 10 years in patients infected by HBV than in matched patients (55% ± 6% *vs* 80% ± 4%, $P = 0.004$). Furthermore, in a study by Chan from Hong Kong[30], HBsAg-positive patients who underwent renal transplantation before 1996, without the availability of lamivudine, had a markedly inferior survival rate compared with that in HBsAg-negative RTRs. Recently, a meta-analysis performed by Fabrizi *et al*[2], which pooled 6050 patients, indicated clearly that HBsAg in serum was an independent risk factor for death after renal transplantation (relative risk: 2.49, $P < 0.0001$).

OUTCOME IN RTRs WITH HBV INFECTION: MORBIDITY AFTER TRANSPLANTATION

Graft survival

The influence of chronic HBV infection on graft survival remains controversial. In a large cohort study by Foraniron[17], better allograft survival was described in HBsAg-

positive than in HBsAg-negative patients (P = 0.0006). Also London *et al*[31] have found a beneficial effect of HBsAg positivity on graft survival. In contrast, Lee *et al*[4] have reported an inferior 10-year graft survival for HBV- or hepatitis C virus (HCV)-infected RTRs, although this was not significant (44% and 50%, P = NS, respectively) compared with non-infected patients (74%). Recently, Mathurin *et al*[3] have observed that 10-year graft survival (36%) in HBsAg-positive RTRs was significantly lower compared with that in non-infected patients (63%). Their case-control study also showed that 10-year graft survival was significantly lower in patients infected by HBV than in matched control patients (36% ± 5% *vs* 61% ± 5%, P < 0.001). Finally, a 2005 meta-analysis has indicated that HBsAg positivity was associated with an increased risk of allograft loss (relative risk: 1.44, 95% CI: 1.02-2.04)[2].

FACTORS AFFECTING PROGRESSION IN HBV-RELATED DISEASE AFTER RENAL TRANSPLANTATION

In chronic HBV patients, viral factors (viral load, genotype and genomic mutations), host factors (age, sex, and immune status), and other factors (alcohol consumption, cigarette smoking, exposure to aflatoxin, and other viral superinfections) contribute to the progression of liver disease[32]. However, in RTRs with HBV infection, the factors that affect HBV-related progression have not been identified. Fairley *et al*[33] have found that the presence of HBV DNA and/or HBeAg in serum prior to renal transplantation was associated with an increased probability of death from liver disease: five of 10 patients in this group died of chronic liver disease; but only one of 15 patients who were HBV DNA and/or HBeAg negative prior to transplantation died of liver disease (P = 0.002). In our previous study[9], 13 of 51 RTRs developed cirrhosis in a period of 57 mo. Among these, HBV DNA levels at baseline could not predict cirrhosis development. However, the elevation of serum HBV DNA ($\geq 10^5$ copies/mL) after renal transplantation was a significant risk factor for development of cirrhosis.

There are at least eight major genotypes of HBV (A-H) with distinct geographical distribution. Genotype A and C variants can induce more severe liver disease than genotype B and D in general immunocompetent chronic HBV patients[34-36]. To date, a paucity of data exists to discuss the HBV genotype that affects liver disease in RTRs. Only our previous study has demonstrated that there is no significant association between genotype and cirrhosis development in RTRs[9]. We do not know the reason for this inconsistency with results from general chronic HBV populations. However, genotype B was the predominant genotype in the RTRs (45/51, 88.2%) of our study, which is considerably higher than that (60%) in the general population[35]. This difference might have been because these patients were selected before renal transplantation for their relatively benign clinical course of hepatitis B.

Chu *et al*[37] have suggested that older RTRs with HBsAg and/or HCV antibody carriers have a greater chance of developing HCC and mortality than younger patients do. In that study, 173 RTRs with serum HBsAg and/or HCV antibody were divided into three groups: older age (≥ 55 years, n = 3); middle age (18-55 years, n = 160); and younger age (≤ 18 years, n = 10). The incidence of HCC and the risk of death due to liver disease post-transplantation in the older, middle and younger age groups were 100%, 3.75% and 0% (P < 0.001), and 100%, 19.8% and 0% (P < 0.001) respectively. These results were in agreement with the findings from the study of Aroldi[38], in which older age (> 40 years) was independently associated with poor survival in RTRs (relative risk: 2.8).

Recent studies have indicated that precore and core promoter mutations are significantly associated with advanced liver disease in chronic HBV carriers[39-41]. For immunosuppressed patients, Günther *et al*[42] have performed serial HBV sequences by polymerase chain reaction (PCR) and DNA sequencing in nine HBsAg-positive RTRs. Seven of them showed either persistent or increasing amounts of the HBV core gene deletion mutants. All seven patients developed cirrhosis, and five died from end-stage liver disease. The incidence of complications was higher than in recipients without mutations. In our previous analysis[9], there was no significant association between core promoter mutations (T1762/A1764) and advanced liver disease. However, we have found that the development of T1762/A7164 mutants can predict an increase in HBV DNA, which was associated with cirrhosis development after renal transplantation. Hence, we hypothesized that immunosuppressive agents induce HBV DNA replication, especially in recipients with T1762/A1764 mutants, which results in cirrhosis development. We think that a smaller case number and/or the use of interventional antiviral therapy might cause the absence of a significant correlation between T1762/A1764 mutants and cirrhosis development. In a study by Preikschat *et al*[43], development of cirrhosis and end-stage liver disease after renal transplantation was associated with persistence and accumulation of specific HBV mutant populations. Their results demonstrate that viruses are characterized by a set of mutations rather than by a single mutation: deletions/insertions in core promoter plus deletion in the C gene and/or deletion in the pre-S region.

THERAPY OF HEPATITIS B IN RTRs

With the improving results of renal transplantation techniques and care, liver disease has emerged as an important cause of morbidity and mortality. Before the advent of effective antiviral agents, chronic liver disease developed in > 80% of HBsAg-positive RTRs, and 37%-57% of mortality in these subjects was attributed to liver complications[17,19,44,45]. Therefore, hepatitis B was considered to be a contraindication for organ donation in some western countries in the era before antiviral agents. However, the past decade has witnessed important developments in the therapy of hepatitis B. The availability

Table 2 Efficacy summary of antiviral monotherapy in renal transplant recipients with hepatitis B virus infection

Antiviral agent	Authors	Reference year	Patients	Duration (mo)	Biochemical response[1] (%)	Virological response[2] (%)	Resistance (%)

[1]Biochemical response was calculated at the end of the treatment as alanine aminotransferase normalization; [2]Virological response was calculated as the disappearance of hepatitis B virus (HBV) viremia at the end of the treatment. HBV DNA was quantified in all studies by non-polymerase chain reaction assay (PCR), hybridization techniques with a limit ranging being 5-6 $\log_{10}$ copies/mL, except for the studies by Thabut, Kamar, Gwak and Fontaine (2005) who used a PCR-based assay. LAM-R: Lamivudine-resistance; ADV-R: Adefovir-resistance; NA: Not available.

of lamivudine in 1998 marked a new era of oral therapy. According the study by Chan *et al*[30], the survival of HBsAg-positive RTRs treated preemptively with lamivudine was similar to that of HBsAg-negative controls, whereas HBsAg-positive RTRs without lamivudine treatment had significantly inferior survival (relative risk of death: 9.7, $P < 0.001$). A study by Ahn *et al*[46] has investigated the clinical outcome of 2054 RTRs to establish the efficacy of lamivudine treatment in HBsAg-positive recipients ($n = 66$). Lamivudine given to 27 recipients markedly improved 10-year patient and graft survival compared to those who did not take lamivudine. Notably, the 10-year patient survival rates were similar between pre-transplant HBsAg-negative and -positive patients (88.2% *vs* 85.3%). Hence, the overall prognosis of patients with HBsAg positivity has probably improved given the increased efficacy of antiviral therapy. Currently, there are seven agents approved for the treatment of chronic hepatitis B by the US Food and Drug Administration[16,47]. They are conventional interferon (IFN)-α, pegylated IFN, lamivudine, adefovir, entecavir, telbivudine and tenofovir. In the non-renal transplant population, IFN-based therapy is modestly efficacious in inducing HBeAg loss or seroconversion (30%-40%) in HBeAg-positive patients[48-51] and entecavir, telbivudine and tenofovir are the most potent in HBV DNA suppression. At 1 year, ⩾ 60% of HBeAg-positive and ⩾ 85% of HBeAg-negative chronic hepatitis B patients achieved undetectable HBV DNA after therapy with these three agents[52-54]. Drug resistance occurs most frequently with lamivudine, followed by telbivudine, adefovir and tenofovir, and is very low with entecavir[52,53,55-59]. However, the optimal antiviral agent for the treatment of RTRs with chronic hepatitis B infection is still unclear because of limited data on the use of these agents in RTRs. Table 2 summarizes antiviral agents used in RTRs with HBV infection.

IFN

IFN has antiviral, antiproliferative and immunomodulatory effects, such as increased cytotoxic T lymphocytes and natural killer cell immune response to viral proteins[60-62]. There have been only a few successful studies of monotherapy with IFN in RTRs. Post *et al*[63] have reported a 38-year-old RTR who developed symptomatic hepatitis. Tests for HBeAg and HBV DNA were both positive. After treatment with 1 MU IFNα three times weekly for 3 wk, followed by an increase to 3 MU three time weekly for a total of 16 wk, hepatitis clinically resolved, with HBeAg seroconversion and HBV DNA negativity. The renal allograft function remained excellent throughout the course of therapy with IFN. Grotz *et al*[64] have reported HBsAg positivity in RTRs suffering from hepatitis flare up. Their patient was HBeAg seropositive, with detectable HBV DNA. IFN was given at a dose of 3 MU three times a week for 14 wk. At the end of treatment, HBeAg seroconversion developed, with a decrease in HBV DNA. However, an acute rejection episode occurred after IFN therapy, and: renal biopsy revealed acute interstitial alterations. Prednisone was prescribed and renal function recovered. Although IFN therapy has been shown to terminate effectively viral replication in some RTRs with HBV infection, the use of IFN for the treatment of hepatitis B in RTRs has been reported infrequently. Reluctance to use IFN in RTRs could be related to concern about precipitating acute allograft rejection, direct nephrotoxicity, and tubulointerstitial nephropathy with glomerular alterations, which are frequently irreversible and steroid resistant[65-68]. As a result, IFN should not be used for treating HBV infection in this setting.

Lamivudine

Lamivudine is a nucleoside analogue that has a potent inhibitory effect on HBV replication by competitive inhibition of viral reverse transcriptase and termination of proviral DNA chain extension. It has been approved worldwide for the treatment of chronic hepatitis B both in non-immunosuppressed[69,70] as well as liver[71] and renal transplantation patients[30,72-83]. Although several authors have reported the use of lamivudine for the treatment of hepatitis B in RTRs, these were small, uncontrolled trials. To assess the efficacy of lamivudine, Fabrizi *et al*[84] have performed a meta-analysis of 14 clin-

ical prospective cohort studies that included 184 RTRs. The mean overall clearance of HBV DNA and HBeAg was observed in 91% and 27%, respectively; and alanine aminotransferase normalization occurred in 81%, with lamivudine resistance being reported in 18%. Frequency of HBeAg loss and lamivudine resistance was positively associated with increased duration of therapy ($r = 0.51$, $P = 0.039$; $r = 0.620$, $P = 0.019$, respectively).

Adefovir

Adefovir has demonstrated safety and efficacy in treatment-naïve patients and those with lamivudine-resistant HBV infection[55,85]. Safety and efficacy also have been proven in immunodeficient patients including HIV-positive patients[86] and after liver transplantation[87]. However, nephrotoxicity and Fanconi-like syndrome with phosphaturia and proteinuria were reported when adefovir was evaluated at higher daily doses (30 mg)[88]. Of note, adefovir dose must be adjusted in accordance with creatinine clearance in patients with impaired renal function[89]. To date, a paucity of studies exists concerning the use of adefovir in RTRs[90,91]. Fontaine *et al*[90] have described the use of adefovir in 12 RTRs with lamivudine-resistant HBV infection. The daily dosage was 10 mg initially and then adjusted based on renal function. After the 12 mo, the median decline in serum HBV DNA was from 8.76 to 2.97 $\log_{10}$ Eq/mL, without virological breakthrough. The efficacy was similar to that reported in the general population. Notably, there has been no experience in the use of adefovir in treatment-naïve RTRs with HBV infection.

Entecavir, telbivudine and tenofovir

In immunocompetent patients, entecavir, telbivudine and tenofovir are the most potent antiviral agents, followed by lamivudine and then adefovir. Entecavir is associated with the lowest rate of drug resistance (< 1% in 5 years among previous treatment-naïve patients)[58,59], and therefore, might be the preferred treatment, since long-term therapy will be needed in most RTRs. To date, there are no published data concerning the use of entecavir, telbivudine and tenofovir in RTRs. Only one study has demonstrated the efficacy and safety of entecavir in RTRs with HBV infection[92]. Eight RTRs, who have become adefovir or lamivudine-resistant, were administered entecavir (0.5-1 mg/d). After a median follow-up of 16.5 mo, there was a significant decrease in HBV DNA viral loss (3.86 to 2.94 $\log_{10}$ copies/mL, $P = 0.004$). Clinical tolerance of entecavir was very good without any rejection episode. Furthermore, there were no statistically significant changes in creatinine level, estimated creatinine clearance, or daily microalbuminuria. Hence, from currently available data, we suggest that entecavir is preferable to lamivudine, to minimize development of potential drug resistance, unless there are concerns about cost or unavailability of entecavir.

Drug resistance

Antiviral resistance is defined as the selection of HBV mutations that confer reduced susceptibility to a drug, which results in primary or secondary treatment failure. Clinically, the emergence of drug resistance is indicated by viral breakthrough, which is defined as a > 1 $\log_{10}$ increase in serum HBV DNA from nadir in a patient who had an initial virological response. Usually, subsequent biochemical breakthrough or raised alanine aminotransferase (ALT) values occurred in > 90% of patients[93], with some hepatic decompensation among patients with advanced fibrosis[94]. In chronic hepatitis B immunocompetent patients, lamivudine is associated with the highest rate of resistance, reaching nearly 70% after 5 years of continuous therapy[16]. Similarly, there was an increasing incidence of lamivudine resistance with longer treatment in RTRs. Thabut *et al*[95] have reported 14 RTRs with a median of 65 mo of lamivudine therapy. Lamivudine resistance appeared in eight patients (57%). In the study of Kamar[96], virological breakthrough was observed in 12/18 (67%) RTRs after 37 mo of lamivudine treatment. Chan *et al*[97] have reported 29 RTRs who received almost 60 mo of lamivudine therapy; 14 (48.3%) patients developed lamivudine resistance at 10-35 mo. Among these, hepatic flares were observed in 11 (79%). Therefore, in 2007, the concept of a roadmap was set up by an internal group of experienced hepatologists and virologists[98]. The panel recommends monitoring of serum HBV DNA levels to identify outcomes of therapy and to reduce the risk of viral resistance. In our analysis (unpublished data), we set forth the roadmap concept into 19 lamivudine-treated RTRs to monitor the efficacy and resistance of lamivudine. At week 24, there were seven patients with inadequate virological response (defined as HBV DNA levels $\geqslant$ 2000 IU/mL ($\geqslant$ 4 $\log_{10}$ copies/mL) at week 24 after antiviral treatment). Three patients developed YMDD mutations at week 52 and therapy was switched to adefovir-based therapy due to virological breakthrough. In the remaining four patients, two developed YMDD mutation at week 104 and shifted to adefovir-based therapy. These results provide a new insight into the roadmap concept for HBV therapy in RTRs.

Timing of antiviral agent initiation

There is lack of an algorithm for therapeutic approaches to antiviral treatment in RTRs with HBV infection. Several points remain to be defined regarding the management of HBV-related liver disease after renal transplantation. The first question is the timing of introduction of the antiviral agent. There are two principal approaches to prevent HBV reactivation after renal transplantation: prophylactic and preemptive strategies. To the best of our knowledge, there have been no studies in the renal transplant setting that have compared directly the prophylactic and preemptive approaches. A prophylactic strategy involves the administration of antiviral agents to patients at increased risk of developing HBV reactivation prior to transplantation; a preemptive strategy permits prompt treatment after the detection a marked increase in serum HBV DNA. Chan *et al*[30] have confirmed that preemptive lamivudine therapy improves survival of RTRs with HBV infection. There is also some evidence that prophylactic

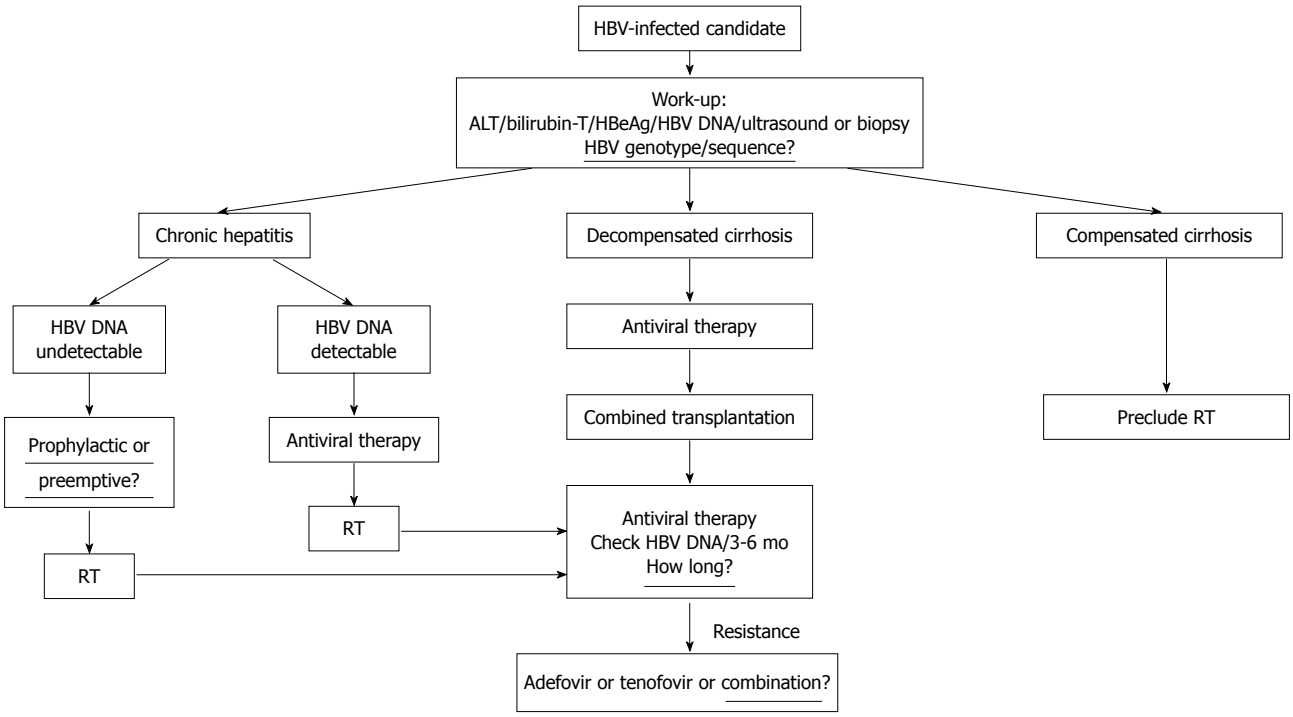

Figure 1 Algorithm for renal transplant candidates with hepatitis B virus infection. The font-underline in figure 1 means that there is no optimal strategy for renal transplant recipients (RTRs) with hepatitis B virus (HBV) infection so far, and they remain to be defined. ALT: Alanine aminotransferase; HBeAg: Hepatitis e antigen.

lamivudine might be beneficial in RTRs[78,83]. Whatever the prophylactic or preemptive strategy, it can be confirmed that salvage treatment after hepatic dysfunction with HBV recurrence is less effective[81].

Duration of treatment

The next unanswered question is whether lifelong treatment is needed in this special patient group. In the era of lamivudine, prolonged therapy is associated with drug resistance. One study has reported that lamivudine resistance was observed in three of 14 (21%) patients after 1 year of treatment, and in eight of 14 (57%) patients after 2 years[95]. Withdrawal of lamivudine is associated with a high risk of relapse, replication of the wild strain, and liver failure, all of which suggest prolonged therapy is necessary. Rostaing *et al*[73] have found that when lamivudine therapy was stopped for four patients after 6 mo, it was associated with a biochemical and virological relapse within the following weeks. However, a study by Chan *et al*[30], in which lamivudine was discontinued in 12 low-risk RTRs (> 9 mo therapy, HBV DNA and HBeAg negative, stable immunosuppression) five patients achieved treatment success, with two maintaining undetectable serum HBV DNA for > 18 mo. It seems that discontinuation is safe in selected patients, to minimize the emergence of drug resistance. Recently, Huang *et al*[99] have reported that the liver-related mortality rate was not significantly higher in patients who discontinued lamivudine treatment compared with continuously treated patients (both, 0%), in a total of 20 HBsAg-positive transplant recipients (discontinued, $n = 9$; continued, $n = 11$). However, these studies all had limitations of small case numbers and short follow-up periods. In the era of adefovir, entecavir, telbivudine and tenofovir, there are only a few studies concerning their efficacy in RTRs with HBV infection. Further large cohort studies with long-term, and/or combination, and/or high-dose antiviral therapy in HBsAg-positive RTRs are required.

Although there are no definite algorithms about antiviral therapy of HBV in RTRs, the 2007 American Association for the Study of Liver Diseases guidelines[100] issued some suggestions. For chronic hepatitis B patients who require immunosuppressive therapy, prophylactic antiviral therapy is recommended for HBV carriers at the onset of a finite course of immunosuppressive therapy. With baseline HBV DNA < 2000 IU/mL, antiviral therapy should be continue for 6 mo after completion of immunosuppressive therapy. In patients with baseline HBV DNA ⩾ 2000 IU/mL level, treatment should be continued until the endpoints are reached. However, there is still a lack of direct evidence for these guidelines to be applied in RTR patients.

CONCLUSION

The reported prevalence of chronic HBsAg carriers receiving renal transplantation is lowering, but it is not negligible, especially in endemic areas for HBV infection. HBV confers a high risk of morbidity and mortality in long-term follow up in RTRs. HBsAg-positive donors can be safely used in anti-HBs-positive recipients. To date, there is no optimal strategy for RTRs with HBV infection. Many points remain to be defined (Figure 1). Lamivudine therapy is effective in serological and virological responses in RTRs, and the tolerance is good. However, resistance to lamivudine frequently occurs with prolonged therapy.

Considering long-term treatment, antiviral agents with a high genetic barrier to resistance and lack of nephrotoxicity (e.g. entecavir) are suggested. Long-term follow-up studies are required in the near future.

Abstract

AIM: To study whether the glucocorticoid receptor (*GR*/*NR3C1*) gene haplotypes influence the steroid therapy outcome in inflammatory bowel disease (IBD).

METHODS: We sequenced all coding exons and flanking intronic sequences of the *NR3C1* gene in 181 IBD patients, determined the single nucleotide polymorphisms, and predicted the *NR3C1* haplotypes. Furthermore, we investigated whether certain *NR3C1* haplotypes are significantly associated with steroid therapy outcomes.

RESULTS: We detected 13 *NR3C1* variants, which led to the formation of 17 different haplotypes with a certainty of > 95% in 173 individuals. The three most commonly occurring haplotypes were included in the association analysis of the influence of haplotype on steroid therapy outcome or IBD activity. None of the *NR3C1* haplotypes showed statistically significant association with glucocorticoid therapy success.

CONCLUSION: *NR3C1* haplotypes are not related to steroid therapy outcome.

Key words: Inflammatory bowel disease; Steroid therapy; Glucocorticoid receptor; Pharmacogenetics; Haplotype analysis

INTRODUCTION

Inflammatory bowel diseases (IBD), Crohn's disease (CD) and ulcerative colitis (UC), are multifactorial disorders, which are characterized by chronic recurrent inflammation of the gastrointestinal tract[1]. The molecular pathogenesis of IBD is not fully elucidated, although an exaggerated mucosal immune response triggered by intestinal bacteria

in genetically susceptible individuals appears to play an important role[2]. The combined prevalence of CD and UC is estimated to be 100 to 200 per 100 000 individuals in developed countries[3]. IBD shows extensive variation in individual clinical presentation and outcomes, which is likely to be caused by differences in genetic susceptibility, environmental factors, intestinal bacteria and activation of the intestinal immune system[3].

Although great advances have been made in the management and therapy of IBD, curative therapy does not yet exist. The anti-inflammatory agents mesalazine (5-aminosalicylic acid, 5-ASA) and sulfasalazine, in combination with glucocorticoids (GCs), are common first line therapy options in induction and maintenance of UC remission. Severe cases of UC are treated intravenously with GCs or cyclosporine. CD is mainly treated with GCs and/or antibiotics, and azathioprine (AZA), 6-mercaptopurine (6-MP), or the anti-folate methotrexate (MTX) are often added to maintain the state of remission[4]. GC-resistant or -dependent disease courses can be treated with anti-TNF-α antibodies, such as infliximab and adalimumab. GCs are often used in the initial treatment of most cases of moderate to severe active UC or CD. However, 20% of patients develop GC resistance within one year of treatment[5,6]. Non-response to GCs often leads to the need for a surgical intervention as a result of a poor therapy outcome. For example, it has been reported that 38% and 29% of steroid-resistant CD and UC patients, respectively, required surgery within one year after beginning GC treatment[5].

Glucocorticoids are potent inhibitors of T cell activation and cytokine secretion, primarily *via* binding to the cytoplasmically located glucocorticoid receptor (GR) as ligands. Due to ligand binding, homodimers consisting of two activated GRs are formed that translocate into the nucleus. The complex subsequently binds to specific glucocorticoid response elements (GREs) within the regulatory regions of GR target genes[7]. The mechanisms by which GC resistance develops, are not fully understood. Three possible mechanisms have been proposed. First, decreased plasma levels of GCs through overexpression of the drug efflux system P-glycoprotein (*MDR1*). Second, an altered function of GR or, third, excessive synthesis of pro-inflammatory cytokines induced by activation of pro-inflammatory transcription factors may reduce the affinity of GR to its ligands and lead to the development of GC resistance[4].

GR is known to be expressed as several polymorphic variants[8]. Several mutations in the *NR3C1* gene have been found to modulate individual GC sensitivity in *in vitro* investigations and in studies with healthy individuals[9,10]. In the present study we evaluated the association between the *NR3C1* gene haplotypes and therapeutic outcome of GC administration in a well-sized cohort of 181 patients with IBD. The aim was to comprehensively determine abundant GR variants by sequencing all protein-coding *NR3C1* exons (exons 2 to 9) and the first 50 bp of the neighbouring intronic regions in all individuals. We hypothesized that *NR3C1* gene polymorphisms may influence GC sensitivity and thus might serve as predictive markers for treatment success with GCs in IBD patients.

MATERIALS AND METHODS

Patients

One hundred and eighty-five clinically diagnosed Swiss IBD patients were recruited at the centers participating in the Swiss Inflammatory Bowel Disease Cohort Study (SIBDCS)[11]. All patients gave their informed consent for inclusion into the study. An ethical approval was obtained from the Medical Ethical Committees of the University Hospital Lausanne, Switzerland, and all local study sites. All patients had been treated with steroids and past steroid therapy outcome had been recorded. The standard employed criteria for the steroid therapy success or failure are available on the website www.epact.ch. Briefly, an insufficient response upon appropriate treatment in terms of doses and duration was considered a steroid therapy failure. EDTA-blood samples were stored at the central tissue repository at the Institute of Pathology, University of Bern, Switzerland. The SIBDCS data center at the University Hospital of Lausanne, Switzerland, provided data on past and current disease characteristics and GC therapy outcome. Diagnosis of IBD (CD or UC) was confirmed by the study investigators based on clinical presentation, endoscopic findings and histology.

Sequencing reactions

DNA was extracted from EDTA-blood using the QIAcube robotic workstation and a standard procedure (QIAamp DNA Mini Kit, QIAGEN, Switzerland). The PCR and sequencing primer design was based on the NCBI reference sequence (GenBank accession number NT_029289). Primers for genomic DNA were designed to span all expressed exons (2 to 9) and at least 50 bp of flanking intronic sequences at both 5'- and 3'-ends. The DNA sequences of purified PCR fragments were obtained with an ABI 3730xl sequencing machine. Details of the PCR primers can be found in the Table 1. Optimized PCR conditions, and methods used for subsequent purification and sequencing of the fragments are available upon request.

Haplotype analysis

The PHASE software was used to calculate the haplotypes based on the detected single nucleotide polymorphisms (SNPs) and mutations in the *NR3C1* gene. PHASE predicts *in silico* haplotypes on the basis of a Bayesian inference algorithm[12,13]. Haplotype calculations were performed on 181 individuals, from which sequence data of adequate quality were obtained. To allow referral to specific haplotypes, a frequency-based priority criterion was used to name them (e.g. *GR_1* for the most often occurring haplotype, Table 2).

Calculation of linkage disequilibria

Linkage disequilibria (LD) were calculated using the r^2 statistics. Calculations were performed using the software package Haploview (www.haploview.com).

Statistical analysis

To detect differences in haplotype distribution between

[1]Haplotypes are arranged in the order of decreasing frequency; [2]1 indicates the reference allele at a certain position, 2 indicates the variant allele; [3]Number of haplotypes not included in the subsequent association analysis (steroid therapy outcome, tables 4, 7 and 8) due to likelihood values ≤ 0.95; [4]Haplotype *GR_2* corresponds to haplotype b, *GR_3* corresponds to haplotype c and *GR_4* corresponds to haplotype d in Figure 2.

groups with different GC therapy outcomes, the Chi-Square test or the Fisher's exact test was used. It was analyzed whether one or two copies of a specific haplotype were associated with a particular therapy outcome compared to the GR wild-type carriers. If the number of subjects per group was large enough, heterozygous carriers with one wild-type allele and homozygous carriers of one distinct haplotype were analyzed together against homozygous wild-type carriers. The latter calculations were only performed for haplotypes which occurred in a reasonably large (> 40) number. The statistical analysis was performed using the software package SPSS 17 (SPSS Inc., Chicago, IL).

RESULTS

NR3C1 sequence variability

DNA samples from 185 IBD patients (CD or UC) were initially sequenced for the *NR3C1* coding exons 2 to 9

[1]Defines both the exon/intron localization and the single nucleotide polymorphism (SNP) number; [2]According to the National Center for Biotechnology Information (NCBI) SNP database; [3]According to the NCBI genomic reference sequence NT_029289.11; [4]According to the NCBI cDNA reference cDNA Sequence NM_000176.2. NA: Not applicable.

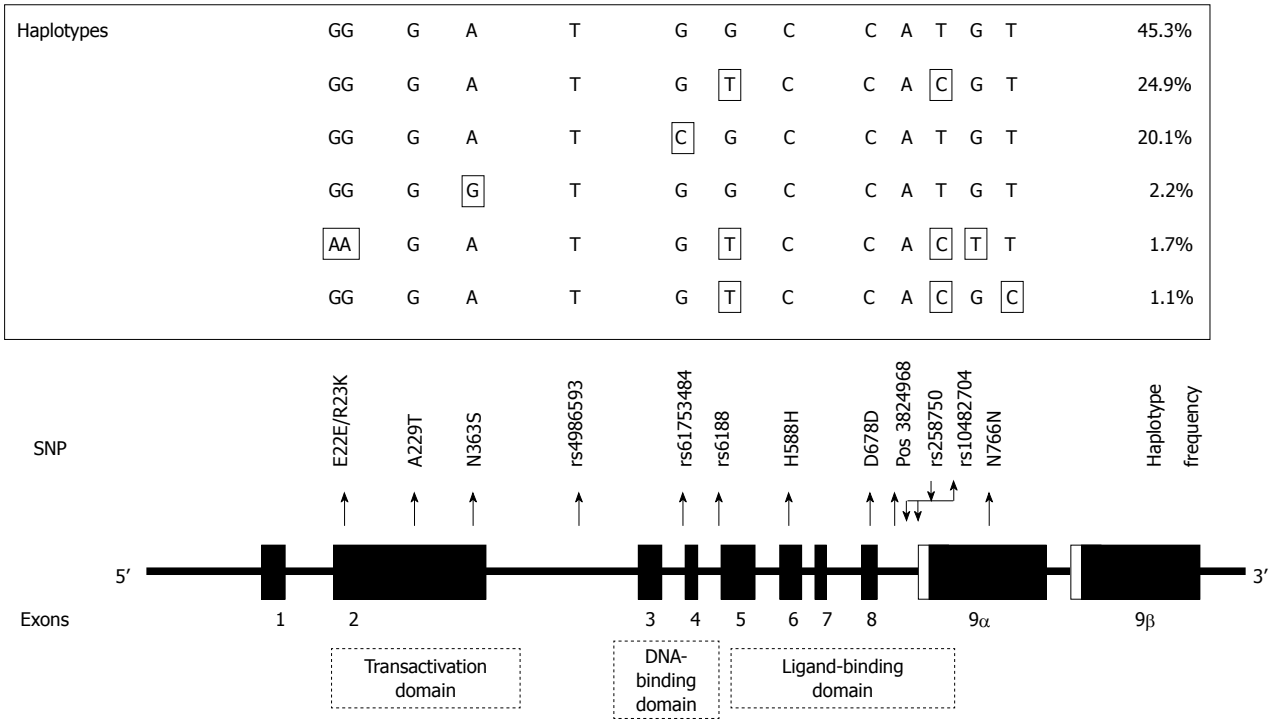

Figure 1 Most frequently occurring *NR3C1* haplotypes and their single nucleotide polymorphisms composition. The localization of the variant nucleotides in the *N3RC1* gene is indicated. All detected non-synonymous single nucleotide polymorphism (SNP) (R23K, A229T, N363S) flank the N-terminal transactivation domain. Only four out of 17 predicted haplotypes occur at a frequency higher than 2%.

and 50 bp of the neighbouring intronic sequences. The sequencing results of 181 individuals were of adequate quality and further used for SNP and haplotype analyses. The sequence data were screened for genetic variations in the *NR3C1* gene, using the Basic Local Alignment Search Tool (BLAST; www.ncbi.nih.gov) and the GenBank entry NT_029289 as the reference sequence.

In Table 3 we list the allele frequencies of all detected SNPs within the IBD cohort under study. Thirteen variants were detected, which were-with exception of one mutation (*rs6196*, $P < 0.01$)-in Hardy-Weinberg equilibrium. All variants were single nucleotide substitutions. Six variants were detected within the intronic regions, whereas seven variants were found in exons (Figure 1). Three of the seven variants detected within the coding regions of the *NR3C1* gene resulted in non-synonymous amino acid exchanges, while four of them did not lead to changes in the GR amino acid sequence. Eight variants occurred with an allelic frequency of more than one percent (*rs56149945*, *rs6189*, *rs6190*, *rs4986593*, *rs6188*, *rs258750*, *rs10482704*, *rs6196*). All non-synonymous amino acid exchanges (R23K, A229T, N363S) were found in the N-terminal half of GR, flanking the N-terminal transactivation domain[14]. The intronic variant found at

Figure 2 *NR3C1* haplotypes predicted by PHASE in the cohort of 181 inflammatory bowel diseases patients. [1]Counter (a to y) for the 25 theoretically arising haplotypes in the inflammatory bowel diseases cohort. SNP: Single nucleotide polymorphism

DNA position 3824968 has not been previously listed in the NCBI SNP database.

Haplotype analysis

The 13 *NR3C1* variants described above were included in the haplotype calculations using the computer program PHASE. All 181 individuals were included in the haplotype prediction analysis (Figure 2). Twenty-five *NR3C1* haplotypes were predicted by PHASE to exist in the studied cohort. Furthermore, PHASE determined 17 different distinct haplotypes, which were found to be in best reconstruction for the cohort (Table 2). Six out of these 17 haplotypes occurred at a frequency higher than 1% (Figure 1). PHASE was only able to determine the haplotype structure of 174 individuals out of 181 subjects with a certainty of $\geqslant$ 95%. The data of one individual were excluded because of missing demographic data. Thus, the predicted haplotypes of 173 individuals were included in the subsequent association analysis.

The two SNPs E22E/R23K were found to be in complete linkage disequilibrium (Figure 3). This finding is in agreement with previous publications[15,16]. Furthermore, a strong but not complete linkage was found between the SNPs *rs6188* and *rs258750* (Figure 3).

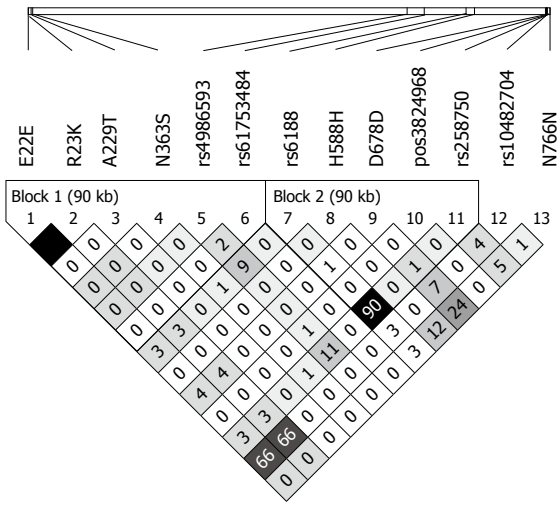

Figure 3 Linkage disequilibrium calculations of single nucleotide polymorphisms in the *NR3C1* gene. Linkage disequilibrium plot of r^2 values of observed variants in the *N3RC1* gene. Colour scheme: r^2 = 0%, white, 0% < r^2 < 100%, shades of grey, r^2 = 100%, black.

Table 4 Demographic data of 173 inflammatory bowel diseases patients included in the association analysis

Characteristics	Crohn's disease	Ulcerative colitis	All
Patients	84 (49%)	89 (51%)	173 (100%)
Age (documented for 171 individuals)	37.5 (± 15.3)	41.7 (± 14.2)	39.7 (± 14.9)
mean ± SD	35	42	39
Median	16	18	16
Minimum	72	82	82
Maximum			
Known GC treatment outcome in the past	50	50	100

Wild-type carriers	15 (16.9%)	20 (23.8%)	35 (20.2%)
Carriers of one variant haplotype	48 (53.9%)	39 (46.4%)	87 (50.3%)
Carriers of two variant haplotypes	26 (29.2%)	25 (29.8%)	51 (29.5%)

GCs: Glucocorticoids.

Analysis of NR3C1 haplotypes in relation to steroid therapy outcome

An overview of the demographic data of the 173 subjects included in the association analysis is shown in Table 4 (further patient data on comedications and extraintestinal manifestations are given in Tables 5 and 6), and the haplotype combinations calculated for all patients are shown in Table 7. As the numbers of homozygous carriers of variant *NR3C1* haplotypes were low, the subjects were analyzed as carriers of one or two copies of a distinct variant haplotype, irrespective of whether the other allele was determined to be wild-type or variant in the case of heterozygotes (Table 8). Furthermore, haplotypes *GR_2* and *GR_3* were analyzed by testing the heterozygous allele combinations *GR_2* + *GR_1* (wt) together with the

homozygous *GR_2* subjects and the allele combination *GR_3* + *GR_1* (wt) together with homozygous *GR_3* carriers against wild-type carriers. For all individuals, prior success of GC therapy was documented, and for patients under GC therapy at the point of study entry the applied dosage was also noted.

No significant associations were observed between haplotype *GR_2* and success of GC therapy (Figure 4). Upon stratification of the patient cohort according to gender or disease subgroup (UC or CD), no significant association between therapy success or haplotype *GR_2* was observed either. Similarly, when stratifying according to the subgroup of heterozygous *GR_2* + *GR_1* and homozygous *GR_2*, no statistically significant difference in therapy response compared to wild-type carriers could be observed.

No significant associations were observed between either haplotype *GR_3* (Figure 5) or *GR_4* (Table 8) and GC therapy outcome, or between individual SNPs and therapy success (Figure 6). Similarly, we observed no significant associations between the severity of disease (active or inactive state of UC or CD) or currently taken GC dose levels and *NR3C1* haplotypes (data not shown).

DISCUSSION

Glucocorticoid receptor (GR) plays an important role in many physiological and pathological processes and is the main target of glucocorticoids, widely used as therapeutic

Table 7 Predicted frequencies of haplotype combinations in 173 inflammatory bowel diseases patients

Haplotype combination	*n*	Frequency
GR_1 + *GR_2* or *GR_2* hom	51	0.295
GR_1 + *GR_3* or *GR_3* hom	41	0.237
GR_1 hom (wt)	36	0.208
GR_2 + *GR_3*	23	0.133
GR_1 + *GR_4* or *GR_4* hom	6	0.035
GR_1 + *GR_5*	3	0.017
GR_3 + *GR_6*	2	0.012

agents to treat a variety of autoimmune diseases[8,17]. Two GR isoforms, GRα and GRβ, generated by alternative mRNA splicing exist[18]. Only GRα can be activated by glucocorticoid ligands, while GRβ does not bind glucocorticoids and may in fact act as an inhibitor of glucocorticoid action[19]. Genetic variation in the *NR3C1* gene has been shown to affect both disease pathophysiology and response to glucocorticoid therapy[15,20-22], suggesting that SNPs might play a role in GR function and associated steroid therapy outcome also in IBD patients. GR is known to regulate the intestinal bile acid uptake transporter ASBT[23,24], the expression of which is altered in IBD patients[25]. While it has been reported that GR mRNA expression levels are not predictors of steroid response in IBD[26] and that the GR polymorphisms R23K and N363S are not associated with CD in a pediatric Caucasian population[27], no studies on the role of *NR3C1* gene variants in steroid therapy success were previously available. The aim of the current study was to analyze sequence variation and

No significant associations were found. Statistical analysis was performed using chi-square or Fisher's exact test.

haplotype structures in the coding parts of the *NR3C1* gene in a cohort of 181 Swiss IBD patients. We investigated whether *NR3C1* genetic variants or haplotypes may influence steroid therapy outcome in IBD patients.

We identified 13 variants in this study, of which 12 had already been previously submitted to the NCBI SNP database. We calculated the corresponding haplotypes in the IBD patient cohort and studied the association of the most prevalent SNP combinations with steroid therapy outcome, disease activity, and age of disease onset. Several *NR3C1* SNPs have been previously associated with altered disease susceptibility or risk of disease progression in other autoimmune diseases, such as Guillain-Barré Syndrome or multiple sclerosis[15,20]. Most of these studies only analyzed the impact of a small number of pre-defined SNPs, such as the BclI polymorphism or the E22E/R23K polymorphisms[15,20,21]. Few reports have been published on the potential influence of *NR3C1* SNPs on sensitivity to endogenous or exogenously given GCs[17,28], and only one significant association between the polymorphism E22E/R23K and sensitivity to exogenously administered GCs in elderly Dutch people has been reported[22]. So far no large cohort studies have been reported in which the influence of *NR3C1* SNPs on GC therapy outcome in IBD patients

has been investigated. Here, we describe five *NR3C1* haplotypes occurring at a frequency > 1% and analyze the potential association of the three most common haplotypes *GR_2*, *GR_3* and *GR_4* with GC therapy outcome in IBD patients. While a large number of *NR3C1* variants are already registered in the NCBI SNP database, we observed only eight variants that occurred at a frequency > 1%, and these were responsible for the composition of a relatively small group of commonly occuring haplotypes. The overall risk for a certain UC and/or CD activity state or for a different steroid therapy outcome was not altered in *GR_2*, *GR_3* or *GR_4* carriers, in comparison with the wild-type carriers. Furthermore, no significant associations were observed between individual SNPs and GC therapy success. In the case of certain SNPs/haplotypes (e.g. *GR_4*, E22E/R23K), a larger cohort would have been preferable in order to obtain more reliable results, as these variants occurred quite rarely in our patient group. Similarly to our observations, Dekker *et al*[20] could not detect any associations between distinct haplotypes and SNPs in a Guillain-Barré Syndrome cohort treated with methylprednisolone, although the authors noted that their study group was too small to obtain statistically reliable results. It remains to be seen whether the rare GR variants present in our study cohort will show significant associations in larger cohorts of IBD patients.

In conclusion, we have performed a comprehensive study analyzing the role of genetic variants in the *NR3C1* gene in glucocorticoid sensitivity in a Swiss cohort of IBD patients. We show that *NR3C1* haplotypes are not a general modulating factor in glucocorticoid therapy outcome.

ACKNOWLEDGMENTS

We thank Christian Hiller for excellent technical assistance, members of our team for fruitful discussions, and the Swiss IBD Cohort Study Group: Michetti P, Vader JP, Burnand B, Pittet V, Ballabeni P, Mueller C, Rihs S, Braegger C, Mottet C, Juillerat P, Felley C, Beglinger C, Froehlich F, Vavricka S, Seibold F, Schoepfer A, von Kaenel R, Begré S, de Saussure P, Meyenberger C, Sagmeister M, Rogler G, Kullak-Ublick GA, Meier R, Straumann A, Criblez D, Engelmann M and Schenk M.

COMMENTS

Background

Crohn's disease and ulcerative colitis are two distinct types of inflammatory bowel disease (IBD), which is an increasingly prevalent disease condition worldwide. Wide variation is observed in clinical manifestation and therapy responses in IBD, partly due to individual genetic variation.

Research frontiers

Glucocorticoid therapy is commonly used in treatment of IBD, however the response to therapy varies between individuals. The authors hypothesized that genetic variation in the *NR3C1* gene encoding the glucocorticoid receptor (GR) may affect the response to glucocorticoids in IBD patients.

Innovations and breakthroughs

In this comprehensive genetic analysis, all coding exons and exon-intron junctions of the *NR3C1* gene were sequenced in 181 IBD patients, who had been treated with glucocorticoids and whose past responses to this treatment had been recorded. This is the first published study on the effects of genetic variation in GR on glucocorticoid therapy in IBD patients, in a modestly sized study cohort.

Applications

If significant associations between genetic GR variants and glucocorticoid therapy outcome had been observed, this could have allowed more considered design of the individual therapy options upon prior genotyping of the patients.

Terminology

The transcription factor of the steroid receptor family, GR, is proposed to be a major mediator of anti-inflammatory pathways elicited by therapeutically administered glucocorticoids.

Peer review

The genetic study investigates the predictive value of *NR3C1* gene variants towards the clinical outcome of patients with Crohn's disease and ulcerative colitis. Although the result of this study was negative, the study was meaningful in that abundant GR variants were determined and analyzed in IBD patients.

Abstract

AIM: To investigate the prognostic significance of S100A4 expression in colorectal cancer and its correlation with expression of E-cadherin and p53.

METHODS: A cohort of archival formalin-fixed paraffin-embedded specimens was selected from 127 patients with colorectal cancer who underwent surgical resection between April 2000 and March 2004 at the Department of Surgery, Korea University Guro Hospital. The expression of protein S100A4 was evaluated according to the proportion of positively stained cancer cells. In each case, three core biopsies with a diameter of 2 mm were punched out and positioned in a recipient paraffin array block. Four-μm sections of these tissue array blocks were used for immunohistochemical analysis of protein S100A4, E-cadherin, and p53. Clinicopathological data were based on the original histopathologic reports and clinical records of patients.

RESULTS: In normal colorectal mucosa, protein S100A4 immunoreactivity was clearly absent in both cytoplasm and nucleus. However, positive immunoreactivity of protein S100A4 was detected in 45 (35.4%) of the tumor cases. There was no significant association between positive immunoreactivity of protein S100A4 and clinicopathological parameters such as tumor differentiation or TNM stage, and also no correlation between the reactivity and E-cadherin or p53 expression. However, positive immunoreactivity of protein S100A4 was found to be associated with tumor recurrence (P = 0.004), and was also associated with significantly worse overall survival in the Kaplan-Meyer survival analysis (P = 0.044). After adjustment for tumor differentiation, tumor depth and nodal status, however, it failed to achieve statistical significance (P = 0.067).

CONCLUSION: The expression of protein S100A4 is associated with tumor recurrence and poor overall survival in patients with colorectal cancer.

Key words: S100A4; E-cadherin; p53; Prognostic factor; Colorectal cancer

INTRODUCTION

Although the last decade has brought significant improvements in the disease-free and overall survival of colorectal cancer (CRC) patients; achieved largely by more accurate staging of disease, an improved and expanded role of surgery and increased number of available chemotherapeutic options, approximately 20% of advanced CRC patients still die of recurrence of the disease[1]. Invasion and metastasis, which are the most life-threatening properties of malignant tumors, result from the interaction between tumor cells and the surrounding tissues. The invasion and metastasis processes themselves consist of pathogenic sequential steps, such as proliferation and detachment of neoplastic cells, invasion to extracellular matrix, angiogenesis, vascular dissemination, lodging in a distant vascular bed, extravasation into the target organ, and proliferation. The activation of many genes and the expression of their products have been involved in this progression[2]. Current conventional staging has a significant impact on survival of CRC patients. However, there is marked variability in outcome that exists within each stage, and certain populations of patients with early recurrence, resistance to chemotherapy and decreased survival cannot be predicted using conventional histopathologic staging. Thus, the identification of molecular factors that have prognostic significance in CRC is essential to improve treatment and outcome[3-5].

Over the past few years, the S100 family of proteins has emerged as an important group with the capacity to promote invasiveness and metastasis of many human neoplasms. In particular, recent studies have established the mechanisms of action of protein S100A4, and indicate its possible prognostic role in human neoplasia[6-8]. However, studies regarding protein S100A4 have mainly been limited to research laboratories. Moreover, the mechanism of action of protein S100A4 in tumors is not fully understood. Therefore, it would be of great interest to find out whether the detection of protein S100A4 has any predictive value, and also whether it may help select patients who require more extensive diagnostic evaluation to rule out metastatic disease and/or more aggressive treatments.

The aims of this study were to investigate immunohistochemically the prognostic significance of protein S100A4 expression in CRC, compared with clinicopathologic parameters and overall survival, and to investigate the correlation between protein S100A4 expression and E-cadherin and p53, which have been suggested as possible targets of protein S100A4.

MATERIALS AND METHODS

Patients

Formalin-fixed paraffin-embedded specimens were selected from 127 patients with CRC who underwent curative or palliative surgical resection between April 2000 and March 2004 at the Department of Surgery, Korea University Guro Hospital. The 127 patients included 76 males (59.8%) and 51 females (40.2%) with a mean age of 59.3 years (range, 28-88). Clinicopathologic data were based on the histopathologic reports and the clinical records of the patients. Using the American Joint Committee on Cancer (AJCC) TNM system[9], tumors were classified as Stage I in 24 specimens (18.9%), Stage Ⅱ in 49 (38.6%), Stage Ⅲ in 49 (38.6%) and Stage Ⅳ in 5 (3.9%). The Korea University Medical Center Institutional Review Board granted permission for the study.

Preparation of tissue microarray

Paraffin blocks of formalin-fixed surgical specimens were obtained from the Department of Pathology, Korea University Guro Hospital. Pathological evaluation of all blocks was performed by two pathologists who did not know any information about the patients. In each case, three core biopsies were obtained from representative areas of the corresponding paraffin blocks with a precision instrument. These tissue cores from each specimen with a diameter of 2 mm were punched out and positioned in a recipient paraffin array block. Each case also included three internal controls consisting of non-neoplastic colorectal mucosa. Four-μm sections of these tissue array blocks were then cut and used for immunohistochemical analysis.

Immunohistochemistry

Immunohistochemical staining for protein S100A4, E-cadherin, and p53 was performed using a standard avidin-biotin complex (ABC) method. In brief, all sections were deparaffinized by using a series of xylene baths and then hydrated using a graded alcohol series. They were then placed in citric acid buffer (10 mmol/L) and heated in a microwave oven (700 W) for 12 min to retrieve the antigenicity. The sections were then immersed in methanol, containing 0.3% hydrogen peroxide, for 20 min to block endogenous peroxidase activity. The sections were then washed three times in phosphate-buffered saline (PBS) and incubated in 2.5% normal goat serum for 20 min to reduce nonspecific antibody binding. After washing with PBS, the sections were incubated with primary antibodies for 30 min at room temperature. Rabbit polyclonal antibodies against protein S100A4 (Ab-8, Neomarker, 1:100), monoclonal mouse anti-human E-cadherin (NCH-38, Dako, 1:100), and monoclonal mouse anti-human p53 (DO-7, Dako, 1:100) were used. The reaction products were visualized with diaminobenzidine as a chromogen, and counterstained with commercial hematoxylin.

Evaluation of immunohistochemical staining

Evaluation of immunohistochemical staining was performed by two independent pathologists. Any discrepancies in scoring were resolved by simultaneous reassess-

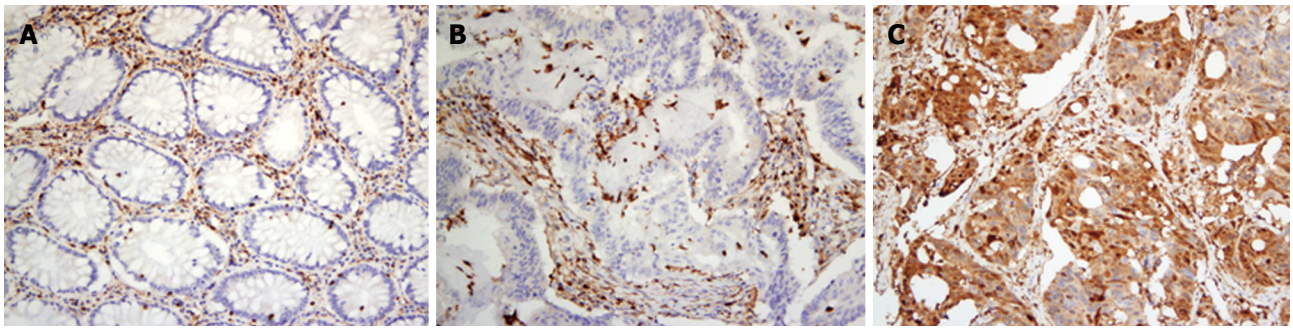

Figure 1 Immunohistochemical expression of protein S100A4. A: Protein S100A4 expression in normal colorectal epithelium. In all normal colonic epithelium, protein S100A4 immunoreactivity was clearly absent at both cytoplasm and nucleus; B: Negative expression of protein S100A4 in colorectal cancer (CRC); C: Positive expression of protein S100A4 in CRC. Cytoplasm of cancer cells was diffusely stained brown (all at × 200 magnification).

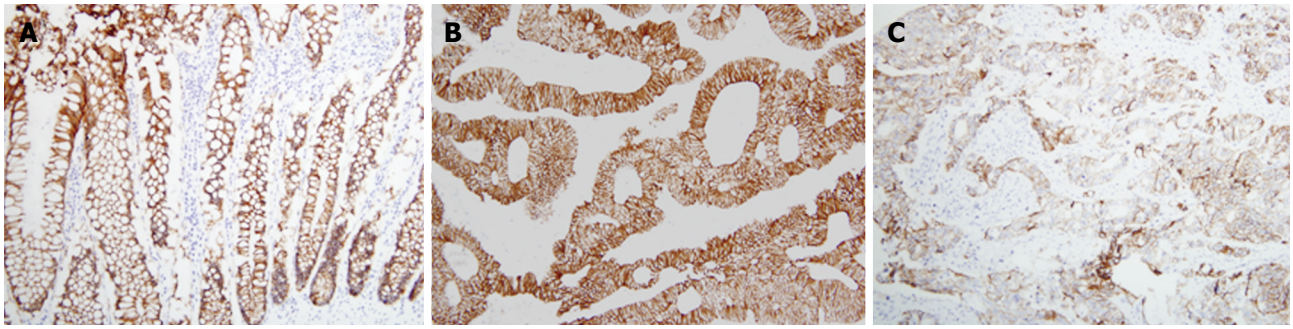

Figure 2 Immunohistochemical expression of E-cadherin. A: E-cadherin expression in normal colorectal epithelium. Normal epithelial cells strongly and homogeneously expressed E-cadherin at intercellular boundaries; B: Preserved expression of E-cadherin in colorectal cancer (CRC); C: Reduced expression of E-cadherin in CRC. Staining of cancer cell at intercellular border was weak and heterogeneous (all at × 200 magnification).

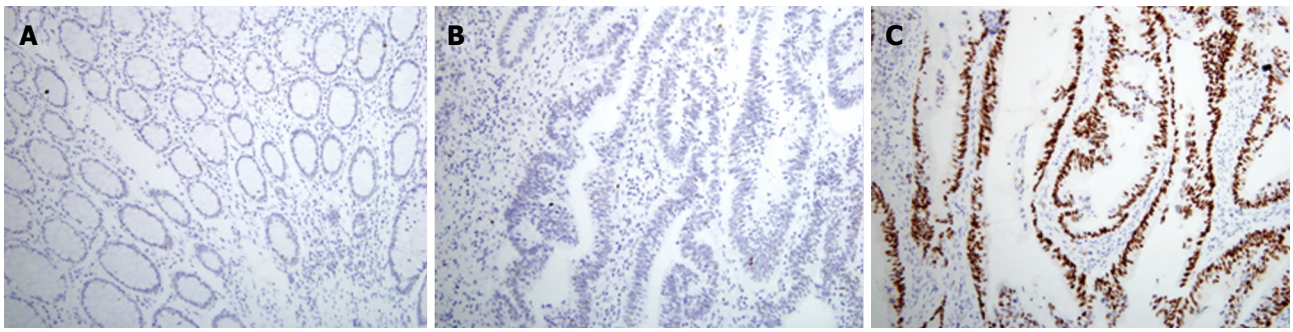

Figure 3 Immunohistochemical expression of p53. A: p53 expression in normal colorectal epithelium. In all normal colonic epithelium, p53 immunoreactivity was clearly absent at nucleus; B: Negative expression of p53 in colorectal cancer (CRC); C: Positive expression of p53 in CRC. More than 10% of cancer cells were stained strongly at their nuclei (all at × 200 magnification).

ment by both pathologists. The tumor cells whose cytoplasm was stained brown were classified as positive. The protein S100A4 expression of tumor cells was evaluated according to the proportion of positively stained tumor cells. When more than 10% of tumor cells were positively stained, the tumor was considered as "positive expression". On the other hand, the tumor was considered as "negative expression" when less than 10% of tumor cells were positively stained (Figure 1). In the case of E-cadherin, when more than 90% of tumor cells were positively stained, the tumor was considered as "preserved expression". On the other hand, the tumor was considered as "reduced expression" when less than 90% of tumor cells were positively stained (Figure 2). p53 expression was evaluated according to the proportion of tumor cells whose nuclei were positively stained. When more than 10% of tumor cells were positively stained, the tumor was considered as "positive expression". On the other hand, the tumor was considered as "negative expression" when less than 10% of tumor cells were positively stained (Figure 3).

Statistical analysis

Statistical analysis was performed using the SPSS for Windows software package (SPSS, Inc., Chicago, IL, Version 12.0). Correlation between the expression

Table 1 Relationship between expression of protein S100A4, E-cadherin, p53 and clinicopathologic parameters *n* (%)

[1]Calculated by Fisher's exact test; [2]Stage Ⅳ patients were excluded.

of protein S100A4, E-cadherin, and p53 and various clinicopathologic parameters was evaluated using the chi-squared test or Fisher's exact test. Overall survival analysis was done by the Kaplan-Meier method. The difference between the survival curves was analyzed by the log-rank test. Significant variables identified on univariate analysis were subjected to multivariate analysis using the Cox regression model. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Expression of protein S100A4, E-cadherin and p53 in CRC

A wide range of cell types in normal colorectal tissues was stained with polyclonal antibody against protein S100A4. There was a high level of staining of smooth muscle, of the smooth muscle in the walls of vessels, and of infiltrating lymphocytes and macrophages in the stroma. However, in normal colorectal mucosa of all 127 cases, immunoreactivity of protein S100A4 was clearly absent in both cytoplasm and nucleus. Positive immunoreactivity of protein S100A4 was detected in 45 (35.4%) of the tumor specimens. E-cadherin was expressed in cell membranes of all normal colorectal mucosa, and reduced expression of E-cadherin was observed in 48 (37.8%) of the tumor specimens. All normal colorectal mucosa showed negative expression for p53; however, 71 (55.9%) tumors were stained for p53 in their nuclei.

Correlation of protein S100A4, E-cadherin, and p53 expression with clinicopathological parameters

Positive reactivity for protein S100A4 was found to be associated with tumor recurrence ($P = 0.004$). However, there was no significant association between the expression of protein S100A4 and other investigated clinicopathological parameters, including tumor location, differentiation or TNM stage. Reduced expression of E-cadherin was significantly correlated with tumor differentiation ($P = 0.001$). As for p53, there was no significant correlation between expression of p53 and clinicopathological parameters (Table 1).

Correlation between protein S100A4 and E-cadherin/p53 expression

There was no significant correlation in co-expression pattern between protein S100A4 and E-cadherin (Kendall's Tau-b correlation coefficient = 0.068, $P = 0.436$, Table 2). Also, there was no significant correlation between protein S100A4 expression and p53 expression (Kendall's Tau-b correlation coefficient = -0.105, $P = 0.239$, Table 3).

Table 2 Correlations of protein S100A4 and E-cadherin

S100A4	E-cadherin	*n* (%)
Co-expression pattern		
Negative	Negative	55 (39.9)
Negative	Positive	34 (24.6)
Positive	Negative	32 (23.2)
Positive	Positive	17 (12.3)

Kendall's Tau-b correlation coefficient = -0.035, $P = 0.681$.

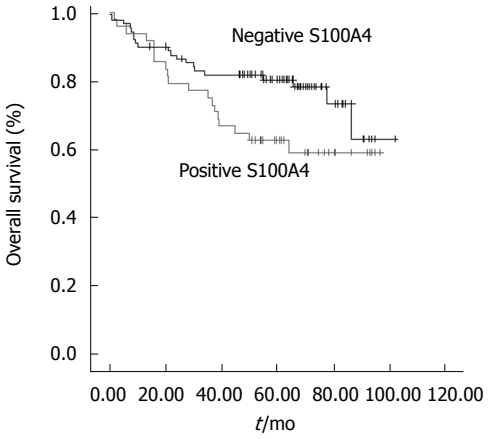

Figure 4 Kaplan-Meier survival curves demonstrating statistically significant differences according to the expression of protein S100A4 (log-rank test, *P* = 0.044). Censored observations are shown as tick marks.

Survival analysis

The median follow-up period for all patients was 58.7 mo (range, 1.1-101.8). The 5-year overall survival rate for the 127 patients was 79.7%. Kaplan-Meier survival analysis showed that tumor differentiation (5-year survival rate 82.3% *vs* 50.0%, $P = 0.001$), depth of tumor (97.1% *vs* 72.9%, $P = 0.001$), lymph node metastasis (88.5% *vs* 68.0%, $P = 0.001$) and positive immunoreactivity of protein S100A4 (86.1% *vs* 68.3%, $P = 0.044$) were associated with poor overall survival (Table 4 and Figure 4).

In a multivariate analysis, however, the positive immunoreactivity of protein S100A4 failed to have association with worse overall survival after adjustment for tumor differentiation, tumor depth and nodal status, which were significant parameters in a univariate analysis (hazard ratio, 1.985; 95% confidence interval: 0.953-4.134; $P = 0.067$, Table 5).

DISCUSSION

Calcium binding proteins form a large family involved in numerous functions ranging from the control of cell-cycle progression and cell differentiation to enzyme activation and regulation of muscle contraction[10,11]. The S100 proteins represent one of the largest subfamilies of the calcium binding proteins with at least 19 different members; the degree of homology ranges from 25% to 65%. They were initially characterized as low-molecular weight acidic proteins and named by their solubility in 100% ammonium sulfate ("S100"). S100A4, also known as p9Ka, CAPL, or calvasculin, is a member of the S100 family consisting of 101 amino acids and with a molecular weight of about 11.6 kDa. The corresponding gene, cloned by different groups, is known as *mts1* (metastasin), *pEL98, 18A2, 42A*, and *fsp* (fibroblast-specific protein)[10-13].

The biologic functions of several S100 proteins in carcinogenesis have not been fully elucidated to date. Recently, however, much interest has focused on S100A4 and some other S100 family members, such as S100A2, S100A6, and S100B, for their potential roles in invasive growth and metastasis of neoplastic diseases. S100A4 or its corresponding mRNA are found at higher levels in

metastatic relative to non-metastatic rat[14] and mouse[15] tumor cell lines. Transfection experiments further showed that rodent or human S100A4 can induce a metastatic phenotype in previously non-metastatic rat mammary cells[16,17]. Conversely, antisense S100A4 RNA or anti-S100A4 ribozyme suppressed the metastatic potential of highly metastatic cell lines[18,19]. Moreover, in pilot studies of human colorectal adenocarcinoma specimens, elevated levels of immunohistochemically detected S100A4 are associated with the more malignant carcinomatous regions of the primary tumors and with liver metastases[20]. The tight association between S100A4 expression and metastasis observed in these laboratory analyses has led to a number of studies examining the utility of S100A4 expression as a prognostic marker in human cancers. Protein S100A4 has been shown to be a prognostic marker in a number of human cancers, including breast cancer[21], esophageal-squamous cancer[22], non-small cell lung cancer[23], gastric cancer[24], malignant melanoma[25], prostate cancer[26], and pancreatic cancer[27]. The universality of S100A4 expression in a variety of cancers illustrates the potential use of S100A4 as a marker for tumor metastasis and disease progression.

The purpose of this investigation was to establish clinical significance of the calcium-binding protein, S100A4, in CRC. It was found that 35.4% of CRC specimens were stained strongly by the polyclonal antibodies against protein S100A4, in concordance with earlier reports[28,29]. The staining in specimens is not restricted to only carcinoma cells, because highly expressed levels are also detected in normal tissues, in particular, smooth muscle cells, endothelial cells of both arteries and veins, and some reactive fibroblast-like cells and lymphocytes[30]. However, the present study was undertaken on only carcinoma cells.

In this study, positive expression of protein S100A4 was associated with tumor recurrence, in accordance with previous study[28]. This result suggests that the protein S100A4 may play a role in predicting a patient subgroup which would show more unfavorable outcome, thus leading us to substage-oriented tailored therapy with more intensive treatment and more strict follow-up surveillance.

This study showed that the overall survival of CRC patients who had immunohistochemically detectable levels of protein S100A4 was significantly worse than those CRC patients with negative expression of protein S100A4 according to univariate analysis. Because S100A4 was first discovered as a metastasis-inducing protein in experimental models[14-19], and metastasis is the major event responsible for death in patients of CRC, it is quite possible that protein S100A4 causes earlier deaths by its ability to induce metastasis in human CRC. Although it failed to achieve statistical significance in multivariate analysis, the present result suggests a need for further and larger studies to investigate the role of protein S100A4 expression in CRC.

As a typical member of the S100 family, S100A4 exerts dual functions, both intracellular and extracellular. Intracellularly, it interacts with and functionally modifies the tumor suppressor protein p53, non-muscle myosin II, and liprin β1[12,13]. S100A4 interacts with the C terminus of p53 and inhibits protein kinase C (PKC) phosphorylation of the tumor suppressor *in vitro*. Likewise, the interaction between p53 and S100A4 inhibits p53 from binding to its consensus DNA-binding sequence[31]; thus it was expected that S100A4 would be a general inhibitor of p53 function. It has been suggested that a complex of S100A4 with p53 and the sequestration of p53 may result in stimulation of the cells to enter the S phase by abrogating the control functions of p53 at the G1-S checkpoint[8,31,32]. However, as shown in this study, this possibility was difficult to prove by immunohistochemical analysis of these two proteins in CRC. An examination of p53-regulated genes in S100A4-expressing cells indicates that the expression of several genes are up-regulated (e.g. *bax*); other genes are down-regulated initially and then later up-regulated (e.g. *mdm2*), and some genes are inhibited (e.g. *p21*, *thrombospondin-1*)[31]. These opposite effects of S100A4 expression on p53-regulated genes could explain why there was no correlation between S100A4 and p53, notwithstanding the potential interaction of these two proteins.

Another possible mechanism of action of S100A4 in carcinogenesis is cytoskeletal dysregulation by down-regulation of E-cadherin induced by protein S100A4. E-cadherin is a member of the large cadherin superfamily. It is the predominant intercellular adhesion molecule expressed by intestinal epithelial cells, and functions to mediate epithelial cell-cell adhesion and maintain the integrity of the epithelium[33-35]. The expressions of E-cadherin and protein S100A4 in two mouse tumor cell lines were found to be inversely regulated, and transfection experiments showed a reciprocal down-regulation of both molecules, suggesting that the invasiveness of tumors expressing protein S100A4 may be at least partially induced by the abrogation of E-cadherin expression[36]. A similar mechanism has also been postulated in humans, on the basis of immunohistochemical analysis of both proteins in a series of non-small cell lung cancer[23] and gastric cancer[24]; an inverse correlation of E-cadherin and protein S100A4 expression was demonstrated. In this study, we attempted to immunohistochemically establish an inverse correlation between the expression of protein S100A4 and E-cadherin in CRC; however, data failed to prove the relationship (Kendall's Tau-b correlation coefficient = -0.035, P = 0.681). Nevertheless, it is quite possible that different antibodies against protein S100A4, different cancer tissue, and small numbers enrolled in this study might have contributed to this difference.

In conclusion, in the present retrospective study, positive immunoreactivity of protein S100A4 is closely associated with cancer recurrence. However, there is no correlation between the expression of protein S100A4 and E-cadherin or p53. The overall survival for patients with CRC expressing immunohistochemically detectable levels of protein S100A4 is significantly worse than for those patients with CRC considered negative for S100A4. Furthermore, protein S100A4 shows borderline tendency toward being a prognostic marker in multivariate regres-

sion analysis. Although these results suggest that protein S100A4 could be a useful biologic predictor of cancer recurrence and poor outcome, subsequent prospective, large-scale studies are required to confirm its importance and relevance in the invasive potential of human CRC.

COMMENTS

Background

Although current conventional staging has a significant impact on survival of colorectal cancer patients, there is marked variability in outcome within each stage. As the protein S100A4 has been known to promote invasiveness and metastasis of many human neoplasms, the question is raised as to whether this protein represents a useful prognostic marker in clinical practice.

Research frontiers

Studies regarding the protein S100A4 have mainly been limited to research laboratories and clinical data are extremely limited. Therefore, it would be of great interest to find out whether the expression of protein S100A4 has any predictive value and may help select patients who require more extensive diagnostic evaluation to rule out metastasis and/or more aggressive treatments.

Innovations and breakthroughs

The results of this study showed that positive immunoreactivity of protein S100A4 was associated with tumor recurrence and worse overall survival.

Applications

Since there is an association between protein S100A4 expression, tumor recurrence and poor overall survival, this can lead to substage-oriented tailored therapy with more intensive treatment and more strict follow-up surveillance in colorectal cancer patients.

Terminology

The protein S100A4 was first discovered as a metastasis-inducing protein in experimental models. It is a polypeptide of 101 amino acids with a molecular mass of 11.5 kDa. The evidence gathered throughout the past few years demonstrates that protein S100A4 is involved in the regulation of invasiveness and metastasis in many human cancers.

Peer review

This paper is very well written and has a strong message about expression of protein S100A4 in 127 cases of colorectal cancer, showing a statistically significant association with tumor recurrence and overall survival.

Abstract

AIM: To study the significance of cap-fitted colonoscopy in improving cecal intubation time and polyp detection rate.

METHODS: This study was a prospective randomized controlled trial conducted from March 2008 to February 2009 in a tertiary referral hospital at Sydney. The primary end point was cecal intubation time and the secondary endpoint was polyp detection rate. Consecutive cases of total colonoscopy over a 1-year period were recruited. Randomization into either standard colonoscopy (SC) or cap-assisted colonoscopy (CAC) was performed after consent was obtained. For cases randomized to CAC, one of the three sizes of cap was used: D-201-15004 (with a diameter of 15.3 mm), D-201-14304 (14.6 mm) and D-201-12704 (13.0 mm). All of these caps were produced by Olympus Medical Systems, Japan. Independent predictors for faster cecal time and better polyp detection rate were also determined from this study.

RESULTS: There were 200 cases in each group. There was no significant difference in terms of demographic characteristics between the two groups. CAC, when compared to the SC group, had no significant difference in terms of cecal intubation rate (96.0% *vs* 97.0%, P = 0.40) and time (9.94 ± 7.05 min *vs* 10.34 ± 6.82 min, P = 0.21), or polyp detection rate (32.8% *vs* 31.3%, P = 0.75). On the subgroup analysis, there was no significant difference in terms of cecal intubation time by trainees (88.1% *vs* 84.8%, P = 0.40), ileal intubation rate (82.5% *vs* 79.0%, P = 0.38) or total colonoscopy time (23.24 ± 13.95 min *vs* 22.56 ± 9.94 min, P = 0.88). On multivariate analysis, the independent determinants of faster cecal time were consultant-performed procedures (P < 0.001), male patients (P < 0.001), non-usage of hyoscine (P < 0.001) and better bowel preparation (P = 0.01). The determinants of better polyp detection rate were older age (P < 0.001), no history of previous abdominal surgery (P = 0.04), patients not having esophagogastroduodenoscopy in the same setting (P = 0.003), trainee-performed procedures (P = 0.01), usage of hyoscine (P = 0.01) and procedures performed for polyp follow-up (P = 0.01). The limitations of the study were that it was a single-center experience, no blinding was possible, and there were a large number of endoscopists.

CONCLUSION: CAC did not significantly different from SC in term of cecal intubation time and polyp detection rate.

Key words: Cap; Hood; Cecum; Colonoscopy; Cecal intubation; Colonic polyps

INTRODUCTION

Colonoscopic examination has been used in clinical practice for approximately 40 years. Despite the fact that colonoscopy is widely available and is performed by many experienced colonoscopists, there are concerns about the quality of colonoscopy as measured by several technical endpoints such as rate of failed cecal intubation and polyp miss rate. A large population-based study[1] has revealed that 13.1% of colonoscopies failed to reach the cecum. In addition, one large review of back-to-back colonoscopies has shown polyp miss rates of 24%[2] for adenoma. Numerous innovations, as described by Rex[3], have been studied to improve these two key issues, with some showing promise.

One potentially promising technique is cap-assisted colonoscopy (CAC). A transparent cap (or hood) is a simple plastic device that can be attached to the tip of a colonoscope before performing the colonoscopy. Several randomized trials from Japan[4-8] have reported mixed results regarding improved cecal intubation times and polyp detection rates. A recent large study from Hong Kong[9] has shown improved time to cecum intubation but a reduced polyp detection rate. To date, as far as we are aware, there is no large randomized study that has used the cap in a western population, in whom the colorectal cancer (CRC) incidence is known to be higher than Asian population[10]. We conducted a randomized controlled trial to investigate the usefulness of CAC in a western population at Royal Prince Alfred Hospital, Sydney.

MATERIALS AND METHODS

This was a prospective randomized controlled trial conducted in a tertiary referral hospital from March 2008 to February 2009. All patients who were referred to our endoscopy service for colonoscopy were invited to participate in the study. All were aged 18 years or older. Exclusion criteria included prior colonic resection, pregnancy, severe comorbidity and acute surgical conditions such as severe colitis, toxic megacolon, ischemic colitis, tertiary referral for endomucosal resection, acute gastrointestinal bleeding, or inability to provide consent, such as dementia. This prospective study was approved by Sydney South West Area Health Service Ethics Review Committee. The trial was registered with ClinicalTrial.gov with the registration identification number NCT00930462.

The preparation for the procedure included a clear fluid diet the day before the procedure, routine bowel preparation with either a sodium picosulfate-based (Picoprep, Pharmatel Fresenius Kabi Pty Ltd., Hornby, Australia), or sodium-phosphate-based (Fleet, Ferring Pharmaceuticals, Gordon, Australia) preparation, and a fasting period of 8 h. Colonoscopy was performed in either the hospital endoscopy unit or a private outpatient endoscopy center associated with our hospital. Procedures were performed by a team of five consultant gastroenterologists and 10 trainees. All procedures were performed under conscious or deep sedation with a combination of intravenous midazolam (Pfizer, Bentley, Australia), fentanyl (Mayne Pharma Ltd, Mulgrave, Australia), and propofol (Fresofol 1%; Pharmatel Fresenius Kabi Pty Ltd.) administered by the assistant or attending anesthetist. As an antispasmodic, hyoscine butylbromide was administered as appropriate. Colonoscopes used were CF-Q160AL, CF-Q180AL, PCF-160AL and PCF-180AL (Olympus Optical Co., Tokyo, Japan).

Three sizes of cap were used: D-201-15004 (with a diameter of 15.3 mm, used for CF-Q180AL), D-201-14304 (14.6 mm, used for CF-Q160AL) and D-201-12704 (13.0 mm, used for both PCF-160AL and PCF-180AL). All of these caps were produced by Olympus Medical Systems (Tokyo, Japan). The cap was placed so that 4 mm was beyond the tip of the colonoscope (Figure 1). Even though the rim of the cap was visible on the monitor, the visual field was not limited as the endoscopist was able to see through the transparent cap.

Once informed consent was obtained, patients were randomized according to a computer-generated randomization protocol to standard colonoscopy without the cap (SC) or CAC. Patients were blinded to the allocation. The colonoscopes were assigned in no specific order and were used according to availability after cleaning. Data were collected during and after the colonoscopic examinations on procedure times, polyps, complications and other parameters.

The procedure was defined as successful if the colonoscope reached the cecum, confirmed by either visualization of the appendicular orifice or the ileocecal valve. Trainee success was only recorded if the cecum was reached without help from a consultant. Terminal ileal intubation was attempted in all cases. The quality of bowel preparation was graded either as good (no or small volume of clear liquid, easily removed), satisfactory (moderate to large volume of liquid stool, removable with suction), or poor (presence of semi-solid stool that could not be cleared or washed away).

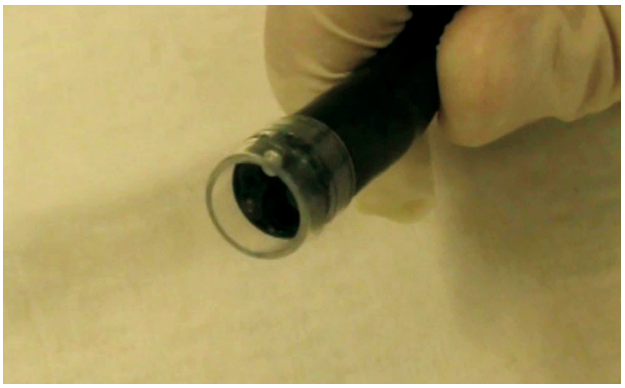

Figure 1 A cap attached to the tip of the colonoscope, with approximately 4 mm of the cap beyond the tip.

Polyps were removed in standard fashion and sent for pathology. The size of the polyps was determined by the endoscopist performing the polypectomy. Advanced lesions were defined as lesions > 10 mm, with high grade dysplasia, or villous in nature. If a diminutive polyp was encountered on insertion and the endoscopist wished to remove this during the insertion phase of the procedure, the time taken for this was subtracted from the insertion time but included in the total procedure time.

Outcome measurement

The primary endpoint of this study was cecal intubation time. The secondary endpoint was polyp detection rate. Other endpoints included ileal intubation rate, total colonoscopy time, trainee success rate and complication rate.

The study also determined the independent predictors for faster cecal time and better polyp detection rate.

Statistical analysis

The study sample size was calculated to be 200 in each arm to detect a difference with a power of 0.8 and an α of 0.05 by two-tailed testing based on historical data[5], for the primary endpoint of cecal intubation time available at the time the study was designed. All statistical analyses were performed using SPSS for Windows version 12.0 (Chicago, IL, USA). The Mann-Whitney test was used for continuous variables that appeared to have a skewed distribution, and the χ^2 or Fisher's exact test for categorical variables. Statistical significance was defined as $P < 0.05$ (two-tailed).

Cecal intubation time and polyp detection rate were log transformed to approximate normality prior to fitting a multiple linear regression model using stepwise variable selection. This model was used to identify only the independent predictors of these parameters.

RESULTS

Baseline demographics

Between March 2008 and February 2009, a total of 400 patients were recruited, with 200 each in the CAC and SC groups. A flow diagram of the enrollment is shown in Figure 2. Mean age was 52 years, and 49% of the subjects were male. The characteristics of the two groups are shown in Table 1, and no significant differences were found between them. Trainees performed a total of 310 (77.5%) procedures in this study.

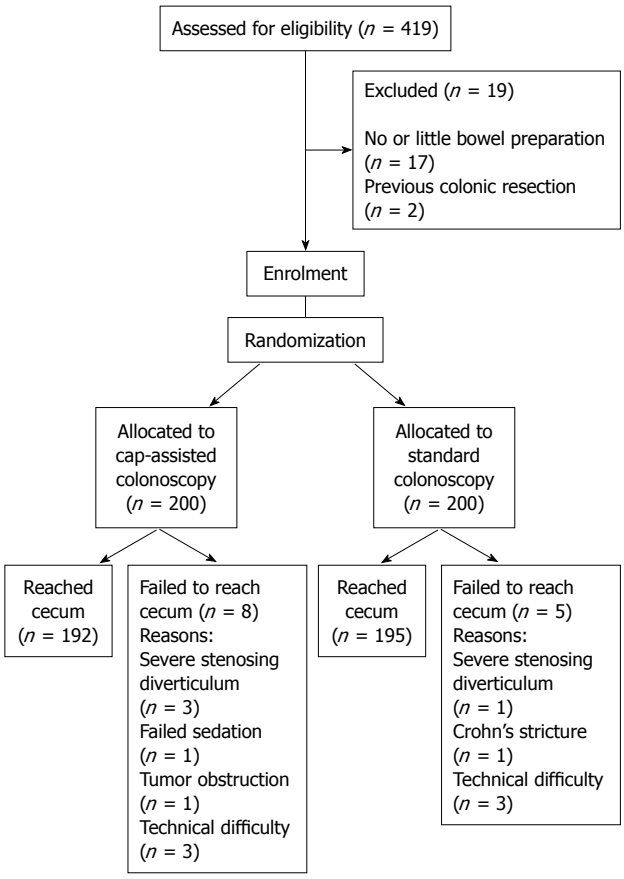

Figure 2 Flow diagram showing enrolment of patients in the study.

Cecal intubation rate

Cecal intubation was achieved in 387 (96.8%) of the 400 colonoscopic examinations. The success rate of cecal intubation was 192/200 (96.0%) in the CAC group and 195/200 (97.5%) in the SC group ($P = 0.40$). When analyzing the data on procedures by trainees only, the unassisted cecal intubation rate was 268/310 (86.5%), with no significant difference between CAC (140/159, 88.1%) and SC (128/151, 84.8%), and P value was 0.40 (Table 2). Forty-two procedures performed by trainees required assistance from consultants, and among these, 32 (76.2%) were successful in reaching the cecum.

Of the 13 cases of failed cecal intubation, four were due to severe sigmoid stenosing diverticular disease (three CAC, and one SC); one each for failed sedation (CAC), Crohn's stricture (SC) and tumor obstruction (CAC); and the other six cases were due to technical difficulties that included irreducible colonic loops (three CAC, and three SC).

Overall ileal intubation rate was 323/400 (80.8%). There was no significant difference between CAC and SC with regards to ileal intubation rate, either overall

Total number of adenomas	75	55	0.26[2]
Total number of advanced adenomas	23	14	0.52[2]

[1]χ^2 test; [2]Mann-Whitney test. CAC: Cap-assisted colonoscopy; SC: Standard colonoscopy.

On univariate analysis, factors found to be significantly associated with faster time to the cecum were: male sex, younger age, colonoscopy by a consultant, good or satisfactory bowel preparation, and non-use of hyoscine. Multiple linear regression confirmed each of these as independent predictors, apart from young age (Table 3).

Polyp detection rate

Among the 387 subjects who had successful cecal intubation, colorectal polyps were detected in 123 (31.8%) of them (63 in the CAC and 61 in the SC group, *P* = 0.75). CAC and SC detected polyps in 32.8% and 31.3% of their subjects, respectively. When confined to subjects aged 50 years and above, CAC detected polyps in 43.2% and SC in 35.9% (*P* = 0.24) (Table 4). The total number of polyps detected was 254, and this also did not differ between the two groups (147 in CAC and 107 in SC, *P* = 0.59). There was no difference between the two groups in terms of the number of polyps of 5 mm or less (*P* = 0.45), adenoma number (*P* = 0.26), or advanced adenoma (*P* = 0.52) (Table 4). On univariate analysis, factors found to be significantly associated with detection of polyp were: male sex, older age, polyp follow-up as the indication, patients who had colonoscopy alone (*vs* patients having combined gastroscopy and colonoscopy), non-use of hyoscine, and colonoscopy performed by a trainee. On multivariate analysis, the independent predic-

Table 5 Multivariate analysis of determinants of higher polyp detection rate

Independent predictors	OR	95% CI	*P* value
Age	1.450	1.213-1.734	< 0.001
Previous abdominal surgery	0.559	0.322-0.971	0.039
Having EGD on the same setting	0.451	0.266-0.765	0.003
Consultant	0.460	0.250-0.845	0.012
Use of hyoscine	2.877	1.374-6.026	0.005
Indication: polyp follow-up	2.722	1.342-5.523	0.006

EGD: Esophago-gastro-duodenoscopy.

tors were older age, polyp follow-up as the indication, no history of prior abdominal surgery, patients having colonoscopy alone, trainee-performed colonoscopy, and the use of hyoscine (Table 5).

Complications

There was no complication associated with the use of the cap. There were two cases of post-polypectomy bleeding, one each in the SC and CAC groups, although these cases were minor and did not require transfusion.

DISCUSSION

Despite the fact that polypectomy prevents 76%-90% of CRC when compared to the expected incidence[11], data from interval CRCs (CRCs diagnosed between the time of a negative screening colonoscopy to that of next recommended colonoscopy) raise important questions about how effective colonoscopy is as a screening practice[12]. Possible reasons for these interval cancers include failed colonoscopy and missed lesions. A large population-based study[1] has revealed that 13.1% of colonoscopy failed to reach the cecum. Rex *et al*[2] have published data on adenoma miss rates based on a large back-to-back colonoscopy series, and estimated that the rate was 17%-48%. Important advances in colonoscopy have been suggested to improve the outcome of colonoscopy. These include improving colonoscopy techniques (optimizing withdrawal time[13-15], chromoendoscopy and bowel preparation quality[16,17]) and technologies (wide-angle colonoscopy in 2003[18], narrow band imaging in 2004[19], and fluorescence confocal endomicroscopy[20].

Caps have been used previously in endoscopic procedures, for instance, in mucosal resection and double balloon enteroscopy. Their use in colonoscopy has been studied in the past with regards to cecal intubation and polyp detection. Our study did not show any benefit of CAC for our primary endpoint of time to cecal intubation Even though all six previous randomized trials of CAC have been faster with the cap, only four were significantly faster. In our study, CAC had a shorter cecal intubation time although this was not statistically significant. One possible explanation is that studies with cecal intubation times below 10 min are inclined to have no significance between the two study arms, with the exception of the study of Lee *et al*[9]. This illustrates a point whereby the benefit of the cap is small in those procedures where cecal intubation times are already short. The short cecal intubation time and high cecal success rate in our study probably left little room for improvement with the cap. The overall cecal intubation rate was 96.8%, this high success rate was probably due to the fact that our center is a tertiary teaching hospital.

Factors that predicted faster colonoscopy in our multivariate analysis (Table 3) were as expected and well-described in the literature[21-23], except for the use of hyoscine. We reserved hyoscine for difficult insertions, which suggests that we selected patients with difficult colonoscopy, hence the prolonged cecal intubation time in that group.

We also showed no significant improvement of the polyp detection rate in the CAC group. This was almost certainly due to a small sample size because this study was powered to look at cecal intubation time rather than polyp detection rate. Furthermore, our study cohort had a mean age of 52 years (*vs* 62.0-66.4 in Asian studies[5-8]), older only than the patients in the study of Lee *et al*[9]. Our low polyp detection rate at 31.8%, despite the fact that the study was carried out on a western population, was likely a consequence of this younger patient population. The youngest population studied to date was in Hong Kong[9], which demonstrated significantly lower polyp detection in the CAC group. Our study does not support the use of a cap for polyp detection, however, the question of any benefit with the cap has not been sufficiently answered. Further studies, particularly in a western population, are required. With the known polyp miss rates at about 24%[2], it is likely that large numbers will need to be recruited in prospective randomized studies to show any benefit of this intervention.

In conclusion, there was no statistically significant difference between CAC and SC with regards to cecal intubation success, time and polyp detection rate.

ACKNOWLEDGMENTS

The authors would like to thank the endoscopy nurses headed by Kaye Ireson at Royal Prince Alfred Hospital, Sydney for their tireless effort in assisting this research.

COMMENTS

Background

Despite 40 years of advances in colonoscopic practices, there are a significant number of incomplete procedures and polyp miss rate. This study looked at the use of cap-assisted colonoscopy (CAC) in improving these endpoints.

Research frontiers

Colonoscopy is the most important screening tool for cancer of the colon. Many new developments are aimed at improving the quality of colonoscopy. These include improving colonoscopy techniques (optimizing withdrawal time, chromoendoscopy and bowel preparation quality) and improved technologies (wide-angle colonoscopy in 2003, narrow band imaging in 2004, and fluorescence confocal endomicroscope in 2005).

Innovations and breakthroughs

CAC is a relatively simple and inexpensive tool that is used to improve the usefulness of colonoscopy. Several Asian centers have performed trials on CAC, with conflicting results, and we aim to add more information on the usefulness of this device.

Applications

This article provides important data on the usefulness of CAC especially in a Western population.

Peer review

This is an interesting study that investigated the use of CAC in a day-to-day setting of a busy tertiary endoscopy unit.

Abstract

AIM: To investigate the effect of tectorigenin on proliferation and apoptosis of hepatic stellate cells (HSC)-T6 cells.

METHODS: HSC-T6 cells were incubated with tectorigenin at different concentrations, and their proliferation was assessed by bromodeoxyuridine incorporation assay. Apoptosis was detected by flow cytometry assay with Hoechst 33342 staining. Also, generation of reactive oxygen species (ROS), intracellular $[Ca^{2+}]_i$, potential of mitochondrial membrane, activities of cytochrome c and caspase-9 and -3 were investigated to explore a conceivable apoptotic pathway.

RESULTS: Tectorigenin suppressed the proliferation of HSC-T6 cells and induced apoptosis of HSC-T6 cells in a time- and dose-dependent manner. Tectorigenin at the concentration of 100 μg/mL greatly inhibited the viability of HSC-T6 cells and induced the condensation of chromatin and fragmentation of nuclei. When treated for 48 h, the percentage of cell growth and apoptosis reached 46.3% ± 2.37% (P = 0.004) and 50.67% ± 3.24% (P = 0.003), respectively. Furthermore, tectorigenin-induced apoptosis of HSC-T6 cells was associated with the generation of ROS, increased intracellular $[Ca^{2+}]_i$, loss of mitochondrial membrane potential, translocation of cytochrome c, and activation of caspase-9 and -3.

CONCLUSION: Tectorigenin inhibits proliferation of HSC-T6 cells and induces apoptosis of HSC-T6 cells.

INTRODUCTION

Hepatic fibrosis, a common wound-healing response to diseases such as chronic hepatitis and alcoholic liver damage, is a result of destruction in architecture of the liver parenchyma and an imbalance between fibrogenesis

and fibrolysis forming scars or fibrous tissues. Hepatic stellate cells (HSC), the major cells in hepatic fibrosis, are responsible for the development of fibrosis[1,2]. Activation and proliferation of HSC are the key to fibrogenesis while apoptosis of HSC is associated with the resolution of fibrosis. So, HSC have attracted increasing attention due to their essential role in liver fibrosis. With a better understanding of their biological properties, inhibiting the activation and proliferation of HSC and inducing apoptosis of activated HSC have been proposed as potential anti-fibrosis strategies.

In traditional Chinese medicine, *Iris tectorum* (*I. tectorum*) has been used in treatment of liver injury for a long time. It has been shown that tectorigenin, an important bioactive compound isolated from *I. tectorum*, has antioxidant, anti-inflammatory, and anticancer activities[3-5]. Experiments on animal models have also demonstrated that tectorigenin exhibits a hepatoprotective effect on CCl_4-induced or *t*-BHP-induced hepatic injury in rats[6,7]. Since hepatic fibrosis is a common wound-healing response to liver injury, we studied whether tectorigenin has anti-fibrosis potentials and exhibits its hepatoprotective effect by playing a role in liver fibrosis.

The present study was therefore performed to investigate the effects of tectorigenin on proliferation and apoptosis-related events of activated HSC-T6 cells and disclose its possible mechanism underlying apoptosis of HSC-T6 cells.

MATERIALS AND METHODS

Materials

Tectorigenin was isolated from *I. tectorum* with a purity of over 98% as confirmed by high-performance liquid chromatography (HPLC) analysis.

Cell culture

HSC-T6 cells, an immortalized rat hepatic stellate cell line, exhibit an activated HSC phenotype[8]. The cells, purchased from Cancer Institute and Hospital, Chinese Academy of Medical Sciences (Beijing, China), were cultured in Dulbecco's-modified Eagle's medium (DMEM; Gibco, NY, USA) supplemented with 100 U/mL penicillin, 100 μg/mL streptomycin, and 12% new bovine serum (Hangzhou Sijiqing Co., Ltd., Hangzhou, China), in a humidified atmosphere containing 5% (v/v) CO_2 at 37℃. L02 cells (a human hepatocyte cell line), purchased from Xiangya Central Experiment Laboratory, Central South University, China, were cultured in DMEM medium (Gibco, NY, USA) supplemented with 100 U/mL penicillin, 100 μg/mL streptomycin, and 10% fetal bovine serum (Hangzhou Sijiqing Co., Ltd., Hangzhou, China), in a humidified atmosphere containing 5% (v/v) CO_2 at 37℃.

Cell viability assay

Cells were plated in 96-well plates at a density of 5×10^5 cells/well and grown for 24 h. Tectorigenin at different concentrations was added to the cells while only DMSO (solvent) was added as a negative control. After growing for 12, 24, and 48 h, cell viability was evaluated by the reduction of 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide (MTT; Amresco, OH, USA)[9].

Bromodeoxyuridine uptake

HSC-T6 cells were incubated for 48 h with 20, 40, 60 and 100 μg/mL tectorigenin, respectively. Two hours before the cells were harvested, bromodeoxyuridine (BrdU; GenMed Scienfics Inc., USA) was added. The cells were fixed in 4% paraformaldehyde and stained with Hoechst 33342 following the manufacturer's protocol[10].

Morphological observation of nuclear change

HSC-T6 cells were incubated for 48 h with tectorigenin at 20, 40, 60 and 100 μg/mL, respectively. Nuclear morphological change was assessed using Hoechst 33342 staining[11]. In brief, cells were fixed in 4% paraformaldehyde for 10 min, washed three times with pre-chilled PBS and exposed to 5 μg/mL of Hoechst 33342 at 37℃ in dark for 15 min. Samples were observed under a fluorescent microscope (Nikon UFX-Ⅱ, Japan). Cells showing cytoplasmic and nuclear shrinkage, chromatin condensation or fragmentation, were defined as apoptotic cells.

Flow cytometry analysis

To quantify apoptotic cells, HSC-T6 cells were harvested after exposed to tectorigenin for 24 and 48 h, respectively, washed twice with cold PBS, resuspended in PBS containing fluorescein isothiocyanate (FITC)-conjugated annexin V and propidium iodide (PI) for 10 min, and measured using a FACScan flow cytometer[12,13] (Becton Dickinson, Franklin Lakes, NJ, USA).

Measurement of ROS generation

Intracellular ROS was quantified with a fluorescence plate reader using 2, 7-dichlorodihydrofluorescein diacetate (DCFH-DA, Sigma)[14]. The cells on black 96-well plates were treated with tectorigenin at with tectorigenin at 20, 40, 60 and 100 μg/mL for 1, 3, 6 and 24 h, respectively, and incubated with DCFH-DA at 37℃ for 30 min. After DCFH-DA was removed, the cells were washed with phosphate buffered saline (PBS). DCFH-DA-loaded cells were read on a Safire fluorescence plate reader (Tecan, Crailsheim, Germany).

Measurement of intracellular $[Ca^{2+}]_i$

$[Ca^{2+}]_i$ was monitored using fluorescent Ca^{2+}-sensitive dye, a Fura 2-acetoxymethyl ester (Fura 2-AM)[15]. Cells were cultured and treated with tectorigenin for 1, 3, 6 and 24 h, respectively, and preloaded with 1 μmol/L Fura2-AM for 30 min in dark at 37℃ in a humidified incubator. After loading with Fura2-AM, cells were collected, gently rinsed three times with D-Hanks' solution, and resuspended in D-Hanks' solution containing 0.2% BSA at 10^6cells/mL. Intracellular $[Ca^{2+}]_i$ was measured at an emission wavelength of 510 nm and an excitation wavelength of 340 and 380 nm on a Safire fluorescence

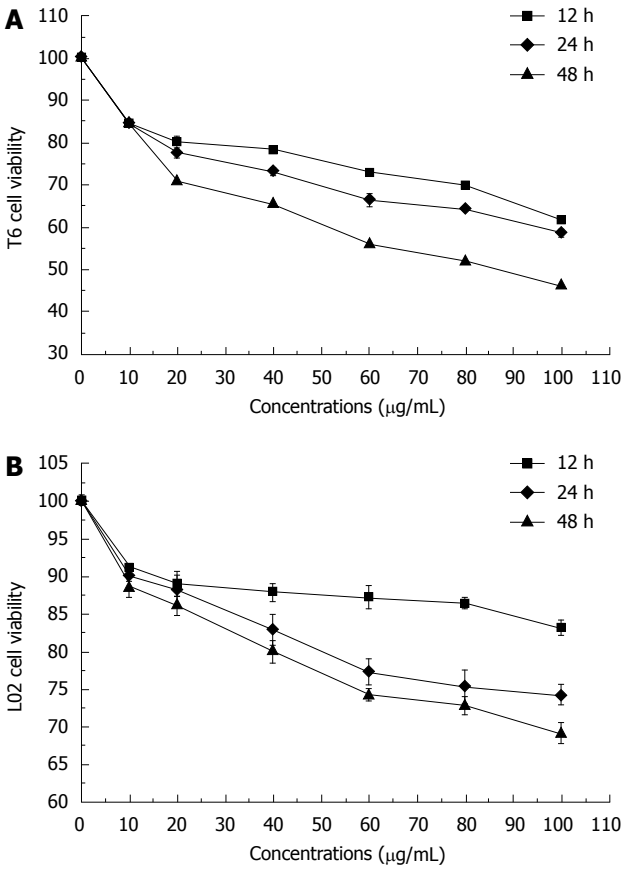

Figure 1 Effects of tectorigenin on the viability of hepatic stellate cell -T6 (A) and -L02 cells (B). Cells were treated for 12, 24 and 48 h with tectorigenin at 10, 20, 40, 60, 80 and 100 μg/mL, respectively, followed by assessing the cell viability relative to that of untreated cells (= control). Bars represent mean ± SD.

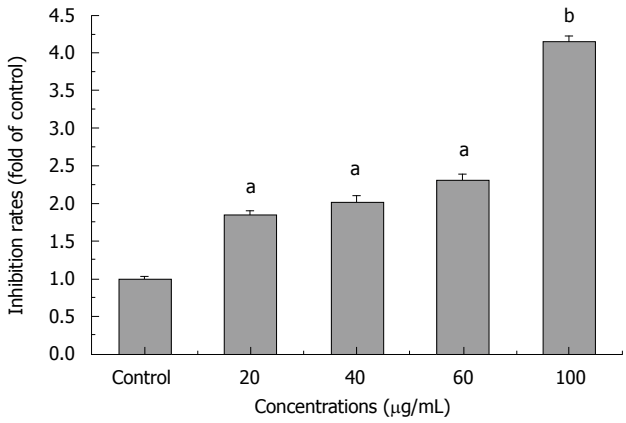

Figure 2 Proliferative inhibition of tectorigenin on hepatic stellate cells-T6 cells. Cells were treated for 48 h with tectorigenin at 0, 20, 40, 60 and 100 μg/mL, respectively. Data are expressed as fold increase over that of untreated cells. Bars represent mean ± SD ($^aP < 0.05$, $^bP < 0.01$).

plate reader (Tecan, Crailsheim, Germany). The ratio of fluorescence intensity at 340 to 380 nm (F340/F380) was used to estimate intracellular free calcium.

Measurement of mitochondrial membrane potential

Change in mitochondrial membrane potential (MMP) was monitored using Rhodamine 123 (Rh-123)[16]. In brief, Rh-123 was added to cells to attain a final concentration of 3 μg/mL. After incubated at 37℃ for 30 min, cells were collected, washed twice with PBS, and analyzed with a FACScan flow cytometer (Becton Dickinson, Franklin Lakes, NJ, USA).

Western blotting analysis

HSC-T6 cells were seeded into 60-mm dishes (1×10^6 cells/dish). After treated on the next day for 48 h with tectorigenin at 0, 20, 40, 60 and 100 μg/mL, respectively, HSC-T6 cells were harvested, resuspended in an ice-cold lysis buffer consisting of 50 mmol/L Tris-HCl, pH 8.0, 50 mmol/L KCl, 5 mmol/L DTT, 1 mmol/L EDTA, 0.1% SDS, 0.5% Triton X-100, and protease inhibitor cocktail tablets (Roche, IN), incubated for 10 min on ice, disrupted in a micro ultrasonic cell disrupter for 10 s and centrifuged at 750 *g* for 15 min at 4℃. The supernatant (cytosolic fraction) was removed and maintained at -80℃. The pellet containing mitochondria was resolved in a lysis buffer. Protein level was measured using a standard colorimetric assay kit (BCA kit). Proteins were separated by polyacrylamide/SDS gel electrophoresis and transferred onto polyvinylidene fluoride (PVDF) membranes (Roche, IN). The membranes were probed with antibodies (cytochrome c and caspase-9 diluted at 1:1000, Cell Signaling Technology, MA, USA) overnight at 4℃, and incubated with a HRP coupled secondary antibody (HRP; 1:5000, Cell Signaling Technology, MA, USA). Detection was performed using a LumiGLO chemiluminescent subtract system (KPL, Guildford, UK). β-actin (1:200, Boster, Wuhan, China) as a loading control. Results were quantified with a scanning densitometer (Bio-Rad, USA).

Measurement of caspase-3 activity

Activity of caspase-3, the main execution caspase, was detected with a caspase-3 colorimetric assay kit (KenGen Biotech, Nanjing, China) according to its manufacturer's instructions. Cultured HSC-T6 cells were washed twice with cold PBS, resuspended in a lysis buffer and left on ice for 20 min. Lysate was centrifuged at 10000 r/min for 3 min at 4℃. Supernatants were collected and protein concentrations were measured with a BCA kit. Proteins (100 μg) were incubated for 4 h at 37℃ with a reaction buffer in a total volume of 105 μL containing 5 μL caspase-3 substrate, and detected with a fluorescence microplate reader (Tecan, Crailsheim, Germany) at λ 405 nm.

Statistical analysis

All data were expressed as mean ± SD. Origin Pro 7.0 statistical package was used to determine statistical significance. Difference between two groups was analyzed by two-tailed Student's *t*-test, and difference among three or more groups was analyzed by one-way ANOVA multiple comparisons. $P < 0.05$ or $P < 0.01$ was considered statistically significant.

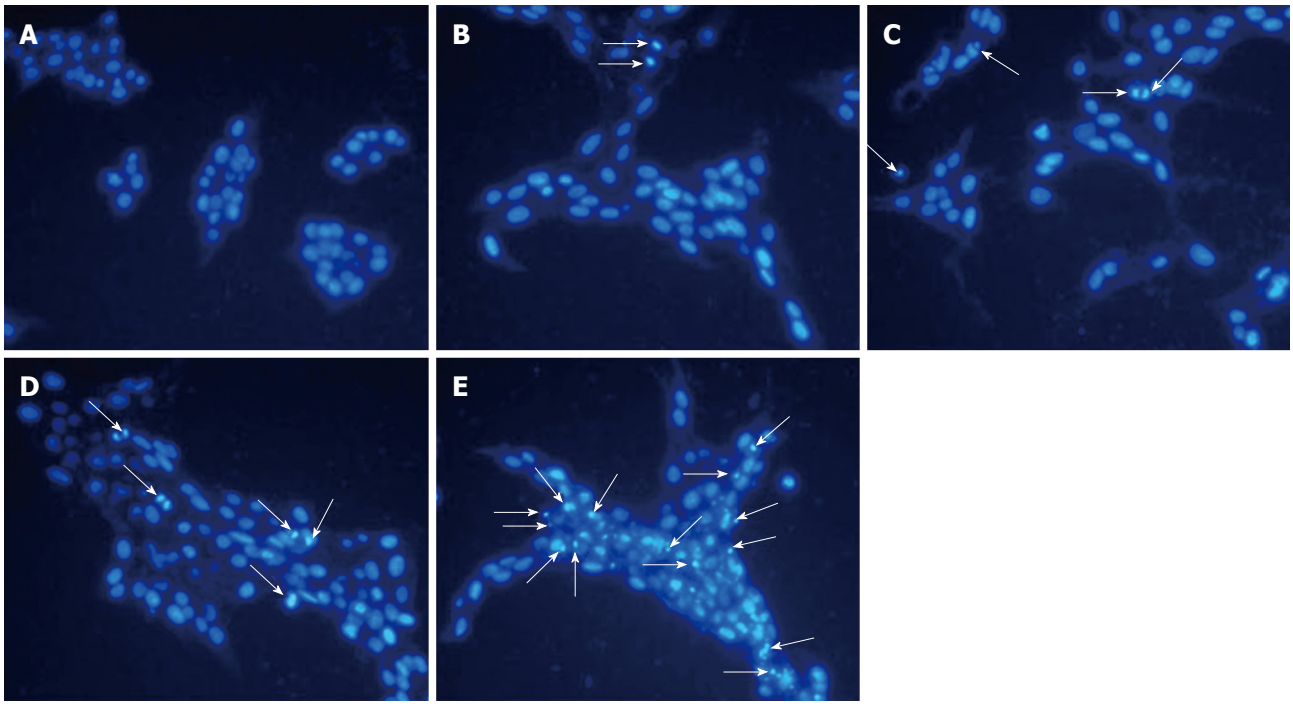

Figure 3 Fluorescent staining of nuclei in hepatic stellate cells-T6 cells (200 ×). Cells were treated with tectorigenin for 48 h at 0 μg/mL (A), 20 μg/mL (B), 40 μg/mL (C), 60 μg/mL (D) and 100 μg/mL (E), respectively. The arrows in B-E indicate the apoptotic cells.

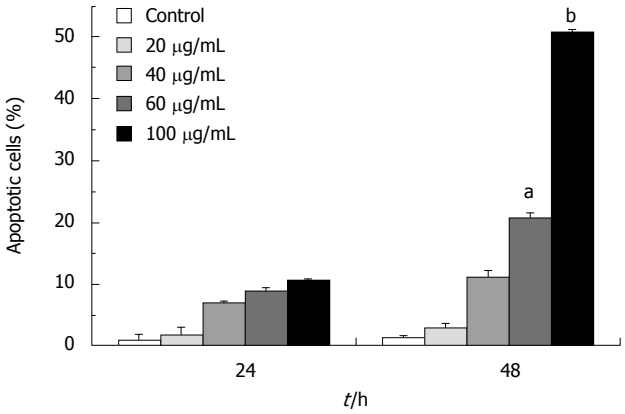

Figure 4 Flow cytometry-evidenced apoptosis of hepatic stellate cells-T6 cells upon exposure to tectorigenin. Cells were incubated for 24 and 48 h with tectorigenin at 20, 40, 60 and 100 μg/mL, respectively, followed by being stained with fluorescein isothiocyanate-conjugated annexin V and propidium iodide. Bars represent mean ± SD ($^aP < 0.05$, $^bP < 0.01$).

RESULTS

Effect of tectorigenin on viability of HSC-T6 and L02 cells

The percentage of cell growth was significantly different between tectorigenin-treated and untreated groups. Tectorigenin inhibited the growth of HSC-T6 cells in a dose-dependent manner (Figure 1A). Increased incubation time of HSC-T6 cells decreased the percentage of cell growth, indicating that tectorigenin also inhibits the growth of HSC-T6 cells in a time-dependent manner. Treatment with tectorigenin at 100 μg/mL resulted in a moderate cytotoxicity to L02 cells after incubated for 48 h (Figure 1B). To further investigate the inhibitory effect of tectorigenin on proliferation of HSC-T6 cells, BrdU incorporation, another indicator of cell proliferation, was detected. Tectorigenin at 20-100 μg/mL could significantly inhibit the proliferation of HSC-T6 cells (Figure 2).

Tectorigenin induced apoptosis of HSC-T6 cells

We studied if tectorigenin can induce apoptosis of HSC-T6 cells. In brief, apoptotic cells were visualized using DNA-binding Hoechst 33342. Regular and round-shaped nuclei were observed in control HSC-T6 cells (Figure 3). After treated for 48 h with tectorigenin at 40 and 60 μg/mL, condensed nuclei were found in HSC-T6 cells, which became smaller in size, and eventually fragmented into apoptotic bodies. Moreover, after treated with 100 μg/mL tectorigenin, the nuclei of HSC-T6 cells were further condensed with the number of apoptotic bodies sharply increased. These data suggest that tectorigenin greatly induces the condensation of chromatin and fragmentation of nuclei. The apoptosis rate of HSC-T6 cells was determined by flow cytometry analysis with annexin V-FITC and PI staining. In the control group, most cells were viable. When HSC-T6 cells were exposed for 48 h to tectorigenin at 60 and 100 μg/mL, the percentage of apoptotic cells increased to 20.69% ± 2.57% and 50.67% ± 3.24% ($P = 0.003$), respectively (Figure 4), which was significantly higher than that of those not exposed to tectorigenin. In addition, tectorigenin induced apoptosis of HSC-T6 cells in a dose- and time-dependent manner.

Tectorigenin induced ROS generation in HSC-T6 cells

To determine whether tectorigenin is able to induce ROS generation in HSC-T6 cells, the level of ROS, measured using the fluorescence probe DCFH-DA, was significantly

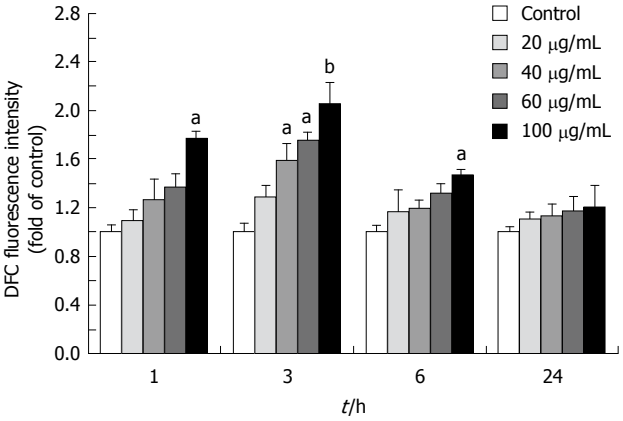

Figure 5 Tectorigenin produces reactive oxygen species in hepatic stellate cells-T6 cells. Cells were treated with tectorigenin for 1, 3, 6 and 24 h, followed by a 30-min incubation at 37℃ with reactive oxygen species detected by dichlorodihydrofluorescein diacetate. Data are expressed as fold increase over that of untreated cells. Bars represent mean ± SD ($^aP < 0.05$, $^bP < 0.01$).

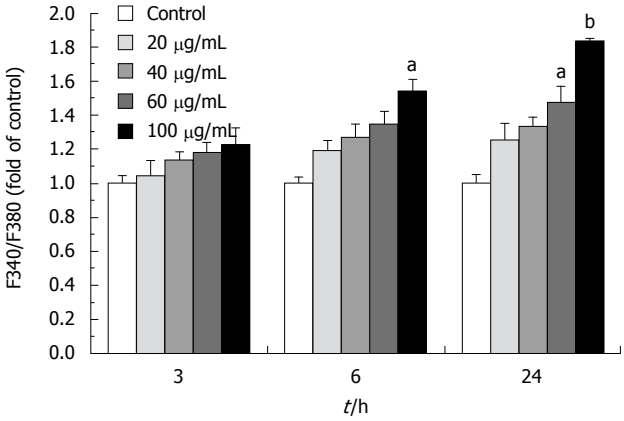

Figure 6 Tectorigenin increases $[Ca^{2+}]_i$ in hepatic stellate cells-T6 cells. Cells were treated with tectorigenin for 3, 6 and 24 h. $[Ca^{2+}]_i$ was detected by Fura-2/AM 380nm/340nm fluorescence ratio (F340/F380). Data are expressed as fold increase over that of untreated cells. Bars represent mean ± SD ($^aP < 0.05$, $^bP < 0.01$).

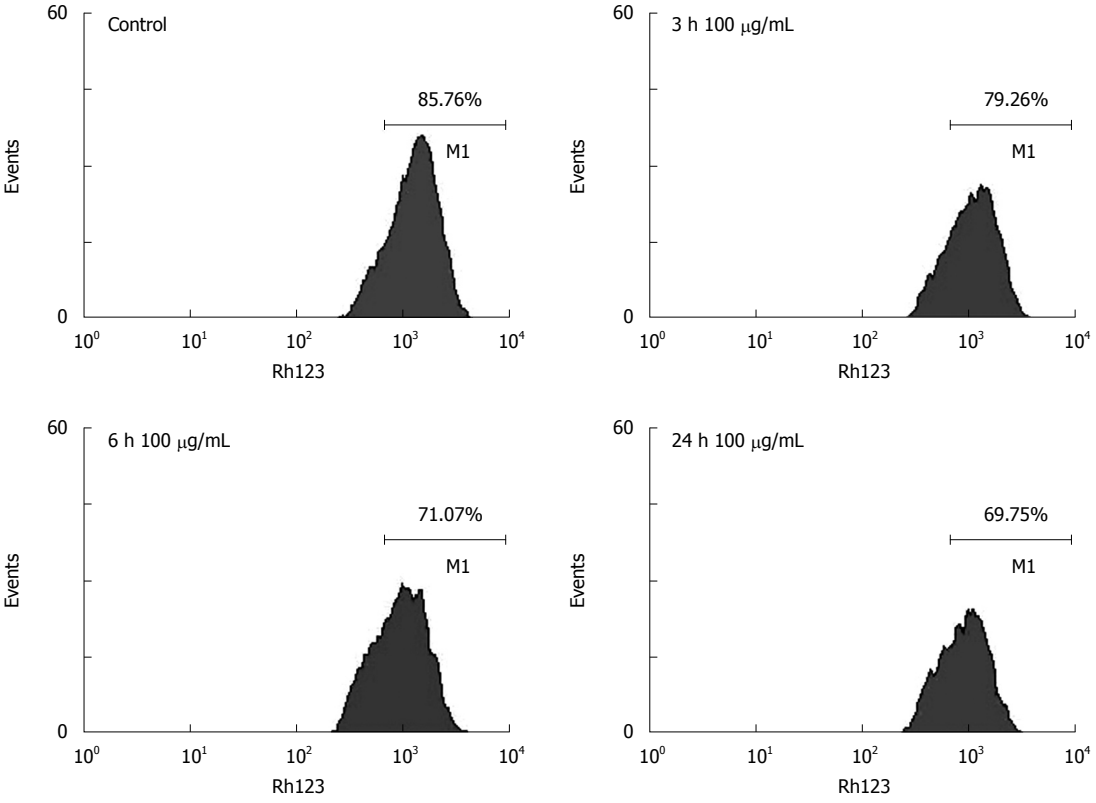

Figure 7 Tectorigenin reduces mitochondrial membrane potential in hepatic stellate cells-T6 cells. After treated with tectorigenin at 100 μg/mL for 3, 6 and 24 h, respectively, cells were harvested and stained with Rhodamine 123 to determine mitochondrial membrane potential by flow cytometry.

higher in HSC-T6 cells than in control cells after treated with 100 μg/mL tectorigenin for 1, 3 (peaked) and 6 h (Figure 5).

Tectorigenin increased $[Ca^{2+}]_i$ in HSC-T6 cells

To determine whether tectorigenin influences the level of intracellular Ca^{2+}, the level of intracellular Ca^{2+} was measured with Fura 2-AM staining. After treated with 100 μg/mL tectorigenin for 3 h, the fluorescence ratio (F340/F380) increased to 123.1% ± 7.18% compared to that not treated with tectorigenin (Figure 6). In addition, tectorigenin increased cytoplasmic Ca^{2+} in a time-dependent manner. When the incubation time was prolonged to 24 h, the F340/F380 value increased from 123.1% ± 7.18% to 183.3% ± 8.64% ($P = 0.002$).

Tectorigenin decreased mitochondrial membrane potential in HSC-T6 cells

To determine whether tectorigenin decreases mitochondrial membrane potential in HSC-T6 cells, flow cytometry

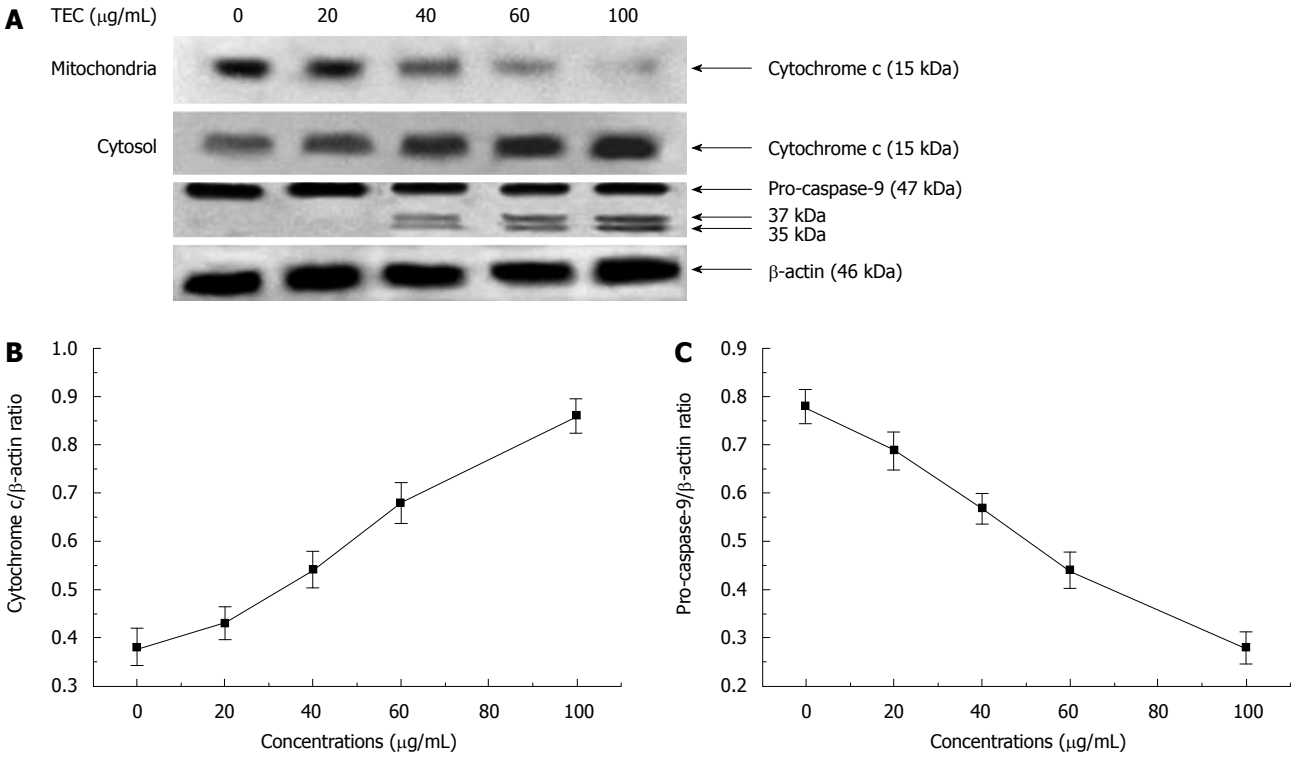

Figure 8 Western blotting analysis. After 48-h exposure to tectorigenin at 0, 20, 40, 60 and 100 μg/mL, respectively, levels of cytochrome c and caspase-9 in hepatic stellate cells-T6 cells (A), along with those of cytochrome c (B) and pro-caspase-9 (C) in cytosol, were evaluated. Protein (30 μg) from each sample was resolved on 12% SDS-PAGE and β-actin was used as a loading control.

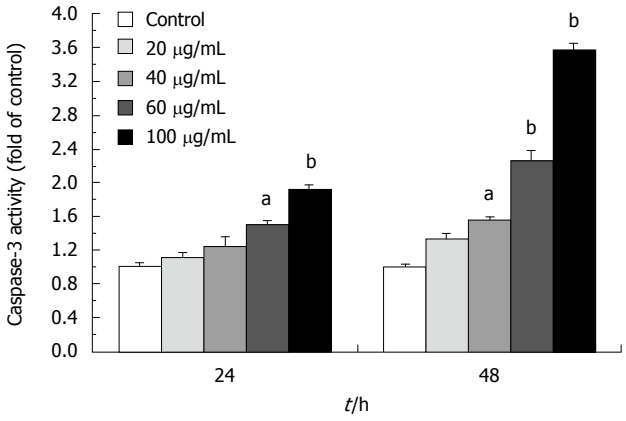

Figure 9 Tectorigenin activates pro-caspase-3 in hepatic stellate cells-T6 cells. Cells were treated for 24 and 48 h with tectorigenin at 0, 20, 40, 60 and 100 μg/mL, respectively. Data are expressed as fold increase over that of untreated cells. Bars represent mean ± SD ($^aP < 0.05$, $^bP < 0.01$).

analysis was carried out using Rhodamine 123. Compared to control cells not treated with tectorigenin, HSC-T6 cells treated with 100 μg/mL tectorigenin for 24 h decreased the mitochondrial membrane potential (MMP) from 85.76% ± 6.39% to 69.75% ± 5.28% ($P = 0.03$) (Figure 7).

Effect of tectorigenin on release of cytochrome c and activities of caspase-9 and -3

To assess whether tectorigenin-treated cells accompany increased cytosolic translocation of cytochrome c, the activated caspases-9 and -3 were detected, and the cytosolic and mitochondrial levels in cytochrome c and intracellular caspases-9 and -3 were measured. The results reveal that tectorigenin releases mitochondrial cytochrome c into cytosol in a dose-dependent manner (Figure 8B). Western blotting also showed that tectorigenin induced proteolytic cleavage of pro-caspase-9 into the active form of HSC-T6 cells and tectorigenin activated the caspase-9 in a dose-dependent manner (Figure 8C). Tectorigenin (100 μg/mL) significantly increased the activity of caspase-3 in HSC-T6 cells (Figure 9).

DISCUSSION

In the present study, tectorigenin, a bioactive compound isolated from *I. tectorum* used traditionally for severe liver disorder, suppressed the proliferation of HSC and induced apoptosis of HSC in a time- and dose-dependent manner.

As an immortalized rat liver stellate cell line, HSC-T6 cell line exhibits an activated phenotype of HSC and a fibroblast-like morphology, which presents as a useful tool in exploring hepatic fibrosis[17]. MTT and BrdU incorporation assay demonstrated that tectorigenin could inhibit the proliferation of HSC-T6 cells, with a lower cytotoxicity to human hepatocytes (L02). Furthermore, flow cytometry analysis indicated that tectorigenin could induce apoptosis of HSC-T6 cells in a dose- and time-dependent manner.

Clarification of the molecular mechanism of tectorigenin underlying the discerned apoptosis is of great importance. It has been shown that ROS generation

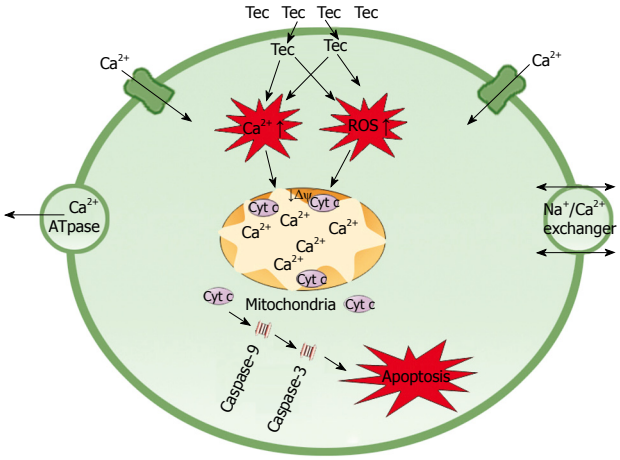

Figure 10 Tectorigenin produces reactive oxygen species and increases Ca^{2+} concentration in cytoplasm of hepatic stellate cells-T6 cells, leading to the depletion of mitochondrial membrane potential and release of cytochrome c from mitochondria. Cytochrome c facilitates apoptosis of hepatic stellate cells-T6 cells by activating caspase cascade. ROS: Reactive oxygen species.

increases membrane permeability of mitochondria, triggers abrupt mitochondrial depolarization and release of cytochrome c from inner mitochondrial membrane[18]. Calcium homeostasis is an essential mechanism underlying physiological process. Since increased cytosolic calcium may induce mitochondria to take up intracellular overloaded Ca^{2+}, a much larger amount of Ca^{2+} will accumulate in mitochondria, which can potentially damage the electron transfer chain, leading to failure in maintaining the mitochondrial membrane potential[19-21]. Damages to mitochondrion result in loss of its function. For example, release of cytochrome c from mitochondria leads to cell apoptosis[22]. In this study, tectorigenin increased the ROS production and Ca^{2+} concentration in cytoplasm of HSC-T6 cells, the intracellular accumulation of ROS and Ca^{2+} further induced the loss of MMP. The disruption of MMP caused release of cytochrome c from mitochondria to cytosol. Cytosolic cytochrome c activated the pro-caspase-9 and subsequently, caspase-9 activated the downstream effector caspases-3, eventually triggered apoptosis of HSC-T6 cells (Figure 10).

In conclusion, tectorigenin suppresses the proliferation of HSC-T6 cells in a dose- and time-dependent manner, and produces a slight cytotoxicity to L02 cells. More importantly, tectorigenin induces apoptosis of HSC-T6 cells and may have anti-fibrosis potentials.

COMMENTS

Background

Liver fibrosis represents a significant health problem worldwide without any currently available and effective therapeutic approach. Advanced liver fibrosis results in cirrhosis, liver failure, and portal hypertension, and often requires liver transplantation. The most characteristic feature of liver fibrosis is excess deposition of type I collagen. A great number of researches have been performed to understand the molecular mechanism underlying liver fibrosis. Activated hepatic stellate cells (HSC) are the primary cell type responsible for the excess production of collagen.

Research frontiers

HSC are the major cells responsible for the development of liver fibrosis and cirrhosis. Activated HSC are proliferative and fibrogenic, with accumulation of extra cellular matrix, including α-smooth muscle actin (α-SMA) and type I collagen. Suppression of activation and proliferation, and induction of apoptosis in HSC have been reported as the therapeutic strategies against liver fibrosis. Tectorigenin, a bioactive compound of *Iris tectorum* (*I. tectorum*), shows antioxidant, anti-inflammatory, anticancer, and hepatoprotective activities, and has been used in therapy for liver injury. However, how tectorigenin works in live fibrosis has not been unequivocally addressed. In this study, tectorigenin suppressed proliferation of HSC and induced apoptotis of HSC.

Innovations and breakthroughs

Currently used drugs such as corticosteroids and colchicine usually show various side effects such as immunosuppression or cytotoxicity. Tectorigenin, an antioxidant, anti-inflammatory, and hepatoprotective compound isolated from *I. tectorum*, shows its inhibitory effect on proliferation of HSC and produces a low toxicity. Furthermore, *in vitro* studies suggest that tectorigenin produces its pro-apoptotic effect on HSC is probably *via* the mitochondrial pathway to some extent.

Applications

By showing how tectorigenin works in HSC, this study may represent a new and future strategy for managing hepatic fibrosis.

Peer review

This study showed that tectorigenin inhibited the growth and viability of rat hepatic HSC-T6 cells in a dose-dependent manner. The authors conclude that the anti-proliferative and pro-apoptotic effects of this component on HSC might explain its anti-fibrotic properties observed *in vivo*. This is an interesting study. However, the mechanism of tectorigenin underlying the growth and viability of HSC-T6 cells needs to be further studied.

Abstract

AIM: To investigate the gene expression pattern of hepatocyte nuclear factor 6 (HNF6) and other liver-enriched transcription factors in various segments of the human intestine to better understand the differentiation of the gut epithelium.

METHODS: Samples of healthy duodenum and jejunum were obtained from patients with pancreatic cancer whereas ileum and colon was obtained from patients undergoing right or left hemicolectomy or (recto)sigmoid or rectal resection. All surgical specimens were subjected to histopathology. Excised tissue was shock-frozen and analyzed for gene expression of liver-enriched transcription factors by semiquantitative reverse transcription polymerase chain and compared to the human colon carcinoma cell line Caco-2. Protein expression of major liver-enriched transcription factors was determined by Western blotting while the DNA binding of HNF6 was investigated by electromobility shift assays.

RESULTS: The gene expression patterning of liver-enriched transcription factors differed in the various segments of the human intestine with HNF6 gene expression being most abundant in the duodenum ($P < 0.05$) whereas expression of the zinc finger protein GATA4 and of the HNF6 target gene ALDH3A1 was most abundant in the jejunum ($P < 0.05$). Likewise, expression of FOXA2 and the splice variants 2 and 4 of HNF4α were most abundantly expressed in the jejunum ($P < 0.05$). Essentially, expression of transcription factors declined from the duodenum towards the colon with the most abundant expression in the jejunum and less in the ileum. The expression of HNF6 and of genes targeted by this factor, i.e. neurogenin 3 (NGN3) was most abundant in the jejunum followed by the ileum and the colon while DNA binding activity of HNF4α and of NGN3 was confirmed by electromobility shift assays to an optimized probe. Furthermore, Western blotting provided evidence of the expression of several liver-enriched transcription factors in cultures of colon epithelial cells, albeit at different levels.

CONCLUSION: We describe significant local and segmental differences in the expression of liver-enriched transcription factors in the human intestine which impact epithelial cell biology of the gut.

INTRODUCTION

Numerous studies established the pivotal role of liver-enriched transcription factors in organ development and cellular function. These nuclear proteins are known to work in a hierarchical and cooperative network. The timely expression of specific transcription factors is necessary for cellular differentiation[1,2] and *in situ* hybridization studies of staged embryos demonstrate that hepatocyte nuclear factor 6 (HNF6) and its target gene FOXA2 are expressed in the hepatic diverticulum. More detailed analysis of the developmental expression patterns of HNF6 and FOXA2 provides evidence for their colocalization in intestinal epithelium. The expression patterns of these 2 transcription factors do not overlap in other endoderm-derived tissues[3].

There is growing evidence that the liver-enriched transcription factor plays a role in cancerous diseases of the digestive tract[4], and recent studies from our own laboratory provide evidence for HNF6 and FOXA2 as key regulators in colorectal liver metastases[5].

To better understand the molecular pathology of colorectal liver metastases we, and others, carried out a genome-wide expression analysis[6,7]. Essentially, the genes coding for the liver-enriched transcription factors HNF6, HNF1β and CCAAT enhancer binding protein γ (C/EBPγ) were selectively regulated but protein expression of regulated transcription factors identified unacetylated HNF6 to be a hallmark of colorectal liver metastases[5]. For its proposed interaction with HNF6, expression of FOXA2 and HNF6 was investigated. Notably, FOXA2 was significantly induced in colorectal liver metastases[5]. From the electromobility shift assay, evidence was obtained for HNF6 DNA binding activity to be specifically repressed in nuclear extracts of colorectal liver metastases. Taken collectively, we found HNF6 expression in colorectal liver metastases to be driven by the hepatic environment. Its expression is not observed in healthy colon nor in primary colonic cancer. Thus, HNF6 DNA binding is selectively prevented through lack of posttranslational modification and interaction with FOXA2.

As HNF6 is only expressed in colorectal liver metastases but not in primary colonic cancer or healthy colonic tissue we wished to investigate the regulation of HNF6 and of other liver-enriched transcription factors in different segments of the human intestine thereby providing information on their expression patterning. We therefore mapped HNF6 and other liver-enriched transcription factors in the human duodenum, jejunum, ileum and colon of patients undergoing large intestinal surgery. Regional differences in the expression and regulation of transcription factors might participate in growth of intestinal tumors and may influence metastatic spread. We also investigated regulation of liver-enriched transcription factors in the human colon carcinoma cell line Caco-2 that is considered to be valuable for the study of gut epithelial biology. The expression patterning of liver-enriched transcription factors was investigated as a function of time and confluency. Note, upon confluency the Caco-2 colon carcinoma cell line acquires many of the features of the enterocyte as detailed elsewhere[8,9]. We additionally investigated the DNA binding of HNF6, HNF4α and the HNF6 target neurogenin 3 (NGN3) to well known regulatory DNA sequences to link the DNA binding activity of these transcription factors to gene expression data.

Overall, we report the gene expression pattern of liver-enriched transcription factors in the human intestine and compare these findings with results obtained from the human colon carcinoma cell line, to facilitate the construction of a gene expression map for a better understanding of their regulation in gut biology.

MATERIALS AND METHODS

Ethical approval and patient's characteristics

Approval for the use of surplus tissue material from elective surgery was obtained from the ethics committee of the Medical School of Hanover, Germany. All patients participating in this study gave written informed consent and were fully aware of the aims of the study. A summary of the patients' characteristics is given in Table 1. Duodenum and jejunum were obtained from patients mainly with pancreatic cancer whereas ileum and colon was obtained from patients undergoing right or left hemicolectomy, (recto)sigmoid resection or rectal resection. All surgical specimens were subjected to histopathology. Excised tissue was shock-frozen in liquid nitrogen and stored at -80℃ until analyzed.

Cell culture

Expression of liver-enriched transcription factors was compared between colonic epithelium obtained from tissue resection material and Caco-2 cells, which were derived from a Caucasian patient with colonic adenocarcinoma. The Caco-2 cell line was obtained from the European Collection of Cell Cultures (Salisbury, UK) and were cultured as described previously[10].

RNA isolation and cDNA synthesis

RNA was isolated form tissue samples using the RNeasy Mini Kit (Qiagen) according to the manufacturer's instructions. Quality and quantity of isolated RNA were checked by capillary electrophoresis (Bioanalyzer 2100, Agilent Technologies) following the manufacturer's instructions or by gel electrophoresis. Reverse transcription (RT) used 2 μg total RNA from each sample. RNA and random

primer (Promega, Mannheim, Germany) were preheated for 10 min at 70℃ and then chilled on ice for 2 min. A total of 5 × RT-avian myeloblastosis virus (AMV) buffer (Promega), dNTP (10 mmol/L), RNAsin, AMV-RT (avian myeloblastosis virus-reverse transcriptase) (all Promega) and DEPC-H_2O were added to a final volume of 20 μL. RT was carried out for 60 min at 42℃ and was stopped by heating to 95℃ for 5 min. The resulting cDNA was frozen at -20℃ until additional experimentation.

Semiquantitative RT polymerase chain reaction

Primer design was done with the program Primer 3 (http://frodo.wi.mit.edu/cgi-bin/primer3/primer3_www.cgi). Cross-reaction of primers with the genes was excluded by comparison of the sequence of interest with a database (Blast 2.2, US National Centre for Biotechnology Information) and all primers used in our study were intron spanning. Polymerase chain reaction (PCR) reactions were undertaken with a 20 μL reaction mixture containing HotStarTaq Master Mix (Qiagen, Hilden, Germany), DEPC, 1 μL cDNA and 1.0 μmol/L concentration of the 3'- and 5'-specific oligomers (synthesized by Invitrogen, Hilten, Germany). PCR reactions were carried out on a thermal cycler (T3, Biometra). Detailed oligonucleotide sequence information and the PCR amplification protocol were published previously[5]. DNA contamination was determined by direct amplification of RNA extracts before conversion to cDNA. Contamination of RNA extracts with genomic DNA was determined by gel electrophoresis and by DNA digest prior to cDNA synthesis. PCR reactions were done within the linear range of amplification, and amplification products were separated using 1.5% agarose gel and stained with ethidium bromide. Gels were photographed on a transilluminator (Kodak Image Station 440), and amplicons were quantified using the Kodak 1D 3.5 network software.

Western blotting experiments

Western immunoblotting was done as follows: total protein (100 μg) or nuclear protein (30 μg) extracts of Caco-2 cell cultures were denaturated at 95℃ for 5 min, followed by sodium dodecyl sulphate polyacrylamide gel electrophoresis on 12% polyacrylamide gels, and blotted onto a polyvinylidene difluoride membrane (NEN, Dreieich, Germany) at 350 mA for 2 h in a buffer containing 400 mmol/L glycine and 50 mmol/L Tris (pH 8.3). Non-specific binding sites were blocked with Rotoblock (Roth, Germany) in 1 × TBS buffer. After electroblotting of proteins, membranes were incubated with polyclonal antibodies for HNF1α (Santa Cruz sc6548), FOXA2 (Santa Cruz sc6554), FOXA3 (Santa Cruz sc5360), HNF4α (Santa Cruz sc 6556), and HNF6 (kind gift of Dr. Costa RH, Chicago, Illinois, USA) for 1 h and washed 3 times with 1 × TBS buffer containing 0.1% Tween-20 (Roth, Germany). Subsequently, the membranes were incubated with a 1:5000 diluted anti-α rabbit antibody (Chemicon, Hofheim, Germany) for 1 h at room temperature, followed by 3 successive washes with 1 × TBS buffer containing 0.1% Tween-20 (Roth, Germany). Immunoreactive proteins were visualized with a chemiluminescence reagent kit (NEN, Dreieich, Germany) according to the manufacturer's instructions, and bands were scanned with the Kodak Image Station CF 440 and analyzed using the Kodak 1D 3.5 imaging software (Eastman Kodak Company, USA).

Electrophoretic mobility shift assay

The procedure for electrophoretic mobility shift assays was adapted from a previously described method[11]. Briefly, 5 μg of Caco-2 nuclear extract were incubated with the binding buffer consisting of 25 mmol/L HEPES (pH 7.6), 5 mmol/L $MgCl_2$, 34 mmol/L KCl, 2 mmol/L DTT, 2 mmol/L Pefablock (Roche Diagnostics GmbH, Mannheim, Germany), 0.5 μL aprotinin (2.2 mg/mL, Sigma-Aldrich Chemie GmbH, Taufkirchen, Germany), 50 ng poly (dl-dC) and 80 ng bovine serum albumin (PAA Laboratories GmbH, Cölbe, Germany). The binding reaction was carried out for 20 min on ice, and free DNA and DNA-protein complexes were resolved on a 6% polyacrylamide gel. For supershift studies, a specific HNF6 and/or HNF4α antibody (Santa Cruz Biotechnology Inc., Heidelberg, Germany) was added to the reaction mix 10 min before addition of the labeled probe. In the case of NGN3, no commercial antibody was available. Thus, a competition assay at 100- and 500-fold access of unlabeled oligonucleotide probe specific to NGN3 was used. Gels were blotted to Whatman 3 MM paper, dried under vacuum, exposed to imaging screens (Imaging Screen-K, Bio-Rad Laboratories GmbH, Munich, Germany) for autoradiography overnight at room temperature and analyzed using a phosphor imaging system (Molecular Imager FX pro plus; Bio-Rad Laboratories GmbH, Munich, Germany) and the Quantity One Version 4.2.2 software (Bio-Rad Laboratories GmbH, Munich, Germany).

Statistical analysis

We applied the Wilcoxon signed rank test and the Student *t*-test to determine significance, with $P < 0.05$ being statistically significant.

RESULTS

Gene expression profiling of liver-enriched transcription factors in different segments of the human intestine

The gene expression of transcription factor was determined relative to mitochondrial ATPase, i.e. a housekeeping gene that was found to be stably expressed. As described in the Material and Methods section, tissue preparations were obtained from surgically removed but healthy gut segments, as part of the Whipple surgery for the removal of pancreatic cancers or alternatively from patients undergoing surgery for colonic cancer. The tissue material was derived from the mucosa and submucosa and processed further as described in the Material and Methods section.

Table 2 gives an overview of the segmental expression pattern of various liver-enriched transcription factors while Figure 1 depicts the expression of HNF6 and of genes targeted by this transcription factor. Note, the data is presented relative to the expression of the mitochondrial ATPase, which serves as a housekeeping gene (Figure 1A). The patterning of individual liver-enriched transcription factors in the duodenum, jejunum, ileum and colon is shown in Figure 1B. Additionally, in Figure 1C expression of some genes of interest in epithelial cell biology are given. In Figure 2 and as described in the Material and Methods section, representative RT-PCR gels are shown. Note, all PCR reactions were done within the linear range of amplification. Essentially, the abundance of transcript expression of HNF1, HNF4 and for some of its splice variants and for C/EBP was significantly more than that of mitochondrial ATPase. Specifically, HNF6 gene expression was most abundant in the duodenum ($P < 0.05$) when compared with other segments of the intestine, whereas expression of the zinc finger protein GATA4 and of the HNF6 target gene ALDH3A1 was most abundant in the jejunum (Figure 1B, $P < 0.05$). Likewise, expression of FOXA2 and the splice variants 2 and 4 of HNF4α were most abundantly expressed in the jejunum ($P < 0.05$). For most of the transcription factors and of genes targeted by these factors, expression of transcripts varied amongst patients rendering statistical significance impossible. With the exception of the colon we were unable to amplify transcripts for FOXA1 and FOXA2 in any of the human intestine tissues examined. Essentially, in the case of HNF6, gene expression declined from the duodenum towards colon, whereas FOXA2 expression was undetectable in the ileum. Likewise, HNF4 expression was most abundant in the jejunum as was expression of its splice variant HNF4α3 and HNF4α2+4 and of HNF4γ. Unlike HNF6 we observed expression of HNF4 and of C/EBPα and γ in colon tissue as well. The expression of HNF6 and of genes targeted by this factor, i.e. NGN3 was most abundant in jejunum followed by ileum and colon but for most of the other genes targeted by HNF6 such as ALDH1A1, ALDH3A1, COL5A1,

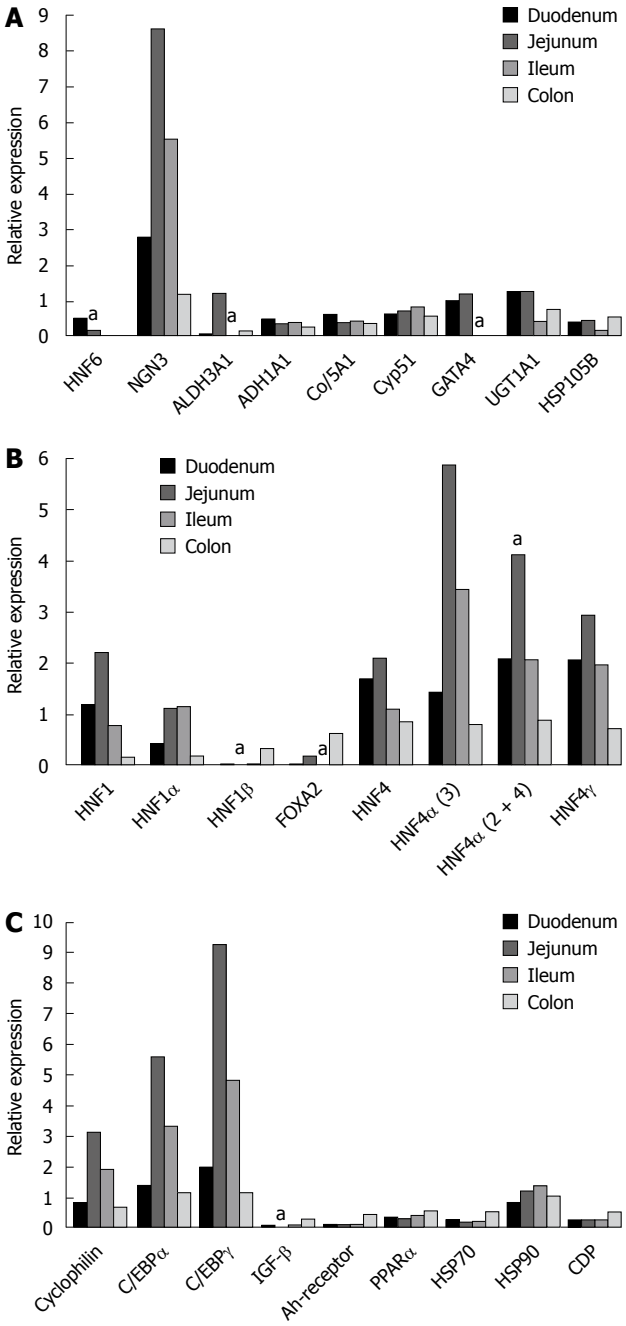

Figure 1 Gene expression of hepatocyte nuclear factor 6 and of other liver enriched transcription factors in the human intestine. A: Hepatocyte nuclear factor 6 (HNF6) and some of its target genes. Bars hallmarked by "a" refer to statistically significant changed expression ($P < 0.05$) when compared to other segments of the gut; B: Hepatic nuclear transcription factors. Bars hallmarked by "a" refer to statistically significant changed expression ($P < 0.05$) when compared to other segments of the gut; C: CAAT enhancer binding proteins and the transcription factors Ah-receptor, PPAR alpha as well as the heat shock proteins HSP70 and HSP90 and IGF-β. Bars hallmarked by "a" refer to statistically significant changed expression ($P < 0.05$) when compared to other segments of the gut.

CYP51, UGT1A1 and HSP105B, expression did not differ amongst the different human intestinal segments. With the exception of heat shock protein 90, the expression of the Ah-receptor and of the nuclear receptor PPARα, HSP70 and the CCAAT enhancer displacement protein CDP, did not differ amongst the different human intestinal segments studied. In contrast, the expression of the

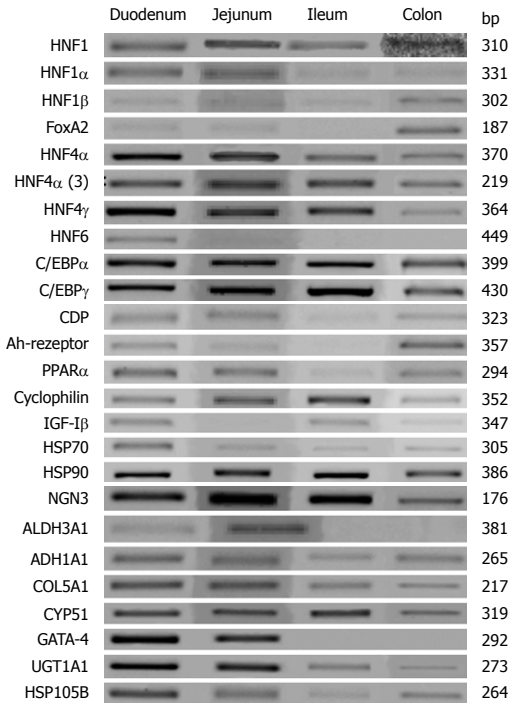

Figure 2 Representative reverse transcription polymerase chain reaction gels of gene expression of hepatocyte nuclear factor 6 and of other liver-enriched transcription factors in the human intestine. Note, all polymerase chain reaction reactions were done within the linear range of amplification.

insulin growth factor binding protein was more abundant in the colon ($P < 0.05$).

Studies using the human colon epithelial cancer cell line Caco-2

The expression of the aforementioned transcription factors was investigated in cultures of Caco-2 cells. Essentially, with time and cell culture confluency HNF6 gene expression increased up to day 11 but declined thereafter (see Figure 3 for microscopic images and Figure 4 for gene expression data). A similar rise in expression of transcription factor gene expression was seen for HNF1, some splice variants of HNF4 (2, 3 and 4) and of C/EBPγ (data not shown). None of these changes were, however, of statistical significance. Importantly, expression of HNF6 transcripts was unexpected, as neither healthy colon nor primary colonic cancers expressed HNF6. Likely, its expression in Caco-2 cells is the result of the cell culture environment with the supply of optimized culture media. We additionally determined the protein expression of liver-enriched transcription factor and observed expression of HNF1α, FOXA2, FOXA3 and HNF4α (Figure 5). In the case of FOXA3 and HNF4α, 2 immunoreactive bands were observed. Obviously the antibodies recognized these liver-enriched transcription factors posttranslational modifications. No HNF6 protein expression could be determined.

DNA binding studies with HNF6

We further investigated the DNA binding of HNF6 and of its downstream target NGN3 as well as HNF4α. As shown in Figure 6A, we were unable to detect HNF6

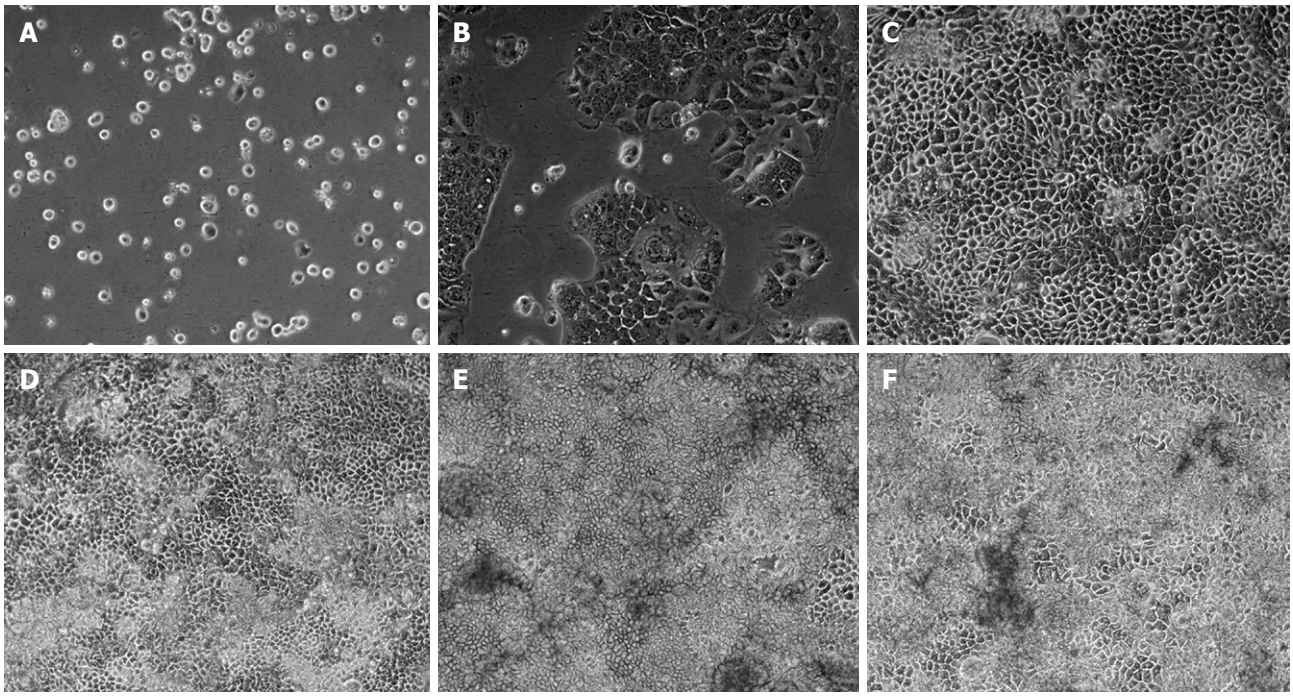

Figure 3 Microscopic images of time depended sequence of Caco-2 cells. Note, *HNF6* gene expression increased with time and cell culture confluency up to day 11 but declined thereafter (see Figure 2 for gene expression data). A: 0 d; B: 3 d; C: 5 d; D: 7 d; E: 11 d; F: 17 d.

DNA binding with nuclear extracts of Caco-2 cells. We previously reported abundant HNF6 protein expression in the liver[5], and therefore used nuclear extracts of the liver as a positive control for HNF6 DNA binding activity. In the past we demonstrated that expression of liver-enriched transcription factors can be modulated by treatment of Caco-2 cell cultures with Acrolor 1254[12]. This treatment did not induce DNA binding of HNF6 but increased expression of an unknown nuclear protein to an optimized HNF6 probe (Figure 6A). To further study HNF6 activity we investigated the DNA binding of the transcription factor NGN3. Essentially, NGN3 was reported to be a downstream target of HNF6 and is therefore regulated by this factor[13]. As shown in Figure 6C, NGN3 DNA binding is observed with nuclear extracts of Caco-2 cell cultures. Furthermore, treatment of Caco-2 cell cultures with Aroclor 1254, an inducer of transcription factors[12], resulted in increased DNA binding of NGN3. We also investigated DNA binding of HNF4α and observed abundant DNA binding activity as illustrated in Figure 6B. In the case of HNF4α a suitable antibody was available. The shifted band in the EMSA assay further documents specificity. As observed with NGN3 treatment of Caco-2 cell cultures with Aroclor 1254 resulted in increased HNF4α DNA binding. In the past we reported induction of HNF4α gene expression in cultures of Caco-2 cells[12]. We now extend our initial observation to DNA binding activity of this protein.

DISCUSSION

This study aimed for an improved understanding of the gene expression pattern of HNF6, FOXA2 and other nuclear transcription factors in the descending human intestine. Essentially, expression of liver-enriched transcription factors differed when the duodenum, jejunum, ileum and colon were compared. Mapping of liver-enriched transcription factors to different segments of the human intestine provided valuable insight into gene regulation that may have significant implications for physiology and disease. Indeed, numerous studies have established an important role of liver-enriched transcription factors in organ development and cellular function and there is conclusive evidence of nuclear transcription factors to act in concert in the orchestration of gene expression[1].

Here we report FOXA2 expression to be significantly upregulated in the colon but the coded protein of this transcription factor has been shown to inhibit HNF6 activity. As originally proposed by Rausa *et al*[14] an interplay of CBP coactivator protein with HNF6 and FOXA2 may regulate steady levels of these transcription factors. In human colorectal liver metastases FOXA2 expression was significantly induced while electromobility shift assays demonstrated HNF6 DNA binding activity to be prevented as previously reported[5].

Notably, no HNF6 DNA binding was observed with nuclear extracts of Caco-2 cells (Figure 6A) whereas DNA binding of HNF4α and of NGN3 was evident. Additionally, we observed increased DNA binding activity for HNF4α and NGN3 upon treatment of Caco-2 cell cultures with Aroclor 1254 (Figure 6B and C). Expression of HNF6 protein was below the limit of detection in untreated cultures of the Caco-2 cell line.

Of all transcription factors investigated, expression of HNF6 was most abundant in duodenum and jejunum whereas expression of GATA4 and of HNF4 including some of its splice variants in addition to C/EBPα and γ

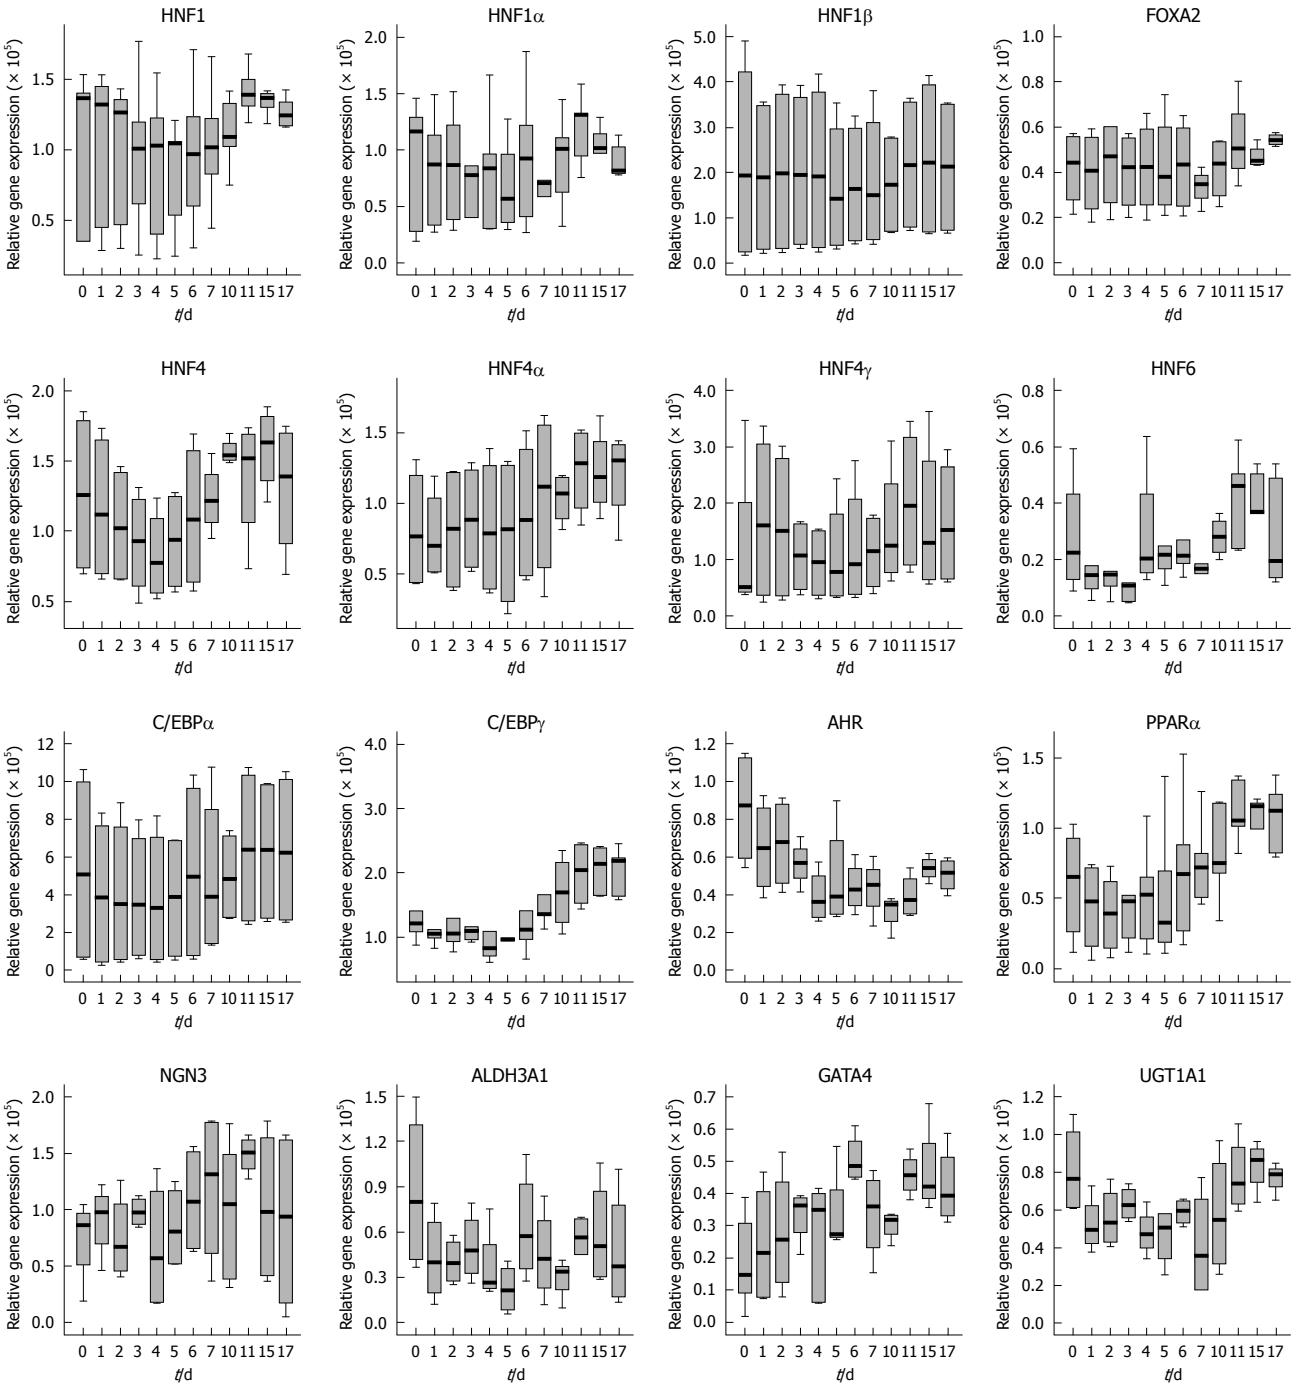

Figure 4 Time-dependent gene expression of liver-enriched transcription factors and some of its target genes in cultures of Caco-2 cells. HNF: Hepatocyte nuclear factor.

was most abundant in the jejunum.

The difference in expression pattern of individual transcription factors amongst the various segments of the human intestine is notable with HNF4 and C/EBP being abundantly expressed in the jejunum and the duodenum. Indeed, HNF4α has been shown to protect the gut against inflammatory bowel disease and there is clear evidence for a role of HNF4α in promoting differentiation of intestinal epithelial cells[15,16]. Furthermore, in the study of Stegmann *et al*[17] the metabolome, transcriptome and bioformatic analysis identified HNF4 as a central regulator of gene expression during enterocyte differentiation and crypt function, but recent evidence identified forkhead box transcription factors FOXA1 and FOXA2 to be important regulators of mucin expression in intestinal epithelial cells as well[18]. Additionally, the human C/EBPα gene was found to expressed at the highest level in the placenta followed by the liver, lungs, skeletal muscle, pancreas, small intestine, colon and in peripheral blood leucocytes[2]. As was reviewed elsewhere C/EBPα plays an important role in cell cycle control, cellular differentiation, many metabolic processes and the detoxification. The difference in C/EBPα expression may in part be the result of control of epithelial replacement through control of the p21

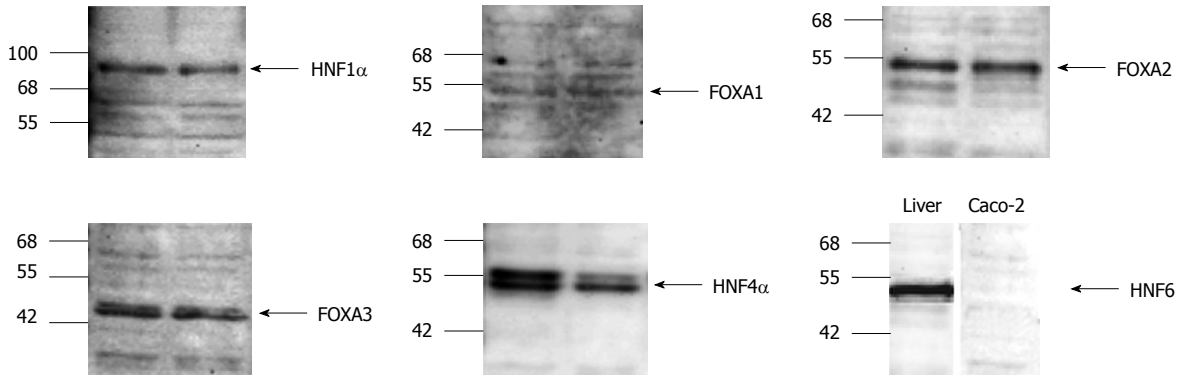

Figure 5 Western blotting of hepatocyte nuclear factor 1α, FOXA1, FOXA2, FOXA3, hepatocyte nuclear factor 4α and hepatocyte nuclear factor 6 in different human colon carcinoma Caco-2 cell line cultures. Note, in case of hepatocyte nuclear factor (HNF) 6 healthy human liver serves as control.

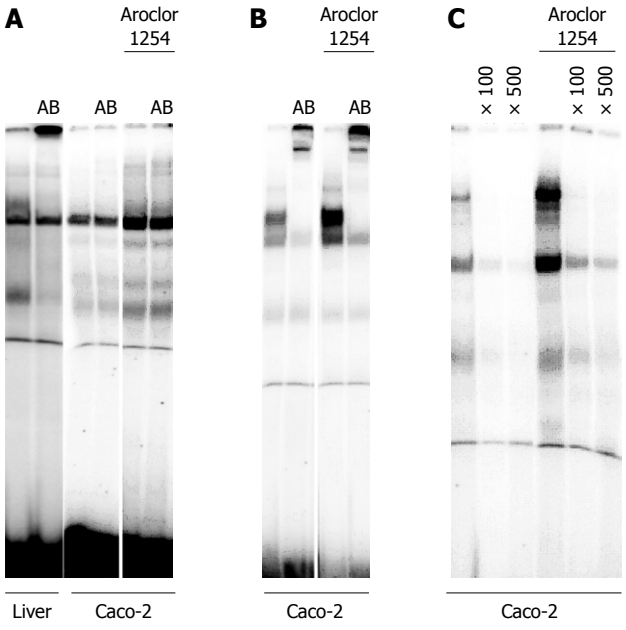

Figure 6 Electromobility shift assay with nuclear extracts of the human colon carcinoma Caco-2 cell line. A: Demonstrates the DNA binding of HNF6 to an optimized oligonucleotide probe using either nuclear protein extract of human liver tissue or Caco-2 cells. Note, the lane labeled as AB refers to the addition of a hepatocyte nuclear factor 6 antibody to demonstrate specificity of the DNA binding assay; B: Demonstrates the DNA binding of HNF4α to an optimized oligonucleotide probe using either nuclear protein extract of human liver tissue or Caco-2 cells. Note, the lane labeled as AB refers to the addition of a HNF4α antibody to demonstrate specificity of the DNA binding assay; C: Demonstrates the DNA binding of NGN3 (a HNF6 target gene) to an optimized oligonucleotide probe using either nuclear protein extract of human liver tissue or Caco-2 cells. Note, the lane labeled as × 100 or × 500 refers to competition assays with excess of unlabeled probe.

protein level thereby determining epithelial replacement[2].

In agreement with our previous study on colorectal liver metastases we were unable to detect HNF6 transcript expression in healthy and cancerous colonic tissue while the expression of splice variants of HNF4α in healthy colonic tissue was a significant finding and is likely to impact HNF4α activity, as we have shown recently in the case of human hepatocellular carcinoma[19]. Indeed, mice lacking HNF4α exhibited decreased levels of polysaccharides and acetic mucopolysaccharides with some altered expression of mucins and aquaporins[15].

The use of the human colon carcinoma cell line Caco-2 allowed us to compare expression of transcription factors in healthy colon and colonic epithelium of adenocarcinoma. Initially, we investigated expression of individual liver-enriched transcription factors as a function of time and confluency of the Caco-2 cell culture. With the exception of HNF6 there was no statistically significant difference in the expression of transcription factors as a function of cell culture time (up to 17 d) or confluency while cellular differentiation of Caco-2 cells was dependent upon the activity of the transcription factor NF-Y and E2F[20,21]. We also compared expression of transcription factors with those in the healthy colon but did not identify a significant difference.

Overall, our study identified local and segmental differences in the expression patterning of liver-enriched transcription factors in the human intestine. Tissue specific transcription factor expression provides a regulatory circuitry for the control of gene expression and cellular differentiation. The present study identifies significant differences in the expression of liver-enriched transcription factors amongst different segments of the human intestine that impacts on the epithelial cell biology of the gut.

COMMENTS

Background

Liver-enriched transcription factors are versatile proteins pertinent for cellular growth and differentiation of the liver. Growing evidence suggests these factors play a wider role in epithelial biology and cancerous diseases of the digestive tract. Indeed, recent studies provided evidence for hepatocyte nuclear factor 6 (HNF6) and FOXA2 as key regulators in colorectal liver metastases. As HNF6 was only expressed in colorectal liver metastases but not in primary colonic cancer or healthy colonic tissue, the authors investigated regulation of HNF6 and of other liver-enriched transcription factors in different segments of the human intestine thereby providing information on their expression pattern. Regional differences in the expression and regulation of transcription factors may be related to growth of intestinal tumors and may influence metastatic spread.

Research frontiers

The authors examined the gene expression pattern of liver-enriched transcription factors in different segments of the human intestine and compared the findings with results obtained from a human colon carcinoma cell line for a better understanding of their regulation in gut biology and disease.

Innovations and breakthroughs

This is the first study to investigate the expression of liver-enriched transcription factors in the human intestine and compare the data with the human colon

carcinoma cell line Caco-2. Knowledge of the expression pattern of liver-enriched transcription factors in different segments of the human intestine help to better understand the importance of HNF6 and FOXA2 in colorectal liver metastases.

Applications

Tissue specific transcription factor expression provides a regulatory circuitry for the control of gene expression and cellular differentiation of the gut epithelium. Restoring attenuated transcription factor DNA binding activity represents a novel strategy for the treatment of secondary malignancies of the liver.

Terminology

Liver-enriched transcription factors play a pivotal role in disease. Essentially, transcription factors are master regulatory proteins and interact with many different molecules including coactivators, repressors, enzymes, DNA and RNA to control gene expression. Such interactions will inevitably repress or activate gene expression and therefore determine cellular phenotype.

Peer review

This paper examines the distribution of liver-enriched transcription factors and related genes in human intestinal tissues. It represents a useful and novel contribution to the field.

Abstract

AIM: To investigate whether irradiation (IR) and partial hepatectomy (PH) may prepare the host liver for non-parenchymal cell (NPC) transplantation.

METHODS: Livers of dipeptidyl peptidase Ⅳ (DPP Ⅳ)-deficient rats were pre-conditioned with external beam IR (25 Gy) delivered to two-thirds of the right liver lobules followed by a one-third PH of the untreated lobule. DPPⅣ-positive liver cells (NPC preparations enriched for liver sinusoidal endothelial cells (LSECs) and hepatocytes) were transplanted via the spleen into the recipient livers. The extent and quality of donor cell engraftment and growth was studied over a long-term interval of 16 wk after transplantation.

RESULTS: Host liver staining demonstrated 3 different repopulation types. Well defined clusters of donor-derived hepatocytes with canalicular expression of DPPⅣ were detectable either adjacent to or in between large areas of donor cells (covering up to 90% of the section plane) co-expressing the endothelial marker platelet endothelial cell adhesion molecule. The third type consisted of formations of DPPⅣ-positive duct-like structures which co-localized with biliary epithelial CD49f.

CONCLUSION: Liver IR and PH as a preconditioning stimulus enables multiple cell liver repopulation by donor hepatocytes, LSECs, and bile duct cells.

INTRODUCTION

Hepatocyte transplantation is considered to be a promising option for the treatment of both acute and chronic liver failure as well as for the correction of end stage metabolic liver disease[1]. However, host liver repopulation by transplanted hepatocytes requires a special preparative regimen combining the induced failure of endogenous cell proliferation with some strong mitogenic stimulus. There are a number of experimental protocols based on the application of DNA-damaging toxins such

as the pyrrolizidine alkaloids retrorsine[2] or monocrotaline[3], which efficiently inhibits the proliferative capacity of endogenous hepatocytes; however these systemically harmful and potentially carcinogenic substances are not suitable for preparation of the human liver.

Recently, we developed a preclinical rat model using external beam liver irradiation (IR) with 25 Gy administered to the right liver lobules (2/3 of liver mass) in combination with 1/3 partial hepatectomy (PH) of the untreated left liver lobule. In that study, the aim was to prime the residual host liver mass for selective donor cell growth, leading to significant liver repopulation by donor hepatocytes[4]. In a further study, we investigated the underlying molecular effects, demonstrating that IR suppressed the regeneration of endogenous hepatocytes in response to PH through a persistent block of the cell cycle[5]. Additionally, we were able to reveal considerable damage to the liver sinusoidal endothelial cells (LSECs), contributing to the notion that these cells are particularly vulnerable to IR[6,7]. However, there is a paucity of data regarding the possible IR damage to bile duct cells and its consequences for cell therapy purposes.

Therefore, the aim of this study was to investigate whether liver injury following IR and PH could not only enable donor hepatocyte proliferation, but more importantly the growth of transplanted non-parenchymal cells (NPCs) in the host parenchyma. With this in mind, we hypothesized that host liver IR permits the replacement and reconstitution of endogenous endothelial as well as biliary cells by donor cells.

MATERIALS AND METHODS

Reagents

Medium and buffers were supplied by Gibco Brl, Germany. All further chemicals were reagent grade and, unless specified otherwise, were supplied by Sigma-Aldrich (Munich, Germany). Primary antibodies were used in this study as summarized in Table 1. Secondary peroxidase-conjugated antibodies (EnVision Kit) were purchased from DAKO Diagnostica, Germany. Secondary species-specific fluorescence conjugated antibodies (Alexa Fluor 488, Alexa Fluor 555) were obtained from Molecular Probes (Goettingen, Germany).

Isolation of primary hepatocytes and NPC preparation

Hepatocytes and NPCs were isolated in a 2-step *in situ* collagenase digestion of the liver[8]. The hepatocytes were segregated using gradual centrifugation steps at 35 *g* for 10 and 5 min and processed separately. Freshly isolated hepatocytes (purification grade approx 98%) displaying a vitality of greater than 90% (tested with trypan blue exclusion) and cell attachment greater than 70% proved to be sufficient for further transplantation experiments. NPCs in the supernatant were centrifuged for 7 min at 400 *g* and resuspended in 20 mL phosphate-buffered saline (PBS). The suspension was further processed by a 2-step Percoll gradient centrifugation (25% and 50%) for 10 min at 1000 *g* aimed at enriching the endothelial cell content. The cells of the interface were washed for 10 min at 200 *g* and resuspended in 800 μL PBS for transplantation. Cytospins were performed to characterize the transplanted cells with immunohistochemistry.

Animals, liver preconditioning, and transplantation experiments

As recipients, a strain of dipeptidyl peptidase Ⅳ (DPP Ⅳ)-deficient Fisher 344 rats was established in the animal care facility of the University Medical Centre Goettingen, Germany. Syngeneic donor Fisher 344 rats were purchased from Charles River, Germany. All animal breeding, care, and experimentation procedures were in accordance with German national legislation on animal protection. All procedures were performed under constant sevoflurane/oxygen inhalation. Buprenorphine (0.1 mg/kg body weight) was applied intraperitoneally during anesthesia, and was repeated subcutaneously 8-12 h later.

Recipient livers of rats were preconditioned with external beam, computed tomography-based partial liver IR (25 Gy) of the right liver lobules (2/3 of hepatic mass) 4 d prior to 1/3 partial hepatectomy (PH) as described previously[4]. For transplantation experiments, the spleen was mobilized and the cell suspension was slowly injected over 3 min into the parenchyma, from where they are known to migrate via the portal vein into the recipient liver (all residual liver lobules). In experimental group 1, rats were transplanted with 20×10^6 NPCs and additionally received 12×10^6 hepatocytes. Experimental group 2 was only transplanted with NPC preparations. Control animals were transplanted with hepatocytes only.

Rats were sacrificed for tissue analysis after 1 wk and after the long-term interval of 16 wk following transplantation. Tissue samples from each liver lobe were excised and snap frozen in 2-methylbutane at -80℃. Cryosections of 5 μm thickness were fixed in ice-cold acetone for 10 min.

Immunofluorescence analysis

Cytospins of cell preparations (3×10^4 cells were centrifuged onto a glass slide at 28 *g* for 5 min) or cryosected tissues were immunostained for the first antigen (incubation with the first primary antibody [anti-CD49f, anti-CD45, anti-desmin, anti-CX32, anti-platelet endothelial cell adhesion molecule (PECAM) or anti-hepatic sinusoidal endothelial (HSE) marker], using Alexa 488-conjugated goat anti-mouse IgG or anti-rabbit for fluorescence detection [1:400, 1 h at room temperature (RT)] and then further processed with the second immunostaining protocol. After rehydration in Tris buffer, specimens were blocked and subsequently incubated with the second primary antibody (anti-DPPⅣ), rinsed with Tris buffer and exposed to the second Alexa Fluor 568 goat anti-mouse IgG2a (1:400, 1 h at RT). Slides were finally covered with Vectashield® mounting medium with DAPI (1 μL/mL) (Vector Laboratories, UK) to visualize the cell nuclei. Negative controls were used for each antibody by omitting the primary an-

Table 1 Antibodies used for immunofluorescence analysis

Antibody/detected antigen	Species	Manufacturer	Cat. No.	Dilution
DPPIV (dipeptidyl peptidase IV = CD26)	Mouse monoclonal IgG2a	BD pharmingen	559639	1:100
CD45 (leukocyte common antigen)	Mouse monoclonal IgG1	BD pharmingen	554875	1:20
CD49f (integrin α6)	Mouse monoclonal IgG1	Serotec	MCA 2034	1:500
Desmin (hepatic stellate cells)	Rabbit	Lab vision	RB-9014	1:500
Connexin 32 = CX32 (gap junction protein)	Rabbit	Sigma-aldrich	C3595	1:5000
HSE (hepatic sinusoidal endothelial cells)	Mouse monoclonal IgG2a	IBL	10078	1:500
CD31 (PECAM-1 = platelet endothelial cell adhesion molecule-1)	Mouse monoclonal IgG1	BD pharmingen	55025	1:1000

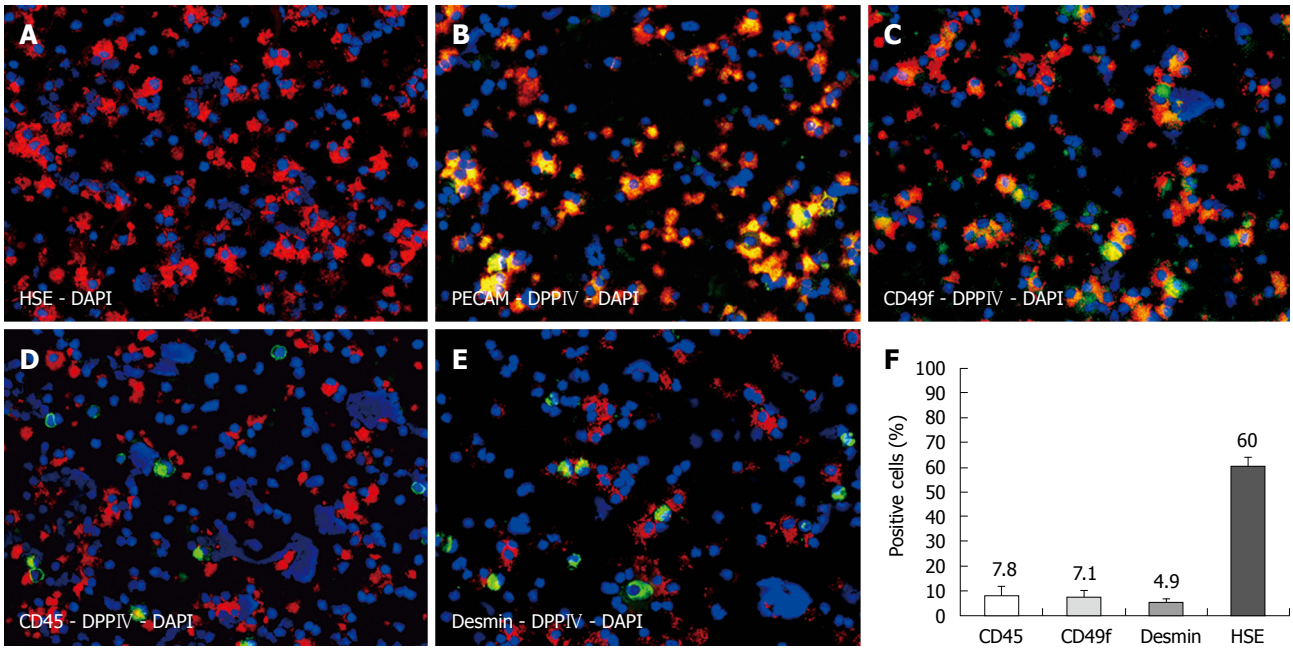

Figure 1 Characterization of non-parenchymal cell preparations by immunofluorescence on cytospins. Hepatic sinusoidal endothelial (HSE) (red) identifying approximately 60% of all cells as hepatic sinusoidal cells (A), donor specific dipeptidyl peptidase IV (DPPIV) (red) co-localized with platelet endothelial cell adhesion molecule (green) (B), and with CD49f as bile duct marker (green) (C). Donor cells were negative for CD45 (D) and desmin (E). Labeling indices (F), nuclear counterstaining with DAPI (blue), original magnification × 200.

tibody from the protocol. Multiple immunofluorescence-labeled specimens were serially excited and observed with the TEXAS Red-, FITC- and UV-filter sets on an inverted confocal microscope (LEICA DM IRE2, Bensheim, Germany). Pictures of each filter set were digitally merged using image layering software (Leica FW 4000, Version 1.1). The labeling index was expressed as a percentage of positive cells counted.

RESULTS

Characterization of NPC preparations

Immunofluorescence co-localization studies were performed on cytospins of freshly isolated NPC preparations enriched with LSECs (Figure 1A), of which 80% were immunoreactive for DPPIV. The majority of all cells displayed the hepatic sinusoidal endothelial marker HSE (60%). For technical reasons, the anti-HSE could not be co-stained with DPPIV, as both antibodies are mouse monoclonal of the same subtype (IgG2a). We therefore used anti-PECAM to co-localize the endothelial marker with the donor-specific antigen in sections of transplanted livers. Indeed, when examining cytospins of NPC preparations, all PECAM-positive cells co-expressed donor specific DPPIV (Figure 1B). Biliary epithelial cells expressing CD49f represented the second largest fraction (7.1%), and these cells were colocalized with DPPIV too (Figure 1C). Furthermore, we assessed co-staining with CD45 and desmin to identify other NPCs. We detected CD45-positive cells (7.8%), representing hematopoietic cells, and were mostly negative for the donor cell antigen (apart from very few activated T lymphocytes) (Figure 1D). Desmin-positive cells (4.9%) did not display DPPIV either (Figure 1E). Figure 1F depicts the labeling indices as stated. We could not detect any cytokeratin 18-positive cells in the NPC preparations, indicating there was no contamination with hepatocytes (data not shown).

Qualitative assessment of liver repopulation

NPC preparations and hepatocytes from donor wild-type rats (DPPIV-positive) (experimental group 1) were transplanted into DPPIV-deficient recipients following the repopulation stimulus of partial IR and PH. Immunofluorescence co-localization studies assessed the extent and

quality of liver repopulation after 1 and 16 wk. One week following transplantation, single DPPIV-positive cells and small clusters were detectable in the host liver parenchyma (data not shown). However, after 16 wk, extensive repopulation by donor cells and descendents was documented in the transplanted livers of all groups. On gross examination, the repopulated areas appeared histologically identical to normal, unharmed liver tissue. Morphological evaluation revealed 3 different types of donor-derived cell [Figure 2A (overview) and more detailed in Figure 2B]. Firstly, well-defined clusters of donor cells displaying DPPIV in a canalicular (garland-like) pattern were found in close proximity to the portal areas. These compact clusters appeared to comprise mature hepatocytes with the characteristic enzyme expression of DPPIV in the basolateral membranes. Their size varied and ranged from 40-50 to several hundred cells in diameter. Cells in these clusters co-expressed the hepatocyte differentiation markers cytokeratin 18, connexin 32 (CX32) (gap junction protein enabling intercellular communication) and cytochrome p450 subtype 2B1, revealing intact metabolic function (data not shown). Secondly, large areas of DPPIV-positive donor cells were arranged in a string-like pattern and emerged from the portal veins. They covered a maximum 90% of the section plane and expressed the donor specific antigen as it is known from LSECs (longitudinal cells expressing DPP IV in the cytoplasm as well in the membranes). Thirdly, formation of duct-like structures expressing DPPIV could be detected. These donor-derived cells were mostly found in association with the bile duct system of the recipient liver and co-stained with an antibody detecting the biliary epithelial CD49f (Figure 2C). The red fluorescent DPP IV on the apical side partially overlapped with the green cytoplasmatic staining of CD49f resulting in a yellow ring. These duct-like structures were also found as individual formations outside the donor hepatocyte clusters, mostly but not always encircled by endothelial donor cells.

In experimental group 2 (transplantation of NPC preparations only), the extent of repopulation was similar, apart from the fact that no clusters of hepatocytes could be detected in these host livers. Subtotal repopulation by DPPIV-positive endothelial cells could be visualized in these animals and donor-derived bile duct structures were as frequent as in group 1, being scattered throughout the parenchyma but generally in close proximity to the portal triads.

Phenotypic analysis of NPC repopulation

Subsequent analysis revealed the phenotypic characteristics of the transplanted cells and their descendents. The pan-endothelial marker PECAM (CD31) is most commonly used to detect LSECs *in situ*. In the present study, this marker was also employed to co-localize LSECs with donor specific DPPIV. Co-staining of DPPIV and PECAM resulted in a yellow-orange overlay, suggesting the endothelial phenotype of the string-like repopulation areas (Figure 3A-C). The merged figure clearly illustrates that both antigens were present in the squamous layer of cells that lined the interior surface of the sinusoids. It has to be pointed out that there was no donor-specific DPPIV co-expression in the endothelial cells of the portal vessels.

When the repopulating LSECs were double-labeled for DPPIV and CX32, the punctuated canalicular pattern seen in hepatocytes was not apparent (Figure 3D). Additionally, the LSECs were negative for desmin, a marker of hepatic stellate cells (Ito cells) (Figure 3E). Indeed, desmin-positive host cells could be clearly visualized in between the repopulating donor endothelial cells but also in the surrounding tissue. In both cases, the distribution pattern was not different from healthy liver. Furthermore, there was no evidence of CD45 co-expressing donor blood cells in transplanted livers (data not shown). Figure 3F shows DPPIV-positive ductular cells co-expressing CD49f. In this picture, the donor biliary epithelial cells form duct-like structures of different sizes, which is representative of the overall repopulation of this kind. Some ductules only have a narrow diameter, whereas others form large ducts consisting of some dozen surrounding cells. On examination of serial sections, it appears that the duct formations possess a 3-dimensional structure of communicating tubes.

DISCUSSION

Hepatocyte transplantation has been used in many animal models. Preconditioning of the host liver prior to cell transfer is regularly used to enhance proliferation of the transplanted cells, up to a near total repopulation of the host liver by donor hepatocytes and their descendents. However, little is known as to whether the replacement of endogenous NPCs may be facilitated in terms of a preparative regimen for cell therapy.

Hepatic IR is an established stimulus for priming the host liver for hepatocyte repopulation purposes in preclinical models[4,9]. Moreover, IR is already being considered for human application in the upper abdomen for the high dose treatment of gastrointestinal and hepatic primary malignancies or metastases[10-13]. IR can be therapeutically targeted to a whole organ or to small portions, but photons always affect the variety of cells present. The liver comprises different cell types, of which the majority represents hepatocytes, making up approximately 80% of hepatic cells[14]. The NPC fraction (20%) comprises endothelial cells, Kupffer cells, stellate cells, epithelial cells of bile ducts, and some neural cells. However, when considering therapeutic strategies, the endothelium and bile duct cells are known to be highly susceptible to injuries following microenvironmental changes (e.g. caused by ischemia/reperfusion, endotoxemia, tumor growth, angiogenesis or the response to cytotoxic treatment)[15-17]. Radiation also induces oxidative stress through the mitochondria-dependent generation of reactive oxygen species and is therefore another potent candidate that may harm NPCs of the liver[18,19]. Considering liver IR as a preparative regimen with clinical prospects, we wanted to demonstrate whether the suggested "multi-cell" damage may be compensated for by subsequent transplantation of liver cell suspensions explicitly containing NPCs solely or in addition to hepato-

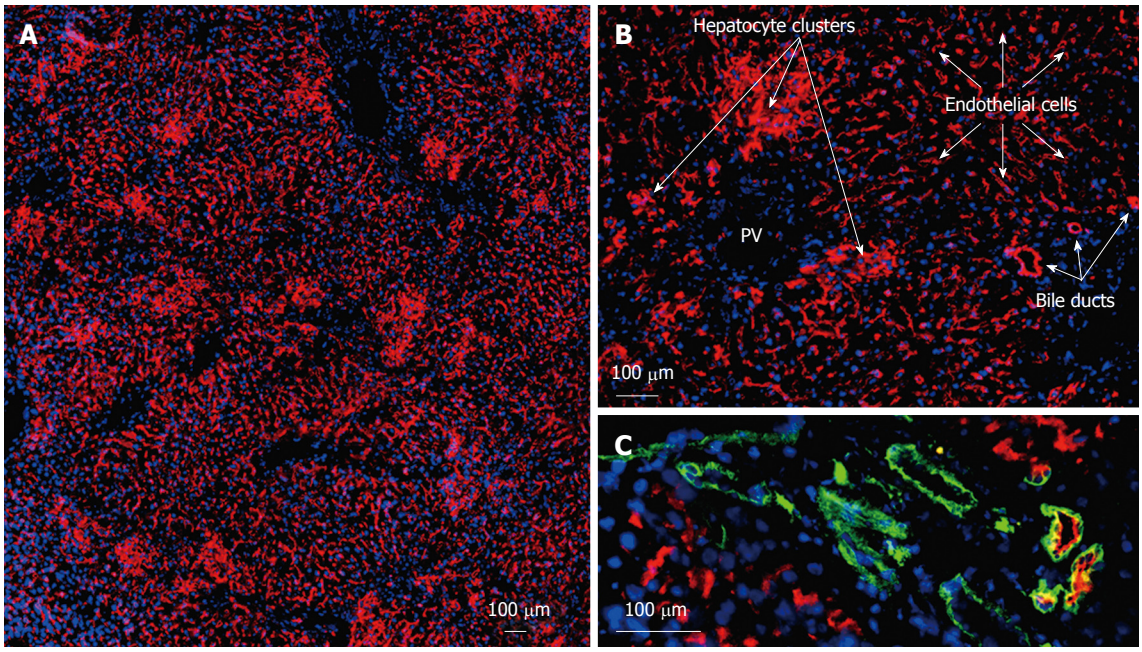

Figure 2 Characteristics of dipeptidyl peptidase Ⅳ-positive cells in the liver following transplantation of non-parenchymal cell preparations and hepatocytes. Frozen sections were obtained from recipient livers present at 16 wk post-transplantation. Acetone-fixed frozen sections were single or double-labeled by indirect immunofluorescence analysis with an antibody detecting the donor cell specific dipeptidyl peptidase Ⅳ (red) (A-C) and bile-duct specific anti-CD49f (green) (C). Merged images are combined with blue nuclear DAPI-staining. Circumscribed and compact clusters of hepatocyte repopulation could be distinguished from large areas of endothelial repopulation which covered a maximum of 90% of the section plane. Formation of bile duct-like structures could be detected by co-staining with the duct marker CD49f. PV: Portal vein.

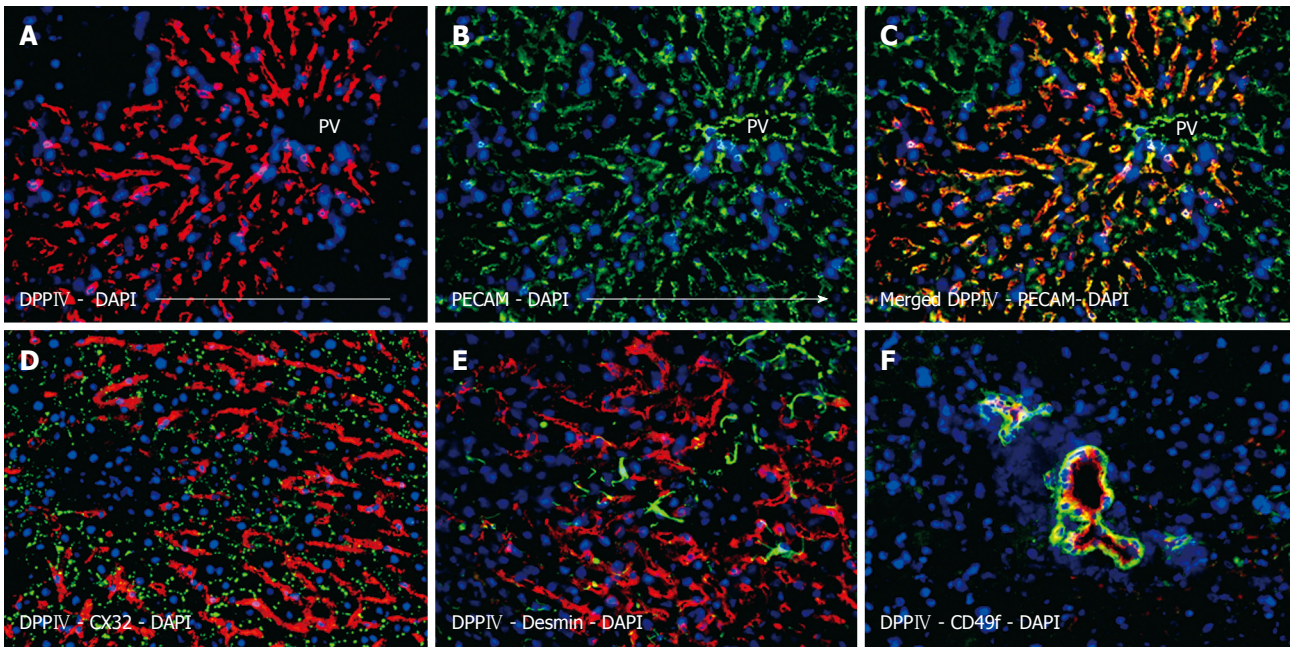

Figure 3 Phenotypic assessment of the non-hepatocytes liver repopulation showing extensive and string-like repopulation by liver sinusoidal endothelial cells emerging from the portal veins. Donor derived cells were identified by dipeptidyl peptidase Ⅳ (DPPⅣ) immunofluorescence staining (red) (A), which co-localized with the endothelial marker PECAM (green) (B), overlay (C). Donor endothelial cells could be clearly distinguished from endogenous hepatocytes which were outlined by the hepatic differentiation marker CX32 (green) (D), desmin-positive cells (green) were detectable with a regular staining pattern for normal (unharmed) liver (E). Additionally, DPPⅣ-positive donor cells formed bile duct structures which expressed the specific marker CD49f (green) (C), nuclear counterstaining with DAPI (blue), original magnification × 200.

cytes. We used a reliable transplantation model (hepatocytes isolated from wild type Fisher 344 rats were transplanted into DPPⅣ-negative hosts) to assess the extent and quality of liver repopulation by donor cells[20].

As proof of concept, our study demonstrated that the preparative regimen of IR and PH led to recipient liver repopulation by sinusoidal endothelial and biliary cells. Replacement of the endothelium was extensive, covering

up to 90% of the section plane. Bile duct-forming structures could often be detected in the neighborhood of endogenous bile ducts, but biliary cells derived from donors were also seen as individual ductular arrangements in the recipient parenchyma. It has to be pointed out that both types of cell engraftment (endothelial and biliary) were not necessarily bound to additional hepatocyte transplantation. In the experimental group of NPC transplantation only, engraftment and repopulation occurred to the same level and extent as following transplantation in addition to hepatocytes. In the latter group, repopulation by all 3 cell types was rarely seen separated from each other, but more frequently at the same site.

Our results are in line with recent literature reporting that hepatic IR is a highly desirable preparative stimulus[9,21,22]. However, IR in those studies was always performed as an invasive procedure (by laparotomy) with doses of 15-50 Gy administered to the whole liver. We focused on a more clinically acceptable approach of non-invasive external beam IR administered to selected lobules of the liver. The workgroup of Guha also demonstrated the outstanding role of the hepatic sinusoidal endothelial barrier as a key player supporting subsequent donor hepatocyte engraftment[9]. They found that IR caused a transient disruption of the endothelial cell lining with exfoliation facilitating the subsequent passage of donor hepatocytes. Indeed, this report confirms our previously published results revealing the significant damage to LECs following IR [prolonged detection of double strand breaks (phosphorylated histone H2AX)][5]. These observations encouraged us to perform the present transplantation study elucidating the feasibility of NPC replacement in irradiated liver.

There are a few reports in the literature confirming the engraftment of NPCs in preconditioned liver. Brilliant and co-workers used injections of mitomycin C to demonstrate that bile ducts and endothelial cells could be generated within 4 wk following transplantation[23]. This substance is commonly known as a cytotoxin widely used as an effective anti-cancer agent, e.g. to treat bladder carcinoma or gastrointestinal tumors[24,25]. Mitomycin C and PH offered a rapid protocol to assess the engraftment efficiency of fetal liver as well as adult liver isolates. However, the preconditioning protocol resulted in a high morbidity (up to 100%) which could be reduced, though not totally eradicated by the additional application of antibiotics (gentamycin). In our study, both morbidity and mortality in all groups prior to and following hepatocyte transplantation remained low overall (1%-2%). The cases of mortality examined were determined to be caused by individual narcotic or surgical complications than to the preconditioning by IR.

The workgroup of Gupta reported using a murine knockout transplantation model in which the liver endothelium was repopulated sufficiently following the administration of the genotoxic pyrrolizidine alkaloid monocrotaline[26]. They demonstrated that transplanted LECs proliferated and reconstituted 9% of the host liver NPCs after 3 mo, thereby correcting the bleeding phenotype of NOD/SCID hemophilia A mice by elevating the Factor Ⅷ activities to over 10% (13 of 15 animals). This study clearly demonstrated the functional correction of a genetic defect as an excellent example for the feasibility of targeted cell therapy. Once again, the preparative agent monocrotaline could not be specifically targeted at the liver. When applied systemically, monocrotaline is known to cause clinically relevant injuries to the endothelium of the lung, resulting in pulmonary hypertension which may obviate its human application[27].

It is well known that high dose IR of the liver is hindered by the induction of radiation induced liver disease (RILD) and more severely by fatal veno-occlusive disease, a non-thrombotic obliteration of the lumina of small intrahepatic veins initially triggered by endothelial injury leading to the deposition of fibrin-related aggregates in the subendothelial zone[28]. These aggregates, and the intramural entrapment of fluid and cellular debris, progressively occlude the hepatic venous flow and generate intrahepatic hypertension. Owing to the risk of RILD, whole liver IR doses exceeding 30 Gy have to be generally avoided in humans[13]. However, we may address the question as to whether endothelial reconstitution following autologous transplantation may allow for the higher IR doses necessary in the local treatment of advanced intrahepatic tumors and multi-lobular metastases.

Endothelial cell reconstitution may also be used to reduce the host immune reaction in liver transplantation[29]. Taking into account that endothelial cells play a pivotal role in both acute and chronic rejection, the transplant immunogenicity could be significantly reduced by endothelial chimerism. A possible strategy would be to generate a chimeric liver, in which damaged endothelial cells are replaced by host cells. Two different mechanisms may be considered: firstly, endothelial damage can result from ischemia/reperfusion injury *sui generis* in whole organ transplantation from cadavers, or secondly may be generated by limited dose IR of the donor liver organ. The workgroup of Murase already demonstrated that circulating endogenous bone marrow-derived cells routinely contributed to LSEC repopulation between 1% and 5% in a rat model of naïve orthotopic liver transplantation[30]. Further experimentation might elucidate whether the rate of engraftment is enhanced by exogenously delivered endothelial cells or progenitors[31,32] or by additional IR.

In the present report, we show for the first time that the preconditioning stimulus of liver IR and PH triggers the repopulation of hepatocytes, LSECs and bile duct cells. We may conclude from our results that this "multicell" repopulation compensates for the liver tissue damage following IR. The extensive engraftment of endothelial cells in particular offers a variety of new therapeutic concepts concerning high dose IR of the liver, immunological cell chimerism in liver allografts, and the treatment of genetic disorders based upon endothelial cells (e.g. lack of coagulation factors such as Factor Ⅷ and von Willebrand Factor).

ACKNOWLEDGMENTS

The authors would like to thank Sabine Wolfgramm and

Sabrina Goldmann for their excellent work in preparing the immunolabeling figures for this article. We would furthermore like to express our appreciation to Andrew Entwistle for his critical review of the manuscript.

COMMENTS

Background

Hepatocyte transplantation is regarded as a promising option to correct acute liver failure and hereditary metabolic liver disease. However, the liver not only constitutes mature hepatocytes, but also a multitude of non-parenchymal cells. So far, little is known concerning the supportive role of non-parenchymal cells in cell therapy studies and whether their engraftment and subsequent proliferation in the host parenchyma may be triggered.

Research frontiers

Liver repopulation is based on the preferential proliferation of engrafted donor cells in response to some mitogenic stimulus. The aim of this study was to investigate whether irradiation, known to suppress endogenous cell proliferation, and partial hepatectomy as the powerful mitogenic stimulus could prepare the host liver not only for hepatocyte but also for non-parenchymal cell transplantation. Both pretreatment techniques may be considered as suitable in the clinical setting and may be targeted to the implantation site, thereby limiting side effects.

Innovations and breakthroughs

The precondition stimulus of liver irradiation and partial hepatectomy prompted the engraftment of hepatocytes, liver sinusoidal cells and bile duct cells. This "multi-cell" repopulation may not only compensate for irradiation-induced liver damage, thus enabling new therapeutic concepts such as high dose radiotherapy, but also generate immunologically relevant cell chimerism and finally facilitate the correction of genetic disorders based upon endothelial cells. This would broaden the therapeutic potential of liver cell therapy.

Applications

As a proof of concept, the study demonstrated that transplanted non-parenchymal cells repopulate the host liver by forming sinusoidal endothelium as well as bile duct-like structures.

Peer review

This is a well-conducted experimental study that deserves early publication in the journal.

Abstract

AIM: To investigate *Helicobacter pylori* (*H. pylori*) CagA diversity and to evaluate the association between protein polymorphisms and the occurrence of gastric pathologies.

METHODS: One hundred and twenty-two clinical isolates of *H. pylori* cultured from gastric biopsies obtained from Colombian patients with dyspepsia were included as study material. DNA extracted from isolates was used to determine *cagA* status, amplifying the C-terminal *cagA* gene region by polymerase chain reaction. One hundred and six strains with a single amplicon were sequenced and results were used to characterize the 3′ variable region of the *cagA* gene. To establish the number and type of tyrosine phosphorylation motifs Glutamine acid-Proline-Isoleucine-Tyrosine-Alanine (EPIYA) bioinformatic analysis using Amino Acid Sequence Analyzer-Amino Acid Sequence Analyzer software was conducted. Analysis of the association between the number of EPIYA motifs and the gastric pathology was performed using χ^2 test and analysis of the presence of EPIYA-C motifs in relation to the pathology was made by logistic regression odds ratios. Comparisons among EPIYA types found and those reported in GenBank were performed using a proportion test in Statistix Analytical Software version 8.0.

RESULTS: After amplification of the 3′ of the *cagA* gene, 106 from 122 isolates presented a single amplicon and 16 showed multiple amplicons. As expected, diversity in the size of the *cagA* unique fragments among isolates was observed. The 106 strains that presented a single amplicon after 3′ *cagA* amplification came from patients with gastritis (19 patients), atrophic gastritis (21), intestinal metaplasia (26), duodenal ulcer (22) and gastric cancer. DNA sequence analysis showed that the differences in size of 3′ *cagA* unique fragments was attributable to the number of EPIYA motifs: 1.9% had two EPIYA motifs, 62.3% had three, 33.0% had four and 2.8% had five motifs. The majority of tested clinical strains (62.3%) were found to harbor the ABC combination of EPIYA motifs and a significant statistical difference was observed between the frequencies of ABCC tyrosine phosphorylation motifs and Western strains sequences deposited in GenBank.

CONCLUSION: The present report describes a lack of association between *H. pylori* CagA-protein polymorphisms and pathogenesis. ABCC high frequency variations compared with Western-strains sequences deposited in GenBank require more investigation.

of association with pathogenesis. *World J Gastroenterol* 2010; 16(31): 3936-3943 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i31/3936.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i31.3936

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a spiral gram-negative microaerophilic bacillus[1]. This bacteria is one of the most common worldwide human pathogens[2], it is present in at least 50% of the world's population, with the highest incidence recorded in industrially underdeveloped areas, including Asia, Africa and South America[3]. *H. pylori* colonizes the human stomach and persists for several decades, causing chronic gastritis and peptic ulcer diseases[4]. Studies have suggested that chronic infection by *H. pylori* is an important risk factor for the development of gastric carcinoma[5,6]. For this reason, *H. pylori* was defined as a type I carcinogen by The International Agency for Research on Cancer - IARC[7].

The cytotoxin-associated antigen A, CagA, was identified in 1989[8]. It is encoded in the cag pathogenicity island (cag PAI), a segment of 40 kb that codifies components required to ensemble a type IV secretion system (TFSS)[9]. More than 90% of isolated strains from East Asia including Korea, Japan, and China are known to harbor cagA, while 50%-60% of isolated strains from Western countries are positive for it[10]. This gene shows variation which is explained by adaptive evolution, where a genetically diverse *H. pylori* population provides the host with a repertoire of varied phenotypes from which a subpopulation with optimal fitness may be selected[11]. This evolution would operate through recombination between *H. pylori* direct DNA repeats that result in deletion (or duplication) of phosphorylation sites in *cag*A gene[12,13] or the entire genomic cag PAI[14].

The *cagA* gene product, CagA, is directly translocated from *H. pylori* into the gastric epithelia cells the bacteria are attached to *via* TFSS[15-18] and upon localizing in the inner surface of the plasma membrane, CagA undergoes tyrosine phosphorylation by Ab1 and Src family kinases on specific tyrosine residues within a Glutamine acid-Proline-Isoleucine-Tyrosine-Alanine (EPIYA) motif[19-25]. Once CagA is phosphorylated, it interacts with Src homology phosphatase 2 (SHP-2) which stimulates downstream signaling cascades involved in the reorganization of the cytoskeleton, resulting in cellular morphological changes such as the "hummingbird" phenotype[16]. Among the various CagA activities that disturb cellular functions, deregulation of SHP-2 by CagA is of potential importance in gastric carcinogenesis because mutations in PTPN11, the gene encoding human SHP-2, have been identified in human malignancies[26,27].

CagA protein varies in size according to the strain[28,29]. The structure of the gene reveals a 5' highly conserved region and CagA size variation is due to the presence of different types and/or numbers of repeat sequences containing the EPIYA motifs within the C-terminal variable region[28]. Four types of EPIYA segments have been described: A, B, C, and D, each of which contains a single EPIYA motif[30]. Moreover, Panayotopoulou *et al*[22] and Kanada *et al*[31] described the pattern around the EPIYA motif to determine the type to which it corresponds as follows: EPIYA-A, EPIYAKVNKKK(A/T/V/S)GQ; EPIYA-B, E(S/P)IY(A/T)(Q/K)VAKKVNAKI; EPIYA-C, EPIYATIDDLG and EPIYA-D, EPIYATIDFDEANQAG. Earlier studies have shown that CagA protein nearly always contains EPIYA-A and EPIYA-B sites, followed by one to three EPIYA-C repeats in Western-type *H. pylori* isolates[32] or by one EPIYA-D motif in East Asian-type isolates[33]. Src kinase in gastric epithelial cells phosphorylates CagA on EPIYA-C tyrosine residue[34,35]. Consequently, among Western CagA strains, the number of EPIYA-C sites is directly associated with the level of tyrosine phosphorylation. Thus, Western CagA proteins with a greater number of EPIYA-C sites are pathophysiologically more virulent and probably more carcinogenic[36]. The tyrosine phosphorylation status of CagA is important for the pathogenicity of *H. pylori*[22] and this variable number of EPIYA could be of clinical relevance in gastroduodenal diseases. For the above stated reasons it is important to analyze the genetic variability of *cag*A gene from clinical strains in relation to the associated pathologies. In this study, we used a polymerase chain reaction (PCR)-sequencing-bioinformatics strategy to characterize the CagA variable region of *H. pylori* from Colombian isolates. Additionally, the association between CagA diversity and the severity of gastroduodenal disease was analyzed.

MATERIALS AND METHODS

Clinical strains and culture conditions

A total of 122 *H. pylori* strains obtained from the stock collection at the Instituto Nacional de Cancerología, in Bogotá, Colombia, were grown on blood agar plates, supplemented with 7% horse serum (Invitrogen, Grand Island, NY), 1% Vitox (Oxoid, Basingstoke, UK), and Campylobacter selective supplement (Oxoid, Basingstoke, UK), at 37℃ for 3 d in microaerophilic conditions. Three *cagA* positive control strains NCTC 11637, NCTC 11638 and ATCC 43579, were also included. Isolates belonged to patients with different types of gastric pathologies including benign, mild and severe conditions associated with *H. pylori* infection. Histopathology diagnosis was recorded for all voluntary participants.

DNA extraction and PCR assay

Genomic DNA was extracted using AquaPure Genomic DNA isolation kit, BIO-RAD, according to manufacturer's instructions and obtained DNA was stored at -20℃ until PCR amplification. In order to amplify the variable *cagA* region, a PCR assay was carried out in a volume of 50 μL containing 50 mmol/L KCl, 20 mmol/L Tris-HCl, pH (8.4), $MgCl_2$ 1.75 mmol/L, 0.2 mmol/L of each dNTP, 1 pmol/μL of each primer (CAGTF 5-3: ACCCTAGTCGGTAATGGG and CAGTR 5-3: GCTTTAGCTTCTGAYACYGC), previously reported by Yamaoka *et al*[37], 1.25 units of Taq DNA Polymerase [Invitrogen, Carlsbad

(California), USA] and 4 μL of DNA (positive controls with GenBank accession numbers: *H. pylori* NCTC 11637 (AF202973.1), NCTC 11638 (AF282853) and ATCC 43579 (AB015414.1). The PCR conditions included an initial denaturation step: 92℃ for 5 min, followed by 35 cycles of 92℃ for 1 min, 61℃ for 1 min, 72℃ for 1 min, and a final extension at 72℃ for 7 min. PCR products were run on 1% agarose gels in 0.5 × TAE buffer at 100 V in a BIO-RAD® electrophoresis system and purified using the Wizard SV Gel and PCR Clean-Up System Kit [Promega, Madison (Wisconsin), USA] according to the manufacturer's instructions, prior to sequencing.

Sequencing of 3' variable region of the cagA region

Sequencing was performed using an ABI PRISM® 310 Genetic Analyzer [Applied Biosystems, Foster City (California), USA], BigDye® Terminator v3.1 Cycle Sequencing kit (Applied Biosystems, Foster City, CA, USA). The reactions were done in a volume of 10 μL containing 0.5 × of Premix, 0.5 × of buffer, 0.16 μmol/L of each primer and 2 μL of purified DNA. The conditions were: one cycle at 96℃ for 1 min, followed by 25 cycles of 10 s at 96℃, 5 s at 50℃ and 4 min at 60℃. All of the 106 sequences obtained were deposited into GenBank/EMBL/DDBJ database with the following accession numbers: FJ755476 and FJ915841 to FJ915945.

Bioinformatics analysis

The sequences (forward and reverse) were edited and assembled using CLC DNA Workbench [CLC Bio A/S, (Aarhus C), Denmark]. For the characterization and quantification of the EPIYA motifs located in the C-terminal of CagA protein, a software called Amino Acid Sequence Analyzer (AASA) was designed for the study, in order to look for the type and number of EPIYA motifs, using the 6 open reading frames of each sequence. The characterization of tyrosine phosphorylation motifs, which contains EPIYA sequences, was done as previously described by Higashi *et al*[30]. Clustal W program[38] was used to generate a multiple alignment from the amino acid sequences of each strain.

In order to test the capability of the software to establish phosphorylation motifs in an accurate manner and the facility of its use, all controls were processed as a first phase. Sequence data results was as expected according to GenBank databases, so based on these results evaluation of clinical strain was done.

Statistical analysis

Analysis of association between the number of EPIYA motifs and the gastric pathology described was performed using χ^2 test. Analysis of the presence of one or more than one EPIYA-C motifs in relation to the pathology was made by logistic regression odds ratios (OR); a 95% confidence interval (CI) was calculated using SPSS statistical software package version 16.0 (SPSS Inc., Chicago, IL, USA). Comparisons among EPIYA types found and those reported in GenBank were performed using a Proportion test in Statistical Analysis Software, version 8.0 (Software, 1985-2003).

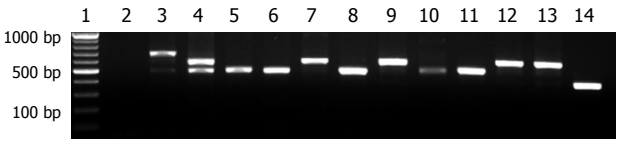

Figure 1 Electrophoretic analysis of the *cagA* 3' variable region by polymerase chain reaction. The polymerase chain reaction amplicons were analyzed on a 1% agarose gels. From left to right, lane 1 shows a 100 base pair DNA ladder, lane 2 negative control, lane 3 reference strain *Helicobacter pylori* NCTC 11637, lanes 4-14 show products of isolates from different patients.

RESULTS

PCR assay

After amplification of the 3' of the *cagA* gene, 106 clinical isolates from 122 isolates presented a single amplicon (a unique band), and 16 showed multiple amplicons (two or more fragments) (Figure 1, lane 4). As expected, diversity in the size of the *cag*A fragment among isolates was observed, and PCR products ranged from 343 to 811 bp. The 106 strains that presented a single amplicon after 3'-*cagA* amplification came from patients with superficial gastritis (19 patients), atrophic gastritis (21), intestinal metaplasia (26), duodenal ulcer (22) and gastric cancer (18).

Bioinformatics analysis of peptide sequences

After sequencing of *cagA* 3' region gene, corresponding peptide sequences from all of the strains with single amplicons were deduced. The combination of the different EPIYA motifs was determined using the ClustalW and AASA software, based on the classification defined by Higashi *et al*[30] and Panayotopoulou and collaborators[22]. The pattern EPIYA(K/Q)VNKKK(A/T)GQ that corresponds to EPIYA-A; the pattern E(P/S)IY(A/T)(Q/K)VAKKV(N/T)(A/Q)KI, to EPIYA-B; and the pattern EPIYATIDDL(G/R) to EPIYA-C were found (Figure 2). All the EPIYA motifs were Western type (Table 1), we did not found strains harboring EPIYA-D, a characteristic pattern of Eastern type.

DNA sequence analysis revealed that 2 of 106 strains (1.9%) had two EPIYA motifs, 66 strains (62.3%) three EPIYA motifs, 35 strains (33.0%) four EPIYA motifs and 3 strains (2.8%) five EPIYA motifs. In 66 out of the 106 (62.3%) strains, the pattern of the EPIYA motifs was ABC type (Table 1). Moreover, 49 of 106 strains had a modified EPIYA-B motif (EPIYT) instead of EPIYA (Figure 2) and there was no association between this type of tyrosine phosphorylation motif (EPIYT) containing a threonine residue instead of an alanine residue and the studied pathologies ($P = 0.51$) (data not shown).

Studies have shown that CagA proteins with more EPIYA-C motifs are expected to be more active biologically than those with a small number of EPIYA-C motifs because they interact more effectively with SHP-2 phosphatases and therefore it could perturb SHP-2-dependent signaling pathways, inducing greater morphological changes or probably contributing to generation of gastric cancer[30,36]. For this reason, in order to determine if there was any relation between the severity of the gastroduodenal

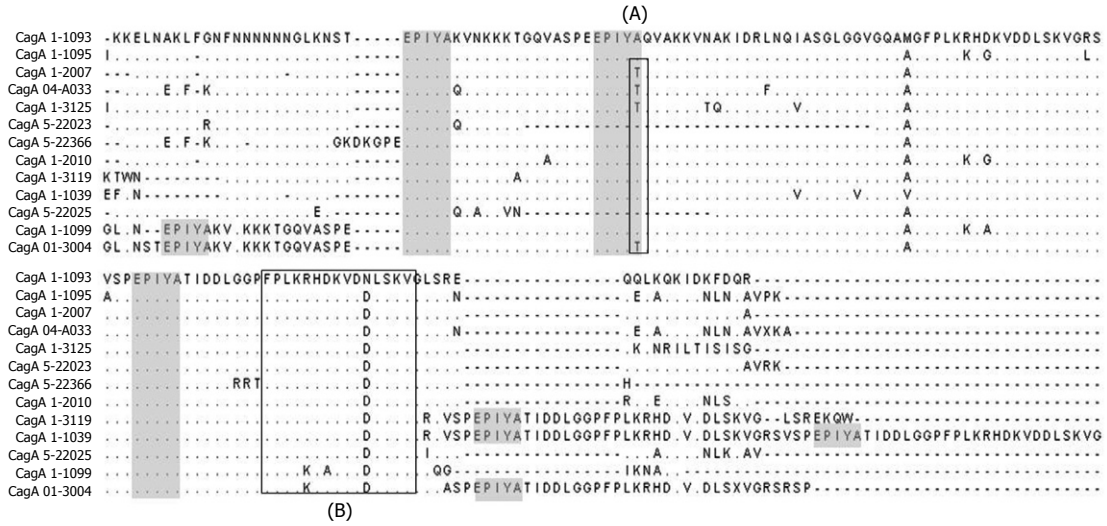

Figure 2 Multiple alignment of the amino acid sequence of the 3' region from *cagA*. First Square (A) shows the Glutamine acid-Proline-Isoleucine-Tyrosine-Alanine (EPIYA) motifs which had a modified EPIYA-B motif (EPIYT) instead of EPIYA. Second Square (B) shows the CagA multimerization (CM) motif which contains the amino acid sequence FPLXRXXXVXDLSKVG. The shaded squares represent the localization of EPIYA motif in the alignment. Amino acids are designated by standard one-letter codes. (·) same residue; (-) gap. disease and the number and type of the EPIYA motifs, statistical analyses were applied.

Statistical tests

A χ^2 test performed showed that in this group of Colombian isolates, the variation of all EPIYA motifs in CagA was not directly associated to the outcome of the disease caused by *H. pylori* ($P = 0.52$). Then, atrophic gastritis, intestinal metaplasia, duodenal ulcer and gastric cancer risks were estimated with respect to a reference group made up of patients with gastritis, infected by *cagA* positive strains with one EPIYA-C motif and those with more than one EPIYA-C motif. No association between the number of EPIYA-C motifs and the pathology was found using logistical regression (Table 2). Proportion test frequencies of the EPIYA genotypes obtained in this study were compared with those of CagA sequences including the C-terminal variable region reported by Argent *et al*[39] and sequences collected from Colombia deposited in GenBank. Statistical differences between the frequencies of ABCC pattern in Western strains previously reported by Argent *et al*[39], and our results were established, $P < 0.002$ (Table 1 and Figure 3).

DISCUSSION

The present work considered amplification and sequencing of the 3' variable *cagA*-gene region and a final bioinformatics analysis of the corresponding C-terminal of CagA protein using AASA software as a single and rapid method for *H. pylori CagA* characterization. Determination of number and type of *H. pylori* CagA phosphorylation motifs has been suggested by some researchers as a way to predict clinical outcome of *H. pylori* associated pathologies and as a prognosis tool by others. So, in order to examine the viability of mentioned approach, 122 Co-

EPIYA: Glutamine acid-Proline-Isoleucine-Tyrosine-Alanine.

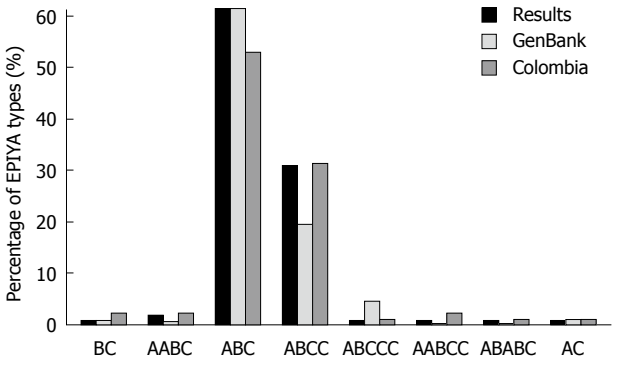

Figure 3 Comparison between the prevalence of different types of CagA tyrosine phosphorylation motifs from this study compared with data obtained from Argent *et al*[39] and Colombian strains reports in gene bank. There is a statistical difference between the frequency of ABCC pattern in Western strains reported in GenBank (19.6%) and our results (31.1%). EPIYA: Glutamine acid-Proline-Isoleucine-Tyrosine-Alanine.

lombian clinical isolates, all of them derived from adults, were analyzed. From 122 initial strains included, 106 isolates that presented a single PCR product were considered for latter analysis. As expected, diversity in the size of the *cag*A fragment among isolates was observed, and PCR products ranged from 343 to 811 bp. This is explained by the fact that *cagA* varies in size depending on the number of EPIYA motifs it has, and because each type of EPIYA adds a certain number of amino acids, since each type is surrounded by a specific amino acid sequence. EPIYA-A represents an additional 32 amino acids in the protein, EPIYA-B 40 more amino acids, and EPIYA-C 34 more amino acids for Western CagA type[40,41]. The remaining 16 strains that showed two or more PCR products were excluded. However, they were considered for further analysis due to: (1) they could represent subclones attributable to a clone microevolution process demonstrating the high recombination rate of *H. pylori* plastic genome; or (2) they could represent a coinfection process with multiple *H. pylori* strains coexisting in the same host. A microevolution process at *cag*A gene has been described previously in the same individual and also in different family members[12,42,43]. Otherwise strains with a polymorphism in the *cagA* variable region have been also observed by Panayotopoulou *et al*[22], Aras *et al*[12] and Reyes-Leon *et al*[42]. The EPIYA patterns found in this study match with those reported by Panayotopoulou *et al*[22], but there were differences for EPIYA-A in which the amino acid Lysine (K) in the 6th position (being the amino acid E of the EPIYA motif the 1st position) changed to K/Q as previously reported[19], EPIYA-B in which the pattern in positions 12 and13 changed from being only Asparagine and Alanine (N, A) to (N/T) and (A/Q) respectively and finally EPIYA-C in which the amino acid in the 11th position changed from Glycine (G) to (G/R) (data not shown, accession number: FJ915913), which had been previously reported by Occhialini[44]. There was no association between the phosphorylation motif, EPIYT, which has a threonine residue instead of an alanine residue and the studied pathologies ($P = 0.51$). However, it has been reported that isolates that harbor the ABCC genotype and have a modification in the 5th residue (EPIYT) in the B type may induce lower levels of cellular elongation and interleukin-8 secretion than isolates with the normal ABCC pattern[42].

EPIYA results from this study were compared with those reported by Argent *et al*[39]. The analyses showed that in our samples the ABC pattern of EPIYA motifs is the most common (62.3%) (Table 1 and Figure 3), which is in agreement with Western sequences reported before (63.3%)[39]. Interestingly, we found a statistical difference between the frequency of ABCC patterns in Western strains reported in GenBank (19.6%) and our results (31.1%) (Table 1) ($P = 0.002$). A search in the GenBank data base was performed in order to look for sequences reported in Colombia[45,46] that included the C-terminal variation region of CagA. A comparison between the frequencies of the different EPIYA patterns with our results showed that there is not a statistically significant difference (Table 1) ($P = 0.98$). Current research showed that the variation of the EPIYA motifs in CagA protein is not directly associated with the outcome of the disease caused by *H. pylori* and that there is no association between the number of EPIYA-C motifs and the pathology (Table 2). Similar results had been reported before in Iranian and Iraqi populations[47], where it seems there is no explicit positive correlation between the number of EPIYA motifs and various gastroduodenal diseases associated to *H. pylori* infection. In contrast, Yamaoka *et al*[37] showed that 7 out of 8 *H. pylori* Colombian strains (87.5%) with more than 3 EPIYA-C motifs were from gastric cancer patients. More recently Sicinschi *et al*[45] evaluated the 3' cagA region in 66 isolates from Colombian patients with gastric precancerous lesions, from areas with low (31 strains) and high risk of gastric cancer (35 strains) in the south of the country. The proportion of strains bearing one EPIYA-C (62.2%), two EPIYA-C (34.3%) and three EPIYA-C (1.5%) motifs were similar to the ones observed in our population of strains. In contrast with our results, they observed a significant association between the presence of two or three EPIYA-C motifs and more severe lesions. Particularly they found a very high prevalence of strains with more than two EPIYA-C motifs in individuals with intestinal metaplasia (16/27, 59%). Sicinschi *et al*[45] included in the study only isolates

from men aged between 39 and 69 years in order to have high prevalence of *H. pylori* infection and preneoplastic lesions; 40% of the analyzed strains were from intestinal metaplasia. Our study included isolates from the Andes Mountains in the central part of the country, a high risk gastric cancer area; we included strains from men and women aged between 19 and 80 years, furthermore we included strains from gastric cancer patients. These differences in the design of the studies and also variations in geographic areas could explain the different results obtained. A limitation of our study is the small size of the analyzed population of strains. Although we could not find differences between EPIYA-C motifs and clinical outcomes, high prevalence of strains with more than one EPIYA-C motif might explain in part the high incidence of gastric cancer in Colombia.

It also must be considered that the absence of association between the CagA polymorphisms and the pathogenesis could be due to other factors such as genetic features of the host and cellular and extracellular environmental variables, which could influence the development of gastric cancer in combination with the type and number of EPIYA motifs in CagA protein. Moreover, another possibility as stated by Püls *et al*[48], using site-specific mutagenesis, suggests that tyrosine phosphorylation at EPIYA-C is sufficient, but not exclusive, to activate translocated CagA, suggesting that other motifs besides EPIYA-C are used for phosphorylation of CagA proteins as well. For this reason it is not only important to study the tyrosine phosphorylation motif, EPIYA, but also other new repetitions that have been discovered recently, such as the 7-AA sequence KIDQLNQ, which occurs in and near the CagA variable region[49]. Another important amino acid sequence is FPLXRXXXVXDLSKVG (Figure 2, second square), which surrounds the EPIYA-C motif and EPIYA-D in Western and East Asian CagA species, this was called CagA multimerization (CM) motif[50]. This CM motif was characterized in all of our strains, and interestingly in the strain 5-22019 (GenBank access number: FJ915938) the mentioned motif does not only surround the EPIYA-C motif but also the EPIYA-A. For this reason, it is important to study the molecular interaction between CagA proteins through the CM motif, because CagA multimerization is critically involved in the formation of the CagA-SHP2 signaling complex, during *cagA*-positive *H. pylori* infection[50]. Thus, it will be important to study the biological activity of Colombian CagA variants that harbor a variation in the C-terminal of the CagA protein, in order to comprehend how the interaction between the EPIYA-C motif and the SRC-2 protein in the epithelial cells works.

At the structural level it is important to determine how the EPIYA motifs are located in the CagA protein and if it influences CagA-SRC interaction, and consequently contribute to elucidate the biological activity of the CagA protein in the development of carcinogenesis in epithelial cells through this interaction. It is also important for future studies to check the evolution of the *cagA* gene in patients with atrophic gastritis, because this pathology has been reported as an early step in the development of gastric cancer[51] and this combined with genetic variability on the *cagA* gene generated by multiple rearrangements such as insertions, deletions, and substitution events on a 102nt region encoding the EPIYA-C motif could increase the probability of developing a gastric cancer pathology[52]. This kind of study has already been developed through hybridization assays with whole-genome DNA microarrays studies from Colombian strains[53] and monitoring the acquisition of additional EPIYA-C motifs throughout adulthood to determine if they contribute to *H. pylori* biological activity at a later age[22].

Our findings suggest that CagA polymorphisms EPIYA motifs, in Colombian patients are not clearly associated with the outcome of the disease. For this reason, it could be important to evaluate if the EPIYA motifs variation can cause an effect in the CagA protein structure and if so, if it can be correlated with its interaction inside the gastric epithelial cells. CagA has a striking functional similarity with Gab, Grb2 associated binder adaptor, in terms of being a protein that recruits SHP-2 to the plasma membrane and activates SHP-2 phosphatase by forming a physical complex[54]. Accordingly, it could be important to understand the role of CagA variants inside the gastric epithelial cells at protein-protein interaction level. On the other hand, microevolution in *cagA* gene has important implications for *H. pylori* pathogenesis because changing CagA type may provide a partial explanation of why studies examining the relationship between bacterial virulence and disease do not show tighter associations[43]. Finally, the CagA variable region characterization was successfully achieved and it gave an important register of the CagA protein polymorphisms in Colombian patients.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) is one of the most common worldwide human pathogens and it is present in at least 50% of the world's population. Studies have suggested that chronic infection by *H. pylori* is an important risk factor for the development of gastric carcinoma, due to the presence of an important virulence factor, CagA protein.

Research frontiers

CagA protein is a potential factor in the development of gastric carcinogenesis in human gastric epithelial cells. However, the relation between the polymorphisms on CagA and the pathogenesis of *H. pylori* in gastric cells has not been addressed in terms of number and type of Glutamine acid-Proline-Isoleucine-Tyrosine-Alanine (EPIYA) motif located in the C-terminal of CagA protein.

Innovations and breakthroughs

Some studies argue that there is an association between the EPIYA motifs in CagA and the pathology presented by the patients. In this study, the authors show that this association is not present in Colombian patients. Furthermore, their results suggest that this association is not equal in different regions of the world because there are others factors such as structural conformation and

protein-protein interactions that could affect the final outcome of the translocation of CagA in the gastric epithelial cells.

Applications

Because there is no association in Colombian samples between the motifs in the C-terminal of CagA and the pathology, it may be important to understand how these motifs interact with their target on gastric cells (Src kinase and Src homology phosphatase 2 proteins) in order to elucidate the function of CagA in the development of cancer gastric.

Terminology

CagA is one of the major virulence factors of *H. pylori*. This protein is involved in the development of gastric cancer because when this protein is translocated into gastric cells it causes changes in the signal transduction pathway which are involved in the proliferation of the cells.

Peer review

The paper by Acosta *et al* assesses EPIYA in Colombian patients with dyspepsia and finds no association with pathology.

Abstract

AIM: To determine the prevalence of steatosis and steatohepatitis in a series of autopsies in Northwestern Greece.

METHODS: Liver biopsy material from a total of 600 autopsies performed over a period of 2 years (2006-2008) to define the cause of death was subjected to histological examination. Patient demographic data were also collected. Tissue sections were stained with different dyes for the evaluation of liver architecture, degree of fibrosis and other pathological conditions when necessary.

RESULTS: Satisfactory tissue samples for histological evaluation were available in 498 cases (341 male, 157 female) with a mean age of 64.51 ± 17.78 years. In total, 144 (28.9%) had normal liver histology, 156 (31.3%) had evidence of steatosis, and 198 (39.8%) had typical histological findings of steatohepatitis. The most common causes of death were ischemic heart disease with or without myocardial infarction (43.4%), and traffic accidents (13.4%).

CONCLUSION: A high prevalence of steatosis and steatohepatitis was detected in postmortem biopsies from Northwestern Greece. Since both diseases can have serious clinical consequences, they should be considered as an important threat to the health of the general population in Greece.

Key words: Fatty liver; Non-alcoholic liver disease; Steatosis; Steatohepatitis; Autopsy

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD), the accumulation of fat within liver cells in individuals who deny a significant history of alcohol ingestion, is emerging as the most frequent liver disease in developed countries[1,2]. The diagnosis of NAFLD and non-alcoholic steatohepatitis (NASH) is based on histological findings of either fat alone, fat plus inflammation, fat plus hepatocyte injury (ballooning degeneration), or fat with fibrosis and cirrhosis[3]. The significance of these histological categories rests on the fact that both the prevalence and clinical outcome vary by histological category[4].

NAFLD is commonly associated with severe obesity, defined as body mass index (BMI) > 35 kg/m^2, with 74%-90% of liver biopsies showing fatty change[5,6]. NASH, first named by Ludwig *et al*[7], is probably a less aggressive condition than alcoholic hepatitis, but nevertheless might progress through necro-inflammatory change and early fibrosis to cirrhosis[8,9]. In contrast, NAFLD without necro-inflammatory change is generally a benign condition[10,11].

There are few published data on the frequency of NASH and NAFLD in Greece, but without biopsies[12]. The present study aimed to determine the prevalence of these diseases in a series of autopsy material from Northwestern Greece.

MATERIALS AND METHODS

Study protocol

The aim of the present study was to estimate the prevalence of steatosis and steatohepatitis in postmortem material from Northwestern Greece. For this purpose, a number of liver specimens from people who died suddenly or in a traffic accident and had undergone autopsy to define the cause of death, were investigated.

The survey took place at the regional University Hospital of Ioannina, from 15 March 2006 until 20 December 2008. The collaborating centers were the Department of Internal Medicine, the Laboratory of Pathology and the Department of Forensic Medicine and Toxicology. The study protocol was approved by the Hospital Ethical Committee.

Autopsy material from 600 people (391 men and 209 women) aged 3-94 years was investigated. All autopsies were forensic cases, being performed in those with unnatural death, such as sudden death and accidents (especially traffic accidents). No academic cases were included.

Demographic information, history of alcohol use and previous hepatic and non-hepatic chronic diseases, such as diabetes mellitus, and use of medication, were obtained from the first-degree relatives of the cases. Gross appearance of the liver was also recorded. Sampling was performed by the same physician.

Cases with a history of liver disease of any type and those with autolysed liver samples were excluded. Wedge biopsies (2 cm × 2 cm × 2 cm) from the right and left lobes and one biopsy of the same size from deeper areas of the liver parenchyma were obtained in each case. Any visually grossly abnormal areas were also sampled.

Isolation of liver specimens and histological assessment

Liver tissue sections from the necrotomic material were fixed in 40 g/L neutral formaldehyde for 24 h. After that, the tissues were dehydrated, embedded in paraffin, cut at 4 μm, and stained with hematoxylin-eosin for light microscopy.

For histochemical staining, additional 4-μm thick tissue sections were cut from paraffin blocks and were stained with silver reticulin and Masson's trichrome methods for the evaluation of liver architecture and the degree of fibrosis, when necessary. In addition, Perl's Prussian blue staining was performed to evaluate iron load based on a grading system of 0-4, as previously described[13].

Immunohistochemical study for the hepatitis B virus surface and core antigens was performed on formalin-fixed, paraffin-embedded liver tissue sections by the labeled streptavidin-avidin-biotin method, using appropriate antibodies (anti-HbsAg monoclonal mouse antibody, clone 3E7; DAKO, Germany; anti-HbcAg polyclonal rabbit antibody; DAKO). Immunohistochemical cytoplasmic and nuclear staining of hepatocytes was shown as HbsAg and HbcAg positivity, respectively.

Each biopsy was scored on a scale for steatosis, injury/inflammation and fibrosis. The grading and staging of steatohepatitis was based on criteria developed by Brunt *et al*[14]. Most specimens contained 12-24 portal tracts.

The two histopathologists involved in this study agreed on terms, definitions and the histological criteria of the pathologic lesions. The liver sections were examined under an Olympus optical microscope and the histopathologists were blind to the patients' personal history. All positive findings were reevaluated for grading and staging by both histopathologists. In cases of diagnostic discrepancy, the result was reported according to the consensus of a joint slide review session. Histological findings were recorded in a standard form.

Statistical analysis

Data are presented as mean ± SD, unless otherwise stated. One-way ANOVA or ANOVA based on ranks, followed by multiple pairwise comparisons, was used for multigroup comparisons. Correlations between variables were determined with the use of the *f* factor. All statistical tests were performed with the use of the Statistica software, version 6.0. $P < 0.05$ was considered significant unless otherwise noted.

An overall statistical analysis was performed at first. After that, the cases were divided into subgroups based on sex, and comparison was performed in correlation with the degree of steatosis and steatohepatitis. The cases were also divided into four age subgroups: < 45 years (65 cases, 13%, age group a); 45-60 years (97 cases, 19.4%, age group b); 60-75 years (187 cases, 37.6%, age group c); and > 75 years (149 cases, 30%, age group d). Statistical analysis based on the histological findings was performed

Table 1 Detailed causes of death in the population study

Cause of death	*n* (%)
Ischemic heart disease and/or myocardial infarction	237 (47.59)
Traffic accidents	67 (13.45)
Pneumonic embolism	41 (8.23)
Cerebrovascular incidents	21 (4.2)
Trauma	16 (3.2)
Rupture of aortic aneurysm	16 (3.2)
Neoplasm	14 (2.8)
Cerebrovascular trauma	12 (2.4)
Drowning	12 (2.4)
Heroin overdose and other toxic agents	11 (2.2)
Hanging	7 (1.4)
Cirrhosis	6 (1.2)
Severe burns	5 (1.0)
Thrombosis of the mesentery with peritonitis	4 (0.8)
Sepsis	3 (0.6)
Lower gastrointestinal bleeding	3 (0.6)
Upper gastrointestinal bleeding	2 (0.4)
Inhalation of CO	2 (0.4)
Subdural hematoma	2 (0.4)
Endocarditis	2 (0.4)
Lobular pneumonia	1 (0.2)
Other (infections, electrocution, *etc*.)	14 (2.8)

in each age subgroup. Finally, the cases were divided in to two subgroups according to the cause of death: in the first subgroup the cause of death was ischemic heart disease with or without myocardial infarction, and in the second, all other vascular diseases. Further correlations with liver histology, age and sex were also performed.

RESULTS

During the study period, 600 cases were assessed. One hundred and two cases were excluded because of moderate to severe autolysis in liver tissue, positive immunohistochemical findings for hepatitis B surface antigen (HBsAg) and hepatitis B core antigen (HBcAg) or a history of known chronic liver disease. Thus, 498 cases were evaluable and included 341 men and 157 women with a mean age of 64.51 ± 17.78 years. Most of the cases (255) were residents of Ioannina, the largest town in Northwestern Greece.

The most common causes of death were: ischemic heart disease with or without myocardial infarction (47.6%), traffic accidents (13.4%), pneumonic embolism (8.2%), cerebrovascular incidents (4.2%), rupture of aortic aneurysm and trauma (3.2%), neoplasm (2.8%), and others (21%). Table 1 presents a detailed description of the causes of death in our study population.

From the 498 cases, 144 (28.9%) had normal liver histology, whilst 156 (31.3%) had evidence of steatosis, and 198 (39.8%) had histological findings typical of steatohepatitis. In the subgroup with steatosis, 112 (71.8%) had steatosis < 33%, 28 (18%) had steatosis between 33 and 66%, and 16 (10%) had steatosis of > 66%. In the steatohepatitis subgroup, 113 (57%) cases were classified as grade 1, 61 (30.8%) as grade 2, and 24 (12.1%) as grade 3. Staging was categorized as stages 1, 2, 3 and 4, respectively. Thus, 69 (35%) were stage 1, 69 (35%) stage 2, 36 (18%) stage 3, and 24 (12) stage 4. Correlations of the grades and the stages of the 198 cases with steatohepatitis are depicted in Table 2. As in other types of chronic hepatitis, the grade and stage of the disease might be disparate, as they are meant to reflect different aspects of liver injury. The degrees of steatosis are presented.

Table 2 Correlation of grade and stage in patients with steatohepatitis

Grade	Stage					Totals
	0	1	2	3	4	
Mild (Ⅰ)	0	55	44	13	1	113
Moderate (Ⅱ)	0	13	21	14	13	61
Severe (Ⅲ)	0	1	4	9	10	24
Totals	0	69	69	36	24	198

The analysis of steatosis, steatohepatitis and normal liver tissues in the aging groups was statistically significant ($P = 0.0005$, $f = 6$, Figure 1). The same analysis in correlation with sex was not significant ($P = 0.148$). Overall analysis of the age groups and sex in correlation with steatosis, steatohepatitis and normal liver tissues showed borderline significance ($P = 0.043$, $f = 3$, Figure 1). Table 3 presents the number of subjects by sex and age group.

History of diabetes mellitus was found in 18 cases with steatosis and in 30 cases with steatohepatitis. Mild iron loading (1+ to 2+) was detected in 41 cases (23 men, 18 women), which accounted for 8.2% of the study population. From these, 39 cases had also steatohepatitis and therefore only two cases of steatosis were detected. Furthermore, analyses based on the age subgroups revealed mild iron loading (1+ to 2+) in eight cases between 45 and 60 years, in 18 cases between 60 and 75, and in 15 cases > 75 years.

Finally, from the 236 ischemic heart disease deaths with or without myocardial infarction, 47 (20%) had normal liver histology, 90 (38%) had steatosis, and 99 (42%) had histological findings typical of steatohepatitis. In the same subgroup, only 11 cases had mild iron loading.

DISCUSSION

The present study demonstrated that steatosis and steatohepatitis are emerging as common silent liver diseases in Northwestern Greece. The true incidence and prevalence of these diseases in different populations is largely unknown[15], even if it is believed that they are the most common liver diseases in the general population[2,16,17]. This might be explained partly because liver histology is required as the gold standard for precise diagnosis of these conditions, and the relatively invasive procedure of liver biopsy is still not considered essential for the management of NAFLD by many physicians. In addition, most of the reports on the prevalence rates of NAFLD are based on ultrasonographic studies and/or the presence of elevated serum levels of aminotransferases, in the

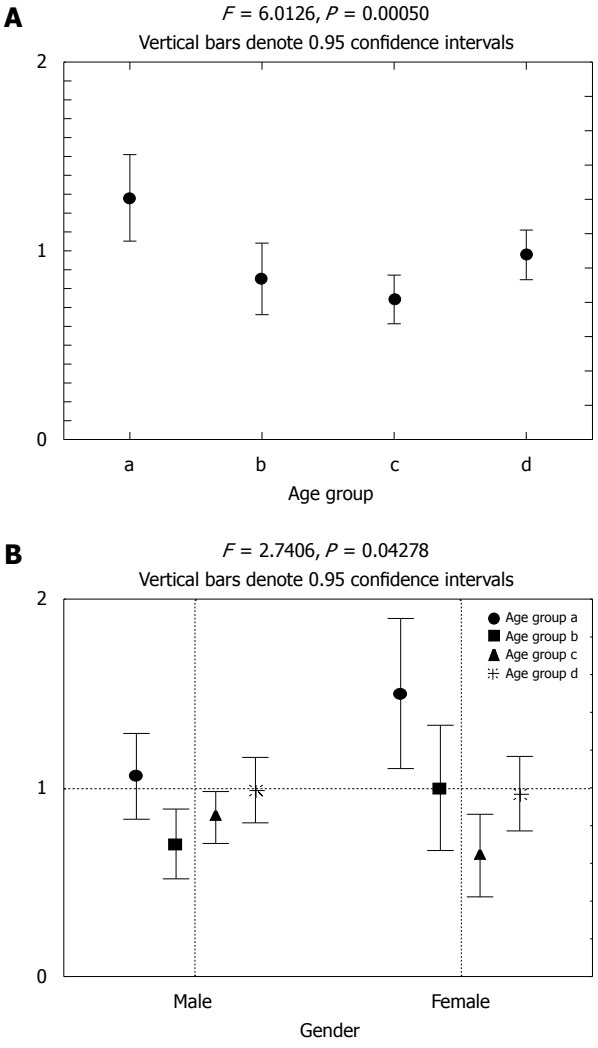

Figure 1 Correlations of age subgroups in different subjects. A: Correlation of age subgroups (a, b, c and d) in subjects with steatohepatitis (0) and steatosis (1), and normal subjects (2). Mean values for each group are presented. The four age subgroups were defined as follows: < 45 years (group a), 45-60 years (group b), 60-75 years (group c), and > 75 years (group d); B: Correlation of sex and age in subjects with steatohepatitis (2) and steatosis (1), and in normal subjects (0). Data are shown for male and female subjects separately, according to age group.

absence of any other known liver disease or significant alcohol consumption[2,18].

In clinical practice, diagnostic liver biopsy is performed only for highly selected patients. For this reason, the reported rates that are based on liver biopsies cannot reflect the true prevalence of NAFLD and NASH in the general population[19,20]. In addition, histological lesions of NASH are unevenly distributed throughout the liver parenchyma; therefore, sampling errors of liver biopsies can result in misdiagnosis and staging inaccuracies[21]. Furthermore, NASH and alcoholic steatohepatitis can share common histological findings[22,23].

Autopsies, performed for those who have passed away for reasons other than liver diseases, are certainly better sources for the determination of a more reliable prevalence for NAFLD and NASH[24]. The particular characteristics of forensic autopsies are the relatively young age of

Table 3 Number of subjects in every age group according to sex

Age groups	a	b	c	d	Totals
Male	49	74	134	84	341
Female	16	23	53	65	157
Total	65	97	187	149	498

a: < 45 years; b: 45-60 years; c: 60-75 years; d: > 75 years.

the subjects and their usually better general health before death. Among our cases, male sex was predominant; most of the subjects had no history of chronic diseases, and in > 80%, the causes of death were acute events such as cardiovascular diseases, traffic accidents and trauma. To the best of our knowledge, this is the first report concerning liver diseases based on an autopsy series in Greece.

Obesity is a major clinical problem in Greece[25]. Unfortunately, we were not able to measure BMI in the study population. As a result, no correlations of steatosis and steatohepatitis with BMI could be performed. In addition, although 10 patients had positive immunohistochemical findings for the HBsAg and HBcAg, serological viral markers for hepatitis B and hepatitis C virus infection were not performed in the present study. However, the prevalence of both infections is low in Greece[26-28].

In none of our cases was the use of medication that induced or predisposed to the progression of NASH[29]. The higher prevalence of NAFLD and NASH in patients with diabetes mellitus has been well documented before[30-32] and is in accordance with our findings. Silent cirrhosis was found in only six of our patients, which indicates a low prevalence of this condition in Northwestern Greece, in comparison with other autopsy series[24,33]. The correlation of cirrhosis with NAFLD and NASH is one of the most controversial issues. Although there is substantial evidence that NASH might lead to cirrhosis in about 20% of cases, and is the most common etiology for cryptogenic cirrhosis[34], well-designed, prospective long-term studies for determination of outcome in patients with NAFLD are lacking[2,3]. However, it seems that older age, obesity and the presence of diabetes mellitus are factors that predispose towards progression of NASH to cirrhosis[35-37]. In particular, the aggressive form of NAFLD is best based on the pathological diagnosis of steatonecrosis with Mallory hyaline and fibrosis[38,39]. The clinical implications of this alarming prevalence of NAFLD and NASH are derived from the fact that these liver conditions may progress to end-stage liver disease and cancer[40,41].

Mild iron loading was detected in 41 cases in our study population. It is clear that, in our cases with steatohepatitis, the role of increased iron stores in the development of fibrosis seemed to be of less importance. The role of lipogenesis and fatty acid oxidation in the development of NAFLD and NASH has been well established[42]. In particular, the complex progression of NAFLD is related to metabolic abnormalities associated with massive steatosis, insulin resistance and reductions

in fatty acid oxidation[43-45]. NASH is attributed to tumor necrosis factor-α, free fatty acid toxicity, toxicity caused by dicarboxylic acids, a decrease in mitochondrial and peroxisomal β-oxidation, generation of reactive oxygen species, lipid peroxidation and many other events that lead to apoptosis and inflammation[46,47].

The reported prevalence of steatosis in our study is in accordance with other studies[24]. However, the reported prevalence of steatohepatitis in this Greek population is much higher in comparison with other population studies[48-51]. Although results from this autopsy study cannot be extrapolated to the general healthy population, the reason for such a high rate could possibly be attributed to the decreased physical activity and the alterations in dietary habits in the Greek population over recent decades.

In conclusion, it seems that steatosis and steatohepatitis are very common liver diseases among postmortem material in Northwestern Greece. Since both diseases can have serious clinical consequences, they should be considered as an important threat to the health of the general population in Greece. Further studies to confirm this prevalence and assess the etiology and natural history of these lesions in the general healthy Greek population, in combination with possible therapeutic strategies, are therefore mandatory.

COMMENTS

Background

The incidence of steatosis and steatohepatitis is currently rising faster than any other liver disease in the western world, although the cause of this increase is largely unknown. These diseases progress from necro-inflammatory change and early fibrosis to cirrhosis and liver cancer. Both diseases can result in end-stage liver disease. Liver biopsy remains the gold standard for diagnosis and treatment. The present study aimed to determine the prevalence of steatosis and steatohepatitis in a series of autopsies in Northwestern Greece.

Research frontiers

Many predisposing factors for the development of non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) have been proposed. Age seemed to be an important one in our population study, whereas the role of sex remains to be investigated. In addition, further studies are important to define the role of genetic factors in both diseases.

Innovations and breakthroughs

Many reports have highlighted the evolution of steatosis and steatohepatitis in liver fibrosis and carcinogenesis. This is believed to be the first study in Greece to report the prevalence of steatosis and steatohepatitis, based on liver histology in the general population. Among our cases, male sex was predominant, most of the subjects had no history of chronic diseases (reported healthy subjects), and in > 80% of the cases, the causes of death were acute events such as cardiovascular diseases, traffic accidents and trauma.

Applications

By understanding the rising prevalence of NAFLD and NASH, this study could represent a future strategy for early therapeutic intervention in the treatment of patients with steatosis and steatohepatitis. Screening of the general population and detecting the possible risk factors is also advisable.

Terminology

Tissue sections were stained with different dyes for the evaluation of liver architecture, degree of fibrosis and other pathological conditions when necessary. Simple steatosis of the liver was staged as follows: < 33%, 33%-66%, > 66%. NASH was diagnosed after excluding other causes of liver inflammation.

Peer review

This paper is interesting and well written. Finding a steatohepatitis prevalence of about 40% is important news in Greece and could have implications throughout Europe.

Abstract

AIM: To study the mechanism underlying carbon tetrachloride (CCl_4)-induced alterations of protein synthesis in liver.

METHODS: Male Sprague-Dawley rats were given CCl_4 (1 mL/100 g body weight) and ^{3}H-leucine incorporation. Malondialdehyde (MDA) level in the liver, *in vitro* response of hepatocyte nuclei nucleotide triphosphatase (NTPase) to free radicals, and nuclear export of total mRNA with 3′-poly A^+ were measured respectively. Survival response of HepG2 cells to CCl_4 treatment was assessed by methyl thiazolyl tetrazolium. Km and Vmax values of nuclear envelope NTPase activity in liver of rats treated with CCl_4 were assayed by a double-reciprocal plot.

RESULTS: The protein synthesis was inhibited while the MDA level was significantly increased in liver of rats treated with CCl_4. In addition, CCl_4 decreased the NTPase binding capacity of nuclear envelope (Km value) in cultured HepG2 cells. Moreover, *in vitro* ferrous radicals from Fenton's system suppressed the NTPase activity of liver nuclear envelope in a dose-dependent manner. Down-regulation of the nuclear envelope NTPase activity indicated a lower energy provision for nucleocytoplasmic transport of mRNA molecules, an evidence in CCl_4-treated HepG2 cells correspondingly supported by the nuclear sequestration of poly $(A)^+$ mRNA molecules in morphological hybridization research.

CONCLUSION: Inhibition of mRNA transport, suggestive of decreased NTPase activity of the nuclear envelope, may be involved in carbon tetrachloride-inhibited protein synthesis in liver.

Key words: Carbon tetrachloride; Nuclear envelope nucleotide triphosphatase; Nucleocytoplasmic transport inhibition; Hydroxyl radical

INTRODUCTION

Carbon tetrachloride (CCl_4) is an organic solvent widely

used in chemical industry. Its hepatotoxicity includes fatty liver and hepatic necrosis[1,2]. Moreover, CCl_4 has also an ability to inhibit protein synthesis in liver with early hepatotoxic damage[3]. Early studies showed that free radicals, such as trichloromethyl ($\cdot CCl_3$) and oxygen-centered lipid radicals (LO$\cdot$ or LOO, or both), are generated during CCl_4 metabolism by hepatic cellular cytochrome P450. These radicals can cause hepatic injury resulting from CCl_4 exposure. Protein synthesis is a cytoplasmic event in eukaryotic cells, in which mRNA templates in the form of a genetic code are employed to guide protein synthesis. A nuclear envelope (NE) of eukaryotic cells causes spatial separation between mRNA and protein synthesis. Thus, mRNA templates in nuclei have to be transported into cytoplasm, a limiting process of protein synthesis. Nuclear membrane-associated nucleotide triphosphatase (NTPase), a specific energy driver of mRNA nucleocytoplasmic export, enables mRNA cytoplasmic accumulation[4,5]. Our previous work demonstrated that reduced NTPase activity in the NE correspondingly decreases mRNA transport[6]. In this report, we studied the role and mechanism of NTPase activity in CCl_4-induced inhibition of protein synthesis in liver.

MATERIALS AND METHODS

Materials

Trypsin, 4,6-diamidino-2-phenylindole dihydrochloride (DAPI), dimethyl sulfoxide (DMSO), DL-dithiothreitol (DTT), adenosine triphosphate (ATP), guanine triphosphate (GTP), cytosine triphosphate (CTP), thymine triphosphate (TTP), and methyl thiazolyl tetrazolium (MTT) were purchased from Sigma Company (St. Louis, MO, USA). DMEM medium was purchased from Invitrogen (Cat.12100-046, Carlsbad, CA, USA), and fetal bovine serum (FBS) was purchased from Beijing New Probe Biotechnology Co., Ltd. (Beijing, China). Trichloride acetic acid (TCA, analytic purity grade), a precipitating agent for protein, and CCl_4 (analytic purity grade) were obtained from Beijing Chemical Reagent Factory (Beijing, China). L-[3, 4-^{3}H]-leucine was purchased from Beijing Atom High Tech., Ltd. (Beijing, China).

Cell culture

HepG2 cells (Cat. HB-8065, human hepatic carcinoma cell line) were obtained from American Type Culture Collection (Manassas, VA, USA). HepG2 cells were grown in a DMEM supplemented with 10% newborn calf serum and maintained at 37℃ in a humidified atmosphere containing 5% CO_2. The 80% confluent-cultured HepG2 cells were treated for 2 h with fresh DMEM with or without CCl_4, the former containing a final concentration at 4 mmol/L CCl_4 (CCl_4 group), and the latter with the same volume of DMSO (control group).

Animals

Sprague-Dawley rats were supplied by the Experimental Animal Center, Peking University Health Science Center. The following procedure was approved by the Medical Animal Ethics Committee of the Health Science Center, Peking University. Male rats weighing 180-220 g were fasted for 14 h prior to the experiment, and then had free access to standard animal food and tap water. The animals were housed in plastic cages and maintained at 23 ± 1℃ under a natural light-dark cycle in a well-ventilated room.

^{3}H-leucine incorporation

Rats (n = 6) in the CCl_4 group were given CCl_4 (dissolved in an equal part of vegetable oil) at 1 mL/100 g of body weight under anesthesia. Rats in the control group (n = 6) received the same volume of vegetable oil. Two weeks following CCl_4 treatment, 50 μCi ^{3}H-leucine (100 g of body weight) was injected into each animal *via* the tail vein. Rats were dispatched by cervical dislocation 1 h later with their livers quickly isolated and perfused in ice-chilled phosphate buffer saline (PBS). Liver tissue samples, free of blood, were divided into two parts and stored at -80℃. To measure the total liver radioactivity, one aliquot of liver tissue was baked at 60℃ until its weight remained constant. The liver tissue samples were then ground into powder and digested at 70℃ in 5 mL 70:30 mixture of perchloric acid/H_2O_2 for 30 min. To measure the radioactivity retained at the TCA-insoluble portion of the liver protein, another aliquot of liver tissue was homogenized in ice-chilled PBS using a Teflon glass homogenizer. Homogenates were precipitated with 10% TCA, and TCA-insoluble sediments were digested at 70℃ in the same volume of perchloride acid/H_2O_2 mixture for 30 min. Protein level in TCA-insoluble sediments was measured using the Bradford method. Radioactivity remaining either in the entire liver or in TCA-insoluble portion was determined with a Beckman liquid scintillation counter. ^{3}H-leucine incorporations in the entire liver or in the TCA-insoluble protein were expressed as count per minute (CPM) over mg of dry liver tissue or TCA-insoluble protein portion[7].

MDA level in rat liver

Twenty male rats were divided into control group, CCl_4-treatment group, taurine group, and CCl_4/taurine group, 6 rats in each group. The rats were treated with or without CCl_4 (dissolved in vegetable oil) *via* subcutaneous injection, and oral administration of taurine if necessary. Two weeks after treatment, the rats were sacrificed under anesthesia with urethane (1 g/kg, ip). Their livers were perfused *in situ* at 37℃ with PBS *via* the left ventricle. Liver tissue samples were homogenized in approximately 10 times the volume of saline to tissue weight. MDA level was measured by assaying rat liver homogenates with a MDA kit (Bio-lab Materials Institute, Beijing) following its manufacturer's instructions. Results were calibrated to their protein content and expressed as nmol MDA/mg protein.

MTT metabolic viability

Cytotoxicity of HepG2 cells to CCl_4 was detected by MTT metabolic viability assay as previously described[8].

Briefly, HepG2 cells were seeded into a 96-well plate (1×10^5 cells/well), incubated for 12 h, and then switched to a DMEM containing CCl_4 at the indicated doses (0, 2, 10, and 50 mmol/L). After incubated for another 4 h at 37℃ and further incubated with 1 mg/mL MTT for 2 h, the activity of cellular mitochondrial succinic dehydrogenase was measured. Absorbance at 570 nm wavelength with a reference wavelength of 655 nm reflected the number of surviving cells.

Isolation and characterization of nuclei

Twenty-four hours after incubation, HepG2 cells were harvested to isolate their nuclei as previously described[5]. Suspended cells were homogenized in Teflon (10 strokes) and centrifuged at 800 *g* for 10 min. The nuclei were suspended in DS/PMSF buffer, layered over cushions in the same buffer, and spun down at 70 000 *g* for 60 min. Isolated nuclei were resuspended in STM/PMSF buffer, relayered over cushions of DS/PMSF buffer, and centrifuged at 70 000 *g* for 30 min. The final pellet was resolved with STM/PMSF to obtain a final protein concentration of 1 mg/mL and stored at -70℃. The marker enzyme activities specific to nuclei or cytoplasm were determined for monitoring the purity of isolated NE preparations.

Kinetics assay of NE NTPase activity

NE NTPase activity was assayed as described by Ramjiawan *et al*[9] with some modifications. In the assay, 40 μL nuclear extracts (containing 40 μg protein) of HepG2 cells with 2 mmol/L CCl_4 or DMSO treatment was preincubated in 200 μL buffer for 10 min at 30℃. After different levels of ATP or GTP substrates were added into the nuclear extracts to initiate NTPase reaction and incubated at 30℃ for 10 min, reactions were terminated by adding 10% SDS and test tubes were immediately placed in ice. Inorganic phosphates produced in these reactions were detected according to the method of Tiffany[10]. The two characteristic constants, i.e. maximum velocity (Vmax) and Michaelis constant (Km) for NTPase, were obtained using the Line weaver-Burke equation, and expressed as nmol Pi/mg, Pr/min and nmol/L, respectively, for ATP or GTP. Preliminary experiments showed a linear relationship between NTPase activity and incubation time.

Nuclear export of total mRNA with 3'-poly A^+ tailing

Double staining of HepG2 cells with a fluorescein isothiocyanate (FITC) probe conjugated with oligo-$(dT)_{15}$ specific for mature mRNA with 3'-poly A^+ tailing and 4, 6-diamidino-2-phenylindole (DAPI) for localization of nuclei was carried out as previously described[11]. Briefly, after formaldehyde fixation, HepG2 cells cultured on cover slips were permeabilized with PBS/0.5% Triton X-100 for 10 min at room temperature. Cover slips were equilibrated in 2 × SSC for 10 min, and incubated with a FITC-labeled oligo-$(dT)_{15}$ probe (showing green fluorescence) for 30 min. The cells on cover slips were washed three times with PBS, and incubated for another 30 min at room temperature with a DAPI solution (showing blue fluorescence). The cells were then washed once with PBS/0.2% Triton X-100 and twice with PBS. To ensure that the FITC-hybridization of mRNA was not resulted from DNA binding, RNase A was introduced into the sample to digest all remaining RNA. Total mature mRNA with 3'-poly A^+ tailing was clearly observed either in nuclei or in cytoplasm with FITC-oligo $(dT)_{15}$ labeling under a fluorescence microscope.

NTPase response of hepatocyte nuclei to in vitro hydroxyl radicals

Hepatocyte nuclei from rats were prepared and characterized using the method described in section "Isolation and characterization of nuclei". Different levels of hydroxyl radicals from *in vitro* Fenton reaction[12] system were freshly prepared by mixing $FeSO_4$ and H_2O_2 in the ratio of 0/0, 0.1/0.5, 0.5/2.5, 1/5, and 5/25 [(μmol/L)/(μmol/L)], respectively. The mixture was immediately added to the hepatocyte nuclei. After hepatocyte nuclei were incubated with different levels of hydroxyl radicals for 30 min at 30℃, NE NTPase activity for the ATP or GTP was determined according to the method described in section "Kinetics assay of NE NTPase activity".

Statistical analysis

All data were expressed as mean ± SE (n = 4-6). Statistical analysis was performed by one-way analysis of variance followed by Student-Newman-Keuls test. $P < 0.05$ was considered statistically significant.

RESULTS

$CC1_4$ inhibited protein synthesis and increased MDA production in liver

Electron micrographs showed an early and widespread dislocation of ribonucleoprotein particles from membranes of the rough endoplasmic reticulum in hepatocytes of rats 3 h after CCl_4 administration. Furthermore, amino acid incorporations into two liver-produced proteins, albumin and fibrinogen, were decreased in the same CCl_4-treated rats. These findings suggest that protein synthesis in liver is influenced by CCl_4 treatment[3].

To confirm that the incorporation of amino acid into liver protein is impaired, 50 μCi ^{3}H-leucine (100 g of body weight) was administered to the rats through the tail vein 2 h after CCl_4 treatment. Trichloride acetic acid (TCA), a general protein-precipitating agent, was used in tissue homogenates to separate total protein from rat liver tissues. The rates of ^{3}H-leucine incorporation into the liver homogenate and TCA-precipitated liver protein are shown in Figure 1A. Treatment with CCl_4 significantly decreased ^{3}H-leucine incorporation into TCA-precipitated liver protein (103.7 ± 5.4 cpm/mg in control group *vs* 71.8 ± 3.8 cpm/mg in CCl_4 treatment group).

No significant difference was observed in total radioactivity in the entire liver between CCl_4 treatment and control groups (66.7 ± 2.4 cpm/g *vs* 64.2 ± 1.8 cpm/g), indicating that the decreased total protein synthesis in CCl_4 treatment group is not due to the difference in leu-

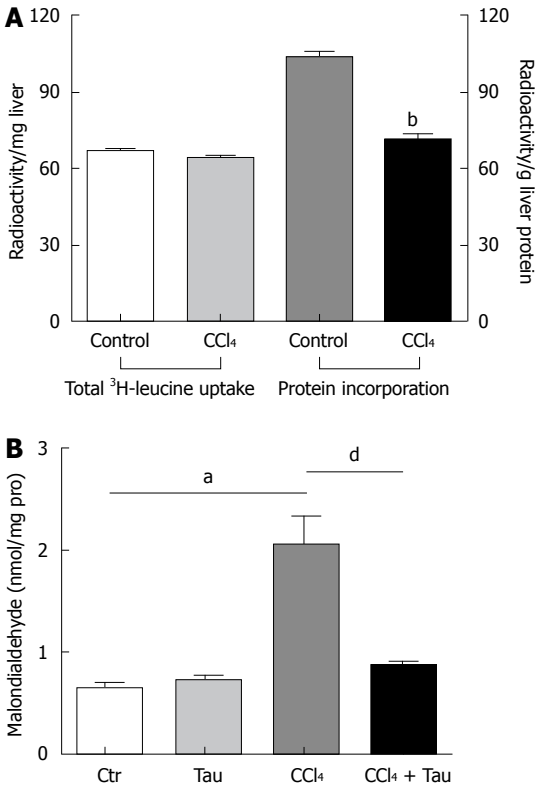

Figure 1 CCl_4 inhibits protein synthesis (A) and increases malondialdehyde production (B) in liver of Sprague-Dawley rats. Data are expressed as mean ± SE. $^aP < 0.05$ *vs* control group; $^bP < 0.01$ *vs* their counterpart control group; $^dP < 0.01$ *vs* CCl_4 treatment group.

cine uptake between the two groups.

· CCl_3 radicals produced in reactions by liver microsomes of animals exposed to CCl_4 were assumed to attack the membrane lipid in hepatocyte endoplasmic reticulum. When these free radicals attacked the membrane lipid in hepatocyte endoplasmic reticulum, malondialdehyde was brought out quickly, suggesting that MDA formation is recognized as an indicator of lipid peroxidation initiated by reactive radicals. Taurine has been well-known to be an effective scavenger of reactive radicals *in vivo* and *in vitro* through an unknown mechanism[5], which ameliorates MDA production in oxidative damaged liver. In the current work, the MDA level was 220% higher in liver of rats treated with CCl_4 than in liver of rats not treated with CCl_4. Meanwhile, the MDA level was 42% lower in liver of rats treated with combined CCl_4 and taurine than in liver of rats treated with CCl_4 alone (Figure 1B), indicating that reactive radicals have formed in liver of rats during CCl_4 metabolism.

$CC1_4$ inhibited nuclear NTPase affinity of HepG2 cells after in vitro incubation

To further investigate the mechanism underlying CCl_4-inhibied protein synthesis in liver, the CCl_4 dose acting on cultured HepG2 cells was maximized by measuring the hepatotoxicity of CCl_4 in a MTT cell survival assay. CCl_4 at the dose of 10 mmol/L and 50 mmol/L decreased the survival rate of HepG2 cells to 32% (0.290 ± 0.08 *vs* 0.196 ± 0.04) and 97% (0.290 ± 0.08 *vs* 0.009 ± 0.01), respectively ($P < 0.01$, Figure 2A). Therefore, CCl_4 at a dose of lower than 10 mmol/L was used to explore the mechanism underlying CCl_4-inhibited protein synthesis in liver of rats in subsequent experiments.

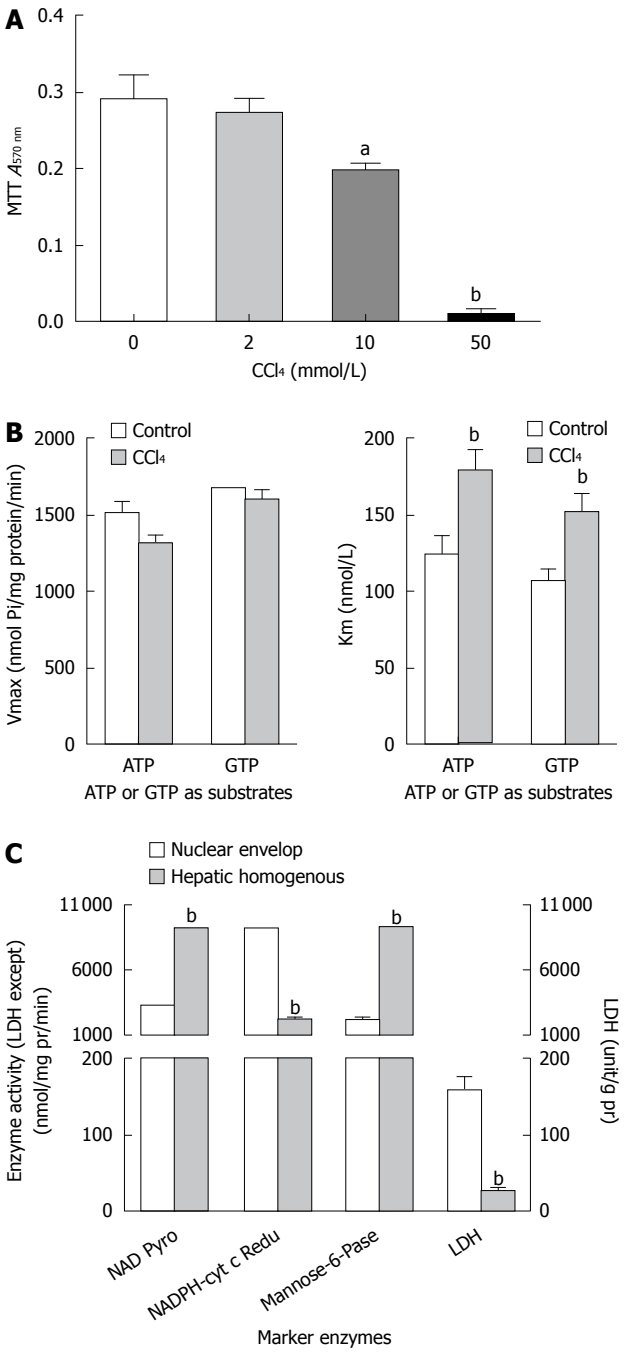

Figure 2 $CC1_4$ inhibits nucleotide triphosphatase affinity in nuclei of HepG2 cells. A: Methyl thiazolyl tetrazolium (MTT) metabolic viability assay at a dose of 10 mmol/L showing the inhibitory effect of CCl_4 on growth of HepG2 cells; B: Substrate-affinity (Km, B2) is decreased without any alterations in the substrate binding sites (Vmax,B1) for adenosine triphosphate (ATP) or guanine triphosphate (GTP) in nuclear nucleotide triphosphatase of HepG2 cells treated with CCl_4 (2 mmol/L); C: Enzyme' activities of nuclei extracts and homogenates from HepG2 cells in control and CCl_4 treatment groups. $^aP < 0.05$ *vs* control group, or nuclear envelop group, respectively; $^bP < 0.01$ *vs* their counterpart control group, or nuclear envelop group, respectively. Protein synthesis in liver, regulated by the richness of

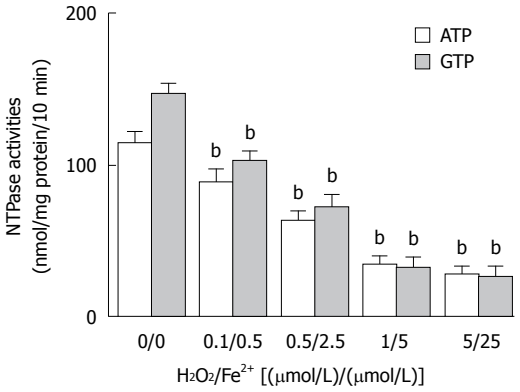

Figure 3 Involvement of reactive radicals in decreased nucleotide triphosphatase activity of nuclei. Data are represented as mean ± SE. $^bP < 0.01$ *vs* H_2O_2/Fe^{2+} group [(0 μmol/L)/(0 μmol/L)]. NTPase: Nucleotide triphosphatase.

cytoplasmic template of mRNA, is a key event in cell survival and metabolism. Down-regulation of nuclear export of mature mRNA into cytoplasm is related to its depressed NE NTPase activity in aged rats (data not shown). NTPase, embedded in eukaryotic nuclear envelope, provides nucleocytoplasmic transport energy and promotes shuttling of macromolecules between nuclei and cytoplasm *via* its hydrolysis action on NTP substrates, such as ATP, GTP, CTP, and TTP. In this study, nuclear envelopes of HepG2 cells were isolated to study the effect of CCl_4 on mRNA export into cytoplasm through NE NTPase action in HepG2 cells.

To characterize the purity of nuclei, several marker enzymes for different organelles were used to assess the quality of isolated nuclear envelopes with reference to their hepatic homogenous counterparts (Figure 2C). The activity of NAD pyrophosphorylase was 6.9-fold higher in the prepared nuclear envelope, previously assumed to be exclusively located in nuclei, than in homogenates of HepG2 cells. The activity of NADPH cytochrome-C reductase (as a marker enzyme in microsome) was only 22% higher in the prepared nuclear envelope than in homogenates of HepG2 cells. The activities of other marker enzymes, such as mannose-6-phosphatase (an indicator of both nuclei and cytoplasm) and lactose dehydrogenase (an indicator of cytoplasm) had a similar changing tendency as NAD pyrophosphorylase and NADPH cytochrome-C reductase, showing that these nuclear envelopes, prepared from HepG2 cells in this experiment, have less cytoplasmic contamination and are comparable with the prepared nuclear envelopes, and can be used in analysis of NTPase activity.

In the present study, CCl_4 significantly depressed the NTPase activity of hepatic nuclei, regardless of whether the ATP or GTP acted as a substrate, in terms of Km but not Vmax value. An estimation using the double-reciprocal plot method (Figure 2B) showed that CCl_4 interfered with the HepG2 NE NTPase Km but not the Vmax, in ATP or GTP acting as a substrate, suggesting that the Km value of liver nuclear membrane NTPase contributes to a lower hydrolysis efficiency on NTP molecules in the CCl_4 treatment group than in the control group, and decreases energy provision for nucleocytoplasmic transport.

Involvement of reactive radicals in decreased NTPase activity of nuclei

The elevated MDA level in liver tissue of Sprague-Dawley rats treated with CCl_4 was significantly correlated with membrane lipid peroxidation initiated by reactive radicals. To observe the involvement of reactive radicals produced by CCl_4 metabolism in hepatic nuclear NTPase activity, Fenton reaction system, an *in vitro* mimic system, was used. In brief, ferrous sulfate and hydroperoxide were simultaneously mixed in different ratios [0.1/0.5, 0.5/2.5, 1/5, and 5/25, (μmol/L)/(μmol/L)] and placed into cultured media to produce unstable reactive radicals. HepG2 nuclear envelope fractions were incubated with an equal volume of *in vitro* radicals at different concentrations. The results showed that the *in vitro* radicals decreased the nuclear NTPase activity in a dose-dependent manner, regardless of whether ATP or GTP was used as a substrate (Figure 3). After nuclei of HepG2 cells were incubated with reactive radicals at a mixing ratio of (5 μmol/L)/(25 μmol/L) of Fe^{2+}/H_2O_2, the NTPase activity on the NE was decreased by 75.4% (for ATP) and 82.2% (for GTP), respectively ($P < 0.01$), indicating that the decreased nuclear NTPase activity in HepG2 cells treated with CCl_4 may be attributed to hepatic microsome CCl_4 metabolites through the action of its reactive radicals.

Total mRNA nuclear export from HepG2 cells blocked by CCl_4 treatment

As described above, the nuclear NTPase activity in HepG2 cells was sharply suppressed by CCl_4 treatment, the exporting process of mRNA templates into cytoplasm was thus assumed to be influenced in CCl_4-treated HepG2 cells. To investigate whether the concurrent export inhibition of mRNA occurs in CCl_4-treated HepG2 cells, the poly $(A)^+$ RNA molecular (i.e. mRNA) shuttling between nuclei and cytoplasm in cultured HepG2 cells treated or not treated with CCl_4 was morphologically observed by fluorescence *in situ* hybridization with a FITC-labeled oligo-$(dT)_{15}$ probe, a specific targeting probe for endogenous 3'-poly$(A)^+$ tailing maturing mRNA (Figure 4). The FITC-labeled oligo-$(dT)_{15}$ hybridization in HepG2 cells not treated with CCl_4 was almost evenly distributed throughout the whole cells. Moreover, a weaker hybridization was observed in cytoplasm of HepG2 cells treated with CCl_4. Pretreatment with RNase A nearly abolished the observed results mainly from the specific hybridization to poly$(A)^+$ mRNA with FITC-labeled oligo-$(dT)_{15}$ staining, demonstrating that CCl_4 treatment inhibits the export of poly $(A)^+$ mRNA molecules from the nuclear site by inhibiting nuclear NTPase activity.

DISCUSSION

In 1987, Enzan[13] conducted a study to observe the pro-

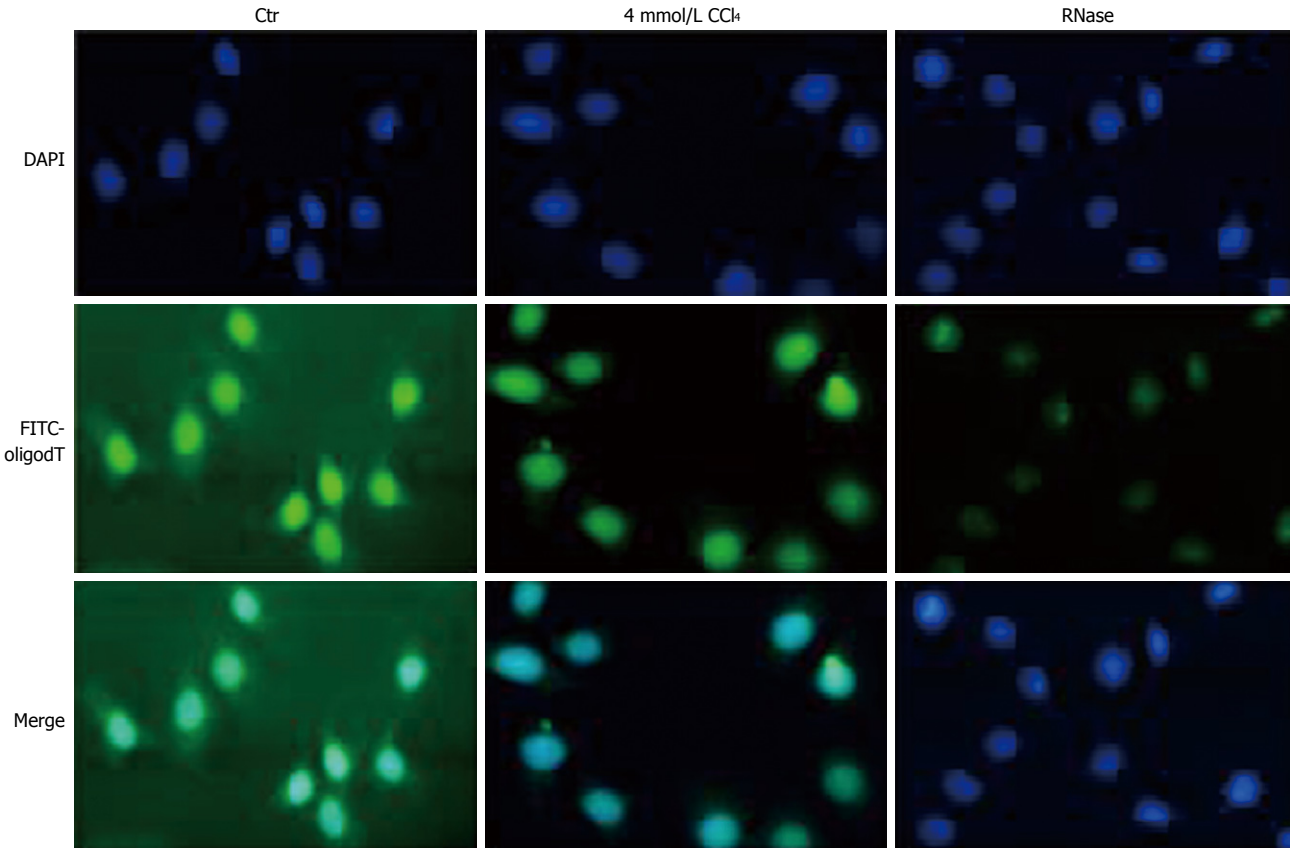

Figure 4 CCl_4 decreases total mRNA nuclear export of HepG2 cells. DAPI: 4,6-diamidino-2-phenylindole dihydrochloride; FITC: Fluorescein isothiocyanate.

tein synthesis of Ito cells in acute liver injury induced by CCl_4. He used small liver tissue blocks from normal and CCl_4-treated mice that was incubated in cultured medium supplemented with ^{3}H-leucine for one hour, and found that a few Ito cells in normal mouse liver tissues were labeled with ^{3}H-leucine, while no labeling over the Ito cells was observed in CCl_4-treated mouse liver without any cellular degeneration, revealing that protein synthesis is blocked in Ito cells after CCl_4 treatment[13]. In this study, ^{3}H-leucine incorporation into liver protein was decreased 30% in CCl_4-treated rats, which is consistent with the findings of Enzan[13].

Both protein synthesis and degradation occur actively in liver in order to maintain the normal metabolism through appropriate steady-state levels of liver proteins. Among the liver protein homeostasis, mature 3'-poly $(A)^+$ mRNA acting as a template appears to be an important determinant regulator for protein synthesis. Thus, all eukaryotic cytoplasmic mature 3'-poly $(A)^+$ mRNA molecules have to be transported from their original nuclei by traversing through the nuclear pore, an active process in which the nuclear membrane-associated NTPase can provide mechanic energy by catalyzing the hydrolysis of nucleoside tri-phosphates[4,10]. Moreover, the effect of changes in nuclear membrane phosphatidylcholine composition by phospholipase A_2 (PLA_2) on mRNA transport is related to the changes in NTPase activity responded to PLA_2[6]. Based on this assumption, we further explored whether protein synthesis in liver inhibited by CCl_4 is related to alterations in nuclear NTPase activity. In brief, the Km value of NE NTPase in CCl_4-treated HepG2 cells increased to 44% (ATP as a substrate) and 42% (GTP as a substrate), respectively (Figure 2B), indicating that NE NTPase in CCl_4-treated HepG2 cells has a lower substrate binding affinity and a lower energy provision for the export process.

Although the nuclear NTPase activity was inhibited by CCl_4 treatment, whether inhibition of protein synthesis in liver inhibited by CCl_4 is also brought out by the decreased the nucleocytoplasmic transport of total mRNA remains unknown. A fluorescent FITC-probe conjugated with 5'-oligomerization with 15 consequent thymine bases was designed to test this hypothesis (Figure 4). The probe can specifically bind to mature mRNA with 3'-poly A^+. Human HepG2 cells treated with CCl_4 decreased the fluorescence strength in cytoplasm, suggesting that CCl_4 inhibits mature mRNA nuclear export and that decreased NE NTPase activity is involved in CCl_4-induced inhibition of total mRNA nucleocytoplasmic transport and protein synthesis in liver.

In this study, the MDA level was 220% higher in CCl_4 treatment group than in control group. However, taurine, a potent scavenger of reactive oxidative radicals, clearly reduced the MDA level in liver of rats treated with CCl_4 (Figure 1B), displaying that CCl_4-induced liver oxidative damage is caused by reactive radicals *via* liver cytochrome P450 metabolism of CCl_4. To further study the effect of free radical levels on alteration in nuclear NTPase activity,

the nuclear extracts were co-incubated with Fenton's radicals at different concentrations for 30 min. The nuclear NTPase activity was inhibited by Fenton's radicals in a dose-dependent manner (Figure 3), suggesting that metabolism of CCl_4 radicals is an intermediate step in inhibiting nuclear NTPase activity, mRNA nucleocytoplasmic transport, and protein synthesis.

The cellular concentration of a protein is determined by a delicate balance of at least seven processes, each one under several potential points of regulation. It has been shown that gene expression is down-regulated by CCl_4 and other chemicals. However, the mechanical mechanism underlying inhibition of protein synthesis in liver induced by CCl_4 is correlated to the decreasing nucleocytoplasmic transport of mature mRNA. Advances in modern chemical industry demand to evaluate the safety of various chemical substances. The comprehensive evaluation of these chemical substances has to be further studied in hepatotoxicity.

COMMENTS

Background

Many proteins produced in liver, such as albumin and prothrombin, are involved in coordination in the body's metabolism. The importance of protein function in pathogenesis of liver disease has been increasingly recognized. Carbon tetrachloride (CCl_4) is an organic solvent widely used in chemical industry. Its hepatotoxicity includes fatty liver and hepatic necrosis, and evidence also shows that CCl_4 inhibits protein synthesis in liver with early hepatotoxic damage. The mechanism underlying alterations in hepatic protein synthesis induced by CCl_4 treatment, however, is largely unknown.

Research frontiers

Among the steady-state levels of liver protein, mature mRNA acting as a template is an important determinant regulator for protein synthesis. The mRNA nucleocytoplasmic transport has to be promoted by mechanic energy from the nuclear membrane-associated nucleotide triphosphatase (NTPase), which can catalyze the hydrolysis of nucleoside triphosphate. Inhibition of protein synthesis in liver is correlated with down-regulation of nucleocytoplasmic transport in total mRNA during hepatotoxicity induced by CCl_4.

Innovations and breakthroughs

This study focused on the effect of mRNA nucleocytoplasmic transport on protein synthesis in liver. The results showed that the decreased NTPase activity of hepatic nuclear envelope inhibits mRNA nucleocytoplasmic transport during protein synthesis in liver inhibited by CCl_4.

Applications

This study highlighted the importance of nucleocytoplasmic mRNA transport in regulation of protein synthesis in liver. Nucleocytoplasmic mRNA transport and gene transcription are deserved in assessment of hepatotoxicity of prospective chemical substances.

Terminology

A nuclear envelope NTPase is a key enzyme involved in nucleocytoplasmic transport by catalyzing the hydrolysis of nucleoside triphosphate. When the activity of injured NTPase in nuclear envelope is decreased, the number of mRNA templates in cytoplasm is influenced.

Peer review

The manuscript is well written and the hypothesis contributes to our understanding of the mechanism underlying CCl_4-induced liver damage.

Abstract

AIM: To analyze the accuracy of computed tomography (CT) angiography in the diagnosis of acute gastrointestinal (GI) bleeding.

METHODS: The MEDLINE, EMBASE, Cancerlit, Cochrane Library database, Sciencedirect, Springerlink and Scopus, from January 1995 to December 2009, were searched for studies evaluating the accuracy of CT angiography in diagnosing acute GI bleeding. Studies were included if they compared CT angiography to a reference standard of upper GI endoscopy, colonoscopy, angiography or surgery in the diagnosis of acute GI bleeding. Meta-analysis methods were used to pool sensitivity and specificity and to construct summary receiver-operating characteristic.

RESULTS: A total of 9 studies with 198 patients were included in this meta-analysis. Data were used to form 2 × 2 tables. CT angiography showed pooled sensitivity of 89% (95% CI: 82%-94%) and specificity of 85% (95% CI: 74%-92%), without showing significant heterogeneity (χ^2 = 12.5, P = 0.13) and (χ^2 = 22.95, P = 0.003), respectively. Summary receiver operating characteristic analysis showed an area under the curve of 0.9297.

CONCLUSION: CT angiography is an accurate, cost-effective tool in the diagnosis of acute GI bleeding and can show the precise location of bleeding, thereby directing further management.

INTRODUCTION

Acute gastrointestinal (GI) bleeding represents a common medical emergency with an annual incidence of 40-150 episodes per 100 000 persons for upper GI hemorrhage and 20-27 episodes per 100 000 persons for lower GI hemorrhage[1]. GI bleeding is usually classified as upper or

lower based on whether the bleeding source is proximal or distal to the ligament of Treitz[2].

Nearly 75% of bleeding will cease spontaneously, however, bleeding can recur in 25% of cases, causing significant morbidity and mortality[3,4]. Mortality rates are generally 3%-5%, but can reach up to 23% with massive bleeding or bleeding that recurs after hospitalization[5].

There are multiple modalities that are currently being used in the evaluation and treatment of acute GI hemorrhage, each with its own strengths and weaknesses[6,7].

Esophagogastroduodenoscopy (EGD) and colonoscopy are currently considered the first-line diagnostic procedures of choice for both upper and lower GI bleeding[8,9]. Endoscopic evaluation allows relatively safe, direct localization and characterization of bleeding lesions within the majority of the upper GI tract as well as in the colon and distal ileum. The distal duodenum and the majority of the small bowel cannot be adequately assessed with conventional endoscopy. The reported sensitivity and specificity of EGD for upper GI bleeding are 92%-98% and 30%-100%, respectively[4].

Noninvasive imaging with technetium-99m (Tc-99m)-labeled red blood cell (RBC) or Tc-99m sulfur colloid scintigraphy can be used to detect and localize GI bleeding. Tc-99m RBC scintigraphy is 93% sensitive and 95% specific for detecting a bleeding site with active arterial or venous bleeding rates as low as 0.2 mL/min[10] anywhere within the GI tract. An advantage of red cell scintigraphy is the ability to carry out delayed scans up to 24 h after radioisotope injection to detect rebleeding. Radionuclide scintigraphy has a false localization rate of approximately 22%, which limits its value as a diagnostic test[11].

Mesenteric angiography can detect bleeding rates greater than 0.5 mL/min and has the advantage of therapeutic intervention through transcatheter embolization. Angiography has a sensitivity of 40%-86%[12,13].

Initial experience indicates that multidetector computed tomography (CT) angiography is a promising first-line modality for the time-efficient, sensitive, and accurate diagnosis or exclusion of active GI hemorrhage and may have a profound impact on the evaluation and subsequent treatment of patients who present with acute GI bleeding.

In this article, we discuss and illustrate the emerging role of CT angiography in the evaluation and localization of acute, active GI hemorrhage.

MATERIALS AND METHODS

Literature search

A comprehensive computer literature search was performed to identify studies assessing the diagnostic value of CT angiography for acute GI bleeding.

The MEDLINE and EMBASE databases, from January 1995 to December 2009, were searched with the following key words: "gastrointestinal hemorrhage" OR "gastrointestinal bleeding" AND "CT angiography" OR "X-ray computed" AND (sensitivity OR specificity OR false-negative OR false-positive OR diagnosis OR detection OR accuracy).

Other databases, such as Sciencedirect, Springerlink, Scopus and the Cochrane library were also checked for relevant articles using the same keywords. The references reported in all retrieved articles were also supplemented with extensive checking.

Selection of studies

Two investigators (Wu LM and Xu JR), who were blinded to the journal, author, institution and date of publication, independently checked retrieved articles. According to a standardized data extraction form, we read all the abstracts to obtain potentially eligible articles, and then we managed to get the full text of these articles to determine whether they were exactly eligible. Disagreements were resolved by consensus.

The inclusion criteria were (1) articles were published in English; (2) CT was used as the index test in the diagnosis of GI bleeding; (3) The reference test had to be angiography, endoscopy, colonoscopy, surgery or a combination; (4) For per-patient statistics, sufficient data were presented to calculate the true-positive (TP), false-negative (FN), false-positive (FP) and true-negative (TN) values; (5) 5 or more patients were included; (6) With regard to the quality of the study design, only articles in which the number of "yes" answers for the 14 questions in the Quality Assessment of Diagnostic Accuracy Studies (QUADAS) quality assessment tool[14] was more than 9 were included; and (7) When data or subsets of data were presented in more than one article, the article with most details or the most recent article was chosen. The authors of abstracts and studies not reporting sufficient data were contacted to request additional information.

The excluded criteria were as follows: (1) Articles which did not include raw data such as reviews, case reports, comments, editorials, letters and congress; (2) Articles which used CT as the tool for diagnosis without information on CT alone; (3) Diagnosis of GI bleeding for other existing diseases and could not be differentiated; and (4) Reports specializing in the etiology of bleeding.

Quality assessment

A quality assessment tool for diagnostic accuracy studies, named "QUADAS", was used to evaluate the quality and to extract relevant study design characteristics of included studies[15]. This tool is an evidence-based quality assessment tool developed for use in systematic reviews of studies of diagnostic accuracy and was fully described by Whiting *et al*[14].

Statistical analysis

2 × 2 tables were extracted on per-patient basis, including the numbers of TP, TN, FP and FN results in each study. Pooled sensitivity and specificity, with 95% CI, were obtained. A value of 0.5 was added to all cells of studies that contained a count of zero to avoid potential

Quality Assessment of Diagnostic Accuracy Studies (QUADAS) score: study quality was evaluated using the 14 items specified in the QUADAS tool. One point was given for each criterion met, giving a total quality score out of 14. N/A: Data not available; CT: Computed tomography.

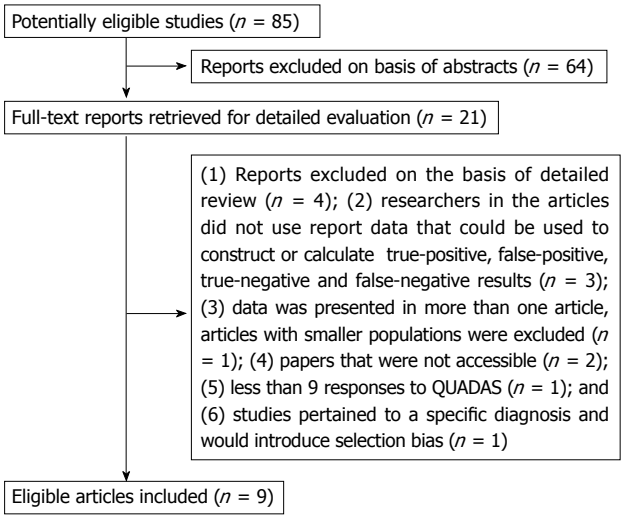

Figure 1 Reports evaluated for inclusion in the meta-analysis. QUADAS: Quality Assessment of Diagnostic Accuracy Studies.

problems in odds calculations for studies with sensitivities or specificities of 100%.

Heterogeneity was assessed with the χ^2-test using a random effects model (DerSimonian and Laird). A summary receiver operating characteristic (SROC) curve was fitted using the Moses and Littenberg model and a weighted area under the curve (AUC) obtained to measure the diagnostic performance of CT angiography. Statistical analysis was conducted using META-DISC software (version 1.4; Clinical Biostatistics Unit, Ramo´ny Cajal Hospital, Madrid, Spain).

RESULTS

Literature search and study design characteristics

The detailed procedure of study selection for the meta-analysis is shown in Figure 1. Eighty five initial studies were searched from all the databases. After reading the abstracts, we reviewed 21 studies in detail. Of these articles, 12 were excluded because: (1) Reports excluded on the basis of detailed review (n = 4); (2) researchers in the articles did not use report data that could be used to construct or calculate TP, FP, TN and FN results (n = 3); (3) data was presented in more than one article, articles with smaller populations was excluded (n = 1); (4) paper was not accessible (n = 2); (5) less than 9 responses to QUADAS (n = 1); and (6) studies pertained to a specific diagnosis and would introduce selection bias (n = 1).

Finally, 9 articles fulfilled all the inclusion criteria and were selected for data extraction and data analysis. We obtained the full text for all 9 eligible studies, some features of each are shown in Table 1.

Study description and study quality

The median number of participants per study was 18 (range 7-41). Our study reported the results by using an individual patient as the unit of analysis. Seven studies used multidetector CT (MDCT), which ranged from a dual-slice CT to a 64-slice CT. Protocols for CT scanning varied among studies, with one study using water as an oral contrast[19], and another study using intraarterial contrast[16]. The criterion for a positive CT was generally extravasation of contrast into the bowel lumen. The study by Ernst *et al*[17] used a broader definition by also including contrast enhancement of the bowel wall, presence of vascular abnormalities, polyp, tumor or spontaneous hyperdensity of peribowel fat. The reference standard among studies consisted of angiography (either digital subtraction or conventional angiography), upper GI endoscopy, colonoscopy and surgery, either alone or in combination.

Of the 9 studies, six[16,17,19,20-23] enrolled patients prospectively. Three studies[18,22,24] were retrospective database reviews.

The severity of GI bleeding varied and included patients who did not require blood transfusion to patients who required multiple transfusions. One study focused on massive GI bleeding - which was defined as hemodynamic

Table 2 Study results

Study	*n*	TP	FP	FN	TN	Sensitivity (95% CI)	Specificity (95% CI)
Ettorre *et al*[16]	18	13	0	3	2	0.81 (0.54-0.96)	1.00 (0.16-1.00)

instability or a transfusion requirement of greater than 4 units of packed cells within a 24-h period[21]. Two primary studies pertained to lower GI bleeding exclusively[18,20].

The quality and completeness of the reporting of studies was variable (quality scores in Table 1). Three studies were retrospective in nature and interpretation of the tests was blinded in only two studies. The reference test was not standardized among studies, raising the possibility of differential verification bias affecting estimates of accuracy.

Pooled sensitivity, pooled specificity and AUC

CT angiography showed pooled sensitivity of 89% (95% CI: 82%-94%) without significant heterogeneity (χ^2 = 12.5, P = 0.13). Pooled specificity was 85% (95% CI: 74%-92%) without showing significant heterogeneity (χ^2 = 22.95, P = 0.003). Using the fitted SROC curve, overall AUC was 0.9297, indicating very good diagnostic accuracy. TP, FN, FP and TN results are shown in Table 2. Sensitivities and specificities are showed in Figure 2, and the SROC curve is shown in Figure 3.

In the study by Miller *et al*[19], six patients had a source of bleeding suggested on CT that was not detected with endoscopy or surgery. One of these patients had a 99mTc red cell scan, which showed a bleeding site in the cecum. The bleeding sites of the other five patients were attributed to bleeding that subsequently stopped or bleeding from a small bowel source, which was difficult to detect with endoscopy. In the absence of any alternative diagnoses, the five positive CT studies were classified as true positives.

DISCUSSION

Acute GI bleeding is an emergency situation with high mortality rates. Therefore, fast detection and localization of the bleeding site are required for effective hemostatic therapy. Currently, the first diagnostic procedure in pa-

tients with upper GI tract bleeding is endoscopy, whereas colonoscopy, conventional angiography or 99mTc-RBC scintigraphy are the standard procedures in patients with lower GI tract hemorrhage. Unfortunately, effective endoscopy may be hampered by blood clots or feces obscuring the bleeding site in unprepared patients, while potential disadvantages of conventional invasive angiography include an increased risk of complications[13]. Inherent drawbacks of scintigraphy are that it is a time-consuming method with only limited sensitivity for the identification of bleeding sites.

Fortunately, with high sensitivity, as shown in our review, CT angiography is a possible option for the investigation of GI bleeding. In an animal model of colonic hemorrhage, Kuhle *et al*[25] reported that single detector helical CT angiography can depict active hemorrhage with a rate of 0.3 mL/min, thus exceeding the sensitivity of mesenteric angiography of 0.5 mL/min and approaching values of RBC scintigraphy of 0.2 mL/min.

Due to higher spatial and temporal resolution provided by MDCT technology, faster scanning times and improved multiplanar reformatted images, the limited number of studies available precludes subgroup analysis to assess whether this has improved the diagnostic accuracy of CT.

Numerous studies have been performed to evidence the role of CT relative to conventional angiography for the diagnostic workup of patients suffering from acute GI bleeding[15,25-27]. These reports include case studies by Krestan *et al*[26], and Singer[27] as well as single-detector row helical CT studies performed in patients[16] and animals[25]. Several studies in our series have shown that CT can diagnose bleeding where angiography failed to locate the source[16,20,28]. In the study by Sabharwal *et al*[20], CT showed the site of bleeding in three patients for whom conventional angiography was negative. Subsequent emergency colonoscopy confirmed the presence of a blood-filled colon without showing the site of bleeding.

Jaeckle *et al*[22] evaluated the accuracy of MDCT for detection and localization of acute upper and lower GI hemorrhage or intraperitoneal bleeding. Thirty-six consecutive patients with clinical signs of acute bleeding underwent biphasic MDCT. MDCT findings were correlated with endoscopy, angiography or surgery. Among the 36 patients evaluated, 26 were examined for GI bleeding and 10 for intraperitoneal hemorrhage. Confirmed sites of GI bleeding were the stomach ($n = 5$), duodenum ($n = 5$), small bowel ($n = 6$), large bowel ($n = 8$) and rectum ($n = 2$). The correct site of bleeding was identifiable on MDCT in 24/26 patients with GI bleeding.

The sensitivity of CT may be higher than reported because GI bleeding is intermittent in nature and the rate of bleeding can vary from minute to minute[29]. A patient may have active GI bleeding shown on CT, which ceased by the time colonoscopy or angiography was carried out. The article by Miller *et al*[19] had five cases with a source of bleeding visible on CT that other methods of investigation failed to detect.

CT angiography is an excellent diagnostic tool for fast and accurate detection and localization of acute GI hemorrhage and intraperitoneal bleeding. Advantages of MDCT for the diagnostic workup of patients with suspected acute abdominal hemorrhage include widespread availability, speed, reproducibility and minimal invasiveness. The complications of invasive angiography, such as groin hematoma, dissection and distal embolization are reported to occur in 1.3%-2.2% of procedures[30,31]. Moreover, CT scanning of the abdomen can be performed immediately during hemorrhagic episodes, and bleeding can be depicted within the small bowel, an anatomic region not readily accessible to endoscopy. Furthermore, when a bleeding site is shown on CT and the initial mesenteric angiographic examination is negative, delayed selective angiography can be carried out to locate and embolize the bleeding vessel[32].

Limitations of CT angiography for detection of acute GI bleeding are the lack of therapeutic options in comparison to those that are available with endoscopy, colonoscopy and angiography, radiation dose, and risks affiliated with contrast material such as allergy, nephropathy, or hyperthyreosis. Another disadvantage of CT angiography is that metallic artifacts can interfere with visualization of contrast in the bowel lumen and lead to false positive results on CT angiography, as shown in the study by Yoon *et al*[33].

In this meta-analysis, bias was considered. To avoid selection bias, not only the MEDLINE and EMBASE databases but also the Sciencedirect, Springerlink, Scopus, and the Cochrane library were searched for relevant articles.

To minimize bias in the selection of studies and in data extraction, reviewers who were blinded to the journal, author, institution and date of publication, independently selected articles on the basis of inclusion criteria. In addition, scores were assigned to study design characteristics and examination results by using a standardized form that was based on the QUADAS tool. The QUADAS tool is an evidence-based quality assessment tool, which was developed for use in systematic reviews of studies of diagnostic accuracy[14].

To ensure all the selected articles were high quality articles, only articles in which the number of "yes" answers for the 14 questions in the QUADAS quality assessment tool[14] was more than 9, were selected. If the number of "no" or "unclear" answers was more than 4, the article was excluded. In this way, we excluded low quality articles to make sure the results of this research are credible.

However, some limitations still exist in this meta-analysis. A potential limitation of any meta-analysis is the possibility of publication bias because studies with optimistic results may be published easier than studies with unfavorable results, and studies with large sample size may be published easier than studies with small sample size. We attempted to examine publication bias by evaluating whether the size of the studies was associated with the results for diagnostic accuracy. No association was found between sample size and diagnostic accuracy.

The inclusion bias should be considered in our study.

Only the studies published in English were selected in this meta-analysis. This could cause unavoidable bias. However, this bias was small because most studies of high quality were published in English. Besides, all primary studies had relatively low numbers of subjects ($n = 7$ to $n = 41$). In practice, larger numbers of subjects are difficult to obtain because CT angiography is not commonly used as an investigation for GI bleeding at most institutions[33]. Thirdly, the overall quality of included studies, as defined in the QUADAS tool, was only moderate. Finally, clinical heterogeneity among studies is also an issue. The severity of GI bleeding varied, with one study focusing on "massive" GI bleeding. The primary different definitions for a positive CT may have resulted in misclassification.

We propose the routine use of CT angiography in the initial radiological investigation of patients who meet the criteria for acute GI hemorrhage. Because it is accurate in the diagnosis of acute GI bleeding and can show the precise location and etiology of bleeding, thereby directing further management. However, further large prospective studies are needed to define the role of CT in acute GI bleeding when other investigations are unable to provide a diagnosis.

COMMENTS

Background

Acute gastrointestinal (GI) bleeding is an emergency situation with high mortality rates. Fast detection and localization of the bleeding site are required for effective hemostatic therapy. Due to higher spatial and temporal resolution provided by multi-row detector computed tomography (MDCT) technology, acquisition of arterial- and portal-venous phase images as well as depiction of active extravasation of contrast material have become feasible.

Research frontiers

MDCT is an excellent diagnostic tool for fast and accurate detection and localization of acute GI hemorrhage and intraperitoneal bleeding. Advantages of MDCT for the diagnostic workup of patients with suspected acute abdominal hemorrhage include widespread availability, speed, reproducibility and minimal invasiveness. Moreover, computed tomography (CT) scanning of the abdomen can be performed immediately during hemorrhagic episodes, and bleeding can be depicted within the small bowel, an anatomic region not readily accessible to endoscopy.

Innovations and breakthroughs

Currently, CT angiography is not widely used in the diagnosis of acute GI bleeding. This meta-analysis confirmed that it has the advantage of being a noninvasive test, which diagnoses the site and cause of bleeding, thereby guiding definitive treatment.

Applications

Invasive selective interventional angiography or surgery can be performed immediately after MDCT has identified the bleeding site. This diagnostic algorithm may lead to a significant reduction in time and may substantially decrease the rate of negative angiographies in the future.

Peer review

This is a systematic review concerning the usefulness of CT angiography on acute GI bleeding. Authors have nicely performed the meta-analysis for the "usefulness of CT angiography in diagnosing acute GI bleeding". This article is well written and beneficial for many physicians.

Abstract

AIM: To evaluate the capacity of ^{18}F-fluorodeoxyglucose positron emission tomography/computed tomography (^{18}F-FDG PET/CT) for detecting multiple primary cancer of upper gastrointestinal (UGI) tract.

METHODS: Fifteen patients (12 without cancer histories and 3 with histories of upper GI tract cancer) were investigated due to the suspicion of primary cancer of UGI tract on X-ray barium meal and CT scan. Subsequent whole body ^{18}F-FDG PET/CT scan was carried out for initial staging or restaging. All the patients were finally confirmed by endoscopic biopsy or surgery. The detection rate of multiple primary malignant cancers was calculated based on ^{18}F-FDG PET/CT and endoscopic examinations.

RESULTS: ^{18}F-FDG PET/CT scan was positive in 32 suspicious lesions, 30/32 were true positive primary lesions, and 2/32 were false positive. In 15 suspicious lesions with negative ^{18}F-FDG PET/CT scan, 12/15 were true negative and 3/15 were false negative. Among the 15 patients, 12 patients had 29 primary synchronous tumors confirmed by pathology, including 8 cases of esophageal cancers accompanied with gastric cancer and 4 of hypopharynx cancers with esophageal cancer. The other 3 patients had 4 new primary metachronous tumors, which were multiple primary esophageal cancers. PET/CT imaging detected local lymph node metastases in 11 patients. Both local lymph node metastases and distant metastases were detected in 4 patients. On a per-primary lesion basis, the sensitivity, specificity, accuracy, negative predictive value and positive predictive value of ^{18}F-FDG PET/CT for detecting multiple primary cancer of UGI tract were 90.9%, 85.7%, 89.4%, 80% and 93.7%, respectively.

CONCLUSION: The whole body ^{18}F-FDG PET/CT may play an important role in evaluating the multiple primary malignant tumors of UGI tract cancer.

Key words: Upper gastrointestinal tract cancer; Esophageal cancer; Gastric cancer; Positron emission tomography/computed tomography; ^{18}F-fluorodeoxyglucose

Multiple primary malignant tumors of upper gastrointestinal tract: A novel role of ^{18}F-FDG PET/CT. *World J Gastroenterol* 2010; 16(31): 3964-3969 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i31/3964.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i31.3964

INTRODUCTION

Metachronous or synchronous esophageal cancer has been identified in patients with head and neck cancer, gastric cancer or colon cancer[1]. Alcohol drinking and tobacco smoking are the major risk factors for upper aerodigestive tract cancers, accounting for a large proportion of cases in developed countries[2,3]. The occurrence of multiple primary cancers in the aerodigestive tract has been explained by the concept of field carcinogenesis. Combined exposure to alcohol and tobacco has a multiplicative effect on carcinogenesis of upper aerodigestive tract[4,5].

X-ray barium meal examination, endoscopic examination, computed tomography (CT) are the main techniques used for the staging and follow-up of upper gastrointestinal (UGI) tract cancer[6,7]. However, the reported increase in sensitivity of ^{18}F-fluorodeoxyglucose positron emission tomography/computed tomography (PET/CT) over CT has been attributed to the capacity of ^{18}F-FDG PET/CT to detect metabolic abnormalities that precede the morphological changes seen by CT. This study was undertaken to further define the value of ^{18}F-FDG PET/CT in evaluating multiple primary metachronous or synchronous cancer of UGI.

MATERIALS AND METHODS

Patients

Fifteen patients with multiple UGI tract cancer (13 males and 2 female, aged 49-78 years with a mean age of 61 years) were selected for a retrospective review from our electronic database, who were imaged by ^{18}F-FDG PET/CT between January 2007 and January 2010 because of the suspicious findings for multiple UGI tract cancer by the X-ray barium meal and endoscopic examinations. All the patients were finally confirmed by endoscopic biopsy or surgery.

^{18}FDG PET/CT technique

The patients were asked to fast for at least 4 h before undergoing ^{18}F-FDG PET/CT. Their blood glucose level should be within the normal range (70-120 mg/dL) prior to intravenous injection of ^{18}F-FDG. The patients received an intravenous injection of 370-666 MBq (10-18 mCi) of ^{18}F-FDG. Data acquisition by an integrated PET/CT system (Discovery STE; GE Medical Systems, Milwaukee, WI, USA) was performed within 60 min after injection. The procedure of data acquisition was as follows: CT scanning was performed first, from the head to the pelvic floor, with 110 kV, 110 mA, a tube rotation time of 0.5 s, a 3.3-mm section thickness, which was matched to the PET section thickness. Immediately after CT scanning, a PET emission scan covering the identical transverse field of view was obtained. Acquisition time was 3 min per table position. PET image data sets were reconstructed iteratively by applying the CT data for attenuation correction, and coregistered images were displayed on a workstation.

PET/CT image interpretation

The ^{18}F-FDG PET/CT images were prospectively interpreted by two experienced nuclear physicians. One had 21 years of experience in both nuclear medicine and radiology, and the other had six years of experience in both nuclear medicine and radiology, who read the ^{18}F-FDG PET/CT images on a high-resolution computer screen, and reached a consensus in cases of discrepancy.

Based the knowledge of the normal biodistribution of ^{18}F-FDG, lesions were identified as foci with increased tracer accumulation relative to that in comparable normal contralateral structures and surrounding soft tissues. The lesions were qualitatively graded as definitely or probably abnormal (categorized as representing a tumor) if the accumulation of ^{18}F-FDG was markedly to moderately increased. Diffuse and mildly increased activity or no increased activity (in the case of an abnormality identified on CT, but no corresponding abnormality was present on PET) was considered to be a normal or benign disease.

Statistical analysis

The results of PET/CT were quantified using the following definitions: accuracy [(true positive) + (true negative)/(total patients)], sensitivity [(true positive)/(true positive + false negative)], specificity [(true negative)/(true negative + false positive)], positive predictive value [(true positive)/(true positive +false positive)], and negative predictive value [(true negative)/(true negative + false negative)].

RESULTS

Clinical presentation

At the time of multiple primary lesions of suspected UGI cancer, the mean age of the patients was 61 years with a predominant tendency in men. Twelve men and one woman had heavy tobacco and alcohol consumption histories in this group of patients.

PET/CT is able to demonstrate the entire UGI tract in almost all patients, even following incomplete endoscopic examination due to obstructing upper esophageal tumors in 4 patients (Figure 1). PET/CT imaging is helpful to guide accurately localization of lower esophageal lesions in the remaining patients.

PET/CT diagnosis

^{18}F-FDG PET/CT scan was positive in 32 suspicious lesions, of which 30 were true positive primary lesions and 2 were false positive. Among 15 suspicious lesions with negative ^{18}F-FDG PET/CT scan, 12 were true negative and 3 were false negative.

On a per-primary lesion basis, sensitivity, specificity, accuracy, negative predictive value and positive predictive value of ^{18}F-FDG PET/CT in detecting multiple primary cancer of UGI tract were 90.9%, 85.7%, 89.4%, 80% and 93.7%, respectively.

Primary tumor, *local lymph node metastases and distant metastases*

Of the 15 patients, 12 patients had 29 primary synchro-

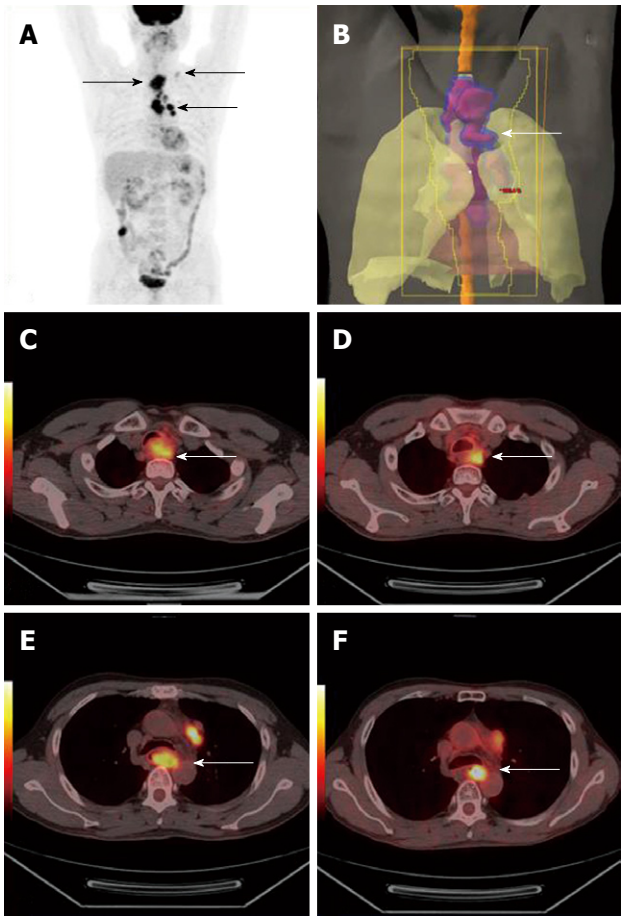

Figure 1 A 52-year-old man with synchronous multiple esophageal cancers. The first positron emission tomography/computed tomography (PET/CT) images revealed multiple hypermetabolic esophageal lesions and hypermetabolic supraclavicular, mediastinal lymph nodes (arrows in A, C, E). PET/CT imaging guided radiation plan (arrows in B). The second PET/CT images after 50Gy radiation treatment demonstrated shrinkage of lesions and decrease of fluorodeoxyglucose uptake (arrows D, F).

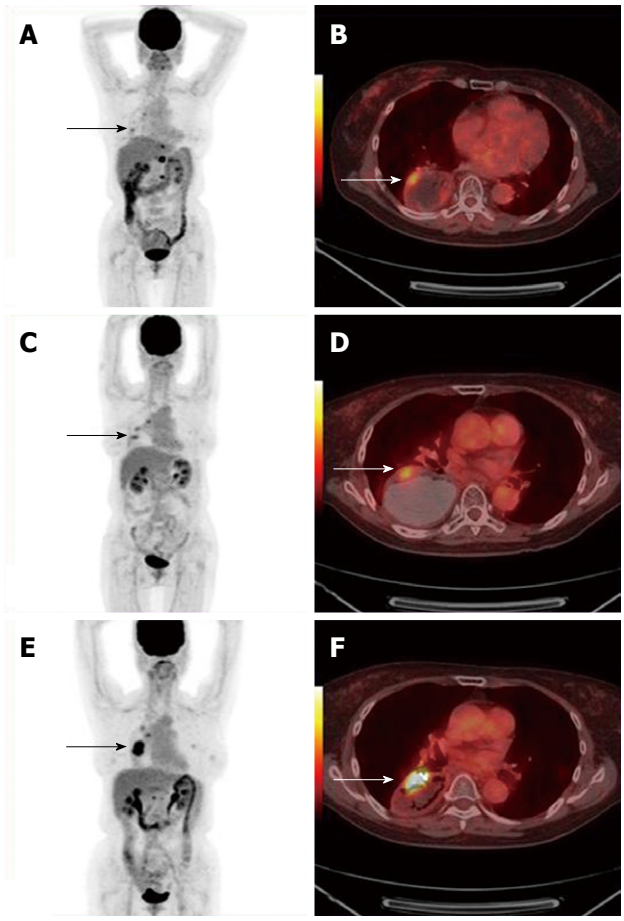

Figure 2 A 56-year-old woman with metachronous gastric cancer after esophageal cancer resection 5 years ago. Positron emission tomography/computed tomography (PET/CT) displayed multi-retroperitoneal lymph node recurrence (arrow in A), which was later verified as esophageal cancer metastasis (squamous cell carcinoma). PET revealed a small lesion at gastric tube, but endoscopy was negative (arrows in A, B, C, D). Third PET/CT showed an enlarged gastric lesion, and endoscopic biopsy verified gastric tube cancer (adenocarcinoma) (arrows in E, F).

nous tumors confirmed by pathology (Table 1), including 8 cases of esophageal cancer combined with gastric cancer and 4 had hypopharynx cancer combined with esophageal cancer. The other 3 patients had 4 new primary metachronous tumors (Table 2 and Figure 2).

PET/CT imaging detected local lymph node metastases in 11 patients (Figure 3). Both local lymph node metastases and distant metastases were detected in 4 patients.

Impact on clinical management

Clinical treatment plans were changed in 11 (73.3%) patients after PET/CT examination. ^{18}F-FDG PET/CT imaging-guided radiotherapy was performed in 11 patients.

DISCUSSION

Synchronous cancers were predominantly located in the aerodigestive tract, primarily in the lung, head and neck and esophagus[8]. Kumagai *et al*[9] reported half of the patients with multiple upper aerodigestive tract squamous cell carcinomas are initially seen with synchronous tumors. It is also believed that these second primary cancers arise independently following exposure to a common carcinogen by a process that has been called field cancerization[10]. At least 75% of head and neck cancers are attributable to a combination of cigarette smoking and alcohol drinking[11]. In our cases, 13 patients (86.7%) had heavy tobacco and alcohol consumption histories. Synchronous tumors of UGI tract were detected in 12 patients. Esophageal cancers combined with gastric cancer (53.3%) were most frequently seen in our study.

Patients with primary head and neck malignancies have a 3%-7% yearly incidence of second primary cancers. Most metachronous squamous cell carcinomas become manifest within 3 years[12]. Detection of second primaries has an important impact on therapy. For the patients treated for advanced squamous cell carcinoma in the oral cavity or oropharynx during the first year after completion of their curative treatment, routine surveillance for detecting early locoregional recurrence, distant metastases, and second metachronous primary tumors is very important[13,14]. Due to the poor prognosis of head

and neck cancer, the data of metachronous cancer of UGI tract were limited. In this study, 3 patients had 4 primary metachronous tumors. The interval from first tumor to second tumor ranged from 5 to 10 years.

In the majority of follow-up protocols, radiologic and endoscopic evaluation has been proven to be useful in the early detection of metachronous and recurrent neoplasms in the follow-up of patients with previously treated carcinomas of the ear, nose, and throat. Adequate staging of UGI cancer including CT and endoscopic ultrasonography has been considered to be helpful for avoiding useless surgery[15,16]. However, more than 30% of the distant metastases have been reported to be radiographically occult with conventional diagnostic strategy and surgery. It has been still performed in a considerable number of patients with distant metastases. Moreover, the overall survival after curative resection does not exceed 25%, with an overall median disease-free survival of only 12 mo.

Conventional staging methods consisting of both CT and EUS evaluate local unresectability or metastatic diseases based on the anatomic alterations. Their low sensitivity and low specificity were related to the low accuracy in determining a curative surgery, indicating the demand for a different approach[17,18]. In contrast to conventional anatomic imaging, PET can reveal metabolic alterations in tumor tissues. Most malignant tumors present a high uptake of ^{18}F-FDG due to an increased anaerobic glycolysis[19]. In our previous studies, ^{18}F-FDG PET/CT was found to be valuable in detecting previously unknown metastases in esophageal cancer. Routinely performed ^{18}F-FDG PET/CT in the preoperative work-up of these tumors may therefore reduce the number of unnecessary surgical procedures[20].

There have been several investigations into the utility of ^{18}F-FDG PET or PET/CT in relation to multiple primary cancers detection. Major advantages of the whole body ^{18}F-FDG PET/CT are the capability to perform full-body scan with the potential to detect local and distant metastases in one single examination and the possibility of distinguishing new active disease from scar or necrotic tissues[21,22] since tumors with increased ^{18}F-FDG uptake are more metabolically active and biologically aggressive[23,24].

The accurate staging of multiple primary cancer of UGI tract is essential to select appropriate treatment and to anticipate disease progression. Conventional imaging methods that rely on detection of the structural changes caused by tumors usually have limitations in determining the extent of UGI, especially lymph node metastasis[25,26]. PET/CT is a fundamentally different imaging technique that identifies focal areas of increased metabolism associated with malignancies. PET/CT is more sensitive than regular CT scan in determining regional and distant lymph node involvement in the squamous cell carcinoma as well as adenocarcinoma of the esophagus. PET can play an important role in evaluating the pretreatment staging of esophageal cancer[27,28]. A noteworthy finding in the present study is the high incidence of 100% (13/13) of local lymph node metastases and distant metastases

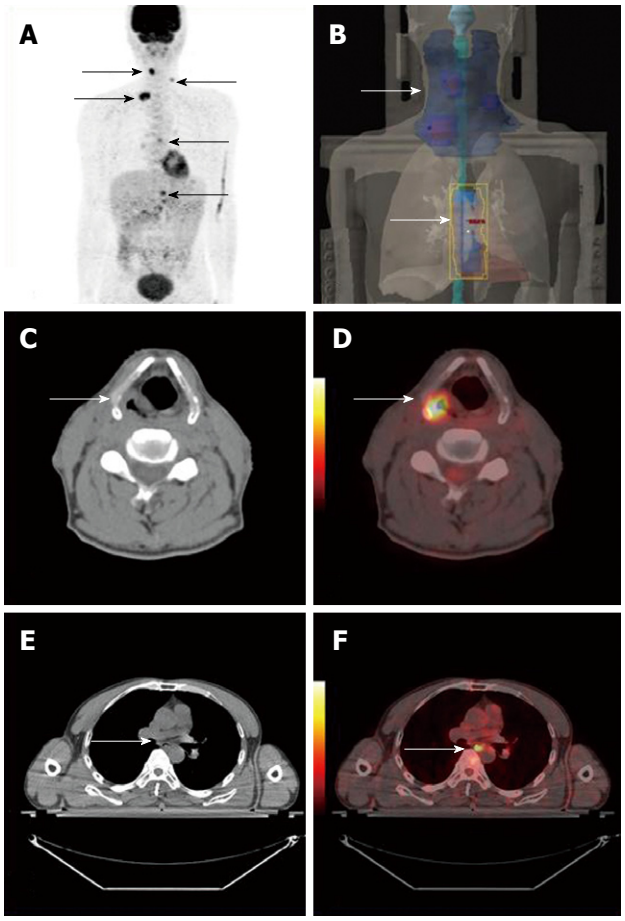

Figure 3 A 53-year-old woman with synchronous hypopharynx cancer combined with esophageal cancer. Positron emission tomography/computed tomography (PET/CT) images revealed hypermetabolic hypopharynx and esophageal lesions, and multiple hypermetabolic supraclavicular, mediastinal lymph nodes (arrows in A). PET/CT imaging guided radiation plan (arrows in B). CT and PET/CT fused images showed hypermetabolic hypopharynx and esophageal lesions (arrows in C, D, E, F).

detected by ^{18}F-FDG PET/CT. Furthermore, clinical decisions of treatment were changed in 11 patients after PET/CT examinations.

There are several limitations in this study. First, due to the retrospective feature of the study, we did not get all of the medical details for some of the patients. There are also some disadvantages associated with PET/CT imaging. For example, small tumors might be undetected because partial-volume effects result in a falsely low measurement of true ^{18}F-FDG activity[29]. Another drawback of PET/CT is that ^{18}F-FDG frequently accumulates in areas of inflammation. Variable physiologic FDG uptake patterns and benign pathological causes of ^{18}F-FDG uptake can be specifically recognized and properly categorized in other instances[30].

The choice of diagnostic techniques must be based on the site and histologic characteristics of the synchronous tumors. Although ^{18}F-FDG PET/CT may be the preferred technique for staging UGI cancer, it can not replace other techniques, such as Lugol chromoendoscopy, for detecting synchronous UGI cancer in high-risk populations[31].

Our results suggested that ^{18}F-FDG PET/CT may be useful in evaluating the multiple primary malignant tumors of UGI cancer. It may play an important role in the initial staging of multiple synchronous or metachronous UGI tract cancers.

COMMENTS

Background

Multiple primary malignancies in a single patient are relatively rare but have increased in frequency in recent decades. Metachronous or synchronous esophageal cancer has been identified in patients with head and neck cancer, gastric cancer or colon cancer. Alcohol drinking and tobacco smoking are the major risk factors for upper aerodigestive tract cancers, accounting for a large proportion of cases in developed countries. The occurrence of multiple primary cancers in the aerodigestive tract also has been explained by the concept of field carcinogenesis. Combined exposure to alcohol and tobacco has a multiplicative effect on carcinogenesis of upper aerodigestive tract.

Research frontiers

Positron emission tomography/computed tomography (PET/CT) provides anatomic landmarks for better characterization of increased ^{18}F-fluorodeoxyglucose (^{18}F-FDG) uptake. PET/CT is a widely accepted imaging method in the management of a wide variety of cancers. The reported increase in sensitivity of PET/CT over conventional techniques has been attributed to the ability of PET/CT to detect metabolic abnormalities that precede the morphologic changes seen by CT. However, the usefulness and limitations of ^{18}F-FDG PET/CT in evaluating multiple primary malignant tumors of upper gastrointestinal tract still need further clinical evaluations.

Innovations and breakthroughs

The early detection of multiple primary malignant tumors of upper gastrointestinal (UGI) cancer will enable prompt management and will increase the cure rate of the disease. Whole body ^{18}F-FDG PET/CT scan could provide valuable information for early detection and might guide salvage treatment for multiple primary malignant tumors of UGI cancer.

Applications

^{18}F-FDG PET/CT may be useful in evaluating the multiple primary malignant tumors of UGI cancer. It may play an important role in the initial staging of multiple synchronous or metachronous UGI tract cancers.

Peer review

The manuscript is very well written and should be accepted for publication.

Abstract

AIM: To assess the clinical outcomes of pre-, pro- and synbiotics therapy in patients with acute pancreatitis.

METHODS: The databases including Medline, Embase, the Cochrane Library, Web of Science and Chinese Biomedicine Database were searched for all relevant randomized controlled trials that studied the effects of pre-, pro- or synbiotics in patients with acute pancreatitis. Main outcome measures were postoperative infections, pancreatic infections, multiple organ failure (MOF), systemic inflammatory response syndrome (SIRS), length of hospital stay, antibiotic therapy and mortality.

RESULTS: Seven randomized studies with 559 acute pancreatic patients were included. Pre-, pro- or synbiotics treatment showed no influence on the incidence of postoperative infections [odds ratios (OR) 0.30, 95% confidence interval (CI): 0.09-1.02, P = 0.05], pancreatic infection (OR 0.50, 95% CI: 0.12-2.17, P = 0.36), MOF (OR 0.88, 95% CI: 0.35-2.21, P = 0.79) and SIRS (OR 0.78, 95% CI: 0.20-2.98, P = 0.71). There were also no significant differences in the length of antibiotic therapy (OR 0.75, 95% CI: 0.50-1.14, P = 0.18) and the mortality (OR 0.75, 95% CI: 0.25-2.24, P = 0.61). However, Pre-, pro- or synbiotics treatment was associated with a reduced length of hospital stay (OR -3.87, 95% CI: -6.20 to -1.54, P = 0.001). When stratifying for the severity of acute pancreatitis, the main results were similar.

CONCLUSION: Pre-, pro- or synbiotics treatment shows no significant influence on patients with acute pancreatitis. There is a lack of evidence to support the use of probiotics/synbiotics in this area.

INTRODUCTION

Acute pancreatitis (AP) is an acute inflammatory process

in mild to severe forms with a high mortality rate, frequently associated with necrosis of the gland[1]. The infected pancreatic necrosis is a principal late complication and a major cause of morbidity and mortality in patients with severe acute pancreatitis. In view of the deleterious effects of infected necrotizing pancreatitis, prophylactic antibiotics have been widely used. However, some randomized controlled trials (RCTs) and meta-analysis have not demonstrated significant benefits of prophylactic antibiotics on patients with necrotizing AP[2-4]. It is also not recommended for the routine use in sterile pancreatic necrosis[5].

A new anti-infectious strategy is needed. The administration of probiotics/synbiotics modulating the intestinal microbiota may be a valuable treatment option. Lilly and Stillwell first defined the term "probiotics" as ingestible microorganisms that benefited the host by improving intestinal microbial balance[6]. Previous studies showed the clinical benefits of probiotics (including *Lactobacilli* and *Bifidobacteria*), such as inhibiting proliferation of harmful bacteria, protecting the intestinal barrier, preventing gut bacterial translocation to blood and distant sites, and modulating the immune function[7,8], all of which contributed to the reduction of the incidence of nosocomial infections related to intestinal microbial imbalance. Prebiotics are also beneficial to enhancing the effects of enteral nutrition and probiotics[9-11]. For example, as one of the most important prebiotics, fibers can selectively stimulate growth or activity of certain colonic bacteria[12]. In addition, fibers are broken down by the probiotic bacteria to produce a whole series of nutrients including short-chain fatty acids which can stimulate mucosal cell growth, reduce translocation, and enhance the intestinal immune function in colon. Combined use of probiotics and prebiotics, which are called synbiotics, have been shown to enhance immunomodulating ability, balance gut microbiota, inhibit bacterial translocation and reduce the incidence of nosocomial infections in clinically surgical patients.

Evidences showed that the use of pro- or synbiotics might reduce postoperative infections after abdominal surgery[13-15]. Several RCTs have also been performed demonstrating a therapeutic and preventive effect of pre-, pro- or synbiotics treatment in patients with acute pancreatitis[16-18]. However, these studies were small in size, and have been underpowered. Recently, a multi-center RCTs reported some unexpected results contradicting the previous studies[19]. This trial was controversial for some shortcomings. Overall, the magnitude of the therapeutic effect remains unknown. We therefore performed this meta-analysis to assess the potential effects of pre-, pro- or synbiotics treatment in patients with acute pancreatitis by reviewing the current literature, and synthesizing the available data.

MATERIALS AND METHODS

Literature search strategy

A systematic review of the literature was performed to identify all RCTs assessing the effects of pre-, pro- or synbiotics treatment in acute pancreatitis. Two authors independently searched the database including Medline (1966 to March 2010), Embase (1980 to March 2010), Web of Science, Chinese Biomedicine Database (1979 to March 2010) and the Cochrane Library (2010, issue 1) with no language restriction using the following terms: "(prebiotic* OR probiotic* OR synbiotic* OR lactobacillus OR Bifidobacterium OR Lactobacilli) AND (acute pancreatitis)". We identified relevant studies initially by title, abstract, and finally by full text. The reference lists of all selected RCTs and previous systematic reviews were also searched by hand. If duplicate article was published by the same author using the same case series, the data from the most recent manuscript publications was included.

Inclusion and exclusion criteria

Only RCTs evaluating the use of pre-, pro- or synbiotics in patients with acute pancreatitis were included in this review. The trials should have at lease one of the followings as a primary outcome variable: number of infections and pancreatic infectious complications, number of multiple organ failure (MOF) and systemic inflammatory response syndrome (SIRS), surgical interventions, length of hospital stay, and mortality. Major reasons for exclusion of studies were (1) animal studies; (2) duplicate publication; and (3) no usable data reported.

Data extraction

Data was abstracted independently by two reviewers according to the following selection criteria: study design and period, population, intervention, and outcome variables listed above. Disagreement was resolved by discussion.

Methodological quality

We assessed the quality of the studies based on the random method, allocation concealment, blinding and follow-up. The methodological quality of the studies included in the meta-analysis was also scored with the Jadad scale[20], which was a 5-point quality scale defining low quality studies as having a score of < 3 and high-quality studies as having a score of $\geqslant 3$.

Statistical analysis

The statistical analysis was performed using the free software Review Manager (Version 5.0; The Nordic Cochrane Centre, The Cochrane Collaboration, Copenhagen, Denmark, 2008). Dichotomous data was presented as odds ratio (OR) with 95% confidence intervals (CI). Statistical heterogeneity was measured using the Chi-square test and the inconsistency index (I^2). A χ^2 P value < 0.05 was considered to indicate statistically significant heterogeneity. Fixed effects model was used when there was no heterogeneity of the results. Otherwise, the random effects model was used. Subgroup analyses stratified by the severity of acute pancreatitis were performed. Sensitivity analyses were performed only in high quality trials to avoid errors caused by poor quality studies. Visual

Table 1 Methodological characteristics of the clinical trials included in this meta-analysis

Trial	Patients (synbiotics/control)	Characteristics of patients (synbiotics/control)	Intervention	Control group	Length of treatment (d)
Oláh *et al*[16] (UK, 2002)	45 (22/23)	Mean Glasgow score (2.5/2.8), mean CRP (206.5/188.7) mg/L	10^9 *L. plantarum* 299 + EN + 10 g oat fiber	EN + heat-killed *L. plantarum* 299 + oat fiber	7
Oláh *et al*[17] (UK, 2007)	62 (33/29)	Mean Imrie score (2.9/3.1), mean CRP (216.7/191.2) mg/L	Four LAB: 10^{10} *P. pentosaceus*, *Leuconostoc mesenteroides*, *L. paracasei* and *L. plantarum* + four bioactive fiber (Synbiotics 2000) + EN	EN + four bioactive fiber	7
Karakan *et al*[25] (Turkey, 2007)	30 (15/15)	Mean APACHE Ⅱ score (9.4/9.6), mean CRP (232/244) mg/L	24 g multi-fibers including soluble fibers and insoluble fibers + EN	EN	6-13
Qin *et al*[18] (China, 2008)	74 (36/38)	Mean APACHE Ⅱ score (8.8/8.9), mean CRP (125/136) mg/L	10^8 *L. plantarum* + EN + PN	PN	7
Besselink *et al*[19] (Netherlands, 2008)	296 (152/144)	Mean APACHE Ⅱ score (8.6/8.4), mean Imrie score (3.3/3.4), mean CRP (268/270) mg/L	Six LAB: 10^{10} *L. acidophilus*, *L. casei*, *L. salivarius*, *L.lactis*, *B. bifidum*, and *B. lactis* (Ecologic 641) + cornstarch + maltodextrins + fiber-riched EN	Cornstarch + maltodextrins + fiber-riched EN	28

inspection of asymmetry in funnel plots was conducted to assess the potential for publication bias.

RESULTS

Main characteristics of the studies

A total of 48 papers relevant to the searching words were identified through the bibliographic search. After initial eligibility screening, 41 of these papers were excluded, of which 24 were not randomized controlled studies, 10 were not conducted in humans, 3 did not report usable data, and 4 were duplicate publications[21-24]. Only 7 RCTs involving 559 patients met the inclusion criteria and were included in the meta-analysis[16-19,25-27]. The flow chart of study selection is summarized in Figure 1.

The main characteristics of the included patients between two groups were well matched in all RCTs (including age and gender). Five studies compared the score of the second acute physiology and chronic health evaluation (APACHE Ⅱ)[18,19,25-27], and five studies compared C-reactive protein[16-19,25]. Two of the studies tested a probiotics[16,18], one of the studies tested a prebiotics[25], while the remaining four studies tested a synbiotics (probiotics plus prebiotics)[17,19,26,27]. Five studies recruited patients with severe acute pancreatitis[17,19,25-27], and two studies recruited patients with mild, moderate and severe degrees of pancreatitis[16,18]. Patients with biliary tract diseases were excluded in one of the studies[16]. Only three studies reported adverse effects associated with administration of pre-, pro- or synbiotics, which included bowel ischemia, catheter-related sepsis, tube intolerance and reintube. The study details are summarized in Table 1. The surgical outcomes from the RCTs included in this meta-analysis are presented in Table 2.

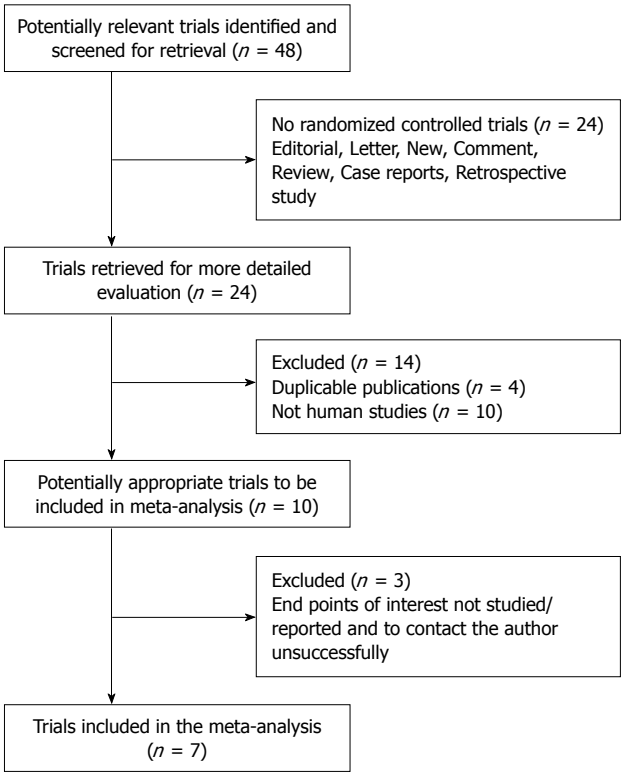

Figure 1 Flow chart showing the study selection procedure.

Quality assessment

Four of these studies were double blind[16,17,19,25]. Allocation concealment was adequate in 3 studies[17,19,25], and unclear in 4 studies[16,18,26,27]. The Jadad score of the studies was evaluated and ranged from 1 to 5 (mean 2.9). Most of the studies were small in size (85.7% had 100 or less

participants). Follow-up was only reported in two studies[18,19]. The quality assessment of the studies is presented in Table 3.

Infectious complications and pancreatic infection

The incidence of infectious complications was reported in all 7 RCTs in the meta-analysis. The type of infections included pancreatic abscess, infected pancreatic necrosis, pneumonia, catheter-related septic complication, urinary tract infections, wound infections, and sepsis or bacteremia. Overall, there were no significant differences of incidence of total infections in pancreatic patients between the probiotics/synbiotics group and the control group (OR = 0.3, 95% CI: 0.09-1.02, P = 0.05) (Figure 2A). There was significant heterogeneity between studies (I^2 = 84%, P < 0.0001).

Only three studies reported pancreatic infections[16,17,19]. Pancreatic infections included pancreatic abscess and infected pancreatic necrosis. There was no significant difference in the pancreatic infections between the probiotics/synbiotics group and the control group (OR 0.50, 95% CI: 0.12-2.17, P = 0.36) (Figure 2B). The test result for heterogeneity was also significant (I^2 = 73%, P = 0.03).

MOF and SIRS

There were no significant differences in the incidence of MOF and SIRS between the probiotics/synbiotics group and the control group. The odds ratio and 95% CI: were 0.88 (0.35-2.21, P = 0.79) in MOF based on five studies[16-19,25], and 0.78 (0.20-2.98, P = 0.71) in SIRS based on three studies[16-18]. Combination analysis of MOF and SIRS also showed no significant differences between the two groups (OR 0.75, 95% CI: 0.23-2.50, P = 0.64) (Figure 2C). The significant heterogeneity was present among the studies (I^2 = 83%, P < 0.0001).

Length of antibiotic therapy, and hospital stay

Four studies involved in the meta-analysis provided applicable data on length of hospital stay[19,25-27]. The length of hospital stay was significantly shorter in the probiotics/synbiotics group (OR -3.87, 95% CI: -6.20 to -1.54, P = 0.001) (Figure 2D). However, there was no significant difference in the length of antibiotic therapy (three RCTs, OR 0.75, 95% CI: 0.50-1.14, P = 0.18) between the probiotics/synbiotics group and the control group[16,18,19]. The test result for heterogeneity was not significant (P = 0.08 in hospital stay, P = 0.33 in antibiotic therapy).

Surgical intervention and mortality

Three studies reported significant difference in surgical intervention (OR 0.59, 95% CI: 0.11-3.07). Mortality was reported in six of seven RCTs[16-19,25,27]. There was no significant difference in the mortality between the probiotics/synbiotics group and the control group (OR 0.75, 95% CI: 0.25-2.24, P = 0.61) (Figure 2E). The significant heterogeneity was present between studies (P = 0.009 in surgical intervention; P = 0.04 in mortality).

Stratification, sensitivity analysis and publication bias

We analyzed the surgical outcomes stratified by the se-

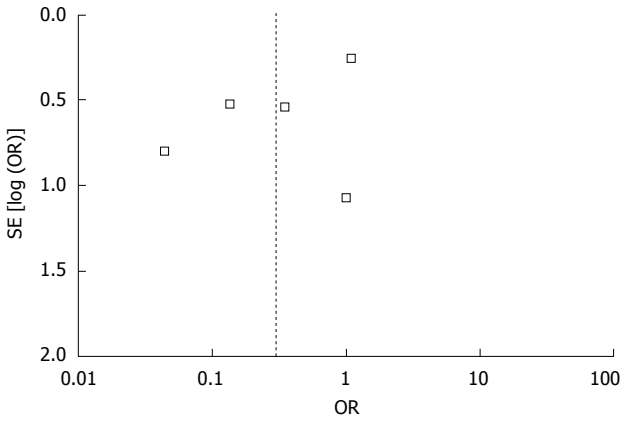

Figure 3 Funnel plot of publication bias.

verity of acute pancreatitis. The use of pre-, pro- or synbiotics had no significant influence on the main surgical outcomes including septic morbidity, pancreatic infections, surgical intervention, mortality, MOF and SIRS in severe acute pancreatitis (Table 4).

Allocation concealment and blinding were unclear in three of included studies[18,26,27]. The results of the sensitivity analysis based on the remaining four studies, after excluding trials of low quality, are similar to the previous results, indicating that the results of meta-analysis are relatively credible. Review of funnel plots is present in Figure 3, which can not rule out the potential for publication bias in all analyses.

DISCUSSION

The microbiota colonizing the gastrointestinal tract has been considered as the main causes of the pathogenesis of the nosocomial infections[28,29]. Surgical trauma, especially surgical trauma of the digestive tract, may result in physical injury and atrophy of the gastrointestinal mucosa, increased intestinal permeability, microbial imbalance, and intraluminal bacterial or bacterial products translocation cross the intestinal barrier to local lymph nodes and distant organs, and ultimately induce an increased morbidity of infectious complications and sepsis[30,31]. At present, probiotics and prebiotics have been administrated in surgical trauma[28,32-34], cancer[30,35,36], active ulcerative colitis[37], and critically ill patients[31,38,39].

Up to now, nine RCTs including 733 patients have been published reporting the effects of pre-, pro- or synbiotics treatment in patients undergoing abdominal surgery. Six studies showed a significantly positive effect of probiotics with or without prebiotics in postoperative septic complications, and the remaining three studies showed no effects. A meta-analysis based on these studies demonstrated that the use of pre-, pro- or synbiotics might reduce the incidence of postoperative infections, duration of hospital stay and length of antibiotic therapy after abdominal surgery[40]. Another meta-analysis based on eight randomized studies reported that the use of pre-, pro- or synbiotics in critically ill adult patients showed no statistically significant benefit in the length of ICU stay, hospital mortality and the incidence of nosocomial infections[41]. However, this meta-analysis did not include postoperative patients and trauma patients admitted to ICU, most of them benefited from probiotics treatment[29-31]. From our meta-analysis, we found that the use of pre-, pro- or synbiotics had no influence on the main outcomes including postoperative infections, pancreatic infections, MOF, SIRS and mortality in patients with acute pancreatitis. In the subgroup analysis and sensitivity analysis, a similar result was observed, after the stratification was conducted by the severity of acute pancreatitis and the trials of low quality were excluded.

There were controversies on the use of pre-, pro- or synbiotics in patients with acute pancreatitis among the recent studies. Three studies suggested that probiotics administration was effective in preventing complications of the experimental acute pancreatitis by decreasing bacterial translocation[42-44]. The first clinical trial was performed by Oláh *et al*[16] to evaluate the use of probiotics and fiber in clinical patients with acute pancreatitis. The study demonstrated that a dose of 10^9 of *L. plantarum* 299 together with oat fiber significantly reduced infected pancreatic necrosis and the number of surgical interventions. Subsequently, several studies reported similarly positive effects of probiotics with or without prebiotics[17,18,25-27]. However, the sample size in these studies was small and the conclusion from them was inconclusive. A large multi-center, randomized double-blinded controlled trial by Besselink *et al*[19] was designed to see whether probiotics could reduce the incidence of infectious complications in patients with severe acute pancreatitis. The trial involved 296 patients in 15 hospitals, and compared the use of a multi-species probiotics preparation with a placebo. The results showed that infectious complications occurred in 30% of the pa-

tients in the probiotics group and in 28% of the placebo group. Nine patients developed bowel ischaemia (8 died) in the probiotics group, whereas none developed this complication in the placebo group. Multiple organ failure occurred in 22% of the patients in the probiotics group and in 10% in the placebo group. In all, 16% patients in the probiotics group and 6% in the placebo group died. The results were opposite to previous evidences, and raised safety question on the use of pre-, pro- or synbiotics. Although Dutch's study was criticized for its design, approval, and conduct, this trial should still be carefully considered for its large sample size[45]. The previous studies have demonstrated that probiotics are safe for use in healthy persons, but should be used with caution in patients with underlying immune compromise, chronic disease, or debilitation because of the risk of sepsis[46]. However, bowel ischemia has never been reported in the previous studies including acute pancreatitis, trauma, critical illness and elective abdominal surgery, and the high incidence of MOF and mortality associated with probiotics treatment were only reported in Besselink's study. Besselink *et al*[19] explained that it was probably not the combination of probiotics but the administration of the combined probiotics together with the severity of the disease that was largely responsible for the effects obtained. This explanation may be one of potential reasons, but not the only one.

There are three major differences between Besselink's study and the other studies in the meta-analysis: the patients in the former received a higher number and more strains of probiotic organisms (six strains of probiotics *vs* 1-4 strains of probiotics in other studies); patients received probiotics administration for a longer period in Besselink's study (28 d *vs* 7 d in the other studies), and the pressor agents were administrated during probiotics feeding in some patients. Little work has been performed and no accepted recommendation was reported on the therapeutic strategy (including the optimal dose and time) of probiotics. The dose of probiotics administered was usually based on the previous studies showing clinical benefit from probiotics. Furthermore, the dose of probiotics varies considerably among different studies. In this meta-analysis, three of the studies tested a probiotics or prebiotics[16,18,25] and showed preventive effects. The remaining four studies tested different doses of synbiotics (probiotics plus prebiotics)[17,19,26,27], 3 of which showed positive results[17,26,27]. Combination of several strains of probiotics was regarded as more powerful in previous opinion. This study indicates that the inappropriate combination of probiotic strains may be harmful, while a single use of probiotics or prebiotics may be safer. Evidences suggest that intestinal blood flow at the mucosal level is generally reduced in acute pancreatitis and critically ill patients[47]. The reduced blood flow and oxygen supply in intestinal mucosa might be further compromised by the administration of enteral nutrition and probiotic bacteria[48,49]. On the other hand, feeding probiotics might cause local mucosal damage with an inflammatory response of the small bowel wall. Multispecies probiotics mixture may strongly increase the concentration of IL-10, and reduce the concentration of IL-6[50]. Experimental studies demonstrated that the increasing IL-10 is able to induce intestinal damage during intestinal ischemia/reperfusion[51], whereas IL-6 is able to protect enterocytes[52]. One may speculate that a long duration of probiotics treatment and a high number of bacterial organisms may lead to probiotics overload in the small bowel, which aggravate the disorder of inflammatory response and reduction of intestinal blood flow and oxygen supply at the phase of acute stage of severe acute pancreatitis, and ultimately lead to bowel ischemia.

The unexpected deleterious effects may refer to more biologic actions of probiotics. It is clear that different strains of probiotics can have different effects. Moreover, their effects may vary in healthy people and patients, in different disease states, and among different age groups. Thus, clinical effects of one probiotics strain in one population cannot be automatically generalized to other strains or to other populations[46]. Although the individual strains used in this study are credible on the basis of their capacity to inhibit growth of pathogenic bacteria and to modulate immune responses, the benefits, disadvantages and interaction of different probiotics strains and their mechanisms of action in special illness is still unclear, and the combination of several strains should be thoroughly evaluated for safety and clinical benefits.

Limitations of study

This meta-analysis has several limitations. The included studies were significantly heterogeneous, so the results should be interpreted with caution. Since these studies include diverse patient groups with diverse severity of disease, the effects of pre- pro- or synbiotics may differ among them. The type and the concentration of the probiotics vary considerably in these reviewed studies, which may explain some of the differences in results between studies. In addition, some strains are effective and some may be harmful, and the interaction of several stains of probiotics as a mixture may lead to the deleterious effects in some special illness. Most of these studies are small in scale and two of them are of low quality, which may influence the analysis. There were also differences in the study design, the population and study team among these studies. Finally, meta-analysis remains retrospective that is subject to the methodological deficiencies of the studies, it is therefore possible that studies with different results may be unpublished, which leads to publication bias.

In conclusion, there are a few recommendations can be offered and further studies are required. In view of the questions raised in safety and efficacy, use of pre- pro- or synbiotics should be cautious in critically ill patients, especially in patients with severe acute pancreatitis. Unless new and strong evidence is presented, probiotics use can no longer be considered risk-free. However, we can not draw a conclusion that the use of pre- pro- or synbiotics is dangerous, and it is too early and inappropriate to deny the beneficial effects of all of pre- pro- or synbiotics in critically ill patients and severe acute pancreatitis. After

all, a single large trial is not sufficient to draw a definitive conclusion. Well-designed randomized controlled trials are needed to further explore the mechanistic issues and probiotic interactions, and assess the effect and safety of pre-, pro- or synbiotics.

COMMENTS

Background

The administration of pre-, pro- or synbiotics has been shown to enhance immunomodulating ability, modulate the intestinal microbiota, inhibit bacterial translocation and reduce the incidence of nosocomial infections in clinically surgical patients, and may be a new anti-infectious strategy for patients with acute pancreatitis.

Research frontiers

Some randomized controlled studies (RCTs) demonstrated a therapeutic and preventive effect of pre-, pro- or synbiotics in patients with acute pancreatitis. However, a multicenter RCTs reported some unexpected results. These studies were controversial for their shortcomings. Overall, the magnitude of the therapeutic effect remains unknown. This meta-analysis was performed to assess the potential effect and safety of pre-, pro- or synbiotics in patients with acute pancreatitis.

Innovations and breakthroughs

Currently, there is still a lack of evidence to support the use of pre-, pro- or synbiotics in patients with acute pancreatitis.

Applications

Pre-, pro- or synbiotics treatment shows no statistically significant benefit in the main outcome of patients with acute pancreatitis. In view of the questions in safety and efficacy, use of pre- pro- or synbiotics should be cautious in critically ill patients, especially in patients with severe acute pancreatitis. Further studies are needed to explore mechanistic issues and probiotic interactions in critical illnesses.

Terminology

Probiotics, is defined as ingestible microorganisms that benefit the host by improving intestinal microbial balance.

Peer review

In this meta-analysis, the use of pre- pro- and synbiotics was compared to placebo in patients with acute pancreatitis. In general, I find the study interesting and clinically relevant. However, the manuscript needs to undergo major revision.

Abstract

AIM: To evaluate the dual-graft living donor liver transplantation (LDLT) with ultrasonography, with special emphasis on the postoperative complications.

METHODS: From January 2002 to August 2007, 110 adult-to-adult LDLTs were performed in West China Hospital of Sichuan University. Among them, dual-graft implantations were performed in six patients. Sonographic findings of the patients were retrospectively reviewed.

RESULTS: All the six recipients survived the dual-graft adult-to-adult LDLT surgery. All had pleural effusion. Four patients had episodes of postoperative abdominal complications, including fluid collection between the grafts in three patients, intrahepatic biliary dilatation in two, hepatofugal portal flow of the left lobe in two, and atrophy of the left lobe in one.

CONCLUSION: Although dual-graft LDLT takes more efforts and is technically complicated, it is safely feasible. Postoperative sonographic monitoring of the recipient is important.

Key words: Liver transplantation; Dual grafts; Complications; Ultrasonography

INTRODUCTION

Adult-to-adult living donor liver transplantation (A-ALDLT) inevitably implies two potential risks including a small-for-size (SFS) graft for the recipient and a small remnant liver for the donor[1]. Problems related to SFS graft and small remnant livers have gradually come to light with the expansion of A-ALDLT[2-4]. The transplantation of SFS grafts may cause an imbalance between hepatic volume and demand of liver function, which may lead to a severe graft dysfunction known as small-for-size syndrome (SFSS)[5]. To overcome this problem and minimize the overall risk of the family, as an alternative, dual grafts from two living donors into one recipient can make up for graft size insufficiency and secure the recipient and donors' safety. Because of the complexity of this procedure, intensive postoperative monitoring of the recipient is required. To our knowledge, there have been few reports about the sonographic findings of dual-graft A-ALDLT. Therefore, in this study we describe our experience of sonographic evaluation of A-ALDLT using dual grafts.

MATERIALS AND METHODS

Clinical data

From January 2002 to August 2007, 110 A-ALDLTs

Table 1 Data of recipients who received dual grafts

No.	Gender/age (yr)	Diseases	Child-Pugh classification	Body weight (kg)	SLV (mL)
1	M/35	Hepatitis B-related cirrhosis, portal hypertension	C	70	1334
2	M/37	Hepatitis B cirrhosis with hepatocellular carcinoma	A	58	1187
3	M/42	Hepatitis-related cirrhosis, portal hypertension	C	75	1037
4	M/34	Hepatitis B-related cirrhosis, portal hypertension	C	71	1310
5	M/38	Hepatitis C cirrhosis with hepatocellular carcinoma	C	65	1210
6[1]	M/28	Hepatitis B cirrhosis with hepatocellular carcinoma	C	59	1290

[1]Received dual left lobe living donor liver transplantation. SLV: Standard liver volume.

Table 2 Data of donors

	Right side graft				Left side graft			Dual-graft GRWR (%)
No.	Gender/age (yr)	Relation	Weight (g)	GRWR (%)	Gender/age (yr)	Relation	Weight (g)	
1	F/56	Mother	630[1]	0.90	M/27	Cadaveric	230	1.22
2	M/35	Brother in law	410	0.71	F/52	Brother	193	1.04
3	F/35	Wife	400	0.53	M/55	Uncle in law	280	0.91
4	F/29	Wife	470	0.66	M/45	Sister	197	0.94
5	F/39	Wife	614[1]	0.94	M/42	Brother	225	1.29
6	F/34[2]	Sister	310	0.53	F/31	Sister	300	1.03

[1]Macrosteatosis of their livers ranged from 20% to 25%; [2]Both donors donated their left lobes. GRWR: The graft to recipient body weight ratio.

were performed in West China Hospital of Sichuan University. Among them, dual-graft implantations were performed in 6 male patients (aged 28-42 years, mean 34.7 years). Clinical data of the recipients is shown in Table 1.

Dual grafts selection

This study was conducted under the approval of the Ethics Committee of our hospital. All donors volunteered to donate their livers. Based on the previous experience, graft recipient weight ratio (GRWR) should be 0.8% or greater to achieve a graft and patient survival of 90%[6]. If GRWR is less than 0.8%, dual grafts should be considered. Furthermore, if macrosteatosis of the liver ranged from 10% to 30% and the grafts with a GRWR less than 1.0%, dual-graft liver transplantation should also be taken into account. Donor candidates who have diabetes, hypertension, or any other significant medical diseases were excluded from the right lobe donation. In order to ensure the safety of the donor, the middle hepatic vein was not harvested in the right lobe graft, and the remnant liver volume was more than 35%[7].

Materials of donors

There were 11 living donors (7 women and 4 men, aged 29-56 years, mean 41.5 years) and one cadaveric donor in this group. The clinical data of the donors is shown in Table 2.

In case 1 and case 5, whose GRWR was 0.90% and 0.94% respectively, dual-graft LDLTs were performed because macrosteatosis of their livers ranged from 20% to 25%. Cadaveric donor liver was split into two parts. The left lobe was used as one portion of dual grafts, and the right lobe including the middle hepatic vein was used in another adult liver transplantation[8].

Ultrasound examination

Ultrasound examinations of the recipients were retrospectively analyzed. Ultrasound scans were performed using a HDI 5000 scanner (Philips Medical Systems, Bothell, WA) with a 2-5-MHz wide band convex transducer or a Sequoia 512 (Acuson, Mountain View, CA, USA) with a 2-6-MHz wide band convex transducer. Patients were examined by ultrasound daily until postoperative day 14 and once a week thereafter until hospital discharge. Intercostal views of the right upper quadrant of the abdomen were obtained to examine the right graft and subcostal views were used to evaluate the left graft. Gray scale and color flow images as well as Doppler spectrums were detected. Angle-corrected velocities were examined with the Doppler angle less than 60°. Parenchyma echogenicity, patency of the hepatic vessels, biliary system and the fluid collection of the thorax and abdomen were documented.

RESULTS

Recipients

All recipients survived the dual-graft A-ALDLT surgery. All recipients (6/6) had bilateral pleural effusion and 2 patients underwent ultrasound-guided drainage. Four patients had episodes of postoperative abdominal complications, including fluid collection between the grafts in 3 patients (Figure 1), and 2 had intrahepatic biliary dilatation (Figure 2). The left-sided graft shrank in size in one patient in whom hepatofugal flow of the left portal vein

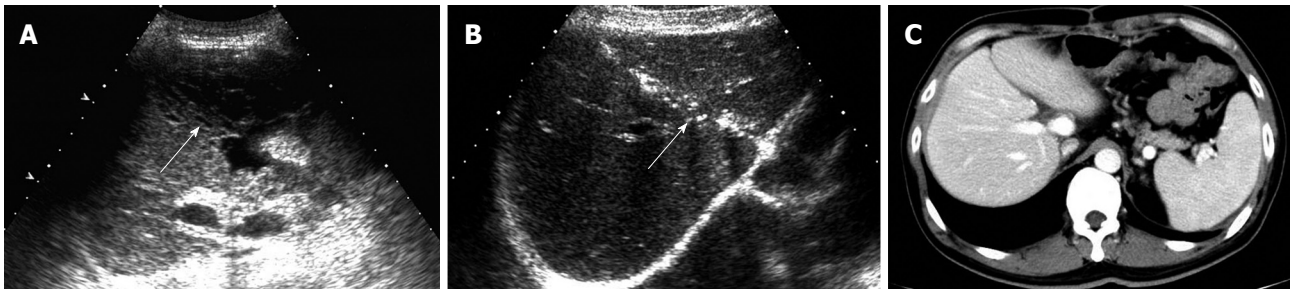

Figure 1 A 42-year-old man with fluid collection between the grafts after dual-graft liver transplantation. A: Gray scale sonogram shows the focal fluid collection with septa inside (arrow); B and C: The grafts joint visibly on follow-up sonogram (arrow) and computed tomography.

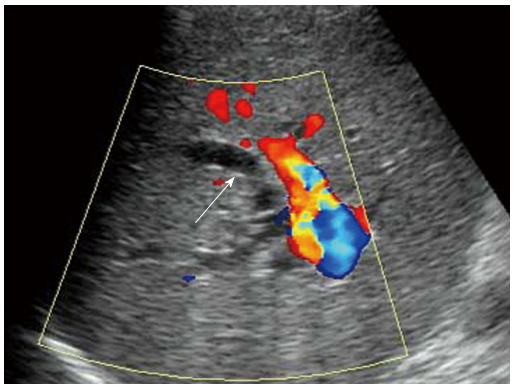

Figure 2 Moderate intrahepatic biliary dilatation (arrow) was shown by the follow-up ultrasound in a 34-year-old man four mos after dual-graft liver transplantation.

was detected 1 mo after surgery (Figure 3). To-and-fro portal venous flow of the left portal vein was found in another case at a routine follow-up 2 years after surgery with a normal size of the left graft. One patient died of tumor recurrence.

Donors

All donors recovered with an uneventful process.

DISCUSSION

The significant gap between available cadaveric grafts and the number of patients on the waiting list for liver transplant triggered the rapid adoption of the right lobe liver transplantation[9-11]. Although the surgical technique of A-ALDLT achieved great progress, SFS grafts still remain a problem[12]. Dual-graft liver transplantation provides an option when the largest single graft available is still small for the recipient.

Dual-graft A-ALDLT is a complicated procedure, therefore, recipients should be monitored intensively after surgery. Ultrasonography has been regarded as the initial imaging modality of choice allowing bedside assessment for detection and follow-up of early and delayed complications, and facilitating interventional procedures[13].

Postoperative pleural effusion is common in liver transplantation recipients. Most of the cases need no special intervention with a small amount of fluid. When the amount of the fluid was large, which may result in atelectasis and higher risk of pulmonary infection and further affected the pulmonary function, ultrasound-guided drainage of the pleural effusion may help resolve the problem.

Hepatofugal portal venous flow was regarded as a serious prognostic sign of critical liver damage after liver transplantation[14,15], but the situation is different in dual-graft A-ALDLT. In our 2 cases, hepatofugal portal venous flow of the left graft was detected, while the hepatic function tests remain normal. This phenomenon could be explained by a compensatory enlargement of the right-sided graft which could meet the metabolic demand of the body even with a compromised left-sided graft. Persistent monophasic Doppler spectrum of the left hepatic vein was obtained during quiet breathing, stenosis of the left hepatic vein was suggested according to Meir and Ko's research[16,17], which may lead to an increased sinusoidal pressure, then the portal vein served as a drainage vein and finally resulted in the atrophy of the graft.

A dual-graft A-ALDLT also has a problem of postoperative biliary complications. Ultrasound detected intrahepatic biliary dilation in 2 patients, but failed to locate the stenosis site. Compared with magnetic resonance cholangiopancreatography and endoscopic retrograde cholangiography, ultrasonography is less sensitive in detecting biliary strictures and ischemic type biliary lesions after liver transplantation[18,19], but ultrasonography is reported to have a high negative predictive value of 95% in the diagnosis of biliary tract complications[20]. Therefore, ultrasound could be used as a screening technique in the aspect of biliary complications.

Fluid collection between the grafts was common in dual-graft LDLT, which occurred in 3 recipients, because a drainage tube was not routinely placed between the grafts. Besides detection, ultrasound facilitates the fluid aspiration procedure which is important to the differential diagnosis of bile leakage or ascites and beneficial to the recovery of patients.

Indeed, some other techniques including splenic artery embolization or ligation, permanent or temporary portacaval shunts play an important role in preventing SFSS under a specific condition that GRWR ratio is near 0.8%[2].

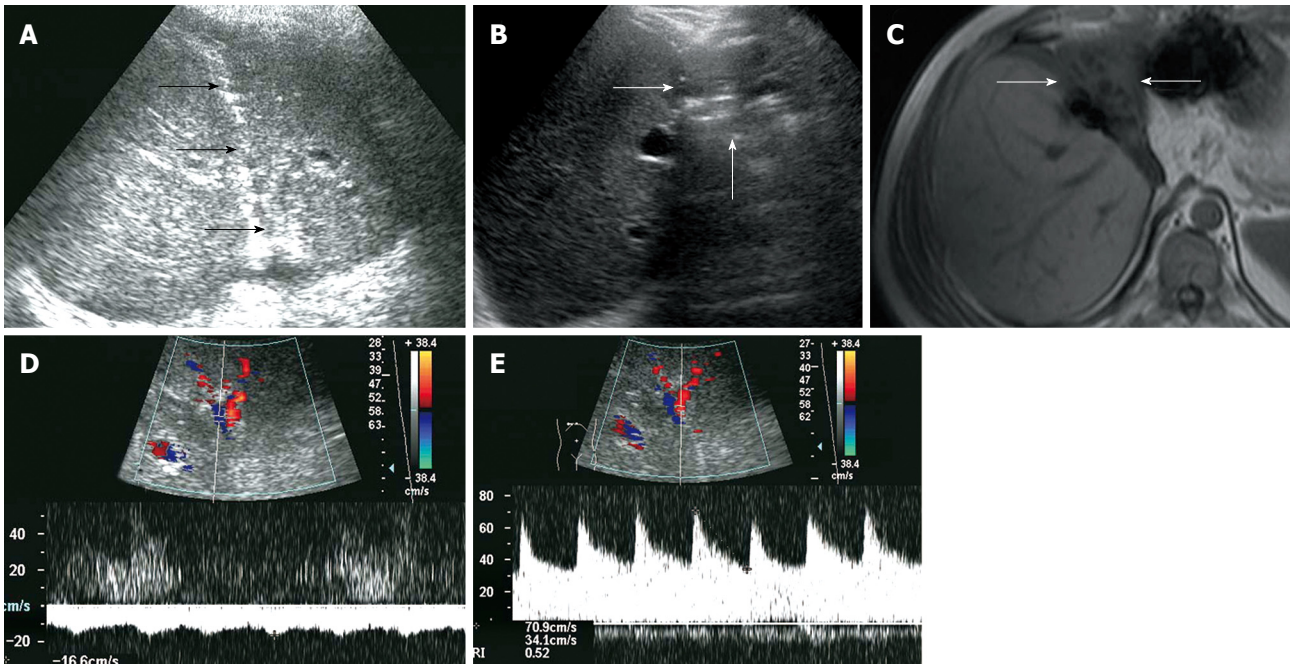

Figure 3 A 37-year-old man with a shranken left graft after dual-graft liver transplantation. A: Gray scale sonogram shows the left graft (arrows) on postoperative day one; B and C: Size of the left graft decreased on follow-up sonogram and magnetic resonance imaging (arrows); D: Doppler spectrum shows the hepatofugal flow of the portal vein of left graft; E: Doppler spectrum shows the normal left hepatic artery.

When the graft is too small, LDLT poses a great danger for the recipients. During the follow-up of 11 donors and 6 recipients over 18 mo, SFSS was not found in the recipients. No liver failure occurred in donors and recipients. Only one patient died of tumor recurrence. Therefore, dual-graft LDLT should be regarded as a feasible method to avoid SFSS if GRWR of the recipients with portal hypertension or acute liver failure was less than 0.8%. However, the number is small and more clinical experience is required.

In conclusion, although A-ALDLT using dual grafts takes more efforts and is technically complicated, it is safely feasible and can increase the donor pool. Whenever a right lobectomy appears to be critical for the donor, the possibility of dual-graft A-ALDLT should be evaluated and discussed to minimize the combined family risk. Postoperative sonographic monitoring of the recipient is important for the early detection and intervention of vascular and non-vascular complications, which is critical to the recovery of recipients.

COMMENTS

Background

Dual-graft adult-to-adult living donor liver transplantation (A-ALDLT) was designed to overcome the problem of small-for-size graft and reduce the overall family risk. Because of the complexity of this procedure, intensive postoperative monitoring of the recipient is required. There have been few reports about the sonographic findings of dual-graft A-ALDLT to date.

Research frontiers

Dual-graft A-ALDLT was evaluated with ultrasonography, with special emphasis on the postoperative complications.

Innovations and breakthroughs

The authors reported six patients who received dual-graft LDLT. Normal and abnormal sonographic findings were discussed. Postoperative sonographic monitoring of the recipient is important for the early detection and intervention of vascular and non-vascular complications, which is critical to the recovery of recipients.

Applications

Ultrasound is important in the diagnosis of postoperative complications and helpful in some interventions, such as ultrasound-guided drainage of fluid. This report adds some evidences to the safety and feasibility of dual-graft liver transplantation by following up the recipients and donors.

Terminology

Living donor liver transplantation: It is the replacement of a diseased liver using partial healthy liver allograft donated by members of the family.

Peer review

This is a nice study, and can be published after minor revisions. Patient number for the dual-graft LDLT procedure appears small (n = 6), but is still the largest published to date. Some editing of the language is needed throughout.

Abstract

Localized malignant pleural mesothelioma (LMPM) is a rare occurrence, and gastrointestinal intra-luminal metastases have not previously been reported. Herein, we report a patient with LMPM who presented with a local recurrence 10 mo after initial *en bloc* surgical resection. Abdominal computed tomography was performed for intractable, vague abdominal pain with episodic vomiting, which showed a "target sign" over the left lower quadrant. Laparotomy revealed several intra-luminal metastatic tumors in the small intestine and colon and a segmental resection of metastatic lesions was performed. Unfortunately, the patient died of sepsis despite successful surgical intervention. Though local recurrence is more frequent in LMPM, the possibility of distant metastasis should not be ignored in patients with non-specific abdominal pain.

Key words: Localized malignant pleural mesothelioma; Intussusception; Distant metastasis

INTRODUCTION

Localized malignant pleural mesothelioma (LMPM) is a rare occurrence, and only a few cases have been reported in the literature[1,2]. Local recurrence is not uncommon; however, distant metastasis with gastrointestinal involvement, especially bowel intussusception (BI), has not been previously reported. Herein, we report a patient with LMPM who experienced local recurrence and metastases to the bowel with multiple BI. The patient died of sepsis despite successful relief of intestinal obstruction.

CASE REPORT

A 57-year-old male complained of right chest pain and presented to our department with a large, localized chest wall tumor in April 2008. He underwent *en bloc* chest wall resection with an adequate tumor free margin and the pathological examination revealed LMPM, sarcomatoid type. A full course of adjuvant chemotherapy with cisplatin and pemetrexed was administered; however, local recurrence was diagnosed 10 mo after the initial surgical

Figure 1 Abdominal computed tomography discloses a typical "target sign" over the small intestine (arrow).

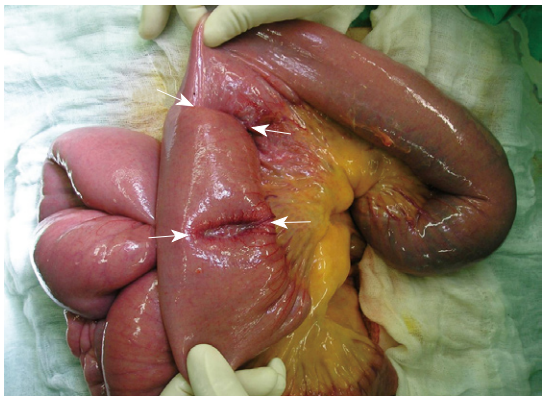

Figure 2 Intraoperative photo showing intussusceptions in the small intestine (arrows).

intervention. At the time of diagnosis, he complained of dizziness, poor appetite, and vague abdominal pain with episodic vomiting. His stool was negative for occult blood and laboratory studies revealed normochromic normocytic anemia (Hgb, 5.9 g/dL). Abdominal computed tomography (CT) revealed a "target sign" in the left lower quadrant (Figure 1).

An emergent laparotomy was performed and 3 intussusceptions with concomitant leading points of intra-luminal, polypoid tumors were found in the small intestine (Figure 2). No peritoneal seeding or extra-luminal invasion was discovered. After a detailed examination of the whole bowel, 7 tumors were found in the jejunum, ascending colon, and transverse colon (Figure 3). Segmental resection of small bowel with end-to-end anastomosis and radical right hemicolectomy with ileocolostomy, and regional lymph node sampling were performed.

Grossly, the surgical specimen consisted of jejunum, ileum, ascending colon and descending colon, 98 cm in length, with 7 polypoid, intra-luminal tumors. Four tumors were in the small bowel, and the others were in the ascending and descending colon. The tumors measured from 2.5 to 8.0 cm in diameter, and the largest, located in the small bowel, was 8.0 cm × 4.0 cm × 3.0 cm in size. When cut, all demonstrated a pinkish-white cut surface without necrosis or hemorrhage.

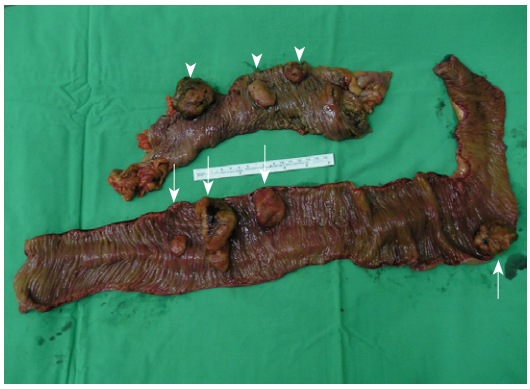

Figure 3 Surgical specimen reveals metastatic localized malignant pleural mesothelioma in the small intestine (arrows) and colon (arrow heads).

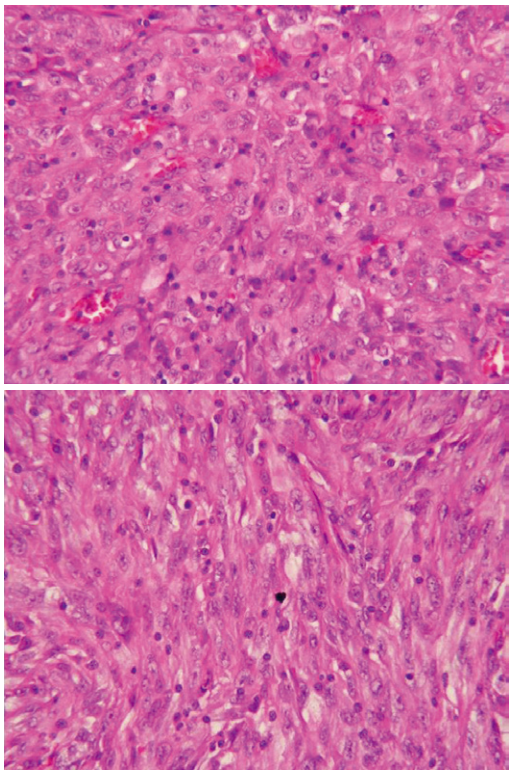

Figure 4 Microscopic examination reveals the tumor to consist of sheets of spindle to epithelioid cells with abundant eosinophilic cytoplasm and vesicular nuclear chromatin with prominent nucleoli (HE stain, × 400).

Microscopically, the 7 tumors were composed of sheets of epithelioid cells and spindle cells which had vesicular nuclei with prominent nucleoli, mixed with inflammatory cells (Figure 4). Mucosal and submucosal involvement was noted. Moreover, tumor metastasis was present in the regional lymph nodes. Immunohistochemical studies showed the tumor cells were negative for calretinin, thyroid transcription factor-1, and cytokeratin 20, and positive for vimentin and cytokeratin. The results were identical to those of the LMPM from the right chest wall.

The patient resumed enteral feeding on the 13th postoperative day. Unfortunately, the patient died of fungemia 32 d after the operation.

DISCUSSION

BI is rare in adults, accounting for 5% of all cases with intussusceptions and almost 5% of bowel obstructions[3]. Secondary BI usually results from organic lesions, such as polyps, inflammatory bowel disease, postoperative adhesions or neoplasms, and manifests with a single leading point. It is reported that malignant tumors are the most common causes of BI in adult patients, accounting for 47% of cases[3]. Nevertheless, distant metastases with multiple BIs are extremely rare, and only few case reports are found in the literature; these have been reported to be associated with melanoma, renal cell carcinoma, or lung cancer[4-6].

LMPMs are extremely rare solitary tumors, and identical to diffuse malignant pleural mesotheliomas microscopically and immunohistochemically. When an extensive review of published English-language literature was carried out, there were found to be a total of 53 LMPMs derived from parietal pleura[1,2,7-9]. Among these reported cases, LMPMs usually presented with local recurrence near prior surgical sites (16 cases, 30%), and there were 2 cases with contralateral recurrence during follow-up. Distant metastasis was less common compared with local recurrence, and only 8 cases were found (2 with brain metastases, 2 with diffuse dissemination, 2 with vertebral metastases, 1 with skin metastasis, and 1 with mediastinal metastasis). No case of intestinal intra-luminal metastases from LMPM has been previously reported. To the best of our knowledge, this is the first case report of multiple BIs from metastatic LMPM despite an initial *en bloc* chest wall resection and adjuvant chemotherapy.

In the case reported herein, the patient had the symptoms of vague abdominal pain and vomiting, and normocytic anemia. Generally, BIs from distant metastasis or malignancy have diverse manifestations. Most patients present with non-specific symptoms consistent with bowel obstruction, such as nausea, emesis, abdominal pain, melena, or weight loss[3]. However, Goh *et al*[10] have stated that anemia and colon intussusception are the predictive determinants for adult BIs resulting from malignancy. Moreover, abdominal CT is the most useful imaging modality and carries an acceptable diagnostic accuracy for adult BIs[3,11]. Early application of CT scanning will facilitate definitive diagnosis and prompt treatment.

Compared with pediatric intussusception, hydrostatic reduction is not mandatory, and aggressive surgical treatment is the gold standard for adult intussusception, though long-term survival remains unsatisfactory in patients with BI from metastases. Complete surgical resection of viable tumors is worthwhile in a select group of patients for the purpose of nutritional support from enteral feeding and metastasectomy with tumor eradication.

In conclusion, this case highlights two important issues. Firstly, clinicians should take gastrointestinal involvement, even malignancy-related intussusception, into consideration when treating patients with a past history of malignancy who are experiencing frequent abdominal pain and have unexplainable anemia. Secondly, though distant metastasis is infrequent compared with local recurrence in patients with LMPM, the possibility should be considered in patients with non-specific symptoms.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in tahe field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page,

Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Beijing Baishideng BioMed Scientific Co., Ltd, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www. clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g., Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g., Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles, rapid communication and case reports, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case

report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.

Abstract

Computed tomography colonography (CTC) in colorectal cancer (CRC) screening has two roles: one present and the other potential. The present role is, without any further discussion, the integration into established screening programs as a replacement for barium enema in the case of incomplete colonoscopy. The potential role is the use of CTC as a first-line screening method together with Fecal Occult Blood Test, sigmoidoscopy and colonoscopy. However, despite the fact that CTC has been officially endorsed for CRC screening of average-risk individuals by different scientific societies including the American Cancer Society, the American College of Radiology, and the US Multisociety Task Force on Colorectal Cancer, other entities, such as the US Preventive Services Task Force, have considered the evidence insufficient to justify its use as a mass screening method. Medicare has also recently denied reimbursement for CTC as a screening test. Nevertheless, multiple advantages exist for using CTC as a CRC screening test: high accuracy, full evaluation of the colon in virtually all patients, non-invasiveness, safety, patient comfort, detection of extracolonic findings and cost-effectiveness. The main potential drawback of a CTC screening is the exposure to ionizing radiation. However, this is not a major issue, since low-dose protocols are now routinely implemented, delivering a dose comparable or slightly superior to the annual radiation exposure of any individual. Indirect evidence exists that such a radiation exposure does not induce additional cancers.

Key words: Computed tomography colonography; Colon neoplasms; Colon polyps; Colorectal cancer screening; Computed tomography colonography safety; Computed tomography colonography accuracy; Computed tomography colonography radiation exposure; Computed tomography colonography cost-effectiveness

Peer reviewer: Dr. John B Schofield, MB, BS, MRCP, FRCP, Department of Cellular Pathology, Preston Hall, Maidstone, Kent, ME20 7NH, United Kingdom

INTRODUCTION

It is now 16 years since Vining *et al*[1] presented the first virtual images of the colon at the 1994 meeting of the Society of Gastrointestinal Radiologists. This marked the birth of "virtual colonoscopy" (VC), an intriguing name useful for marketing to patients, providers and the public, or "CT colonography" (CTC), the name most radiologists prefer.

When discussing the role of CTC in colorectal cancer (CRC) screening, it is necessary to separate the present and existent role from the potential one.

The present role is, without any further discussion, the integration into established screening programs as a replacement for barium enema (BE) in the case of incomplete colonoscopy (CC). In fact, since 2006 the American Gastroenterological Association (AGA) Clinical Practice and Economics Committee has endorsed CTC as the method of choice for colon investigation in cases of incomplete colonoscopy[2] and numerous evidence exists in the literature showing a clear superiority of CTC over BE in the detection of CRC and polyps[3-5]. It is also clear that performing CTC in patients with a positive Fecal Occult Blood Test (FOBT) would not be an efficient triage technique in terms of cost-effectiveness, due to the high prevalence of clinically relevant colonic lesions[6,7].

The potential role of CTC is to act as a first-line CRC screening modality. In this regard, it was in March 2008 that CTC obtained its major success: the American Cancer Society (ACS), the US Multi-Society Task Force on Colorectal Cancer and the American College of Radiology (ACR) released consensus guidelines on CRC screening for average-risk individuals. These guidelines distinguished diagnostic tests into two groups: those able to detect CRC, thus potentially reducing mortality (FOBT; Fecal Immunochemical stool Testing, FIT; and stool DNA testing), and those able to detect both polyps and cancer, thus potentially reducing both the incidence of and the mortality from CRC. This latter group of tests includes CC, sigmoidoscopy, BE and - for the first time - also CTC, with the recommendation that it be performed every 5 years starting at 50 years of age[8]. Unfortunately, this position did not remain unequivocal: in fact, the US Preventive Services Task Force (USPSTF) considered the evidence insufficient because of the unknown impact of both extra-colonic findings and radiation exposure, the poor data on cost and cost-effectiveness, and the still unsolved problem of ideal bowel preparation[9]. Other associations, such as the Asia Pacific Working Group on Colorectal Cancer[10] and the American College of Gastroenterology[11], consider CTC a second-line screening test for those unwilling or unable to undergo CC and for those in whom CC was incomplete. Furthermore, in 2008 in the USA, the Centers for Medicare and Medicaid Services denied the reimbursement of screening exams done with CTC[12].

These facts mean on one hand that CTC is considered useful by clinicians, but, on the other hand, that radiologists have much to do until this imaging method is implemented for screening, as testified by a survey conducted among US primary care physicians (PCP)[13]. When asked which diagnostic tests they perceive as being very effective in reducing CRC mortality, 22% answered CTC *vs* 95% CC; and when asked which test they would recommend for CRC screening, most respondents indicated CC (95%) and FOBT (80%), but only about 5% answered CTC.

Keeping in mind these facts, the potential role of CTC in CRC screening will be discussed in the next paragraphs, taking into consideration that an ideal screening test is not yet available and that any screening test is a compromise among four major variables: efficacy, compliance, safety and cost.

EFFICACY

The issue of diagnostic accuracy of CTC for CRC and polyps has been debated for a long time, because of the conflicting results in some of the papers published in the literature[14-16]. This has been recently confirmed by a meta-analysis showing that "CTC is highly specific for the detection of colorectal polyps and tumors" and that "some studies reported high sensitivities, but the results of the studies were highly heterogeneous, while the studied variables explained only part of this discrepancy"[17].

These results led researchers to design three important studies: two large, multicenter trials testing the performance of CTC in comparison with CC in respectively asymptomatic subjects at average risk, i.e. a typical screening population [the American College of Radiology Imaging Network (ACRIN) trial performed in the USA][18] and in a mixed population of asymptomatic subjects at risk higher-than-average and in patients referred for a positive FOBT [Italian Multicenter Polyps Accuracy CTC study (IMPACT) trial][19]; and one multicenter trial [Special Interest Group in Gastrointestinal and Abdominal Radiology (SIGGAR) trial run in the UK] conducted on symptomatic patients with the aim to detect CRC[20]. In particular, the ACRIN trial tried to minimize the variables possibly affecting CTC performance. For this reason only $\geqslant$ 16-row MDCT scanners were used, patients were administered oral contrast agent for stool tagging together with cathartic agent and training of the radiologists observing the images was an important component of the study. In particular, CTC readers were obligated to have read at least 500 cases, or to have attended a 1.5-d training course, and all had to pass a certified exam in which they detected at least 90% of adenomas 1 cm or larger in 50 cases. More than half of the readers had to undergo additional training in order to pass the certified exam initially and, with additional training, all the readers eventually passed.

Results from ACRIN and IMPACT have been recently published[18,19], whereas those from SIGGAR[20] are still under data analysis. Both the ACRIN and IMPACT trials reported per-patient sensitivity of 90% for polyps > 10 mm and 78%-84% for polyps larger than 6 mm; per-patient specificity was extremely high as well, over 85% independently of lesion size (Table 1). The major drawback of ACRIN was represented by the poor positive predictive value (PPV) (23% for polyps $\leqslant$ 10 mm), which might negatively affect a screening program, leading to useless CC, with patient discomfort, embarrassment of radiologists, potential risk of complications and increased costs. Unfortunately there is no explanation for these data, unless one would claim a psychological attitude to overcall in order to reach the threshold of 90% for clinically significant polyps despite a loss in specificity. A definitely better PPV was documented in the IMPACT trial (62% for lesions larger than 6 mm) as well as in studies obtained

Table 1 Results from major trials on a per-patient basis: sensitivity, specificity, positive and negative predictive values

Multicenter trials	All polyp size	Polyps (≥ 5 mm)	Polyps (≥ 6 mm)	Polyps (≥ 7 mm)	Polyps (≥ 8 mm)	Polyps (≥ 9 mm)	Polyps (≥ 10 mm)
Per patient sensitivity							
ACRIN	N/A	65%	78%	84%	87%	90%	90%
IMPACT	N/A	N/A	85%	86%	88%	91%	91%
Munich	84%	91%	N/A	N/A	N/A	N/A	92%
Per patient specificity							
ACRIN	N/A	89%	88%	87%	87%	86%	86%
IMPACT	N/A	N/A	88%	87%	86%	85%	85%
Munich	47%	93%	N/A	N/A	N/A	N/A	98%
Per patient PPV							
ACRIN	N/A	45%	40%	35%	31%	25%	23%
IMPACT	N/A	N/A	62%	N/A	N/A	N/A	N/A
Munich	48%	N/A	70%	N/A	N/A	N/A	79%
Per patient NPV							
ACRIN	N/A	95%	98%	99%	99%	99%	99%
IMPACT	N/A	N/A	96%	N/A	N/A	N/A	N/A
Munich	84%	N/A	98%	N/A	N/A	N/A	99%

Results are categorized according to polyp size. PPV: Positive predictive value; NPV: Negative predictive value; N/A: Not assessable.

in high-experience centers, the University of Wisconsin (PPV, 91.5%) and a group of Korean hospitals (PPV, 69% for lesions > 6 mm and 92% for those > 10 mm)[21,22].

However, the negative predictive values in both the ACRIN and the IMPACT trials was rather high, approaching 100%; this is extremely important in order to reassure negative patients about the significance of the examination.

Excellent results were also obtained in the Munich Colorectal Cancer Prevention Trial[23], a single-center study where around 300 asymptomatic subjects underwent low-dose CTC in comparison with other screening tests (CC, sigmoidoscopy and FOBT).

It is noteworthy to mention that in a screening project offered by the University of Wisconsin[24], after 2 years of recruitment over 3000 subjects of two different, non-randomized groups underwent CTC and CC. The detection rate for advanced adenomas was 3.2% for CTC and 3.4% for CC (difference not statistically significant), with the advantage of a large reduction in the number of polypectomies in the CTC group without any complication as opposed to seven perforations which occurred in the CC group.

Despite the good results there are still some open issues under debate within the radiological as well as the gastroenterological communities. These are the significance of diminutive (< 6 mm) polyps, the management of intermediate (6-9 mm) lesions, the detection rate for non-polypoid, flat lesions and the impact of the extra-colonic findings.

According to a very recent systematic review[25] of published studies reporting the distribution of advanced adenomas in asymptomatic screening cohorts, diminutive polyps have a minimal clinical impact. In fact, the frequency of advanced lesions among patients whose largest polyp was ≤ 5 mm, 6-9 mm, < 10 mm, and > 10 mm in size was 0.9%, 4.9%, 1.7%, and 73.5%, respectively (Figure 1). As a consequence, a 6-mm polyp size threshold for polypectomy referral would identify over 95% of subjects with advanced adenomas, whereas a 10-mm threshold would identify 88% of cases. From a cost-effectiveness point of view, detection and removal of all polyps including those smaller than 5 mm, would be very inefficient, with a cost per year of life gained > $460 000[26], absolutely unacceptable in terms of cost-effectiveness. It is also true that this approach, not removing diminutive polyps, necessitates an extensive education of patients and PCP. In fact, according to a recently published survey[27], the majority of patients, PCP and gastroenterologists would not choose to follow up small polyps identified by CTC with CC because of the fear of missing precancerous lesions.

The management of intermediate (6 to 9 mm) lesions is also under debate, despite the fact that today any polyp 6 mm or larger should be preferably referred for CC and polypectomy, also according to ACS CRC screening guidelines[2]. However, evidence does exist from cost-effectiveness[28] as well as follow-up[29] studies indicating that, for the future, polyp follow-up might be an alternative to referral for CC and polypectomy. These data have been recently reinforced by studies conducted with CC and subsequent polypectomy, where the rate of advanced adenoma in 6-9 mm polyps was demonstrated to be 6.6%[30].

A potential disadvantage of CTC would be the possible impaired ability to detect non-polypoid, flat lesions (Figure 2). This issue deserves some consideration. First of all, flat lesions represent a subset of sessile polyps, and according to a recent publication[31] the overall prevalence in a screening population is around 5.8% (if flat lesions are defined as those with a height not exceeding 0.5 of the diameter[32]). However, within this definition, slightly elevated lesions are also included, which, in some cases, may be classified as sessile. For this reason, an elevation not higher than 3 mm is often used, especially for small lesions not larger than 2-3 cm. The other important remarks are that "completely flat lesions are exceedingly

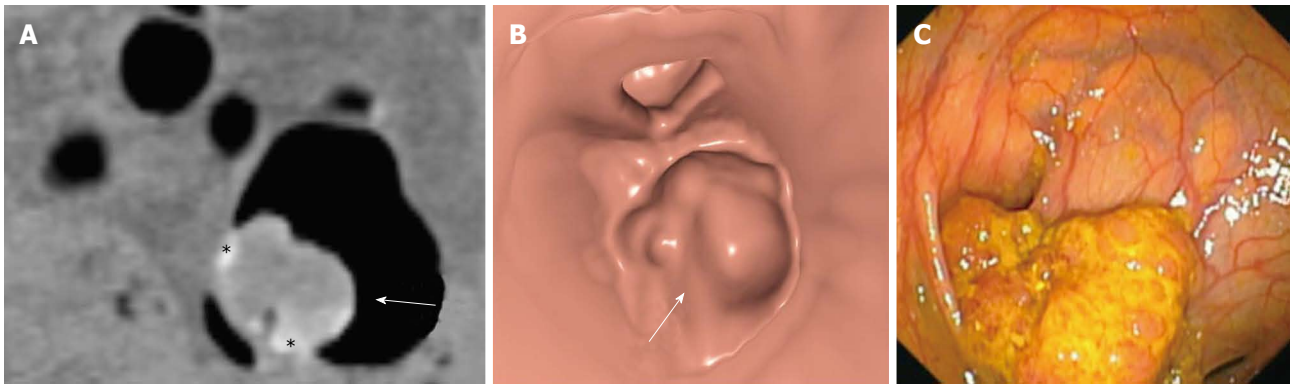

Figure 1 Sessile polyp: adenoma with low-grade dysplasia. A: Coronal reformatted image showing a polypoid lesion (arrow), partly surrounded by tagged fluid (asterisks); B: The same lesion as shown on 3D endoluminal view (arrow); C: Conventional colonoscopy.

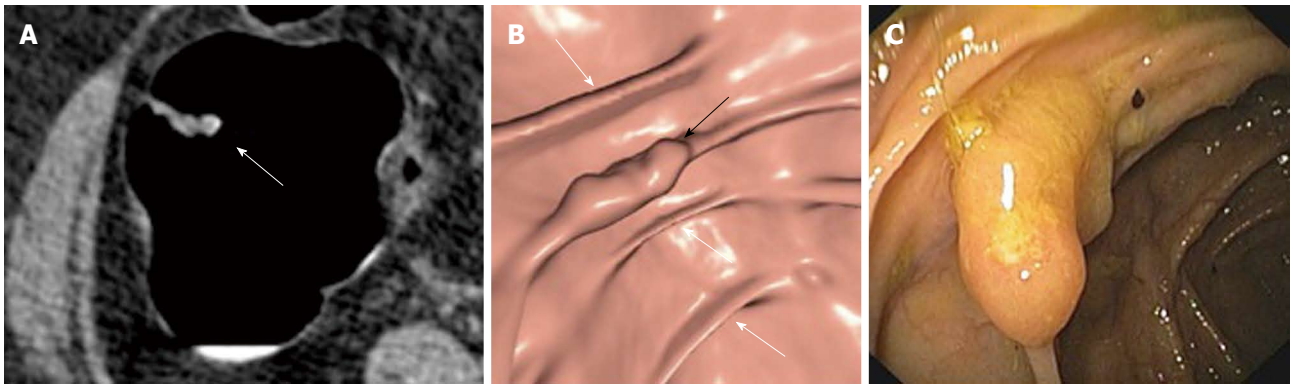

Figure 2 Non-polypoid (flat) lesion: advanced adenoma. A: On 2D axial computed tomography image an irregularly thickened fold (arrow) is detected; B: On 3D endoluminal image the lesion is better appreciated (black arrow), in particular if compared with the normal adjacent colonic folds (white arrows); C: The same lesion at colonoscopy before removal.

rare" and that depressed lesions are less than 1% of all colorectal lesions and only a quarter of those are observed in a screening population. This means that the majority of non-polypoid lesions are at least slightly elevated and this works in favor of the possible detection with CTC. Unfortunately, at the moment only few and conflicting data about the sensitivity of CTC for flat lesions are available. At the beginning disappointing results were published[33,34], because of technical limitations as well as readers' experience. More recently, better results were reported, with sensitivity in the range of 80%-90% for flat adenocarcinomas[32,35]. These results seem to be confirmed by a recent retrospective analysis of the data from the ACRIN trial showing a sensitivity of 89% for flat adenomas ≤ 6 mm (at the prospective analysis, sensitivity was 68%) (Fidler J, presented at ACRIN meeting, October 1, 2009).

The impact of extra-colonic findings will be discussed in the paragraph concerning costs.

COMPLIANCE (ADHESION TO A SCREENING PROGRAM)

Compliance means adhesion of healthy individuals to a screening program. This is a very complex issue, long debated in the literature and presently without a solution, since virtually in any Western country a high proportion of adults 50 years of age or older have not undergone any CRC screening test[36]. Colonoscopy, considered to be the most effective screening method, suffers from a very low participation rate. Very recent data from Italy[37] underline the difficulties and barriers in implementing a CC population screening, at least through primary care. Reported participation in a CC screening arm was extremely low in Southern Italy (2.8%), and higher, but still disappointing, in North-Central Italy (12.4%).

To increase screening uptake is extremely important, since the adhesion rate of the invited population directly affect the efficiency of the program. For example, if we consider that the efficacy of CC in reducing the incidence of CRC is around 76%[38], the efficiency with regard to CRC prevention rate, considering an adhesion rate of 20%, drops to 15% (76% × 20% = 15%).

The question is whether CTC would be able to increase screening uptake. The three most common deterrents that patients expressed about receiving CC were bowel preparation, embarrassment and fear of discomfort[39,40]. The advantage of CTC is the use of a gentler preparation or unprepped (laxative-free) examination[41]. Furthermore, the pain related to colon distension by air may be minimized by the use of carbon dioxide delivered

by an electronic pump. The use of carbon dioxide is also associated with a faster absorption, making the patient more comfortable immediately after the examination[42].

Unfortunately, only few data are available regarding adhesion rate and CTC. In a study conducted in Western Australia[43], 2000 people were invited and 28.4% accepted to undergo CTC for screening, with 62% of them preferring CTC over optical colonoscopy. The fact remains that we need data resulting from real screening experiences.

SAFETY

CTC is a safe test, definitely safer than colonoscopy. The results of different surveys show a perforation rate associated with CTC ranging between 0.06% and 0.08%[44,45], even lower in screening[46], compared with 0.1%-0.2% for diagnostic colonoscopy[47]. It should also be noted that the comparison between CTC and CC is very difficult, with the risk of overestimating the clinically significant perforations at CTC, because of the much higher sensitivity of CT in the detection of even tiny air bubbles. In fact, most of the perforations reported in a UK survey[44] were treated conservatively, without surgical intervention. CTC complications in most of the cases are due to technical factors, such as the use of a rigid catheter for bowel distension (now replaced by thin rubber devices), manual distension with air (now minimized by the use of an electronic pump delivering carbon dioxide and able to control pressure and volume), inexpert personnel and incorrect patient selection.

Other complications occasionally reported have been vasovagal reactions due to colonic overdistention[48].

The main potential drawback of screening with CTC is the exposure to ionizing radiation[49] and the consequent theoretical risk of inducing cancer. The risk is theoretical because there are still many uncertainties with regard to the true effects of ionizing radiation at low doses, such as those used in diagnostic radiology[50,51]. According to the Health Physics Society[52], "below 5-10 rem (50-100 mSv) (which includes occupational and environmental exposures), risks of health effects are either too small to be observed or are nonexistent"; and the French Academy report[53] stated that the linear no-threshold (LNT) hypothesis for assessing the risk associated with low doses is not based on scientific evidence. However, in contrast, the International Commission on Radiological Protection (ICRP)[54] and the Biological Effects of Ionizing Radiation (BEIR) Ⅶ report[55] considered LNT as the best method to assess low dose exposures, in order to be more conservative and more protective towards patients because of the multiple uncertainties. Unfortunately even if this hypothesis may be true it cannot be proved since we have little direct evidence of harm below 100 mSv.

Even if the LNT hypothesis is considered the most accurate, the problem of radiation exposure of patients undergoing CTC seems to be minimal. In fact, the mean exposure in the case of a screening examination has been calculated in a recent survey[56] to be around 5-6 mSv, which is twice the normal background radiation exposure in the US (2.5-3.0 mSv per year)[57]. In addition we have to consider, in a screening scenario, that CTC should be repeated every 5 years, not earlier. For a radiation dose of around 5-8 mSv at age 50 years, the lifetime risk of death from cancer varies between 0.02% and 0.03%[58]. If we think about cost/benefit of the examination, this minor risk should be compared with the theoretical risk of CRC in average risk individuals, which is around 5%[59].

A more precise idea about the amount of radiation exposure comes from a comparison with other categories of workers continuously exposed to low dose radiation, such as, for example, airline crews and nuclear workers. As an example, the value of 5-6 mSv, to be received in a screening scenario every 5 years, should be compared with radiation exposure of airline crews, who are submitted to an average of 5 mSv per year every single year of their activity, with a long life exposure close to 80 mSv. A recent survey of airline pilots from eight different European countries has shown no increase in mortality from radiation-induced cancers over a 30-year period of time[60]. Similar data were observed in nuclear workers in two recently published experiences[61,62].

COSTS

Cost analysis is a very difficult task, especially in the absence of real data and based only on mathematical models. Among the studies published in the literature[63-69] 5 out of 7 are in favor of CC and only two were able to demonstrate a better cost-effectiveness of CTC. A recent review of the literature[70] has pointed out the profound differences among the models as well as the weakness of such an approach, where a minimal variation of a single input may completely alter the final results. As an example, if the cost ratio between CTC and CC is ⩽ 0.7, the model is usually in favor of CTC, but if the cost of CTC is higher than 80% of the cost of CC, it will be CC which is the most cost effective method. Another very important issue, adhesion rate, is never taken into account in the models, where it is considered to be equal among the different screening tests, although this is probably not the case. In addition, differences in healthcare systems, reimbursement, cost of the equipment and personnel are other important variables affecting the final outcome.

When considering cost, the issue of extra-colonic findings should be taken into account. The detection of extra-colonic findings can be considered a potential advantage of CTC, since previously unknown life-threatening diseases, which are not insignificant[71], can be diagnosed and treated, with a clear impact on patients' life expectancy. However, the major problem is the extra time necessary for reporting these findings and the cost induced by unnecessary investigation of common benign abnormalities, especially because of their high prevalence[72,73]. In a recent publication[74], the mean cost per patient was $31.02 for nonsurgical and $67.54 for surgical work-up procedures. Although extra-colonic findings have been traditionally

regarded as an additional cost, they have been recently considered as a potential benefit (i.e. detection of unsuspected abdominal aortic aneurysm or renal cancer), able to improve CTC cost-effectiveness[75].

CONCLUSION

In conclusion, CTC has a present role in CRC screening programs, i.e. the replacement of BE in the case of incomplete colonoscopy. The potential role is the proposal of CTC as a first-line CRC screening modality. In this setting, CTC has clear advantages, such as accuracy, safety and subject acceptance. Further research should be warranted to clarify, in particular, two aspects: the uptake rate of the general population and the real cost and benefits derived from a CTC screening program.

Abstract

Acute pancreatitis (AP) is an inflammatory condition of the pancreas caused by an imbalance in factors involved in maintaining cellular homeostasis. Earliest events in AP occur within acinar cells accompanied by other principal contributors to the inflammatory response i.e. the endothelial cells, immunocytes (granulocytes, monocytes/macrophages, lymphocytes) and neutrophils. Monocytes/macrophages are important inflammatory mediators, involved in the pathophysiology of AP, known to reside in the peritoneal cavity (in the vicinity of the pancreas) and in peripancreatic tissue. Recent studies suggested that impaired clearance of injured acini by macrophages is associated with an altered cytokine reaction which may constitute a basis for progression of AP. This review focuses on the role of monocytes/macrophages in progression of AP and discusses findings on the inflammatory process involved.

Key words: Acute pancreatitis; Monocytes; Peritoneal macrophages; Alveolar macrophages; Kupffer cells

Peer reviewer: Zoltan Rakonczay, MD, PhD, First Department of Medicine, University of Szeged, PO Box 427, H-6701 Szeged, Hungary

INTRODUCTION

Inflammation is a complicated progressive process which is initiated by the body in response to tissue injury or infection. Inflammation proceeds *via* the sequential release of mediators that leads to vasodilatation and increased blood flow, increased vascular permeability, causing the accumulation of a fluid exudates, and the activation of neurosensory pain fibers giving rise to the classical signs of acute inflammation i.e. heat, redness, swelling, and pain[1]. Acute inflammation is associated with high levels of polymorphonuclear cells, particularly neutrophils, whereas chronic or adaptive immune inflammation has higher levels of mononuclear cells, macrophages, T- and B-lymphocytes.

Regulated release of chemokines and expression and activation of cellular adhesion molecules recruits leukocytes at the site of inflammation. Leukocyte recruitment is a critical step in the inflammatory process[2]. Membrane bound vascular cell adhesion molecule-1 (VCAM-1), intracellular cellular adhesion molecule-1 (ICAM-1), endothelial leukocyte adhesion molecule-1 and E-selectin are expressed on endothelial cells, smooth muscle cells, and tissue macrophages. These adhesion molecules in coordination with others, for example, selectins, allow binding of ligands on leukocytes to mediate rolling, firm attachment and transendothelial migration. Endothelial cells being the interface between the tissue and circulation play

an important role in inflammatory and immune-relevant cells[3,4].

Acute pancreatitis (AP) is an inflammatory condition of the pancreas that involves peripancreatic tissue and remote organs. Excessive systemic inflammatory response syndrome (SIRS) in AP leads to distant organ damage and multiple organ dysfunction syndrome (MODS), which is the primary cause of morbidity and mortality in this condition. Mild AP is self limiting but up to 25% of the patients suffer a severe attack and around 30% of these will die. Approximately half of the deaths in AP occur within the first 2 wk of illness and are generally attributed to organ failure. The rest of the deaths occur weeks to months later, characterized by extensive retroperitoneal pancreatic necrosis and septicemia[5]. AP involves a complex cascade of events initializing in pancreatic acinar cells. An unknown trigger within the pancreas leads to conversion of digestive proenzymes into their active form, initiating auto digestion of the gland causing hemorrhage, necrosis, edema and complete destruction of pancreatic parenchyma. Intrapancreatic activation of trypsinogen by lysosomal hydrolases is an early triggering event in AP[6]. Interestingly both pharmacological and genetic deletion of lysosomal hydrolases like cathepsin B can reduce the severity of pancreatitis[7]. Other pharmacological agents which block trypsinogen activation can also modulate the outcome of AP[8,9].

Immune cells involved in elaborating the inflammatory mediators in AP are the pancreatic acinar cells, endothelial cells, neutrophils, lymphocytes, monocytes and macrophages. Inflammatory mediators believed to participate in the pathophysiology of this condition include: tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1β), interleukin-6 (IL-6), platelet activating factor (PAF), ICAM-1, IL-8, growth related oncogene-a/cytokine-induced neutrophils chemo attractant (GRO-α/CINC), monocyte chemotactic protein-1 (MCP-1), IL-10, complement component C5a, substance P (SP), hydrogen sulfide (H_2S), and neutral endopeptidase (NEP)[10]. In recent years, it has become clear that the signaling molecule nuclear factor κB (NF-κB) plays a central role in the initiation and progression of AP[11]. The emerging body of evidence suggest that blocking NF-κB activation can markedly reduce the severity of AP[12,13]. These findings have opened a window of opportunity for the use of selective NF-κB inhibitors in regulating the inflammatory process in AP. The expression levels of various proinflammatory mediators like TNF-α and IL-1β in AP are positively regulated by NF-κB[14,15]. Systemic amplification of AP is associated with excessive release of these inflammatory mediators from local tissue and systemically. This systemic amplification is responsible for most of the mortality associated with AP[16]. Studies indicate that both pancreatic and extra pancreatic (lung, liver, monocytes, macrophages and endothelial cells) activation of NF-κB is associated with development of MODS in AP[17,18].

In this review we discuss the recent advances, till date, pointing towards the fundamental role of different monocyte/macrophage populations in the progression of AP.

MONOCYTE/MACROPHAGE SYSTEM

Macrophages are among the most versatile cells of the body. Compelling evidence has emerged in recent years with respect to their roles in innate immunity, inflammation, and tumor progression. Macrophages are released from bone marrow into the bloodstream as promonocytes which develop into monocytes and migrate to tissue and undergo final differentiation into specific types of tissue resident macrophages[19]. The phenotypes of these tissue resident macrophages vary markedly within tissues, including Kupffer cells in liver, alveolar macrophages in lungs, osteoclasts in bone, microglial cells in brain, Langerhans cells in skin.

Monocyte and macrophage in AP

Since macrophages orchestrate both the initiation and the resolution of inflammation, they are an interesting target for designing a therapeutic strategy focused on the control of systemic effects of AP. Macrophage activation constitutes a key component of the immune response and several proinflammatory cytokines and bacterial products participate actively in the triggering of this process.

The degree of macrophage activation might be one of the important factors that determine the severity of AP[40]. Besides acinar cells, monocytes/macrophages are the main inflammatory cell population involved in the pathogenesis of AP (Figure 1). In AP, the inflammatory process starts with the migration of monocytes and neutrophils in the circulation into the pancreatic interstitial space, mediated by adhesion molecules on leukocytes. These infiltrating cells assist the production of different cytokines and various inflammatory mediators. As a result, amplification of non-infectious inflammation initiated in the pancreas to specific distant organs such as the lung, liver and spleen occurs[20]. The CC chemokines such as MCP-1, macrophage inflammatory protein (MIP)-1α and RANTES (CCL5) are believed to activate primarily monocytes, whereas the CXC chemokines, such as IL-8, tend to preferentially activate neutrophils. Bhatia *et al*[21] have shown that administration of bindarit, a blocker of MCP-1 synthesis (prophylactically or therapeutically), significantly reduces the severity of AP suggesting that MCP-1 may be an early inflammatory mediator in AP.

CD14, is a glycosyl-phosphatidylinositol anchored cell surface molecule expressed on the cell surface of immune effector cells of myeloid and monocytes hematopoietic lineage, which acts in concert with mammalian Toll-like receptors (TLR). It exists in 2 forms - soluble and membrane bound - and the soluble form has both immune stimulatory and inhibiting activities. Increased soluble CD14 expression and expansion of the proinflammatory CD14/CD16 monocytes subset has been reported in AP, suggesting that soluble CD14 receptor may serve as a key mediator of the systemic endothelial response, and its targeted disruption with anti-CD14 monoclonal antibodies may afford some therapeutic benefit in preventing the development of MODS and septic complications associated with AP[22]. Li *et al*[23] demonstrated that during early stages of

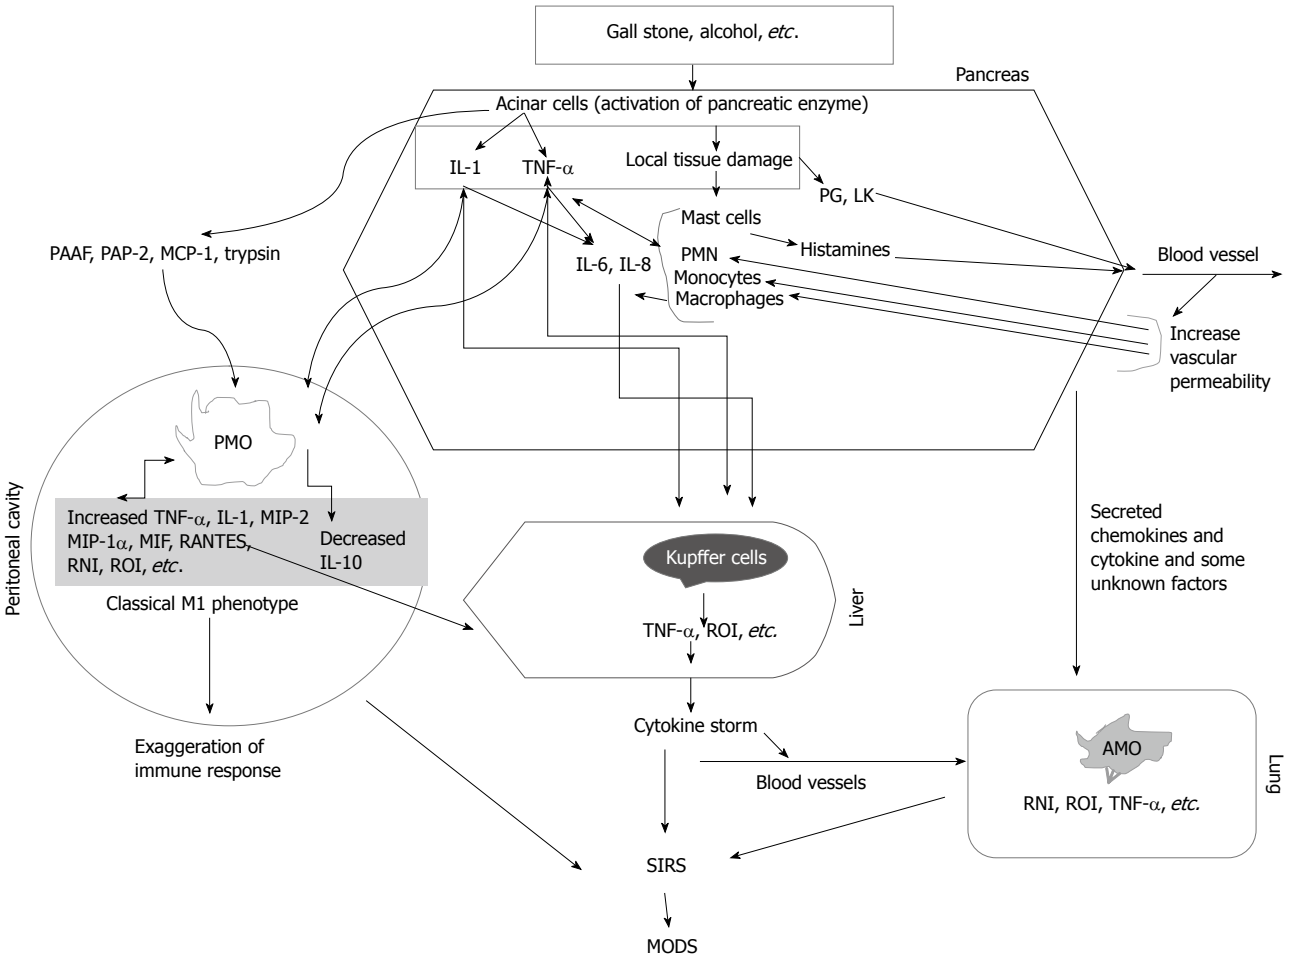

Figure 1 Our current understanding of the role of monocytes and macrophages in the pathogenesis of acute pancreatitis. Local inflammation in the pancreas leads to secretion of pro-inflammatory cytokines and some unknown factors. These inflammatory mediators activate peritoneal macrophages (PMO), Kupffer cells, and alveolar macrophages (AMO), which if uncontrolled can cause multiple organ dysfunction syndrome (MODS). PMO display a classical M1 type activation in acute pancreatitis thus supporting the inflammatory process. TNF: Tumor necrosis factor; RNI: Reactive nitrogen intermediates; ROI: Reactive oxygen intermediates; PAAF: Pancreatitis associated ascitic fluid; PAP: Pancreatitis-associated protein; MCP: Monocyte chemotactic protein-1; PG: Prostaglandins; LK: Leukotrienes; SIRS: Systemic inflammatory response syndrome; PMN: Polymorphonuclear leukocytes; MIP: Macrophage inflammatory protein.

AP, expression of TLR4 is upregulated in peripheral blood mononuclear cells (PBMC) with a simultaneous increase in TNF-α expression suggesting an important role of TLR-4 in pathogenesis of AP. TNF-α and IL-1β are regarded as most prominent "first-line" cytokines. Studies have indicated that during the course of pancreatitis, initially IL-1β and TNF-α are produced in the pancreas by acinar cells, in a process mediated by leukocytes, and organs such as liver, lungs and spleen which have large populations of macrophages, serve as subsequent sources of production of pro-inflammatory cytokines[24]. The pancreas itself contains an unknown proportion of resident macrophages. The liver and lung are susceptible to injury and organ failure during AP. Peritoneal macrophages, Kupffer cells and alveolar macrophages play a pivotal role in controlling the progression of AP, due to their ability to generate pro- and anti-inflammatory mediators.

Peritoneal macrophages

Peritoneal inflammatory cells play an important role in the production of chemical mediators and in the defense against infection of the abdominal cavity. Macrophages are the major resident immune cells within the pancreas and in the peritoneal cavity. Severe AP (SAP) and early multi system organ failure are associated with the sustained release of both pro- and anti-inflammatory cytokines in the ascitic fluid, the thoracic lymph and the systemic circulation. The peritoneal compartment which is in the close vicinity to the site of pancreatic inflammation and necrosis is the site for net proinflammatory reaction. Release of IL-1β and TNF-α by peritoneal macrophages in early stages of AP induces a cascade of other inflammatory cytokines, activation of neutrophils, and induction of the pro-inflammatory response whereas the anti-inflammatory response is mainly systemic in nature. Preventing the activity of both cytokines concurrently has no additional effect on the degree of pancreatitis but does attenuate the systemic stress response and is associated with an additional but modest decrease in mortality[10]. Thus, in AP, peritoneal macrophages act as a principal contributor to the acute systemic inflammatory response that in turn determines the severity of disease. Peritoneal macrophages isolated from rats with SAP showed over production of nitric oxide. Increased nitric oxide secretion is implicated in progression of AP[25].

Abnormal trypsin activation in the pancreas contributes to the pathogenesis of AP. Lundberg *et al*[26] showed that trypsin stimulates the production of cytokines in peritoneal macrophages and that injection of trypsin into the peritoneal cavity induces lung injury. Hori *et al*[27] demonstrated that TGF-β produced by peritoneal macrophages induces hepatocellular injury *via* apoptosis in the rat SAP model.

Studies demonstrate that pancreatitis associated ascitic fluid (PAAF) of SAP affects peritoneal macrophage functions thereby contributing to the pathologic course of disease. They showed that incubation of peritoneal macrophages with PAAF leads to rapid and prolonged activation of NF-κB and TNF-α production[28]. The major site of TNF-α gene transcription in AP is the pancreatic activated macrophages[29]. Their deactivation in the early course of AP increases survival and decreases the severity of disease. Liu *et al*[30] suggested that activation of NF-κB and p38 MAPK in monocytes/macrophages from animals with AP might play a role in transcription and biosynthesis of TNF-α and IL-6. Animal experiments indicated that sterile ascites without cytokines from AP can stimulate production of cytokines from macrophages derived from spleen and lung *in vitro* and can induce cytokine production systemically *in vivo*[31].

Mikami *et al*[32,33], by depleting peritoneal macrophages using liposome encapsulated dichloromethylene biphosphonate, suggested that peritoneal macrophages extend inflammation from the pancreas to the peritoneal cavity and subsequently induce lung injury leading to SIRS and multiple organ failure opening the possibility that therapeutic modification of peritoneal macrophages may be a new therapeutic approach in patients with AP. The immune response in AP depends to a larger extent on macrophages as they represent about a third of infiltrating mononuclear cells. Macrophages are the main source for the production of inflammatory mediators; their presence in pancreatitis might contribute to the amplification of the immune response during disease progression.

With the progression of AP, there is a change in number and ratio of CD4+ and CD8+ lymphocytes indicating the possible involvement of T-lymphocytes. Observation by Demlos *et al*[34] demonstrated that CD4+ T cell depletion reduces the severity of pancreatitis. CD4+ T cells act as a costimulator for macrophage activation *via* antigen presentation and proinflammatory cytokine release[35].

Activation and trafficking of inflammatory cells involves chemokines and their receptors. Interestingly deletion of the receptor for MIP-1α and RANTES, the CCR1 receptor, was associated with protection from pulmonary inflammation but did not reduce the severity of cerulein-induced pancreatitis. This protection from lung injury is associated with decreased levels of TNF-α in a temporal sequence indicating the critical role of CCR1 receptor in the extension of pancreatic injury to the systemic response. The authors underline these findings by suggesting that CCR1 may be activated on either peritoneal or lung macrophages, leading to an autocrine process whereby increased levels of TNF-α drive further induction of both α and β chemokines, resulting in recruitment of inflammatory cells to the pancreas and lung[36]. However, in the same model, inhibition of CXCL2 (MIP-2) protected partially against both pancreatic and lung injury[37]. Attenuation of pancreatic injury in this study may be due to the fact that CXCL2 (MIP-2), in contrast to CCL5 (RANTES) and CCL3 (MIP-α), also attracts neutrophils in addition to monocytes. Macrophage migration inhibitory factor (MIF), a proinflammatory cytokine released by macrophages and lymphocytes, is emerging as an important player in the pathogenesis of AP. Pre-treatment with anti-MIF antibodies improved the survival in rats with AP[38]. Recently, work by Sorli *et al*[39] suggested that peritoneal macrophages showed a classical M1 phenotype in AP, characterized by high expression of TNF-α and lack of changes in the mannose receptor. TNF-α can in turn activate macrophages for release of other macrophage derived inflammatory cytokines thus exaggerating the inflammatory response. Their study also indicates that peritoneal macrophages could be reprogrammed *in vitro* to reparative alternatively activated (M2) macrophages by IL-4 and IL-13 thus opening the possibility that therapeutic modulation of macrophage activation can help in the treatment of AP[39].

In any immune response dying cells are normally phagocytosed by macrophages; this elimination of dying cells is associated with anti-inflammatory cytokine switching. Recent observations by Liang *et al*[40] have suggested that there is a close relation between modes of pancreatic acinar cell death, the release of cell contents and the inflammatory reaction of peritoneal inflammatory cells.

In recent years, neuropeptide SP has gained considerable attention as a mediator of neurogenic regulation of inflammation. Earlier work by Sun *et al*[41] has suggested that neuropeptide SP is a pro-inflammatory mediator involved in pancreatitis and during acute inflammation, SP induces chemokine release from macrophages infiltrating into local and distant damaged tissues. Mice lacking NK-1Rs which bind to SP are protected against cerulein induced pancreatitis and associated lung injury. Macrophages have receptors for SP. Recently we have also shown the effect of SP on the murine macrophage cell line RAW264.7, as well as isolated primary macrophages, indicating that SP, at nanomolar concentrations, elicited selective chemokine production from murine macrophages[42]. Indeed, unpublished observations from our lab indicate that macrophages isolated from mice lacking NK-1R receptors show M2 phenotype displaying an anti-inflammatory cytokine switch. These observations led us to conclude that SP, acting *via* NK-1R on macrophages, plays an important role in regulating the severity of pancreatitis and associated lung injury.

Pancreatitis-associated proteins (PAP) are members of the *Reg* gene family; these 14-17 kDa proteins have been shown to be strongly induced during AP[43]. Although originally identified during AP, they have been reported in other inflamed pathologic organ systems including Crohn's disease, inflammatory bowel disease, liver injury, neuronal, ovarian, and cardiac tissue damage[44,45]. Recent investigation suggests that PAP2 is a potential mediator of early

inflammation in AP, its act specifically by orchestrating the macrophage inflammatory response, and may do so by working in concert with other PAP isoforms[46]. They also demonstrated that macrophages may express a potential PAP2 receptor[46].

Kupffer cells

Liver macrophages or Kupffer cells are the most abundant mononuclear phagocytes in the body. They are a predominant source of inflammatory cytokine released in the systemic circulation. Cytokine release from the liver represents about 50% of total cytokine release from the body[47]. Recent studies have shown the involvement of the liver in complex networks of events triggering the multiorgan dysfunction associated with AP. During AP the inflamed pancreas generates soluble inflammatory mediators. Once pancreatic mediators reach the liver, they strongly activate Kupffer cells (resident macrophages), they then greatly amplify the release of cytokines into the blood stream and thus contribute to the systemic manifestation of AP. Activated Kupffer cells release different inflammatory mediators, immunoregulatory and inflammatory cytokines, reactive nitrogen intermediates (RNI), reactive oxygen intermediates (ROI), hydrogen peroxide, *etc.* which play a significant role in progression of pancreatic inflammation into a systemic process[48]. TNF-α released from the pancreas triggers the early events in AP, as pancreatitis progresses TNF-α reaches the liver, further manifesting the disease outcome by causing a cytokine storm. This cytokine is considered as one of the most important mediators of the systemic complications associated with AP[49]. The observation that in native pancreatitis the systemic manifestation of AP is more severe as compared to graft pancreatitis (as the mediators released by pancreas in graft pancreatitis are sent directly through the iliac vein) suggested that the liver plays an active role in the development of lung injury secondary to AP[50]. Gloor *et al*[51,52] further confirm this observation by preventing the passage of blood coming from pancreas to liver. Interestingly it has been shown that blocking the activity of Kupffer cells by gadolinium chloride in a sodium taurocholate AP model significantly reduces the increased TNF-α in serum during pancreatitis to its control levels, followed by reducing the inflammatory response in the lung, and in turn reducing the systemic complications associated with AP and improving the survival rate in mice. The authors confirm their observation *in vitro*, by using cultured Kupffer cells[53,54]. Additionally, inhibiting the Kupffer cell activity before induction of AP significantly diminished the associated lung injury with a decrease in NF-κB activity[55]. Altogether, these results show a link between the local inflammatory process in the pancreas and its manifestation by liver cells, especially Kupffer cells, causing the appearance of systemic organ dysfunction secondary to AP.

Alveolar macrophages

Patients with AP may develop acute lung injury, manifest clinically as the adult respiratory distress syndrome (ARDS). Most patients who die during the early stages of SAP die either with or as a result of this lung injury. However, the events that link AP to acute lung injury are not fully understood. It has been postulated that alveolar macrophages (AM) are involved in development of acute local disorders as a consequence of extra pulmonary stimuli like pancreatitis, peritonitis, or trauma. AM have the capacity to secrete a very large number of inflammatory mediators, including lipid mediators, chemokines, cytokines, growth factors and reactive oxygen and nitrogen species. They may therefore play multiple roles in the respiratory tract and may be pro-inflammatory or anti-inflammatory. They may be activated by several stimuli, including cigarette smoke, pro-inflammatory cytokines, endotoxin and immune stimuli. Their capacity to release multiple chemokines leads to the recruitment of several cell types from the circulation, including monocytes, neutrophils and T lymphocytes. Polymorphonuclear neutrophils play an important role in the development of ARDS and activation of the complement system, and generation of AM derived factors promotes neutrophil aggregation into lungs. The capacity of AM to mobilize a large amount of leukocyte and to release secretory products such as RNI and ROI suggests that these cells can be involved in lung damage associated with AP. The activation of AM seems to be regulated by cytokines and inflammatory mediators, which are generated during the course of AP. Sailai *et al*[56] suggested that the inhibition of NF-κB activation may reverse the lung injury of acute necrotizing pancreatitis (ANP) by inhibiting the release of inflammatory mediators by AM. Nitric oxide (NO) is an important marker of oxidative injury in the lung. High TNF-α and NO released by activated AM in ANP suggest a role for AM in inducing lung injury associated with ANP[57]. Studies have suggested that, during the early phase of AP, AM-derived NO contributes to lung injury. Administration of the NOS inhibitor L-NMMA prevented lung injury in this model. In conclusion, this study shows that lung damage induced by experimental AP develops with AM activation. The liver plays an active role in the activation of AM in this experimental model[58]. In addition, neutrophil recruitment into the lungs during AP seems to be mediated by chemotactic mediators (TNF-α and MIP-2) released by activated AM.

In AP, endothelial cells, polymorphonuclear neutrophils and macrophages release PAF, which has been implicated as a key mediator in the progression of AP, leading to complications and unacceptably high mortality rates. PAF participates in the occurrence and development of AP and administration of platelet-activating factor receptor antagonists (PAF-RAs) could significantly reduce local and systemic events after AP[59]. BN52021 (PAF-RA) prevented the labilization of the lysosomal membrane of AM thus suggesting that complications of AP could be dependent on the stabilization of AM lysosomes[60]. Another PAF antagonist (TCV-309) prevented hyperactivity of AM by reducing cytokine induced neutrophil chemoattractant expression by AM[61]. These studies further point to the use of PAF antagonist in reducing the secondary complications associated with AP.

Hsp72 induction is associated with the early stages of

lung neutrophil infiltration. In a study using a 5% sodium taurocholate model of AP it was found that Hsp72-was over expressed in bronchial epithelium, alveolar macrophages, infiltrating neutrophils, blood vessels and blocking of P-selectin activity diminished the expression of Hsp72 in lungs thus suggesting that Hsp72 induction is mediated by neutrophil infiltration into the lungs[62].

Macrophages generate ROI and therefore contribute to the increased oxidative stress. Increased levels of pancreatic phospholipase A2 (PLA2) are detected in the systemic circulation and bronchoalveolar lavage fluid from patients with lung injury in AP. Reports indicate that PLA2 regulates the cytokine production of monocyte/macrophages and the phagocytosis and superoxide (O2-) generation of neutrophils[63]. AMs are activated by PLA2 and produce a large amount of NO that contributes to lung injury in AP. Blocking of PLA2 activity prevented the lung injury associated with pancreatitis[64].

The secretion of multiple inflammatory proteins by AM is largely a result of increased expression of inflammatory genes orchestrated by proinflammatory transcription factors, such as NF-κB and AP-1. Sphingosine-1-phosphate (S1P), a biological active lipid generated by numerous cell types, significantly reduced the NF-κB activation of the AM, ameliorating pulmonary injury[65], thus suggesting that AM could be a therapeutic target of S1P for combating pulmonary injury associated with pancreatitis.

CONCLUSION

Though the role of monocytes/macrophages has long been considered as evidence for a host response against the inflammatory process, recent findings suggest that monocytes/macrophages are active players in the progression of AP. Over the past few years understanding of molecular mechanisms underlying the progression of AP has improved considerably. A better understanding of regulation and function of different macrophage populations involved in AP will help to establish more therapeutically effective novel therapies for AP management. Strategies targeting molecules (NF-κB and STAT-3) and mechanisms supporting M2 type macrophages will further help in restraining the inflammatory process.

Abstract

Lymph node metastasis is the hallmark of colon cancer progression, and is considered one of the most important prognostic factors. Recently, there has been growing evidence that tumor lymphangiogenesis (formation of new lymphatic vessels) plays an important role in this process. Here, we review the latest findings of the role of lymphangiogenesis in colorectal cancer progression, and discuss its clinical application as a biomarker and target for new therapy. Understanding the molecular pathways that regulate lymphangiogenesis is mandatory to pave the way for the development of new therapies for cancer. In the future, tailored treatments consisting of combinations of chemotherapy, other targeted therapies, and anti-lymphangiogenesis agents will hopefully improve patient outcomes. This progression to the clinic must be guided by new avenues of research, such as the identification of biomarkers that predict response to treatment.

Key words: Colorectal neoplasms; Angiogenesis; Lymphangiogenesis; Lymphatic vessels; Lymphatic metastasis; Vascular endothelial growth factor; Monoclonal antibody D2-40; Therapy-related neoplasms; Biomarkers

INTRODUCTION

Colorectal cancer (CRC) is the third most common type of cancer to develop and to cause death in the United States[1]. Although the pattern of spread of CRC may vary, the initial step involves lymphatic invasion and metastasis to regional lymph nodes[2]. Patients with lymphatic invasion have a less favorable outcome, and lymph node metastasis is one of the most important prognostic factors in CRC[3]. In fact, both the Dukes and TNM staging systems, which have been the most widely used staging systems for CRC, are based on the assessment of lymph node metastasis in addition to the extent of primary tumor and distant metastatic disease[4,5]. Patients with an early stage tumor without evidence of lymph node metastasis (Dukes A, TNM stage Ⅰ) have an excellent post-operative prognosis and a 5-year survival rate of 80%-90%, while patients with advanced tumors with regional lymph node disease (Dukes C, TNM stage Ⅲ) have a 5-year rate of 25%-60%. Furthermore, patients with distant metastatic disease (Dukes D, TNM stage Ⅳ) have a 5-year rate of less than 10%[6-8]. In addition, the number of nodes with metastatic disease has an important impact on the prognosis of patients with CRC. In fact, the influence of lymph node metastatic

disease on prognosis in CRC is so great that there is not only a difference between N1 and N2 (1 to 3 nodes *vs* 4 or more nodes), but based upon separate analyses by the Surveillance Epidemiology and End Results program, there is also a significant prognostic difference within each of these groups. Accordingly, N1 is subdivided into N1a (1 node involvement) and N1b (2-3 node involvement), and N2 is subdivided into N2a (4 to 6 node involvement) and N2b (7 or more). This new TNM staging system lymph node sub-categorization is based on survival[8], which is in further agreement with the importance of lymph node metastatic disease in CRC patient outcome. Moreover, detailed analysis of lymph node status allows for accurate staging, which is now shown to be associated with better outcomes[8].

While local or regional CRC can be controlled with complete surgical resection, combination therapy is required to treat systemic disease. Among patients with newly diagnosed CRC, 25% will first present with metastatic disease[9]. Even among patients who present with localized, resectable disease, 30% will have a recurrence with metastatic disease[9]. There has been remarkable progress in the treatment of metastatic CRC during the last decade in the fields of surgery, radiation, chemotherapy, and targeted therapy[9-11]. Over the last decade, a better understanding of the processes involved in tumorigenesis and cancer metastasis has led to the development of a new category of systemic drugs called targeted therapies. The term targeted therapy refers to drugs that selectively target specific molecular pathways involved in tumorigenesis and/or tumor metastatic progression[11]. In CRC, two targets have been intensively investigated and are currently under Phase Ⅲ clinical trials: the vascular endothelial growth factor (VEGF) pathway that controls angiogenesis, the phenomenon where new blood vessels are formed to feed the enlarging tumor and develop access to the blood stream; and the epidermal growth factor pathway that controls cell survival and proliferation. The former is targeted by the anti-VEGF monoclonal antibody, bevacizumab (Avastin™), and the latter is targeted by the anti-EGFR monoclonal antibodies, cetuximab or panitumumab[9,12]. Recently, there has been growing evidence that not only angiogenesis, but also lymphangiogenesis, the formation of new lymphatic vessels, is important in CRC metastatic progression[2,13-23]. This article will review the latest reports on lymphangiogenesis not only in experimental models, but also in clinical studies, and also review its clinical application as a biomarker and as a new targeted therapy.

WHY IS ANGIOGENESIS IMPORTANT FOR CANCER PROGRESSION AND METASTASIS?

In order for cancer to progress and metastasize, the primary tumor must have access to the systemic circulation, either through blood or lymphatic vessels. Angiogenesis is defined as the process whereby new blood vessels are formed from existing vessels, and as such, is a natural physiological process. Under normal physiologic conditions, angiogenesis only occurs in adults during menstruation, gestation and wound healing. At other times, anti-angiogenic factors maintain the endothelial cells that form blood vessels in a quiescent state[24]. The theory that angiogenesis could support tumor metastatic progression and therefore be a target for cancer therapy was proposed by Folkman *et al*[25,26] in the 1970s. He hypothesized that cancer requires angiogenesis to "feed" the cancer enabling it to grow beyond a certain size, and to allow for systemic spread. After 2 decades of developing this theory, modern molecular and cell biology techniques verified the role of angiogenesis in cancer growth *via* animal tumor models and clinical trials of bevacizumab, a humanized monoclonal antibody that neutralizes VEGF[27,28].

Tumors secrete multiple angiogenic factors and/or down-regulate angiogenesis inhibitors to induce tumor angiogenesis. VEGF-A is one of the key factors responsible for stimulation and maintenance of the disorganized, leaky, and torturous tumor vasculature. Other factors include members of the platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), insulin-like growth factor, angiopoietin, and hepatocyte growth factor (HGF) families[29]. Conversely, blockade of VEGF function inhibits angiogenesis and suppresses tumor growth *in vivo*[30]. While the discovery of factors important for angiogenesis has not yet led to a new cure for cancer, understanding that this process is essential for tumor metastasis has revealed several possibilities for targeted therapy. Applying this research approach to lymphangiogenesis can produce new potential targeted therapies.

WHY IS LYMPHANGIOGENESIS IMPORTANT FOR CANCER PROGRESSION AND METASTASIS?

The importance of lymph node metastasis in the progression of CRC has been well established and has a great impact on prognosis[8]. For cancer metastasis to the lymph node to occur, the cancer cells must access the lymphatic vessels to reach the regional lymph nodes. Applying approaches similar to the ones used to understand angiogenesis is expected to identify molecular mechanisms that control the processes related to lymphangiogenesis[31]. Therefore, understanding how lymphatic vessels are formed under physiologic and non-cancerous pathologic conditions can help provide an understanding of lymphangiogenesis in cancer in order to provide new avenues for targeted therapy development.

Although the ancient Greeks had already described aspects of the lymphatic system, the lymphatic vasculature was only properly considered to be a distinct circulatory system in 1622 by Asselli[32]. The lymphatic vasculature forms a vessel network that drains interstitial fluid from tissues and returns it to the blood circulation *via* the thoracic duct. Lymphatic vessels are also known to be an essential part of the body's immune defense. Descrip-

tions of the metastatic spread of cancer can be found as far back as the 14th century[33], and the involvement of the lymphatic system in metastatic progression has been described since the 18th century[34]. The traditional theory was that tumor cells metastasized to lymph nodes by utilizing pre-existing lymphatic vessels, and that lymphatic vessel entry occurred by permeation or embolization, not through the creation of new lymphatic vessels in response to cancer. Although the regeneration of lymphatic vessels was observed by Clark and Clark in 1932, cancer metastasis and the concept of lymphangiogenesis were not linked until the last two decades[35]. Despite an acceptance for centuries of the important role of the lymphatic system as the primary pathway for the metastatic spread of tumor cells to regional lymph nodes, and possibly even also to distant organs, the exact mechanism of this process has remained unclear until recently[36].

Over the past few years, understanding of the cellular and molecular aspects of physiologic lymphangiogenesis and tumor-induced lymphangiogenesis has advanced after the discovery of VEGF-C and its function to promote the growth of lymphatic vessels[37]. Initially, the study of lymphangiogenesis largely focused on the primary site of tumor growth and adjacent tissues, which is known as "tumoral lymphangiogenesis"[38,39]. However, lymphangiogenesis was also observed around regional lymph nodes, in particular the sentinel nodes where tumor cells first metastasize, a phenomenon now known as "lymph node lymphangiogenesis"[6,40]. Lymph node lymphangiogenesis and increased lymph flow through tumor-draining lymph nodes are speculated to actively promote metastasis *via* the lymphatics[41]. Recent evidence indicates that tumor cells can also induce lymph node lymphangiogenesis - even before they metastasize - and that metastatic tumor cells continue to induce lymphatic vessel growth within sentinel lymph nodes, theoretically promoting their further metastatic dissemination[42,43].

As expected, the majority of studies point to a positive correlation between tumor-induced lymphangiogenesis and lymphatic metastasis[6,13-17,44,45]. Because the physiologic role of the lymphatic system is to collect interstitial fluid from peripheral tissues and return it to the systemic blood circulation, it is hypothesized that tumor-induced lymphangiogenesis occurs in order to drain interstitial fluid away from the tumor. Therefore, targeting this process provides a potential avenue for cancer therapy[46]. In fact, experimental inhibition of this process in animal models suggested that lymphangiogenic growth factors facilitate the metastatic spread of tumor cells *via* the lymphatics[14,18-20]. The results highlight the key role that lymphangiogenic growth factors and new lymphatic vessels play in tumor metastatic progression. These early studies indicate that targeting lymphangiogenic growth factors in tumors could be a strategy for restricting the metastatic spread of cancer[31].

IN VIVO AND *IN VITRO* MODELS OF LYMPHANGIOGENESIS

The recent discovery of the key lymphangiogenic factors

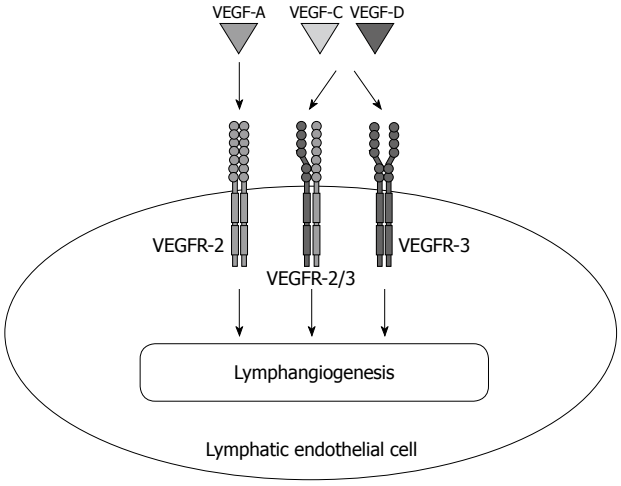

Figure 1 Lymphangiogenic growth factors and their receptors expressed by lymphatic endothelium. Vascular endothelial growth factor (VEGF) receptor (VEGFR)-3 is a member of the fms-like tyrosine kinase family and specifically binds VEGF-C and VEGF-D, but not VEGF-A. Recent studies also indicate an important role for the VEGF-A/VEGFR-2 signaling pathway in lymphangiogenesis.

VEGF-C and VEGF-D, other proteins related to these factors, and their receptor VEGF receptor (VEGFR)-3, have provided novel insights into how the lymphatic vessels and blood vessels coordinately grow and affect human disease[47]. In fact, these factors are associated with a number of human tumor types[31]. These secreted glycoproteins largely signal *via* the cell surface tyrosine kinase receptor VEGFR-3/Flt4 present on the surface of lymphatic endothelial cells (LECs), and VEGFR-3 activation promotes LEC proliferation, migration, and survival, which result in lymphatic vessel proliferation *in vitro* and *in vivo*[6]. Furthermore, recent studies indicate that the VEGF-A/VEGFR-2 signaling pathway plays a major role not only in angiogenesis, but also in lymphangiogenesis[48,49] (Figure 1).

In vitro techniques to study lymphangiogenesis have evolved with the development of methods to isolate and culture LECs. LECs have been isolated from lymphatic vessels or skin followed by enzymatic digestion and flow cytometric cell sorting using markers specific to LECs. Several LEC markers have been recently identified, including: lymphatic vessel endothelial hyaluronan receptor-1[50]; glomerular podocyte membrane mucoprotein, podoplanin (D2-40)[51]; the homeobox gene product, Prox-1[52,53]; and VEGFR-3[54,55]. Although these markers have aided in the purification of LECs, the limited quantity of cells obtained and the reduced growth potential of these cells have posed a challenge. To address the challenge of only having a limited quantity of cells after the purification of LECs, immortalization with SV40 large T antigen[56] or transformation with human telomerase reverse transcriptase[57] have been utilized to extend the life span of LECs, and transgenic mice have been developed to harvest immortalized LECs[58]. Protocols for the isolation of LECs from microlymphatic vessels in different tissues in rats have recently been established[59,60]. In most experimental assays, LECs are seeded as monolayers on culture plates or onto the surface of matrix-coated plates. While 2-D cul-

tures cannot undergo all of the steps of lymphatic vessel formation, these culture systems allow the analysis of each step individually, using various assays of cell activity (e.g. gene expression profiling), cell proliferation, apoptosis, adhesion, migration (wound scratch assay, Boyden chamber assay), and morphogenesis (tubulogenesis)[61].

Numerous *in vivo* models to study the growth of lymphatic vessels have utilized the same techniques as those used for blood vessel growth. The growth of vessels into the avascular cornea in response to specific factors or inflammation has been historically utilized as a model to study lymphangiogenesis[62-64]. Another extensively used model is the development of lymphedema and lymphangiomas. Lymphedema is swelling due to the failure of fluid drainage by the lymphatics which occurs as a result of obstruction or secondary changes impairing lymph flow. Several mouse models carrying mutations or chromosomal aberrations recapitulate this phenotype[65,66], and surgical ablation of lymphatic vessels can induce lymphedema and subsequently lymphangiogenesis[67,68]. Lymphangiomas, characterized as benign malformations of the lymphatic system, have been induced by injection of incomplete Freund's adjuvant, either into the mouse ear[69] or intraperitoneally[70], causing lymphatic vessel hyperplasia leading to inflammation and lymphangiogenesis[71].

Breast, gastric or CRC cells over-expressing VEGF-C implanted into transgenic mice induced tumor-associated lymphangiogenesis in orthotopic mouse models[13,72,73]. Skin carcinogenesis models in transgenic mice over-expressing VEGF-A or C showed that tumors in these mice were significantly more likely to metastasize[40,74]. As compared to VEGF-A, VEGF-C did not increase the size of the primary tumors, but induced the expansion of metastatic networks within the lymph nodes and promoted metastasis to distant sites such as distant lymph nodes and the lungs[74]. In addition to VEGF, PDGF-BB, FGF-2, HGF and angiopoietin enhance lymphangiogenesis[75-79]. Sphingosine-1-phosphate (S1P) also stimulates lymphangiogenesis in both *in vitro* and *in vivo* models[80,81]. S1P is generated by the action of two sphingosine kinases, sphingosine kinase 1 and 2[82,83]. Tumor cells, which are characterized by high levels of sphingosine kinase 1 expression, can release S1P into the extracellular space[84], which in turn can lead to paracrine-induced angiogenesis and lymphangiogenesis[81]. Interestingly, LEC-specific deletion of sphingosine kinase 1 in the sphingosine kinase 2 knockout mouse inhibits lymphatic vessel maturation[85].

In vivo models demonstrate that lymphangiogenesis promotes CRC metastasis, suggesting new avenues for the development of targeted therapy and prognostic markers. VEGF-C and VEGF-D, which are up-regulated in CRC, appear to drive tumor lymphangiogenesis through the VEGF-C/VEGF-D/VEGFR-3 pathway, while other growth factors, such as VEGF-A, have modulatory effects on this process[48,49]. VEGF-A expression levels significantly correlate with metastasis to the lymph nodes in CRC[48,49]. Orthotopic implantation of VEGF-C over-expressing DLDA colon cancer cells demonstrated that VEGF-C induced lymphangiogenesis-mediated tumor spread and the formation of metastatic disease in the lymph nodes[13], while the inhibition of VEGF-C expression reduced lymphangiogenesis, the extent of lymph node metastatic disease, and enhanced survival in mice[14]. The inhibition of VEGF-C expression also dramatically suppresses tumor lymphangiogenesis, tumor growth, and regional lymph node metastasis in mice[18]. Inhibition of VEGFR-3 using small interfering RNA also significantly inhibited tumor growth[19,20]. These *in vitro* and *in vivo* mouse data demonstrate the possible clinical application of lymphangiogenesis as a biomarker and/or as a new target for therapy in CRC in humans.

LYMPHANGIOGENESIS IN HUMAN SAMPLES

The role of intra- and peri-tumoral lymphatics in tumor biology and the initial steps of lymphatic metastatic progression, i.e. the invasion of tumor cells into the lymphatic vessels, are just beginning to be elucidated in human samples[44]. Animal studies have demonstrated that intra-tumoral lymphatic vessels are poorly functional due to high intra-tumoral pressure and may not be required for lymphatic metastatic progression. Conversely, lymphatic vessels in the tumor periphery are functional and can drain colloids from the tumor. In several common human tumors, such as cutaneous melanoma[86,87], head and neck squamous cell carcinoma[38,88], transitional cell carcinoma of the bladder[89,90] and non-small cell lung cancer[91], tumoral lymphangiogenesis detected by lymphatic vessel density (LVD) can be readily appreciated and has been shown to be of prognostic significance. In contrast, in breast[92,93], cervical and prostate carcinoma[94] tumors that metastasize to the lymph nodes, there is little evidence of significant tumoral lymphangiogenesis detected by LVD, with most proliferating vessels lying within the peritumoral tissues[6]. Another important factor to consider is the location of the tumor in relationship to the amount of pre-existing lymphatic vessels, such as in biliary cancer, which is very prone to metastasize *via* the lymphatic system[95,96]. Furthermore, mouse models of cecal cancer metastasis to the liver have demonstrated that both VEGF-C and VEGF-D produced less metastatic disease in the liver compared to primary cecal tumors, suggesting the importance of the tumor microenvironment for the production of these lymphangiogenic factors[97]. Taken together, the pattern of tumoral lymphangiogenesis and metastasis to the lymph node varies between tumor histological type and anatomic location of the tumor, involving both the lymphatic system and the microenvironment. Clearly, further studies are awaited to understand this complex process.

Although several studies have reported the discrepancy between LVD measurements and clinical outcome, it should be noted that there is a great deal of variability in their methodologies and consequently also in their results. In addition to tumor characteristics, the discrepancies in terms of the correlation of LVD with metastasis

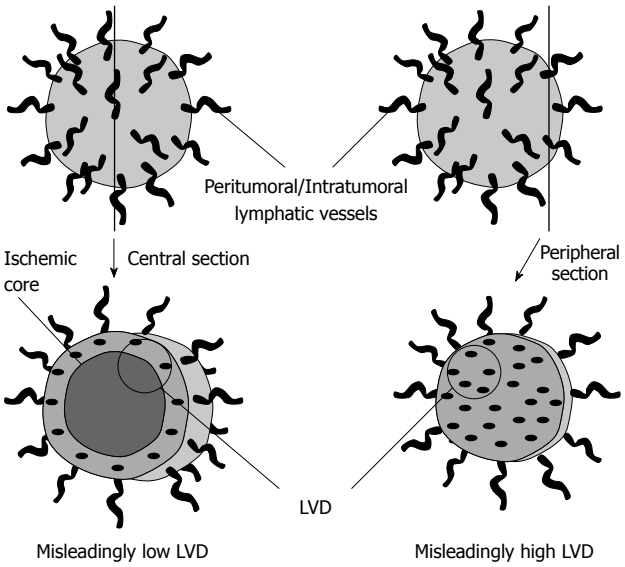

Figure 2 Limitations of lymphatic vessel density estimations. The central section of a tumor with a necrotic central core may estimate a misleadingly low lymphatic vessel density (LVD) (left), while the peripheral section of the same tumor may estimate a misleadingly high LVD (right).

to the lymph nodes and prognosis in these studies can be attributed to the limitations of the methodologies used. The limitations include the different types of tissue preservation, variable immunostaining techniques, different LVD quantification methods employed, and the lack of standardization in the estimation of lymphangiogenesis[98] (Figure 2). To address the limitations of this qualitative analysis methodology, some studies have attempted to quantify the expression of VEGF-C and VEGF-D mRNA or protein in excised primary tumor tissue of patients with various cancers. They frequently report that the levels of these molecules exhibit a strong correlation with parameters associated with poor patient outcome, such as the invasion of lymphatic vessels by tumor cells, the extent of lymph node metastatic disease, and disease-free as well as overall survival[31]. However, even these attempts to quantifiably measure lymphangiogenesis have not been entirely successful. In fact, recent epigenetic studies demonstrated that the analysis of mRNA or protein expression may not reflect actual lymphangiogenesis due to posttranscriptional modifications of proteins. In order to adequately assess the degree of lymphangiogenesis, a better method to accurately quantify the amount of lymphangiogenesis is needed.

LYMPHANGIOGENESIS AS A BIOMARKER FOR CRC PROGRESSION

Although animal models show a strong relationship between lymphangiogenesis and lymph node metastasis and survival, the clinical significance of lymphangiogenesis in CRC remains uncertain, as is the case for other tumors[6]. Parr *et al*[21] showed that the expression of VEGFR-3 receptor, prox-1, 5'-nucleotidase expression, and podoplanin expression in cancer tissue were significantly higher than in the normal background tissue. Jia *et al*[16] showed that the extent of lymph node metastatic disease in VEGF-C-positive patients (81.1%) was significantly higher than that in the negative group (42.1%). Lu *et al*[17] showed that quantitative analysis of podoplanin in CRC specimens correlates with metastasis to regional lymph nodes. Yan *et al*[22] showed that the co-accounting of LVD and microvessel density (MVD) was an independent prognostic factor in CRC. Moehler *et al*[15] showed that the expression of VEGF-D is significantly associated with lymphatic involvement in CRC patients and that cetuximab can block such expression effectively. In addition, the quantification of VEGF-C and VEGF-D in blood samples has the potential to serve as a biomarker to predict the extent of lymph node metastatic disease[23]. Interestingly, Sundlisaeter *et al*[99] showed that LVD was significantly increased in tumor tissue compared with the normal mucosa, but there were no changes in LVD between stage Ⅱ and Ⅲ CRC. This indicates that lymphangiogenesis occurs in CRC, and indeed suggests that it is triggered at an early stage of tumor development. Taken together, these studies suggest that these lymphangiogenesis-related markers indicate an increase in lymphangiogenesis in CRC, and might therefore have prognostic value for CRC patients.

However, other reports failed to find an association between higher LVD, the aggressiveness of tumor behavior and poorer clinicopathological variables. Kazama *et al*[100] revealed that the expression of VEGF-C was significantly correlated with lymphatic involvement, lymph node metastatic disease and tumor size, but not with venous involvement, metastasis to the liver in invasive carcinomas, or overall survival. Miyazaki *et al*[101] showed that an elevated level of plasma VEGF-C correlated with deeper invasion, and more severe venous and lymphatic invasion of the primary tumor, although there was no significant difference in the plasma level between patients with CRC and the healthy controls. Gao *et al*[98] showed that MVD and LVD were higher in the tumor compared with the corresponding normal mucosa, but they were not related to clinicopathological variables and overall survival. However, it should be noted that these studies rely on qualitative analysis methodologies, which are not objectively quantifiable assays. Duff *et al*[102] showed that the balance between the expression of VEGF-C and VEGF-D at the invading tumor edge may enhance lymphatic metastasis by promoting tumor lymphangiogenesis or by activating pre-existing lymphatic vessels. However, no relationship was identified between LVD and clinicopathological variables. Again, it should be noted that these reports rely on qualitative analysis methodologies, which are not objectively quantifiable assays. Taken together, lymphangiogenesis occurs in CRC development, but it has not been clearly linked to CRC patient prognosis. The conflicting reports in the literature regarding the possible correlation of LVD with clinical factors can be attributed to the use of qualitative analysis methodologies. Therefore, the development of a new quantifiable assay that uses standardized metrics is necessary.

In the future, the intra-tumoral expression of specific molecules, e.g. deleted in CRC[103,104] or 18q loss of heterozygosity[104], DNA microsatellite instability[103-105], KRAS mutation[103-105], or thymidylate synthase[103,104] could become biomarkers to predict prognosis or the response to therapy, independently of TNM stage group or histologic grade. It is now clear that there is an interaction between the T and N designations that is likely to rely on the expression of specific molecules within the cancer. In the latest edition of their cancer staging manual, the American Joint Committee on Cancer has stated that they will add molecular profiling information to the TNM classification to enhance the prediction of prognosis and/or even response to therapy[8]. Because lymphatic invasion and metastasis to the lymph nodes have a great impact on patient prognosis, lymphangiogenesis-related molecules are good candidates for the biomarkers that will be included in future editions of the TNM staging system.

LYMPHANGIOGENESIS AS A NEW THERAPEUTIC TARGET FOR CRC

Based upon the importance of angiogenesis and lymphangiogenesis in cancer progression, specific antibodies against angiogenic factors have been developed. The humanized VEGF antibody, known as bevacizumab (Avastin™), has been approved by the United States Food and Drug Administration (FDA) for treating metastatic carcinoma of the colon or rectum, and recurrent or metastatic non-squamous non-small cell lung cancer. Recently, bevacizumab also received accelerated FDA approval for the treatment of metastatic HER2-negative breast cancer[31]. However, the addition of bevacizumab to chemotherapy as adjuvant therapy in CRC did not improve disease-free survival[106]. Bevacizumab is being tested in other clinical settings such as adjuvant therapy, maintenance therapy, and in combination with both cytotoxic chemotherapy and other targeted agents, such as the epidermal growth factor receptor kinase inhibitor, erlotinib[106]. In addition to bevacizumab, other antibody-based therapies targeting the VEGF pathway are being tested. Ramucirumab and IMC-18F1 are monoclonal antibodies that target the VEGF receptors VEGFR-2 and VEGFR-1, respectively.

In addition to anti-angiogenesis therapies, many clinical trials in cancer patients are underway or have been completed with inhibitors that have the potential to suppress tumor-induced lymphangiogenesis. However, analysis of the effects of these treatments on tumor lymphatics is not always explicitly mentioned in the trial descriptions listed by the U.S. National Institutes of Health. There is only one study that has mentioned the role of VEGF-C in tumor progression, with VEGFR-3 being considered a target. This study is a Phase Ⅱ trial of sunitinib for patients with chemo-refractory metastatic gastric cancer[34]. It is hoped that more clinical trials will consistently address the possible effects of novel cancer therapeutics on tumor-induced lymphangiogenesis so that correlative data regarding the possible effects of interfering with tumor lymphatics on patient survival can be generated[34]. It is also important to note that treatment with the VEGFR tyrosine-kinase inhibitors sunitinib and sorafenib is associated with a significant increase in the risk of bleeding[107]. Further assessments need to be performed for treatment with these inhibitors.

Inhibition of metastatic spread may be achieved by restriction of lymphatic vessel growth by using targeted therapeutic strategies against molecules involved in lymphangiogenic signaling, in addition to the inhibition of angiogenesis. Because VEGF-A has been shown to promote tumor lymphangiogenesis, and because VEGF-C and VEGF-D are also able to activate VEGFR-2, the combined inhibition of VEGFR-2 and VEGFR-3, or of VEGF-A and VEGF-C/D, may result in an even more potent blockade of tumor-induced lymphatic vessel growth. Indeed, a combination of both anti-VEGFR-2 and anti-VEGFR-3 blocking antibodies has been shown to be more efficient in reducing experimental lymph node and distant breast cancer metastatic disease than each antibody alone, and it will be of interest to see whether a recently developed biospecific antibody against VEGFR-2 and VEGFR-3 will also show enhanced activity *in vivo*[42]. On the other hand, several recent trials have shown that the addition of anti-EGFR monoclonal antibodies to bevacizumab and chemotherapy resulted in worse outcomes. This was surprising, given that preclinical and early clinical studies had suggested a benefit in combining anti-VEGF and anti-EGFR antibodies. Taken together, further clinical trials are required to reveal the efficacy of the combination of targeted therapies against lymphangiogenesis with other targeted therapies, and/or other anti-cancer therapies.

Which patients will benefit from anti-angiogenesis and anti-lymphangiogenic therapies? Considering that tumors appear to undergo angiogenesis and lymphangiogenesis at an early stage[99], the anti-lymphangiogenic effect may have an even greater impact on the micrometastatic and/or the in-transit metastatic disease of concern after the resection of early stage malignancies. Therefore, these anti-angiogenesis and anti-lymphangiogenesis therapies may be more effective in patients with early stage CRC. However, the role of adjuvant therapy in stage Ⅱ CRC is still controversial[108]. Although there is a cohort of stage Ⅱ CRC patients who will have recurrent disease even after complete resection, there are no markers to identify this cohort. This subgroup appears to be a good candidate for anti-angiogenesis and anti-lymphangiogenesis therapies, if they could be identified with the appropriate biomarkers. Lymphangiogenesis factors have the potential to be used as biomarkers to predict which patients would benefit from adjuvant therapy with anti-lymphangiogenesis therapies to both prevent recurrence and improve overall survival. In the future, tailored treatments consisting of combinations of chemotherapy, other targeted therapies, and anti-angiogenesis and anti-lymphangiogenesis agents will hopefully result in better patient outcomes.

In addition to the development of the ideal combina-

tion therapies, the prevention of CRC is also essential to improve patient outcomes. Cancer chemoprevention is a strategy that uses treatments with natural or synthetic agents to inhibit, delay, or reverse the carcinogenesis process even before the development of invasive cancer[109,110]. The rationale for chemopreventive approaches to prevent CRC comes from epidemiologic and observational studies indicating that the long term ingestion of aspirin may reduce mortality in CRC[111]. Recent clinical trial studies demonstrated that celecoxib, a selective COX-2 inhibitor, is equally effective in reducing colorectal adenomas in animal models and patients with familial adenomatous polyposis (FAP), and it is approved by FDA for the chemoprevention of CRC in patients with FAP[112]. Prostaglandin E2 (PGE2) induced by COX-2 exerts several biological properties that may be advantageous for carcinogenesis, including promoting angiogenesis with increased VEGF, bFGF, and PDGF production[112]. Celecoxib enhances tumor cell apoptosis, thereby inhibiting the growth and angiogenesis of tumors by inhibiting COX-2, PGE2 synthesis, and VEGF expression in tumors in a mouse model of human CRC[113]. Interestingly, VEGF-C and COX-2 are coexpressed and are significantly associated with metastasis to the lymph nodes as well as prognosis in human CRC[114]. Moreover, celecoxib inhibits not only angiogenesis, but also lymphangiogenesis by blocking the VEGF pathway in mouse lung cancer models[115,116]. Taken together, lymphangiogenesis appears to play an important part in carcinogenesis in connection with the COX-2 pathway, and to be one of the important targets in chemoprevention, although the role of lymphangiogenesis in CRC within the adenoma-carcinoma sequence is still unknown. Further investigation will be required in this field.

CONCLUSION

Understanding the molecular pathways that regulate lymphangiogenesis is mandatory to pave the way for the development of new targeted therapies for cancer patients. A new quantifiable assay using standardized metrics is required to measure lymphangiogenesis and evaluate its impact on clinical outcome. In the future, tailored treatments consisting of combinations of chemotherapy, other targeted therapies, and anti-lymphangiogenesis agents will hopefully improve patient outcomes. This progression to the clinic may be guided by new avenues of research such as the identification of biomarkers that predict response to treatment.

Abstract

Diverticular disease (DD) of the colon is very common in developed countries and is ranked the fifth most important gastrointestinal disease worldwide. The management of acute diverticulitis without perforation and peritonitis is still debated. Health related quality of life (HRQL), subjectively perceived by patients, is becoming a major issue in the evaluation of any therapeutic intervention, mainly in patients with chronic disease. To date only a few published studies can be found on Medline examining HRQL in patients with DD. The aim of this study was to review the impact of surgery for DD on HRQL. All Medline articles regarding HRQL after surgery for colonic DD, particularly those comparing different surgical approaches, were reviewed. DD has a negative impact on HRQL with lower scores in bowel function and systemic symptoms. Both surgery-related complications and disease activity have a significant impact on patients' HRQL. While no significant differences in HRQL between different operations for DD in non-randomized studies were revealed, the only prospective double-blind randomized study that compared laparoscopic and open colectomy found that patients undergoing laparoscopic colectomy had significantly reduced major postoperative complication rates and subsequently had better HRQL scores. Formal assessment of HRQL could be a good instrument in the selection of appropriate patients for elective surgery as well as in the assessment of surgical outcome.

Key words: Colonic diverticular disease; Health related quality of life; Laparoscopy

INTRODUCTION

Diverticular disease (DD) of the colon is very common in developed countries and is ranked the fifth most important gastrointestinal disease worldwide. It is probably even more common in the Western world with a prevalence of approximately 33% in persons over 60 years[1-3] placing a substantial burden on inpatient and outpatient resources[2]. In

fact, 10%-25% of these patients will suffer an acute attack with a further 30% developing complicated DD[3,4]. The frequency of perforation associated with DD is increasing, indeed it reached a prevalence of almost 4 cases per 100 000 in 2000[4]. Colonic resection is standard practice in cases of perforation and peritonitis in DD and primary anastomosis with defunctioning stoma seems to be the optimal surgical strategy for fit patients, while Hartmann's procedure is recommended in high risk patients[5].

The management of acute diverticulitis without perforation and peritonitis is still debated. In these cases, medical therapy is usually successful[1,6], but up to 25% of these patients may end up requiring an urgent operation[7], and more than half of these procedures involve a colostomy[8-10]. Elective colectomy is, thus, often recommended to avoid the risks and high mortality rate connected with emergency surgery usually associated with recurrent diverticulitis. The timing of elective surgery is, nevertheless, controversial with most advisory bodies recommending surgery after the second episode[2,11]. Many surgeons advise prophylactic colon resection after a single hospitalization in younger patients because the disease is considered more virulent in these subjects[11-15].

The evolution of laparoscopic colorectal surgery in the past decade has brought immediate short-term benefits to patients, including earlier postoperative pain relief and return of bowel function, shorter hospital stay, and better cosmesis. There is some evidence in the recent literature that immediate postoperative health related quality of life (HRQL) is better after certain laparoscopic procedures than after open surgery[16].

In the case of acute complications such as perforation with peritonitis in an emergency setting, the surgical approach can be in one stage or multiple stages and quality of life assessment is increasingly being recognized as an integral factor in surgical decision-making regarding disease management choices[17].

However, the results of one of our previous studies did not show any long-term advantage in terms of quality of life, symptoms recurrence and risk of surgery in submitting patients to colonic resection for DD without perforation and peritonitis[18]. The decision to electively operate on patients after their recovery from an acute episode of diverticulitis is still debated.

Although the use of objective outcome measures after surgical procedures is an important means of defining a patient's degree of health, the patient's subjective perceptions and expectations need to be factored into that objective assessment to determine the patient's actual quality of life, particularly in the treatment of benign disease such as DD. Moreover, HRQL measures have been shown to be useful in predicting health care expenditures. With the development of well-validated reliable and sensitive non-disease specific (generic) questionnaires such as the Short Form survey 36 (SF-36) or disease specific questionnaires like the gastrointestinal quality of life (GIQLI)[19-26], there is a HRQL measuring tool than can be applied to post-operative quality of life research not only to define the long-term outcome in elective operations, but may also be useful in comparing different surgical approaches and techniques. The aim of this study was to review the impact of surgery for DD on HRQL.

A text word literature review was performed using the PubMed and Medline databases. Although this was not a systematic review, the search terms used were as follows: DD, acute diverticulitis, surgery, elective OR emergency resection OR surgery AND HRQL. The reference lists of identified articles were searched for further relevant publications. Aided by a clinical librarian, the databases were consulted from January 1965 to April 2010. Two researchers (Angriman I and Ruffolo C) independently selected the studies, particularly those comparing different surgical approaches. Whenever there was discordance regarding study inclusion the two researchers negotiated an agreement.

DD HAS AN IMPACT ON QUALITY OF LIFE

In the majority of patients, colonic diverticula (diverticulosis) are asymptomatic[27]; nevertheless, an estimated 20% of affected individuals develop symptoms in their lifetime, such as abdominal pain and/or discomfort, bloating and disturbance of bowel habits. This clinical condition is termed DD[28] and may be symptomatic uncomplicated, recurrent symptomatic, or complicated. DD treatment is aimed at relieving symptoms and preventing major complications. HRQL, subjectively perceived by patients, is becoming a major issue in the evaluation of any therapeutic intervention, mainly in patients with chronic disease where the aim of therapy is to keep patients either symptom-free or to reduce the discomfort caused by the disease. To date only a few published studies can be found on Medline examining HRQL in patients with DD.

Bolster *et al*[29] suggested that DD does affect a person's HRQL. In their study they used a disease specific questionnaire which had been validated for patients with inflammatory bowel disease and consisted of 32 questions which assessed four aspects of patients' lives: gastrointestinal symptoms, systemic symptoms, emotional function and social function. Patients with DD had mean scores well below the optimal scores of the questionnaire in all four categories, and compared with a control group of healthy volunteers, patients with DD had statistically significant lower scores in all categories. The authors concluded that DD has a negative impact on HRQL.

Similar results were observed by Comparato *et al*[30] in 58 patients affected by uncomplicated symptomatic DD. They used the SF-36 questionnaire and clinical evaluation was registered by means of global symptomatic score at baseline and after 6 mo. They concluded that DD has a negative impact on HRQL compared with the normal population and medical therapy improves HRQL if symptoms are relieved.

QUALITY OF LIFE AFTER SURGERY FOR DD

Surgical resection for DD, outside of the emergency setting, is primarily intended to obviate future hospitalization and/or emergency surgery for the patient, even though the risk of any single individual suffering a subsequent acute exacerbation is unpredictable. In contrast, symptomatic DD itself causes considerable ongoing disruption in terms of lifestyle and general "well-being". However, little formal weight is currently given to quality of life consideration *per se*. This is probably because it remains unclear whether surgery can restore the missing HRQL, but outcome may instead represent the most compelling reason to offer surgery to an individual.

Several studies observed a significant improvement in quality of life and social function following elective sigmoid resection in the majority of patients.

Most of those studies compared the HRQL before and after surgery. Forgione *et al*[16] performed a prospective analysis of 46 patients undergoing elective, laparoscopic sigmoidectomy for prior acute diverticulitis demonstrated by CT scans over an 18-mo period. Preoperative measures of HRQL were assessed by the GIQLI questionnaire administered at baseline and then again regularly throughout the first postoperative year. Mean preoperative GIQLI score was 99.5 and postoperative scores were significantly higher at each postoperative time point. The mean GIQLI score 12 mo after operation was 111.5 ($P < 0.05$). Postoperative augmentation of GIQLI was correlated most with improvements in the symptoms domain and was inversely correlated with the preoperative score. The authors concluded that the development of a more disease-specific questionnaire for patients being considered for elective surgery after prior diverticulitis may allow even greater discrimination in preoperative selection.

Roblick *et al*[31] observed a significantly higher HRQL after surgery in patients suffering from DD and only slightly below a validated normal population. In this study, a total of 45 patients who underwent surgery for diverticulitis at stage Ⅰ-Ⅱa (Hinchey classification) were included. HRQL was measured using the SF-36 questionnaire and the follow-up period was at least 2 years.

In one of our previous studies[18], to evaluate the impact of colonic resection for DD on the natural history and long-term quality of life in these patients, HRQL of DD patients undergoing surgery was compared to those on medical treatment. The study was particularly focused on the long-term clinical outcome of non-complicated diverticulitis. HRQL was also assessed in 69 healthy subjects [39 males and 30 females with a mean age of 43 (22-85) years] without gastroenteric symptoms enlisted from hospital employees and their relatives.

For HRQL assessment, the Cleveland Global Quality of Life (CGQL) score[32], which consists of three items (current quality of life, current quality of health, and current energy level), each on a scale of 0 to 10 (0, worst; 10, best), was used. The CGQL was created to assess HRQL in patients affected by ulcerative colitis after restorative proctocolectomy and was then used in HRQL analysis of patients with Crohn's disease[33,34]. No significant differences were observed in the rate and in the timing of readmission and surgical procedures for DD in the two groups. The CGQL total score as well as the two items on current quality of life and current energy level responses were similar in the two groups of patients and in the group of healthy subjects. Only the scoring on the current quality of health was significantly worse in patients who had undergone colonic resection. Similarly, in the Hinchey 1 subgroup, no significant differences in CGQL score, current quality of health, current quality of life and current energy level were observed in patients who had been operated on and those who had been treated conservatively. Those results indicated that there are no long-term advantages to colonic resection for DD if the goal of the surgical treatment is to improve HRQL, and these data seemed to be supported by the analysis of the small group of Hinchey stage 1 patients.

QUALITY OF LIFE AFTER OPEN AND LAPAROSCOPIC SIGMOID COLECTOMY

Long-term outcome and HRQL were evaluated in patients undergoing laparoscopic colectomy (LC) *vs* open colectomy (OC) for benign colorectal diseases, based on standardized, validated measures, in a retrospective study[35]. All consecutive patients who underwent elective LC for uncomplicated diverticulitis in an 8-year time period were evaluated and compared to controls treated with conventional OC in the same period. HRQL was assessed by the SF-36 Physical and Mental Component Summary Scale (PCS; MCS) and by the SF-36 Health Survey. None of the 8 SF-36 Health Survey domains or the PCS and the MCS showed significant differences in HRQL between LC patients and OC patients. The occurrence of postoperative incisional hernias and bowel obstructions, which represented the only surgery-associated long-term complications, was comparable in both groups, as was the patients' HRQL. The two limitations of this study were the small patient cohort and the short follow-up (6-9 mo postoperatively with no long-term available). The lack of statistical difference between LC and OC patients in SF-36 scores related to the development of long-term complications may have been due to these limitations. Surgery-related complications were the only events that had a significant impact on the patients' HRQL, reflecting lower SF-36 scores in certain areas. The laparoscopic colorectal surgery itself had no significant influence on the patients' HRQL in the follow-up of these patients. The authors observed that better immediate postoperative HRQL after laparoscopic procedures may have been related to treatment of the disease *per se* and to favourable parameters such as faster convalescence, shorter hospital stay, and better cosmesis. On the other hand, long-term HRQL seemed to be influenced by chronic sequelae of the surgical procedures. Interestingly, more favourable cosmesis

itself had no impact on either the patients' overall HRQL or the emotional and social domains of the SF-36.

Another comparison of long-term HRQL between patients undergoing LC and OC was performed by Seitz *et al*[36] using the GIQLI questionnaire. Fifty-four patients who underwent sigmoid colectomy for recurrent diverticulitis were included. Patients who underwent LC seemed to feel better after surgery compared with those undergoing OC; however, this trend did not reach statistical significance. Patients' satisfaction regarding the cosmetic result was significantly higher in those undergoing LC than patients treated with OC. All patients had a similar GIQLI postoperatively, independent of the type of surgery. Eypasch's GIQLI did not identify clear differences between LC and OC. The limitation of this study was that only the *status quo* was determined and a comparison before and after surgery was not performed. The missing difference between LC and OC may be secondary to the higher rate of persistent symptoms in the LC group compared with the OC group, which was determined by simply asking the patients whether they felt that the disease had recurred. Thus, the authors commented that possible long-term advantages after LC with regard to HRQL may have been lost owing to this difference in "subjective recurrence".

Recently, a prospective, multicentre, double-blind, randomized controlled trial was designed to compare the impact of LC and OC on postoperative complication rates in patients with symptomatic diverticulitis[37]. Quality of life was assessed using the SF-36 questionnaire measured preoperatively and 6 wk after surgery. One hundred and four consecutive patients who underwent elective surgery for symptomatic diverticulitis of the sigmoid colon were randomized in 5 centres. Fifty-two LC patients were compared to 52 OC patients for gender, age, body mass index, American Society of Anesthesiology classification, prevalence of comorbidities, previous abdominal surgery, preoperative workup, and indication for surgery. SF-36 data showed no preoperative intergroup differences. Postoperative SF-36 data were significantly better in LC patients for role limitations due to physical and emotional problems, social functioning, and pain level. The main finding of this randomized controlled trial was that LC patients had significantly reduced major postoperative complication rates as compared with OC patients for symptomatic diverticulitis. Subjectively, patients who underwent LC scored significantly better than OC patients on the Visual Analogue Scale (VAS) for quality of life-pain score and SF-36 questionnaire. Several items in the latter showed improved role limitations due to physical health, role limitations due to emotional problems, social functioning, and pain.

A multicentre study compared HRQL in patients affected by DD submitted to LC *vs* those who underwent OC during long term follow up, using the Padova Inflammatory Bowel Disease Quality of Life (PIBDQL) score, CGQL score, VAS, Body Image Questionnaires (BIQ) and cosmetic score (CS), ad hoc DD symptom score (DDSS) and Bristol Stool Form Scale[38]. Sixty consecutive patients were included: 20 underwent LC, 15 OC and 25 had only medical therapy. The PIBDQL[35,39,40] was validated for use in patients with DD. Preliminary results showed that the PIBDQL scores were significantly worse in all patients with DD than those obtained from healthy subjects and correlated with the symptoms score. The CGQL was similar in patients who had LC compared to healthy subjects. BIQ scores correlated inversely with the presence of a stoma. The intestinal symptoms item was worse in patients who had LC than in those who had OC. On multivariate regression, the DDSS score was the only independent predictor of the PIBDQL score. No significant difference was observed in VAS for quality of life among the three groups of patients and in total CS in the two groups submitted to surgery. Only the scar score item was significantly better in patients who underwent LC compared to that in patients who had OC. Similarly, no significant difference was observed in the BIQ items and total score in the two groups submitted to surgery. The authors concluded that disease activity is the only independent predictor of the disease-specific quality of life.

QUALITY OF LIFE AFTER STAGED RESECTION FOR COMPLICATED DD

Constantinides *et al*[17] assessed long-term differences in HRQL using the SF-36 questionnaire between single and staged resections, in complicated DD. The authors divided the study population into two groups: one group consisting of patients who underwent primary colonic resection and anastomosis and the other group who underwent staged resections followed by restoration of intestinal continuity (HP). Three subgroups were created for each of the single staged and staged resection groups on the basis of when HRQL was assessed (1 group less than 3 years after primary surgery, 1 group 3-6 years after primary surgery and 1 group more than 6 years after primary surgery). One hundred and fifty-eight patients who underwent single staged resections and 30 patients who underwent staged resections with restoration of intestinal continuity were included. Significant differences were observed between the two groups in patients suffering from major comorbidities. No statistically significant differences were found in any of the eight domains between the single and staged resection groups. No significant differences were found between the two surgical methods across any of the eight SF-36 domains, for any of the time periods. The PF and RP domains were both subject to a significant decrease in mean score with advancing age. The BP domain had a progressive, but not statistically significant, decrease in score with advancing age.

Patients with no postoperative complications had significantly higher scores in the PF domain, the RP domain and the BP domain. According to these authors, in the setting of complicated DD, long-term HRQL tends to be similar between surgical interventions but remains significantly lower in selected domains when compared to the general population norms.

The main limitations of this study were that: (1) the two groups were inhomogeneous in terms of patient comorbidities and therefore, the effect of comorbidity on HRQL as a confounder could not be eliminated; and (2) no patient had a residual stoma and as a result, the study did not assess the impact of a colostomy on quality of life. Furthermore, HRQL was not assessed in the preoperative state.

CONCLUSION

The conclusions that can be drawn from these different studies are that DD has a negative impact on HRQL with lower scores in bowel function and systemic symptoms. Currently, the criteria for selection of DD patients for elective surgery remain debatable. Formal assessment of HRQL could be a good instrument in the selection of appropriate patients for elective surgery as well as in the assessment of surgical outcome. Both surgery-related complications and disease activity have a significant impact on patients' HRQL. While no significant differences in HRQL between different operations for DD in the non-randomized studies were revealed, the only prospective double-blind randomized study that compared LC and OC found that patients undergoing LC had significantly reduced major postoperative complication rates and subsequently had better HRQL scores.

Abstract

The liver is an exceptional organ, not only because of its unique anatomical and physiological characteristics, but also because of its unlimited regenerative capacity. Unfolding of the molecular mechanisms that govern liver regeneration has allowed researchers to exploit them to augment liver regeneration. Dramatic progress in the field, however, was made by the introduction of the powerful tool of gene therapy. Transfer of genetic materials, such as hepatocyte growth factor, using both viral and non-viral vectors has proved to be successful in augmenting liver regeneration in various animal models. For future clinical studies, ongoing research aims at eliminating toxicity of viral vectors and increasing transduction efficiency of non-viral vectors, which are the main drawbacks of these systems. Another goal of current research is to develop gene therapy that targets specific liver cells using receptors that are unique to and highly expressed by different liver cell types. The outcome of such investigations will, undoubtedly, pave the way for future successful clinical trials.

Key words: Liver regeneration; Gene therapy; Genetic vectors; Growth factors

INTRODUCTION

The need to enhance the capacity of liver regeneration has long been recognized but only avidly pursued recently. The clinically successful massive liver resection or small-for-size liver transplant carry the risk of liver failure due to impaired regeneration of the remnant/split liver[1]. Liver regeneration is also an integral component of the recovery processes of liver cirrhosis, fibrosis or liver failure[2]. Major advances in understanding the molecular mechanisms that govern liver regeneration have been made over the past few years[3,4]. Identification and molecular characterization of specific growth factors that promote liver regeneration has allowed the development of recombinant growth factors and their use to promote liver regeneration. The success of this strategy was hampered by the short half-life of these proteins in the circulation and the need for them to be administered continuously[5-9]. To overcome this problem, investigators successfully used gene transfer technology to transfer the genes that encode these growth factors. The intrinsic production of growth factor proteins following the transfer of their encoding genes enhances liver proliferation in various animal models with partial hepatectomy and/or chemical injury. Despite the success of proof of principle studies of gene therapy to enhance liver regeneration, and the potential of translation into clinical settings, no systematic review of published studies has appeared so far. Therefore, an evaluation of the current literature on gene therapy for liver regeneration is required and a look at future perspectives is

warranted. This article briefly summarizes the current key concepts in liver regeneration and gene therapy as they are related to each other, gives an overview of the published studies, and envisions future progress in the field.

LIVER REGENERATION: BASIC CONSIDERATIONS

Following two-thirds partial hepatectomy, the residual liver lobes enlarge within a week to make up for the mass of the removed lobes. Liver regeneration is carried out by proliferation of all adult liver cells including hepatocytes, sinusoidal endothelial cells, biliary epithelial cells, Kupffer cells and hepatic stellate cells (HSCs)[10]. It has been firmly established that mature hepatocytes are not terminally differentiated and that they have an almost unlimited capacity to proliferate, so that the liver can be entirely repopulated by intact hepatocytes that represent 1% of the hepatocyte population[10-15].

The molecular mechanisms of liver regeneration can be divided into two critical steps: the transition of the quiescent G_0 phase hepatocyte into the cell cycle (priming phase), and progression beyond the restriction point in the G_1 phase of the cycle (progression phase). These phases are under separate control; priming by the cytokines tumor necrosis factor (TNF) and interleukin-6 (IL-6), and cell cycle progression by the growth factors hepatocyte growth factor (HGF) and transforming growth factor (TGF)-α[11]. The priming phase does not lead to DNA replication unless the cells can progress through the cell cycle which is accomplished by growth factors. Once hepatocytes pass the G_1 restriction point they are irreversibly committed to replication (Figure 1)[16,17].

The mechanisms that initiate cytokine cascade liver regeneration have not yet been fully identified. It has been proposed that liver injury causes the release of reactive oxygen species and lipopolysaccharide (LPS), which trigger the activation of the complement system. After complement activation, cleavage of C3 or C5 leads to generation of the potent anaphylatoxins C3a and C5a. LPS, C3a and C5a in turn activate the non-parenchymal cells (NPCs) such as Kupffer cells, through the cell surface receptor TLR4 and C3aR and C5aR, which causes activation of the transcription factor nuclear factor (NF)-κB signaling pathway and the production of cytokines such as TNF-α and IL-6[18,19]. Also, the cytokine cascade can be triggered through the binding of TNF to its receptor TNFR1, which leads to activation of the NF-κB in NPCs, with the production of TNF and IL-6. Thus, the released TNF acts on the same NPCs in an autocrine fashion and on hepatocytes by a paracrine mechanism. Released IL-6 binds to its receptor on hepatocytes and leads to activation of the transcription factor STAT3 (signal transduction and activator of transcription), which translocates to the nucleus where it induces transcription of a number of target genes (Figure 2). The precise role played by each cytokines is, however, debatable[3,11]. TNF is not a direct mitogen for hepatocytes. It does, however, enhance the mitogenic effects of direct mitogens such as HGF. For example, it has been shown in stellate cells in culture that TNF and IL-6 activate the transcription factor C/EBPβ (CCAAT/enhancer-binding protein β), which induces HGF mRNA expression[20]. TNF is also involved in the activation of TGF-α[4]. IL-6 has both mitogenic and anti-apoptotic effects on hepatocytes and protects the regenerating liver against ischemic injury[11]. IL-6 has a crucial role in initiating acute phase response in hepatocytes, with the production of many proteins that assist in controlling acute or chronic inflammation[21].

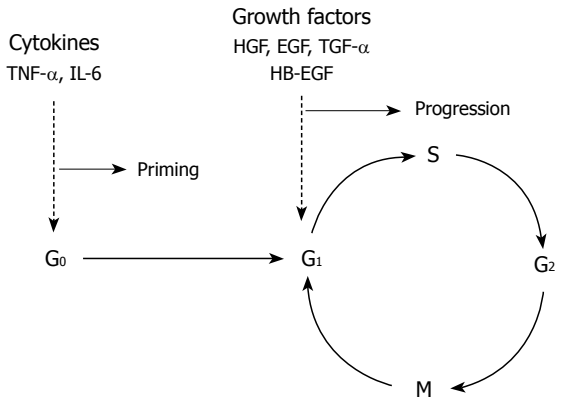

Figure 1 Effect of cytokines and growth factors on hepatocyte cell cycle. TNF-α: Tumor necrosis factor-α; IL-6: Interleukin-6; HGF: Hepatocyte growth factor; EGF: Epidermal growth factor; TGF-α: Transforming growth factor-α; HB-EGF: Heparin-binding EGF-like growth factor.

While cytokines are responsible for the passage of quiescent hepatocytes into the cell cycle (G_0 to G_1), cell cycle progression is then driven by growth factors, which override a restriction point in the late G_1 phase[3]. HGF and ligands of epidermal growth factor receptor (EGFR) are important growth factors that drive cell cycle progression during liver regeneration. Studies have shown that despite the expression of many mitogenic receptors, including receptors for platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), and fibroblast growth factor (FGF), the only mitogens for hepatocytes are HGF and ligands of EGFR. The family of ligands that bind EGFR, in addition to EGF, includes TGF-α, heparin-binding EGF-like growth factor (HB-EGF), and amphiregulin (AR)[3,22]. Stimulation of the tyrosine kinase receptors for HGF and the EGF ligands activates numerous intracellular signaling pathways that regulate transcription factors involved in liver regeneration[3,4]. It is important to mention, with the possible exception of HGF, that complete elimination of a single growth factor does not entirely abrogate liver regeneration.

HGF is the most extensively investigated growth factor for liver regeneration. It stimulates regeneration in normal and injured liver. It is produced by NPCs and stimulates hepatocytes by a paracrine or endocrine mechanism. Following binding to its receptor, cMet, on hepatocytes, it stimulates DNA synthesis. HGF effects are multiple including mitogenic, motogenic, morphogenic and anti-apoptotic effects[4,11,17,23].

EGFR ligands are direct mitogens for hepatocytes. EGF is continually available to the liver through the portal

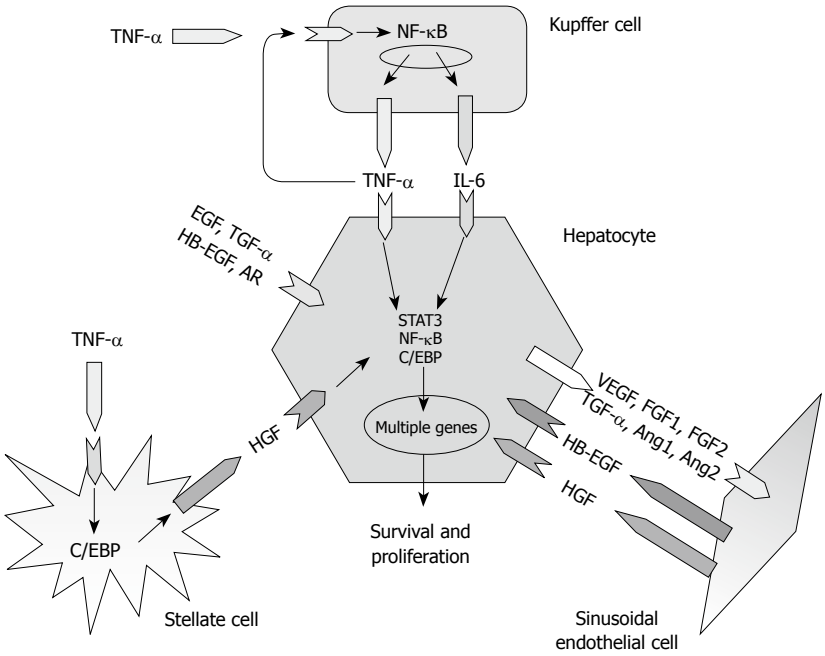

Figure 2 Major cytokine and growth factor signals during liver regeneration. NF-κB: Nuclear factor-κB; TNF-α: Tumor necrosis factor-α; IL-6: Interleukin-6; EGF: Epidermal growth factor; TGF-α: Transforming growth factor α; VEGF: Vascular endothelial growth factor; FGF: Fibroblast growth factor; HB-EGF: Heparin-binding EGF-like growth factor; AR: Amphiregulin; C/EBP: CCAAT/enhancer-binding protein; HGF: Hepatocyte growth factor.

vein, and is produced from Brunner's glands of the duodenum. EGF given to intact animals causes hepatocyte proliferation. TGF-α is an autocrine growth factor that is produced by and active on hepatocytes. Transgenic mice that overexpress TGF-α display hepatocyte proliferation and develop tumors[24]. On the other hand, TGF-α knockout mice have no defects in liver regeneration; probably because of the overlap between various ligands of the EGF family. TGF-α is also a mitogen for endothelial cells and bile duct epithelial cells. HB-EGF is produced by endothelial and Kupffer cells and is a key factor for hepatocyte progression through G_1/S transition during liver regeneration[25]. AR also contributes to liver regeneration, because mice deficient in AR have deficient liver regeneration[26]. It is likely that the different growth factors have independent but partially overlapping functions in liver regeneration[3,4].

Cytokine and growth factor pathways interact during different phases of liver regeneration[3,27,28]. For example, TNF activates TGF converting enzyme (TACE) that results in release of TGF-α, activation of EGFR and hepatocyte proliferation[3]. It should be noted at this point that there is significant redundancy between the components of each pathway, such that the lack of a single component generally causes a delay and/or reduction of regeneration. In other words, loss of an individual component gene rarely leads to complete inhibition of liver regeneration[3,23]. In contrast to the large number of hepatocyte growth promoters, very few inhibitors of liver regeneration have been identified. The most potent of these inhibitors is TGF-β[22]. For a more detailed review on molecular mechanisms of liver regeneration, readers should refer to references[1,3,4,23,29-33].

The molecular events involved in liver regeneration are significantly influenced by the extent of resection, as massive (85%-90%) liver resection leads to suppression and delay of liver regeneration, compared to 70% partial hepatectomy (PH), because of suppressed and delayed induction of the regenerative genes TNF-α and IL-6 after 90% PH. Moreover, apoptosis rates are also elevated in 90% PH compared to 70% PH[34]. Several studies have shown that growth factors that promote liver regeneration (HGF and TGF-α) are upregulated in 70% PH, whereas no or only reduced induction occurs after 90% resection. These findings suggest that expression of the factors relevant to the regeneration of liver tissue is influenced by the extent of resection[17,34-36].

A simplified summary of the interactions between cytokines and growth factors and between different cell types during liver regeneration is shown in Figure 2. Hepatocytes are the first to undergo proliferation, based on external stimuli from a variety of sources. HGF is rapidly becoming available to hepatocytes very rapidly through local matrix release and activation induced by urokinase-type plasminogen activator. Stellate and endothelial cells are sources of new HGF, which is synthesized after 3 h following PH. Hepatocytes produce growth factors that are mitogenic for stellate cells (PDGF)[37] and for endothelial cells (VEGF, FGF1, FGF2, stem cell factor, angiopoietins 1 and 2, and TGF-α). Proliferation of endothelial cells aims to restore the network of sinusoids that occurs over a long period of time, from days 3 to 6 after PH. Kupffer cells have not been clearly proven to proliferate during regeneration; however, they do produce TNF and IL-6, which appear to have a contributory role in STAT3 and NF-κB activation during the early stages of liver regeneration. Of note, the original hepatocyte mass is not restored through proliferation of stem cells, but through replication of residual mature hepatocytes. Hepatic stem cells (oval cells) are mobilized and differentiate into hepatocytes, only when proliferation of hepatocytes is totally blocked or when hepatocytes are chronically destroyed[10,23,33,38,39].

Identification and molecular characterization of spe-

Table 1 General characteristics of most commonly used vectors

System	Size of insert (kb)	Infect non-dividing cell	Genomic integration	Duration of expression	Immune response
Adenovirus					
1st generation	5	Yes	No	3-4 wk	High
2nd generation	8	Yes	No	Longer with	High
Gutless	35	Yes	No	Immuno-supression	Less
Adeno-associated virus	< 4.8	Yes	Yes and episomal	Long-term	Low
Herpes simplex virus 1	35	Yes	No	Long	High
Retrovirus	≤ 8	No	Yes, random	Long-term	Low
Lentivirus	≤ 8	Yes	Yes, into active genes	Long-term	Low
Baculovirus	> 20	Yes	No	Transient	Low
Plasmid-naked	Large	Yes	No	Short	Low
Plasmid-polymer	Large	Yes	No	Short	Low
Plasmid-lipid (liposomes)	Large	Yes	No	Short	Low

cific growth factors that promote liver regeneration allow the development of recombinant growth factors and their use to promote liver regeneration[6,40-43]. The success of this strategy is hampered by the short half-life of these proteins in the circulation and the need for them to be administered continuously. To overcome this problem, investigators have successfully used gene transfer technology to transfer the genes that encode these growth factors into liver cells.

GENE THERAPY FOR LIVER REGENERATION: KEY CONCEPTS

The strategy of introducing genetic material into liver cells to enhance proliferation or to inhibit apoptosis has been employed in experimental liver research for more than a decade. The transferred genetic material can be a natural gene[44-46], gene segment[47], chimeric gene[48], oligodeoxynucleotides (ODN)[49,50], or siRNAs. To facilitate transfer (transduction) into cells, the foreign gene (transgene) is packaged into construct named vectors. Gene transfer vectors are classified as either viral or non-viral. Viral vectors provide a powerful means for delivering therapeutic genes to targeted cells due to their high transduction efficiency. They are made replication-defective by deletion of viral genes involved in the replication and pathogenesis of the virus. This allows for the inclusion of non-viral genetic material in the viral genome. The general characteristics of most commonly used vectors are shown in Table 1. The most commonly used viral vectors are retrovirus, adenovirus, adeno-associated virus (AAV), herpes simplex virus, lentivirus and baculovirus. For a gene to be expressed inside a cell, its coding DNA sequence should be linked to an appropriate promoter. These regulatory DNA sequences can be categorized as viral (universal) promoters, which allow transgene expression in most transduced cells, housekeeping promoters, or tissue-specific promoters, which drive gene transcription only in selected cell types[51]. Because of their universal activity, viral promoters were components of many first-generation vectors. However, many of the viral promoters, such as the cytomegalovirus (CMV) promoter, are attenuated or completely shut-off in organs such as the liver. In comparison to viral or housekeeping promoters, tissue- or liver-specific promoters direct higher levels of expression *in vivo*. Successful application of gene therapy depends on the choice of relevant therapeutic genes, appropriate promoters, and effective vectors that allow an adequate level and duration of transgene expression[52-54].

Although retroviral vector transfection results in long-term survival of the gene in the transduced cell, its major disadvantage is the risk of insertional mutagenesis as a result of random integration of the virus into the host chromosome. Moreover, the transduction rate after retroviral gene transfer into hepatocytes *in vivo* is disappointingly low. Efficient retrovirus integration into the host-cell genome requires the active proliferation of target cells with DNA replication and nuclear membrane breakdown during mitosis. Under normal physiological conditions at any given time, only 0.005% of hepatocytes divide. For retrovirus liver transduction, hepatocyte proliferation induced by PH must occur on or about the time of retroviral delivery. To increase gene transfer without hepatectomy, mouse hepatocytes have been transduced *in vivo* with a recombinant adenovirus that transiently expressed urokinase[55], or with recombinant HGF[56]. The induced liver regeneration allowed persistent and efficient retroviral-mediated gene transfer in hepatocytes[55,56].

Adenoviral vectors are the most investigated vectors in animal and human gene therapy studies. Adenoviral vectors exhibit several merits that make them suitable for liver regeneration gene therapy. Adenoviruses are highly hepatotropic and it is relatively easy to produce high titers of recombinant adenoviral particles[57]. Unlike retroviruses, adenoviruses transduce dividing and non-dividing cells and do not integrate into the host chromosomes, thereby eliminating the risk of insertional mutagenesis. These merits make adenoviral vectors suitable for proof of principle experimental studies to verify the effect of overexpression of a specific growth factor gene on liver regeneration. The major limitation of adenoviral vectors is their serious and potentially fatal toxicity as exemplified by the death of an 18-year-old man who received 6×10^{11} viral particles/kg of E1/E4-deleted human adenovirus type 5 vector that contained human ornithine transcarbamylase cDNA[58,59]. Moreover, the severe immune response of the host contributes to the limited survival of the adenovirus

DNA in targeted cells and results in transient expression of the therapeutic gene. Until resolved, adenoviral-vector-induced toxicity will limit its application in clinical gene therapy studies. The transient nature of gene expression with adenoviral vectors may be advantageous because the process of liver regeneration is usually completed in approximately 1 wk. However, liver regeneration is seldom the only goal of therapy. Treating associated liver fibrosis or cirrhosis requires a longer period of gene expression. Furthermore, transduction efficiency of diseased liver is much lower than that of healthy liver. Garcia-Bañuelos *et al*[60] have demonstrated that adenovirus-mediated gene transfer *via* the iliac vein at 3×10^{11} viral particles per rat resulted in approximate 40% transduction in livers made cirrhotic by chronic intoxication with carbon tetrachloride, compared with approximate 80% in control non-cirrhotic livers. In rats made cirrhotic by bile-duct obstruction only, 10% efficiency of transduction was observed. Yu *et al*[61] have shown that NPCs are transduced with greater frequency than hepatocytes at all adenoviral titers tested, both *in vitro* and *in vivo*. After liver injury, adenoviral transduction is reduced for all liver cell types compared with that for cells from normal livers (at all virus titers). Again, transduction efficiency remains greater in NPCs than in hepatocytes after liver injury.

Non-viral vectors can be divided into two categories: physical and chemical. Physical methods involve the introduction of plasmid DNA into cells using electroporation, ultrasound, or hydrodynamic delivery. Chemical methods use lipid or polymer carriers that complex with DNA to deliver the transgene into cells[62,63]. Several non-viral vectors have been used for *in vivo* liver gene therapy including various liposome preparations, protein-DNA conjugates, nanoparticles, and naked or complexed DNA[57,64,65]. Expression is usually both transient and at low level because the DNA is not stable in cells. Despite these limitations, non-viral vectors offer many advantages including being simple to use, ease of production of large quantities, and absence of host immune response.

A major advance in the intravascular delivery of vectors followed the development of the hydrodynamic injection technique. The technique involves rapid tail vein injection of a large volume of the vector (around 10% of the body weight of a mouse or rat) in a short time period (5-7 s in mice and 15-20 s in rats). The hydrodynamic method results in dramatically higher hepatic transfection efficiency compared to conventional injection. Typically, 10%-15% of hepatocytes are transfected in mouse liver following injection of 10 μg plasmid, but levels up to 40% have been reported[66]. Liver enzymes are transiently elevated and liver histology shows minimal damage that resolves within a week, which is similar to the results obtained from intravascular delivery into liver vessels[66,67]. It has been postulated that increased pressure in the inferior vena cava causes retrovenous blood flow from the central to the portal vein, and the resultant increased intrahepatic vascular pressure promotes massive endocytosis that generates intracellular water movement that facilitates gene entry[68,69]. There are multiple lines of evidence that the species differences in the diameter of sinusoidal fenestrae are a critical determinant of transgene expression after adenoviral transfer. The small diameter of fenestrae in humans should be considered in any rational design of gene transfer technology for hepatocyte-directed transfer. Hydrodynamic gene transfer is highly successful in rodents. The significantly lower efficacy in higher species may also partially be due to species differences in liver architecture[70]. Intrinsic factors, in particular compliance (elasticity) of the liver are likely to be crucial in determining the degree of swelling for a given level of intrahepatic vascular pressure. Liver compliance is likely to be the major reason for the low level of hydrodynamic gene delivery in the pig model, and will influence the effectiveness of the approach in humans, both in general and in different disease states[71].

This procedure has great limitations for application to clinical practice, therefore, a clinically relevant method for regional hydrodynamic delivery of vectors has been developed. The method entails the use of an occlusion balloon catheter into the inferior vena cava and retro dynamically injecting towards the liver and through the hepatic vein, 100 mL of the plasmid in saline solution (20 mg/mL), at a rate of 7.5 mL/s. This retrodynamic hepatic vein gene delivery method has been performed in pigs, and was as well tolerated as in mice and led to liver transgene expression, however, the plasma levels of the transgene protein were four orders of magnitude lower than those reached in the murine model[68,72]. A variety of different modifications have been reported recently[73,74].

Recently, retrograde administration of adenoviruses into the common bile duct has been shown to induce efficient transgene expression in the liver without causing severe adverse effects, thus supporting the feasibility of adenovirus-mediated gene transfer into the liver in clinical settings by means of endoscopic retrograde cholangiography[75-77]. Repeat administration of adenoviruses into the common bile duct is successful in re-expressing the transgene in the liver[78]. This contrasts with the failure of re-expression of transgene following intravenous readministration of an adenoviral vector long after the initial administration[79].

OVERVIEW OF PUBLISHED STUDIES

The general features of the reviewed gene therapy studies for enhancing liver regeneration are summarized in Table 2. Gene therapy investigations that fulfilled the following criteria were selected for review: (1) demonstrated, objectively, enhanced liver cell proliferation and or increased survival as compared with controls; (2) animals and/or livers receiving gene therapy were not genetically modified as they do not directly represent human liver diseases (e.g. liver cirrhosis, fibrosis or failure) in which liver regeneration has a critical role in recovery; and (3) gene therapy was administered *in vivo*. The selection of homogeneous cohort studies based on these criteria allows us to delineate the main characteristics of these studies, and more importantly, envision what needs to be done in fu-

Table 2 Main features of reported gene therapy experiments[39,44-50,80-96]

Vector, Ref.	Dose	Transgene (promoter)	Liver model, animals, route	Measured parameters
Adenovirus vector				
Hogaboam *et al*[80], 1999	1×10^8 pfu	r-MIP-2	Acetaminophine injury, mice, IV	↑DNA synthesis, ↑survival
Phaneuf *et al*[46], 2000	1-4 × 10^{11} vp	h-HGF (CMV)	Healthy, mice, IV	↑DNA synthesis, ↓apoptosis and ALT
Shiota *et al*[39], 2000	1×10^9 pfu	r-HGF (CAG)	AAF/70% PH, rats, IV	↑Oval cell proliferation
Nomi *et al*[95], 2000	1×10^9 pfu	r-HGF (CAG)	D-Gal/LPS liver failure, rats, IP	↓Apoptosis, ↑survival
Hecht *et al*[48], 2001	1×10^8 TU	h-HIL-6 (CMV)	D-Gal liver failure, mice, IP	↑Survival, ↑proliferation
Hwang *et al*[81], 2003	1×10^{11} vp	h-HGF (CMV)	TAA liver failure, mice, IV	↑Survival, ↑DNA synthesis, no hepatic necrosis
Iwaki *et al*[49], 2003	2×10^9 pfu	m-MIF antisense	BCG-LPS liver failure, mice, IV	↑Survival
Oe *et al*[45], 2004	7×10^8 pfu	h-VEGF + or r-HGF (CAG)	DMN cirrhosis 70% PH, rats, IV	↑SECs and hepatocytes proliferation
Oe *et al*[82], 2005	7×10^8 pfu	r-HGF, or h-VEGF (CAG)	AAF/70% PH, rats, IV	↑Oval cell proliferation, ↑regeneration
Wullaert *et al*[84], 2005	2.5×10^9 pfu	m-ABIN-1 (CMV)	TNF + Gal-liver injury, mice, IV	↑Survival, ↓apoptosis,
Ichiba *et al*[94], 2005	1×10^9 pfu	r-TPO (CAG)	AAF/70% PH, rats, IV	↑Oval cell proliferation
Khai *et al*[44], 2006	1×10^{11} vp	h-HB-EGF or h-HGF (RSV)	Fas-induced injury, mice, IV	↓Apoptosis and ↑proliferation by both
Ozawa *et al*[47], 2006	5×10^8 pfu each	r-HGF, +/or h-TGFβ2R (CAG)	DMN cirrhosis 10% PH, rats, PV	↑Proliferation, ↑survival, ↓cirrhosis
Tan *et al*[96], 2006	1×10^{11} vp	m-HNF6 (CMV)	70% PH, mice, IV	↑Proliferation
Yuasa *et al*[85], 2007	1×10^9 pfu	r-HGF, (CBA)	85% PH, rats, IV	↓Apoptosis, ↑proliferation, ↑survival
Ueno *et al*[83], 2007	5×10^8 pfu	r-HGF (CAG)	DMN cirrhosis 70% PH, rats, sPV	↑Proliferation, ↑survival, ↓cirrhosis
Atta *et al*[93], 2009	7×10^9 pfu	h-HGF, h-VEGF (CMV)	Healthy, dogs, IV	↑SEC and hepatocytes proliferation
Naked plasmid DNA				
Yang *et al*[90], 2001	10-40 μg/wk × 8	h-HGF (CMV)	Healthy, mice, IV	↑Proliferation
Xue *et al*[89], 2003	50 μg × 3	r-HGF	CCl_4 cirrhosis 70% PH, mice, IM + EP	↑Proliferation
Zhang *et al*[91], 2005	200 μg/kg per 12 h × 4	r-ALR	CCl_4 liver injury, rats, IV, IP	↓ALT and AST, ↑proliferation, ↑survival
Horiguchi *et al*[86], 2009	-	h-HGF	DMN cirrhosis, dogs, IA	↓ALT and AST, ↓fibrosis, ↑survival
HVJ Liposomes				
Ueki *et al*[88], 1999	20 or 40 mg weekly × 4	h-HGF (SRa)	DMN cirrhosis, rats, IM	↓Apoptosis, ↑survival, ↑r-HGF, ↓fibrosis
Ogushi *et al*[92], 2003	50 nmol	NF-κB decoy ODN	*P. acnes*-LPS liver injury, mice, PV	↑Survival, ↑proliferation, ↓apoptosis
Nishino *et al*[87], 2008	20 μg	h-HGF (SRα)	DMN cirrhosis 70% PH, rats, PV	↑Proliferation, ↑survival, ↓apoptosis
Takahashi *et al*[50], 2009	50 nmol	NF-κB decoy ODN	90% PH, mice, PV	↑Survival, ↓apoptosis

AAF: Acetylaminofluorene; ALT: Alanine transaminase; AST: Aspartate transaminase; ABIN-1: A20 binding inhibitor of nuclear factor κB; ALR: Augmenter of liver regeneration; BCG: Bacille Calmette-Guerin; CAG: Chicken β-actin promoter and cytomegalovirus enhancer; CBA: Chicken β-actin; D-Gal: D-galactosamine; TNF: Tumor necrosis factor; HVJ: Hemagglutinating virus of Japan; DMN: Dimethylnitrosamine; EP: Electroporation; Gal: Galactosamine; h: Human; h-HIL-6: Human hyper-interleukin-6 (IL-6) cDNA gene coding the human sIL-6R (amino acid residues 1-323) and human IL-6 (amino acid residues 29-212) fused by a synthetic DNA linker; HNF6: Hepatocyte nuclear factor 6; IA: Intra-arterial injection (hepatic artery); IM: Intramuscular injection; IP: Intraperitoneal injection; IV: Intravenous injection; M: Murine; HGF: Hepatocyte growth factor; MIF: Macrophage migration inhibitory factor; MIP-2: Macrophage inflammatory protein-2; VEGF: Vascular endothelial growth factor; CMV: Cytomegalovirus; ODN: Oligodeoxynucleotides; PH: Partial hepatectomy; LPS: Lipopolysaccharide; SECs: Sinusoidal endothelial cells; *P. acnes*: *Propionibacterium acnes*; PV: Portal vein injection; r: Rat; sPV: Selective portal vein injection; SRα: Simian virus 40 early promoter and the R-U5 segment of human T-cell leukemia virus type 1 long terminal repeat; TAA: Thioacetamide; TGFβ2R: Truncated transforming growth factor β type 2 receptor; TPO: Thrombopoietin; TU: Transducing units (1 vp = 25 TU); vp: Viral particles (1 vp = 100 pfu).

ture studies as a preparation for clinical trials. An overview of the different elements of gene therapy for liver regeneration studies are given below.

Vector type

Given the merits of adenoviruses as a powerful vector that has the highest transduction rate for liver cells, it is not surprising that two-thirds of all reviewed studies used it to prove the effect of the therapeutic gene (Table 2). It was the only viral vector used. The non-viral vectors employed in the rest of the reviewed studies are divided between naked DNA and liposomes. Despite the lower transfection rate of the non-viral vectors, their safety makes them suitable candidates for preclinical studies.

Vector dose

The administered adenoviral dose ranged between 1×10^8 pfu and 4×10^9 pfu with a dose of 1×10^9 pfu used in 80% of the studies[39,44-47,80-85,97]. The average vector dose for mice was no different from that for rats despite considerable differences in their body weights. Phaneuf *et al*[46] have examined the effect on liver regeneration of increasing doses (1×10^9 to 4×10^9 pfu) of adenoviral vector encoding for human HGF. They have found that DNA synthesis of hepatocytes and liver weight increased in a dose-dependent fashion, such that the maximal effect was seen after the infusion of 3×10^9 pfu, which resulted at day 5 in a > 130% increase in relative liver mass, with little cytopathic effect. The average single dose of naked DNA was 10-50 μg and that of liposomes was 50 nmol[50,86-91,98].

Therapeutic genes

By far the most studied therapeutic gene was HGF, which is not surprising given the fact that it is the single most important growth factor implicated in liver regeneration. It has been used in about two-thirds of studies, either alone

or in combination with other growth factors (Table 2). Other genetic materials used include growth factors, cytokines or transcription factors involved in direct liver cell proliferation, e.g. VEGF, HB-EGF, C/EBPβ, and IL-6. Two studies have reported the use of antisense ODN to NF-κB (NF-κB decoy ODN) encapsulated in hemagglutinating virus of Japan (HVJ) liposomes to prevent endotoxin- or massive hepatectomy-induced liver failure[50,92]. Antisense ODNs are not natural genes, and they are short (15-20 bases in length) synthetic oligonucleotides that are designed to hybridize to RNA through Watson-Crick base pairing. Upon binding to the target RNA, ODNs prevent expression of the encoded gene product. Although stimulation of the transcription factor NF-κB in Kupffer cells, with production of inflammatory cytokines, has been shown to be involved in liver proliferation, excessive production of cytokines is thought to be responsible for liver failure following excessive hepatectomy[50].

Route of administration

The liver is an attractive target for *in vivo* gene transfer studies because hepatocytes are readily accessible *via* the blood stream. The endothelium of hepatic sinusoids displays fenestrations that are 100 nm wide and that allow macromolecules such as viral particles to cross the endothelium and reach hepatocytes. Moreover, the hepatic blood flow represents one-fifth of the cardiac output. Thus, any particle injected into the blood circulation can quickly reach the liver[54]. For this reason, the vascular route constitutes the most commonly used in 80% of the reviewed studies. The intravenous route is the commonest among the vascular routes not only because it is the easiest route compared with intra-arterial or portal vein administration, but also due to the enhanced transduction rate following the recent modification of the hydrodynamic technique mentioned above.

Duration of transgene expression

Few of the reviewed studies have reported the duration of expression of the transduced gene or its protein[39,45,81,83,85,87,88,93-95]. Those studies that had extended observation periods have shown that the duration of transgene expression does not extend beyond 1 wk following vector administration[39,81,83,87,88,94]. These data agree with the accumulated knowledge that gene therapy using adenoviral vectors or non-viral naked DNA and liposomes confers a limited duration of gene expression. Moreover, it should be noted that the efficiency of gene transduction, which directly affects the duration of gene expression, is lower in cirrhotic liver than in normal liver due to capillarization of sinusoidal endothelial cells as a result of the decreased size or loss of the fenestrae of sinusoidal endothelial cells[99]. Nishino *et al*[87] have demonstrated that only 5%-6% of hepatocytes in cirrhotic rat livers were successfully transfected with human HGF plasmid enveloped in HVJ liposomes.

Non-hepatic gene transfection

There was a tendency towards excluding gene therapy studies for liver regeneration in which gene transduction involved organs other than the liver, e.g. skeletal muscles. Although this could be appropriate for the sake of presenting a homogeneous group of investigations, it was felt however that this would have omitted an important cluster of studies that represented an emerging direction in gene therapy for liver regeneration. In this regard, two studies used liposomes and naked plasmid to transduce skeletal muscles with HGF in animals with liver cirrhosis. They demonstrated expression of the transduced HGF gene and elevation of its plasma levels that exerted proliferative and antifibrotic effects on the liver[88,89].

FUTURE PERSPECTIVES

In 20 years of gene therapy research, there have been few studies that have aimed at enhancing liver regeneration. However, the accumulated knowledge from these studies has allowed the validation of proof of principle gene therapy investigations for promoting liver regeneration in different animal models of liver diseases. Future progress in this field is expected to tackle several points.

First, determination of the combination of gene therapy that works better for a specific disease condition. As mentioned above, enhancing liver regeneration is seldom the only goal of therapy. Treating associated liver fibrosis/cirrhosis or toxic injury requires the combined effects of genetic materials such as growth factor genes and antisense ODN. This should be based on the outcomes drawn from experimental comparative studies of different combinations of therapeutic genes for each defined disease. An example of such comparative studies is that of Ozawa *et al*[47]. In rats with liver cirrhosis, combination gene therapy of HGF, a powerful liver mitogen, and truncated type Ⅱ TGF-β receptor that specifically inhibits TGF-β signaling that is responsible for progression of liver fibrosis[100], resulted in decreased liver fibrosis and improved liver function, compared with monotherapy with either gene alone. These studies provide an opportunity to shed light on how the administered genes influence the pathogenesis of the multifactorial disease process. Also, it could identify synergistic combinations that could enhance regeneration, disease resolution and reduce the amount of transferred genetic material. An example of such studies would make use of HGF and NF-κB decoy ODN, which prevents excessive cytokine production, to prevent hepatocyte apoptosis and enhance regeneration after massive resection or liver injury[50,92].

Secondly, evaluation of the trade-off of risk against the benefits of viral *vs* non-viral gene therapy. Unlike gene therapy for liver genetic diseases that require a high rate of liver transduction to express the therapeutic protein efficiently in the systemic circulation, at a clinically relevant concentration, gene therapy for liver regeneration or resolution of fibrosis aims at locally expressing the desired proteins, which act in an autocrine or paracrine fashion[93]. Thus, despite non-viral systems having a lower transfection rate, they are safer, easy to produce in large quantities, and can be repeatedly administered, which can

aid in gauging the amount and duration of gene expression. Moreover, hydrodynamic injection in murine models and its clinically relevant retrodynamic hepatic vein gene delivery in large animals have dramatically increased transfection efficiency of non-viral systems.

Thirdly, employing the recently developed vectors that target specific liver cell types, and promoters that are capable of liver-specific sustained transgene expression in gene therapy studies to augment liver regeneration and treat associated liver injury. These new developments can be summarized as follows: (1) Cell-specific expression of therapeutic genes of interest is an extremely attractive strategy in gene therapy. Several investigators have developed selective hepatic cell delivery systems using receptors that are unique to and highly expressed by different liver cell types: (A) The asialoglycoprotein receptor (ASGPR) on the hepatocyte membrane is a specific targeting marker for gene and drug delivery. Studies have targeted the hepatocyte ASGPR using its natural ligand, asialoorosomucoid[101,102]. Chiba *et al*[103] recently have developed cationically modified biocompatible phospholipid polymer conjugated with hepatitis B surface antigen for the specific transfer of genes into human hepatocytes; (B) Quiescent HSCs lack specific receptors or motifs on their cell surface, thus, attempts to target HSCs have been a challenging task[104]. (a) The mannose 6-phosphate/insulin-like growth factor Ⅱ (M6P/IGF-Ⅱ) receptor expression is increased on activated HSCs, particularly during fibrosis. The receptor has binding sites for IGF-Ⅱ and M6P-containing ligands[105]. Beljaars *et al* have developed a carrier system that consists of human serum albumin modified with M6P, which binds to the M6P/IGF-Ⅱ receptors on HSCs[104-107]; (b) Vitamin A receptors on HSCs have been used to deliver siRNA against collagen-specific chaperone heat shock protein 47 *via* vitamin A-coupled liposomes[108]; and (c) Liposomes labeled with a cyclic RGD-peptide that recognizes the collagen type Ⅵ receptors[109,110]; (C) Sinusoidal endothelial cells (SECs) possess unique hyaluronan receptors that recognize and internalize hyaluronic acid (HA). SECs have been targeted using HA, the endogenous ligand for the HA receptor for endocytosis[111,112]; and (D) Kupffer cells possess receptors that recognize galactose and N-acetylgalactosamine. Studies have shown that galactosylation can target various DNA preparations including liposomes, low-density lipoprotein and chitosan polymer to Kupffer cells[113-115]; and (2) Liver-specific sustained transgene expression can be obtained at very high levels from optimized promoters[116]. Many experimental gene therapy vectors described in this review express transgenes under the control of non-specific promoters such as CMV, Rous sarcoma virus, simian virus 40 (SV40) and mammalian elongation factor 1α (EF1α) (Table 2). These promoters direct strong gene expression but are shut off rapidly *in vivo*[117,118]. A tissue-specific promoter is a promoter that has activity in only certain cell types. Use of a tissue-specific promoter in the expression cassette can restrict unwanted transgene expression as well as facilitate persistent transgene expression[119]. Ongoing developments are based on two liver-specific promoters, the albumin promoter and the α1 antitrypsin promoter. Wooddell *et al*[116] have demonstrated that when using a plasmid vector that contains albumin promoter combined with an α-fetoprotein (AFP) MERⅡ enhancer, 5' intron from the factor Ⅸ gene, and the 3'UTR from the albumin gene, including intron 14, the reporter gene expression levels remained high for 1 year, at levels comparable to those obtained from the CMV promoter on day 1. Ziegler *et al*[120] have shown that intravenous administration of a recombinant AAV2 vector encoding human α-galactosidase A under the transcriptional control of a liver-restricted enhancer/promoter consisted of human serum albumin promoter (nucleotides -486 to +20), to which were appended two copies of the human prothrombin enhancer (nucleotides -940 to -860). The enhancers were placed 5' of the promoter in the forward orientation. This vector mediated sustained hepatic expression of α-galactosidase A for 12 mo and was associated with a significantly reduced immune response to the expressed enzyme. Several investigators have reported encouraging long expression of transgenes using different modifications of α1 antitrypsin promoter[117,121-123]. Jacobs and his colleagues have compared 22 hepatocyte-specific expression cassettes and have found that a promoter that consists of an 890-bp human α1-antitrypsin promoter and two copies of the 160-bp α1-microglobulin enhancer results in the highest expression levels[124]. Comparisons between different liver-specific promoters have shown that α1-antitrypsin promoters induce higher levels and prolonged expression of transgenes than other liver-specific promoters such as AFP and albumin promoter[125-127]. The most recent investigations have shown the unlimited possibilities for gene therapy modifications. Li *et al*[128] have developed a small DNA fragment (347 bp) from the AAV chromosome 19 integration site that is capable of providing efficient and enhanced liver-specific transcription when used in recombinant AAV vectors. Previously described tissue-specific promoters for gene therapy are typically too big for AAV vectors. Wolff *et al*[129], in an effort to increase long-term expression of transgene products, have designed a plasmid DNA vector under the control of a tissue-specific promoter and have included microRNA target sites in the transcripts, in order to silence expression in antigen-presenting cells.

CONCLUSION

The success of several proof of principle studies of gene therapy for liver regeneration, coupled with the recent extensive search for the mechanisms of selective targeting of specific liver cells, should pave the way towards future clinical trials. As liver regeneration is usually an integral part of the therapeutic goals of many liver diseases, gene therapy to enhance liver regeneration needs to be combined with gene therapy for associated liver disease. Consequently, clinically relevant gene transfer protocols should be developed to address specific goals of such combined gene therapy trials.

Abstract

AIM: To assess the effects of bile and pancreatic juice on structural and mechanical resistance of extracellular matrices (ECMs) *in vitro*.

METHODS: Small-intestinal submucosa (SIS), porcine dermal matrix (PDM), porcine pericardial matrix (PPM) and bovine pericardial matrix (BPM) were incubated in human bile and pancreatic juice *in vitro*. ECMs were examined by macroscopic observation, scanning electron microscopy (SEM) and testing of mechanical resistance.

RESULTS: PDM dissolved within 4 d after exposure to bile or pancreatic juice. SIS, PPM and PDM retained their integrity for > 60 d when incubated in either digestive juice. The effect of bile was found to be far more detrimental to mechanical stability than pancreatic juice in all tested materials. In SIS, the loss of mechanical stability after incubation in either of the digestive secretions was less distinct than in PPM and BPM [mFmax 4.01/14.27 N (SIS) *vs* 2.08/5.23 N (PPM) *vs* 1.48/7.89 N (BPM)]. In SIS, the extent of structural damage revealed by SEM was more evident in bile than in pancreatic juice. In PPM and BPM, structural damage was comparable in both media.

CONCLUSION: PDM is less suitable for support of gastrointestinal healing. Besides SIS, PPM and BPM should also be evaluated experimentally for gastrointestinal indications.

Key words: Extracellular matrix; Intestinal regeneration; *Ex-vivo* testing; Gastrointestinal surgery; Gastrointestinal fistula; Bioscaffolding

INTRODUCTION

Extracellular matrices (ECMs) have been introduced for clinical therapy of gastrocutaneous, enterocutaneous and anal fistulas and for buttressing of gastrointestinal staple lines. Moreover, they have been evaluated experimentally as bioscaffolds for tissue regeneration in different gastrointestinal hollow organs[1-14] and for reinforcement of gastrointestinal anastomoses[15,16]. In particular, small-intestinal submucosa (SIS) has been tested clinically and experimentally. SIS is a biodegradable, commercially available, acellular, immunologically inert collagen matrix, which is extracted from the submucosal layer of porcine small bowel.

Several clinical studies have been performed to evaluate SIS for plug repair of gastrointestinal fistula. Prospective studies have shown high rates of success in the treatment of anal fistulas[17,18], but enterocutaneous[19,20] and gastrocutaneous[21,22] fistulas have also been treated successfully by implantation of SIS plugs. Furthermore, it has been shown that sealing of intestinal anastomoses promotes the healing of intestinal anastomoses[15,16]. For successful application in luminal gastrointestinal organs, temporary maintenance of structure and stability of ECM against gastrointestinal fluids should be guaranteed. To date, SIS has never been examined because of its resistance against gastrointestinal digestive juices. Other biological collagenous acellular scaffolds, which are promising for the support of gastrointestinal healing, are extracted from porcine dermis, porcine pericardium or bovine pericardium.

The aim of our study was to assess the effect of physiological intraluminal intestinal components human pancreatic juice and bile on 3D surface ultrastructure and mechanical resistance of different natural biological scaffolds *in vitro*.

MATERIALS AND METHODS

Materials

Single-layer SIS was prepared as previously described[23]. Sections of porcine jejunum were obtained from the local slaughterhouse and immediately placed in 0.9% saline solution. Jejunal sections were cut into 10-cm lengths and luminally cleaned with 0.9% saline solution. The mesenteric tissues were removed from the segment of the small intestine, followed by mechanical removal of the tunica serosa and tunica muscularis from its outer surface by gentle abrasion using a scalpel handle and saline-moistened gauze. The segment was inverted and the tunica mucosa was mechanically removed by similar mechanical abrasion and reverted to its original orientation. The remaining 0.1-0.2-mm thick translucent tube actually consisted of the tunica submucosa. The stratum compactum that originally was in contact with the more superficial luminal mucosa was now the luminal surface of the SIS graft. After sterilization of the SIS graft by 2 h incubation in 0.1% perchloric acid, it was rinsed with sterile normal saline and stored in refrigerated 0.05% gentamicin at 4℃. Storage time for the graft materials ranged from 3 to a maximum of 7 d until the material was used for *in vitro* testing.

Four-layer SIS was provided as Surgisis® from Cook Surgical (Lafayette, IN, USA). Porcine dermal matrix (PDM) was provided as Xenoderm® from MBP (Neustadt-Gleve, Germany). Cleansed porcine pericardial matrix (PPM) was provided from aap Biomaterials (Dieburg, Germany). Bovine pericardial matrix (BPM) was provided as Lyoplant® from Braun Dexon (Melsungen, Germany). The materials were divided under sterile conditions into pieces of 1 cm × 1 cm for scanning electron microscopy (SEM) and for measurement of degradation time. For assessment of mechanical properties, samples of 1 cm × 3 cm were used.

Incubation

Human bile had been collected during laparotomy from patients in whom cholecystectomy was performed. Microbiological assessment of bile excluded an infectious biliary syndrome. Pancreatic juice was obtained from patients with pancreatic duct drainage after pancreatic head resection for chronic pancreatitis. Patient consent to use the secretions for the study was given. Both fluids were checked for bacterial contamination in aerobic and anaerobic microbiologic cultures, and only sterile bile and pancreatic juice were used for experiments. ECM specimens of 1 cm × 1 cm and 1 cm × 3 cm were incubated at 37℃ for 1, 7, 14 or 60 d in bile and pancreatic juice. For reference, the material was also incubated in sterile phosphate buffered saline (PBS). The pH of human bile used for incubation was 8.37. Pancreatic enzyme concentrations were measured by routine diagnostic methods at the central laboratory of the University Hospital Freiburg. Initial concentration of amylase was on average 86 040 U/L, concentration of lipase was 210 630 U/L in pancreatic juice, and pH was 8.42. After 24 h of incubation, concentration of amylase was on average 68 440 U/L, and concentration of lipase was 28 670 U/L in pancreatic juice. Due to this degradation of active enzymes during incubation, both media were replaced every 24 h under sterile conditions.

Measurement of degradation time and macroscopic evaluation

All incubated samples were macroscopically inspected daily for signs of degradation for 60 d. After incubation in PBS, human bile and human pancreatic juice, the size of the specimens was measured after 1, 7, 24 and 60 d.

Mechanical testing

Assessment of mechanical resistance using a sero-hydraulic material testing machine with a 200-N force transducer (UTS 20; UTS Systeme GmbH, Germany) was performed after 24 h and 14 d. Test Expert II Software (Zwick GmbH, Ulm, Germany) was used for analysis of force/distension diagrams. All mechanical experiments were carried out in triplicate. ECM strips of 1 cm × 3 cm were removed from incubation medium, rinsed in PBS and fixed in the testing device of the material testing machine. The sample was distended longitudinally at a speed of 12 mm/min until the sample broke. The required force until failure of the SIS strip was measured and reported as Fmax in Newtons.

SEM

After 7 d incubation in PBS, bile or pancreatic juice ECM samples (1 cm × 1 cm) were rinsed in PBS and subsequently fixed with 4% buffered formaldehyde for 48 h at room temperature. The samples were dehydrated in a graded series of acetone, dried in a critical-point dryer, mounted for SEM, and coated with gold in an evaporator unit. The samples were mounted such that one of the sides and the cross-section were visible. Examination was then performed in an LEO 435 VP scanning electron microscope (LEO Electron

PPM	> 60	> 60	> 60
BPM	> 60	> 60	> 60

Degradation time is given in days. Incubation was performed at 37℃ for 60 d. [1]Enzyme concentration: amylase 86040 U/L; lipase 210630 U/L. PBS: Phosphate buffered saline; SIS: Small-intestinal submucosa; PDM: Porcine dermal matrix; PPM: Porcine pericardial matrix; BPM: Bovine pericardial matrix.

Microscopy Ltd., Cambridge, UK). A grading system was developed for comparison of ultrastructural alterations after incubation in bile and pancreatic juice. As reference, original materials incubated for 60 min in PBS were used. Changes in porosity, surface fibrillar arrangement and erosion of the ECM surface were measured and scored (Table 1).

RESULTS

Macroscopic examination and degradation time

SIS one-layer, SIS four-layer, PPM and BPM samples were intact, without macroscopic signs of degradation after 60 d of incubation in bile, pancreatic juice and PBS. Apart from deep green-brown color after incubation in bile, there were no macroscopic differences recognizable after 7, 14 and 60 d of incubation. No shrinkage and no change in size of the patches were macroscopically detectable, regardless of the medium of incubation in SIS, PPM and BPM samples. PDM was dissolved within 40 d in PBS, within 2 d in bile, and within 4 d in pancreatic juice (Table 2).

Mechanical testing

For SIS, PPM and BPM, testing revealed the most distinctive loss of mechanical strength after incubation in bile at 24 h and 14 d. Incubation in pancreatic juice also caused a significant decrease of breaking strength at 14 d. No marked difference could be detected between saline and pancreatic juice incubation for SIS four-layer, PPM and BPM after 24 h. As a result of early structural degradation, PDM could only be tested after 24 h of incubation. No marked differences in mechanical resistance in the three different media were detected for PDM after 24 h. Numerical mean values of mechanical testing are shown in Table 3.

Surface structure of the ECMs

SEM of SIS showed a non-directed fibrous and fine surface structure of abluminal surface of the material. On the opposite side, which represents the stratum compactum of the submucosal layer of the porcine bowel wall, the surface appeared dense without a porous aspect (Figure 1). The single layers of the 4-layer SIS were distinguishable in the cross-sectional view. Arrangement of collagenous fibers in PDM appeared to be more directed. Single fibers looked chubby and showed a scaly surface (Figure 2). The collagenous fibers in PPM appeared fine and were assembled almost straight. Porosity of the material was verified by SEM, although some parts of the heterogeneous surface appeared dense (Figure 2). In BPM, SEM showed

a directed but wormed arrangement of the fibers. Single collagenous fibers appeared fine-structured with a slick surface (Figure 2).

Structural changes after incubation in bile

After 7 d of incubation in bile, the stratum compactum surface of SIS appeared clearly damaged. The dense surface was scarified and a fibrous structure of the deeper parts of the material could be recognized. After biliary incubation in PPM, collagenous fibers were grouped together with a gross scaly surface. The dense surface of the single strands appeared eroded and very fine reticular structures were recognized. In BPM, SEM after 7 d exposure to bile also revealed the phenomenon of collagenous fibrous structures that appeared to be grouped together (Figure 3 and Table 4).

Structural changes after incubation in pancreatic juice

After exposure to pancreatic juice, SEM revealed structural changes in SIS. In the stratum compactum, surface porosity of SIS was increased and the fibrillar structure of the deeper parts was recognizable. Surface structure of the single fibrils and the surface texture of the SIS sheet appeared to be altered. A slight decrease in thickness of the SIS was seen after pancreatic juice incubation for both types of SIS samples in the cross-sectional view. Single layers of four-layer SIS could not be separated in the cross-sectional view. In PPM, the straight arrangement of the collagenous fibers was no longer recognizable after pancreatic juice incubation. The PPM surface appeared dense and partially eroded with a fine undirected fibrillar aspect. In BPM, the fibers of the matrix appeared grouped together with a chubby surface (Figure 3 and Table 4).

DISCUSSION

A prerequisite to the *in vivo* implantation of a biomaterial as a tissue substitute in a gastrointestinal luminal organ is its resistance against gastrointestinal contents, with maintenance of integrity until gastrointestinal healing has progressed and integrity of the host tissue is restored. Physi-

ological digestive fluids are extremely aggressive substances that are able to destroy most biological tissues. At present, only one experimental study has examined the resistance of ECM against digestive juices[24]. Human placental extracts, human collagen patches, bovine elastin, and bovine collagen matrices were tested for their resistance against bile and pancreatic juice. Only human collagen patches showed sufficient maintenance of integrity, whereas human placental extracts and all bovine materials failed in *in vitro* incubation in bile and pancreatic juice. Recent bioscaffolds like SIS, which have been successfully evaluated for therapy of gastrointestinal fistula, but also have proven potential for gastrointestinal tissue substitution and regeneration at different locations and organs, have so far not been examined systematically for structural and mechanical resistance against digestive contents. This study was designed to examine the effects of biological digestive fluids on the mechanical and structural resistance of current ECM.

It has been shown that ECM, implanted *in vivo* in gastrointestinal luminal organs, is able to induce regenerative responses in the host, and that anatomical tissue structure and tissue function are restored[1-13]. Different expressions of morphological and functional regeneration have been reported in the literature (Table 5). In the past, the majority of experimental work on ECM as a bioscaffold for gastrointestinal regeneration has been performed with SIS[1-13]. Other biological ECMs have only been tested in one single study in an *in vivo* setting in rodents[14]. Nearly complete and anatomical regeneration with SIS as a bioscaffold has been shown for the esophagus and the small bowel. Complete mucosal regeneration and regeneration of muscular layers has been reported within 3-6 mo[2,4,10,11]. After implantation in the rodent stomach, mucosal and muscular

restoration, along with regeneration of innervation of the stomach wall were evident within 6 mo[6]. In contrast, limited mucosal regeneration and complete absence of muscular regeneration have been reported in the repair of duodenal and lower colonic defects with SIS[7-9]. These differences in SIS-induced gastrointestinal tissue regeneration could be explained by the effects of varying intraluminal chemical and bacterial environments on the integrity and intactness of the collagenous matrix and the 3D structure of the matrix. Biliary and pancreatic enzyme aggression is likely to play a major role in these processes. Toxicity of bile is explained by the detergent capacity of bile salts and alkaline pH of bile. The destructive effects of pancreatic juice on biological tissues and membranes are best explained by its content and the high concentration of enzymes like proteases, glucosidases, elastases and lipases. It is assumed that these enzymes are able to degrade the ECM components that are present in biological and artificial scaffolds[24]. Physiologically, bile and pancreatic juice are slowly secreted and diluted by other intraluminal gastrointestinal contents such as chyme. In our study, ECM was exposed to concentrated and very aggressive media *in vitro*, although they almost never encounter such demanding conditions *in vivo*.

The most pronounced effects of bile and pancreatic juice in our study were seen in PDM. It was dissolved within a few days in both digestive juices. SIS, PPM and BPM maintained their integrity for at least 60 d of incubation in pure bile or pancreatic juice. In ECM of porcine origin, SIS and PPM, the loss of mechanical stability after incubation in the two digestive media was less distinct than in BPM. Our examination revealed bile to be much more efficacious in degrading ECM than pancreatic juice in all tested materials. In SEM, ECM incubated in bile was more eroded than after incubation in pancreatic juice. Moreover, SEM showed obvious changes in the 3D surface structure and arrangement of the collagenous fibers in SIS, PPM and BPM. It is assumed that the 3D structure of the fibrillar collagens and adhesive glycoproteins in the naturally occurring biopolymer SIS are involved in tissue regeneration induced by SIS[25], therefore, it has to be assumed that those changes in 3D structure impair gastrointestinal tissue regeneration. Moreover, destruction of regulatory proteins that are present in SIS, such as fibronectin, heparin sulfate proteoglycan, fibroblast growth factor-2, transforming growth factor-β and vascular endothelial growth factor, by aggressive contents of bile and pancreatic juice could also impair tissue regeneration[25-27]. This is a possible explanation for limited mucosal and missing muscular regeneration in duodenal patch repair by SIS[8,9]. Although nearly complete regeneration of biliary epithelium was reported, no formation of a muscular layer was seen when SIS was used for defect repair of the common bile duct in a canine model[1]. Based on these *in vivo* reports, it can be assumed that in the presence of higher intraluminal concentrations of bile and pancreatic enzymes, in particular, muscular regeneration is impaired if SIS is used as a bioscaffold.

Different clinical studies have reported successful application of SIS as a plug system for the therapy of enterocutaneous fistulas. For this indication, SIS is commercially available as Surgisis AFP Anal Fistula Plug® (Cook Biotech Inc.). For plug repair of anorectal fistulas, Champagne *et al*[17] have reported an overall success rate of 83% in a prospective study in 46 patients with a follow-up of 24 mo. In another prospective examination in 60 patients, Schwandner *et al*[18] have reported effective closure in anorectal fistula systems in 62% of cases, with a follow-up of 12 mo. In both studies, no serious adverse effects like impairment of continence function were reported.

Besides the prospective trials for therapy of anorectal fistulas, only case reports have been published for other enterocutaneous fistulas. Small-bowel-derived fistulas have been reported to be closed successfully in three patients[19,20]. Recently Toussaint *et al*[21] have reported a case series of five patients with gastrocutaneous fistulas after gastric sleeve and gastric bypass with a success rate of 80%. Furthermore, effective closure of persistent gastrocutaneous fistulas after removal of a gastric feeding tube[22], as well as successful therapeutic approaches for rectovaginal and ileal pouch-vaginal fistulas have been reported in case series and reports[28].

Although only experimental work has been published, SIS is commercially available for reinforcement of linear gastrointestinal staple lines (Surgisis Biodesign Staple Line Reinforcement®, Cook Biotech Inc.). It has been proven experimentally that SIS-reinforced staple lines in the porcine small bowel have increased mechanical stability if tested for bursting pressure in small bowel *in vitro*[29] and immediately after application of staple lines *in vivo*[30]. To date, no information is available concerning the effects of SIS in buttressing circular staple lines and its consequences for the intestinal healing process in staple lines. Most experimental and clinical examinations concerning buttressing of staple lines have been carried out on bovine pericardium. Especially in the field of obesity surgery, bovine

pericardium is commercially available and widely used for reinforcement of staple lines. In a prospective randomized trial, Angrisani *et al*[31] have reported significant effects in prevention of staple line bleeding and a reduction of operating time due to dry operating fields compared to non-buttressed staple lines in laparoscopic gastric bypass. However, not only beneficial effects have been reported for bovine pericardium. Ibele *et al*[32] have recently published a retrospective analysis of 500 patients in which buttressing of the circular staple lines with bovine pericardium during laparoscopic Roux-en-Y gastric bypass was associated with an increased staple line leak rate.

Evaluation of ECM for anastomotic reinforcement in terms of sealing of colonic anastomoses by SIS has been experimentally performed in animal models. In rodents, sealing of colonic anastomoses by SIS showed microscopically and mechanically improved intestinal healing in the most vulnerable early phase of anastomotic healing[16]. In the porcine model, although no information about the effects of SIS on early anastomotic healing and long-term effects of SIS on circular stapled colonic anastomoses beyond 30 d was gained, the feasibility and safety of anastomotic sealing by SIS were demonstrated[15].

In summary, most clinical and experimental evaluation of ECM application in gastrointestinal surgery has been performed on SIS. Apart from staple line reinforcement, other biologically derived ECMs have only been rarely examined for gastrointestinal tissues. We therefore compared the mechanical and ultrastructural characteristics of SIS with ECM derived from porcine dermis, porcine pericardium and bovine pericardium in the presence of aggressive gastrointestinal fluids. Compared to SIS and PPM, mechanical resistance of BPM after 2 wk of exposure to bile or pancreatic juice is clearly weaker. These differences, however, could not be reproduced for structural degradation. Therefore, neither ECM of porcine nor bovine origin can be judged as more resistant to one or other of the human digestive juices. Early degradation of PDM in the presence of bile and pancreatic juice could be an explanation for the failure of acellular dermal matrix as a bioscaffold for intestinal regeneration placed in gastrointestinal continuity, whereas after prevention of exposure to bile and pancreatic juice by implantation in a defunctionalized blind jejunal limb, acellular dermal matrix remained sufficient and allowed mucosal regeneration[14]. These findings are important for application of ECM to gastrointestinal luminal organs, because our data suggest that deviation of bile and pancreatic juice upstream from the repair, should be applied in further experimental and clinical testing.

SIS, PPM and BPM retain their integrity in the presence of high concentrations of human bile and pancreatic juice. Ultrastructural degradation with changes in porosity, surface fibrillar arrangement and erosion of matrix surface were detectable in all three ECMs. The extent of ultrastructural alterations in SIS was more pronounced after incubation in bile than in pancreatic juice. In PPM and BPM, these differences were less distinct. Therefore, we conclude that PPM and BPM should also be evaluated as bioscaffolds for intestinal regeneration, as sealing materials for anastomotic reinforcement, and for plug repair of gastrointestinal fistulas in *in vivo* studies. As a result of early dissolution in the presence of digestive juices, PDM is less suitable for application in gastrointestinal luminal organs. To verify the results from *in vitro* testing, the bioscaffolds used should be tested *in vivo* by implantation in different gastrointestinal luminal organs, with and without deviation from bile, pancreatic juice and stool at the site of repair in upcoming experimental studies. Finally, PPM and BPM should also be evaluated experimentally for treatment of gastrointestinal fistula and reinforcement of intestinal anastomoses *in vivo*.

COMMENTS

Background

Extracellular matrices (ECMs) have been introduced for clinical therapy of gastrocutaneous, enterocutaneous and anal fistulas and for buttressing of gastrointestinal staple lines. They have been experimentally evaluated as bioscaffolds for tissue regeneration at different gastrointestinal hollow organs and for reinforcement of gastrointestinal anastomoses.

Research frontiers

ECMs have been tested for different indications and at different locations in the gastrointestinal tract. It is not known if there are any relevant structural and mechanical changes in ECM caused by exposure to digestive juices. *In vivo* models have reported varying degrees of morphological intestinal regeneration after implantation of ECM as a bioscaffold at different gastrointestinal locations. This phenomenon could be explained by the effects of digestive juices on the structural and mechanic traits of the ECM. In this study, the authors investigated the effects of bile and pancreatic juice on different ECMs.

Innovations and breakthroughs

Small-intestinal submucosa (SIS) was found to be mechanically the most resistant tested material. It was demonstrated that porcine dermal matrix (PDM) is not suitable for therapeutic purposes in intestinal tissue regeneration due to its early degradation. However, SIS, porcine pericardial matrix (PPM) and PDM retained their integrity for up to 60 d when exposed to bile and pancreatic juices. Ultrastructural alterations were found to be more important in SIS when exposed to the juices.

Applications

As a result of their proven ultrastructural and mechanical resistance, PPM and bovine pericardial matrix (BPM) should be evaluated for treatment of gastrointestinal fistulas, as bioscaffolds for intestinal regeneration, and for reinforcement of intestinal anastomoses *in vivo*.

Terminology

ECMs are biodegradable, acellular collagen matrices that are derived from biological tissues. SIS is extracted from the submucosal layer of porcine small bowel. PDM is extracted from the porcine dermis. PPM and BPM are extracted from porcine and bovine pericardia.

Peer review

In general, this is an interesting study with new perspectives on various biomatrices that can be used for intestinal regeneration. These analyses could have an impact on the development of therapeutic approaches in the field of bioengineering.

Abstract

AIM: To investigate whether curcumin could attenuate nuclear factor (NF)-κB p65 expression and macromolecular leakage in the gastric mucosa of *Helicobacter pylori* (*H. pylori*)-infected rats.

METHODS: Twenty-five male Sprague-Dawley rats were equally divided into five groups: control rats (Control), control rats supplemented with 600 mg/kg curcumin, *H. pylori*-infected rats (*Hp*), *H. pylori*-infected rats supplemented with 200 mg/kg curcumin (*Hp* + cur Ⅰ), and *H. pylori*-infected rats supplemented with 600 mg/kg curcumin (*Hp* + cur Ⅱ). In *H. pylori*-infected groups, rats were inoculated with *H. pylori* suspension twice a day at an interval of 4 h for 3 d. Two weeks later, 200 or 600 mg/kg curcumin was given once daily to curcumin-supplemented groups for 7 d. On the day of the experiment, macromolecular leakage in gastric mucosa was examined by intravital fluorescence microscopy. The stomach tissue was removed to examine NF-κB p65 expression in gastric epithelial cells by immunohistochemistry.

RESULTS: The expression of NF-κB p65 in gastric epithelial cells and the macromolecular leakage from gastric mucosal microcirculation significantly increased in the *Hp* group compared with the Control group. The percentages of NF-κB p65 immunoreactive cells in Control and *Hp* groups were 10.72% ± 2.10% *vs* 16.02% ± 2.98%, $P = 0.004$, respectively. The percentages of macromolecular leakage in Control and *Hp* groups were 10.69% ± 1.43% *vs* 15.41% ± 2.83%, $P = 0.001$, respectively. Curcumin supplementation in *Hp* + cur Ⅰ and *Hp* + cur Ⅱ groups significantly decreased NF-κB p65 immunoreactive cells and macromolecular leakage compared with results in the *Hp* group. The percentages of NF-κB p65 immunoreactive cells in *Hp* + cur Ⅰ and *Hp* + cur Ⅱ groups were 11.79% ± 2.13% ($P = 0.017$) and 11.42% ± 1.68% ($P = 0.010$), respectively. The percentages of macromolecular leakage in *Hp* + cur Ⅰ and *Hp* + cur Ⅱ groups were 12.32% ± 2.13% ($P = 0.025$) and 12.14% ± 1.86% ($P = 0.018$), respectively.

CONCLUSION: *H. pylori*-induced gastric inflammation in rats is associated with increased NF-κB activation and macromolecular leakage which can be reduced by curcumin supplementation.

Key words: Curcumin; *Helicobacter pylori*; Nuclear factor-κB p65; Macromolecular leakage

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a spiral-shaped Gram-negative bacterium. The infection causes chronic gastritis and peptic ulcer diseases in patients. *H. pylori* infection is also related to mucosa-associated lymphoid tissue lymphoma and gastric cancer diseases in patients[1,2]. The pathogenesis of *H. pylori* infection is associated with the bacterial virulence factors. After *H. pylori* bacteria adhere to gastric epithelial cells, they inject their virulence factors into the host cells *via* a type Ⅳ secretory system[3]. The virulence factors can induce the activation of nuclear factor (NF)-κB in gastric epithelial cells[4].

NF-κB is an important regulator of many cellular processes including the control of the immune response and inflammation[5,6]. NF-κB is a dimeric complex composed of the five mammalian Rel proteins, p65, c-Rel, p50/NF-κB1, p52/NF-κB2, and RelB, in almost any combination. In resting cells, the inhibitors of NF-κB (IκB) form complexes with NF-κB. Upon stimulation, specific intracellular signalling pathways are activated, leading to the activation of the IκB kinase complex (IKK complex). The activated IKK complex phosphorylates the IκB at specific amino acids for the poly-ubiquitination of these NF-κB inhibitors. The ubiquitination of IκB and its subsequent degradation by a proteasome are required for NF-κB activation. NF-κB is now free to translocate into the nucleus and regulate NF-κB-dependent gene expression[7]. The target of activated NF-κB includes the genes encoding proinflammatory cytokines and chemokines that are the causes of *H. pylori*-induced gastric inflammation[4,8,9].

In *H. pylori*-associated gastric inflammation, inflammatory mediators could induce vascular damage. A previous study demonstrated that *H. pylori*-infected patients showed erythema, edema, and vasodilation as well as neutrophil infiltration in the mucosa[10]. Our previous study suggested that leukocyte adhesion in postcapillary venules was increased in *H. pylori*-infected rats. Moreover, the degree of leukocyte adhesion was correlated with the level of the proinflammatory cytokine, tumor necrosis factor (TNF)-α[11]. In addition, previous studies have demonstrated that water-soluble extracts of *H. pylori* induced leakage of macromolecules from rat gastric mucosal microcirculation[12-14].

Curcumin (diferuloylmethane) is an active ingredient of *Curcuma longa* (turmeric) and is pharmacologically safe for human and animals. Curcumin has many biological activities, including anti-inflammatory properties[15]. Most of the anti-inflammatory effects can be explained by the efficient inhibition of NF-κB mediated by this substance[16-18]. Recently, a previous study showed that curcumin can inhibit NF-κB activation in *H. pylori*-infected gastric epithelial cells[19]. Curcumin is also a potent antibacterial agent against *H. pylori* as shown in *in vitro* study[20]. In contrast, curcumin did not eradicate *H. pylori* in *H. pylori*-infected patients[21].

However, it is not clear whether curcumin has any *in vivo* effects in *H. pylori*-induced gastric inflammation. Therefore, we examined the anti-inflammatory effect of curcumin, which may reduce mucosal macromolecular leakage through the suppression of gastric epithelial NF-κB p65 expression induced by *H. pylori* infection in rats.

MATERIALS AND METHODS

Experimental design

Male Sprague-Dawley rats (National Laboratory Animal Center, Mahidol University, Nakorn pathom, Thailand) weighing 200-250 g were used. All experiments and procedures carried out on the animals were approved by the Ethics Committee of the Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand. Rats were housed in a controlled temperature room at 25 ± 1℃ under standard conditions (12-h day-night rhythm). Twenty-five rats were divided into five groups (five rats each) as follows.

Control rats (Control): rats were fed normal saline (1 mL/rat) orally *via* intragastric tube twice a day at an interval of 4 h for 3 consecutive days. Two weeks later, 0.1% DMSO (1 mL/rat) was given once daily to the rats by intragastric tube for 7 d.

Control rats supplemented with 600 mg/kg curcumin (Cur): rats were fed normal saline (1 mL/rat) orally *via* intragastric tube twice a day at an interval of 4 h for 3 consecutive days. Two weeks later, 600 mg/kg curcumin (95% purified curcumin, Cayman Chemical, Ann Arbor, MI, USA) dissolved in 0.1% DMSO (1 mL/rat) was given once daily to the rats by intragastric tube for 7 d.

H. pylori-infected rats (*Hp*): rats were inoculated with *H. pylori* suspension according to Thong-Ngam *et al*[22]. Briefly, *H. pylori* suspension (10^{10} CFU/mL; 1 mL/rat) was given to the rats by intragastric tube twice a day at an interval of 4 h for 3 consecutive days. Two weeks later, 0.1% DMSO (1 mL/rat) was given once daily to the rats by intragastric tube for 7 d.

H. pylori-infected rats supplemented with 200 mg/kg curcumin (*Hp* + cur Ⅰ): 2 wk after *H. pylori* inoculation, 200 mg/kg curcumin dissolved in 0.1% DMSO (1 mL/rat) was given once daily to the rats by intragastric tube for 7 d.

H. pylori-infected rats supplemented with 600 mg/kg curcumin (*Hp* + cur Ⅱ): 2 wk after *H. pylori* inoculation, 600 mg/kg curcumin dissolved in 0.1% DMSO (1 mL/rat) was given once daily to the rats by intragastric tube for 7 d.

H. pylori

H. pylori strains used for all experiments were originally

obtained from peptic ulcer patients who visited the King Chulalongkorn Memorial Hospital. The bacteria were grown in Brucella broth (pH 7.0) supplemented with 10% goat serum for 24 h at 37℃ in an automatic CO_2-O_2 incubator (85% N_2, 10% CO_2, and 5% O_2).

Animal preparation

The method of preparing animals for *in vivo* fluorescent microscopy was adapted from a previous study[14]. The animal was anesthetized with thiopental (General Drug House, Thailand; 60 mg/kg, intraperitoneal). A constant level of anesthesia was maintained throughout the experiment by a supplement dose (20% of original dose) every 30-45 min[11]. A tracheotomy was performed. The arterial blood pressure was recorded in the common carotid artery using a pressure transducer (Nihon Kohden, Tokyo, Japan). The abdominal cavity was opened *via* a midline laparotomy. A 1.0 cm incision was made using an electrical microcautery device (Hyfrecator plus®, Conmed, Utica, NY, USA) at the posterior wall, being parallel to the "limiting ridge" of the exteriorized stomach[12]. Next, the stomach was gently extended and placed on a designed board. The incision in the anterior wall was opened using microclamps and covered with Saran wrap to allow visualization of the posterior mucosal surface[12]. The animals were terminated after studying intravital fluorescent videomicroscopy.

Intravital fluorescent videomicroscopy

Observations were made from the glandular portion of the posterior mucosa. Fluorescence tracer [0.3 mL of 0.5% fluorescein isothiocyanate (FITC)-labeled dextran (FITC-dx, MW = 250 000, Sigma-Aldrich, USA)] was injected into the jugular vein[23]. The posterior mucosal microcirculation was visualized under an intravital fluorescence videomicroscope (Nikon Optiphot-2, Nikon, Tokyo, Japan), and examined under × 20 objective lens (Nikon). The selected area included the characteristic honeycomb-like network of mucosal capillaries and at least one postcapillary venule (PCV; diameter 15-30 μm)[24]. Five minutes after FITC-dx administration, a recording was performed as a baseline using a video-recorder (Sony SVT-124p, Sony, Tokyo, Japan). Thirty minutes later, recording was performed again.

Measurement of macromolecular leakage in gastric mucosa

Based on the recorded video images, we measured macromolecular leakage from the PCV in the selected area. Computerized image analysis (GLOBAL LAB® image Ⅱ program, USA) was used to measure fluorescence intensity in the interstitial space and in the PCV at both time points during the experiment. The fluorescence intensities between outside and inside vessels (I_{out}/I_{in}) at baseline and 30-min time points were measured[25]. The molecular leakage in percentage was calculated using the equation: Macromolecular leakage (%) = [(I_{out}/I_{in}) at 30 min - (I_{out}/I_{in}) at baseline]/[(I_{out}/I_{in}) at baseline] × 100.

Assessment of H. pylori infection

The presence of *H. pylori* infection in individual rats was determined by urease test and histological examination by a pathologist. After studying intravital fluorescent microscopy, the rat was terminated by injection of an overdose of thiopental. Then the stomach was removed and longitudinally dissected along the greater curvature. A 2 mm^3 segment of gastric mucosa from the antrum was immediately cut and placed in the urease test tube.

Regarding histological examination, the stomach was fixed with 4% paraformaldehyde in phosphate-buffered saline, pH 7.4 at room temperature for 24 h. The tissue was processed, embedded in paraffin, and cut at 5 μm thickness. The sections were stained with hematoxylin and eosin, and microscopically examined for the presence of *H. pylori*. The presence of *H. pylori* was also detected by Warthin-Starry staining in unclear cases. The level of bacterial colonization was recorded by using a grading system as follows, score 0: no bacteria detected; score 1: mild colonization in some gastric crypts; score 2: mild colonization in most gastric crypts; score 3: moderate colonization in all gastric crypts; and score 4: dense colonization in some gastric crypts. The results were presented as the bacterial colonization scores for each group. Moreover, gastric inflammation was classified by using the Sydney system[26]. The infiltrations of mononuclear and polymorphonuclear leukocytes in the gastric mucosa defining the inflammatory scores were recorded. Score 0 to 3 represented normal, mild, moderate, and marked histopathology changes, respectively.

Immunohistochemistry

The stomach sections were deparaffinized with xylene and gradually dehydrated in ethyl alcohol. Next, antigen retrieval was performed by immersing the sections in citric acid buffer (pH 6.0) in a microwave oven for 13 min. Endogenous peroxidase activity and nonspecific binding were blocked with 3% hydrogen peroxide (Merck, Hohenbrunn, Germany) for 5 min and 3% normal horse serum (Gibco, Carlsbad, CA, USA) for 20 min, respectively. After that, the sections were incubated with polyclonal antibody against the p65 subunit of NF-κB (sc109; Santa Cruz Biotechnology, Santa Cruz, CA, USA) at a dilution of 1:100 in a humidified chamber for 1 h at room temperature. Then the sections were incubated with biotinylated anti-rabbit immunoglobulin (DAKO, Glostrup, Denmark) in the humidified chamber for 30 min. The reaction was visualized using the substrate diaminobenzidine (DAKO). The sections were then counterstained with hematoxylin.

Under light microscope, the expression of NF-κB p65 was cytoplasmic with scattered positive nuclear staining[27]. Thus, NF-κB p65 immunoreactive cells were defined as those with dark brown stain in their nuclei. To quantify, one thousand gastric epithelial cells were counted for each rat under × 40 objective lens. All counting was manually performed by an investigator who was blinded to the treatment groups. The data were shown as percentage of immunoreactive cells calculated from this equation: Percentage of immunoreactive cells (%) = (number of immunoreactive cells × 100)/1000.

Table 1 Demonstrated level of *Helicobacter pylori* colonization and gastric inflammation scores

Group	No.	Level of *H. pylori* colonization					Score of gastric inflammation			
		0	1	2	3	4	0	1	2	3
Control	5	5	-	-	-	-	5	-	-	-
Cur	5	5	-	-	-	-	5	-	-	-
Hp	5	-	5	-	-	-	-	3	2	-
Hp + cur Ⅰ	5	-	5	-	-	-	3	2	-	-
Hp + cur Ⅱ	5	-	3	2	-	-	3	2	-	-

Level of *Helicobacter pylori* (*H. pylori*) colonization: Score 0 = no *H. pylori* detected; Score 1 = mild colonization in some gastric crypts; Score 2 = mild colonization in most gastric crypts; Score 3 = moderate colonization in some gastric crypts; Score 4 = dense colonization in some gastric crypts. Score of gastric inflammation: Score 0 = normal gastric tissue; Score 1 = mild inflammation and histopathology changes; Score 2 = moderate inflammation and histopathology changes; Score 3 = marked inflammation and histopathology changes. Control: Control rats; Cur: Control rats supplemented with 600 mg/kg curcumin; *Hp*: *H. pylori*-infected rats; *Hp* + cur Ⅰ: *H. pylori*-infected rats supplemented with 200 mg/kg curcumin; *Hp* + cur Ⅱ: *H. pylori*-infected rats supplemented with 600 mg/kg curcumin.

Statistical analysis

All data were presented as mean ± SD. The means were compared by one-way analysis of variance (one-way ANOVA) followed by LSD post hoc test. Correlation between the percentages of NF-κB p65 immunoreactive cells and macromolecular leakage was analyzed using Pearson's correlation. All the statistical tests were performed using the computer program SPSS, version 13.0, for Windows (SPSS Inc., Chicago, IL, USA). Probability value of less than 0.05 was considered to be statistically significant.

RESULTS

H. pylori colonization and histological changes

H. pylori infection in rats was judged based on a urease test and histological examination. From histological examination, *H. pylori* colonization was observed in the *Hp* group (Figure 1) as well as in the *Hp* + cur Ⅰ and *Hp* + cur Ⅱ groups, whereas colonization was not observed in the Control and Cur groups. Figure 2 demonstrates histological differences between Control and *Hp* groups. The data are shown in Table 1.

Effects of *H. pylori* infection on NF-κB p65 expression and role of curcumin

NF-κB p65 expression in gastric epithelial cells was studied using immunohistochemistry (Figure 3). *H. pylori* infection increased NF-κB p65 expression in gastric epithelial cells. The percentage of immunoreactive cells significantly increased in the *Hp* group (16.02% ± 2.98%) compared with the Control group (10.72% ± 2.1%, $P = 0.004$) (Figure 4A).

The expression of NF-κB p65 in gastric epithelial cells was diminished by curcumin supplementation in both *Hp* + cur Ⅰ and *Hp* + cur Ⅱ groups. The percentage of immunoreactive cells significantly decreased in *Hp* + cur Ⅰ (11.79% ± 2.13%, $P = 0.017$) and *Hp* + cur Ⅱ (11.42% ± 1.68%, $P = 0.010$) compared with the *Hp* group (Figure 4A). However, there was no significant difference between the number of immunoreactive cells in *Hp* + cur Ⅰ and *Hp* + cur Ⅱ. Curcumin administration in the Cur group did not alter the baseline NF-κB p65 expression (Cur group, 9.47% ± 3.46%, $P = 0.447$) in gastric epithelial cells.

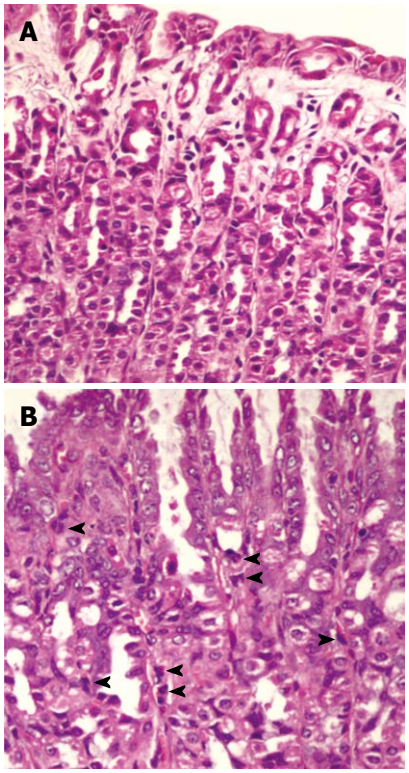

Figure 2 Pathological changes of rat gastric mucosa in control (A) and *Helicobacter pylori*-infected rats (B) (HE stain, × 400). A: Normal gastric mucosa; B: *Helicobacter pylori*-infected gastric mucosa showing inflammatory cell infiltration in the lamina propria (arrowheads).

Effects of *H. pylori* infection on macromolecular leakage and role of curcumin

The macromolecular leakage was studied by intravital fluorescent videomicroscopy. The captured images of

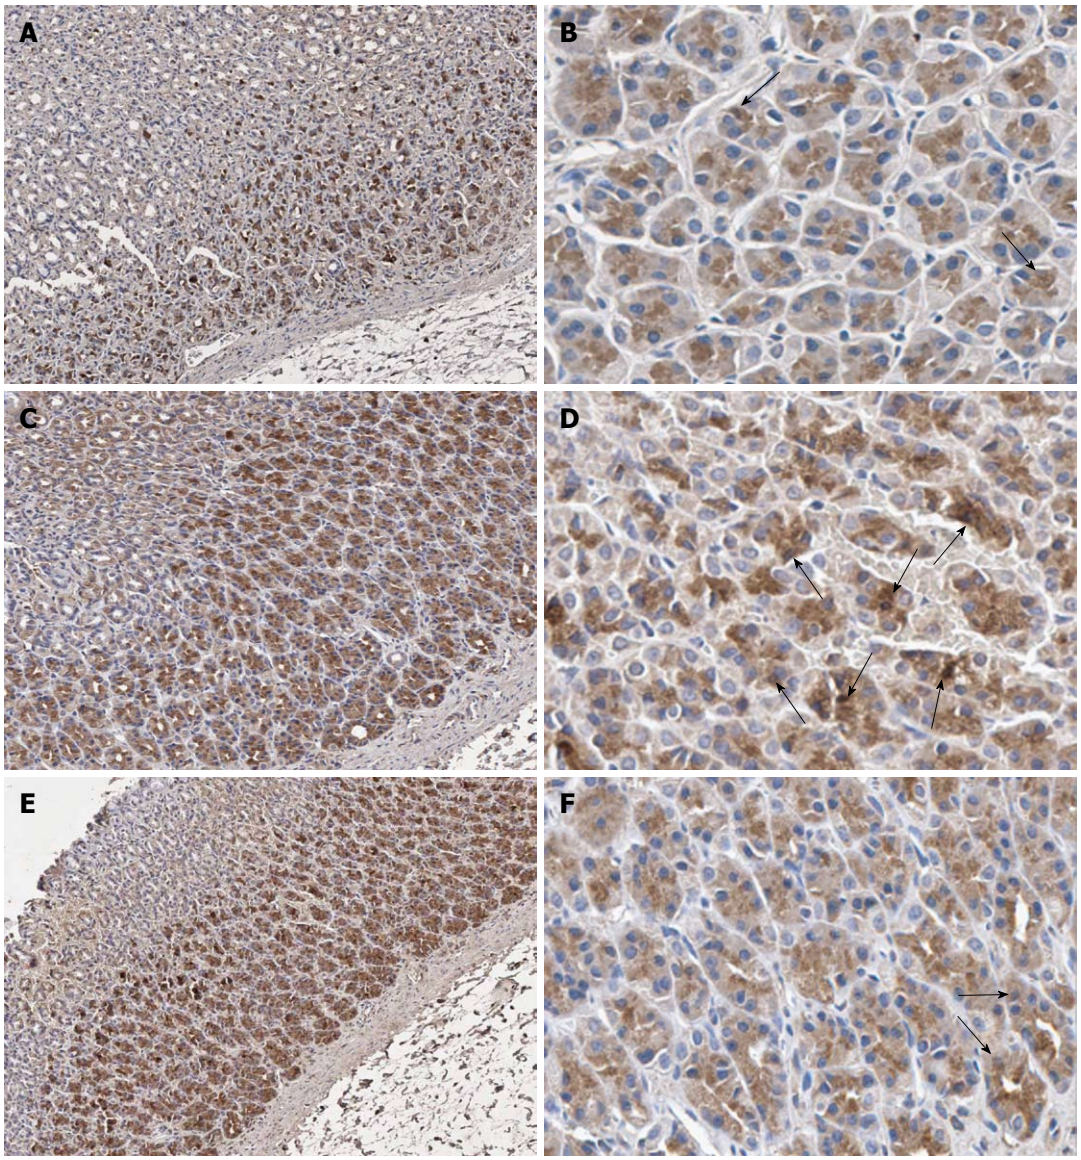

Figure 3 Immunohistochemical staining of nuclear factor-κB p65 antibody in representative tissue specimens. A, B: Control rats; C, D: *Helicobacter pylori* (*H. pylori*)-infected rats; E, F: *H. pylori*-infected rats supplemented with 200 mg/kg curcumin. Nuclear counterstaining was performed with hematoxylin. The examples of immunoreactive cells are those with dark brown stain in their nuclei (arrows). Images were obtained at × 100 (A, C and E) and × 400 (B, D and F).

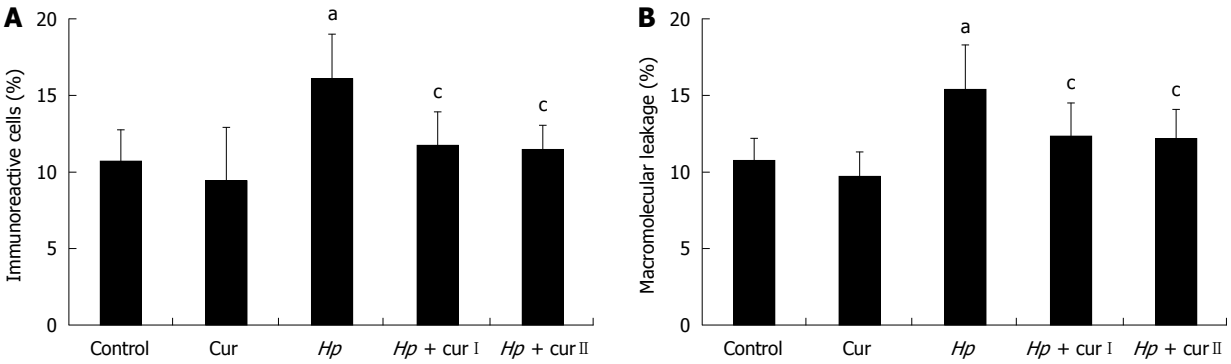

Figure 4 mean ± SD of the percentage of nuclear factor-κB p65 immunoreactive cells (A) and macromolecular leakage (B) in all experimental groups. $^{a}P < 0.05$ *vs* control rats (Control); $^{c}P < 0.05$ *vs Helicobacter pylori* (*H. pylori*)-infected rats (*Hp*). Cur: Control rats supplemented with 600 mg/kg curcumin; *Hp* + cur Ⅰ: *H. pylori*-infected rats supplemented with 200 mg/kg curcumin; *Hp* + cur Ⅱ: *H. pylori*-infected rats supplemented with 600 mg/kg curcumin.

gastric mucosal microcirculation from Control, *Hp*, and *Hp* + cur I groups at the 30-min time point are shown in Figure 5. *H. pylori* infection led to a significant increase of macromolecular leakage in the *Hp* group (15.41% ±

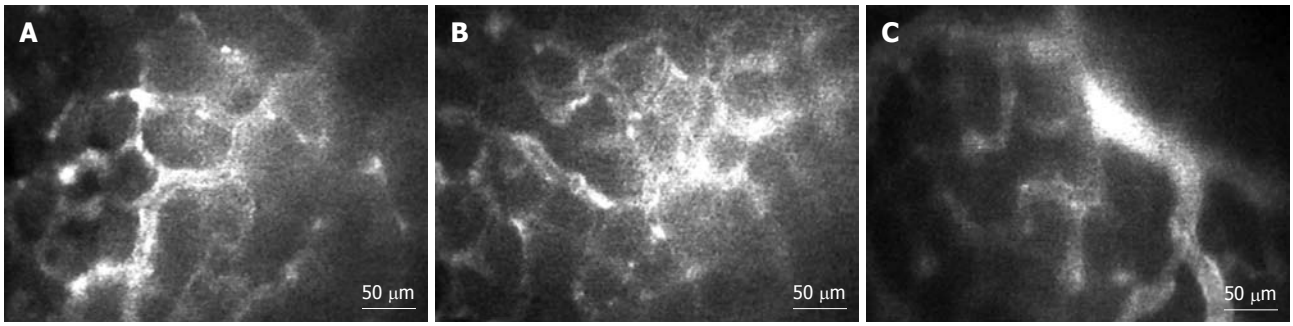

Figure 5 Intravital fluorescent microscopic images (× 200) demonstrate macromolecular leakage from vessels to the interstitial space at 30-min time points. A: Control rats; B: *Helicobacter pylori* (*H. pylori*)-infected rats; C: *H. pylori*-infected rats supplemented with 200 mg/kg curcumin.

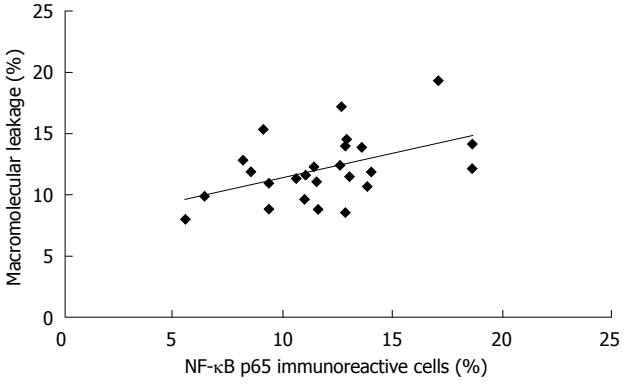

Figure 6 Correlation between the percentage of nuclear factor-κB p65 expression in gastric epithelial cells and the macromolecular leakage (r^2 = 0.2228, P = 0.017). NF-κB: Nuclear factor-κB.

2.83%) compared with the Control group (10.69% ± 1.43%, P = 0.001) (Figure 4B).

Oral treatment with curcumin over 1 wk attenuated *H. pylori* infection-induced macromolecular leakage significantly in both *Hp* + cur I (12.32% ± 2.13%, P = 0.025) and *Hp* + cur II (12.14% ± 1.86%, P = 0.018) groups (Figure 4B). However, there was no significant difference between the extent of macromolecular leakage in *Hp* + cur I and *Hp* + cur II. In addition, macromolecular leakage showed no significant differences between the Control group and the Cur group (Cur group, 9.74% ± 1.5%, P = 0.463).

Relationship between NF-κB p65 expression and macromolecular leakage

The percentages of NF-κB p65 immunoreactive cells and of macromolecular leakage from the same rat in all groups were plotted against each other (Figure 6). Interestingly, the level of NF-κB p65 expression was moderately correlated with the degree of macromolecular leakage (r^2 = 0.2228, P = 0.017).

DISCUSSION

The present study demonstrated that *H. pylori* infection activated NF-κB in gastric epithelial cells. This result corresponds to previous observations studied in both *in vitro* and *in vivo* models[4,19,28]. NF-κB is an important transcription factor which activates many genes involved in inflammatory and immune responses[5,6]. Activated NF-κB induced by *H. pylori* infection upregulates cytokine production and is associated with gastric inflammation[9]. Clinically, NF-κB was also seen to be activated in the stomach of patients with *H. pylori*-induced gastritis[29-31]. Therefore, gastric epithelial NF-κB activation may play an important role in the initiation of *H. pylori*-induced gastric inflammation.

From the results, this study can also demonstrate an increased macromolecular leakage after *H. pylori* infection. This alteration is in good agreement with previous reports[12,14]. Several mechanisms may contribute to the increased macromolecular leakage. A previous study demonstrated that the transmigration of activated neutrophils expressing a specific protein could regulate endothelial permeability, allowing macromolecules to leak[32]. Furthermore, many proinflammatory cytokines such as TNF-α and interleukin (IL)-1β could be directly modulating vascular permeability[33-35]. Neutrophil transmigration and proinflammatory cytokine production were also suggested in a NF-κB-dependent manner in gastric mucosa during *H. pylori* infection[4,8,36-38]. *H. pylori* infection may directly influence the leakage *via* the transportation of *H. pylori* toxin and activation of NF-κB in endothelial cells. Previously, *in vitro* studies indicated that endothelial cells infected with *H. pylori* have changes in protein expression and function[39,40]. Our results substantiate these findings by showing that increased NF-κB p65 expression in gastric epithelial cells is accompanied by increased macromolecular leakage during *H. pylori* infection. Thus, the increased macromolecular leakage may result from inflammatory mediator production and vascular permeability changes through *H. pylori*-induced NF-κB activation.

Our experiments show that curcumin supplementation can suppress *H. pylori*-induced gastric inflammation, as indicated by decreased NF-κB p65 expression in gastric epithelial cells and decreased macromolecular leakage in the gastric microcirculation. The activation of NF-κB is essential for transcription of many genes involved in inflammatory and immune responses influencing gastric inflammation induced by *H. pylori* infection. In the present study, NF-κB p65 expression in the nucleus indicated that curcumin may possibly suppress the translocation of activated NF-κB into transcriptional sites. *H. pylori*-

induced NF-κB activation affects recruitment of neutrophils and vascular permeability that reflect gastric inflammation. Curcumin decreased these parameters, indicating that curcumin could decrease gastric inflammation.

Inhibition of *H. pylori* growth was unlikely to be a mechanism that contributed to the effect of curcumin observed in this study, since positive results regarding *H. pylori* infection were still obtained from both urease test and histological examination after curcumin treatment in *Hp* + cur I and *Hp* + cur II animals. Recently, Di Mario *et al*[21] demonstrated that 7-d treatment with curcumin significantly improved gastric inflammation in *H. pylori*-positive patients despite *H. pylori* persistence. However, eradication by curcumin may be dependent on a high dose of curcumin, the safety of which has to be confirmed in animals and humans[41].

A previous study demonstrated that curcumin at the doses of 200 mg/kg and 600 mg/kg had an anti-inflammatory property[42]. In this study, 200 mg/kg curcumin was a sufficient dose for reducing gastric epithelial NF-κB p65 expression and mucosal macromolecular leakage. The possible mechanism cited was that curcumin inhibited *H. pylori*-induced NF-κB activation. This finding corresponded to an earlier *in vitro* study showing that *H. pylori*-induced NF-κB activation and the subsequent release of IL-8 were inhibited by curcumin[19]. In addition, the correlation between NF-κB p65 expression and macromolecular leakage found in our study suggests that *H. pylori*-induced mucosal macromolecular leakage may be mediated *via* NF-κB activation in gastric epithelial cells. Thus, the decreased macromolecular leakage may be explained by the reduction of inflammatory mediators due to epithelial NF-κB inhibition by curcumin.

In conclusion, the present study showed that *H. pylori* infection induced gastric epithelial NF-κB activation and increased mucosal macromolecular leakage. Curcumin supplementation may exert its anti-inflammatory effect by reducing macromolecular leakage through the suppression of NF-κB p65 expression in gastric epithelial cells. Hence, curcumin might be a novel therapeutic strategy against gastric inflammation induced by *H. pylori* infection.

COMMENTS

Background

The pathogenesis of *Helicobacter pylori* (*H. pylori*) infection is associated with bacterial virulence factors. The virulence factors can induce the activation of nuclear factor (NF)-κB in gastric epithelial cells, causing gastric inflammation and inducing vascular damage. Curcumin has many biological activities, including anti-inflammatory properties resulting from inhibition of NF-κB.

Research frontiers

Curcumin (diferuloylmethane) is an active ingredient of *Curcuma longa* (turmeric) that has many biological activities mediated by the efficient inhibition of NF-κB. *H. pylori* infection induces gastric epithelial NF-κB activation and increases mucosal macromolecular leakage. The hotspots of this study indicate that curcumin supplementation may exert its anti-inflammatory effect by reducing macromolecular leakage through the suppression of NF-κB p65 expression in gastric epithelial cells.

Innovations and breakthroughs

A previous study showed that curcumin is a potent antibacterial agent against *H. pylori* and can inhibit NF-κB activation in *H. pylori*-infected gastric epithelial cells *in vitro*. However, it is not clear whether curcumin has any *in vivo* effects on *H. pylori*-induced gastric inflammation. Therefore, in this study, the authors examined the anti-inflammatory effect of curcumin, which was shown to reduce mucosal macromolecular leakage through the suppression of gastric epithelial NF-κB p65 expression induced by *H. pylori* infection *in vivo* in rats.

Applications

Curcumin might be a novel therapeutic strategy against gastric inflammation induced by *H. pylori* infection.

Peer review

The merits of the manuscript are in showing the conclusion that curcumin can reduce the gastric inflammation reflected in attenuated levels of NF-κB and leakage of dextran.

Abstract

AIM: To compare the impact of ErbB2 on cell invasion and proliferation in cholangiocarcinoma (CCA) cell lines.

METHODS: Level of endogenous ErbB2 expression in three CCA cell lines, namely HuCCA-1, KKU-100 and KKU-M213, was determined by real-time reverse-transcriptase polymerase chain reaction. Two ErbB2 inhibitory methods, a small molecule ErbB2 kinase inhibitor (AG825) and siRNA, were used to disrupt ErbB2 function in the cell lines. CCA cell invasion, motility and proliferation under ErbB2-disrupted conditions were detected using Transwell and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assays. In addition, ErbB2 downstream effectors were investigated by Western blotting analysis.

RESULTS: Suppression of ErbB2 activity, using a specific kinase inhibitor (AG825), reduced invasion, motility and proliferation of all three CCA cell lines. The ability of this drug to inhibit neoplastic properties (invasion, motility and proliferation) increased concomitantly with the level of ErbB2 expression. Similarly, knockdown of ErbB2 level by siRNA inhibited cell invasion and proliferation of KKU-M213, a high-ErbB2-expressing cell, better than those of the lower-ErbB2-expressing cells, HuCCA-1 and KKU-100. Thus, both inhibitory methods indicated that there is more ErbB2-dependency for malignancy of the high-ErbB2-expressing cell, KKU-M213, than for that of low-ErbB2-expressing ones. In addition, interrupting ErbB2 activity decreased phosphorylation of AKT and p70S6K, but not extracellular signal-regulated kinase 1/2, in the high-ErbB2-expressing CCA cell line.

CONCLUSION: Our data indicated that high ErbB2 expression enhances CCA invasion, motility and proliferation *via* the AKT/p70S6K pathway, which suggests the possibility of targeting these molecules for CCA therapy.

Key words: AKT; Cholangiocarcinoma; ErbB2; Invasion; p70S6K; Cell proliferation

INTRODUCTION

Cholangiocarcinoma (CCA) is an incurable and lethal cancer. Its incidence has been increasing worldwide during the past three decades and all cases have almost the same mortality rate[1]. Strikingly, the highest incidence of CCA

has been found in Northeastern Thailand (96 per 100 000 men), followed by China and Japan[2]. As a result of the lack of a specific tumor marker and its silent symptoms, this tumor is difficult to diagnose and the majority of patients present at the late stage (stage Ⅲ or Ⅳ) of disease progression[3]. From 70% to 80% of CCA patients are inoperable and are generally treated by chemotherapy and radiation, which unfortunately have no significant impact on long-term survival[3]. Thus, new diagnostic/prognostic markers and targeted therapies for CCA need to be investigated.

Human epidermal growth factor receptor (EGFR) 2, ErbB2 (also known as HER2/Neu), belongs to subclass I of receptor tyrosine kinases in the ErbB family. Unlike other members of the ErbB family, the conformation of the ErbB2 ectodomain is similar to the ligand-activated state of other ErbBs[4]. Therefore, activation of ErbB2 can occur without ligand binding[5]. Overexpression of ErbB2 results in receptor dimerization (either homodimerization with its own or heterodimerization with other ErbBs). Upon dimerization, cytoplasmic domains of ErbBs become autophosphorylated and act as docking sites for downstream proteins that bear an Src-homology 2 or a phosphotyrosine-binding domain, which recognizes specific phosphorylated tyrosine sites in the receptors, and leads to activation of such downstream pathways as mitogen-activated protein kinase/extracellular signal-regulated kinase (ERK) and phosphoinositide 3-kinase (PI3K)/AKT[6]. Furthermore, ErbB2 can block internalization of EGFR for degradation, which results in an elevation in the membrane steady state level[7]. Thus, aberrant ErbB2 expression can lead to an extensive activation of its downstream signals and an aberration from the normal regulation, which promotes cancer development.

ErbB2 overexpression is found in approximately 30% of human breast carcinomas and in many other types of human malignancies, such as prostate, pancreas, colon and ovarian cancers[8]. Cancer patients with high ErbB2 expression tend to have a more aggressive disease, identified by clinical outcomes such as high metastasis and low response to treatment. Typically, ErbB2-positive tumors have high proliferation rates and more extensive invasion, with frequent metastasis[9]. In addition, clinical studies using ErbB2-targeted therapy with trastuzumab (a humanized monoclonal antibody against ErbB2) have shown that the response rates of breast cancer patients with ErbB2 overexpression are higher than those with normal ErbB2 expression[10].

Several lines of evidences have implicated the role of ErbB2 in aggressive forms of CCA. High expression of ErbB2 has been found in a variety of non-cancerous biliary proliferative diseases, such as in hepatolithiasis and primary sclerosing cholangitis, both of which are risk factors associated with CCA[11,12]. Immunohistochemical data have demonstrated that 20%-30% of tumor specimens from CCA patients show moderate to strong immunostaining for ErbB2[13], and most of them confer poor clinical outcomes (high metastasis and low survival rate)[13-16]. Moreover, about 30% of transgenic mice that constitutively express wild-type Neu develop gallbladder cancer and intrahepatic CCA within 8 mo[17]. Although many reports have indicated the involvement of ErbB2 in cholangiocarcinogenesis and CCA progression, the mechanism of aberrant ErbB2 expression in promoting CCA progression remains unclear.

In this study, the role of ErbB2 in governing the malignant phenotype (invasion and proliferation) of CCA was investigated by suppressing ErbB2 function in three human CCA cell lines that expressed different levels of ErbB2. Two strategies, inhibition of its kinase function and siRNA, were used to reduce ErbB2 activity. We demonstrated that downregulation of ErbB2 expression and activity suppressed CCA cell invasion, motility and proliferation, particularly in the high-ErbB2-expressing cells. Downstream signaling pathways of ErbB2 also were investigated.

MATERIALS AND METHODS

Cell culture

HuCCA-1 cell line was a generous gift from Professor Stitaya Sirisinha (Mahidol University, Thailand)[18] and KKU-100[19] and KKU-M213 cell lines were kindly provided by Dr. Banchob Sripa, (Khon Kaen University, Thailand). These three CCA cell lines were developed from Thai patients. The cells were maintained in HAM's F-12 medium (Invitrogen, Grand Island, NY, USA) supplemented with 10% heat-inactivated fetal bovine serum (FBS) (Invitrogen), 2 mmol/L glutamine, 15 mmol/L HEPES and 14 mmol/L sodium bicarbonate, 100 U/mL penicillin G and 100 U/mL streptomycin. All cell cultures were incubated at 37℃, in a 5% CO_2 humidified atmosphere.

Quantitative polymerase chain reaction

Cells (80% confluent) were harvested with 0.1% trypsin/EDTA and RNA was extracted using the RNeasy Mini kit (Qiagen, Valencia, CA, USA). Two micrograms of RNA were converted into cDNA using the Superscript™ RNase H Reverse Transcriptase kit (Invitrogen), which was amplified by quantitative polymerase chain reaction (PCR) (ABI 7500; Applied Biosystems, Foster City, CA, USA) in a 20-μL reaction volume that contained 0.5 U HotStart *Taq* polymerase (Qiagen), 1 × FastStart Universal SYBR Green Master cocktail (Roche, Germany) and 4 pmol of specific primer pairs (5'-CCAGGACCTGCTGAACTGGT-3' and 5'-TGTACGAGCCGCACATC-3' for ErbB2[20] and 5'-CTCTTCCAGCCTTCCTTCCT-3' and 5'-AGCACTGTGTTGGCGTACAG-3' for β-actin[21], used as internal control). The reactions were started with an initial heat activation step at 95℃ for 15 min and the following thermal cycling conditions: 94℃ for 30 s, 58℃ for 30 s and 72℃ for 1 min. ErbB2 mRNA levels among the test cells were determined using the $2^{-\Delta Ct}$ method[22].

Immunoblot assay

Cells transfected with siRNA (for 72 h) or treated with AG825 (for 6 h) were washed twice with PBS and lysed on ice with freshly prepared lysis buffer that contained 150 mmol/L Tris-HCl pH 7.4, 150 mmol/L NaCl, 5 mmol/L EGTA, 5 mmol/L EDTA, 0.1% SDS, 1% so-

dium deoxycholate, 1% Nonidet P-40, 1 × protease inhibitor cocktail (Roche Diagnostics, Germany), 50 mmol/L NaF, 2 mmol/L Na_3VO_4, 40 mmol/L β-glycerophosphate, and 1 mmol/L dithiothreitol. Cells were centrifuged at 12000 × *g* for 15 min. Protein lysate (80 μg) was separated by 8% SDS-PAGE and transferred to a nitrocellulose membrane (GE Healthcare, Munchen, Germany). After incubating with a blocking solution (5% skimmed milk/TBST), membranes were treated with primary antibodies specific for ErbB2, phospho-ErbB2 Y1248 (Labvision, Fremont, CA, USA), β-actin, AKT, phospho-AKT T308 (Santa Cruz Biotechnology, Santa Cruz, CA, USA), ERK1/2, phospho-ERK1/2, p70S6K, and phospho-p70S6K T389 (Cell Signaling, Beverly, MA, USA), and then with horseradish-preoxidase-conjugated secondary antibodies (Santa Cruz Biotechnology). Signals were detected using enhanced chemiluminescence (ECL plus) (GE Healthcare, Little Chalfont, Bucks, UK) and quantified by Alpha Imager (Alpha Innotech, San Leandro, CA, USA).

siRNA transfection

Two Silencer® validated siRNAs against ErbB2 (Ambion, Austin, TX, USA) were used to target mRNA at different exons. CCA cells were transiently transfected with siRNA using Effectene (Invitrogen) following the manufacturer's protocol. In brief, 3.25 μg of siErbB2 was mixed with Effectene and Enchancer (32.5 and 26.0 μL), incubated for 5 min, and then added to HAM's F-12 medium that contained 10% FBS. The mixture was added to 80% confluent CCA cells in 60-mm dishes that contained 10% FBS medium. After 6 h of incubation, medium was removed, cells were washed with PBS and replenished with fresh medium. Cells transfected with Silencer® Cy™-3 labeled non-targeting siRNA (Ambion) were used as a negative control. Protein expression, cell invasion and motility were determined at 72 h post-transfection and cell proliferation was analyzed during 24-96 h post-transfection.

In vitro invasion and motility assay

Cell invasiveness was determined using a Transwell chamber (6.5-mm diameter polyvinylpyrrolidone-free polycarbonate filter of 8-μm pore size) (Corning, NY, USA) precoated with 30 μg Matrigel (BD Biosciences, San Jose, CA, USA). A 200-μL aliquot of cells (10^5) transfected with siRNA or treated with various concentrations of AG825 in 0.2% FBS medium was added to the upper compartment of the Transwell, and 10% FBS medium was added to the lower chamber. After 6 h of incubation at 37℃ in a humidified CO_2 incubator, non-invaded cells in the upper compartment were removed with a cotton swab, and the invaded cells were fixed and stained with 0.5% crystal violet in 25% methanol for 30 min, followed by washing twice with tap water. Finally, the invaded cells were counted under a microscope with a 10 × objective in five random fields. Cell motility assay was performed as described for the invasion assay but using a Matrigel-free system.

Cell viability assay

Cells (3000/well) transfected with siRNA or resuspended in various concentrations of AG825 were plated onto 96-well plates and incubated for 72 h. Cell viability was determined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay as follows. Fifty micrograms of MTT were added to each well and the cells were incubated for a further 4 h. The supernatant was removed and insoluble formazan dye produced from MTT by living cells was solubilized by 200 μL DMSO. Percentage cell viability was quantified by measuring absorbance at 540 nm. Cell survival during the invasion assay was determined in the same way, except that 5000 cells/well were incubated for 6 h prior to addition of MTT.

Statistical analysis

Data are presented as the mean ± SE from three independent experiments conducted in triplicate. Comparison of data between groups was analyzed by one-way analysis of variance, followed by Newman-Keuls multiple comparison test (GraphPad Software, La Jolla, CA, USA).

RESULTS

ErbB2 mRNA expression level in human CCA cell lines and inhibition of its phosphorylation by AG825

The role of ErbB2 in CCA was investigated in three cell lines that were established from tumor tissues of Thai CCA patients, namely, HuCCA-1, KKU-100 and KKU-M213. Steady-state level of ErbB2 mRNA was determined by quantitative reverse-transcriptase-PCR, normalized to β-actin mRNA. KKU-M213 cell line expressed the highest level of ErbB2 mRNA, with that of HuCCA-1 and KKU-100 being comparable at 60% (Figure 1A).

Like other tyrosine kinase receptors, ErbB2 is activated by phosphorylation. Total and phosphorylated ErbB2 levels in the three CCA cell lines as analyzed by Western blotting showed correspondence with levels of ErbB2 mRNA, but in this case, the level of phosphorylated ErbB2 in KKU-100 cells was significantly lower than that in HuCCA-1 (Figure 1B). Inhibition of ErbB2 activity by treating for 6 h with its specific kinase inhibitor, AG825 (30 μmol/L), resulted in marked reduction ErbB2 phosphorylation at Y1248 in all three cell lines, without any significant effect on total ErbB2 levels (Figure 1B).

Invasive and proliferative abilities of CCA cell lines

The abilities of the three CCA cell lines to migrate and invade were determined by Transwell *in vitro* assays. Among the three cell lines, KKU-M213 showed the highest invasive and motility abilities, which were related to its level of ErbB2 expression (Figure 2A). However, KKU-100, which contained the lowest phospho-ErbB2 level, still had a somewhat high invasive ability (about four fold higher than HuCCA-1, but still lower than KKU-M213). This suggested that other pathways might be involved in enhancing the invasive ability of KKU-100. However, the proliferative rates of the three CCA cell lines as assessed by MTT assay were comparable (Figure 2B), which suggested that ErbB2 is not the key player in regulating proliferation of these cell lines.

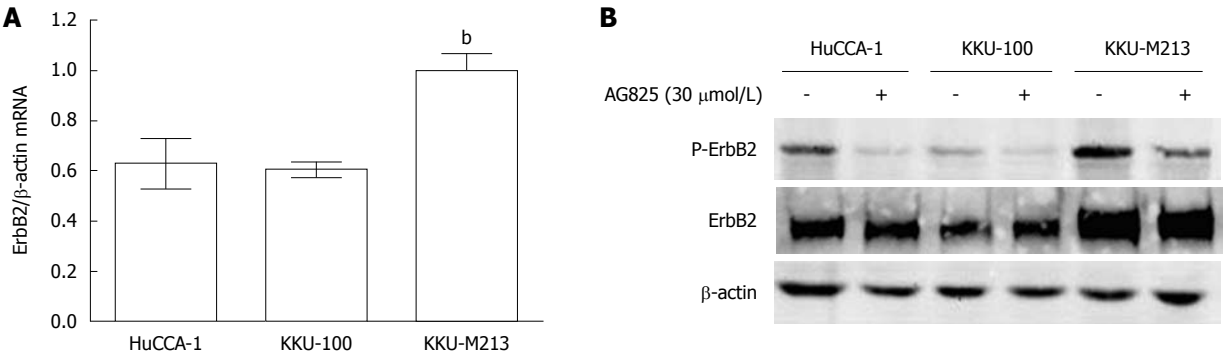

Figure 1 Levels of ErbB2 expression in three cholangiocarcinoma cell lines and inhibition of ErbB2 phosphorylation by AG825. A: Cells cultured in 10% fetal bovine serum (FBS)-containing medium were lysed and the lysates were analyzed for ErbB2 mRNA by real-time reverse-transcriptase polymerase chain reaction. Data are presented as mean ± SE of ErbB2 mRNA level normalized with β-actin mRNA obtained from three independent experiments; B: Cells were incubated without and with 30 μmol/L AG825 in 10% FBS medium for 6 h, then lysed and analyzed for ErbB2, phospho-ErbB2 (Y1248) and β-actin by Western blotting. The results shown are representative of three separate experiments. $^{b}P < 0.01$ *vs* HuCCA-1 and KKU-100.

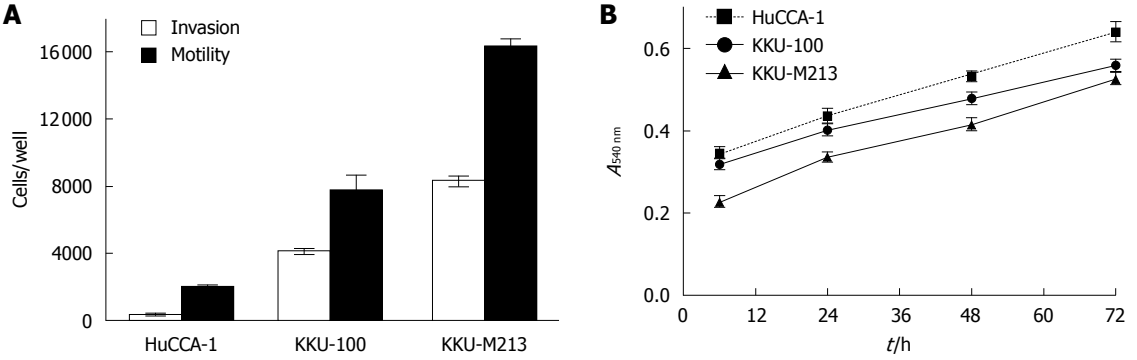

Figure 2 Invasion motility and proliferation of three cholangiocarcinoma cell lines. A: Cells resuspended in 0.2% fetal bovine serum (FBS) medium were plated in the upper compartment of a Transwell chamber coated with and without Matrigel, for invasion and motility assays. The lower compartment was filled with 10% FBS medium. After 6 h incubation, numbers of invading/motile cells were counted; B: Cells were plated on 96-well plates in 10% FBS medium. After incubation for 12-72 h, cell survival was determined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay. Data are presented as mean ± SE of the percentage relative to controls obtained from three separate experiments.

Effects of ErbB2 kinase inhibitor on CCA cell invasion and proliferation

As ErbB2 has been detected in CCA and other related cancers, and its expression level has been shown to correlate with highly proliferating diseases of the bile duct and with the degree of CCA local invasion and metastasis[11,23], the role of ErbB2 on invasion and motility of the CCA cell lines was investigated by examining the effects of AG825 on these properties using a Transwell assay. Treatment of AG825 (10-100 μmol/L) for 6 h suppressed cell invasion and motility (Figure 3A-C) in all three CCA cell lines with different IC_{50} values, with KKU-M213 being the most sensitive and KKU-100 the least. During the assay period, the drug marginally affected CCA cell survival (Figure 3A-C), which indicated that inhibition of invasion and motility were not due to drug cytotoxicity. However, incubation with AG825 for 72 h resulted in inhibition of cell proliferation, with KKU-M213 showing the most sensitivity and KKU-100 the least (Figure 3D).

Effects of suppression of ErbB2 expression on CCA cell invasion, motility and proliferation

As ErbB2 kinase inhibitor experiments indicated the role of ErbB2 on malignant phenotypes (invasion, motility and proliferation) of CCA cell lines, we confirmed the specificity of this phenomenon using siRNA targeting of ErbB2 mRNA to suppress *ErbB2* gene expression. In KKU-M213, the CCA cell line that expressed the highest ErbB2 level among the three cell lines, ErbB2 level was reduced in a time-dependent manner (up to 72 h), and was partially restored at 96 h post-transfection (Figure 4A). After 72 h of siRNA transfection, ErbB2 level in all three CCA cell lines was reduced by > 70% (Figure 4B). During this post-transfection period, there was attenuation of invasion and motility of KKU-M213 and HuCCA-1 cells, but not of KKU-100 cells (Figure 5A and B). Although proliferation of KKU-M213 cells was suppressed, that of HuCCA-1 and KKU-100 cells was marginally affected (Figure 5C).

These results on suppression of *ErbB2* gene expression, together with those conducted on inhibition of ErbB2 kinase activity, indicated that a threshold level of ErbB2 is necessary to induce properties associated with malignancy (invasion, motility and proliferation) in CCA cells (viz. KKU-M213).

Involvement of ErbB2 in activation of downstream effectors, AKT, p70S6K and ERK1/2

ERK1/2 and PI3K/AKT are the two major signaling

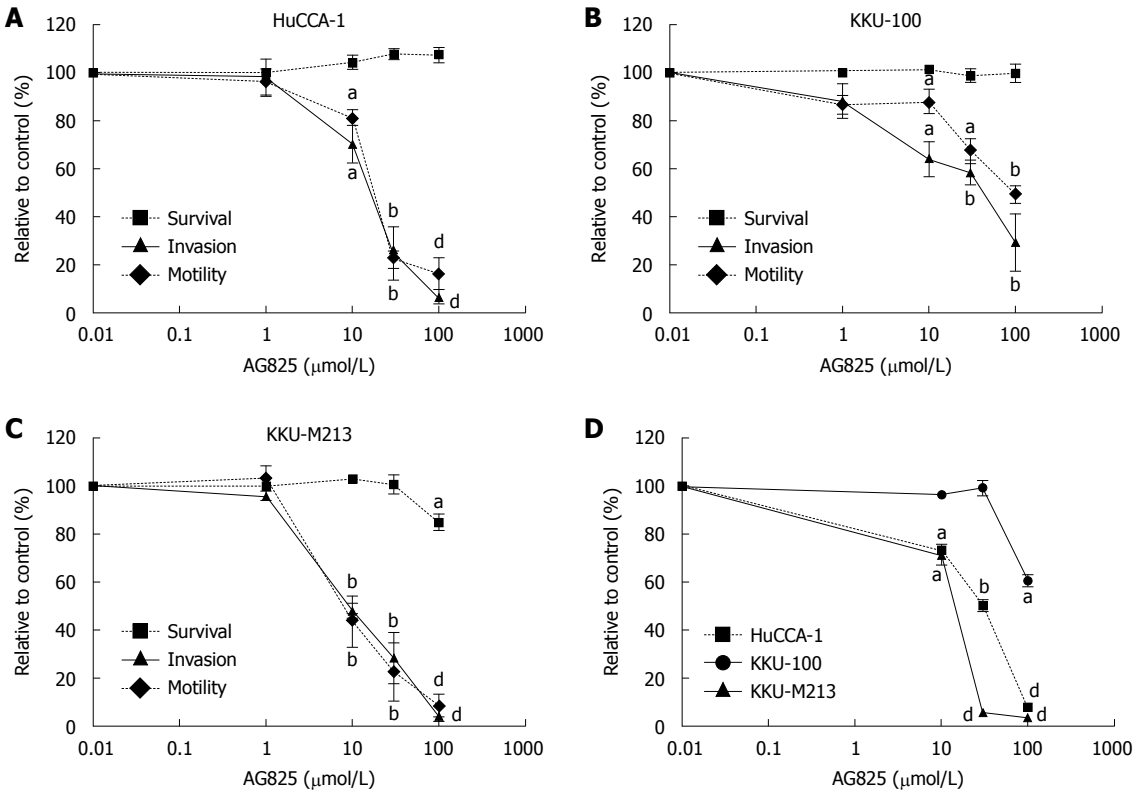

Figure 3 Effects of AG825 on cholangiocarcinoma cell invasion, motility and proliferation. A-C: Cells resuspended in medium that contained 0.2% fetal bovine serum (FBS) and indicated concentrations of AG825 were plated in the upper compartment of a Transwell chamber coated with and without Matrigel, for invasion and motility assays. After 6 h incubation, numbers of invading/motile cells were counted. Cells treated with the same vehicle were used as controls. Cell survival after 6 h of AG825 treatment was determined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay; D: Cells were treated with various concentrations of AG825 in 10% FBS medium for 72 h, and cell survival was determined using the MTT assay. Data are presented as mean ± SE of the percentage relative to the controls obtained from three separate experiments, each done in duplicate. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{d}P < 0.001$ *vs* control.

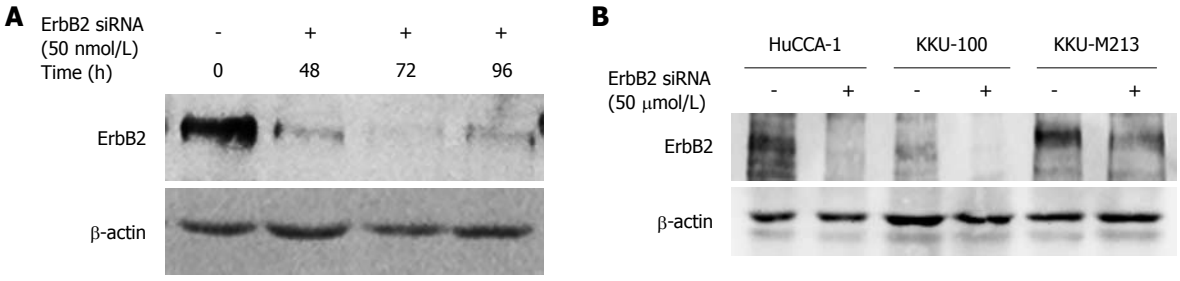

Figure 4 Inhibition of ErbB2 expression by siRNA against ErbB2. A: KKU-M213 cells were transfected with siErbB2 and the levels of ErbB2 at 0-96 h after transfection were determined by Western blotting; B: After 72 h of siRNA transfection, ErbB2 expression in HuCCA-1, KKU-100, and KKU-M213 cells was determined. Scramble siRNA (siNeg) was used as a negative control. The results shown are representatives of two (A) and three (B) separate experiments.

pathways that regulate cell proliferation, motility and invasion in response to a variety of growth factors/receptor tyrosine kinases[24]. To investigate the pathways by which ErbB2 promoted invasion and proliferation of CCA cells, we examined the effects of ErbB2 inhibition (by kinase inhibitor or siRNA) on effectors activated by ErbB2 in these two main signaling pathways. Suppression of *ErbB2* gene expression by siRNA transfection (72 h) reduced phospho-AKT level in all three CCA cell lines, but without affecting total AKT level (Figure 6A). Phosphorylation of its downstream effector, p70S6K, was similarly affected in KKU-M213 and HuCCA-1 cells, but not in KKU-100 cells (Figure 6A). On the other hand, ERK1/2 phosphorylation was marginally, if at all, affected in all three CCA cell lines (Figure 6A). Similarly, treatment of KKU-M213 cells with AG825 (30 μmol/L, 6 h) suppressed AKT and p70S6K phosphorylation but did not affect phospho-ERK1/2 level (Figure 6B). Thus, the PI3K/AKT/p70S6K and not ERK1/2 pathway is responsive to ErbB2 activity related to CCA cell invasion, motility and proliferation.

DISCUSSION

ErbB2 is overexpressed in 20%-30% of epithelial bile duct cancers[13]. Its overexpression is associated with lymph node metastasis in intrahepatic CCA[23]. Unlike

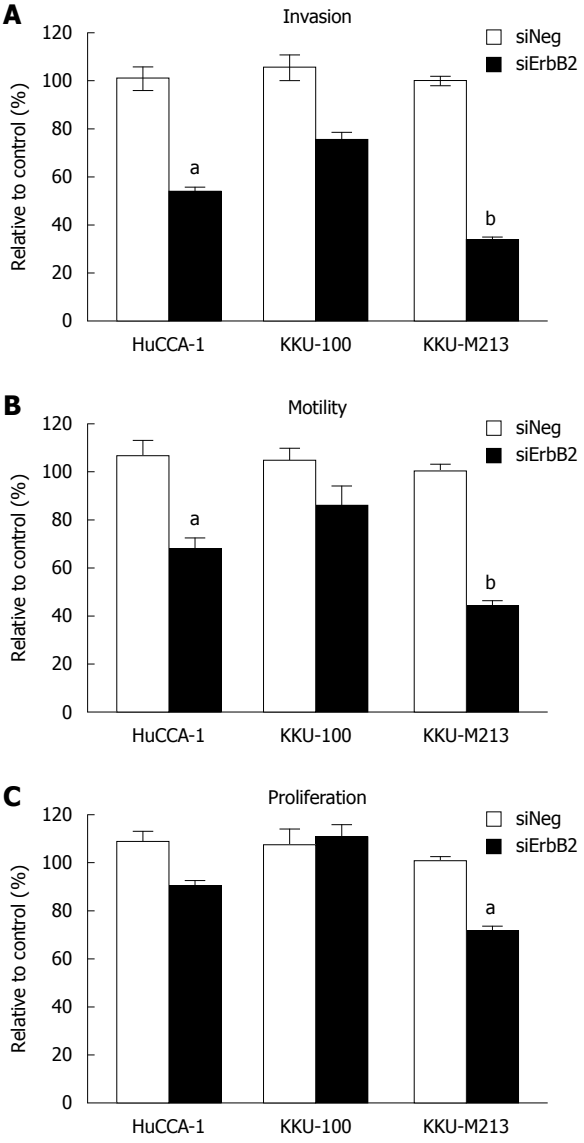

Figure 5 Effects of ErbB2 knockdown on cell invasion motility and proliferation of the three cholangiocarcinoma cell lines. Cells transfected with siRNA (negative control and ErbB2 targeted siRNA) for 72 h were analyzed for *in vitro* invasion (A) and motility (B) by using a Transwell chamber coated with and without Matrigel. After 6 h of incubation, numbers of invading/motile cells were counted. Cell proliferation (C) was analyzed by determining the number of viable cells during 24-96 h post-transfection by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay. Data are expressed as mean ± SE of the percentage relative to the controls obtained from three independent experiments. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* controls.

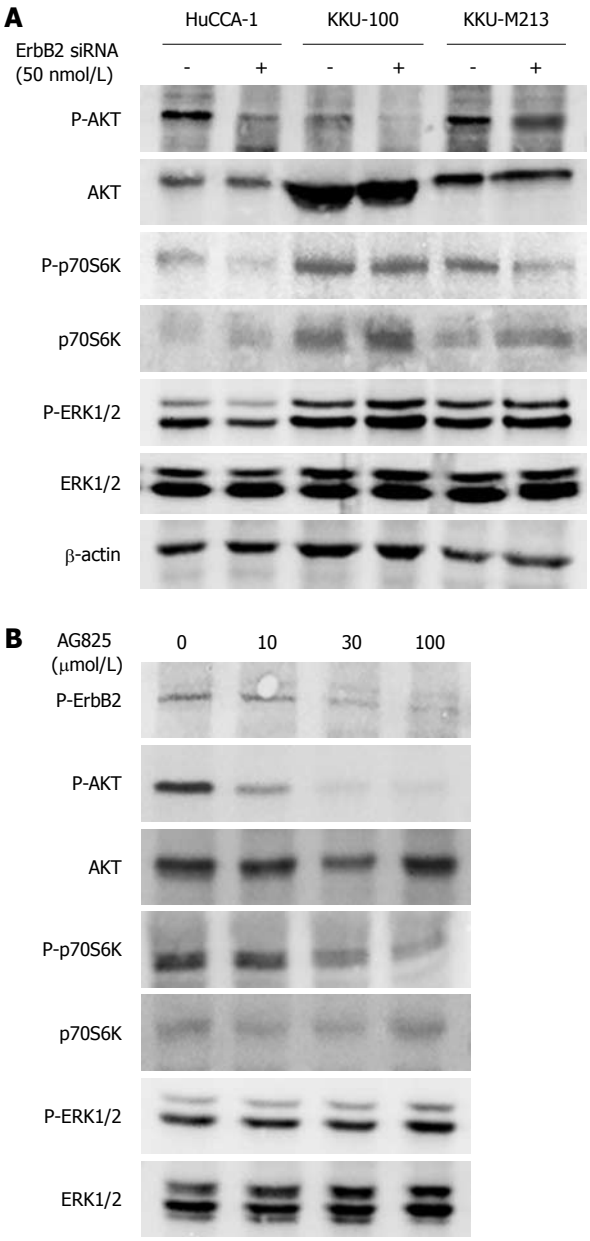

Figure 6 Effects of ErbB2 inhibition (using siRNA and specific kinase inhibitor) on ERK1/2, AKT, and p70S6K phosphorylation in the cholangiocarcinoma cell lines. A: Cholangiocarcinoma cell lines were transfected with siErbB2 and siNeg, as a control, for 72 h and the collected cell lysates were analyzed by Western blotting; B: KKU-M213 cells were treated without and with AG825 in medium that contained 10% fetal bovine serum for 6 h, then lysed and analyzed by Western blotting. The results shown are representatives of three separate experiments.

other ErbBs, ErbB2 is not expressed in normal adult liver (both hepatocytes and cholangiocytes) or in fetal liver[11,25] which makes it an interesting candidate for molecular targeting therapy for liver and bile duct cancers.

The mechanism by which ErbB2 exerts tumorigenicity in CCA is not completely understood. Here, the role of ErbB2 involved in controlling critical characteristics of CCA, namely, invasion, motility and proliferation, was investigated in three human CCA cell lines that expressed different levels of ErbB2, as shown by measurements of mRNA and phosphorylated (P-Y1248) ErbB2 levels. Data showed that ErbB2 was more important for these properties in the highest ErbB2-expressing cell line (KKU-M213), through activation of the AKT/p70S6K pathway.

Upregulation of ErbB2 is implicated in cancer aggressiveness. Studies in transgenic mice have revealed that animals bearing either an activated form of Neu (ErbB2) or overexpressing wild-type Neu frequently develop mammary tumors and lung metastases[26,27]. ErbB2 overexpression plays an important role in cell proliferation and invasion of many cancers, especially those of breast, ovary, stomach and bladder[28,29]. In breast cancer, application of antisense RNA or siRNA against ErbB2 inhibits growth

of high-ErbB2-expressing cells, but has only a little effect on lower-ErbB2-expressing cells[30,31]. In the present study, disruption of ErbB2, by both inhibition of ErbB2 kinase activity using AG825 and knock-down of ErbB2 expression using siRNA, suppressed the neoplastic phenotype of the high-ErbB2-expressing CCA cell line, KKU-M213, to a greater extent than that of the low-ErbB2-expressing cell line, KKU-100. This indicated that the neoplastic phenotype of the high-ErbB2-expressing cell line, KKU-M213, was highly dependent on ErbB2 compared to the low-ErbB2-expressing cells.

There are several possible explanations for the increase in the requirement of ErbB2 in cancer malignancy. Firstly, in cancer cells that have evolved high ErbB2 expression, this pathway has become predominant in regulating cell proliferation and invasion, which results in cells with dependency on this protein. Moreover, Kaelin[32] has suggested that an increase in the requirement of a given protein for cancer cell survival is due either to intrinsic (genetic/epigenetic) or extrinsic (microenvironment) changes. In this case, accumulation of genetic/epigenetic alteration during cancer development might cause a loss of proteins with functional redundancy to ErbB2, or a gain of those with opposing functions. However, cancer cells with ErbB2 overexpression are able to overcome the selective pressures and therefore survive and propagate, thus yielding cells with high dependency on ErbB2. Therefore, the malignant behavior of such ErbB2-dependent cells responds to inhibition of ErbB2 function, whereas those with low or no ErbB2 expression depend on other pathways for their survival, and hence are refractory to such treatment. This has provided the rationale for application of ErbB2-targeted therapy in ErbB2-overexpressing cancer. In fact, trastuzumab, a monoclonal antibody that targets ErbB2, has been used successfully for the treatment of ErbB2-positive metastatic breast cancer as well as for adjuvant therapy of early breast cancer[33]. Although ErbB2-targeted therapy has not been studied in CCA, our data on the inactivation of ErbB2 suggest that this is a crucial oncogene for maintaining the malignant phenotype of CCA, thus becoming a potential target for future therapy.

In the CCA cells, inhibition of ErbB2 by both kinase inhibitor and siRNA suppressed phosphorylation (activation) of AKT and its downstream effector, p70S6K, but not that of ERK1/2. This might be because the regulation of ERK1/2 by other signals overrides the importance of ErbB2 for its activation, or because signaling pathways downstream of ErbB2 are diverse. This diversity depends partly on dimerization partners of ErbB2. For instance, PI3K/AKT is the most important oncogenic signal downstream of ErbB2-ErbB3 heterodimerization[34]. In this case, overexpressed ErbB2 might dimerize with ErbB3, thereby activates PI3K/AKT as a major pathway. The role of AKT in the malignant characteristics of CCA has also been previously reported. Upregulation of AKT pathway has been reported to be related to low survival rate[35]. Moreover, LY294002, a specific inhibitor of PI3K/AKT pathway, attenuates CCA cell proliferation and promotes apoptosis in 10% serum-containing medium[36], and suppresses KKU-M213 and HuCCA-1 cell invasion induced by HGF[37]. In other systems such as ovarian cancer[38,39] and chick embryo fibroblasts[40], both AKT and p70S6K have been reported to regulate cell invasion, motility and proliferation. Therefore, this implies that ErbB2 regulates invasion and proliferation *via* the PI3K/AKT/p70S6K pathway.

In summary, the results presented here demonstrate that ErbB2 is particularly important for malignant properties (invasion, motility and proliferation) of human high-ErbB2-expressing CCA cells. ErbB2 acts through activation of the AKT/p70S6K pathway. These findings lend support for the therapeutic targeting of ErbB2 and/or its effector molecules in CCA with ErbB2 overexpression.

ACKNOWLEDGMENTS

The authors thank Professor Stitaya Sirisinha and Dr. Banchob Sripa for providing HuCCA-1 and KKU-100 and KKU-M213 cell lines respectively, and Prof. Prapon Wilairat for critical reading of the manuscript.

COMMENTS

Background

Cholangiocarcinoma (CCA), a malignancy of the biliary tract, is an aggressive and currently incurable cancer. The incidence is high in Thailand, China and Japan. Disease progression, especially metastasis, is correlated with ErbB2 overexpression.

Research frontiers

ErbB2 promotes many oncogenic properties, including cell growth, survival, adhesion, motility, invasion, and metastasis. Although many reports have shown the involvement of ErbB2 in CCA, the mechanism that underlies ErbB2-promoted CCA progression is not clearly understood.

Innovations and breakthroughs

Suppression of ErbB2 activity/expression reduced invasion, motility and proliferation in CCA cell lines. This is believed to be the first report to show that, in CCA cell lines with high ErbB2 expression, such neoplastic behavior is more sensitive to ErbB2 inhibition than that in cells with lower ErbB2 expression. Moreover, AKT and p70S6K, but not extracellular signal-regulated kinase 1/2, play important roles as ErbB2 downstream effectors in high-ErbB2-expressing CCA cells.

Applications

As ErbB2 is overexpressed in 20%-30% of CCA, our finding that the malignant phenotypes of CCA cells with high ErbB2 expression are highly dependent on ErbB2 supports the potential use of ErbB2-targeted therapy for the treatment of patients with ErbB2-overexpressing CCA.

Terminology

ErbB2/HER2, human epidermal growth factor receptor 2, is a member of the epidermal growth factor receptor family. Both AKT and p70S6K are downstream effectors of many receptor tyrosine kinases including ErbB2. Their activations induce proliferation and invasion of cancer cells, which leads to metastasis. This study shows that aberrant ErbB2 expression is involved in CCA cell proliferation and invasion *via* AKT/p70S6K.

Peer review

This study provides evidence that high ErbB2 expression in CCA cell lines might be an indicator that blockage of this molecule could be beneficial in cancer therapy. This was a well performed and clearly presented study.

Abstract

AIM: To examine the association between macronutrient dietary patterns and alcohol consumption using the Third National Health and Nutritional Examination Survey Ⅲ.

METHODS: A total of 9877 subjects (5144 males) constituted the study cohort. Dietary interviews were conducted with all examinees by a trained dietary interviewer in a mobile examination center (MEC). Subjects reported all foods and beverages consumed except plain drinking water for the previous 24-h time period. Physical examination and history of alcohol consumption were obtained. Pearson correlation coefficients were used to evaluate the association of the levels of alcohol consumption and the percentage of energy derived from macronutrients. Univariate and multivariate regression analyses were performed accounting for the study sampling weight to further explore the relationships between alcohol consumption and calories derived from each macronutrient.

RESULTS: Subjects who drank were younger than non-drinker controls in both genders ($P < 0.01$). Alcohol intake was inversely associated with body mass index and body weight in women. Of all macronutrients, carbohydrate intake was the first to decrease with increasing alcohol consumption. In the multivariate analyses, the level of alcohol consumption was found to be an independent predictor associated with lower intake of other macronutrients.

CONCLUSION: Our results show that there is an alteration in the daily dietary pattern with increasing alcohol consumption and that energy derived from alcoholic beverages substitutes that from other macronutrients such as carbohydrate, protein, and fat.

Key words: Alcohol; Macronutrients; National Health and Nutritional Examination Survey Ⅲ

INTRODUCTION

Aside from fat, ethanol is the macronutrient with the highest energy density. Though alcohol can serve as the energy source, how the body processes and utilizes the en-

ergy from alcohol is very complex. Because of additional energy supplementation from alcohol, we might anticipate many drinkers to be obese. In fact, data have shown that drinkers are no more obese than non-drinkers, despite higher caloric intake[1,2]. Moreover, weight loss and malnutrition are common clinical presentations among drinkers. Alcohol intake may be associated with altered patterns of food intake resulting in the replacement of alcohol for other nutrients[1]. We hypothesized that energy derived from alcoholic beverages might substitute energy from other macronutrients such as carbohydrate, protein, and fat. In this study, we examined an association between the macronutrient dietary patterns and alcohol consumption using the Third National Health and Nutritional Examination Survey (NHANES Ⅲ).

MATERIALS AND METHODS

Study population

NHANES Ⅲ was conducted in the United States from 1988 through 1994 by the National Center for Health Statistics of the Centers for Disease Control and Prevention. The NHANES Ⅲ survey used complex, multi-stage, stratified, clustered samples of civilian, non-institutionalized populations of age 2 mo and older to collect information about the health and diet of people residing in the United States. A detailed description of the survey and its sampling procedures is available elsewhere[3]. This study was approved by the CDC Institutional Review Board and all participants provided written informed consent.

During the survey period, 18162 subjects underwent physical examination and laboratory assessment at a mobile examination center (MEC). Exclusion criteria for this study included minors (age < 20 years old), breast feeding or pregnant women, and those with missing values of specific variables (hepatitis B and C serologies, body mass index, aspartate aminotransferase (AST), alanine aminotransferase (ALT), serum creatinine, and drinking history). Additionally, subjects with history of diabetes, congestive heart failure/heart disease, renal insufficiency were also excluded. History of diabetes was defined by self-report and/or taking diabetes medications and/or the subjects having been told by his/her physicians that he/she has diabetes or sugar diabetes. Subjects with history of congestive heart failure/heart disease were defined by self-report of prior myocardial infarction and/or they had been told by their physicians that they have congestive heart failure. For study purposes, we defined subjects with renal insufficiency as those with creatinine ⩾ 2.5 mg/dL. Subjects with diabetes, congestive heart failure and renal insufficiency were excluded from this study because of the possibilities of dietary restrictions due to underlying diseases. Thus, our analytic population included 5144 men and 4733 women.

NHANES Ⅲ dietary data

Dietary interviews were conducted with all examinees by a trained dietary interviewer in the MEC. Subjects reported all foods and beverages consumed except plain drinking water for the previous 24-h time period (midnight to midnight). An automated, microcomputer-based dietary interview and coding system known as the Dietary Data Collection (DDC) System was used to collect all dietary recall data. The detailed method for data collection is described elsewhere[3].

Estimation of alcohol consumption

The amount of alcohol consumed was determined based on the responses to two survey queries that questioned the number of days of drinking over the past 12 mo and the number of drinks per day on a given drinking day. To avoid any arbitrariness in the choice of a cutoff point, we further stratified the extent of alcohol consumption in subjects who reported a history of alcohol use into four groups using quartiles.

Estimation of physical activity

Physical activity assessment was part of the comprehensive interview in NHANES Ⅲ. In brief, subjects were asked to identify specified exercises in which they participated during their free time (jogging or running; riding a bicycle or exercise bicycle; swimming; aerobic dancing; other dancing; calisthenics or floor exercises; gardening or yard work; and weight lifting). They were requested to specify the number of times they participated in an identified activity during the past month. Responses were standardized as "times per week" using the conversion factors 4.3 wk/mo and 30.4 d/mo, then rounded to the nearest whole number. The frequency of performance of other reported exercises, sports or physically active hobbies was also recorded. The physical activity was specified as the sum of intensity rating multiplied by times (of each activity) per month[4].

Laboratory measurements

All venous blood samples were immediately centrifuged and shipped weekly at -20℃ to a central laboratory. The laboratory procedures followed in the NHANES Ⅲ are described in detail elsewhere[3].

Statistical analysis

Descriptive statistics such as means, SD, ranges, and percentages were used to characterize the study patients. Comparisons among groups were made using Analysis of Variance for the continuous and χ^2 test for the categorical variables. Pearson correlation coefficients were used to evaluate the association of the levels of alcohol consumption and the percentage of energy derived from macronutrients. Multivariate regression analyses were performed accounting for the study sampling weight. All statistical analyses and database management were performed using SAS-callable SUDANN software accounting for stratification, sample weight, and clustering. This analysis method also takes into account the different sample weights and the effects of the complex sample design on variance estimation.

Table 1 Clinical characteristics and dietary patterns in male cohorts (n = 5144)

[1]Adjusted for age, body weight, physical activity, and smoking status.

RESULTS

Relationship between dietary pattern and alcohol consumption in males

Among male participants (n = 5144), 69% reported no history of alcohol use (Table 1).

There were no differences in waist-to-hip ratio among groups. In this study cohort, only subjects who drank < 16 g of alcohol/d weighed less than non-drinker controls. The percentage of subjects who smoked increased in accordance with the level of alcohol consumption. As expected, markers of hepatic inflammation, AST and ALT, were increased with the level of alcohol consumption. The total energy consumption per day increased with the level of alcohol consumption. The increment in such energy was mainly due to the calories provided by alcohol. In the univariate analysis (Table 1), we found that the percentage of energy derived from carbohydrate, protein, and fat decreased with increasing alcohol consumption. Carbohydrate intake started to decrease at a daily consumption of ≤ 35 g/d. When the daily levels of alcohol consumption continued to increase (> 35 g/d), subjects consumed less protein and fat. In those who drank alcohol at a level of > 64 g/d, the energy intake which was derived from protein and fat was reduced by 4% and 7%, respectively. In the multivariate linear regression analyses adjusting for covariates (such as age, body weight, smoking status and physical activity), the level of alcohol consumption was found to be an independent predictor associated with lower percent calories derived from macronutrients. The adjusted calories from macronutrients stratified by alcohol consumption are shown in Table 2. In the correlation analyses, the amount of alcohol consumed per day was inversely associated with the percentage of calories derived from each macronutrient (Figure 1A-C).

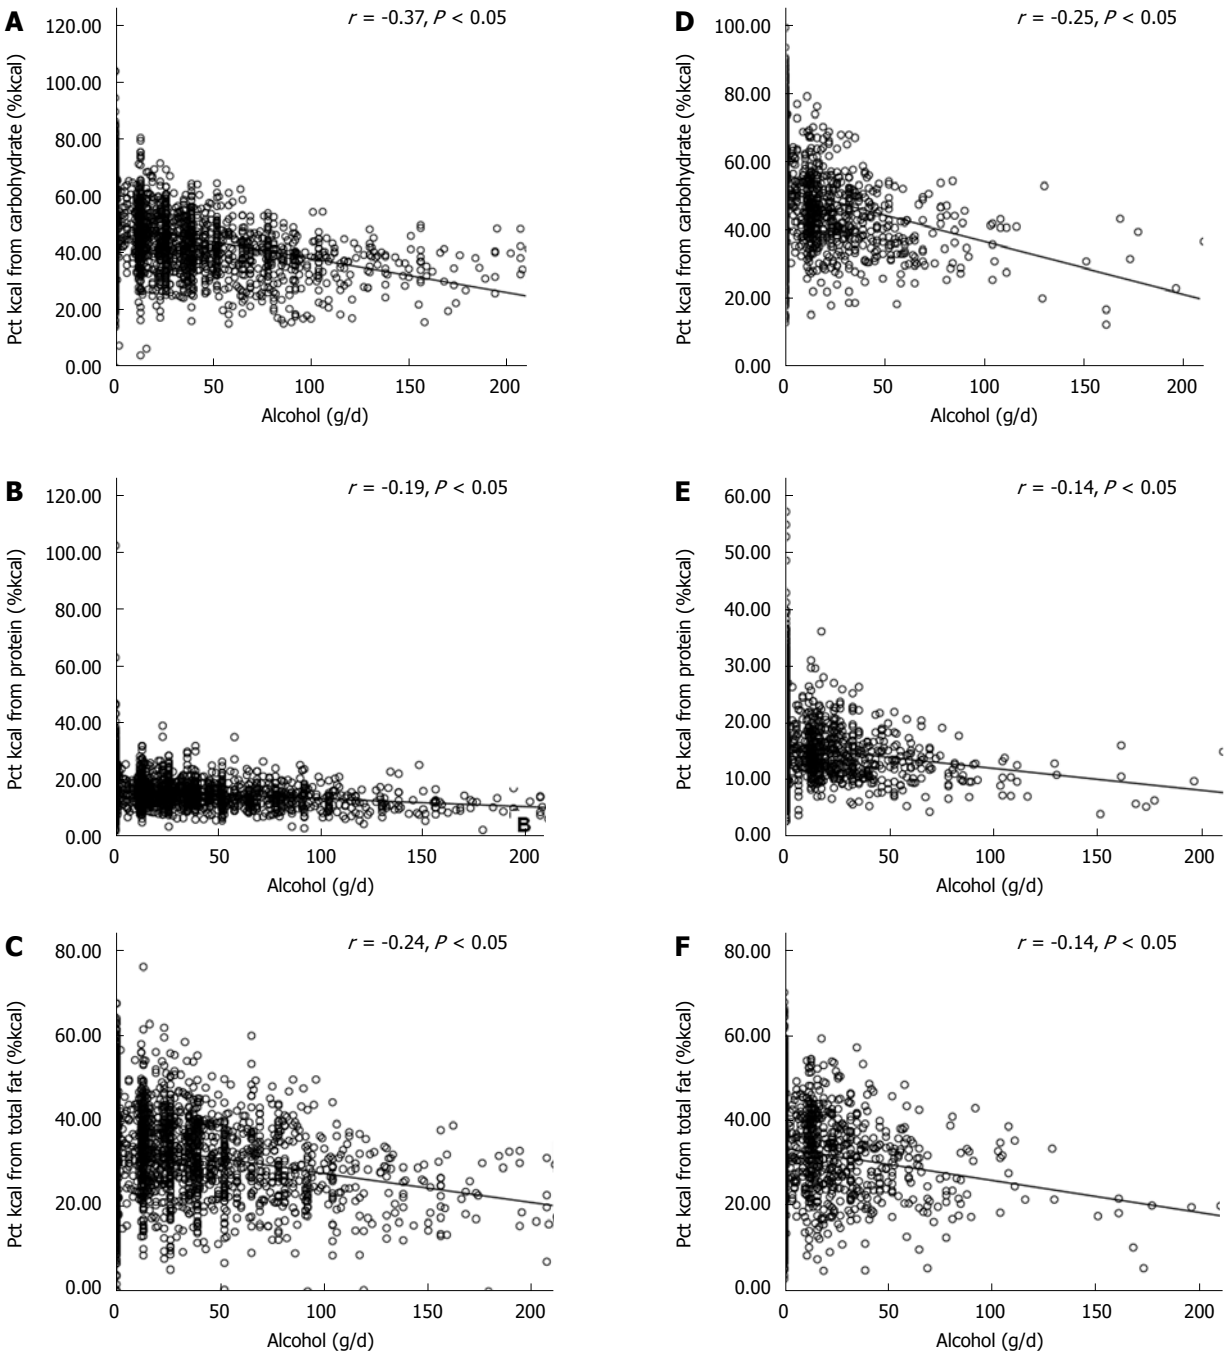

Figure 1 Relationship between the levels of alcohol consumption and the percentage of calories derived from each macronutrient in males (A-C) and females (D-F).

Relationship between dietary pattern and alcohol consumption in females

As observed with male participants, women who drank higher amounts of alcohol were younger than non-drinker controls ($P < 0.05$). Alcohol intake was inversely associated with body mass index and body weight in women. Again, no differences in waist-to-hip ratio were observed among groups (Table 3). As with male subjects, we found a higher prevalence of cigarette smokers in those who drank higher amounts of alcohol. Because of the energy provided from alcohol, the total energy consumed per day was higher in those who drank any amount of alcohol when compared to controls. We again found that female drinkers started to consume less carbohydrate even when they drank < 13 g/d. The calories derived from protein and fat were reduced once the subjects drank > 21 g of alcohol/d. In the multivariate linear regression analyses, the level of alcohol consumption was found to be an independent predictor associated with lower percent calories derived from macronutrients (Table 2). In the correlation analyses, the amount of alcohol consumption per day was inversely associated with the percentage of calories derived from each macronutrient, as observed in male subjects (Figure 1D-F).

DISCUSSION

In this large population-based study, we found that (1) alcohol consumption was inversely related to body mass index and body weight, primarily in women; (2) energy derived from alcohol replaced that from macronutrients in both genders; and (3) carbohydrate was the foremost macronutrient in which the energy was replaced by that from alcohol. With increasing alcohol consumption, we found a significant reverse relationship between alcohol and all macronutrient intakes.

Although alcohol is an energy source, how the body processes and uses the energy from alcohol is more complex than can be explained by a simple calorie conversion value. Energy derived from alcohol has been consider as "empty calories" because alcohol contains no beneficial nutrients. Additionally, it can also replace the energy derived from other macronutrients. As shown in this study, particularly in female subjects, alcohol provides an average of 23% of the calories when intake is > 38 g/d (Table 2). Despite higher caloric intake from alcohol, females who drank at this level were less obese than non-drinkers. It is postulated that chronic drinking triggers the microsomal ethanol-oxidizing system (MEOS)[1,5,6], an inefficient system of alcohol metabolism. Much of the energy from MEOS-driven alcohol metabolism is lost as heat rather than used to supply the body with energy. The association between gender, body weight, and alcohol intake is debatable. Though our results are consistent with those reported by Colditz *et al*[1], there have been previous reports that men who drank weighed more than non-drinkers[7,8]. The inconsistency in these results is likely due to the study design and data collection.

We observed that the major difference in nutrient intake for both genders was a significantly lower intake of carbohydrates by drinkers (r = -0.37 and -0.25, in male and female subjects, respectively). Our findings are similar to those reported by Thompson *et al*[9], where they observed a decreased absolute intake of carbohydrate, protein, and fat with increasing alcohol intake.

Several limitations in using NHANES datasets deserve discussion. First, the cross-sectional design in NHANES does not enable us to truly address potential temporal associations between significant alcohol consumption and the variables of interest. Second, the accuracy of the alcohol consumption data, as with other retrospective study designs, is unknown. Since the extent of alcohol consumption will be derived from self-report questionnaires, it is vulnerable to a recall bias in each participant.

In summary, our results showed that there is an alteration in the daily dietary pattern with increasing alcohol consumption and that energy derived from alcoholic beverages substitutes that from other macronutrients such as carbohydrate, protein, and fat. Female drinkers were less obese than non-drinkers, suggesting that alcohol calories may be less utilized in female subjects. However, further research is needed to explore the role of gender and body weight in alcoholics.

COMMENTS

Background

Aside from fat, ethanol is the macronutrient with the highest energy density. Though alcohol can serve as the energy source, how the body processes and utilizes the energy from alcohol is very complex. Because of additional energy supplementation from alcohol, the authors might anticipate many drinkers to be obese. In fact, data have shown that drinkers are no more obese than non-drinkers, despite higher caloric intake. Moreover, weight loss and malnutrition are common clinical presentations among drinkers. Alcohol intake may be associated with altered patterns of food intake resulting in the replacement of alcohol for other nutrients. In this study, the authors examined the association between the macronutrient dietary patterns and alcohol consumption using the Third National Health and Nutritional Examination Survey (NHANES Ⅲ).

Research frontiers

In this large population-based study, the authors found alterations in the daily dietary pattern with increasing alcohol consumption and that energy derived from alcoholic beverages substitutes that from other macronutrients such as carbohydrate, protein, and fat.

Innovations and breakthroughs

To the best of the authors' knowledge, this is the first population-based study to address the relationship between alcohol consumption and dietary pattern. The authors found that alcohol consumption was inversely related to body mass index and body weight, primarily in women. With increasing alcohol consumption, they found a significant reverse relationship between alcohol and all macronutrient intakes.

Applications

Energy derived from alcohol has been considered as "empty calories" because alcohol contains no beneficial nutrients. In this study, the authors also found that energy derived from alcohol consumption can replace that from other macronutrients.

Peer review

Dr. Liangpunsakul describes in his manuscript the relationship between alcohol consumption and the macronutrient dietary patterns using data from the NHANES 1988-1994. He found that increasing alcohol intake is associated with an altered daily dietary pattern and that the energy of alcoholic beverages substitutes that from carbohydrates, protein and fat.

Abstract

AIM: To investigate and characterise patients with chronic hepatitis C virus (HCV) infection presenting with hepatocellular carcinoma (HCC) in the absence of cirrhosis.

METHODS: Patients with chronic hepatitis C infection without cirrhosis presenting with HCC over a 2-year period were identified. The clinical case notes, blood test results and histological specimens were reviewed to identify whether additional risk factors for the development of HCC were present.

RESULTS: Six patients (five male, one female) with chronic hepatitis C infection without cirrhosis presented to a single centre with HCC over a 2-year period. Five patients were treated by surgical resection and one patient underwent liver transplantation. Evaluation of generous histological specimens confirmed the presence of HCC and the absence of cirrhosis in all cases. The degree of fibrosis of the background liver was staged as mild (n = 1), moderate (n = 4) or bridging fibrosis (n = 1). Review of the clinical case notes revealed that all cases had an additional risk factor for the development of HCC (four had evidence of past hepatitis B virus infection; two had a history of excessive alcohol consumption; a further patient had prolonged exposure to immune suppression).

CONCLUSION: HCC does occur in patients with non-cirrhotic HCV infection who have other risk factors for hepatocarcinogenesis.

Key words: Hepatitis C virus; Hepatocellular carcinoma; Non-cirrhotic; Screening

Hepatocellular carcinoma in patients with chronic hepatitis C virus infection without cirrhosis. *World J Gastroenterol* 2010; 16(32): 4061-4065 Available from: URL: http://www.wjgnet.com/1007-9327/full/v16/i32/4061.htm DOI: http://dx.doi.org/10.3748/wjg.v16.i32.4061

INTRODUCTION

Hepatocellular carcinoma (HCC) is a well-recognised complication of cirrhosis regardless of aetiology; the risk of malignancy differs according to the underlying cause of liver damage. As a consequence, patients with cirrhosis undergo routine interval screening in most liver centres using a combination of serum α-foetoprotein (AFP) and liver ultrasound, although solid evidence to support this

approach post-dates adoption of the strategy[1,2]. Surveillance is restricted to those at higher risk in some centres. Patients with cirrhosis secondary to chronic infection with hepatitis B virus (HBV) or hepatitis C virus (HCV) are at particular risk of HCC[3]. Furthermore, there are numerous reports indicating that chronic infection with HBV is associated with HCC in the absence of cirrhosis.

In contrast, HCC in patients with chronic HCV infection without cirrhosis appears to be very rare[4-7]. We describe six such cases that presented to one tertiary referral centre in the past 2 years (Table 1).

MATERIALS AND METHODS

Patients with chronic HCV infection without cirrhosis presenting with HCC over a 2-year period were identified. The clinical cases were reviewed to identify any additional risk factors for hepatocarcinogenesis. Details obtained included ethnic origin, alcohol consumption, past or present infection with HBV, medical co-morbidity, medication history and family history of liver disease or HCC. Histological specimens were reviewed by an experienced liver pathologist to confirm the presence of HCC and to assess the degree of fibrosis of the background liver tissue. Furthermore, histological specimens were evaluated for the presence of additional hepatic pathology including the presence of iron, steatosis and α-1 antitrypsin globules.

RESULTS

Six cases with non-cirrhotic chronic HCV infection and HCC presented to one centre over a 2-year period. Table 1 summarises the clinical and histological characteristics of the cases including additional risk factors for hepatocarcinogenesis. The first case, a 53-year-old Caucasian male, was referred to the service having been found to be HCV-RNA positive (genotype 1). He had a history of previous injecting drug use and a high alcohol intake exceeding 30 U/wk. Evaluation of hepatitis B serology demonstrated that he was surface antigen (HBsAg) negative, and positive for core antibody (anti-HBc) in keeping with past infection. Screening liver ultrasound demonstrated a focal lesion. Computerised tomography (CT) confirmed a mass with arterial enhancement. Serum AFP was 239 IU/L (normal range < 10 IU/L). Histology of the resected mass revealed a 3.5-cm multi-focal HCC, with moderate to poor differentiation and vascular invasion. Histology of the background liver revealed minimal inflammation but moderate fibrosis. He is recurrence-free 24-mo post resection. HCV-RNA was undetectable at completion of 48-wk therapy with pegylated interferon-α and ribavirin.

The second case, a 57-year-old Caucasian male, presented with fever and abdominal pain. CT of the abdomen revealed a 5 cm × 3 cm, inflammatory mass in the right side of the abdomen in close proximity to bowel and in addition a 2 cm hypodense lesion within the liver. A right hemi-colectomy was performed which revealed extra-colonic fibrosis and abscess formation secondary to a caecal diverticulum. Biopsy of the liver mass demonstrated HCC; the background liver comprised moderate inflammation and mild fibrosis consistent with chronic HCV infection. He was HCV-RNA positive (genotype-3), HBsAg negative, anti-HBc positive with a history of previous injecting drug use. Liver function tests were normal. Serum AFP was 3 IU/L. After hepatic resection, histology revealed a 3.1 cm HCC with moderate differentiation, without vascular invasion; the background liver confirmed mild inflammation and mild fibrosis. He has completed therapy with pegylated interferon-α and ribavirin with sustained virological response. He is recurrence-free 22 mo following surgery.

Case three, a 67-year-old Nigerian lady with chronic HCV infection, had a 4 cm focal lesion detected on screening liver ultrasound. CT imaging confirmed the mass with arterial enhancement. Biopsy of the lesion demonstrated HCC and the background liver revealed moderate inflammation and mild fibrosis consistent with chronic HCV infection. She was HCV-RNA positive (genotype 1), HBsAg negative, anti-HBc positive. Liver function tests were unremarkable. Serum AFP was 206 IU/L. After hepatic resection, histology revealed a 4.5 cm HCC with moderate to poor differentiation and lymphovascular invasion on a background liver with moderate fibrosis. She was unable to tolerate antiviral therapy due to profound anaemia and remains HCV-RNA positive. She is recurrence-free 20 mo after resection.

The fourth case was a 46-year-old Caucasian man known to have chronic HCV (genotype 1) with a history of previous injecting drug use; he was HBsAg negative, anti-HBc positive. Liver biopsy demonstrated moderate activity and moderate fibrosis consistent with chronic HCV infection. He had failed to respond to pegylated interferon and ribavirin. Six years later investigation of a raised AFP (77 IU/L) revealed a 1.5 cm arterially enhancing lesion in the liver. Surgical resection revealed a 1.7 cm moderately - well differentiated HCC without vascular invasion on a background liver with bridging fibrosis but not cirrhosis. He is recurrence-free 16 mo after resection.

Case 5 was a 46-year-old Indian man with chronic HCV infection with a history of renal transplantation 15-year previously, treated with ciclosporin and prednisolone. Liver function tests were unremarkable. Screening ultrasound detected a 3 cm focal lesion in the liver; biopsy of the mass revealed HCC. He was HCV-RNA positive (genotype 1) without evidence of exposure to HBV. Serum AFP was 5 IU/L. Further imaging with CT, magnetic resonance imaging and angiography confirmed the mass and revealed two further smaller lesions. He was deemed to meet Mazzaferro criteria[8] and listed for liver transplantation. The explant revealed a 3 cm HCC with poor differentiation and vascular invasion and several small satellite lesions. The background liver demonstrated moderate fibrosis and moderate inflammation. He developed HCC within the grafted liver after 6 mo leading to death 8 mo following transplantation.

The final case, a 63-year-old Russian doctor, acquired HCV (genotype 1) 9 years previously following a needle stick injury from a patient. He had a long history of excess alcohol consumption (30 U/wk) but was immune

Table 1 Patient characteristics

Age (yr)	Sex	HCC	Background liver histology at time of HCC treatment	AFP (IU/L)	HCV status	HBV status	Alcohol (U/wk)
53	M	3.5 cm Moderate/poor differentiation Vascular invasion	Minimal inflammation Moderate fibrosis	239	RNA positive Genotype 1	HBsAg negative Anti-HBc positive	10-30
57	M	3.1 cm Moderate differentiation No vascular invasion	Mild inflammation Mild fibrosis	3	RNA positive Genotype 3	HBsAg negative Anti-HBc positive	0
67	F	4.5 cm Moderate/poor differentiation Lymphovascular invasion	Moderate inflammation Moderate fibrosis	206	RNA positive Genotype 1	HBsAg negative Anti-HBc positive	0
52	M	1.7 cm Moderate differentiation No vascular invasion	Moderate inflammation Bridging fibrosis	77	RNA positive Genotype 3	HBsAg negative Anti-HBc positive	20
46	M	3 cm Poorly differentiated with satellite lesions	Moderate inflammation Moderate fibrosis	5	RNA positive Genotype 1	Negative	0
62	M	6.5 cm Moderate differentiation Vascular invasion	Moderate inflammation Moderate fibrosis	10	RNA positive Genotype 1	Negative	30

HCC: Hepatocellular carcinoma; AFP: α-foetoprotein; HCV: Hepatitis C virus; HBV: Hepatitis B virus; HBsAg: Hepatitis B surface antigen.

to HBV and was anti-HBc negative. At presentation, liver biopsy revealed mild fibrosis with moderate inflammation. Nine years later he was found to have a 6.5 cm HCC. Serum AFP was 10 IU/L. He underwent surgical resection; histology revealed a moderately differentiated HCC on a background liver with moderate fibrosis. He is well 5 mo after.

DISCUSSION

Six cases with non-cirrhotic chronic HCV infection and HCC presented to one centre over a 2-year period. All were considered at low risk of HCC and none was in a surveillance programme. One had symptoms but the identification of a liver mass in the remaining five patients was fortuitous. Cirrhosis was excluded confidently in all cases by careful histological review of generous tissue specimens revealing at worst bridging fibrosis. No patient had histological features to suggest any diagnosis other than HCV related injury. All patients had a normal body mass index and none were diabetic. However, all patients had an additional risk factor for liver injury or HCC: four had evidence of past HBV infection; two had a history of excessive alcohol consumption; a further patient had prolonged exposure to immune suppression.

The incidence of HCC is increasing across the developed world[9]. Cirrhosis of any cause is an important precursor for HCC, although liver disorders including chronic HBV or HCV infection, haemochromatosis, non-alcohol-related fatty liver disease (NAFLD) and alcohol-related liver disease carry a particular risk[3]. The risk is also much higher in men and older patients[10,11]. The current increase in the prevalence of chronic liver disease secondary to chronic HCV infection and NAFLD (a consequence of the increasing prevalence of obesity and an ageing population) are the main reasons for the increasing incidence of HCC in the developed world[12-15], although improved screening and diagnosis may also play a part. The underlying mechanisms that lead to malignant transformation of HCV-infected hepatocytes, however, remain uncertain, but as most HCV-related HCC occurs on a background of severe fibrosis or cirrhosis it is thought that the mechanism of carcinogenesis is more likely to be indirect, such that the process of tissue damage, regeneration and repair are important, rather than a direct oncogenic effect of HCV infection or the inflammatory response to the virus.

It is well recognised that chronic HBV infection can lead to HCC in the absence of cirrhosis[16]. HBV is a DNA virus that can integrate into the host cell genome; integration may be mutagenic directly by causing genomic instability, loss of tumour suppressor activity or over-expression of genes involved in regulation of cell cycle proliferation. In addition, HBV encodes HBx protein, which functions as a transcriptional trans-activator of cellular genes that are involved in cell proliferation control such as c-jun, c-fos and c-myc. This may lead to dysregulation of the cell cycle and interference with cellular DNA repair and apoptosis[17].

This series raises the possibility that HCV may be oncogenic. HCV is an RNA virus, which replicates in the cytoplasm and does not integrate into host cellular DNA. However, some HCV proteins, such as HCV core and non-structural proteins NS3, NS4B and NS5A have a regulatory effect on cellular promoters and interact with a number of cellular proteins involved in carcinogenesis under certain conditions[18-21]. In addition, hepatocytes from patients with chronic HCV infection are arrested in G1 and may undergo replicative senescence, which may predispose to malignancy[22]. Direct evidence for a carcinogenic role for HCV *in vivo* is lacking.

HCC has been described very rarely in chronic HCV infection in the absence of cirrhosis[4-7], which suggests that other aetiological factors may be more important. Analyses of case series in Japan have suggested that ageing increases the risk of developing HCC in patients with HCV who do not have cirrhosis, particularly in wom-

en[10,11]. In the series presented here, however, five of six cases were men and the median age at diagnosis of HCC was 55, suggesting that alternative factors are important. None of the cases described had histological evidence of additional injury such as steatohepatitis or iron accumulation that are recognised co-factors in the development of liver injury and HCC[23,24]. However, four of six patients had serological evidence of previous exposure to HBV. It is possible that integration of HBV genes had occurred, increasing the risk of HCC as in HBV infection without cirrhosis. Long-term immune suppression in another may have increased the risk of HCC[25]. Furthermore, it has been reported that renal transplant patients might have an increased susceptibility to HCC even without viral infection purely as a result of immune suppression[26]. In the final patient there was a long history of excess alcohol use but no evidence of alcohol related liver damage on biopsy.

A third of patients with HCV have been exposed to HBV because of common risk factors[27]. In the Cambridge series 35% of 1500 patients with chronic HCV infection were anti-HBc positive/HBsAg negative while 2% were co-infected with HBV. Past HBV infection is associated with an increased risk of progressive liver injury in some series of patients with chronic HCV infection and other liver disorders[28,29] although the presence of anti-HBc was not associated with progressive fibrosis in our own series[30]. HBV genomic material has been identified in liver from patients with HCC who were HBsAg negative but HCV RNA positive[31,32] and the presence of HBV genes in this setting has been linked to HCC[33]. In a prospective observational study, serum anti-HBc was a marker of high risk for HCC among patients with HCV related cirrhosis, but was not a significant risk factor in those without cirrhosis[34]. The presence of HBV genes in HCC tissue of HBsAg negative, HCV negative patients has also been described[35]. Thus, long-term persistence of HBV genes in liver tissue may cause HCC without inflammation, necrosis or regeneration. While abnormal alanine aminotransferase (ALT) fluctuation is associated with carcinogenesis in HCV positive patients[36], the presence of integrated HBV DNA in the liver may promote carcinogenesis independently. Patients with low levels of ALT and minimal histological change may still be at risk of HCC development if they have had previous exposure to HBV.

Surveillance for HCC has been conducted for many years but a survival benefit for screening with 6-monthly ultrasound and AFP monitoring has only been demonstrated recently[1]. However, surveillance is practiced widely and recommended in high-risk groups such as those with cirrhosis due to HBV, HCV, alcohol, or haemochromatosis[2]. In addition, because of the high risk of HCC in non-cirrhotic HBV infection, current guidelines recommend screening in high-risk groups (family history of HCC, Asian males > 40 years, Asian females > 50 years and Africans > 20 years and could be extended to those with high serum HBV DNA levels). In HCV infection with cirrhosis there is a high risk of HCC development (2%-8% per year); surveillance is recommended and cost effective[37]. At the current time it is unclear whether patients with bridging fibrosis should be offered screening and it is not recommended for patients with mild or moderate disease regardless of patient age or length of time of infection.

All HCV-infected patients with cirrhosis in our centre are offered 6-monthly screening with liver ultrasound by a small group of experienced liver radiologists or ultrasonographers; serum AFP is not sought in this particular cohort because of a lack of specificity and sensitivity, as demonstrated in this series. This experience has prompted review of our policy; for example should older men with chronic HCV infection without cirrhosis but with an additional risk factor for HCC, such as anti-HBc or excess alcohol consumption, undergo ultrasound screening? The increased workload for our service would be enormous and it is probable that the number of patients identified with HCC that could be cured by intervention would be too low to justify such an approach. Further data on the incidence of HCC in HCV-infected patients without cirrhosis are required before a change in policy can be recommended as routine practice; a national register of such cases could be helpful.

COMMENTS

Background

Cirrhosis of any cause is associated with a significant risk of developing hepatocellular carcinoma (HCC). Chronic hepatitis B virus (HBV) infection in the absence of cirrhosis is also a recognised risk factor for HCC and screening is recommended in some high risk groups. HCC occurs rarely in non-cirrhotic hepatitis C virus (HCV) infection and there are no recommendations for screening in these patients.

Research frontiers

Due to the observation of an increase in HCC in non-cirrhotic HCV patients, a detailed evaluation of these patients was undertaken.

Innovations and breakthroughs

In each patient with HCC and non-cirrhotic HCV infection, an additional risk factor for hepatocarcinogenesis was identified. These included previous infection with HBV, high alcohol intake and immunosuppression.

Applications

Patients with chronic HCV without cirrhosis may be at risk of developing HCC if there are other risk factors for liver injury and carcinogenesis present. It is possible that these patients should be considered for surveillance programmes although this would result in a dramatic increase in workload for radiological departments and may not be cost effective.

Abstract

AIM: To undertake a baseline study comparing quality of life (QoL) in patients with chronic pancreatitis (CP) on Antox to those with CP, matched for disease duration, who were not on this medication.

METHODS: CP was defined according to the Zurich classification. Sixty eight consecutive patients with CP who were taking Antox (antioxidants) were compared with 69 consecutive control CP patients not on Antox. European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core questions 30 and Pancreatic Modification (28 questions) were used to assess QoL. Out of a total of 137 patients 28 in each group were matched for disease duration (within 12 mo). Median disease duration was 8 (1-22) years in the Antox group and 7 (1-23) years in the Non-Antox cohort (P = NS, Mann-Whitney U-test). Other parameters (age, gender, etiology, endocrine and exocrine insufficiency) were similar between groups.

RESULTS: Median visual analogue pain score in the Antox group was 3 (0-8) compared with 6 (0-8) in the Non-Antox group ($P < 0.01$). Perceptions of cognitive, emotional, social, physical and role function were impaired in the Non-Antox group compared to Antox patients ($P < 0.0001$, $P = 0.0007$, $P = 0.0032$ and $P < 0.005$ and $P < 0.001$, respectively). Analgesics and opiate usage was significantly lower in the Antox group ($P < 0.01$). Overall physical health and global QoL was better in the Antox group ($P < 0.0001$, 95% CI: 1.5-3).

CONCLUSION: Contemporary quality of life assessments show that after correction for disease duration and cigarette smoking, patients with CP taking antox had better scores than non-antox controls.

Key words: Chronic pancreatitis; Antioxidants; Quality of life; Assessment; Management

INTRODUCTION

Chronic pancreatitis (CP) is a chronic inflammatory con-

dition of the pancreas characterized histologically by loss of normal pancreatic parenchymal architecture with varying degrees of fibrosis and inflammatory infiltration[1]. Clinically, CP presents a spectrum of disease most often marked by chronic or recurrent abdominal pain together with varying features of pancreatic exocrine deficiency, most typically fat-related, resulting in steatorrhea, and manifestations of pancreatic endocrine deficiency, such as diabetes mellitus[1].

Although there are no national incidence registries, population-based data indicate a frequency of 8.6/100 000 per year[2] with similar incidence being recognized in the United States[3] and other Northern European countries[4,5]. The clinical course of CP can be characterized by variable background abdominal pain with episodic exacerbations. Although the later stages of the illness are marked by pancreatic exocrine and endocrine insufficiency, abdominal pain is the dominant symptom for many sufferers.

Until now there has been no specific therapy for CP. Rose *et al*[6] demonstrated that CP arose as a result of pathological exposure of the pancreatic acinar cells to short-lived oxygen free radicals - a process termed oxidative stress. The peripheral blood samples taken from patients with clinical CP have shown that antioxidants (the term given to inhibitors of the oxidative stress response), their precursors and co-factors in physiologic antioxidant pathways are depleted during the course of this illness[7]. In addition, there is elevation of peripheral blood markers of oxidative injury. Braganza *et al*[8] reasoned that exogenous supplementation with antioxidants or precursors for antioxidant pathways may augment these deficient pathways and help to quench ongoing acinar injury. From a series of exploratory studies they concluded that co-factors of the endogenous glutathione peroxidase pathway were key components for supplementation. Selenium, vitamin C (ascorbic acid) and methionine were proposed as key antioxidants[8-10]. A commercially-available formulation, Antox (Pharma Nord, Morpeth, UK) was developed comprising vitamin C, vitamin E, β-carotene, selenium and methionine.

There is anecdotal evidence from small, underpowered, randomized trials that oral antioxidant therapy reduces the frequency and severity of episodes of pain[11,12]. More recently, a well-conducted randomized trial from India demonstrated that oral antioxidant therapy was associated with a reduction in hospital admission and "pain days"[13].

In contemporary healthcare terms, perhaps the critical issue in the treatment of CP is assessment of the effect of intervention on quality of life (QoL). In this regard, formal, well-validated questionnaire-based QoL scoring systems are now available for assessment of patients with CP[14].

The European Organization for Research and Treatment of Cancer (EORTC) QoL study group has developed a modular approach to the development of QoL instruments designed for use in clinical trials[15]. A 30-item core cancer questionnaire; the EORTC Quality of Life Questionnaire (QLQ) Core questions 30 (C-30) was developed. It was initially developed and validated for use in patients with non small cell lung cancer[16]. The 30-item core questionnaire is intended to be supplemented by additional questionnaire modules to assess disease symptoms and treatment side-effects. The EORTC QLQ Pancreatic Modification (26 questions) (PAN-26) was developed and mainly used for pancreatic cancer[17]. During the development of the QLQ PAN-26, interest was expressed in the feasibility of using this assessment system in patients with CP[14].

Two questions have been added to PAN-26 to produce a questionnaire for use in CP, the QLQ PAN (CP)-28[17].

The aim of this study is to compare QoL, using an appropriately validated, disease-specific questionnaire-based approach in a cohort of patients with CP receiving oral antioxidant therapy to individuals with CP who are not receiving this medication.

MATERIALS AND METHODS

Study design

This is a prospective, single-centre clinical study comparing QoL as assessed using validated, disease-specific EORTC questionnaires[17] in a group of patients with a clinical diagnosis of CP receiving oral antioxidant therapy in the form of Antox (Pharma Nord, Morpeth, UK) to a cohort of patients with CP from the hepatobiliary and gastroenterology services of the same hospital who were not receiving oral antioxidant supplementation.

Patients and treatment algorithm

The terminology advocated by the Zurich International Workshop was used to define alcohol-related CP[18]. All patients had radiological evidence of CP on either computed tomography or magnetic resonance imaging; in addition some patients had supplementary evidence from endoscopic retrograde pancreatography or endoscopic ultrasonography. Routine monitoring of blood glucose was undertaken in the outpatient setting. Pancreatic exocrine function testing was not routinely employed in patients in this study. In general, antioxidant therapy was offered for the treatment of patients with a diagnosis of CP if there was no evidence of a pancreatic lesion potentially requiring surgical intervention, or if there was no marked pancreatic ductal dilatation amenable to endoscopic or surgical drainage. Thus, for the purposes of this study, patients were categorized into those taking Antox and those not taking this medication. Clinical characteristics of these 2 groups are shown in Table 1.

Administration of questionnaire, data registration and analysis

Patients completed the EORTC QLQ C-30 and QLQ PAN-28 questionnaires in the presence of an interviewer as part of a dedicated interview. Pain was assessed using a visual analogue score (VAS), where 0 is no pain and 10 is the maximum (scale 0-10). All interviews were undertaken by the same interviewer (NS). Interviews were conducted

CP: Chronic pancreatitis.

with patients attending the Hepatobiliary and Gastroenterology clinics in this hospital during the study period February 2007 to February 2009. The interviewer was a clinical research fellow and not involved in the clinical care of any of the patients. Questionnaires were completed prospectively but analyzed retrospectively as a batch after completion of the study. Questionnaire results were not used to inform clinical decision-making. Questionnaire results were transcribed onto an electronic database (Microsoft Excel, Microsoft, Redmond, Washington, USA) for subsequent analysis. The interviews were conducted on a single time point basis: no patients underwent repeat interview. All patients in the Antox group had been receiving therapy for at least 6 mo. No patients had undergone surgery in the 6 mo prior to interview.

Disease duration-matched cohort

Interim analysis of the whole cohort data showed that there were significant differences in the median age and disease duration between patients in the Antox group and those in the Non-Antox cohort. In an effort to correct for at least one of these factors, disease duration matching was undertaken. The disease duration was recorded for each patient from the clinical chart. Patients in the Non-Antox group were then matched with corresponding individuals from the Antox group. A disease duration of the same time period ± 12 mo was selected for matching. No patient was included twice and data were paired by searching chronologically according to date of interview from first interviewee to the last.

Ethics committee approval

This study was approved by regional research ethics committee.

Statistical analysis

Continuous data are presented as median (range). Statistical comparisons were by non-parametric test using the Mann-Whitney U-test for 2 group comparisons and Fisher's exact test for contingency tables. The Wilcoxon signed ranks test (two-sided test) was used for comparison of paired data. Statistical significance was at the $P < 0.05$ level. The StatsDirect software program was used for statistical analyses (StatsDirect version 2.6.5, http://www.statsdirect.com).

RESULTS

Entire cohort comparison (NOT matched for disease duration)

Alcohol was the most common etiologic agent in 84 (61%) of patients. The median age of the group taking Antox was 56 (24-82) years compared to 47 (24-74) years in those not taking Antox. This difference was statistically significant. Disease duration and proportion of patients with diabetes mellitus were also greater in the Antox groups (although the difference in incidence of diabetes mellitus was not significant).

Entire cohort outcome (NOT matched for disease duration)

VAS, overall physical health scores and global QoL were significantly better in patients with CP taking Antox. These results are reflected in the significantly lower number of patients in the Antox group taking analgesics and opiates.

Disease-duration matched cohort outcome

Table 1 shows that the disease duration-matched cohort were also similar in terms of age, etiology of CP and gender ratio. There were more smokers in the Non-Antox group, and alcohol intake prior to diagnosis was also greater in this group.

The outcome data in the disease duration-matched patients show that patients taking Antox had lower pain scores and fewer were taking analgesics (including opiates). There was no difference in the proportions of patients who were diabetic or who were taking pancreatic exocrine supplements (Table 2). A significantly greater number of patients in the Non-Antox group had undergone either surgical or endoscopic intervention.

Detailed global outcome data from the disease duration-matched cohort are shown in Table 3. Answers to questions were ranked on a scale of 1 to 4 [(1) not at all affected; (2) a little affected; (3) quite a bit affected and (4) very much affected]. In addition to lesser pain scores (as above) factors which were significantly better in patients

Table 2 Quality of life, pain scores and analgesic usage in disease duration-matched patients with chronic pancreatitis

	CP patients on Antox (n = 28)	CP patients NOT on Antox (n = 28)	P-value
Median visual analogue pain scores (range 0-10)	3 (0-8)	6 (0-8)	< 0.01 (Mann-Whitney U-test)
Patients taking analgesics	16	26	< 0.01
Patients taking opiate analgesics	11	23	< 0.01
Diabetes	10 (36%)	11 (39%)	0.80
Pancreatic exocrine supplements	14 (50%)	16 (57%)	0.60

taking Antox were: physical functioning, role functioning and cognitive and emotional functioning. These translated into a significant improvement in global QoL. Digestive function, jaundice and bowel function were not significantly different.

DISCUSSION

This study has examined QoL in patients with CP. Contemporary criteria were used for definition of disease and the Zurich Workshop recommendations were used for assessment of alcohol-related CP[18]. QoL has been evaluated in 2 cohorts of patients: those taking oral antioxidant therapy for CP and those not taking this medication. Specific disease-validated questionnaires were used for assessment of QoL[17].

Antioxidant therapy has been available for the treatment of CP for over 20 years[19]. However, the lack of good-quality randomized trial evidence and the dearth of information about clinical outcome in patients taking antioxidants has meant that this treatment remains on the periphery of practical management.

Thus, the importance of the present study is that it is believed to be the first to utilize specific disease-validated questionnaire methodology to assess QoL in patients with well-defined CP taking oral Antox. Potential sources of bias in these data should be borne in mind when interpreting the results.

Patients were not randomly allocated to Antox or Non-Antox; those receiving Antox were older and had longer disease duration (Table 1). Although disease-duration matching may have corrected for some of these factors, other confounding factors could persist: there were more smokers in the Non-Antox group and a sequential, multiple interview strategy would have yielded a more accurate reflection of QoL. This is accepted but must be balanced against the inconvenience to patients resulting from completing the lengthy questionnaires involved in this study. Also on a practical basis all patients were interviewed at relatively stable points in their disease with no history of recent surgery or change in medication.

Accepting these likely sources of bias, measures of QoL showed a significant benefit in patients on Antox: pain scores, physical health scores and global QoL together with analgesic (including opiate) intake were significantly better in the Antox group.

However, these findings may simply reflect a more mature population in the Antox group who have had more time to adjust to their illness and in some of whom the disease may be "burnt out"[20].

It is accepted that disease duration in a long-term chronic illness such as CP can be unreliably recalled[21] but prospectively recorded duration data were taken from the patients' charts and thus any error should be similar in both groups. The process of matching for disease duration produces a cohort of 28 pairs who are also reasonably well matched in terms of age, gender and etiology (Table 3). Although alcohol consumption in the Non-Antox group was greater prior to diagnosis, there was no difference after diagnosis.

The outcome data from the disease duration-matched cohort show some striking findings. VAS were significantly lower in the Antox group with a corresponding lower use of analgesics including opiate analgesics. There were no differences in the proportion of patients with diabetes or those taking pancreatic exocrine supplements, suggesting that if Antox modified symptoms in CP, there was no effect on the underlying disease course. Examined in detail, using the full EORTC questionnaires, the study showed improvement in global QoL in patients taking Antox. There were no differences in jaundice and digestive function answers, again suggesting that antioxidant therapy may modify symptoms without affecting disease progression.

These data should be considered together with the results of a recent large randomized trial from India of oral multi-compound antioxidants in painful CP. Although the Indian study did not use QoL measurement and had soft principal end-points in the form of reduction in hospital admission and reduction in "pain days" the study showed benefit from treatment with antioxidants.

In summary, this study has used well-validated, disease-specific questionnaires to assess QoL in patients with well-defined CP and compared a cohort of patients taking Antox to a group who were not. When corrected for differences in disease duration and age, patients on Antox had significantly lower VAS, lower analgesic use and better global QoL. Caution in interpretation is required. We would state that these data support a renewal of interest in the role of antioxidant therapy in CP and favor the conduct of a formal, randomized placebo-controlled trial of Antox in painful CP.

COMMENTS

Background

Chronic pancreatitis (CP) is associated with severe, disabling, frequent abdominal pain. It often leads to endocrine (diabetes) and exocrine (diarrhea and weight loss) disorders. In general, patients with CP have very poor quality of life (QoL) and outcome. No treatment has been found to combat long-term pain and cure.

Research frontiers

There has been anecdotal evidence of upregulation of the oxidative stress response and deficiency in antioxidants levels in patients with CP. The cascade of events due to repeated exposure and non correction leads to pancreatic fibrosis. This in turn leads to severe, chronic abdominal pain and poor QoL. In this study we demonstrated improvement in QoL for patients who were on antioxidant therapy.

Innovations and breakthroughs

Antioxidant therapy for CP was suggested in the mid 1990s. There have been a few studies showing the benefit of antioxidant therapy in CP. However, due to the paucity of data, it has not been universally accepted. This is the first comparative study to report QoL assessment in patients with CP on antioxidant therapy and those NOT on antioxidant therapy.

Applications

The study has renewed interest in antioxidant therapy for CP. The data lack randomization. This report supports the progression to a formal randomized double-blind trial of antioxidant therapy assessing QoL and outcome in patients with CP.

Terminology

Antioxidants is the term given to inhibitors of the oxidative stress response. They are typically selenium, vitamin E, methionine and ascorbic acid. European Organization for Research and Treatment of Cancer (EORTC) Quality of Life Questionnaire Core questions 30 and Pancreatic Modification (28 questions) (PAN-28) (EORTC, QoL core questionnaire and its pancreatic modification, PAN-28) are the QoL assessment tools validated and used for patients suffering from CP. Such a methodology is important and vital in measuring the outcome in chronic diseases.

Peer review

In general, this study by Shah *et al* has high originality and is interesting because they revealed the effectiveness of antioxidant treatment for CP which focused on QoL.

Abstract

AIM: To evaluate the diagnostic value of cancer-testis antigen (CTA) mRNA in peripheral blood samples from hepatocellular carcinoma (HCC) patients.

METHODS: Peripheral blood samples were taken from 90 patients with HCC before operation. Expression of melanoma antigen-1 (MAGE-1), synovial sarcoma X breakpoint-1 (SSX-1), and cancer-testis-associated protein of 11 kDa (CTp11) mRNA in peripheral blood mononuclear cells (PBMC) was tested by nested reverse transcripts-polymerase chain reaction (RT-PCR). Serum α-fetoprotein (AFP) in these patients was also determined.

RESULTS: The positive rate of MAGE-1, SSX-1 and CTp11 transcripts was 37.7%, 34.4%, 31.1% in PBMC samples, and 74.4%, 73.3%, 62.2% in their resected tumor samples, respectively. The positive rate for at least one of the transcripts of three CTA genes was 66.7% in PBMC samples and 91.1% in their resected tumor samples. MAGE-1, SSX-1 and/or CTp11 mRNA were not detected in the PBMC of those patients from whom the resected tumor samples were MAGE-1, SSX-1 and/or CTp11 mRNA negative, nor in the PBMC samples from 20 healthy donors and 10 cirrhotic patients. Among the 90 patients, the serum AFP in 44 patients met the general diagnostic standard (AFP > 400 μg/L) for HCC, and was negative (AFP ⩽ 20 μg/L) or positive with a low concentration (20 μg/L < AFP ⩽ 400 μg/L) in the other patients. The positive rate for at least one of the transcripts of three CTA genes in PBMC samples from the AFP negative or positive patients with a low concentration was 69.2% and 45.0%, respectively. Of the 90 patients, 71 (78.9%) were diagnosed as HCC by nested RT-PCR and serum AFP. Although the positive rate for at least one of the transcripts of three CTA genes in PBMC samples from 53 patients at TNM stage Ⅲ or Ⅳ was obviously higher than that in PBMC samples from 37 patients at stage Ⅰ or Ⅱ (77.9% *vs* 51.4%, $P = 0.010$), the CTA mRNA was detected in 41.7% and 56.0% of PBMC samples from HCC patients at stages Ⅰ and Ⅱ, respectively.

CONCLUSION: Detecting MAGE-1, SSX-1 and CTp11 mRNA in PBMC improves the total diagnostic rate of HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common and lethal cancers in the world[1-3]. More than one million cases of HCC occur in the world each year[4]. Although many treatment modalities for HCC are available (including hepatic resection, liver transplantation, radiofrequency ablation, transarterial chemoembolization, *etc.*) at present, the prognosis of HCC patients remains dismal because it is detected at an advanced, non-resectable stage. Early diagnosis of HCC can improve the prognosis of HCC patients. So far, α-fetoprotein (AFP) is the generally accepted serological marker. Serum AFP alone contributes to the diagnosis of HCC if its level is markedly elevated (over 400 μg/L as a threshold value), which occurs in less than 50% of cases at the time of diagnosis[5-8]. Moreover, serum AFP level is negative or slightly elevated in 20%-40% patients, which can significantly reduce the sensitivity of an assay based on over-expression of AFP. The serum AFP level in patients with acute or chronic hepatitis or liver cirrhosis but without malignant disease is often elevated. Since detection of serum AFP level in blood samples appears to be nonspecific[7-10]. Therefore, the diagnostic sensitivity and specificity of AFP are unsatisfactory and questionable. It is thus necessary to select other specific methods for the diagnosis of HCC.

Transcripts of tumor-specific genes can be amplified and detected by reverse transcripts-polymerase chain reaction (RT-PCR), which is a reliable technique to detect circulating tumor cells (CTC). In 1991, Smith *et al*[11] first successfully adopted RT-PCR technique to assess tyrosinase messenger RNA (mRNA) as a tumor marker in detecting circulating melanoma cells. Since then, this technique has been applied to the detection of CTC in solid tumors[12-14]. Melanoma antigen-1 (MAGE-1)[15], synovial sarcoma X breakpoint-1 (SSX-1)[16] and cancer-testis-associated protein of 11 kDa (CTp11)[17] antigens have been designated as cancer-testis antigens (CTA). It has been reported that MAGE-1 and SSX-1 mRNA are expressed with a high percentage and specificity in HCC[16,18-20]. Our group has verified a relatively high and specific expression of CTp11 mRNA in HCC tissues but not in the corresponding adjacent non-HCC and cirrhosis tissues[21]. In this study, we evaluated the diagnostic significance of a highly sensitive nested RT-PCR assay for the MAGE-1, SSX-1 and CTp11mRNA in peripheral blood of HCC patients.

MATERIALS AND METHODS

Cell lines

Human HCC cell lines BEL7405 expressing MAGE-1 mRNA and LM3 expressing both SSX-1 and CTp11 mRNA, purchased from the Cell Bank, Chinese Academy of Sciences, and Liver Cancer Institute, Zhongshan Hospital, Fudan University, respectively, were grown in RPMI1640 medium with 10% fetal calf serum and served as a positive control of the assay used in this study.

Patients and tissue samples

Ninety consecutive patients (79 men and 11 women) with a mean age of 45.6 ± 2.7 years (range 18-79 years) undergoing operation for HCC, including hepatectomy (48 cases) or orthotopic liver transplantation (42 cases), at the 2nd Hospital of Peking University Health Science Centre, were enrolled in this study. Of the 83 patients with virus infection, 79 were infected with hepatitis B virus, 2 with hepatitis C virus, and 2 with both hepatitis B and C viruses. The serum AFP level was negative (≤ 20 μg/L) in 26 patients, positive with a low concentration (20 μg/L < AFP ≤ 400 μg/L) and a high concentration (> 400 μg/L) in 20 and 44 patients, respectively. According to the TNM classification of International Union Against Cancer[22], 12 cases were classified as stage Ⅰ, 25 as stage Ⅱ, 9 as stage Ⅲ, and 44 as stage Ⅳ, respectively. HCC and its adjacent non-cancerous tissue samples (the distance to the edge of HCC tissue > 2 cm) were collected during operation. Control samples collected by surgical biopsy included 20 liver tissue samples from cirrhotic patients and 20 normal liver tissue samples from patients without liver disease. Testis tissue (kindly provided by Urological Department of the 2nd Hospital of Peking University Health Science Centre) was used as a positive control. Clinical diagnosis was confirmed by pathological examination. Each sample was immediately frozen in liquid nitrogen and stored at -80℃ until extraction of total RNA. Informed consent was obtained from each patient before the study. The study protocol was approved by the Ethic Committee of Peking University.

Blood samples

Whole blood samples were taken from the 90 HCC patients on the day before operation. Control blood samples were collected form 20 healthy volunteers and 10 cirrhotic patients. Ten mL of blood from each patient was collected into a heparinzed tube and peripheral blood mononuclear cells (PBMC) were isolated by density gradient centrifugation[15].

Extraction of total RNA and synthesis of cDNA

Total RNA was extracted from frozen tissue specimens (50-100 mg) and freshly isolated PBMC (1×10^7 cells) using TRIZOL reagent (GIBCOL BRL) according to its manufacturer's instructions. Total RNA (2.5 μg) was primed with an Oligo (dT)15 oligonucleotide (Promega, USA) and reverse-transcribed with Superscript Ⅱ (GIBCO BRL, USA) according to their manufacturers' instructions.

PCR amplification of CTAs

PCR amplification reaction (50 μL) contained 5 μL of

Table 1 Primers and conditions used in nested reverse transcripts-polymerase chain reaction

Primers	Primers from 5' to 3'	PCR conditions denaturation annealing extension
MAGE-1 outer primers	Forward primer: 5'-CGGCCGAAGGAACCTGACCCAG-3'	94℃ for 45 s
	Reverse primer: 5'-GCTGGAACCCTCACTGGGTTGCC-3'	65℃ for 45 s
		72℃ for 45 s

PCR: Polymerase chain reaction; MAGE-1: Melanoma antigen-1; SSX-1: Synovial sarcoma X breakpoint-1; CTp11: Cancer-testis-associated protein of 11 kDa.

cDNA, 1 μL each of 10 μmol/L outer/inner primers, 1 μL of 10 mmol/L dNTP mixture, 2.5 U *Taq* polymerase (GIBCO BRL, USA) in a buffer solution. Thirty-five cycles of PCR amplification of cDNA from liver tissue were performed with a pre-programmed UNO Ⅱ thermocycler (Biometra, German) under the following conditions: an initial denaturation at 94℃ for 5 min, a final extension at 72℃ for 8 min. The PCR products were 421 base pair (bp) (MAGE-1), 422 bp (SSX-1) and 297 bp (CTp11), respectively. Twenty-five cycles of PCR amplification of cDNA from PBMC were performed with its first round conditions identical to those of cDNA from liver tissue. For the second round of PCR, 1 μL of the first-round PCR products was used as a template in combination with 1 μL each of 10 μmol/L inner primers. After heated for 2 min at 94℃, the samples were subjected to 35 cycles of PCR amplification, followed by a final extension at 72℃ for 8 min. The PCR products were 299 bp (MAGE-1), 398 bp (SSX-1) and 188 bp (CTp11), respectively. The PCR conditions and outer/inner primers for MAGE-1[15], SSX-1[16] and CTp11[17] used in this study are shown in Table 1. To verify the integrity of cDNA[18], β2-microglobin (β2-MG) (primers: forward: 5'-CTCGCGCTACTCTCTCTTTCTGG-3' and reverse: 5'-GCTTACATGTCTCGATCCCACTTAA-3', 335 bp) was amplified for 30 cycles (at 94℃, 55℃ and 72℃ for 45 s). For analysis, 8 μL of reaction products was run in 2% agarose gel (Promega, USA), followed by ethidium bromide staining and digital camera photographing (Korda D3.5, USA).

Sensitivity of nested RT-PCR technique

The sensitivity of our nested PCR assay was evaluated by performing the procedure on healthy volunteer blood samples mixed with a certain number of hepatoma cells. Ten-fold serial dilution experiments from 10^4 hepatoma cells were carried out using human hepatoma cell lines BEL7405 expressing MAGE-1 transcript and LM3 expressing both SSX-1 and CTp11 mRNA. Hepatoma cells (1×10^3, 1×10^2, 1×10^1 and 1×10^0) were added to 5×10^6 PBMC from healthy donors, then total RNA was extracted and subjected to RT-PCR amplification with primers for β2-microglobin, MAGE-1, SSX-1 and CTp11 genes.

Sequence analysis of PCR products

PCR amplification-purified cDNA was cloned into the pGEM-T easy vector (Promega) by T4 DNA ligase and amplified in *Escherichia coli*, JM109. Four positive colonies were selected and assessed using EcoR Ⅰ digestion of mini-prepared DNA. Putative MAGE-1, SSX-1 and CTp11 cDNA samples were sequenced with T7 sequencing primers in Sangon Co., Shanghai, China.

Statistical analysis

Statistical analysis was performed by chi-square test and Fisher's exact test. $P < 0.05$ was considered statistically significant.

RESULTS

Sensitivity of nested RT-PCR technique

After two rounds of PCR amplification, MAGE-1, SSX-1 and CTp11 transcript genes could be detected in the PCR products, indicating that our assay is able to detect a hepatoma cell in 5×10^6 PBMC (Figure 1).

Expression of CTA genes in HCC tissue samples

Expression of MAGE-1, SSX-1 and CTp11 mRNA was detectabled in 74.4%, 73.3% and 62.2% of the 90 HCC tissue samples, respectively. No expression of these genes was detected in the corresponding adjacent non-HCC tissue samples, or in the normal and cirrhotic liver tissue samples. Eighty-two HCC tissue samples (91.1%) were

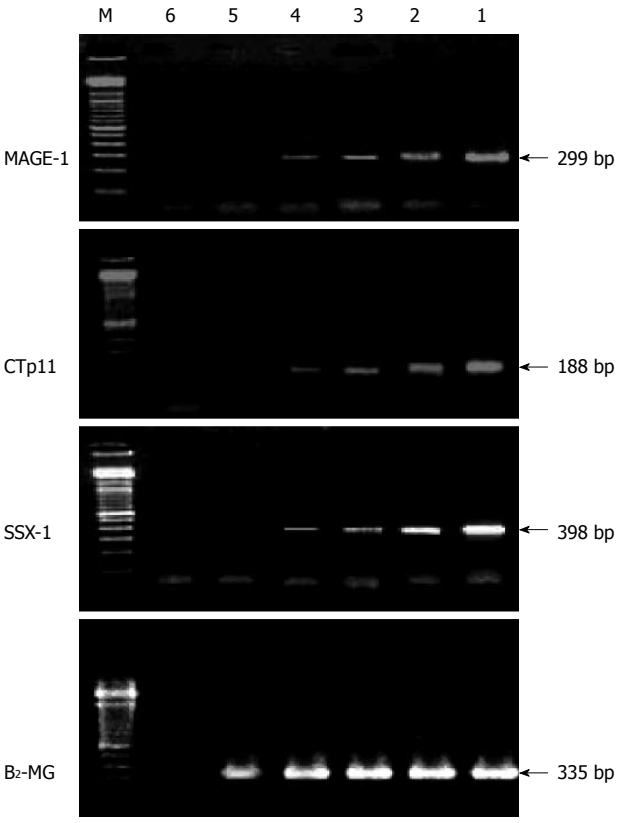

Figure 1 Sensitivity of nested polymerase chain reaction assay to tumor-specific markers in hepatocellular carcinoma cell lines. Lanes 1-4: 1 × 10^3, 1 × 10^2, 1 × 10^1 and 1 × 10^0 hepatoma cells detected by nested reverse transcripts-polymerase chain reaction using melanoma antigen-1 (MAGE-1), synovial sarcoma X breakpoint-1 (SSX-1), cancer-testis-associated protein of 11 kDa (CTp11), and β2-microglobin; Lane 5: Peripheral blood mononuclear cells (PBMC) from healthy donors only; Lane 6: negative control; Lane M: Molecular marker, 100 bp DNA ladder (Gibco).

positive for at least one of the transcripts of three CTA genes.

Nested RT-PCR results in HCC PBMC samples

After two rounds of PCR amplification, MAGE-1, SSX-1 and CTp11 were detected in 37.7%, 34.4% and 31.1% of the PBMC samples, respectively. At least one of the three genes was expressed in 66 PBMC samples (66.7%). Of the 82 MAGEE-1, SSX-1 or CTp11mRNA positive HCC tissue samples, at least one of the transcripts of three genes was detected in PBMC from 60 patients with a positive correlation rate of 73.2%. These gene transcripts could not be detected in PBMC from patients with MAGEE-1, SSX-1 or CTp11mRNA undetectable in their liver tissue samples. MAGE-1, SSX-1 or CTp11 gene was not expressed in the 30 control PBMC samples from 20 healthy volunteers and 10 cirrhotic patients. The typical electrophoresis of nested RT-PCR products amplified from cDNA in PBMC samples from HCC patients is shown in Figure 2.

Sequence analysis of PCR products

Sequence analysis of PCR products verified that the nucleotide sequences of MAGE-1, SSX-1, and CTp11 cDNA fragments were identical to those in GenBank, indicating that the RT-PCR products are MAGE-1, SSX-1, and CTp11 cDNA.

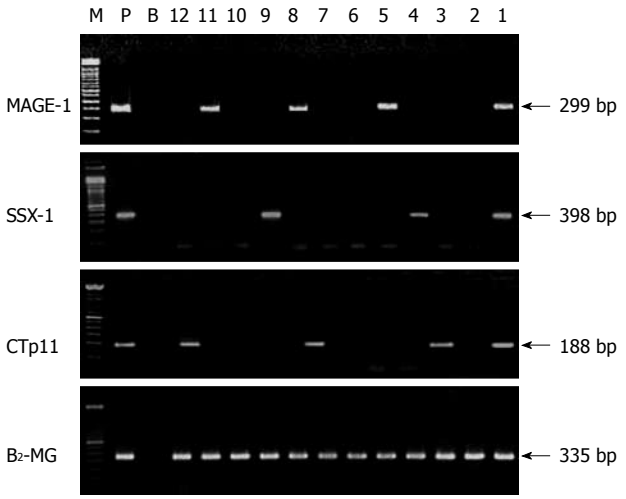

Figure 2 Electrophoresis of second round polymerase chain reaction products amplified from cDNA of peripheral blood mononuclear cells samples. Lane M: Molecular marker, 100 bp DNA ladder (Gibco); Lane P: Positive control; Lane B: Blank control; lane B2-MG (335 bp) as cDNA quality control; Lanes 1, 5, 8, 11: Positive melanoma antigen-1 (MAGE-1) transcript; Lanes 1, 4, 9: Positive synovial sarcoma X breakpoint-1 (SSX-1) transcript; Lanes 1, 3, 7, 12: Positive cancer-testis-associated protein of 11 kDa (CTp11) transcript; Lanes 2, 6 and 10: Negative transcript of all three CTA genes.

CTA transcripts in PBMC and serum AFP level

The overall positive rate of AFP with a high concentration in serum and MAGE-1, SSX-1 and/or CTp11 mRNA in PBMC samples was 48.9% and 66.7%, respectively. No correlation was observed between positive AFP rate and CTA transcripts. However, the serum AFP was negative (≤ 20 μg/L) in 26 HCC patients and positive with a low concentration (20 μg/L < AFP ≤ 400 μg/L) in 20 HCC patients. Of these 46 patients, 27 (18 cases with negative AFP and 9 cases with low concentration AFP) had MAGE-1, SSX-1 and/or CTp11 mRNA transcripts detected in their PBMC samples. By contrast, of the 30 patients with negative CTA transcripts in PBMC samples, 21 had the serum AFP level higher than 400 μg/L. Totally, 78.9% of HCC patients had either the AFP level higher than 400 μg/L in serum or positive CTA transcripts in PBMC. The parameters of AFP in serum and CTA transcripts in PBMC in combination with the results of imaging studies, would enable to make a clear diagnosis of 78.9% of HCC patients, which is much higher than the test with single AFP ($\chi^2 = 17.555$, $P < 0.01$)

CTA transcripts in PBMC from early HCC patients

The frequency of positive MAGE-1, SSX-1 and/or CTp11 transcripts detected in PBMC from patients with HCC was 41.7% at stage Ⅰ, 56.0% at stage Ⅱ, 66.7% at stage Ⅲ, and 79.5%% at stage Ⅳ, respectively. Of note, MAGE-1, SSX-1 and/or CTp11 mRNA was detected in PBMC from 51.4% of HCC patients at stages Ⅰ and Ⅱ and from 77.9% of HCC patients at stages Ⅲ and

Ⅳ, showing that advanced stages of HCC are correlated with the higher expression frequency of MAGE-1, SSX-1 and/or CTp11 gene mRNA (χ^2 = 6.632, P = 0.010). As many as 59.5% of the HCC patients at stages Ⅰ and Ⅱ could be diagnosed when CTA transcripts in PBMC and serum AFP level were combined with imaging findings. However, the serum AFP level was higher than 400 μg/L in 35.1% of the HCC patients. The diagnosis rate made by combined CTAs and AFP was significantly higher than that based on single AFP (χ^2 = 4.391, P = 0.036).

DISCUSSION

The integration of molecular and immunological techniques has led to the identification of a new category of tumor-specific antigens, also known as cancer-testis antigens, such as melanoma antigen (MAGE), synovial sarcoma X breakpoint (SSX), B melanoma antigen (BAGE), G melanoma antigen (GAGE), synaptonemal complex protein-1 (SCP-1), New York esophagus-1 (NY-ESO-1), and CTp11[23]. The CTAs are a distinct and unique class of differentiation antigens. Attributing genes to this gene group is based on their characteristics, including mRNA expression in normal tissues of testis, fetal ovary, and placenta, and mRNA expression in different cancers. Until now, at least 70 families of cancer-testis gene with 140 members have been attributed to this group and their expression has been studied in different types of tumors[23-26]. MAGE-1, SSX-1 and CTp11 belong to the CTA family members. The growing knowledge about CTAs indicates that the expression of CTA often shows a marked specificity for tumor cells[23,27-30]. These markers can be used to target tumor cells for early detection.

In the present study, CTAs (MAGE-1, SSX-1 and CTp11) were expressed with a high percentage and specificity in HCC. The positive rate for at least one of the transcripts of three CTA genes in HCC tissue samples was as high as 91.2%. Conversely, no expression was detected in the adjacent normal and cirrhotic liver tissue samples, or in the PBMC samples from healthy donors and cirrhotic patients. Based on the prevalent invasion of HCC cells to hepatic vessels, it is reasonable to consider that MAGE-1, SSX-1 and CTp11 are the appropriate tumor-specific markers for the detection of circulating HCC cells, which may play a complementary role in HCC diagnosis.

In this study, a sensitive and specific technique was developed, which is capable of detecting circulating HCC cells using MAGE-1, SSX-1 and CTp11 transcripts as tumor-specific markers by nested RT-PCR. Through the ten-fold serial dilution experiments with positive control cell lines, our results verified that exponential amplification of target cDNA converted from mRNA could allow to detect a single malignant cell within millions of normal blood cells and hence, to sensitively detect the metastatic tumor cells in peripheral blood. The sensitivity of this assay is within the range of other published reports[31-34], which is much more sensitive than antibody-based serology[35,36]. The positive rate of nested RT-PCR was as high as 66.7% for at least one of the transcripts of three CTA genes in the PBMC samples from HCC patients. In addition, detecting any of the transcripts of three CTA genes in PBMC samples from HCC patients would directly represent the presence of tumor cells in peripheral blood, suggesting that this method has a higher specificity than serum AFP and is thus able to improve the diagnosis of HCC. However, no expression of CTAs was detected in 8.9% of HCC tissue samples, showing that it is necessary to screen other CTAs or tumor specific antigens in these patients. If we can filter out 1-2 other markers, the diagnostic sensitivity of this method would be further improved.

Both albumin[37,38] and AFP[39-41] mRNA have been widely used as tumor markers for detecting HCC cells in circulation. However, the reliability is challenged, because albumin is abundantly expressed in normal liver cells[37] and AFP is expressed in liver cells infected with hepatitis virus or in cirrhotic liver[34]. In recent years, although an increasing number of genetic markers, such as telomerase reverse transcriptase[42], Des-g-carboxyprothrombin[43], squamous cell carcinoma antigen-immunoglobulin M complexes[44] and human cervical cancer oncogene[45], have been used in the diagnosis of early HCC, they have significant diagnostic limitations in their specific nature. In this study, MAGE-1, SSX-1 or CTp11 was not detected in PBMC from patients with their HCC tissue samples negative for these three CTA genes mRNA or in PBMC from 20 healthy donors and 10 cirrhotic patients, indicating that detecting CTA transcripts in PBMC from HCC patients has a high specificity for HCC.

So far, no methods or biomarkers demonstrate absolute superiority for early detection of HCC. It is difficult to simultaneously solve their sensitivity and specificity. Our assay by nested RT-PCR using MAGE-1, SSX-1 and CTp11 mRNA as tumor-specific makers showed a high sensitivity and specificity, indicating that it can establish the diagnosis of HCC.

Molecular biology technology contributes to the early diagnosis of HCC. However, its disadvantages are also obvious, including its cost and availability. PCR assay, a commonly used molecular biology technology, is more expensive and troublesome than serological tests, and is thus not the first choice in early detection of HCC. However, it plays a supplementary role in the diagnosis of HCC. Hopefully in the not so distant future, this technology will become increasingly popular and automatic with its cost decreased.

At present, the serum AFP level is still the gold standard for diagnosis of liver cancer. The AFP level is normal in 20%-40% of HCC patients at the time of diagnosis and usually remains low even in patients with advanced HCC[7-10]. AFP > 400 μg/L is considered diagnostic for HCC, although fewer than 50% of HCC patients may meet this standard[5-8]. With values of that magnitude, the specificity of AFP is close to 100% at the cost of its sensitivity fallen to less than 45%[6,7]. In this study, 51.1% of HCC patients were negative or positive for AFP with

a low concentration. MAGE-1, SSX-1 and/or CTp11 gene was expressed in 69.2% and 45.0% of HCC patients in the two groups, respectively, suggesting that mRNA, a tumor-specific marker, can be used as an adjuvant diagnostic tool. Detecting the transcripts of three CTA genes combined with serum AFP test in PBMC from HCC patients, can improve the total diagnostic rate of HCC.

In this study, the expression of CTAs in PBMC was significantly correlated with the clinical TNM classification of HCC. Although the positive frequency of CTA mRNA in PBMC was significantly higher in HCC patients at stages Ⅲ and Ⅳ than in those at stages Ⅰ and Ⅱ, MAGE-1, SSX-1 and/or CTp11 mRNA transcripts were detected in 41.7% of the HCC patients at stage Ⅰ and in 56.0% of the HCC patients at stage Ⅱ, showing that these three CTAs are reliable markers for screening hematogenous spread of early HCC cells. The combination of CTA transcripts in PBMC and serum AFP level improves early diagnosis of HCC. The classic TNM staging method[22] does not accurately reflect the actual process of HCC patients. The TNM classification criteria for HCC include tumor size, presence of portal vein invasion, and extrahepatic metastasis, *etc*. According to the TNM criteria, HCC at stage Ⅰ (T1N0M0) or stage Ⅱ (T2N0M0) should have no metastasis of tumor cells except for intra-hepatic metastasis. Assay by nested RT-PCR to detect MAGE-1, SSX-1 and/or CTp11 transcripts, the tumor-specific markers, revealed that 51.4% patients with HCC in early stages (stage Ⅰ and Ⅱ) have already had micrometastasis to the peripheral blood, indicating that blood dissemination of tumor cells has already occurred in the early stage of HCC when distant metastasis cannot be confirmed. Furthermore, it may be the reason why some early HCC patients still suffer from recurrence even after complete removal of the tumor. Detecting CTA transcripts in PBMC of early HCC patients can demonstrate hematogeneous dissemination of tumor cells more specifically than conventional methods, thus playing a supplementary role in the diagnosis of HCC. The traditional TNM staging criteria ignoring the presence of circulating HCC cells need to be perfected.

COMMENTS

Background

The prognosis of hepatocellular carcinoma (HCC) is poor because it is detection at an advanced, non-resectable stage. So far, α-fetoprotein (AFP) is a generally accepted serological marker. Its diagnostic accuracy is unsatisfactory and questionable. Serum AFP alone is helpful when its level is markedly elevated, occuring in less than 50% of cases at the time of diagnosis. Therefore, more sensitive and specific biomarkers are needed.

Research frontiers

The limitations of conventional AFP as a marker has led to a search for more sensitive and specific markers. In recent years, although an increasing number of genetic markers have been used in diagnosis of early HCC, they have significant diagnostic limitations in the specific nature. Cancer-testis antigens (CTAs) are frequently expressed in different types of cancer and have received considerable attention as ideal biomarkers of tumor cells.

Innovations and breakthroughs

The sensitivity and specificity of nested reverse transcripts-polymerase chain reaction assay using melanoma antigen-1, synovial sarcoma X breakpoint-1 and cancer-testis-associated protein of 11 kDa mRNA as tumor-specific multiple-makers are high and can thus be as an adjuvant diagnostic tool. This assay combined with serum AFP level may improve the diagnosis of HCC.

Applications

Detecting transcripts of CTA genes in peripheral blood mononuclear cells from HCC patients, combined with serum AFP test, improves the total diagnostic rate of HCC.

Peer review

The authors investigated the expression of some CTA genes in peripheral blood of HCC patients and showed that the positive rate for at least one of the three CTA genes was 67% in blood samples and 90% in resected tumor samples. They also showed a high specificity and sensitivity of their method for HCC. The study is very interesting and important for early diagnosis of HCC.

Abstract

AIM: To observe the analgesic effects of moxibustion in rats with chronic visceral hyperalgesia and its influence on the concentration of dynorphin (Dyn) and endomorphin (EM) in spinal cord.

METHODS: The rat model of chronic visceral hyperalgesia was established by colorectal distention (CRD). In moxibustion (MX) group, moxibustion was applied once daily for 7 d; in sham moxibustion (SM) group, moxibustion was given to the same acupoints but with the non-smoldered end of the moxa stick. Model control (MC) group and normal control group were also studied. The scoring system of abdominal withdrawal reflex was used to evaluate visceral pain for behavioral assessment. Enzyme linked immunosorbent assay was performed to determine the concentrations of Dyn and EM in spinal cord.

RESULTS: Moxibustion significantly decreased visceral pain to CRD in this rat model, and no significant difference was detected between the SM group and the MC group. In MX group, moxibustion also increased the concentrations of Dyn and EM in spinal cord, and no significant difference was found between the SM group and the MC group.

CONCLUSION: Moxibustion therapy can significantly enhance the pain threshold of rats with chronic visceral hyperalgesia, and the effect may be closely related to the increased concentration of Dyn and EM in spinal cord.

Key words: Moxibustion; Analgesia; Hypersensitivity; Dynorphins; Endomorphin

INTRODUCTION

Acupuncture-Moxibustion is an ancient therapy with a history of 3000 years in China, and it has spread to more than 160 countries for its good effects in management

of pain, nausea induced by radiotherapy/chemotherapy, vomiting, *etc.*[1]. Many studies have proved the analgesic effect of acupuncture from the view point of neurophysiology, neurochemistry, molecular biology, and brain functional imaging[2-6]. As a twin therapy of acupuncture, moxibustion has shown its effects in treatment of irritable bowel syndrome (IBS)[7], ulcerative colitis[8], Crohn's disease[9] and chronic/acute gastritis[10], especially in alleviating visceral pain. Some studies believed that acupuncture could relieve pain by increasing the concentration or expression of dynorphin (Dyn) and endomorphin (EM) in spinal cord[11,12]. It has been reported that visceral sensory nerves are closely associated with the spinal cord fragments[13,14], so that moxibustion might achieve its analgesic effect in treating visceral pain by modulating the concentrations of Dyn and EM in the spinal cord fragments.

Our previous studies have revealed the analgesic effects of moxibustion in reducing abdominal pain in IBS patients[15] and IBS rat models[16,17]. However, the analgesic mechanism of moxibustion has not been clearly elucidated. In this study, a rat model of chronic visceral hyperalgesia was established by colorectal distention (CRD), and abdominal withdrawal reflex (AWR) scoring system was adopted for behavioral assessment in the evaluation of visceral pain after moxibustion intervention. The analgesic effect of moxibustion and increase of the concentration of Dyn and EM in spinal cord were demonstrated, which partially explained the mechanism of the analgesic effect of moxibustion in management of visceral pain.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats (5 d old) were obtained from the Experimental Animal Center of Shanghai University of Traditional Chinese Medicine (TCM). They were maintained in a plastic cage containing corn chip bedding with controlled temperature (22 ± 2℃), 60% ± 5% humidity and light-dark cycle (12:12 h) with a maximum of five rats per cage. Studies were performed in accordance with the proposals of the Committee for Research and Ethical Issues of the Council for International Organizations of Medical Sciences and approved by the Committee on the Use of Human and Animal Subjects in Teaching and Research, Shanghai University of TCM.

Study design

Neonatal rats were given daily mechanical colon distention beginning 8-21 d after their birth. After the distention was finished, the rats were kept until they reached adulthood (at least 6 wk old), and then experiments were conducted using behavioral test for visceral pain by acute CRD stimulus. Moxibustion (MX) group (n = 10): moxibustion was given to the acupoints of bilateral Tianshu (ST 25) and Shangjuxu (ST 37) using fine moxibustion stick with the smoldered end 2 cm away from the acupoints, once daily, 10 min each time, 7 times in total (Figure 1A). Sham moxibustion (SM) group (n = 10): intervention was given to bilateral Tianshu (ST 25) and Shangjuxu (ST 37) points

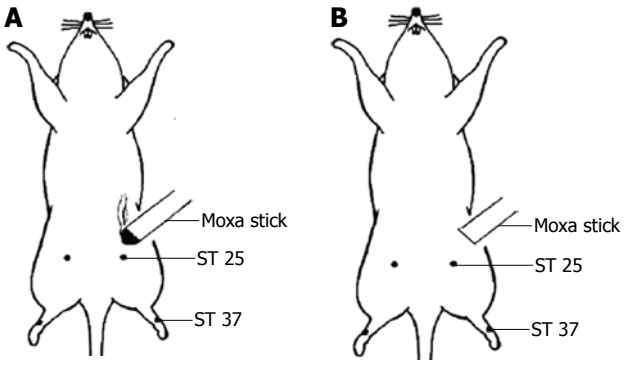

Figure 1 Moxibustion (A) and sham moxibustion (B).

Table 1 Abdominal withdrawal reflex scoring criteria

Score	
0	No behavioral response to colorectal distention
1	Immobile during colorectal distention and occasionally clicked the head at the onset of the stimulus
2	A mild contraction of abdominal muscles, but not lifting the abdomen off the platform
3	A strong contraction of the abdominal muscles and lifting the abdomen off the platform, not lifting the pelvic structure off the platform
4	Arching body and lifting the pelvic structure and scrotum

using fine moxibustion stick with the non-smoldered end 2 cm away from the acupoints, once daily, 10 min each time, 7 times in total (Figure 1B). Normal control (NC) group (n = 10) and model control (MC) group (n = 10): received no treatment except for constraining. After seven treatments, AWR was performed within 90 min, and a segment of spinal cord (L_4-S_1) was harvested and Dyn/EM concentration in spinal cord tissue was detected by enzyme linked immunosorbent assay (ELISA) (Figure 2).

Neonatal CRD irritation

Neonatal rats received CRD daily (the procedure was modified from previous reports[18,19]. Mainly, balloon (constructed from a condom; length: 20.0 mm; diameter: 3.0 mm) was inserted rectally into the descending colon. The balloon was distended with 0.5 mL air for 1 min and then deflated and withdrawn. The distention was repeated twice daily at a 30-min interval.

AWR scores

The AWR was assessed within 90 min after intervention using CRD based on semi-quantitative analysis. Prior to CRD, the rats were gently touched around anus for activating defecation. When the balloon was inserted into the descending colon, CRD was produced by rapidly inflating the balloon at strengths of 20, 40, 60, and 80 mmHg for a period of 20 s. Each score was tested three times, and each rat was tested by two people who were not involved in this research. There was a 3-min intervals between the two tests to allow the rats to adapt. The scoring criteria of AWR were referred to the method of Al-Chaer *et al*[18] (Table 1).

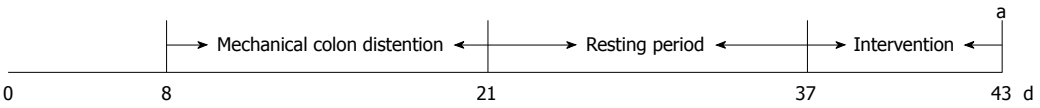

Figure 2 Experimental protocol of the study. [a]Abdominal withdrawal reflex sores after seven treatments.

ELISA for Dyn and EM

The dissected spinal cord tissue (L_4-S_1) was homogenized and weighed (10%), centrifuged for 30 min at 4℃, 4000 r/min. The supernatant was separated for assessment, and 100 μL standards and 100 μL dilution were mixed with 100 μL biotin, respectively. After incubation for 20 min at 20-25℃, 100 μL horse radish peroxidase was added. Followed by another 20 min of incubation at 20-25℃, 100 μL 3,3',5,5'-Tetramethylbenzidine substrate was added. Then 100 μL stop solution was put in after 20 min of incubation at 20-25℃. Calibration curve was drawn with OD value as the Y-coordinate and sample concentration as the X-coordinate. The concentration could be read according to the corresponding OD value. Rat Dyn and EM ELISA kits (THERMO MULTISKAN-MK3) were obtained from Finland.

Dyn in spinal cord (ng/L) = concentration × dilution times of the sample.

EM in spinal cord (ng/L) = concentration × dilution times of the sample.

Statistical analysis

The statistical analysis was done using SPSS 10.0 (SPSS Inc., USA). All data were expressed as mean ± SE for normally distributed continuous variables and as median (QL-QU) for abnormal variables. The differences in the mean values of the AWR score among the four groups (groups NC, MC, MX and SM) at each pressure of CRD were compared using the one-way analysis of variance (ANOVA, $P < 0.05$ as significant in differences). The differences in the median values of the concentration of Dyn and EM among the four groups were compared using the Kruskal-Wallis one-way analysis of variance on ranks. If the Kruskal-Wallis test result was significant ($P < 0.05$), we performed pairwise comparisons using a Wilcoxon rank sum test with a Bonferroni correction at 0.05/4 to correct for multiple comparisons. P value of < 0.05/4 was considered significant in differences.

RESULTS

Analgesic effects of moxibustion on chronic visceral hyperalgesia

At different levels of CRD stimuli (20, 40, 60 and 80 mmHg), the AWR scores in the MC group were significantly higher than in the NC group ($P < 0.01$); the AWR scores of MX group were significantly lower than that of the MC group ($P < 0.01$). There was no significant difference in the AWR scores between the MC group and SM group. This indicated that moxibustion treatment had a beneficial effect in chronic visceral hyperalgesia (Figure 3).

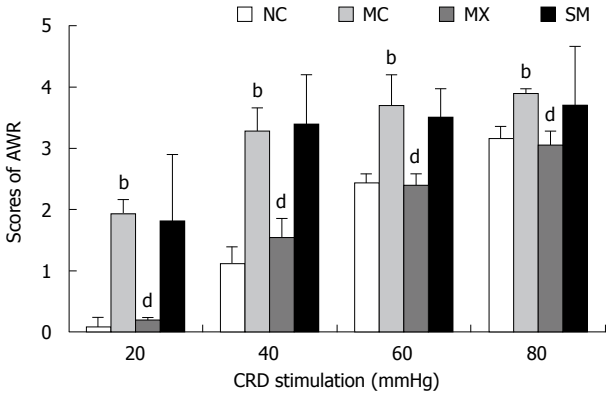

Figure 3 Analgesic effects of moxibustion on chronic visceral hyperalgesia. [b]$P < 0.01$ *vs* normal control (NC); [d]$P < 0.01$ *vs* model control (MC). AWR: Abdominal withdrawal reflex; MX: Moxibustion; SM: Sham moxibustion; CRD: Colorectal distention.

Influence of moxibustion in the Dyn concentration in spinal cord

The statistical analysis for the concentration of Dyn in spinal cord demonstrated a significant difference among the four groups, $F = 25.172$, $P = 0.000$. The concentration of MC group was significantly lower than that of NC group ($P < 0.01$). Compared with the MC group, the concentration of Dyn was significantly higher in the MX group ($P < 0.01$). No significant difference was detected in Dyn concentration between MC group and SM group (Figure 4A).

Influence of moxibustion on the EM concentration in spinal cord

Statistical analysis for the concentration of EM in spinal cord demonstrated a significant difference among the four groups, $F = 43.370$, $P = 0.000$. The concentration of MC group was significantly lower than that of NC group ($P < 0.01$). Compared with the MC group, the concentration of EM was significantly higher in the MX group ($P < 0.01$). No significant difference was detected in the EM concentration between the MC group and SM group (Figure 4B).

DISCUSSION

Visceral pain is commonly encountered by patients with functional intestinal disorders, leading to a miserable life and financial burden of the patients. Mertz *et al*[20] hold that the alterations of rectal sensitivity could be a biological indicator of IBS as IBS is featured by chronic abdominal pain. Alleviating abdominal pain is considered to be the main target in the management of IBS.

Moxibustion has been adopted as an analgesic method

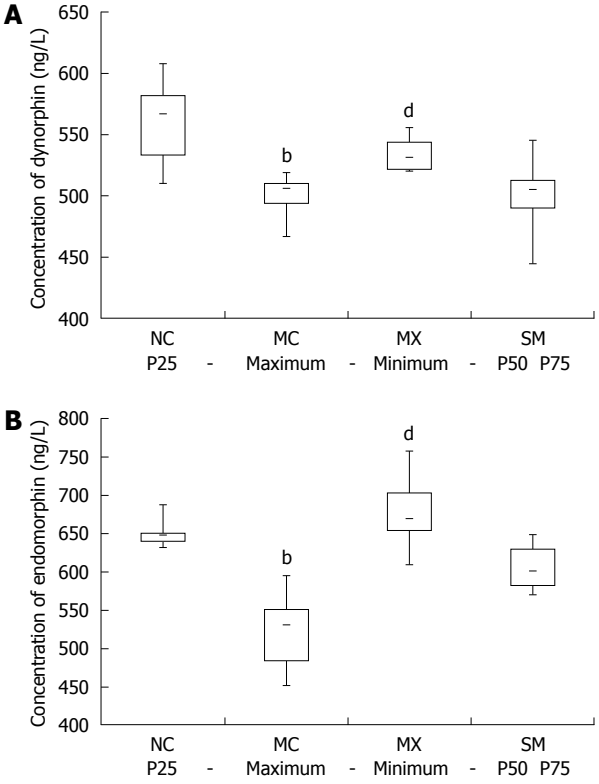

Figure 4 Influence of moxibustion on the concentration of dynorphin (A) and endomorphin (B) in spinal cord. $^{b}P < 0.01$ *vs* normal control (NC); $^{d}P < 0.01$ *vs* model control (MC). MX: Moxibustion; SM: Sham moxibustion.

for thousands of years in China, and is still frequently used in the present clinical practice. Many researches have shown its analgesic effect in treatment of primary dysmenorrhea[21], knee osteoarthritis[22], rheumatoid arthritis[23] and cancer pain[24]. Our previous studies also revealed that moxibustion could alleviate abdominal pain induced by IBS[16,17]. Although moxibustion has been practiced for thousand years, it is still difficult to establish its biological basis.

In the present study, CRD was adopted to establish a rat model of visceral hyperalgesia, and AWR was used for the behavioral assessment. The results showed that the AWR scores in the MC group were significantly higher than in the NC group at various CRD pressure levels (20, 40, 60 and 80 mmHg). Compared with the MC group, a marked reduction in AWR score was detected in the MX group ($P < 0.01$), and no significant difference was found in comparison with the SM group. It indicates that moxibustion has analgesic effects in management of visceral hyperalgesia, which is consistent with the results of our previous studies[16,17]. According to the previous studies adopting the same visceral pain model, herb-partitioned moxibustion could significantly inhibit the increase of AWR score and pain threshold induced by CRD. It has been also found that moxibustion could lower the expression of 5-HT in colon and modulate the expression of 5-HT in spinal cord, indicating a possible relationship between analgesic effect of moxibustion and central nervous system. Rats could keep quiet during the intervention of moxibustion, suggesting that modulating 5-HT was not the only way to reduce visceral hypersensitivity, some endogenous analgesic substances could also play a role in the process.

The analgesic effect of acupuncture has been widely accepted, especially in the study on chronic pain[25]. The endogenous opioid peptides (EOP) have been considered as important fundamental substances in acupuncture analgesia. According to Han JS[6,11,12,26], electro-acupuncture could activate the generation of EOP in spinal cord, such as orphanin, enkephalin, endomorphin, endorphin, and dynorphin.

The present study showed that the concentrations of Dyn and EM in spinal cord of the MC group were significantly lower than that of the NC group ($P < 0.01$). Compared with the MC group, the concentrations were significantly higher in the MX group ($P < 0.01$), and no significant difference was found from the SM group. It suggests that moxibustion could enhance the concentrations of Dyn and EM in spinal cord. Moxibustion may achieve its analgesic effect through multiple pathways and levels. Spinal cord may be the primary integrating center of moxibustion signal, increasing the concentrations of Dyn and EM in spinal cord, inducing a fragmental inhibition (including post-synaptic inhibition and pre-synaptic inhibition), and then blocking the further transmission of pain signal.

It has been shown that midbrain periaqueductal gray descending inhibitory system includes at least three transmitters: EOP, 5-HT and NA. Our findings indicate that moxibustion stimulation accelerates the synthesis and release of central EOP endorphin (dynorphin and endomorphin) and other neurotransmitters (5-HT) in the spinal dorsal horn neurons or nociceptive primary afferents, exerting analgesic effects.

In a word, moxibustion can significantly reduce AWR score and enhance the pain threshold of rats with chronic visceral hyperalgesia, and the analgesic effect may be closely related to the increased concentrations of Dyn and EM in spinal cord.

COMMENTS

Background

Previous studies into the mechanism of acupuncture analgesia have focused on the dynorphin (Dyn) and endomorphin (EM) in spinal cord. Whether analgesic effect of moxibustion is related to Dyn and EM in spinal cord remains unknown. In the previous studies, the authors have demonstrated the analgesic effect of moxibustion in reducing abdominal pain in irritable bowel syndrome (IBS) rats. However, the analgesic mechanism of moxibustion has not been clearly elucidated.

Research frontiers

More and more data have shown that the analgesic effect of moxibustion is closely related to the spinal cord fragments, which has become a hot spot of study.

Innovations and breakthroughs

Moxibustion is found effective against visceral pain. Moxibustion therapy exerts its effect on IBS by increasing the concentration of Dyn and EM in spinal cord

Applications

The experimental data can be used in further studies on moxibustion therapy for visceral pain.

Peer review

This is a good experimental investigation in which authors evaluate the effect of moxibustion, a Traditional Chinese Medicine, and possible involvement of endogenous dynorphin and endomorphin in the spinal cord in rats.

Abstract

AIM: To investigate the serological diagnostic factors for liver metastasis in patients with colorectal cancer.

METHODS: One hundred and six adult in-patients with colorectal cancer were studied and divided into patients with liver metastasis (n = 56) and patients without liver metastasis (n = 50). Serum levels of tumor and biochemical markers for liver were measured at the time of diagnosis.

RESULTS: The mean survival time was 55.9 mo, 36.8 mo and 68.3 mo for the overall patients, patients with liver metastasis and patients without liver metastasis, respectively. Lactate dehydrogenase (LDH) level was significantly correlated with the survival time of colorectal cancer patients. The levels of alanine aminotransferase, aspartate aminotransferase, γ-glutamyltransferase (GGT), LDH and carcinoembryonic antigen (CEA) were significantly higher in patients with liver metastasis than in those without liver metastasis. Patients with lymph node metastasis had a higher risk of liver metastasis than those without lymph node metastasis. The cut points of LDH, GGT and CEA for screening liver metastasis were 180 U/L, 30 U/L and 5.0 μg/L, respectively. The sensitivity was 64.3%, 69.6% and 70.4%, and the specificity was 64.0%, 60.0% and 52.4%, respectively. The sensitivity of parallel test was 85.2% for LDH and CEA, and 92.6% for GGT and CEA, respectively. The specificity of serial test was 85.7% for LDH (or GGT) and CEA.

CONCLUSION: Early diagnosis of liver metastasis is of great significance. The sensitivity and specificity of combined tumor and biochemical markers are rather good in screening colorectal liver metastasis.

Key words: Liver metastasis; Colorectal cancer; Lactate dehydrogenase; γ-glutamyltransferase; Carcinoembryonic antigen

INTRODUCTION

Colorectal cancer is the 3rd most common malignancy worldwide and the second most lethal cancer type in the developed world[1]. Most patients with colorectal cancer succumb to the effects of distant metastatic lesions, especially liver metastasis rather than the primary colorectal cancer itself[2]. The liver is a primary target organ of metastatic lesions and the main cause of death. About 25%

of patients with colorectal cancer have liver metastases at the time of diagnosis and another 25%-30% of them will present with liver metastases in the following 2-3 years[3]. Without treatment, the life expectancy for patients with colorectal metastases is poor and ranges from 5 to 9 mo[2,4]. Thus early diagnosis of liver metastases of colorectal caner leads to timely treatment, which favors a better prognosis.

Laparoscopy has not been advocated as a screening test for colorectal liver metastases due to its invasiveness. Fine needle aspiration cytology also has not been advocated as a screening test, because of its high risk of complications[5]. It has been shown that the incidence of needle tract metastases is 0.4%-5.1% after fine needle aspiration and use of the procedure in abdominal tumors is fatal in 0.006%-0.031% of cases[6,7]. Most deaths are due to hemorrhage of liver tumors[3]. Imaging modalities, such as contrast enhanced computed tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography CT (PET-CT), may establish the diagnosis of liver metastasis of colorectal cancer[8]. However, it is more difficult to make the clinical diagnosis of early liver metastases of colorectal cancer due to the absence of typical symptoms or signs. Serological examination including tumor and biochemical markers for liver function evaluation is routinely performed, though its accuracy is not high[9]. The level of carcinoembryonic antigen (CEA) is elevated in 63% of patients, while the activity of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) is increased in about 30% of patients with liver metastases of colorectal cancer[10]. To reduce metastases-related mortality, the development of new methods for diagnosis of liver metastases of colorectal cancer is of great significance.

The purpose of the present study was to determine whether CEA and biochemical hepatic tests can be used in assessing liver metastasis in patients with colorectal cancer.

MATERIALS AND METHODS

Patients

One hundred and six in-patients with colorectal cancer admitted to Cancer Institute and Hospital, Tianjin Medical University, from December 1996 to January 2004, were included in this study. Pathological test was performed to confirm their colorectal cancer and contrast enhanced CT, MRI or PET-CT was performed to confirm their liver metastasis. Moreover, liver metastasis was confirmed by operation, biopsy or progression of the disease. The patients who had a history of liver disease and did not undergo contrast enhanced CT and MRI were excluded from this study.

Investigation indexes

Blind tests were performed for total bilirubin (TB), direct bilirubin (DB), ALT, AST, serum total protein (TP), globulin (GLOB), γ-glutamyltransferase (GGT), alkaline phosphatase (ALP), lactate dehydrogenase (LDH), and CEA. Liver biochemical test was performed within 1 wk after liver metastasis was diagnosed by contrast enhanced CT and MRI in our hospital. The methods to determine biomarkers and upper or lower limits of normality used in our laboratory are shown in Table 1.

Table 1 Methods to determine biomarkers and upper or lower limits of normality used in our laboratory

Diagnostic factors	Methods	Lower and upper limits
Total bilirubin (μmol/L)	Jendrassik-Grof	2-20
Direct bilirubin (μmol/L)	Jendrassik-Grof	0-10
Alanine aminotransferase (U/L)	Rate	0-40
Aspartate aminotransferase (U/L)	Rate	0-42
Serum total protein (g/L)	Biuret	60-80
Globulin (g/L)		27-35
γ-glutamyltransferase (U/L)	Nitrophenol rate	0-50
Alkaline phosphatase (U/L)	P-nitrophenol phosphate rate	45-132
Lactate dehydrogenase (U/L)	Rate	80-240
Carcinoembryonic antigen (μg/L)	Elisa	0-5

Statistical analysis

One-sample Kolmogorov-Smirnov test was used to determine the distribution of ALP, TP, ALB, GLOB, GGT, ALT, AST, TBIL, DBIL, LDH and CEA. Data with the skewed distribution were presented as median (Quartile interval). Two-independent-sample test and χ^2 test were respectively used to determine whether there is any significant difference between patients with and without liver metastasis. Cox regression analysis was performed for GGT, ALP, LDH, TB, DB, ALT, AST, TP, GLB, CEA, lymph node metastasis in order to find the characteristic factors for survival time. Screening test for LDH, GGT and CEA, parallel test and serial test for GGT and LDH, CEA and LDH, CEA and GGT were used to determine the diagnostic factors for liver metastasis in patients with colorectal cancer. Statistical analysis was performed by SPSS (Version: 16.0, Chicago, USA).

The screening tests were evaluated by calculating their sensitivity (SE), specificity (SP), diagnostic index (DI), false positive rate (α), false negative rate (β), crude accuracy (CA), positive predictive value (PV+), negative predictive value (PV-).

SE was defined as the proportion of patients with LM testing positive (A/A + C) where C is the number of false negative cases. SP was defined as the proportion of patients without LM testing negative (D/B + D) where B is the number of false positive cases. DI was defined as the (SE + SP)-1. α was defined as the proportion of negative cases that were erroneously reported as positive while β was defined as the proportion of positive cases that were erroneously reported as negative. CA was defined as the proportion of cases correctly diagnosed by the test (A + D/A + B + C + D) where B + C is the number of cases erroneously diagnosed by the test. PV+ was defined as the proportion of patients testing positive with LM confirmed by pathology (A/A + B) while PV- was defined as the proportion of patients testing negative proved to be free of LM by pathology (D/C + D).

Serial test was defined as positive only if all the re-

sults were positive when we considered two or more tests together in the single patient. Parallel test was defined as positive if one of the results was positive when two or more tests were considered in the single patient.

RESULTS

Characteristics of patients

The age of our patients ranged 26-80 years with a median of 56 years. Males constituted 68 of patients with a male to female ratio of 1.788 to 1. No significant difference was found in age and sex of the patients with and without liver metastasis. The characteristics of patients with primary tumor and lymph node metastasis are shown in Table 2.

Survival analysis and cox regression

The median survival time was 47, 30 and 64 mo for the overall patients, patients with liver metastasis and patients without liver metastasis, respectively. Their mean survival time was 55.9 ± 5.5 mo, 36.8 ± 6.5 mo and 68.3 ± 7.0 mo, respectively. The survival curves for patients with and without liver metastasis were significantly different (P = 0.005) (Figure 1). Cox regression analysis showed that LDH was significantly correlated with the survival time of colorectal cancer patients with an increased risk of liver metastasis (P = 0.005) (Table 3).

Table 3 Cox regression analysis of patients with colorectal cancer

	χ^2	P
Serum total protein (g/L)	0.093	0.761
Globulin (g/L)	< 0.000	0.994
Alanine aminotransferase (U/L)	1.943	0.163
Aspartate aminotransferase (U/L)	0.143	0.705
Total bilirubin (μmol/L)	0.122	0.726
Direct bilirubin (μmol/L)	0.063	0.801
γ-glutamyltransferase (U/L)	1.126	0.289
Alkaline phosphatase (U/L)	1.006	0.316
Lactate dehydrogenase (U/L)	11.254	0.001
Carcinoembryonic antigen (μg/L)	0.159	0.690
Lymph node metastasis	1.601	0.206

Table 4 Levels of γ-glutamyltransferase, alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase and carcinoembryonic antigen in patients with and without liver metastasis of colorectal cancer

	With liver metastasis	Without liver metastasis	P
GGT (U/L)	43.00 (64.75)	24.00 (35)	0.001
ALT (U/L)	22.00 (22.75)	13.00 (12.50)	< 0.001
AST (U/L)	22.00 (17.50)	16.00 (10.00)	< 0.001
LDH (U/L)	201.5 (169.50)	164.50 (70.75)	0.003
CEA (μg/L)	13.70 (93.8)	4.87 (12.82)	0.039

GGT: γ-glutamyltransferase; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; LDH: Lactate dehydrogenase; CEA: Carcinoembryonic antigen.

Test of normality and two-independent-sample test

One-sample Kolmogorov-Smirnov test showed that the distribution of ALP, TP, ALB, GLOB and ALB/GLOB was normal, while that of GGT, ALT, AST, TBIL, DBIL, LDH and CEA was skewed. The levels of GGT, ALT, AST, LDH and CEA were significantly higher in patients with liver metastasis than in those without liver metastasis (P < 0.05) (Table 4). Patients with lymph node metastasis had a higher risk of liver metastasis than those without lymph node metastasis (χ^2 = 9.046, P = 0.003). No significant difference was found in ALP, TP, ALB, GLOB, ALB/GLOB, TBIL, and DBIL levels between patients with and without liver metastasis (data not shown).

Screening test

Because the diagnostic indices of LDH, GGT and CEA at 180, 30 and 5.0 for screening liver metastasis were the greatest, the cut off points were selected at 180, 30 and 5.0, respectively (Figure 2). The area under the curves of LDH, GGT and CEA was 0.671, 0. 687 and 0.675, respectively (P = 0.05). The κ of parallel test and serial test for CEA and LDH, CEA and GGT was 0.293, 0.326, and 0.357, 0.284, respectively (P = 0.05). The SE, SP, DI, false positive rate (α), false negative rate (β), CA, adjusted agreement, PV+ and PV- are shown in Table 5.

Table 5 Screening test for liver metastasis in patients with colorectal cancer

	Sen (%)	Spe (%)	DI	CA	AA	PV+	PV-	*P*	α	β

DISCUSSION

Colorectal cancer metastasis occurs in various organs, most frequent in lymph nodes and liver[1]. In this study, the patients with lymph node metastasis had a higher risk of liver metastasis than those without lymph node metastasis, indicating that regular imaging modalities, such as contrast enhanced CT and MRI, may be performed every 3 or 6 mo after surgery for patients with colorectal cancer to establish an early diagnosis of liver metastasis.

The overall life expectancy of patients with colorectal cancer is mainly determined by the progression of liver metastasis rather than by the primary carcinoma itself[3]. The median survival time was 47, 30 and 64 mo for the overall patients, patients with liver metastasis and patients without liver metastasis, respectively, with a mean survival time of 55.9, 36.8 and 68.3 mo, respectively. A significant difference was observed in survival curves for patients with and without liver metastasis. The levels of GGT, ALT, AST, LDH and CEA were significantly higher in patients with liver metastasis than in those without liver metastasis. Cox regression analysis showed that LDH was significantly correlated with the survival time of colorectal cancer patients, indicating that LDH may be used to predict the life expectancy of patients with liver metastasis of colorectal cancer.

CEA was demonstrated in fetal gut tissue and gastrointestinal tract tumor four decades ago, and subsequently detected in the circulation of patients and recognized as a serum marker for colorectal cancer. Expression of carbohydrate antigen (CA) 19-9 has been described in colorectal cancer, but its sensitivity is lower than CEA[11]. Lack of sensitivity and specificity precludes the use of any available serum markers, such as CEA, CA 19-9, CA 242, CA 72-4, tissue polypeptide antigen or tissue polypeptide-specific antigen, for the early detection of colorectal cancer[12]. However, a preoperative CEA serum level can predict the prognosis of recurrence and survival time of colorectal cancer patients[11,13]. Moreover, circulating levels of LDH, ALP, and GGT in malignant tissues can directly contribute to liver replacement[14,15]. In patients with metastatic colorectal cancer, CEA, ALP and LDH have been reported as prognostic factors[16-19].

A screening test was performed to show whether LDH, GGT and CEA can be used to screen liver metastasis in patients with colorectal cancer. Because the diagnostic indices of LDH, GGT and CEA at 180 U/L, 30 U/L and 5.0 μg/L for screening liver metastasis were the greatest, the cut off points were selected at 180 U/L, at 30 U/L, and at 5.0 μg/L, respectively. The sensitivity were 64.3%, 69.6% and 70.4%, respectively. The sensitivity were 64.0%, 60.0% and 52.4%, respectively. As a tumor marker, CEA test had a moderate sensitivity and a low specificity for liver metastasis in patients with colorectal cancer. Thus, tumor markers in combination with biochemical markers for liver function may improve the sensitivity and specificity for screening liver metastases in patients with colorectal cancer.

Couples of tests, usually CEA and another, would demonstrate a better accuracy than a single test[20,21], which

is consistent with the findings in our study. In the present study, the sensitivity of parallel test for LDH and CEA, GGT and CEA was 85.2% and 92.6%, respectively. The specificity of serial test for LDH and CEA was 85.7% and the specificity of serial test for GGT and CEA was 85.7% too, indicating that its sensitivity and specificity of tumor marker (CEA) in combination with biochemical markers including LDH and GGT are rather good in patients with colorectal cancer, if LDH > 180 U/L and CEA > 5.0 μg/L, or GGT > 30 U/L and CEA > 5.0 μg/L. Contrast enhanced CT, MRI or PET-CT may be performed immediately to confirm liver metastasis and timely treatment may improve the survival of patients with liver metastasis of colorectal cancer. Thus metastatic liver disease may be diagnosed before symptoms occur and liver metastases of colorectal cancer can be diagnosed more rapidly and accurately.

COMMENTS

Background

The overall life expectancy of patients with colorectal cancer is mainly determined by the progression of liver metastasis rather than by the primary carcinoma. Improved early screening modalities are still needed and molecular beacons may be sufficiently sensitive, specific, and cost-effective for screening of colorectal liver metastases.

Research frontiers

Although various diagnostic modalities, such as ultrasonography, computed tomography scan and magnetic resonance imaging have been used in demonstrating metastases, but their accuracy is low, particularly when the lesions are small. The present study demonstrated the value of carcinoembryonic antigen (CEA) and some biochemical hepatic tests in detection of hepatic metastases in patients with primary colorectal cancer.

Innovations and breakthroughs

Laboratory tests have limits in detecting LM but they can rapidly and accurately evaluate liver metastasis in patients with primary colorectal cancer. This study showed that measurements of plasma biomarkers increase the sensitivity and selectivity of liver metastasis diagnosis.

Applications

The results of this study can improve early screening modalities. Furthermore, combination of markers and even modalities with imaging or endoscopic ultrasound will be needed to achieve a sufficient reliability.

Peer review

It is a very interesting paper describing the diagnosis of liver metastases of colorectal cancer. The authors studied 106 patients with colorectal cancer, showing that the alanine aminotransferase, aspartate aminotransferase, γ-glutamyltransferase, lactate dehydrogenase and CEA levels are increased in patients with liver metastasis of colorectal cancer.

Abstract

AIM: To study the expression profiles of MUC2 and MUC5AC in tumorigenesis of colorectal carcinoma and in its different pathologic types.

METHODS: Formalin-fixed, paraffin-embedded human colorectal tissue specimens were immunostained with antibodies against MUC2 and MUC5AC. Six samples of normal mucosa (NM), 12 samples of hyperplastic polyp (HP), 15 samples of tubular adenoma with low-grade dysplasia (LGD), 14 samples of tubular adenoma with high-grade dysplasia (HGD), 26 samples of conventional colorectal adenocarcinoma (CCA), 15 samples of mucinous carcinoma (MC), and 8 samples of signet-ring cell carcinoma (SRCC) were collected.

RESULTS: MUC2 was the most widely expressed protein in each study group, although the number of MUC2-positive cases was less in CCA group than in other groups ($P < 0.05$). The staining score for MUC2 was significantly decreased in the HP-LGD-HGD-CCA sequence ($r = -0.73436$, $P < 0.0001$). Among the neoplasms, MC and SRCC were more frequently associated with the high expression of MUC2 ($P < 0.05$) than with that of CCA. MUC5AC expression was detected in all groups but not in NM group. Furthermore, the staining score for MUC5AC was higher in HP, LGD, HGD, MC and SRCC groups than in NM and CCA groups ($P < 0.05$). The frequency of simultaneous expression of MUC proteins was significantly higher in MC and SRCC groups than in CCA group ($P < 0.05$).

CONCLUSION: Alterations in MUC expression occur during colorectal tumorigenesis. The transformation process in MC and SRCC may be different from that in the traditional adenoma-carcinoma sequence.

INTRODUCTION

Mucins are high-molecular-weight glycoproteins, which are heavily decorated with a large number of O-linked oligo-

saccharides and a few N-glycan chains, linked to a protein backbone[1]. Mucins are known to play a central role in the protection, lubrication and hydration of the external surface of human epithelial tissue layers lining the intricate network of ducts and passageways. Mucins have also been implicated in the pathogenesis of benign and malignant diseases of secretory epithelial cells. The identification of novel transmembrane mucin MUC21[2], means that a total of 20 human mucins have now been recognized. According to their structure and function, mucins can be divided into secreted mucins and transmembrane mucins. Secreted mucins can be gel-forming or non-gel-forming, and include MUC2, MUC5AC, MUC5B, MUC6, MUC7, MUC8, MUC9 and MUC19. Transmembrane mucins include MUC1, MUC3A, MUC3B, MUC4, MUC11, MUC12, MUC13, MUC15, MUC16, MUC17, MUC20 and MUC21, and possess a transmembrane domain for anchoring themselves to the plasma membrane of various cells. These mucin proteins are encoded by various *MUC* genes[1].

The genes for gel-forming mucins MUC2 and MUC5AC are found in a cluster on chromosome 11p15.5, and synthesis of the proteins is regulated by biologically active molecules, including cytokines, bacterial products, and growth factors[3-5]. The *MUC2* gene codes for a typical secretory mucin, which is predominantly found in colorectal goblet cells. The *MUC5AC* gene is mainly expressed in gastric and tracheo-bronchial mucosa. Changes in the expression levels and/or distribution profiles of MUC2 and MUC5AC occur in cancers of the lung, gastrointestinal tract, pancreas, hepatobiliary system and reproductive system. For example, it has been found that MUC5AC is down-regulated in peritumoral epithelium and squamous metaplasia of non-small cell lung carcinoma (NSCLC), and MUC5AC expression is reduced in NSCLC, irrespective of their histologic subtype[6]. The expression of sLe^x is related to MUC5AC protein in NSCLC, and patients with tumors co-expressing both MUC5AC and sLe^x antigen have the poorest survival[7]. MUC2 appears to act as a protective protein and has been shown to be associated with tumors of mucinous type, both in biliary system and in pancreatic system, which carry a more favorable prognosis[8]. MUC5AC expression in intrahepatic cholangiocarcinoma is associated with a higher incidence of lymph node metastasis and has been identified as an independent prognostic factor by multivariate survival analysis[9].

Interestingly, altered expression of MUC in colorectal cancer may be significantly correlated with histologic type, sensitivity to chemotherapeutic drugs, and prognosis of colorectal cancer[10-13]. Colorectal cancer constitutes a suitable model for studying the mechanisms of carcinogenesis and tumor progression in the well-established adenoma-carcinoma sequence. It is possible to observe a dynamic progression from benign adenomatous polyp to adenoma with varying degree of dysplasia, to intramucosal and invasive carcinoma[14]. Moreover, a pathway involving a hyperplastic polyp-adenoma-carcinoma sequence has also been introduced[15]. Alterations in the expression of mucin proteins and genes have been observed in colorectal adenoma and carcinoma, although their significance in neoplastic transformation of the colorectal epithelium is yet to be determined. The present study therefore aimed to study the expression profiles of MUC2 and MUC5AC during tumorigenesis and in different pathologic types of colorectal carcinoma, using immunohistochemical staining.

MATERIALS AND METHODS

Tissue samples

Formalin-fixed, paraffin-embedded human colorectal tissue specimens were obtained from Department of Pathology, Nanjing First Hospital of Nanjing Medical University. Six samples of normal mucosa (NM), 12 samples of hyperplastic polyps (HP), 15 samples of tubular adenoma with low-grade dysplasia (LGD), 14 samples of tubular adenoma with high-grade dysplasia (HGD), 26 samples of conventional colorectal adenocarcinoma (CCA), 15 samples of mucinous carcinoma (MC), and 8 samples of signet-ring cell carcinoma (SRCC) were analyzed in this study. HP was diagnosed when a serrated polyp with no overt cytological atypia showed narrowed crypt bases, predominantly lined with immature cells. Adenoma was further classified as low or high grade based on the degree of glandular intraepithelial neoplasia (dysplasia), according to the World Health Organization classification. Colorectal cancer was defined as mucinous carcinoma if more than 50% of the lesion contained a mucin lake. Cancer where more than 50% of the tumor cells were signet-ring cells was defined as SRCC. Histologically normal mucosa from margins of the specimens served as control tissue. All tissue samples were diagnosed and classified by two pathologists.

Immunohistochemistry

Paraffin-embedded blocks of different tissues were cut into 4-μm thick sections. Slides were deparaffinized in xylene and rehydrated using a graded ethanol series. Antigen was retrieved by boiling the slides in a microwave oven for 15 min in 0.01 mol/L citrate buffer (pH 6.0). Endogenous peroxidase was blocked with a 3% H_2O_2-methanol solution, and the slides were incubated in 10% normal goat serum for 30 min to prevent nonspecific staining. The tissue sections were then incubated overnight at 4℃ with primary antibody (MUC2 or MUC5AC, 1:100; Santa Cruz, CA). The standard biotin-streptavidin-peroxidase method was then used, and the sections were lightly counterstained with hematoxylin. Histologically normal colon mucosa and gastric biopsies were used as positive controls for MUC2 and MUC5AC, respectively. The sections incubated with phosphate-buffered saline (0.01 mol/L, pH 7.4) instead of primary antibody were used as negative controls.

Analysis of immunohistochemical data

Both goblet and non-goblet columnar cells of normal colon and hyperplastic polyps were evaluated. MUC staining was only scored in neoplastic cells of tissues containing either dysplastic epithelium or carcinoma. The range of cytoplasmic staining (0: 0%-5%; 1: 6%-30%; 2: 31%-60%; and 3: 61%-100%) and the intensity of staining (0: no stain; 1: weak staining; 2: intermediate staining; and 3:

strong staining) were assessed in at least 8 high-power fields by two observers, and averages of the grades were taken. The final staining score was defined as the product of scores for the range and intensity of cytoplasmic staining. Staining was designated as negative if the staining score was 0 or 1, intermediate for 2, 3, or 4, and high for 6 or 9. All specimens were scored blindly.

Statistical analysis

Statistical comparison of immunohistochemical staining was performed using SAS software version 9.0 (SAS Institute, Cary, NC). The rank-sum test and Spearman's rank correlation analysis were used to determine differences between the groups and to evaluate correlations, respectively. The T approximation test in Wilcoxon's rank-sum test and Fisher's exact test were used to compare differences between CCA and other groups. $P < 0.05$ was considered statistically significant.

RESULTS

Immunohistochemical localization of MUC2 and MUC5AC

The expression of MUC2 and MUC5AC proteins differed among the study groups, which was prominently characterized by perinuclear and diffuse cytoplasmic staining. The MUC2 was expressed in perinuclear cytoplasm of partial goblet cells in NM group (Figure 1A). The MUC2 labeling was generally increased in cytoplasm of columnar cells and goblet cells in HP group (Figure 1B), and the positive signals were also observed in apical cytoplasm of columnar cells, especially in LGD and HGD groups (Figure 1C and D). MUC2 expression was positive in the cytoplasm of cancerous cells, while the extracellular mucin remained unstained (Figure 1E-G). The staining pattern for MUC5AC was largely similar to that for MUC2 in all groups but not to that in NM group, and positive signals were found in extracellular mucin (Figure 2).

Immunohistochemical analysis of MUC2 and MUC5AC

The frequency of MUC protein expression in different groups was examined with immunohistochemical staining, and the results are summarized in Table 1. MUC2 was the most widely expressed antigen in all groups, but the number of MUC2-positive cases (46.15%) was less in CCA group than in other groups. Both the expression frequency and staining intensity of MUC2 were significantly decreased in the HP-LGD-HGD-CCA sequence ($r = -0.73436$, $P < 0.0001$). The frequency of MUC2 expression was significantly higher in MC and SRCC groups than in CCA group ($P < 0.05$). The MUC5AC expression was detected in all groups but not in NM group. Furthermore, the frequency of MUC5AC expression was dramatically lower in CCA group (30.77%) than in other groups with the exception in NM group. The proportion of high staining scores was significantly higher in MC and SRCC groups than in CCA group ($P < 0.05$), which was similar to that of MUC2 expression. Concordance between MUC2 and MUC5AC expression was also noted in individual specimens from different groups (Table 2). Concordance was defined as positive (intermediate or high) or negative MUC2 and MUC5AC expression. The frequency of simultaneous expression of MUC proteins was significantly higher in MC and SRCC groups than in CCA group ($P < 0.05$).

DISCUSSION

MUC expression has been studied in colorectal carcinoma, but few reports are available on the expression in relation to the hyperplastic polyp-adenoma-carcinoma sequence, or in different pathologic types of colorectal cancer. This study focused on the altered and *de novo* expression profiles of MUC2 and MUC5AC in the tumorigenic sequence, and in different pathologic types of colorectal cancer.

MUC2 is characteristically expressed in goblet cells of native intestinal epithelium and intestinal metastasis of gastric mucosa, but not in normal gastric epithelium. The results of the present study, with immunohistochemical staining of paraffin-embedded human tissue samples, are consistent with those of previous studies showing reduced MUC2 expression in colorectal adenocarcinoma[16-18]. Decreased MUC2 expression in nonmucinous colon cancer can result from methylation of the MUC2 promoter[1]. Gratchev *et al*[19] demonstrated that MUC2 promoter methylation is lower in normal goblet cells than in columnar cells and in specimens of mucinous colorectal carcinoma than in those of nonmucinous adenocarcinoma. Loss of functional p53 is also related to the down-regulation of MUC2 expression in colorectal carcinoma. It has been shown that MUC2 expression is transcriptionally regulated by p53 protein in several cell lines[20]. There are two potential p53-binding sites in the MUC2 promoter, each of which contributes to stimulation of promoter activity. It was reported that MUC2 immunoreactivity is inversely correlated with p53 alteration in mucinous carcinoma, i.e. the level of p53 alteration is lower in regions with a high MUC2 expression level[21]. Decreased *in vivo* expression of MUC2 is related to colon carcinogenesis accompanying increased proliferation, decreased apoptosis, and increased migration of intestinal epithelial cells[22].

MUC5AC is not expressed in normal colonic epithelium, but *de novo* expression occurs in adenoma and colorectal cancer. The number of immunoreactive cells and the intensity of MUC5AC staining are greatest in larger adenoma with moderately villous histology and dysplasia, while immunostaining is lower in highly villous polyps with severe dysplasia[23]. However, in the current study, the score for MUC5AC staining was higher in HGD group than in LGD group, in contrast to the expression of MUC2 in the two groups. This discrepancy in MUC5AC expression in the two studies might be due to the use of a different histologic type of adenoma. Although MUC5AC expression correlates with neural invasion and advanced stage of intrahepatic cholangiocarcinoma[24], the relation between MUC5AC expression and progression of colon cancers may be different. Kocer *et al*[25] found that the expression of MUC5AC in colon cancer is associated with a better

prognosis of its patients. Patients with MUC5AC-negative tumors have a poorer prognosis and a lower survival rate than those with MUC5AC-positive tumors, suggesting that the absence of MUC5AC expression in tumors is a prognostic factor for highly aggressive colorectal carcinoma. The *de novo* expression of MUC5AC in mucinous adenocarcinoma and SRCC was inconsistent in our study. The variability of MUC polypeptide expression in individual adenocarcinomas may reflect tumor cell heterogeneity and aberrant differentiation in invasive tumors, compared with their dysplastic precursors.

SRCC and MC have similar biological behaviors, but their molecular compositions may differ. Signet-ring cells rarely express adhesion molecules, implying disruption of cell-cell adhesion[18], which can explain their aggressive behavior in terms of the invasion and metastasis of tumor cells. Mucinous colorectal carcinoma is associated with microsatellite instability (MSI). It has been hypothesized that MSI may directly influence mucus production in both sporadic and hereditary colon cancer, by alternating the genes involved in mucin synthesis or degradation[26]. Colorectal cancer with a high MSI usually has a higher MUC2- and MUC5AC-positive rate than microsatellite-stable cancer[27]. Boland *et al*[28] recently suggested that colorectal tumor with MSI has more distinctive features, including a poor differentiation, mucinous or signet-ring appearance, as well as a different response to chemotherapeutics, than colorectal tumor without MSI. It is interesting that a similar phenotype (MUC2+/MUC5AC+) has been identified in adenoma and hyperplastic polyp. The classic adenoma-carcinoma pathway usually involves the loss of tumor suppressor genes, although a minority of colorectal cancers may develop in an other pathway associated with mutations in mismatch repair genes or hypermethylation of the hMLH1 gene (in sporadic cancers)[29-31].

In conclusion, alterations in MUC expression occur during colorectal tumorigenesis. The transformation process in MC and SRCC may be different from that in the traditional adenoma-carcinoma sequence. *De novo* expression of MUC5AC can occur in both mucinous and non-mucinous colorectal carcinomas, but its expression is stronger in mucinous colorectal carcinoma than in non-mucinous colorectal carcinoma. Further investigations using molecular biological techniques based on a larger clinical sample size are needed to confirm our findings.

COMMENTS

Background

Although alterations in mucins have been observed in colorectal cancer, little is known about their expression during the development and progression of colorectal tumor. Mucinous and signet-ring cell carcinomas are the two types of colorectal cancer characterized by abundant mucin secretion. However, whether the mechanism underlying the tumorigenesis of mucinous and signet-ring cell carcinomas differs from that of other colorectal cancer remains controversial.

Research frontiers

Mucinous components, such as MUC2 and MUC5AC, are associated with the distinct clinical pathologic features of colorectal cancer and the survival rate of such patients.

Innovations and breakthroughs

The abnormal expression of MUC2 and MUC5AC in mucinous and signet-ring cell carcinomas suggests that a different process may be involved in the tumorigenesis of these types of colorectal cancer.

Terminology

Mucins are high-molecular-weight glycoproteins, which are heavily decorated with a large number of O-linked oligosaccharides and a few N-glycan chains, linked to a protein backbone. Mucins are known to play a central role in the protection, lubrication and hydration of the external surface of human epithelial tissue layers lining the intricate network of ducts and passageways. Mucins have also been implicated in the pathogenesis of benign and malignant diseases of secretory epithelial cells.

Applications

The clinical treatment of mucin-secreting tumor may differ from that of other types of colorectal cancer.

Peer review

This is a good paper that provides new data regarding MUC expression profiles in specific types of colorectal carcinoma.

Abstract

AIM: To evaluate the efficacy and safety of telbivudine (LDT) in hepatitis B e antigen (HBeAg)-positive chronic hepatitis B (CHB) patients who have high baseline alanine aminotransferase (ALT) levels between 10 and 20 times the upper limit of normal.

METHODS: Forty HBeAg-positive CHB patients with high baseline ALT levels between 10 and 20 times the upper limit of normal were enrolled and received LDT monotherapy for 52 wk. Another forty patients with baseline ALT levels between 2 and 10 times the upper limit of normal were included as controls. We compared the virological, biochemical, serological and side effect profiles between the two groups at 52 wk.

RESULTS: By week 52, the mean decrease in hepatitis B virus (HBV) DNA level compared with baseline was 7.03 $\log_{10}$ copies/mL in the high baseline ALT group and 6.17 $\log_{10}$ copies/mL in the control group, respectively ($P < 0.05$). The proportion of patients in whom serum HBV DNA levels were undetectable by polymerase chain reaction assay was 72.5% in the high baseline ALT group and 60% in the control group, respectively ($P < 0.05$). In addition, 45.0% of patients in the high baseline ALT group and 27.5% of controls became HBeAg-negative, and 37.5% of those in the high baseline group and 22.5% of controls, respectively, had HBeAg seroconversion ($P < 0.05$) at week 52. Moreover, in the high baseline group, 4 out of 40 patients (10%) became hepatitis B surface antigen (HBsAg)-negative and 3 (7.5%) of them seroconverted (became HBsAg-positive). Only 1 patient in the control group became HBsAg-negative, but had no seroconversion. The ALT normalization rate, viral breakthrough, genotypic resistance to LDT, and elevations in creatine kinase levels were similar in the two groups over the 52 wk.

CONCLUSION: High baseline ALT level is a strong predictor for optimal results during LDT treatment.

Key words: Chronic hepatitis B; Hepatitis B e antigen; Serum alanine aminotransferase level; Telbivudine

INTRODUCTION

Chronic infection with hepatitis B virus (HBV) affects

approximately 350 million people worldwide and is usually associated with continuing inflammatory activity and progression of liver diseases, which in turn lead to an increased risk of cirrhosis, decompensated liver disease, and hepatocellular carcinoma (HCC)[1,2]. Recently, several prospective follow-up studies of large cohorts of chronic hepatitis B (CHB) patients from Asia found that the presence of hepatitis B e antigen (HBeAg) and high levels of HBV DNA were independent risk factors for the subsequent development of advanced liver diseases[3]. Therefore, suppression of HBV replication is the main therapeutic goal in the treatment of CHB patients.

Up till now, seven drugs have been available for the treatment of CHB: they include conventional interferon α, pegylated interferon α, and nucleoside/nucleotide analogues (NUCs). NUCs for HBV therapy belong to three classes: L-nucleosides [lamivudine, telbivudine (LDT), emtricitabine], deoxyguanosine analogues (entecavir) and acyclic nucleoside phosphonates (adefovir and tenofovir). Lamivudine, adefovir, LDT, entecavir and interferon α have been approved in China for HBV treatment. LDT is an orally bioavailable L-nucleoside with potent and specific anti-HBV activity. It has been proved that LDT has a potent effect and a relatively high seroconversion rate for patients with CHB[4,5].

According to national and international guidelines, the antiviral treatment of patients with CHB is initiated when HBV DNA levels are above 2000 IU/mL and/or the serum alanine aminotransferase (ALT) levels are over 2 times the upper limit of normal (ULN), and liver biopsy shows moderate to severe active necroinflammation and/or fibrosis (e.g. at least A2F2 by METAVIR scoring)[6-8]. Many clinical trials have shown positive results of the antiviral treatments in hepatitis B patients with ALT levels between 2 and 10 times the ULN range. Nevertheless, a proportion of patients have serum ALT level over 10 times the ULN. There are few reports on the issue of whether to treat these patients right away or wait until a decline of ALT level. This paper summarizes the efficacy of LDT treatment in 40 hepatitis B patients with serum ALT level over 10 times the ULN range. We found that these patients obtained a better therapeutic effect when they received LDT treatment immediately.

MATERIALS AND METHODS

Patients and study design

This study was approved by the Ethics Review Committee of the First Affiliated Hospital, School of Medicine, Zhejiang University. All patients provided written informed consent before antiviral therapy was given. The diagnosis of CHB was made according to the diagnostic standard from the National Program for Prevention and Treatment of Viral Hepatitis[9]. All patients were diagnosed as CHB based on hepatitis B surface antigen (HBsAg) positivity for more than 6 mo. Forty HBeAg-positive CHB patients were enrolled in this study. All of them had ALT levels between 10 and 20 times the upper normal level. Another 40 HBeAg-positive CHB patients whose ALT level was between 2 and 10 times the ULN were recruited as controls. All 80 CHB patients had serum HBV DNA level > 10^5 copies/mL and had never received anti-HBV therapy before. Patients were given LDT 600 mg daily as initial antiviral treatment for at least 52 wk. Patients were excluded from this study if they were coinfected with human immunodeficiency virus, hepatitis C virus, hepatitis D virus, had liver cirrhosis or hepatic decompensation, pancreatitis, hepatocellular carcinoma, fatty liver or alcoholic hepatitis.

The present study focused on main therapeutic endpoints at 52 wk for CHB patients with high baseline ALT levels, including proportions of patients with non-detectable serum HBV DNA, serum ALT normalization, HBeAg and HBsAg seroconversion and LDT resistance. Resistance was defined as emergence of treatment-associated resistance mutations, identified by direct sequencing of the amplified HBV DNA at baseline and from sera of all patients with serum HBV DNA > 3 $\log_{10}$ copies/mL at week 52. Viral breakthrough was defined as persistent (two consecutive determinations) on-treatment increase of serum HBV DNA > 1 $\log_{10}$ copies/mL above nadir level[10].

Serum assay

Analyses of liver function, renal function and creatine kinase level were performed at baseline and at week 2, 4, 8, 12, 16, 24, 32, 36, 48 and 52 of LDT therapy using the Automatic Biochemistry analyzer (Hitachi 7600). HBsAg, HBeAg, anti-HBc, anti-HBe and anti-HBs were quantified using radioimmunoassay (Abbott Laboratories Ltd.). HBV DNA was measured using the Amplicor HBV Test (Roche Diagnostics, Basel, Switzerland) with a detection limit of 300 copies/mL. LTD-associated mutations were assessed by direct sequencing.

Statistical analysis

Quantitative data were presented as mean ± SD, categorical data were presented as counts and percentages, and HBV DNA levels were presented as log transformation. Data were analyzed using the SPSS software package version 13.0 (SPSS Inc., Chicago, IL, USA). Pearson chi-square or Fisher exact tests were used for categorical variables. In all cases, *P* values less than 0.05 were considered statistically significant.

RESULTS

Patients

Baseline characteristics for all 80 HBeAg-positive CHB patients are presented in Table 1. In the high baseline ALT CHB patient group, patients consisted of 29 males and 11 females, with ages ranging from 21 to 38 years (28.12 ± 3.71 years). Baseline data are as follows: the median level of serum HBV DNA was 7.78×10^7 copies/mL (range: 4.67×10^5-8.58×10^9 copies/mL), the median ALT level was 658.0 IU/L (range: 513.0-978.0 IU/L).

Virological response

By week 52, the mean decrease in HBV DNA level compared with baseline was 7.03 $\log_{10}$ copies/mL in the high

Table 1 Patient baseline characteristics

Variables	High baseline ALT group	Controls
Patients (*n*)	40	40
Male, *n* (%)	29 (72.5)	28 (70)
Age (yr, mean ± SD)	28.12 ± 3.71	31.12 ± 5.43
ALT (IU/L)	885.6 ± 7.89	128.4 ± 5.33
TBiL (μmol/L)	45.43 ± 6.67	29.12 ± 2.56
HBV DNA (copies/mL)		
Median	7.78×10^8	7.56×10^8
Range	4.67×10^5-8.58×10^9	5.89×10^5-7.34×10^9

ALT: Alanine aminotransferase; TBiL: Total bilirubin; HBV: Hepatitis B virus.

Table 2 Efficacy and safety at week 52 *n* (%)

Variables	High baseline ALT group	Controls	*P* value
Decrease in HBV DNA level (log_{10} copies/mL)	7.03	6.17	< 0.05
HBV DNA negative rate	29/40 (72.5)	24/40 (60)	< 0.05
ALT normalization rate	30/40 (75.0)	31/40 (77.5)	> 0.05
HBeAg negative rate	18/40 (45.0)	11/40 (27.5)	< 0.05
HBeAg seroconversion rate	15/40 (37.5)	9/40 (22.5)	< 0.05
HBsAg negative rate	4/40 (10.0)	1/40 (2.5)	< 0.05
HBsAg seroconversion rate	3/40 (7.5)	0	< 0.05
Viral breakthrough	2/40 (5.7)	3/40 (7.5)	> 0.05
Viral resistance	1/40 (2.9)	2/40 (5)	> 0.05
Increased blood creatine kinase	5/40 (12.5)	4/40 (10)	> 0.05

ALT: Alanine aminotransferase; HBV: Hepatitis B virus; HBeAg: Hepatitis B e antigen; HBsAg: Hepatitis B surface antigen.

baseline ALT group and 6.17 log_{10} copies/mL in the control group, respectively ($P < 0.05$). The proportion of patients in whom serum HBV DNA levels were undetectable by polymerase chain reaction assay was greater in the high baseline ALT group than in the control group (72.5% *vs* 60%, $P < 0.05$) as indicated in Table 2.

Serological response

At week 52, 45.0% of HBeAg-positive CHB patients in the high baseline ALT group and 27.5% ($P < 0.05$) of controls became HBeAg-negative, and 37.5% of those in the high baseline group and 22.5% of those in the control group had HBeAg seroconversion ($P < 0.05$). Moreover, in the high baseline group, 4 out of 40 patients (10%) became HBsAg-negative and 3 (7.5%) of them seroconverted (became HBsAb-positive). Only 1 patient in the control group became HBsAg-negative, but had no seroconversion (Table 2).

Biochemical response

At week 52, ALT normalization was achieved for 30 of the 40 patients (75.0%) in the high baseline ALT group and 31 of 40 patients (77.5%) in the control group ($P > 0.05$).

Resistance and side effects

As indicated in Table 2, viral breakthrough and genotypic resistance to LDT were similar between patients with high baseline ALT levels and controls. Resistance developed in 2.9% of patients with high baseline ALT levels and in 5% (2/40) of control patients. Consistent with previous reports, M204I was the only mutation associated with LDT resistance in this study. After the emergence of resistance, adefovir dipivoxil was added to treatment. Resistance patients are considered treatment failures in this study.

The frequencies of adverse events through week 52 were similar in both groups treated with LDT. Elevations in creatine kinase level through 52 wk were observed in 12.5% (5/40) of patients in the high baseline ALT group and in 10% (4/10) of controls, respectively. Grade 3 or 4 elevations in creatine kinase level (at least seven times the ULN) were found only in 1 patient in the high baseline ALT group and in 1 patient in the control group, respectively; levels decreased spontaneously during LDT treatment to normal within the next two visits (6 mo). No patients in either group stopped LDT treatment because of creatine kinase elevations in this study (Table 2).

DISCUSSION

The goal of therapy for hepatitis B is to improve quality of life and survival by preventing progression of the disease to cirrhosis, decompensated cirrhosis, end-stage liver disease, HCC and death. This goal can be achieved if HBV replication can be suppressed in a sustained manner, the accompanying reduction in histologic activity of chronic hepatitis lessening the risk of cirrhosis and decreasing the risk of HCC[11]. To date, two types of antiviral drugs can be used in the treatment of CHB: interferon and nucleoside/nucleotide analogs. In China, four types of nucleoside/nucleotide analogs (lamivudine, adefovir dipivoxil, entecavir and LDT) are available. Among them, LDT is potent and induces a relatively high seroconversion rate[12]. LDT has become widely used in anti-HBV therapy in China.

Besides serum HBV DNA levels and histological grade and stage of the liver disease, baseline ALT level of CHB patients is one of the determinants for the initiation of antiviral therapy. The antiviral effect of LDT is associated with the baseline ALT level, as in interferon and lamivudine therapy[13,14]. Taking HBeAg seroconversion as an example, 32% of patients with pretreatment ALT levels between 2 and 5 × ULN and 46% of those with ALT > 5 × ULN achieved HBeAg seroconversion after 2 years of treatment with LDT[5]. Our study focused, we believe for the first time, on the antiviral effect of LDT on HBeAg-positive patients whose baseline ALT level was 10-20 × ULN, showing the HBeAg seroconversion rate was 37.5% at 52 wk, which is the same as reported for peg-interferon therapy at 48 wk[15]. More encouragingly, our results also showed 7.5% (3/40) patients had HBsAg seroconversion at 52 wk after LDT treatment.

The main mechanism of ALT elevation in CHB patients is the activated immune response to eliminate HBV, which theoretically shows the positive association between ALT level and the degree of inmune activation. High baseline ALT level has been shown to be independently associ-

ated with an increased rate of HBeAg response after either interferon or NUC treatment[16,17]. In the present study, our results clearly showed that increased serum baseline ALT levels predict a higher HBeAg seroconversion when patients are treated with LDT.

HBeAg has been recognized as a successful serologic marker in the treatment of HBeAg-positive CHB[18]. Compared with other NUCs, LDT has a relatively high seroconversion rate. Whether this is related to its immune regulation ability needs further exploration. Evans *et al*[19] reported the relatively low expression of programmed death-1 receptor on CD8+ T cells in HBeAg-positive CHB patients who received LDT therapy and had HBeAg seroconversion, compared with those counterparts who did not achieve HBeAg seroconversion.

Entecavir and tenofovir are potent HBV inhibitors and they have a high barrier to resistance. They are widely used as first-line monotherapies in developed countries. However, in China tenofovir is not available yet, and entecavir is expensive for most patients. LDT and lamivudine are still widely used. In order to reduce the incidence of resistance to these drugs, optimal treatment has been used in clinical practice. For example, pretreatment serum HBV DNA $< 10^9$ $\log_{10}$ copies/mL and ALT levels $\geqslant 2 \times$ ULN for HBeAg-positive patients were shown to be associated with a high rate of non-detectable HBV DNA, a high rate of HBeAg seroconversion and lower resistance to LDT treatment after 2 years[5]. Our study also proved that if we select the right patients to treat with LDT, there will be optimal conditions to achieve the desired results. Taken together, if baseline serum HBV DNA $< 10^9$ $\log_{10}$ copies/mL and ALT levels $\geqslant$ 2-20 $\times$ ULN for HBeAg-positive patients, we can consider the administration of LDT treatment in daily clinical practice.

In conclusion, our results indicate relatively higher HBeAg and HBsAg seroconversion in HBeAg-positive CHB patients whose baseline ALT levels were 10-20 $\times$ ULN and who received LDT monotherapy immediately. In addition, there were no significant differences in safety between these patients and their counterparts with lower ALT levels. We suggest that this treatment strategy deserves clinical application.

COMMENTS

Background

There is a proportion of chronic hepatitis B (CHB) patients with serum alanine aminotransferase (ALT) levels over 10 times the upper limit of normal. There are few reports regarding the issue of treatment for these patients, whether to treat them right away or whether to wait until the decline of ALT level.

Research frontiers

In China tenofovir is not available yet, and entecavir is expensive for most patients. Telbivudine (LDT) and lamivudine are still widely used. In order to reduce the incidence of resistance to these drugs, optimal treatment has been used in clinical practice. However, how to select optimally for LDT has not been unequivocally addressed. In this study, the authors demonstrate relatively high hepatitis B e antigen (HBeAg) and hepatitis B surface antigen (HBsAg) seroconversion in HBeAg-positive CHB patients whose baseline ALT levels were 10-20 times the upper limit of normal (× ULN) and who received LDT monotherapy immediately.

Innovations and breakthroughs

Recent reports have highlighted the importance of baseline characteristics, such as serum hepatitis B virus (HBV) DNA level, ALT level and histological grade and stage, in antiviral therapy. This is the first study to report the antiviral effect of LDT on HBeAg-positive patients whose baseline ALT level was 10-20 × ULN, showing the HBeAg seroconversion rate was 37.5% at 52 wk. More encouragingly, our results also showed 7.5% (3/40) patients had HBsAg seroconversion at 52 wk after LDT treatment.

Applications

By understanding that the antiviral results are related to the baseline ALT levels in addition to HBV DNA titer, this study may represent a future strategy for therapeutic intervention in CHB patients with high baseline ALT level.

Terminology

ALT is a common indicator of liver damage and is one of the key predictors of initiation of antiviral therapy. This study suggests that high baseline ALT level is a strong predictor for optimal results during LDT treatment.

Peer review

This study shows favorable results in patients with high baseline ALT values. The authors conclude that in patients with high baseline ALT levels antiviral treatment with LDT should be started immediately.

Abstract

AIM: To investigate the effects and mechanism of disruption of focal adhesion kinase (*FAK*) expression on collagen metabolism in rat hepatic stellate cells (HSC).

METHODS: The plasmids expressing *FAK* short hairpin RNA (shRNA) were transfected into HSC-T6 cells, and the level of *FAK* expression was determined by both real-time quantitative polymerase chain reaction (Q-PCR) and Western blotting analysis. The production of type Ⅰ collagen and type Ⅲ collagen in *FAK*-disrupted cells was analyzed by real-time Q-PCR. The level of collagen metabolism proteins, including matrix metalloproteinases-13 (MMP-13) and tissue inhibitors of metalloproteinases-1 (TIMP-1) was also determined by both real-time Q-PCR and Western blotting analysis.

RESULTS: The transfection of *FAK* shRNA plasmids into HSC resulted in disrupted *FAK* expression. Compared with the HK group, the levels of type Ⅰ collagen and type Ⅲ collagen mRNA transcripts in *FAK* shRNA plasmid group were significantly decreased (0.69 ± 0.03 *vs* 1.96 ± 0.15, $P = 0.000$; 0.59 ± 0.07 *vs* 1.62 ± 0.12, $P = 0.020$). The production of TIMP-1 in this cell type was also significantly reduced at both mRNA and protein levels (0.49 ± 0.02 *vs* 1.72 ± 0.10, $P = 0.005$; 0.76 ± 0.08 *vs* 2.31 ± 0.24, $P = 0.000$). However, the expression of MMP-13 mRNA could be significantly up-regulated by the transfection of *FAK* shRNA plasmids into HSC (1.74 ± 0.20 *vs* 1.09 ± 0.09, $P = 0.000$).

CONCLUSION: These data support the hypothesis that shRNA-mediated disruption of *FAK* expression could attenuate extracellular matrix (ECM) synthesis and promote ECM degradation, making *FAK* a potential target for novel anti-fibrosis therapies.

INTRODUCTION

Liver fibrosis results from excessive deposition of extracellular matrix (ECM) components[1]. These components, which are mainly composed of type I collagen and type Ⅲ collagen, are produced by hepatic stellate cells (HSC). The activation, proliferation and migration of HSC play a central role in liver fibrogenesis[2,3]. Activated HSCs are the main producers of collagens and matrix metalloproteinases (MMPs) in the fibrotic liver. The MMP which is able to degrade type I collagen and type Ⅲ collagen is MMP-13. However, this can be specifically inhibited by tissue inhibitors of metalloproteinases-1 (TIMP-1), and its level is found to be high in the fibrotic liver of rats.

Focal adhesion kinase (FAK) is a non-receptor protein tyrosine kinase, whose phosphorylation can promote the proliferation and collagen synthesis of HSC[4-8]. It had previously been shown that when FAK related non-kinase (FRNK) plasmids were transfected into fibronectin (FN)-stimulated HSC using liposome transfection, the over-expression of FRNK significantly decreased the collagen synthesis of HSC *in vitro*[9,10]. This led us to speculate that suppression of FAK expression may provide a new target in the treatment of liver fibrosis.

To date, RNA interference has been the most effective gene silencing technology. It can specifically inhibit the transcription of target genes, and in turn reduce the expression and function of the corresponding proteins[11]. We aim to inhibit FAK expression by transfecting FAK short hairpin RNA (shRNA) plasmids into HSC. To our knowledge, this is the first report that FAK expression is specifically inhibited in HSC cells. This allows us to further analyze the role of FAK in collagen synthesis and degradation in this cell type, and find out how FAK regulates the expression of MMP-13 and TIMP-1.

MATERIALS AND METHODS

Reagents

The shRNA-expressing plasmids, pEGFP-*FAK* shRNA, were purchased from Wuhan Genesil Biotechnology Co. Ltd. (Wuhan, China). One additional plasmid, p-EGFP-HK, was used to express nonsense shRNA and served as the control. Sofast™ Transfection Reagent was purchased from Xiamen Sunma Biological Engineering Co. Ltd. (Xiamen, China).

Cell line and cell culture

The cell line HSC-T6, which is the phenotypically activated HSC, was donated by Professor Xu LM, from Hepatopathy Institute of Shanghai University of Traditional Chinese Medicine. HSCs were cultured in HG-DMEM medium supplemented with 8% FBS, 100 IU/mL penicillin, 100 g/mL streptomycin, 4 mmol/L glutamine and 1 mol/L HEPES. Cells were cultured in a 5% CO_2 humidified incubator at 37℃. All experiments were conducted when cells were at an exponential stage of growth. Cells were seeded into a 25 cm^2 plastic culture flask with a total of 2-3 × 10^5 cells or were seeded in 96-well plates to a density of 3 × 10^4/mL × 200 μL/well. When cells were approximately 70%-80% confluent, shRNA plasmid was transfected into FN-stimulated HSC using a cationic polymer. The cells were divided into five groups: (1) blank control group (control); (2) FN stimulation group (FN); (3) transfection reagent group (Sofast); (4) pEGFP-HK shRNA group (HK); and (5) pEGFP-*FAK* shRNA group (*FAK* shRNA). FN was added to groups 2-5 at a concentration of 10 mg/L.

Efficiency of transfection

At 48 h after transfection, the cells were analyzed by fluorescence microscopy and flow cytometry (FCM) to obtain the efficiency of transfection.

Semiquantitative real-time quantitative polymerase chain reaction

The expressions of the gene *FAK*, *type I collagen* and *type Ⅲ collagen*, *MMP-13* and *TIMP-1* were characterized by semiquantitative real-time quantitative polymerase chain reaction (Q-PCR). Briefly, total RNA was extracted from the cells that had been transfected with the plasmid expressing the *FAK* or HK shRNA and reversely transcripted into cDNA, which was used as the template for PCR. Using the primer design software, Primer Express 2.0, the specific primers for each gene were synthesized by Beijing Saibaisheng Gene Technique Co., Ltd. and the following primers were generated: *FAK*-Forward 5'-ACTTGGACGCTGTATTGGAG-3', *FAK*-Reverse 5'-CTGTTGCCTGTCTTCTGGAT-3' (833 bp amplicon); Collagen type I -Forward 5'-TACAGCACGCTTGTGGATG-3', Collagen type I -Reverse 5'-TTGAGTTTGGGTTGTTGGTC-3' (256 bp amplicon); Collagen type Ⅲ-Forward 5'-ATGGTGGCTTTCAGTTCACC-3', Collagen type Ⅲ-Reverse 5'-TGGGGTTTCAGAGAGTTTGG-3' (425 bp amplicon); MMP-13-Forward 5'-GCGGGAATCCTGAAGAAGTCTAC-3', MMP-13-Reverse 5'-TTGGTCCAGGAGGAAAAGCG-3' (424 bp amplicon); TIMP-1-Forward 5'-TCCCCAGAAATCATCGACAC-3', TIMP-1-Reverse 5'-ATCGCTGAACAGGGAAACAC-3' (329 bp amplicon); *GAPDH*-Forward 5'-GAGGACCAGGTTGTCTCCTG-3', *GAPDH*-Reverse 5'-GGATGGAATTGTGAGGGAGA-3' (298 bp amplicon). Reaction system: 10 μL 2.5 × real master Mix, 1.25 μL 20 × SYBR solution, 0.5 μL upstream primer, 0.5 μL downstream primer and 2 μL DNA template were brought up to 25 μL with purified water. Reaction conditions: 93℃ 5 min, 1 cycle; 93℃ 45 s, 55℃ 1 min, 10 cycles; 93℃ 30 s, 55℃ 45 s, 30 cycles. The PCR reactions were subjected to 93℃ for 5 min, 1 cycle; and then 10 cycles of 93℃ 45 s, 55℃ 1 min, and 30 cycles of 93℃ 30 s, 55℃ 45 s. The size and quantity of amplified prod-

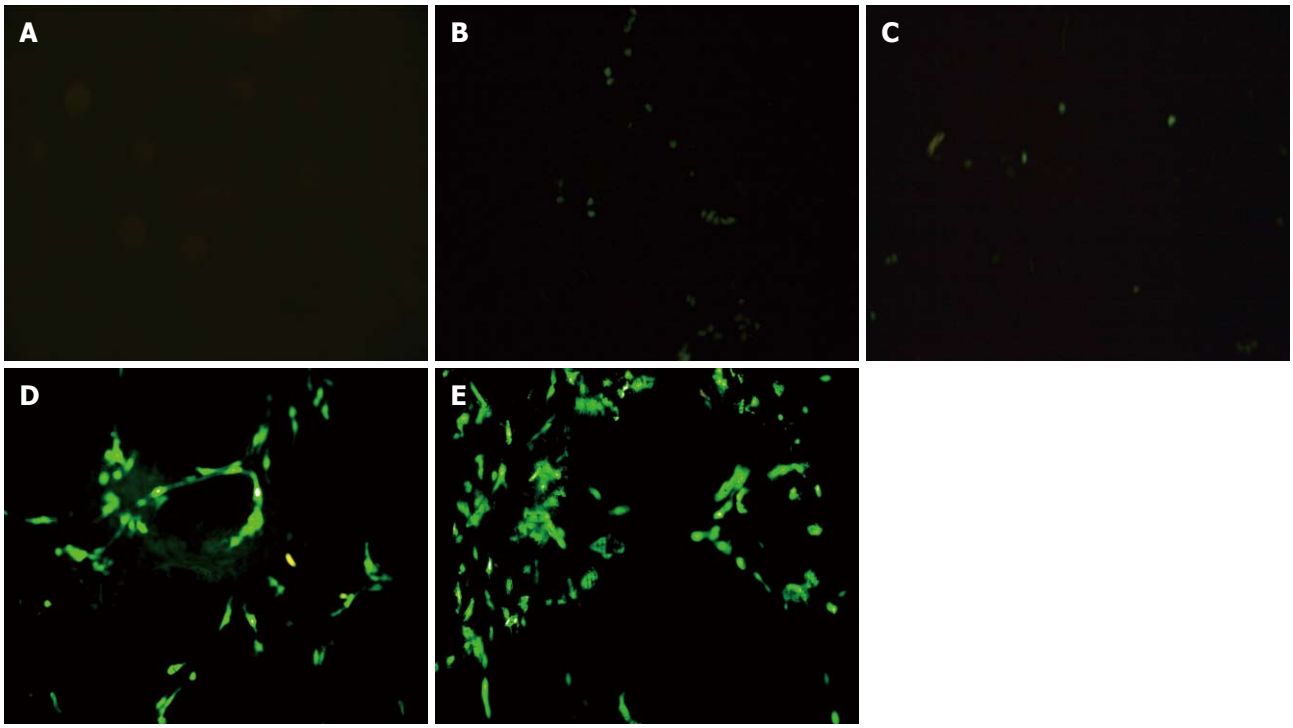

Figure 1 Expression of enhanced green fluorescent protein at 48 h after treatment (fluorescent images, original magnification × 200). A: Control group; B: Fibronectin group; C: Sofast group; D: HK group; E: Focal adhesion kinase (FAK) short hairpin RNA group. *FAK* short hairpin RNA plasmids were successfully transfected into hepatic stellate cells. The results from fluorescence microscopy and flow cytometry showed that the transfection efficiency was 40% at 48 h.

ucts were confirmed by 2% agarose gel electrophoresis. Fluorescent quantitative analysis was performed with the thermal cycler's software package to calculate the ΔCt value. The expression levels of *FAK*, type I collagen and type Ⅲ collagen, *MMP-13* and *TIMP-1* were calculated by the $2^{-\Delta\Delta Ct}$ analysis. The $2^{-\Delta\Delta Ct}$ was presented as the relative expression of the gene expression[12].

Western blotting

At 24 or 48 h after transfection of *FAK* shRNA, HSCs were harvested, washed with phosphate-buffered saline (PBS), and lysed in the improved RIPA buffer (50 mmol/L Tris-HCL, pH 7.5; 100 mmol/L NaCl; 1% NP-40; 0.5% sodium deoxycholate; 2 μg/mL leupeptin; 1% SDS; 2 mmol/L EDTA; 1 mmol/L PMSF; 50 mmol/L HEPES; 1 mmol/L sodium orthovanadate). The supernatant was collected and the protein concentration was determined using comassie brilliant blue assay. Cell extracts containing equal quantities of proteins (100-110 μg) were electrophoresed in 8% or 10% polyacrylamide gel. Subsequently, the separated proteins were transferred to nitrocellulose membrane. The membrane was blocked for non-specific binding for 30 min (5% skimmed milk in PBS), and then incubated overnight at 4℃ with rabbit anti-FAK polyclonal antibody (1:400), rabbit anti-MMP-13 polyclonal antibody (1:200), rabbit anti-TIMP-1 polyclonal antibody (1:200) or mouse anti–GAPDH monoclonal antibody (1:100). The membrane was subsequently incubated at room temperature for 2 h with goat anti-rabbit IgG (1:2000). Blots were developed with enhanced chemiluminescence detection reagents (Santa Cruz Biotechnology Inc.), exposed on Kodak Xdmat blue XB-1 film and quantified by Bandscan 5.0 software using GAPDH as internal control. Densitometry is reported using the integral optical density value (IOD). The results were represented in the form of IOD ratio of the target protein to GAPDH.

Statistical analysis

All the data were expressed by mean ± SD and analyzed with SPSS 13.0 software. The comparison of mean variability among all groups was conducted by one-way ANOVA analysis and two group comparison with LSD test. Student's *t* test was carried out for independent samples. Statistical significance was considered at $P < 0.05$.

RESULTS

Expression of FAK effectively down-regulated by FAK shRNA in HSC

FAK shRNA plasmids were successfully transfected into HSC. The results from fluorescence microscopy and FCM showed that the transfection efficiency was 40% at 48 h (Figure 1). The levels of *FAK* mRNA transcripts and protein expression were determined by real-time Q-PCR and Western blotting analysis. The expression of *FAK* mRNA and FAK protein in the FN group was significantly higher than that of the control group, $P = 0.000$ and $P = 0.024$, respectively. There was no difference between the FN group, Sofast group and HK group. In comparison with the HK group, the expression of *FAK* mRNA and FAK

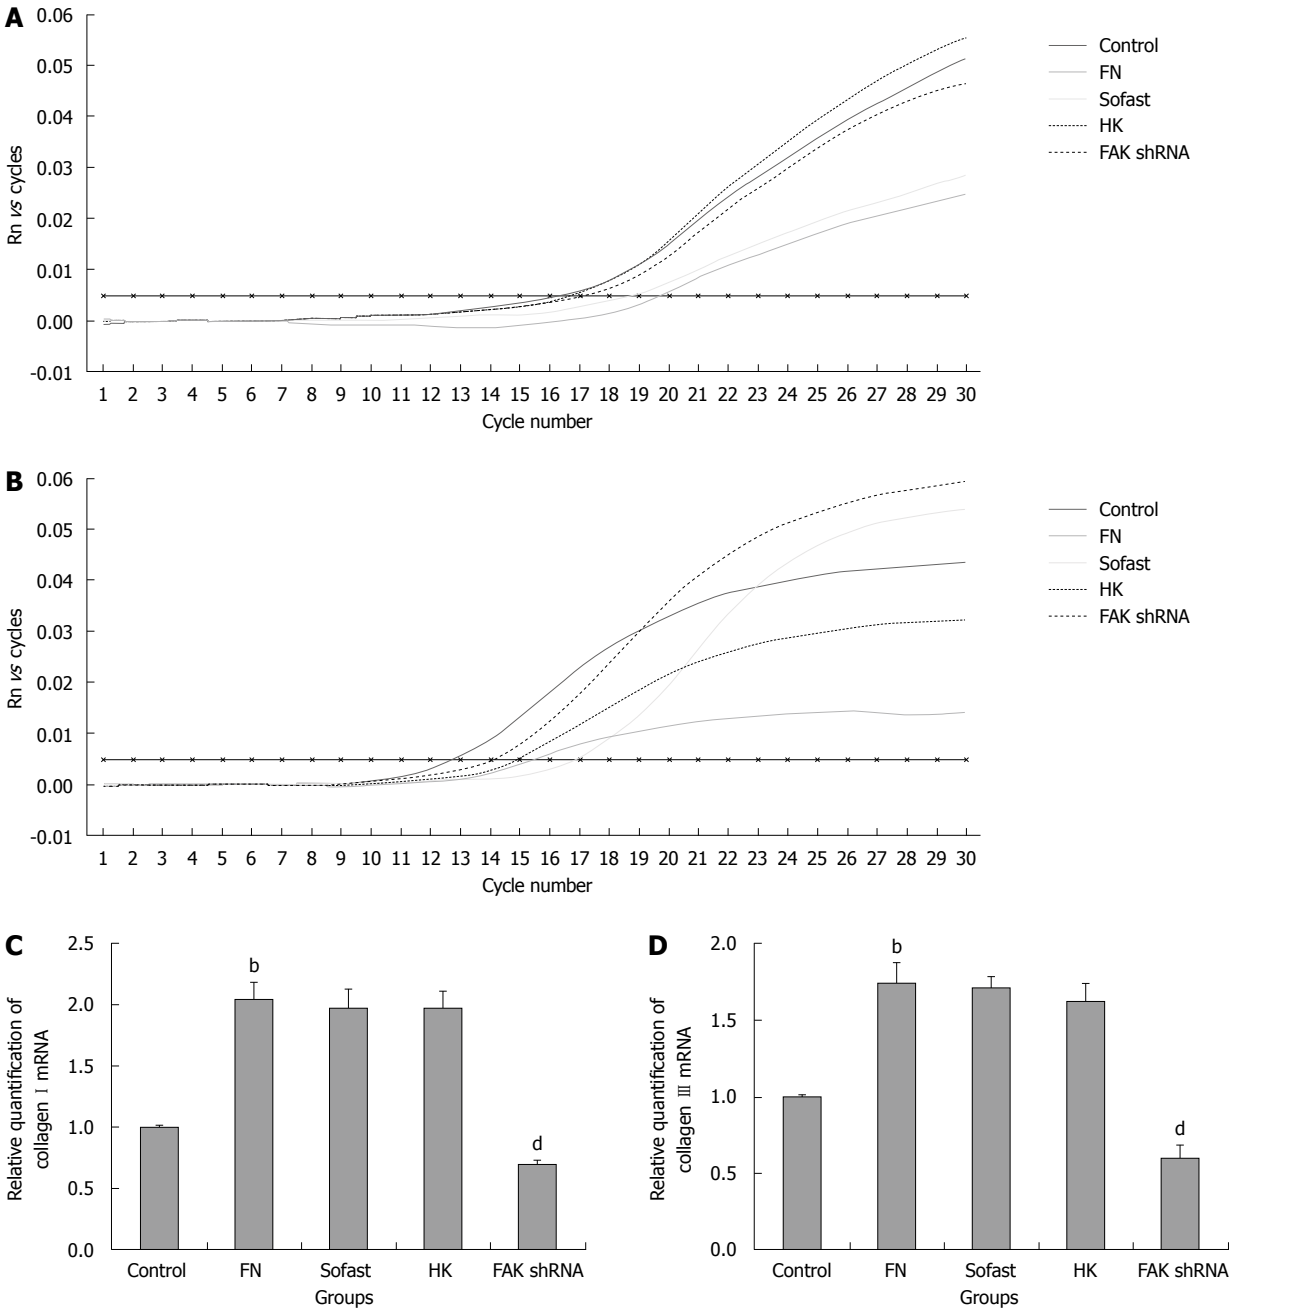

Figure 2 Focal adhesion kinase short hairpin RNA selectively inhibited the expressions of collagen Ⅰ mRNA and collagen Ⅲ mRNA in hepatic stellate cells after focal adhesion kinase short hairpin RNA transfection. A, B: Real-time polymerase chain reaction SYBR Green Ⅰ fluorescence history *vs* cycle number of target gene 1 (collagen Ⅰ, A) and target gene 2 (collagen Ⅲ, B) in sample cDNA. The cycle threshold (Ct) is shown by the darker horizontal line; C, D: The relative quantification of collagen Ⅰ mRNA (C) and collagen Ⅲ mRNA (D) are calculated according to $2^{-\Delta\Delta C(t)}$, [$\Delta\Delta$Ct = ($Ct_{Collagen\ I\ or\ III}$ - Ct_{GAPDH}) experimental group - ($Ct_{Collagen\ I\ or\ III}$ - Ct_{GAPDH}) control group] and shown in the bar graphs (n = 3, ^{b}P < 0.01 *vs* control, ^{d}P < 0.01 *vs* HK). It showed that the levels of type Ⅰ collagen and type Ⅲ collagen mRNA transcripts in fibronectin (FN) group was significantly higher than in the control group. FAK: Focal adhesion kinase; shRNA: Short hairpin RNA.

protein in the *FAK* shRNA plasmid group was significantly decreased (0.37 ± 0.03 *vs* 1.59 ± 0.06, P = 0.000; 0.77 ± 0.03 *vs* 2.24 ± 0.20, P = 0.000), and the rates of down-regulation were 70.51% and 72.53%, respectively.

Effects of FAK by shRNA on the collagen synthesis in HSC

Investigation was carried out in the influence of disruption of FAK expression mediated by *FAK* shRNA on ECM synthesis in HSC. The levels of type Ⅰ collagen and type Ⅲ collagen mRNA transcripts were determined by real-time Q-PCR. The levels of type Ⅰ collagen and type Ⅲ collagen mRNA transcripts in FN group were significantly higher than that of the control group. The levels of type Ⅰ collagen and type Ⅲ collagen mRNA transcripts in *FAK* shRNA plasmid group were significantly decreased compared with the HK group (0.69 ± 0.03 *vs* 1.96 ± 0.15, P = 0.000; 0.59 ± 0.07 *vs* 1.62 ± 0.12, P = 0.020) and the down-regulated rates were 64.80% and 63.58%, respectively (Figure 2).

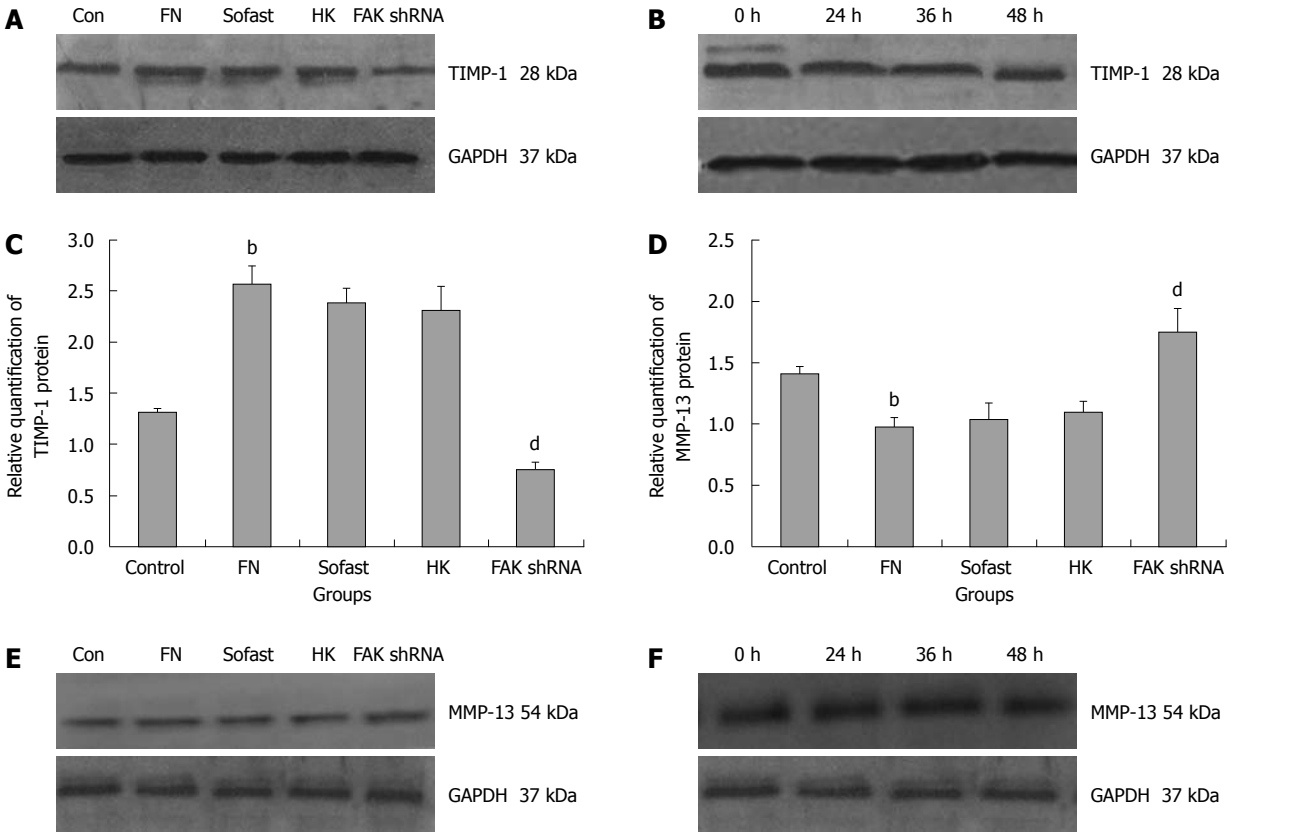

Figure 3 Focal adhesion kinase short hairpin RNA specifically inhibits the expressions of tissue inhibitors of metalloproteinases-1 protein and promotes the expressions of matrix metalloproteinases-13 protein in hepatic stellate cells. A: Cells were harvested, lysed and total protein extracts were separated by SDS-PAGE and analyzed by Western blotting with polyclonal anti-tissue inhibitors of metalloproteinases-1 (TIMP-1) antibody. GAPDH served as a loading control; B: Western blotting analysis was used to detect the expressions of TIMP-1 at different time points; C: TIMP-1 expression levels obtained from scanning densitometry were expressed as a ratio of integral optical density value (IOD) TIMP-1/IOD GAPDH (n = 3, $^{b}P < 0.01$ *vs* Con, $^{d}P < 0.01$ *vs* HK); D: Matrix metalloproteinases-13 (MMP-13) expression levels obtained from scanning densitometry were expressed as a ratio of IOD MMP-13/IOD GAPDH (n = 3, $^{b}P < 0.01$ *vs* Con, $^{d}P < 0.01$ *vs* HK); E, F: Western blotting analysis was carried out at different groups (E) and different time points (F) using polyclonal anti-MMP-13 antibody and monoclonal anti-GAPDH antibody. FN: Fibronectin; FAK: Focal adhesion kinase; shRNA: Short hairpin RNA.

Effects of FAK by shRNA on the collagen degradation in HSC

To further explore the effects of *FAK* shRNA on the ECM degradation in HSC, the levels of MMP-13 and TIMP-1 were determined by real-time Q-PCR and Western blotting analysis. The transfection of HK shRNA did not modulate the levels of MMP-13 and TIMP-1, the cells expressing HK shRNA were similar to that in FN group and Sofast group, $P > 0.05$. However, the knockdown of FAK expression by the *FAK* shRNA significantly reduced the levels of *TIMP-1* mRNA and TIMP-1 protein (0.49 ± 0.02 *vs* 1.72 ± 0.10, $P = 0.005$; 0.76 ± 0.08 *vs* 2.31 ± 0.24, $P = 0.000$), and the down-regulated rates were 69.78% and 67.10%, respectively (Figure 3A-C). The results of real-time Q-PCR and Western blotting analysis showed that the levels of MMP-13 of FN group were significantly down-regulated compared with that of control group. Compared with the HK group, the expression of MMP-13 mRNA was significantly up-regulated by 56.96% at 36 h after transfection of *FAK* shRNA plasmids into HSC (1.24 ± 0.04 *vs* 0.79 ± 0.03, $P = 0.020$), and the expression of MMP-13 protein could be increased by 59.63% at 48 h after transfection (1.74 ± 0.20 *vs* 1.09 ± 0.09, $P = 0.000$) (Figure 3D-F).

DISCUSSION

The current knowledge on the pathophysiology of liver fibrogenesis refers to the increased synthesis and decreased degradation of ECM, mainly type I collagen and type Ⅲ collagen, thereby ECM was overproduced and deposited in the liver. Although several hepatic cell types can synthesize ECM proteins, HSCs are the major source of increased ECM in chronic liver diseases. They can undergo a proliferative and phenotypic change. Excessive deposition of ECM, mainly type I collagen and type Ⅲ collagen, results in liver fibrosis; and the up-regulation of TIMPs blocks activity of MMPs and inhibits the degradation of ECM, thereby aggravating liver fibrosis.

The interaction of HSC and ECM mainly lies between integrins, and FAK plays an integral role in the integrin signal pathway. Activated FAK has been implicated in a diverse array of cellular behaviors, such as cell proliferation[4,5], apoptosis, cell migration[6], collagen metabolism[7,8] and the transfer of tumor cells. It is closely related to numerous fibrotic diseases and it plays a vital role in the occurrence and development of liver fibrosis[13]. This is consistent with our previous studies, which indicated that FAK phosphorylation could promote collagen synthesis

of HSC *in vivo*. Furthermore, using *in vitro* cell culture techniques, we found that the synthesis of total collagen and type I collagen in HSC could be inhibited by the endogenous inhibitor FRNK[9]. We hypothesized that FAK gene silencing may represent a novel method for the treatment and reversal of liver fibrosis. Therefore, in this study, *FAK* shRNA plasmids were transfected into HSC transiently to test our hypothesis, and the expressions of FAK mRNA and FAK protein were significantly decreased, the down-regulation rates being 70.51% and 72.53%, respectively. We have found that *FAK* shRNA can effectively and specially suppress the expression of FAK.

A substantial change in liver fibrosis or liver cirrhosis is the deposition of ECM, which is mainly composed of type I collagen and type Ⅲ collagen, covering approximately 80%-90% of the increased total collagen. The increase of type I collagen and type Ⅲ collagen is an important symbol of liver fibrosis or liver cirrhosis. Therefore, in this study, *FAK* shRNA plasmids were transfected into FN-stimulated HSC transiently and the expression of type I collagen mRNA and type Ⅲ collagen mRNA was significantly down-regulated by 64.80% and 63.58%, respectively. These data show that *FAK* shRNA can effectively suppress the synthesis of collagen and *FAK* gene silencing may, therefore, represent a novel direction for the treatment and reversal of liver fibrosis.

Furthermore, we attempted to assess the role of FAK in the regulation of collagen metabolism in HSC. In the liver, ECM is regulated by MMPs and their specific inhibitors, TIMPs. A principal feature of hepatic fibrosis is a disturbance in the balance between MMPs and TIMPs. Collagenases such as MMP-1 and MMP-13 are able to degrade fibrillar collagens, mainly type Ⅰ, Ⅱ and Ⅲ collagen. These may be responsible for key events in the degradation of ECM. MMP-13 is the interstitial collagenase in rats and its specific inhibitor is TIMP-1. Although the expression of MMP-13 was increased in the liver tissues of CCl_4-induced rat liver fibrosis models, fibrosis still occurred as there was also a corresponding increase in the expression of TIMP-1[14]. This strongly suggests that a disruption in the balance between MMP-13 and TIMP-1 is possibly an important factor in liver fibrogenesis[15]. According to some studies, FAK is closely related to the expression of TIMP-1 and MMP-13[16,17]. In this study, *FAK* shRNA plasmids were transfected into FN-stimulated HSC transiently and the expression of MMP-13 mRNA and MMP-13 protein was significantly up-regulated by 56.96% and 59.63%. Correspondingly, the levels of TIMP-1 mRNA and TIMP-1 protein were significantly down-regulated by 69.78% and 67.10%, respectively. *FAK* shRNA inhibited the ratio of TIMP-1/MMP-13 expression in mRNA and protein levels in HSC after transfection. The data indicate that *FAK* shRNA regulated the collagen metabolism in HSC by disturbing the balance between MMP-13 and TIMP-1.

In summary, we have effectively disrupted the expression of FAK by *FAK* shRNA. The knockdown of FAK expression significantly reduced the synthesis of type I collagen and type Ⅲ collagen, which may be related to the up-regulation of MMP-13 and down-regulation of TIMP-1. These data support the hypothesis that *FAK* disruption by shRNA may be an efficient and specific approach for treatment of liver fibrosis. Future studies will address the signal transduction pathway by which FAK regulates the collagen metabolism in HSC.

COMMENTS

Background

Focal adhesion kinase (FAK) plays an essential role in the activation of hepatic stellate cells (HSCs) which are the major source of collagens and matrix metalloproteinases in the fibrotic liver. Liver fibrosis results from excessive deposition of extracellular matrix components, composed of mainly type Ⅰ collagen produced by HSC.

Research frontiers

The central events in the liver fibrogenesis have been proved to be the activation, proliferation and migration of HSC, and their proliferation and collagen synthesis are promoted by phosphorylation of FAK, a non-receptor protein tyrosine kinase. In the area of knockdown or inhibition of FAK with various molecular biological technologies, an area of intense research is to establish a method to knockdown or inhibit FAK expression thoroughly so as to enhance the collagen metabolism.

Innovations and breakthroughs

Recent reports have highlighted the importance of HSC including activation, proliferation and migration in pathogenesis of liver fibrosis. The collagen metabolism in HSC, particular in activated HSC, is currently an area of intense research. This is the first study to report that shRNA-mediated disruption of *FAK* expression can attenuate extracellular matrix (ECM) synthesis and promote ECM degradation. This represents a potential target for novel anti-fibrosis therapies.

Applications

The results of this study indicated that suppression of *FAK* expression may represent a novel method and direction for the treatment and reversal of hepatic fibrosis.

Peer review

The study focuses on modification of hepatic stellate cell metabolism by shRNA mediated inhibition of FAK, a non-receptor protein tyrosine kinase involved in proliferation and collagen synthesis. The authors demonstrate that FAK inhibition is associated with a decrease in collagen synthesis by HSCs.

Abstract

Coinfection with hepatitis B virus (HBV) is not uncommon in human immunodeficiency virus (HIV)-infected individuals and patients with HIV-HBV coinfection are at high risk for progression of liver disease. Current guidelines regarding the treatment of HIV infection recommend that patients who are coinfected with HIV and HBV receive highly active antiretroviral therapy (HAART) with activity against hepatitis B. While HIV-HBV coinfected patients often experience liver enzyme elevations after starting antiretroviral therapy, acute liver failure (ALF) is rare and typically occurs with older antiretroviral agents with known potential for hepatotoxicity. We describe two cases of fatal ALF in the setting of HIV-HBV coinfection after initiation of HAART. These cases occurred despite treatment with antiretrovirals that have activity against HBV and highlight the challenges in distinguishing drug hepatotoxicity and HBV immune reconstitution inflammatory syndrome. HIV-HBV coinfected patients should be monitored closely when initiating HAART, even when treatment includes agents that have activity against HBV.

Key words: Hepatitis B virus; Human immunodeficiency virus; Liver failure

INTRODUCTION

It is estimated that 10% of human immunodeficiency virus (HIV)-infected patients in the United States and Europe are chronically coinfected with hepatitis B virus (HBV)[1,2]. In other regions, rates of HBV coinfection in HIV-infected patients may be even higher[3]. HIV-HBV coinfected patients have higher rates of liver-related morbidity and mortality compared to patients infected with either virus alone[4,5]. Therefore, current guidelines suggest that HIV-infected patients with HBV infection should be treated with a highly active antiretroviral therapy (HAART) regimen that is also active against HBV[6]. However, HIV-HBV coinfected patients are particularly susceptible to certain complications of HAART. The vast majority of antiretroviral medications have been associated with some degree of hepatotoxicity and the presence of HBV infection is an independent risk factor for the development of clinically significant hepatotoxicity[7-9]. Additionally, coin-

fected patients are at risk for HBV immune reconstitution inflammatory syndrome (IRIS), which is characterized by a paradoxical hepatitis flare corresponding to an initial improvement in plasma HIV RNA level and CD4+ T-cell count on HAART[10]. Overall, liver enzyme elevations in HIV-HBV coinfected patients after starting HAART are not uncommon, but acute liver failure (ALF) is rare[11]. Reported cases have typically involved treatment with older thymidine analogue drugs such as stavudine and didanosine[12]. We describe two cases in which fatal ALF occurred in patients with HIV-HBV coinfection after beginning HAART regimens which did not include thymidine analogues but which did have activity against HBV.

CASE REPORT

Patient A

A 42-year-old African-American male with longstanding HIV/HBV coinfection was seen in clinic. He had been diagnosed with HIV infection over 10 years previously but had been on antiretrovirals for only short periods since diagnosis. As a result, his CD4+ T-cell count had reached a nadir of 5 cells/μL (1%) with a plasma HIV RNA level of 51 230 copies/mL. His plasma HBV DNA level was 147 million IU/mL. Both hepatitis B endogenous antigen (HBeAg) and anti-HBe antibody were negative. He was started on a new regimen of ritonavir-boosted atazanavir, lamivudine, and abacavir. At that time, his alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels were both slightly elevated at 94 U/L (normal range 17-63 U/L) and 73 U/L (normal range 10-42 U/L), respectively, with a normal bilirubin level. The patient had never undergone a liver biopsy. Eight weeks after starting therapy, he returned to clinic with nausea, vomiting, and jaundice. The ALT level had increased to 1352 U/L and the AST was 1765 U/L. Total bilirubin was 14.1 mg/dL, direct bilirubin was 8.9 mg/dL, and prothrombin time was 18.9 s (INR 1.62). HIV RNA level had decreased to 100 copies/mL. He was admitted to the hospital for further workup. The patient did not drink alcohol and acetaminophen level was undetectable. Hepatitis C virus (HCV) RNA was undetectable, hepatitis D virus (HDV) antibody was negative, and hepatitis A virus (HAV) IgM was negative. HBV DNA had decreased to 4.42 million IU/mL. Antinuclear antibody screen was negative. All medications were held for 48 h. His ALT and AST levels decreased to 992 U/L and 1505 U/L. The appearance of the liver was normal on computed tomography of the abdomen with no suggestion of cirrhosis or portal hypertension. He was then discharged after starting a new regimen of ritonavir-boosted fosamprenavir, emtricitabine, and tenofovir. Ten days later he was re-admitted to the hospital with nausea, vomiting, and abdominal pain. ALT and AST levels had risen to 1214 U/L and 1992 U/L. Total bilirubin was 29.5 mg/dL, direct bilirubin was 18.3 mg/dL, and prothrombin time was 35.4 s (INR 3.19). HBV DNA level had decreased to 83 100 IU/mL. The ritonavir and fosamprenavir were discontinued and he was continued on emtricitabine/tenofovir. A liver biopsy showed marked septal fibrosis with nodule formation that was consistent with cirrhosis (Figure 1A and B). There was a severe mixed inflammatory infiltrate in portal and periportal areas containing lymphocytes, plasma cells and scant eosinophils (Figure 2A). The liver eosinophils were readily identified and no other special stains such as sirius red were used. Peripheral blood eosinophil count was within normal limits. Severe piecemeal necrosis was present diffusely around most of the portal tracts linking some of them together in so-called bridging necrosis (Figure 2B). After 10 d, his ALT and AST levels had come down to 405 U/L and 758 U/L, but total and direct bilirubin remained elevated at 28.8 mg/dL and 13.6 mg/dL. Due to concern for creating HIV resistance, he was switched from emtricitabine/tenofovir to adefovir. After 1 wk, he developed worsening renal failure and was switched from adefovir to emtricitabine and telbivudine. However, his condition continued to deteriorate. After 3 wk in the hospital, he became progressively encephalopathic, thrombocytopenic with a platelet count of 33 000/μL, and coagulopathic with prothrombin time of 37.7 s (INR 3.41). He developed hematemesis and became increasingly unresponsive with an ammonia level of 96 μmol/L (normal range 11-35 μmol/L). The patient was thought to be too unstable to undergo liver transplantation. After discussions with his family, he was placed on comfort care and died.

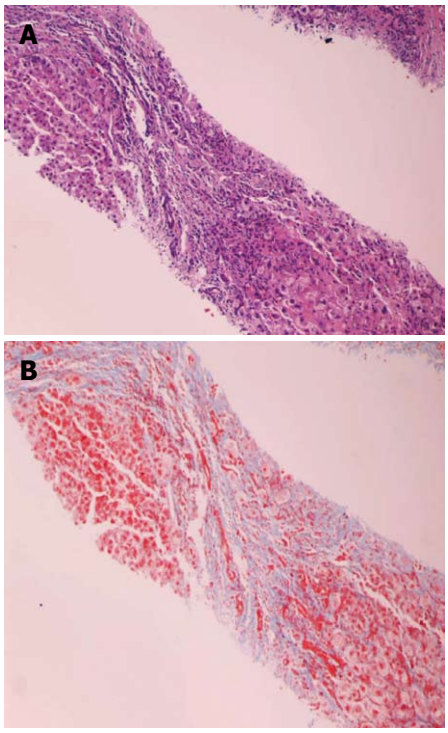

Figure 1 Liver biopsy, low power magnification (100 ×). A: Hematoxylin and eosin stain showing a low power view of two cirrhotic nodule surrounded by fibrosis. The edges of the nodules and the fibrous septi contain intense chronic inflammatory infiltrate; B: Trichrome stain delineating fibrous septa that surround liver nodules in blue color.

Patient B

A 46-year-old African-American male came to clinic with

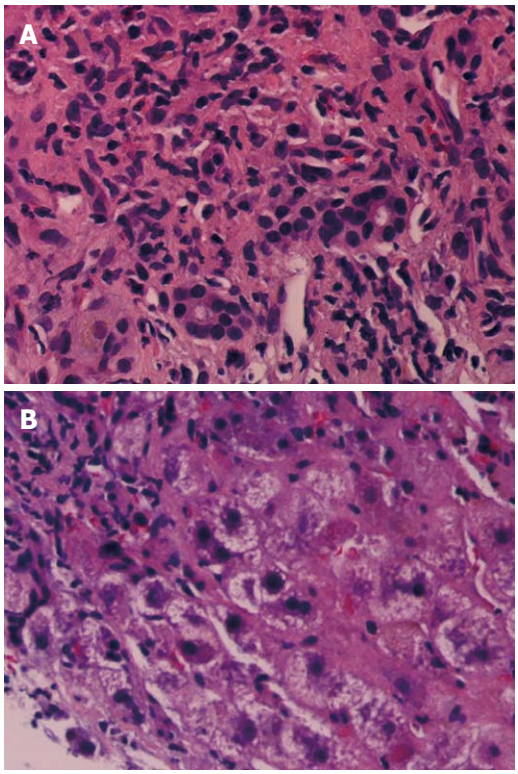

Figure 2 Liver biopsy, high power magnification (hematoxylin and eosin stain, 600 ×). A: Marked portal inflammatory infiltrate composed of plasma cells and a few eosinophils; B: High power view of a cirrhotic nodule composed of markedly swollen hepatocytes, some with granular eosinophilic cytoplasm and intense inflammatory infiltrate at the interface between parenchyma and fibrosis.

a new diagnosis of HIV infection. CD4+ T-cell count was 44 cells/μL (8%) with a plasma HIV RNA level of 9620 copies/mL. He was also diagnosed with hepatitis B infection with HBV DNA level > 500 million IU/mL. Duration of HBV infection was not known but HBV core IgM was negative. HCV antibody was negative, HBeAg was negative, anti-HBe antibody was positive, and HDV antibody was negative. ALT level was normal at 62 U/L and AST was slightly elevated at 53 U/L. He was started on a regimen of once daily ritonavir-boosted darunavir and tenofovir/emtricitabine. Five weeks after starting this regimen, he presented with nausea, vomiting, and jaundice. ALT was 1195 U/L and AST was 1396 U/L. Total bilirubin was 13.5 mg/dL, direct bilirubin was 7.7 mg/dL, and prothrombin time was 27.4 s (INR 2.42). HBV DNA level had decreased to 342000 IU/mL. HIV RNA level was undetectable at < 50 copies/mL and CD4+ T-cell count was 52 cells/μL (10%). HAV IgM was negative and HCV antibody was negative on recheck. Both serum ethanol and acetaminophen levels were undetectable. The patient reported no sexual activity for over 1 year and he never used injectable drugs. Magnetic resonance imaging of the abdomen showed fibrotic changes throughout the liver and portal hypertension evidenced by splenomegaly, a recanalized umbilical vein and minimal perigastric and perisplenic varices. After all medications were held for 72 h, he was restarted on a regimen of ritonavir-boosted fosamprenavir and tenofovir/emtricitabine. Over the next week, his ALT and AST levels trended down to 803 U/L and 773 U/L and his platelets remained within normal limits. However, over that period of time his prothrombin time increased to 42.5 s (INR 3.88) and he became profoundly encephalopathic with an ammonia level of 137 μmol/L. The patient was thought to be too unstable for liver transplantation. After a total of 10 d in the hospital he developed cardiac arrest and died.

DISCUSSION

The development of elevated liver enzymes is not uncommon in HIV-HBV coinfected patients after starting HAART[13]. In the majority of cases, these elevations are mild and do not require modification of treatment[11]. The development of more severe hepatotoxicity (liver enzymes > 10 times the upper limit of normal) is not common and ALF is rare[9]. Among HIV-infected patients in general, those who develop ALF while on HAART have experienced very high rates of mortality[14]. Therefore, an HIV-HBV coinfected patient who develops ALF after starting HAART may be at particularly high risk for mortality, given the presence of underlying liver disease and potentially impaired reserve.

The most appropriate management of such patients is not completely clear, and the optimal management of HIV-HBV coinfected patients who develop liver enzymes > 10 times the upper limit of normal after starting HAART but who do not have evidence of decompensated liver disease may be even more difficult to delineate. One question is whether it is possible to determine if the hepatic injury is from drug toxicity or HBV IRIS and whether this changes management of the patient. Liver biopsy may be helpful in identifying an opportunistic infection, such as mycobacterial disease or cytomegalovirus, that may contribute to liver disease. Liver biopsy may also indicate the presence of cirrhosis. The latter was present in the case of patient A and would have also been found in the case of patient B given radiographic findings. In patient A, liver biopsy showed severe inflammation with lymphocytes, plasma cells, and scant eosinophils. Many cases of HAART-induced ALF in patients without HBV show only mild hepatic inflammatory cell infiltration on biopsy[15]. However, the presence of portal plasma-lymphocytic infiltrate is nonspecific and can be found in chronic viral hepatitis, autoimmune hepatitis, primary biliary cirrhosis and even some medication reactions[16]. The presence of eosinophils may be more specific for a drug reaction[17], though these were scant in this case. Overall, distinguishing between HBV IRIS and drug hepatotoxicity in such cases of ALF may not change management, particularly because it is not clear if anti-inflammatory medications such as corticosteroids are beneficial in HBV IRIS. Corticosteroids have been found to increase HBV replication[18] and this has led some to recommend against the use of corticosteroids in the setting of HBV IRIS[19].

The patients in our series met criteria for ALF according to the American Association for the Study of Liver

Diseases guideline for liver failure[20]. In this guideline, it is recommended that "all non-essential medications" be discontinued in patients with ALF. Due to the fact that the majority of antiretrovirals, including protease inhibitors[8], have been associated with hepatotoxicity, it is advisable to hold HAART at least in the short term. However, HBV flares have been associated with the discontinuation of HAART regimens that contain anti-HBV activity[21]. This theoretically could contribute to ALF. At the same time, continuing single or dual therapy with anti-HBV agents such as lamivudine or tenofovir would create an environment in which HIV resistance might develop. This has led some to recommend stopping HAART and considering treatment of HBV with agents that do not have activity against HIV in cases of significant hepatitis flares on HAART in the setting of hepatitis B cirrhosis[22]. Adefovir is an option, but this drug has less potency against HBV than other agents[23]. Interferon α-based therapies might be considered, but are contraindicated in patients with decompensated cirrhosis. Entecavir was initially thought to have no significant anti-HIV activity, but has subsequently been shown to be associated with the development of HIV resistance mutations when used in the absence of other antiretrovirals[24]. One report suggests that telbivudine may also have activity against HIV[25]. Overall, we believe that the effort to help the patient survive an episode of ALF overrides the preservation of one particular antiretroviral class for future use and that at least one agent with anti-HBV activity should be given in such a scenario. In general, it appears that patients who develop liver failure on HAART, whether coinfected with HBV or not, have a very poor prognosis. These patients should be considered for liver transplantation evaluation, as emerging data show that HIV-HBV coinfected patients have excellent outcomes with liver transplantation[26].

It is prudent to closely monitor the clinical status and liver enzymes of HIV-HBV infected patients after initiation of HAART in order to identify cases of hepatotoxicity early on. Additionally, two new antiretroviral classes have been introduced in recent years. These include the integrase inhibitor class currently represented by raltegravir and the CCR5 antagonist class currently represented by maraviroc. Based on published reports to date, these new agents appear to have minimal hepatotoxicity[27]. While they have only been available since 2007 and toxicities have yet to be fully described, these agents hold promise for HIV-infected patients with chronic liver diseases such as HBV. Perhaps most importantly, efforts should be made to prevent the acquisition of chronic HBV infection, and the HBV vaccine is recommended for all patients with HIV infection[28].

Abstract

Prompt revascularization of the superior mesenteric artery (SMA) thrombotic occlusion can prevent intestinal infarction and decrease necrosis of the bowel segment. Herein, we describe two cases who underwent successful endovascular recanalization for acute SMA thrombosis using a primary aspiration thrombectomy because of possible consequent laparotomy for survey of bowel viability. The two patients had dramatic pain relief immediately after the procedure and remained symptom-free during the follow-up period.

Key words: Superior mesenteric artery; Thrombosis; Aspiration thrombectomy

INTRODUCTION

Acute mesenteric ischemia (AMI) is a fatal vascular emergency, representing 1%-2% of acute abdominal emergencies, and develops from a sudden decreased perfusion to the intestines caused by occlusive or non-occlusive impairment of arterial or venous blood flow. The reported overall mortality of AMI is 60%-80%, and its incidence is increasing[1-3]. Superior mesenteric artery (SMA) embolism is the most frequent cause of AMI, which is responsible for approximately 40%-50% of cases[4]. Among the diagnostic tools, conventional angiography shows a complete obstruction of the proximal SMA, 1-2 cm away from the origin of SMA without collateral circulation, which correlates with acute obstruction, and needs relevant treatment[5,6]. We report two cases who underwent successful endovascular thrombolysis of AMI with different methods, despite the presence of early changes in bowel ischemia.

CASE REPORT

Case 1

A 72-year-old man sought evaluation in the emergency room (ER) because of sudden aggravation of abdominal pain and rebound tenderness 3 d ago. He had a 2-year history of diffuse, dull postprandial abdominal pain. The attending physician suspected a surgical abdomen. The patient was on medication for hypertension during the last 16 years. Laboratory data showed no significant abnormalities.An initial abdominal computed tomography (CT) showed a segmental, occlusive acute thromboembolism in the mid-portion of the main stem, and jejunal and colic branches of SMA with circumferential bowel wall

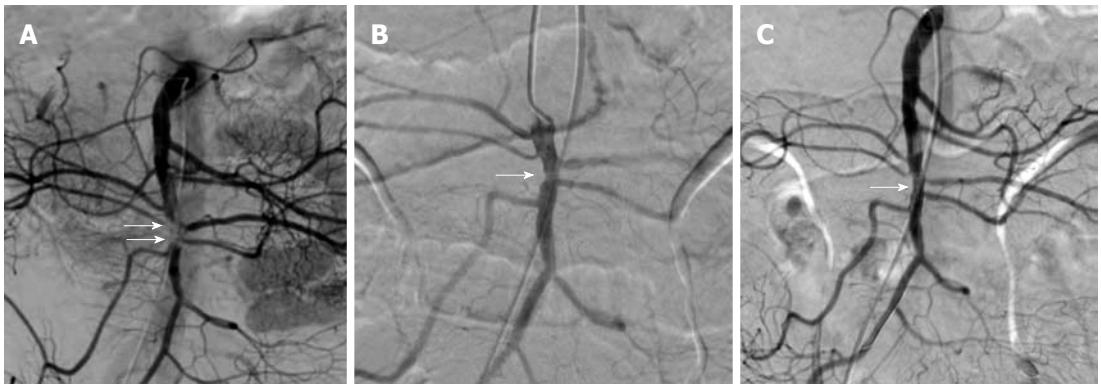

Figure 1 Successful treatment of focal thrombotic occlusion on mid-trunk of superior mesenteric artery with primary aspiration thrombectomy and additional stent implantation. A: Superior mesenteric artery (SMA) angiography showing acute thromboembolism in the mid-trunk of SMA and the origin of jejunal and colic branches (arrows); B: Completely resolved thrombi and focal severe stenosis in the mid-portion of SMA main stem which was considered the leading cause of thromboembolism (arrow) after repetitive primary aspiration thrombectomy using a 6F aspiration catheter; C: A markedly improved stenosis and luminal blood flow of SMA without residual or migrated thrombi after implantation of a 6 mm x 18 mm balloon expandable stent (arrow).

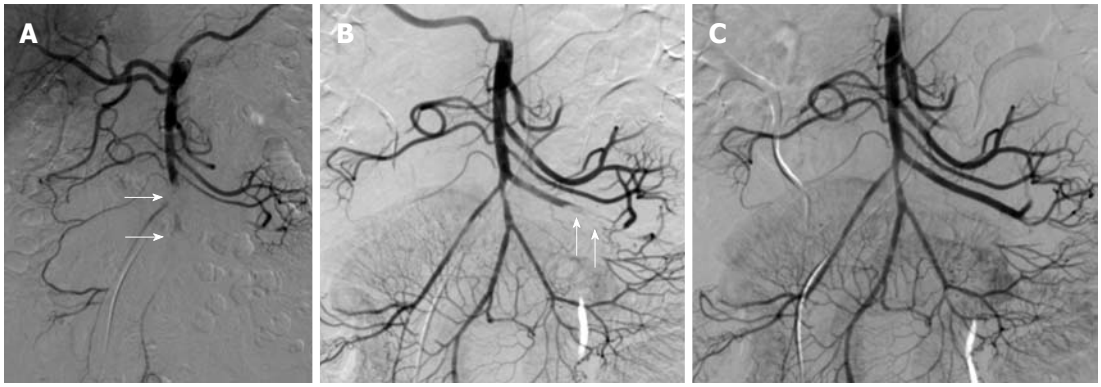

Figure 2 Successful treatment of segmental complete thrombotic occlusion on mid-trunk of superior mesenteric artery with primary aspiration thrombectomy. A: Superior mesenteric artery (SMA) arteriography showing a complete thrombotic occlusion of the mid-portion of the main stem and the origin of ileocolic and right colic branches of SMA due to a large amount of thromboembolism (arrows); B: Complete removal of thromboembolism in the main stem of SMA but an intraluminal filling defect and flow occlusion at the distal portion of jejunal branch of SMA due to migrated thrombi during the procedure (arrows) after multiple courses of aspiration thrombectomy with a 6F aspiration catheter; C: A completely recanalized main stem and jejunal branch of SMA.

thickening and decreased enhancement of mucosal layer in the right colon.

Initial SMA angiography confirmed an acute occlusive thromboembolism in the mid-trunk of SMA and the origin of jejunal and colic branches of SMA (arrows) (Figure 1A). Initially, we performed primary aspiration thrombectomy using a 6F aspiration catheter (Cordis, Johnson and Johnson, San Diego, CA, USA) after IV infusion of 5000 IU heparin. Angiography after repetitive thrombectomy showed nearly complete thrombi removal from the SMA main trunk and its branches and residual focal severe stenosis in the mid-portion of SMA main stem (arrow) (Figure 1B), which was considered the leading cause of thromboembolism. Final angiogram showed completely restored perfusion to the ischemic bowel through the patent main stem, and jejunal and colic branches of SMA after implantation of a 6 mm × 18 mm balloon expandable stent (arrow) (Genesis; Cordis, Johnson and Johnson, San Diego, CA, USA) (Figure 1C). The patient's symptoms improved almost immediately after the operation, and he no longer complained of postprandial abdominal pain. He was instructed to continue taking warfarin after discharge.

Case 2

A 67-year-old man complained of acute abdominal pain 2 d after admission. The patient's symptom was localized at the periumbilical area, and direct tenderness was present at physical examination. The patient had a history of atrial fibrillation and myocardial infarction, which was treated with coronary angioplasty 2 years ago.

Echocardiography showed a 30% ejection fraction and no evidence of thrombi in the left atrium. Laboratory data showed an elevated hs-CRP level of 14.22 mg/dL (normal range, 0-0.3 mg/dL).

Emergent CT angiography showed complete occlusion of the mid-portion of the main stem and origin of the ileocolic and right colic branches of SMA due to thromboembolism, with circumferential bowel wall thickening at the cecum and ascending colon. Surgical laparotomy was later considered because of heart failure.

The initial SMA arteriography showed complete thrombotic occlusion of the mid to distal SMA trunk and the origin of ileocolic and right colic branches of SMA (arrows) (Figure 2A). Initially, we performed primary aspiration thrombectomy using a 6F aspiration catheter (Cordis, John-

son and Johnson, San Diego, CA, USA) after Ⅳ infusion of 5000 IU heparin. After repetitive aspiration thrombectomy, follow-up angiography showed that although most thrombi were removed from the SMA main trunk, small thrombi had a migrated and occluded distal portion of the jejunal branch of SMA during aspiration thrombectomy (arrows) (Figure 2B). Finally, most thrombi in the main stem and jejunal branch of SMA were completely removed immediately after an additional aspiration thrombectomy, and the lumen of SMA was completely recanalized (Figure 2C). After the procedure, the patient's symptoms dramatically improved and the hs-CRP level decreased to 2.2 mg/dL, and he did not have recurrent symptoms during the 12-mo follow-up period.

DISCUSSION

AMI is caused by embolism (40%-50%), SMA thrombosis (20%-25%), non-occlusive mesenteric ischemia (20%), and mesenteric venous thrombosis (5%)[1-4]. Embolic or thrombotic occlusion of SMA frequently occurs on a background of generalized atherosclerotic changes in the involved arteries.

In our two cases, acute mesenteric thrombosis was managed with aspiration thrombectomy without any pharmacologic thrombolysis due to consequent laparoscopic survey to bowel.

Unfortunately, the non-specific symptoms are a frequent cause of delayed diagnosis, and most AMIs and CMIs can be asymptomatic for a long time. Contrast-enhanced CT can shows an arterial occlusion of SMA, frequently accompanied with severe stenosis of the celiac artery, and findings suggestive of bowel ischemia, including pneumatosis intestinalis, bowel wall thickening, ileus, and bowel dilatation[7]. Angiography can define the location and origin of the arterial occlusion and provide the potential for intervention if mesenteric ischemia is diagnosed prior to ischemic bowel necrosis[5,6]. Bloody diarrhea or signs of peritonitis, including abdominal rigidity and rebound tenderness, are signs of advanced bowel ischemia and bowel infarction, requiring urgent surgery. An area of transmural bowel necrosis in AMI can appear within 15 min after onset and after 6 h, and irreversible gangrene of the affected segments may ensue[8]. In our cases, the two patients were diagnosed with AMI by CT examination soon after the onset of symptoms. Although we performed endovascular treatment despite the presence of early ischemic bowel changes, such as bowel wall thickening and engorgement of the vasa recta, on initial or follow-up CT, we obtained good results as reflected by the dramatic improvement in symptoms.

Because of its favorable results, endovascular thrombolysis of acute SMA occlusion has gained popularity and has become one of the most used methods with or without combined open surgery[9]. Pharmacologic thrombolysis with or without mechanical aspiration thrombectomy is a good treatment option in terms of high survival, bowel preservation rates and low complication rate regardless of the nature of thromboembolism, period of occlusion, presence of collateral vessels and severe atherosclerotic disease.

The effect of primary aspiration thrombectomy for acute SMA thrombosis without pharmacologic thrombolysis remains a matter of debate and requires better definition. If consequent laparotomy is considered for assessment of bowel viability and use of anticoagulant is restricted due to a bleeding tendency, aspiration thrombectomy can be performed as the primary procedure. Despite contraindication or strict use of anticoagulant, a small amount of local anticoagulant use is mandatory for prevention of distal migration of small thrombi or recurrent thrombus formation.

Treatment of the underlying stenosis with angioplasty and stent implantation after intra-arterial thrombolysis has been described with at least good short-term results, but the higher restenosis rate of stents during follow-up has been reported in the recent literature[10]. We had a good short-term outcome, despite early ischemic changes, and continued long-term follow-up for recurring symptoms and restenosis of stents with CT angiography.

In conclusion, if the diagnosis of AMI is made early and there are no signs of advanced bowel ischemia, such as peritonitis, endovascular treatment for AMI. Primary aspiration thrombectomy can be performed for rapid and sufficient revascularization of acute thrombotic SMA occlusion in limited cases, consequent laparotomy must be planned to survey for bowel viability or if there is a contraindication to use an anticoagulant.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1144 experts in gastroenterology and hepatology from 60 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systemically progress and unresolved problems in tahe field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensuses and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Ab-

stract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the International Committee of Medical Journal Editors to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/1007-9327office. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by International Committee of Medical Journal Editors, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no more than 256 words) and structured abstracts (no more than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no more than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections. AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/…; MATERIALS AND METHODS (no more than 140 words); RESULTS (no more than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the

editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: http://www.wjgnet.com/1007-9327/13/4520.pdf; http://www.wjgnet.com/1007-9327/13/4554.pdf; http://www.wjgnet.com/1007-9327/13/4891.pdf; http://www.wjgnet.com/1007-9327/13/4986.pdf; http://www.wjgnet.com/1007-9327/13/4498.pdf. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc*. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc*., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of P values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of P values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc*., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *H. pylori*, *E coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version includes manuscript and high-resolution image figures. The author should re-submit the revised manuscript online, along with printed high-resolution color or black and white photos; Copyright transfer letter, and responses to the reviewers, and science news are sent to us *via* email.

Editorial Office

World Journal of Gastroenterology

Editorial Department: Room 903, Building D,
Ocean International Center,
No. 62 Dongsihuan Zhonglu,
Chaoyang District, Beijing 100025, China
E-mail: wjg@wjgnet.com
http://www.wjgnet.com
Telephone: +86-10-5908-0039
Fax: +86-10-85381893

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (http://www.eurekalert.org). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

Authors of accepted articles must pay a publication fee.
EDITORIAL, TOPIC HIGHLIGHTS, BOOK REVIEWS and LETTERS TO THE EDITOR are published free of charge.
